Referring to [figure B1.10.7](#) consider electrons from the event under study as well as from other events all arriving at the two detectors. The electrons from the event under study are correlated in time and result in a peak in the time spectrum centred approximately at the delay time. There is also a background level due to events that bear no fixed time relation to each other. If the average rate of the background events in each detector is R_1 and R_2 , then the rate that two such events will be recorded within time $\Delta\tau$ is given by R_B , where

$$R_B = R_1 R_2 \Delta\tau.$$

Let the rate of the event under study be R_A . It will be proportional to the cross section for the process under study, σ_A , the incident electron current, I_0 , the target density, n , the length of the target viewed by the detectors, ℓ , the solid angles subtended by the detectors, $\Delta\omega_1$ and $\Delta\omega_2$ the efficiency of the detectors, ε_1 and ε_2 .

$$R_A = \sigma_A I_0 n \ell \Delta\omega_1 \Delta\omega_2 \varepsilon_1 \varepsilon_2.$$

The product $I_0 n^{\ell}$, depends on the properties of the region from which the two electrons originate and is called the

-13-

source function, S . The properties of the detectors are described by the product, $\Delta\omega_1 \cdot \Delta\omega_2 \varepsilon_1 \varepsilon_2$.

For the background, each of the rates, R_1 and R_2 , will be proportional to the source function, the cross sections for single electron production and the properties of the individual detectors,

Combining the two expressions for R_1 and R_2

Comparing the expressions for the background rate and the signal rate one sees that the background increases as the square of the source function while the signal rate is proportional to the source function. The signal-to-background rate, R_{AB} , is then

It is important to note that the signal is always accompanied by background. We now consider the signal and background after accumulating counts over a time T . For this it is informative to refer to [figure B1.10.8](#) the time spectrum. The total number of counts within an arrival time difference $\Delta\tau$ is N_T and this number is the sum of the signal counts, $N_A = R_A T$, and the background counts, $N_B = R_B T$,

The determination of the background counts must come from an independent measurement, typically in a region of the time spectrum outside of the signal region, yet representative of the background within the signal region. The uncertainty in the determination of the signal counts is given by the square root of the uncertainties in the total counts and the background counts

The essential quantity is the relative uncertainty in the signal counts, $\delta N_A / N_A$. This is given by

-14-

Expressing R_A in terms of R_{AB} results in the following formula

$$\delta N_A / N_A = \sqrt{\frac{(R_{AB} + 2) \Delta\tau}{\frac{\sigma_A^2}{\sigma_1 \sigma_2} \Delta\omega_1 \Delta\omega_2 \varepsilon_1 \varepsilon_2 T}}$$

There are a number of observations to be drawn from the above formula: the relative uncertainty can be reduced to an arbitrarily small value by increasing T , but because the relative uncertainty is proportional to $1/\sqrt{T}$, a reduction in relative uncertainty by a factor of two requires a factor of four increase in collection time. The relative uncertainty can also be reduced by reducing $\Delta\tau$. Here, it is understood that $\Delta\tau$ is the smallest time window that just includes all of the signal. $\Delta\tau$ can be decreased by using the fastest possible detectors, preamplifiers and discriminators and minimizing time dispersion in the section of the experiment ahead of the detectors.

The signal and background rates are not independent, but are coupled through the source function, S , as a consequence the relative uncertainty in the signal decreases with the signal-to-background rate, $R_{AB} = 1$, a somewhat unanticipated result. Dividing $\delta N_A / N_A$ by its value at $R_{AB} = 1$ gives a reduced relative uncertainty $[\delta N_A / N_A]_R$ equal to $\sqrt{(R_{AB} + 2)/3}$. A plot of $[\delta N_A / N_A]_R$ as a function of R_{AB} is shown in [figure B1.9](#).

Figure B1.10.9. Plot of the reduced relative uncertainty of a double coincidence experiment as a function of the signal-to-background ratio. Note that the relative uncertainty decreases as the signal-to-background rate decreases.

To illustrate this result, consider a case where there is one signal count and one background count in the time window $\Delta\tau$. The signal-to-background ratio is 1 and the relative uncertainty in the signal is $\sqrt{2+1}/1 = 1.7$. By increasing the source strength by a factor of 10 the signal will be increased by a factor of 10 and the background by a factor of 100. The signal-to-background ratio is now 0.1, but the relative uncertainty in the signal is $\sqrt{110+100}/10 = 1.45$, a clear improvement over the larger signal-to-background case.

-15-

Another method for reducing the relative uncertainty is to increase the precision of the measurement of background. The above formulae are based on an independent measurement of background over a time window, $\Delta\tau$, that is equivalent to the time window within which the signal appears. If a larger time window for the background is used, the uncertainty in background determination can be correspondingly reduced. Let a time window of width $\Delta\tau_B$ be used for the determination of background, where $\Delta\tau / \Delta\tau_B = \rho < 1$. If the rate at which counts are accumulated in time window $\Delta\tau_B$ is R_{BB} , the background counts to be subtracted from the total counts in time window $\Delta\tau$ becomes $\rho R_{BB} T = \rho N_{BB}$. The uncertainty in the number of background counts to be subtracted from the total of signal plus background is $\sqrt{\rho^2 N_{BB}}$. The relative uncertainty of the signal is then

$$\sqrt{\frac{1 + 2\rho^2 N_{BB}/N_A}{N_A}} = \sqrt{\frac{1 + 2\rho N_B/N_A}{N_A}}$$

The expression for the reduced relative uncertainty is then

$$[\delta N_A / N_{AB}]_R = \sqrt{\frac{(R_{AB} + 2\rho)}{3}}$$

For coincidence experiments where the detectors record time correlated events, maximum efficiency and sensitivity is attained when the detectors accept particles originating from the same source volume, in other words, the length, ℓ , that defines the common volume of the source region seen by the detectors should be the same as the lengths and corresponding volumes for each of the detectors separately. If the two volumes are different, only the common volume seen by the detectors is used in the calculation of coincidence rate. Events that take place outside the common volume, but within the volume accepted by one of the detectors will only contribute to the background. This is shown schematically in [figure B1.10.10](#). The situation is potentially complex if the source region is not uniform over the common volume viewed by the detectors and if the efficiencies of the detectors varies over the volume they subtend. Full knowledge of the geometric acceptances of the detectors and the source volume is necessary to accurately evaluate the size and strength of the source. Such an analysis is typically done numerically using empirical values of the view angles of the detectors and the spatial variation of target density and incident beam intensity.

-16-

Figure B1.10.10. Schematic diagram of the effect of detector view angles on coincidence rate. The view angles of two detectors are shown along with the common view angle. Maximum signal collection efficiency is achieved when the individual view angles have the maximum overlap and when the overlap coincides with the maximum density of the incident beam.

B1.10.5.3 MULTIPLE PARAMETER MEASUREMENTS

It is often the case that a time correlation measurement alone is not sufficient to identify a particular event of interest. For this reason, coincidence measurements are often accompanied by the measurement of another parameter such as energy, spin, polarization, wavelength, etc. For the case of the electron impact ionization experiment of [figure B1.10.7](#) electrostatic energy analysers can be placed ahead of the detectors so that only electrons of a preselected energy arrive at the detectors. In this case the coincidence rate must take into account the energy bandpass of the analysers and the fact that in this example the energies of the scattered and ejected electrons are not independent, but are coupled through the relation that the energy of the incident electron equals the sum of the energies of the scattered and ejected electrons and the binding energy of the ejected electron

$$E_0 = E_1 + E_2 + BE,$$

where E_0 is the energy of the incident electron, E_1 is the energy of the scattered electron, E_2 is the energy of the ejected electron and BE is the binding energy of the ejected electron. The coincidence rate now has an additional term, ΔE , that is the overlap of the energy bandwidths of the two detectors, ΔE_1 and ΔE_2 , subject to

the energy conservation constraint. An often used approximation to ΔE is $\Delta E = \sqrt{\Delta E_1^2 + \Delta E_2^2}$. The background rates in the detectors depend only on the individual energy bandwidths, and are independent of any additional constraints. Maximum efficiency is achieved when the energy bandwidths are only just wide enough to accept the coincident events of interest.

B1.10.5.4 MULTIPLE DETECTORS

The arrangement for a single coincidence measurement can be expanded to a multiple detector arrangement. If, for example, it is necessary to measure coincidence rates over an angular range, detectors can be placed at the angles of

-17-

interest and coincidence rates measured between all pairs of detectors. This is a much more efficient way of collecting data than having two detectors that are moved to different angles after each coincidence determination. Depending on the signal and background rates, detector outputs can be multiplexed and a detector identification circuit used to identify those detectors responsible for each coincidence signal. If detectors are multiplexed, it is well to remember that the overall count rate is the sum of the rates for all of the detectors. This can be an important consideration when rates become comparable to the reciprocal of system dead time.

B1.10.5.5 PREPROCESSING

It is often the case that signal rates are limited by the processing electronics. Consider a coincidence time spectrum of 100 channels covering 100 ns with a coincidence time window of 10 ns. Assume a signal rate of 1 Hz and a background rate of 1 Hz within the 10 ns window. This background rate implies an uncorrelated event rate of 10 kHz in each of the detectors. To register 99% of the incoming events, the dead time of the system can be no larger than 10 μ s. The dead time limitation can be substantially reduced with a preprocessing circuit that only accepts events falling within 100 ns of each other (the width of the time spectrum). One way to accomplish this is with a circuit that incorporates delays and gates to only pass signals that fall within a 100 ns time window. With this circuit the number of background events that need to be processed each second is reduced from 10,000 to 10, and dead times as long as 10 ms can be accommodated while maintaining a collection efficiency of 99%. In a way this is an extension of the multiparameter processing in which the parameter is the time difference between processed events. A preprocessing circuit is discussed by Goruganthu et al [10].

B1.10.5.6 TRIPLE COINCIDENCE MEASUREMENTS

A logical extension of the coincidence measurements described above is the triple coincidence measurement shown schematically in [figure B1.10.11](#). Taking as an example electron impact double ionization, the two ejected electrons and the scattered electron are correlated in time. On a three-dimensional graph with vertical axes representing the number of detected events and the horizontal axes representing the time differences between events at detectors 1 and 2 and 1 and 3, a time correlated signal is represented as a three-dimensional peak with a fixed base width in the horizontal plane. A triple coincidence time spectrum is shown in [figure B1.10.12](#). Unlike the situation for double coincidence measurements the background has four sources, random rates in each of the three detectors, correlated events in detectors 1 and 2 with an uncorrelated signal in 3, correlated events in detectors 1 and 3 with an uncorrelated signal in 2 and correlated events in detectors 2 and 3 with an uncorrelated signal in detector 1. The first source gives a background that is uniform over the full horizontal plane. The three other sources produce two walls that are parallel to the two time axes and a third wall that lies at 45° to the time axes. These can be seen in [figure B1.10.12](#).

Figure B1.10.11. Electron impact double ionization triple coincidence experiment. Shown are the source of electrons, target gas, three electron detectors, one for the scattered electron and one for each of the ejected electrons. Two time differences, t_{13} and t_{23} , are recorded for each triple coincidence. t_{13} is the difference in arrival times of ejected electron 1 and the scattered electron; t_{23} is the difference in arrival times of ejected electron 2 and the scattered electron. Two sets of time-to-amplitude converters (TACs) and pulse height analysers/analogue-to-digital converters (PHA/ADC) convert the times to binary encoded numbers that are stored in the memory of a computer. The data can be displayed in the form of a two-dimensional histogram (see figure B1.10.12).

Figure B1.10.12. Schematic diagram of a two-dimensional histogram resulting from the triple coincidence experiment shown in figure B1.10.10. True triple coincidences are superimposed on a uniform background and three walls corresponding to two electron correlated events with a randomly occurring third electron.

For any region of the horizontal plane with dimensions $\Delta\tau_{12}$ $\Delta\tau_{13}$, the uniform background rate is

$$R_{123} = R_1 R_2 R_3 \Delta\tau_{12} \Delta\tau_{13} = [S\sigma_1 \Delta\omega_1 \varepsilon_1][S\sigma_2 \Delta\omega_2 \varepsilon_2][S\sigma_3 \Delta\omega_3 \varepsilon_3] \Delta\tau_{12} \Delta\tau_{13}$$

where R_1 , R_2 and R_3 are the random background rates in detectors 1, 2 and 3. The background due to two time correlated events and a single random event is $R_{12} + R_{13} + R_{23}$, where

$$R_{12} = [S\sigma_{12}\Delta\omega_1\Delta\omega_2\varepsilon_1\varepsilon_2][S\sigma_3\Delta\omega_3\varepsilon_3]\Delta\tau_{13}$$

$$R_{13} = [S\sigma_{13}\Delta\omega_1\Delta\omega_3\varepsilon_1\varepsilon_3][S\sigma_2\Delta\omega_2\varepsilon_2]\Delta\tau_{12}$$

$$R_{23} = [S\sigma_{23}\Delta\omega_2\Delta\omega_3\varepsilon_2\varepsilon_3][S\sigma_1\Delta\omega_1\varepsilon_1]\Delta\tau_{23}.$$

The signal rate R_A , is

$$R_A = S\sigma_A\Delta\omega_1\Delta\omega_2\Delta\omega_3\varepsilon_1\varepsilon_2\varepsilon_3$$

where the symbols have the same meaning as in the treatment of double coincidences. If the signal falls within a two-dimensional time window $\Delta\tau_{12}\Delta\tau_{13}$, then the signal-to-background rate ratio is $R_A/[R_{123} + R_{12} + R_{13} + R_{23}] = \chi$, and the statistical uncertainty in the number of signal counts accumulated in time T is

$$\delta N_A/N_A = \sqrt{\frac{1 + 2/\chi}{K_A S T}}$$

where $K_A = \sigma_A\Delta\omega_1\Delta\omega_2\Delta\omega_3\varepsilon_1\varepsilon_2\varepsilon_3$. In contrast to simpler double coincidence experiments, S , the source function is not directly proportional to $1/\rho$. The full expression for $\delta N_A/N_A$ is

$$\delta N_A/N_A = \sqrt{\frac{1 + 2/\chi}{\frac{K_A}{2} \left[-\frac{K_1}{K_2} + \sqrt{\left(\frac{K_1}{K_2}\right)^2 + 4\left(\frac{K_A}{K_2}\right)\frac{1}{\chi}} \right] T}}$$

where

$$K_1 = \sigma_1\Delta\omega_1\varepsilon_1\sigma_2\Delta\omega_2\varepsilon_2\sigma_3\Delta\omega_3\varepsilon_3\Delta\tau_{12}\Delta\tau_{13}$$

and

$$K_2 = \sigma_{12}\Delta\omega_1\Delta\omega_2\varepsilon_1\varepsilon_2\sigma_3\Delta\omega_3\varepsilon_3\Delta\tau_{13} + \sigma_{13}\Delta\omega_1\Delta\omega_3\varepsilon_1\varepsilon_3\sigma_2\Delta\omega_2\varepsilon_2\Delta\tau_{12} + \sigma_{23}\Delta\omega_2\Delta\omega_3\varepsilon_2\varepsilon_3\sigma_1\Delta\omega_1\varepsilon_1\Delta\tau_{23}.$$

-20-

As is the case for the double coincidence arrangement $\delta N_A/N_A$ is inversely proportional to the square root of the acquisition time, however $\delta N_A/N_A$ does not approach a minimum value in the limit of $\chi = 0$, but rather has a minimum in the region between $\chi = 0$ and $\chi = \infty$, the precise value of χ depending on the experimental conditions and the magnitudes of the cross sections for the different electron producing events. A detailed treatment of this topic with examples is given by Dupré et al [11].

B1.10.6 ANTI-COINCIDENCE

In high-energy physics experiments there can be many interfering events superimposed on the events of interest. An example is the detection of gamma rays in the presence of high-energy electrons and protons. The

electrons, protons and gamma rays all produce very similar signals in the solid state detectors that are used, and it is not possible to distinguish the gamma rays from the charged particles. A technique that is frequently used is to surround the gamma ray detectors with a plastic scintillation shield that produces a flash of light when traversed by a charged particle, but is transparent to the gamma rays. Light from the shield is coupled to photomultiplier detectors via light pipes. Signals that occur simultaneously in the photomultipliers and solid state detector are due to high-energy charged particles entering the instrument and are excluded from any analysis. An example of such an anti-coincidence circuit can be found in the energetic gamma ray experiment telescope (EGRET) on the gamma ray observatory (GRO) space craft that was launched in 1991 and continues to provide information on the energies and sources of gamma rays in the 20 MeV to 30 GeV energy range. Figure B1.10.13 is a schematic diagram of the EGRET experiment showing the anticoincidence shield.

Figure B1.10.13. EGRET experiment showing spark chambers and photomultiplier tubes for the detection of gamma rays. The gamma ray detectors are surrounded by an anticoincidence scintillator dome that produces radiation when traversed by a high-energy charged particle but is transparent to gamma rays. Light pipes transmit radiation from the dome to photomultiplier tubes. A signal in a anticoincidence photomultiplier tube causes any corresponding signal in the gamma ray detectors to be ignored. The NaI crystal detector and photomultiplier tubes at the bottom of the unit provide high-resolution energy analysis of gamma rays passing through the spark chambers.

B1.11 NMR of liquids

Oliver W Howarth

B1.11.1 INTRODUCTION

Nuclear magnetic resonance (NMR) was discovered by Bloch, Purcell and Pound in 1945, as a development of the use of nuclear spins in low-temperature physics. Its initial use was for the accurate measurement of nuclear magnetic moments. However, increases in instrumental precision led to the detection of chemical shifts (B1.11.5) and then of spin–spin couplings (B1.11.6). This stimulated use by chemists. There have been spectacular improvements in sensitivity, resolution and computer control since then, so that NMR equipment is now essential in any laboratory for synthetic chemistry. Within moments or hours, it can determine the structure and, if desired, conformation of most medium-sized molecules in the solution phase. For this reason, a large pharmaceutical company will typically generate several hundred NMR spectra in one working day. NMR is also widely used in biochemistry for the much more challenging problem of determining the structures of smaller proteins and other biomolecules. The rates and extents of molecular motions can also be measured, through measuring the rates of energy transfer to, from and between nuclei (relaxation, B1.13). Outside of chemistry, it is used in a different mode for medical and other imaging, and for the detection of flow and diffusion in liquids (B1.14). It can also be used for clinical and *in vivo* studies, as the energies involved present no physiological dangers.

B1.11.2 NUCLEAR SPINS

NMR depends on manipulating the collective motions of nuclear spins, held in a magnetic field. As with every rotatable body in nature, every nucleus has a spin quantum number I . If $I = 0$ (e.g. ^{12}C , ^{16}O) then the nucleus is magnetically inactive, and hence ‘invisible’. If, as with most nuclei, $I > 0$, then the nucleus must possess a magnetic moment, because of its charge in combination with its angular momentum $\hbar\sqrt{I(I+1)}$. This makes it detectable by NMR. The most easily detected nuclei are those with $I = \frac{1}{2}$ and with large magnetic moments, e.g. ^1H , ^{13}C , ^{19}F , ^{31}P . These have two allowed states in a magnetic (induction) field B_0 : $m_{1/2}$ and $m_{-1/2}$, with angular momentum components $\pm\hbar/2$. Thus these nuclear magnets lie at angles $\pm \cos^{-1}((\frac{1}{2})/(\frac{3}{4}))^{1/2} = 54.7^\circ$ to B_0 . They also precess rapidly, like all gyroscopes, at a rate ν_L . This is called the Larmor frequency, after its discoverer. The $2I + 1$ permitted angles for other values of I differ from the above angles, but they can never be zero or 180° , because of the uncertainty principle.

The energy difference ΔE corresponding to the permitted transitions, $\Delta m = \pm 1$, is given by

$$\Delta E = \gamma \hbar B_0 / 2\pi = h\nu_L.$$

Therefore, in NMR, one observes collective nuclear spin motions at the Larmor frequency. Thus the frequency of NMR detection is proportional to B_0 . Nuclear magnetic moments are commonly measured either by their magnetogyric ratio γ , or simply by their Larmor frequency ν_L in a field where ^1H resonates at 100 MHz (symbol Ξ).

B1.11.2.1 PRACTICABLE ISOTOPES

Almost all the stable elements have at least one isotope that can be observed by NMR. However, in some cases the available sensitivity may be inadequate, especially if the compounds are not very soluble. This may be because the relevant isotope has a low natural abundance, e.g. ^{17}O , or because its resonances are extremely broad, e.g. ^{33}S . Tables of such nuclear properties are readily available [1], and isotopic enrichment may be available as an expensive possibility. Broad resonances are common for nuclei with $I > 0$, because these nuclei are necessarily non-spherical, and thus have electric quadrupole moments that interact strongly with the electric field gradients present at the nuclei in most molecules. Linewidths may also be greatly increased by chemical exchange processes at appropriate rates (B2.7), by the presence of significant concentrations of paramagnetic species and by very slow molecular tumbling, as in polymers and colloids. For nuclei with $I = 1/2$, a major underlying cause of such broadening is the magnetic dipolar interaction of the nucleus under study with nearby spins. This and other interactions also lead to very large linewidths in the NMR spectra of solids and of near-solid samples, such as gels, pastes or the bead-attached molecules used in combinatorial chemistry. However, their effect may be reduced by specialized techniques (B1.13).

Fortunately, the worst broadening interactions are also removed naturally in most liquids and solutions, or at least greatly reduced in their effect, by the tumbling motions of the molecules, for many of the broadening interactions vary as $(3 \cos^2\theta - 1)$ where θ is the angle between the H–H vector and B_0 , and so they average to zero when θ covers the sphere isotropically. As a result, the NMR linewidths for the lighter spin- $\frac{1}{2}$ nuclei in smallish molecules will commonly be less than 1 Hz. Resolution of this order is necessary for the adequate resolution of the shifts and couplings described below. It requires expensive magnets and physically homogeneous samples. The presence of irregular interfaces degrades resolution by locally distorting the magnetic field, although the resulting spectra may still have enough resolution for some purposes, such as *in vivo* NMR.

It is occasionally desirable to retain a small proportion of molecular orientation, in order to quantitate the dipolar interactions present, whilst minimizing their contribution to the linewidth. Partial orientation may be achieved by using a nematic solvent. In large, magnetically anisotropic molecules it may occur naturally at the highest magnetic fields.

Figure B1.11.1 shows the range of radiofrequencies where resonances may be expected, between 650 and 140 MHz, when $B_0 = 14.1$ T, i.e. when the ^1H resonance frequency is 600 MHz. There is one bar per stable isotope. Its width is the reported chemical shift range (B1.11.5) for that isotope, and its height corresponds to the log of the sensitivity at the natural abundance of the isotope, covering about six orders of magnitude. The radioactive nucleus ^3H is also included, as it is detectable at safe concentrations and useful for chemical labelling. It is evident that very few ranges overlap. This, along with differences in linewidth, means that a spectrometer set to detect one nucleus is highly unlikely to detect any other in the same experiment.

Figure B1.11.1. Resonance frequencies for different nuclei in a field of 14.1 T. Widths indicate the quoted range of shifts for each nucleus, and heights indicate relative sensitivities at the natural isotopic abundance, on a log scale covering approximately six orders of magnitude. Nuclei resonating below 140 MHz are not shown.

B1.11.2.2 PRACTICABLE SAMPLES

Once the above restrictions on isotope, solubility, chemical lability and paramagnetism are met, then a very wide range of samples can be investigated. Gases can be studied, especially at higher pressures. Solutions for ^1H or ^{13}C NMR are normally made in deuteriated solvents. This minimizes interference from the solvent resonances and also permits the field to be locked to the frequency as outlined below. However, it is possible to operate with an unavoidably non-deuteriated solvent, such as water in a biomedical sample, by using a range of solvent-suppression techniques. An external field–frequency lock may be necessary in these cases.

NMR spectra from a chosen nucleus will generally show all resonances from all such nuclei present in solution. Therefore, if at all possible, samples should be chemically pure, to reduce crowding in the spectra, and extraneous compounds such as buffers should ideally not contain the nuclei under study. When chromatographic separations are frequently and routinely essential, then on-line equipment that combines liquid chromatography with NMR is available [2]. Some separation into subspectra is also possible within a fixed sample, using specialized equipment, when the components have different diffusion rates. The technique is called diffusion ordered spectroscopy, or DOSY [3]. If the spectral crowding arises simply from the complexity of the molecule under study, as in proteins, then one can resort to selective isotopic labelling: for example, via gene manipulation. A wide range of experiments is available that are selective for chosen pairs of isotopes, and hence yield greatly simplified spectra.

The available sensitivity depends strongly on the equipment as well as the sample. ^1H is the nucleus of choice for most experiments. 1 mg of a sample of a medium-sized molecule is adequate for almost all types of ^1H -only spectra, and with specialized equipment one can work with nanogram quantities. At this lower level, the problem is not so much sensitivity as purity of sample and solvent. ^{13}C NMR at the natural isotopic abundance of 1.1% typically requires 30 times this quantity of material, particularly if non-protonated carbon atoms are to be studied. Most other nuclei necessitate larger amounts of sample, although ^{31}P [4] and ^{19}F are useful exceptions. *In vivo* spectroscopy generally calls for custom-built probes suited for the organ or organism under study. Human *in vivo* spectra usually require a magnet having an especially wide bore, along with a moveable detection coil. They can reveal abnormal metabolism and internal tissue damage.

NMR can be carried out over a wide range of temperatures, although there is a time and often a resolution penalty in using temperatures other than ambient. An effective lower limit of $\sim -150\text{ }^\circ\text{C}$ is set by the lack of solvents that are liquid below this. Temperatures above $\sim 130\text{ }^\circ\text{C}$ require special thermal protection devices, although measurements have even been made on molten silicates.

B1.11.3 THE NMR EXPERIMENT

B1.11.3.1 EQUIPMENT AND RESONANCE

Figure B1.11.2 represents the essential components of a modern high-resolution NMR spectrometer, suitable for studies of dissolved samples. The magnet has a superconducting coil in a bath of liquid He, jacketed by liquid N_2 . The resulting, persistent field B_0 ranges from 5.9 to 21.1 T, corresponding to ^1H NMR at 250 to 900 MHz. This field can be adjusted to a homogeneity of better than 1 ppb over the volume of a typical sample. The sample is commonly introduced as 0.5 ml of solution held in a 5 mm OD precision glass tube. Microcells are available for very small samples, and special tubes are also available for, for example, pressurized or flow-through samples. The sample can be spun slowly in order to average the field inhomogeneity normal to the tube's axis, but this is not always necessary, for the reduction in linewidth may only be a fraction of a hertz. The field aligns the spins as described above, and a Boltzmann equilibrium then develops between the various m_l Zeeman states. A typical population difference between the two ^1H levels is 1 part in 10^5 . Thus 10^{-5} of the ^1H spins in the sample are not paired. These are collectively called the bulk nuclear magnetization, and in many ways they behave in combination like a classical, magnetized gyroscope. The time required for the establishment of the Boltzmann equilibrium is approximately five times the spin-lattice relaxation time, T_1 (B1.14). Because the population difference between the two ^1H levels is proportional to the field, the sensitivity of NMR also rises with the field.

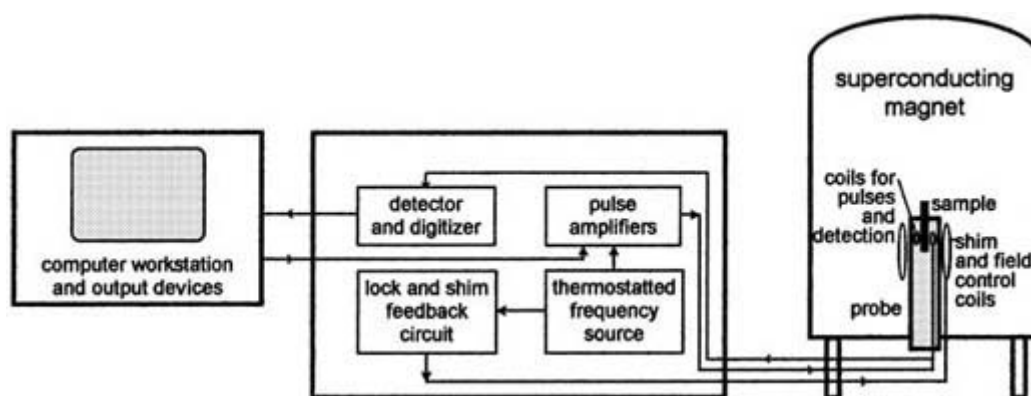

Figure B1.11.2. Simplified representation of an NMR spectrometer with pulsed RF and superconducting magnet. The main magnetic field B_0 is vertical and centred on the sample.

The bulk magnetization is stimulated into precessional motion around B_0 by a radiofrequency (RF) pulse at ν_L , applied through a solenoid-like coil whose axis is perpendicular to B_0 . This motion amounts to a nuclear magnetic resonance. Typically, 10^{-5} s of RF power tilts the magnetization through 90° and thus constitutes a 90° pulse. The coil is then computer-switched from being a transmitter to becoming a receiver, with the free precessional motion of the magnetization generating a small RF voltage in the same coil, at or near the frequency ν_L . The decay time of this oscillating voltage is of the order of T_1 , unless speeded by contributions from exchange or field inhomogeneity. After appropriate amplification and heterodyne detection it is reduced to an audiofrequency and digitized. These raw data are commonly called the free induction decay, or FID,

although the term applies more properly to the original bulk precession.

One further consequence of the use of a pulse, as against the older method of applying a single RF frequency, is that its underlying frequency is broadened over a range of the order of the reciprocal of the pulse length. Indeed, the RF power is in many cases virtually uniform or 'white' across a sufficient range to stimulate all the nuclei of a given isotope at once, even though they are spread out in frequency by differences of chemical shift. Thus, the repeat time for the NMR measurement is approximately T_1 , typically a few seconds, rather than the considerably longer time necessary for sweeping the frequency or the field. Most FIDs are built up by gathering data after repeated pulses, each usually less than 90° in order to permit more rapid repetition. This helps to average away noise and other imperfections, relative to the signal, and it also permits more elaborate experiments involving sequences of multiple pulses and variable interpulse delays.

However, it also necessitates a strictly constant ratio of field to frequency, over the duration of the experiment. Although the master frequency source can be held very constant by a thermostatted source, the field is always vulnerable to local movements of metal, and to any non-persistence of the magnet current. Therefore the field is locked to the frequency through a feedback loop that uses continuous, background monitoring of the ^2H solvent resonance. The probe containing the sample and coil will also normally have at least one further frequency channel, for decoupling experiments (B1.11.6). The lock signal is also simultaneously employed to maximize the field homogeneity across the sample, either manually or automatically, via low-current field correction 'shim' coils. A feedback loop maximizes the height of the lock signal and, because the peak area must nevertheless remain constant, thereby minimizes the peak's width.

-6-

The digitized FID can now be handled by standard computer technology. Several 'spectrum massage' techniques are available for reducing imperfections and noise, and for improving resolution somewhat. The FID is then converted into a spectrum by a discrete Fourier transformation. Essentially, digital sine and cosine waves are generated for each frequency of interest, and the FID is multiplied by each of these in turn. If the product of one particular multiplication does not average to zero across the FID, then that frequency, with that phase, is also present in the FID. The resulting plot of intensity versus frequency is the spectrum. It is normally 'phased' by appropriate combination of the sine and cosine components, so as to contain only positive-going peaks. This permits the measurement of peak areas by digital integration, as well as giving the clearest separation of peaks.

The information within the spectrum can then be presented in many possible ways. In a few cases, it is possible to identify the sample by a fully automatic analysis: for example, by using comparisons with an extensive database. However, most analyses require the knowledge outlined in the following sections.

Many other pulsed NMR experiments are possible, and some are listed in the final sections. Most can be carried out using the standard equipment described above, but some require additions such as highly controllable, pulsed field gradients, shaped RF pulses for (for example) single-frequency irradiations, and the combined use of pulses at several different frequencies.

B1.11.4 QUANTITATION

The simplest use of an NMR spectrum, as with many other branches of spectroscopy, is for quantitative analysis. Furthermore, in NMR all nuclei of a given type have the same transition probability, so that their resonances may be readily compared. The area underneath each isolated peak in an NMR spectrum is proportional to the number of nuclei giving rise to that peak alone. It may be measured to $\sim 1\%$ accuracy by digital integration of the NMR spectrum, followed by comparison with the area of a peak from an added standard.

The absolute measurement of areas is not usually useful, because the sensitivity of the spectrometer depends on factors such as temperature, pulse length, amplifier settings and the exact tuning of the coil used to detect resonance. Peak intensities are also less useful, because linewidths vary, and because the resonance from a given chemical type of atom will often be split into a pattern called a multiplet. However, the relative overall areas of the peaks or multiplets still obey the simple rule given above, if appropriate conditions are met. Most samples have several chemically distinct types of (for example) hydrogen atoms within the molecules under study, so that a simple inspection of the number of peaks/multiplets and of their relative areas can help to identify the molecules, even in cases where no useful information is available from shifts or couplings.

This is illustrated in [figure B1.11.3](#) the integrated ^1H NMR spectrum of commercial paracetamol in deuteriodimethylsulfoxide solvent. The paracetamol itself gives five of the integrated peaks or multiplets. Two other integrated peaks at 3.4 and 1.3 ppm, plus the smaller peaks, arise from added substances. The five paracetamol peaks have area ratios (left to right) of 1:1:2:2:3. These tally with the paracetamol molecule (see diagram). The single H atoms are OH and NH respectively, the double ones are the two distinct pairs of hydrogens on the aromatic ring and the triple ones are the methyl group. Few other molecules will give these ratios, irrespective of peak position.

Figure B1.11.3. 400 MHz ^1H NMR spectrum of paracetamol (structure shown) with added integrals for each singlet or multiplet arising from the paracetamol molecule.

The other peaks demonstrate the power of NMR to identify and quantitate all the components of a sample. This is very important for the pharmaceutical industry. Most of the peaks, including a small one accidentally underlying the methyl resonance of paracetamol, arise from stearic acid, which is commonly added to paracetamol tablets to aid absorption. The integrals show that it is present in a molar proportion of about 2%. The broader peak at 3.4 ppm is from water, present because no attempt was made to dry the sample. Such peaks may be identified either by adding further amounts of the suspected substance, or by the more fundamental methods to be outlined below. If the sample were less concentrated, then it would also be possible to detect the residual hydrogen atoms in the solvent, i.e. from its deuteriodimethylsulfoxide- d^5 impurity, which resonates in this case at 2.5 ppm.

It is evident from the figure that impurities can complicate the use of NMR integrals for quantitation. Further complications arise if the relevant spins are not at Boltzmann equilibrium before the FID is acquired. This may occur either because the pulses are repeated too rapidly, or because some other energy input is present, such as decoupling. Both of these problems can be eliminated by careful timing of the energy inputs, if strictly accurate integrals are required.

Their effects are illustrated in [figure B1.11.4](#) which is a ^1H -decoupled ^{13}C NMR spectrum of the same sample of paracetamol, obtained without such precautions. The main peak integrals are displayed both as steps and also as numbers below the peaks. The peaks from stearic acid are scarcely visible, but the dms- d_6 solvent multiplet at 30 ppm is prominent, because ^{13}C was also present at natural abundance in the solvent. The paracetamol integrals should ideally be in the ratios 1:1:1:2:2:1, corresponding to the carbonyl carbon, the four chemically distinct ring carbons and the methyl carbon to the right. However, the first three peaks correspond to carbons that have no attached H, and their integrals are reduced by factors of between 2 and 3. The methyl peak is also slightly reduced.

Figure B1.11.4. Hydrogen-decoupled 100.6 MHz ^{13}C NMR spectrum of paracetamol. Both graphical and numerical peak integrals are shown.

These reductions arose because the spectrum was obtained by the accumulation of a series of FIDs, generated by pulses spaced by less than the $5 \times T_1$ interval mentioned above, so that a full Boltzmann population difference was not maintained throughout. The shortfall was particularly acute for the unprotonated carbons, for these have long relaxation times, but it was also significant for the methyl group because of its rapid rotational motion. These losses of intensity are called 'saturation'. If they are intentionally introduced by selective irradiation just prior to the pulse, then they become the analogues of hole-bleaching in laser spectroscopy. They are useful for the selective reduction of large, unwanted peaks, as in solvent suppression. Also, because they are a property of the relevant nuclei rather than of their eventual chemical environment they can be used as transient labels in kinetic studies.

The integrals in figure B1.11.4 are, however, also distorted by a quite different mechanism. The spectrum was obtained in the standard way, with irradiation at all the relevant ^1H frequencies so as to remove any couplings from ^1H . This indirect input of energy partly feeds through to the ^{13}C spins via dipolar coupling, to produce intensity gains at all peaks, but particularly at protonated carbons, of up to $\times 3$, and is an example of the nuclear Overhauser enhancement. The phenomenon is quite general wherever T_1 is dominated by dipolar interactions, and when any one set of spins is saturated, whether or not decoupling also takes place. It was discovered by A W Overhauser in the context of the dipolar interactions of electrons with nuclei [5]. The

NOEs between ^1H nuclei are often exploited to demonstrate their spatial proximity, as described in the final section. It is possible to obtain decoupled ^{13}C NMR spectra without the complications of the NOE, by confining the decoupling irradiation to the period of the FID alone, and then waiting for $10 \times T_1$ before repeating the process. However, the $\times 3$ enhancement factor is useful and also constant for almost all protonated carbons, so that such precautions are often superfluous. Both carbon and hydrogen integrals are particularly valuable for identifying molecular symmetry.

-9-

Figure B1.11.5 is an example of how relative integrals can determine structure even if the peak positions are not adequately understood. The decavanadate anion has the structure shown, where oxygens lie at each vertex and vanadiums at the centre of each octahedron. An aqueous solution of decavanadate was mixed with about 8 mol% of molybdate, and the three peaks from the remaining decavanadate were then computer-subtracted from the ^{51}V NMR spectrum of the resulting equilibrium mixture [6]. The remaining six peaks arise from a single product and, although their linewidths vary widely, their integrals are close to being in a 2:2:2:1:1:1 ratio. This not only suggests that just one V has been replaced by Mo, but also identifies the site of substitution as being one of the four MO_6 octahedra not lying in the plane made by vanadiums 1, 2 and 3. No other site or extent of substitution would give these integral ratios.

Figure B1.11.5. 105 MHz ^{51}V NMR subtraction spectrum of the $[\text{MoV}_9\text{O}_{28}]^{5-}$ anion (structure shown). The integrals are sufficient to define the position of the Mo atom.

When T_1 is very short, which is almost always true with nuclei having $I > 1/2$, the dipolar contribution to relaxation will be negligible and, hence, there will be no contributions to the integral from either NOE or saturation. However, resonances more than about 1 kHz wide may lose intensity simply because part of the FID will be lost before it can be digitized, and resonances more than 10 kHz wide may be lost altogether. It is also hard to correct for minor baseline distortions when the peaks themselves are very broad.

B1.11.5 CHEMICAL SHIFTS

Strictly speaking, the horizontal axis of any NMR spectrum is in hertz, as this axis arises from the different frequencies that make up the FID. However, whilst this will be important in the section that follows (on coupling), it is generally more useful to convert these frequency units into fractions of the total spectrometer frequency for the nucleus under study. The usual units are parts per million (ppm). Because frequency is strictly proportional to field in NMR, the same ppm units also describe the fractional shielding or deshielding of the main magnetic field, by the electron clouds around or near the nuclei under study. The likely range of such shieldings is illustrated in [figure B1.11.1](#) [figure B1.11.3](#) and [figure B1.11.4](#).

B1.11.5.1 CALIBRATION

The ppm scale is always calibrated relative to the appropriate resonance of an agreed standard compound, because it is not possible to detect the NMR of bare nuclei, even though absolute shieldings can be calculated with fair accuracy for smaller atoms. Added tetramethylsilane serves as the standard for ^1H , ^2H , ^{13}C and ^{29}Si NMR, because it is a comparatively inert substance, relatively immune to changes of solvent, and its resonances fall conveniently towards one edge of most spectra. Some other standards may be unavoidably less inert. They are then contained in capillary tubes or in the annulus between an inner and an outer tube, where allowance must be made for the jump in bulk magnetic susceptibility between the two liquids. For dilute solutions where high accuracy is not needed, a resonance from the deuteriated solvent may be adequate as a secondary reference. The units of chemical shift are δ . This unit automatically implies ppm from the standard, with the same sign as the frequency, and so measures deshielding. Hence $\delta = 10^6(\nu - \nu_{\text{ref}})/\nu_{\text{ref}}$

B1.11.5.2 LOCAL CONTRIBUTIONS TO THE CHEMICAL SHIFT

The shielding at a given nucleus arises from the virtually instantaneous response of the nearby electrons to the magnetic field. It therefore fluctuates rapidly as the molecule rotates, vibrates and interacts with solvent molecules. The changes of shift with rotation can be large, particularly when double bonds are present. For example, the ^{13}C shift of a carbonyl group has an anisotropy comparable to the full spectrum width in [figure B1.11.4](#). Fortunately, these variations are averaged in liquids, although they are important in the NMR of solids. This averaging process may be visualized by imagining the FID emitted by a single spin. If the emission frequency keeps jumping about by small amounts, then this FID will be made up from a series of short segments of sine waves. However, if the variations in frequency are small compared to the reciprocal of the segment lengths, then the composite wave will be close to a pure sine wave. Its frequency will be the weighted average of its hidden components and the rapid, hidden jumps will not add to the linewidth. This is described as ‘fast exchange on the NMR timescale’ and it is discussed more fully in B.2.7. The same principles apply to rapid chemical changes, such as aqueous protonation equilibria. In contrast, somewhat slower exchange processes increase linewidths, as seen for the OH and NH resonances in [figure B1.11.3](#). In this sample, the individual molecules link transiently via hydrogen bonding, and are thus in exchange between different H-bonded oligomers.

The two primary causes of shielding by electrons are diamagnetism and temperature-independent paramagnetism (TIP). Diamagnetism arises from the slight unpairing of electron orbits under the influence of the magnetic field. This always occurs so as to oppose the field and was first analysed by Lamb [7]. A simplified version of his formula,

appropriate for a single orbital in isolated atoms, shows that the diamagnetic shielding contribution to δ is

proportional to $-\rho_e \langle r^2 \rangle$ where ρ_e is the electron density and $\langle r^2 \rangle$ is the average squared radius of the electron orbit [8]. Thus diamagnetic shielding is lowered and, hence, δ is increased, by the attachment of an electronegative group to the atom under study, for this decreases both ρ_e and $\langle r^2 \rangle$. Similarly, in conjugated systems, δ will often approximately map the distribution of electronic charge between the atoms.

The TIP contribution has the opposite effect on δ . It should not be confused with normal paramagnetism, for it does not require unpaired electrons. Instead, it arises from the physical distortion of the electron orbitals by the magnetic field. A highly simplified derivation of the effect of TIP upon δ shows it to be proportional to $+\langle r^{-3} \rangle / \Delta E$, with r as above. ΔE is a composite weighting term representing the energy gaps between the occupied and the unoccupied orbitals. A small ΔE implies orbitals that are accessible and hence vulnerable to magnetic distortion. ΔE is particularly large for H, making the TIP contribution small in this case, but for all other atoms TIP dominates δ . The effect of an electronegative group on the TIP of an atom is to shrink the atom slightly and, thus, to increase δ , i.e. it influences chemical shift in the same direction as described above in the case of diamagnetism, but for a different reason.

These effects are clearly seen for saturated molecules in [table B1.11.1](#), which correlates the ^1H and ^{13}C NMR chemical shifts of a series of compounds $\text{X}-\text{CH}_3$ with the approximate Pauling electronegativities of X. Both δ_{H} and δ_{C} increase with X as predicted, although the sequence is slightly disordered by additional, relativistic effects at the C atoms, when X is a heavy atom such as I. The correlations of shift with changes in the local electric charge and, hence, with orbital radius, are also seen for an aromatic system in [figure B1.11.6](#). Here the hydrogen and carbon chemical shifts in phenol, quoted relative to benzene, correlate fairly well both with each other and also with the charge distribution deduced by other means.

Figure B1.11.6. ^1H and ^{13}C chemical shifts in phenol, relative to benzene in each case. Note that δ (H or C) approximately follows δ (the partial charge at C).

Table B1.11.1. Effect of an electronegative substituent upon methyl shifts in $\text{X}-^{13}\text{C}^1\text{H}_3$.

X	δ_{H}	δ_{C}	Electronegativity of X
---	---------------------	---------------------	------------------------

Si(CH ₃) ₃	0.0	0.0	1.8
H	0.13	-2.3	2.1
CH ₃	0.88	5.7	2.5
I	2.16	-20.7 ^a	2.5
NH ₂	2.36	28.3	2.8
Br	2.68	10.0 ^a	2.8
Cl	3.05	25.1	3.0
OH	3.38	49.3	3.5
F	4.26	75.4	4.0

^a Heavy-atom relativistic effects influence these shifts.

The effects of TIP also appear in [figure B1.11.3](#) and [figure B1.11.4](#). In the ¹³C NMR spectrum, all the resonances of the sp² carbons lie above 100 ppm (a useful general rule of thumb) because ΔE is smaller for multiple bonds. The highest shifts are for the carbonyl C at 169 ppm and the ring C attached to oxygen at 155 ppm, because of the high electronegativity of O. In the ¹H spectrum, H atoms attached to sp² carbons also generally lie above 5 ppm and below 5 ppm if attached to sp³ carbons. However, the NH and OH resonances have much less predictable shifts, largely governed by the average strength of the associated hydrogen bonds. When these are exceptionally strong, as in nucleic acids, δ_{H} can be as high as 30 ppm, whereas most normal H shifts lie in the range 0–10 ppm.

[Table B1.11.2](#) gives a different example of the effects of TIP. In many fluorine compounds, ΔE is largely determined by the energy difference between the bonding and antibonding orbitals in the bond to F, and hence by the strength of this bond. The ¹⁹F shifts correlate nicely in this way. For example, C–F bonds are notoriously strong and so give low values of δ_{F} , whereas the remarkable reactivity of F₂ depends on the weakness of the F–F bond, which also gives F₂ a much higher chemical shift. The weakness of the bond to F is even more apparent in the chemical shifts of the explosive compounds XeF₆ and FOOF. In some compounds the spectra also reflect the presence of distinct types of fluorine within the molecule. For example, ClF₃ has a T-shaped structure with the Cl–F bond stronger for the stem of the T, giving this single F atom a lower shift.

-13-

Table B1.11.2. Fluorine-19 chemical shifts.

Organic compounds	δ_{F}	Inorganic compounds	δ_{F}	Metal fluorides	δ_{F}
-------------------	---------------------	---------------------	---------------------	-----------------	---------------------

CH ₃ F	-272	HF	-221	MoF ₆	-278
CH ₃ CH ₂ F	-213	LiF	-210	SbF ₅	-108
C ₆ F ₆	-163	[BF ₄] ⁻	-163	WF ₆	+166
CH ₂ F ₂	-143	BF ₃	-131	ReF ₇	+345
F ₂ C=CF ₂	-135	ClF ₃	-4 (1), +116 (2)		
H ₂ C=CF ₂	-81	IF ₇	+170		
CF ₃ R	-60 to -70	IF ₅	+174 (1), +222 (4)		
CF ₂ Cl ₂	-8	ClF ₅	+247 (1), +412 (4)		
CFCl ₃	0 (reference)	XeF ₂	+258		
CF ₂ Br ₂	+7	XeF ₄	+438		
CFBr ₃	+7	XeF ₆	+550		
		F ₂	+421.5		
		ClF	+448.4		
		FOOF	+865		

The shifts for other nuclei are not usually so simple to interpret, because more orbitals are involved, and because these may have differing effects on $\langle r^{-3} \rangle$ and on ΔE . Nevertheless, many useful correlations have been recorded [9]. A general rule is that the range of shifts increases markedly with increasing atomic number, mainly because of decreases in ΔE and increases in the number of outer-shell electrons. The shift range is particularly large when other orbital factors also lower and vary ΔE , as in cobalt[III] complexes. However, the chemical shifts for isotopes having the same atomic number, such as ¹H, ²H and ³H, are almost identical. Each nucleus serves merely to report the behaviour of the same electron orbitals, except for very small effects of isotopic mass on these orbitals.

B1.11.5.3 CHEMICAL SHIFTS ARISING FROM MORE DISTANT MOIETIES

Hydrogen shifts fall within a narrow range and, hence, are proportionally more susceptible to the influence of more distant atoms and groups. As an example, aromatic rings have a large diamagnetic anisotropy, because the effective radius of the electron orbit around the ring is large. This affects the chemical shifts of nearby atoms by up to 5 ppm, depending on their position relative to the ring. It also explains the relatively high shifts of the hydrogens directly attached to the ring. The diamagnetism of the ring is equivalent to a solenoid opposing B_0 . Its lines of force necessarily loop backwards outside the ring and therefore deshield atoms in or near the ring plane. The effect is illustrated in figure B1.11.7 for a paracyclophane. The methylene shift values fall both above and below the value of 1.38, expected in the absence of the aromatic moiety, according to the average positioning of the methylene hydrogens relative to the ring plane. Similar but smaller shifts are

observed with simple double and triple bonds, because these also generate a significant circulation of electrons. Polycyclic aromatic systems generate even larger shifts, in regions near to more than one ring.

Figure B1.11.7. ^1H chemical shifts in [10]-paracyclophane. They have values on either side of the 1.38 ppm found for large polymethylene rings and, thus, map the local shielding and deshielding near the aromatic moiety, as depicted in the upper part of the figure.

Shifts are also affected by steric compression of any kind on the atom under study. The effect on a C atom can reduce δ_C by up to 10 ppm. For example, the ^{13}C chemical shifts of the methyl carbons in but-2-ene are 5 ppm lower in the *cis* isomer than in the *trans*, because in the *cis* case the methyl carbons are only about 3 Å apart. Steric shifts are particularly important in the ^{13}C NMR spectra of polymers, for they make the peak positions dependent on the local stereochemistry and, hence, on the tacticity of the polymer [10].

B1.11.5.4 SHIFT REAGENTS

Nearby paramagnetic molecules can also have a similar effect on shifts. Their paramagnetic centre will often possess a substantially anisotropic *g*-factor. If the paramagnetic molecule then becomes even loosely and temporarily attached to the molecule under study, this will almost always lead to significant shift changes, for the same reasons as with nearby multiple bonds. Furthermore, if the molecule under study and its paramagnetic attachment are both chiral, the small variations in the strength and direction of the attachment can effect a separation of the shifts of the two chiral forms

and thus detect any enantiomeric excess. The paramagnetic species thus acts as a chiral shift reagent. In practice, the effect of the paramagnetic additive will be complicated, because there may be further shifts arising from direct leakage of free electron density between the paired molecules. There will also be broadening due to the large magnetic dipole of the unpaired electrons. These complications can be reduced by a judicious choice of shift reagent. It may also be possible to use a diamagnetic shift reagent such as 2,2'-trifluoromethyl-9-anthrylethanol and thus avoid the complications of paramagnetic broadening altogether, whilst hopefully retaining the induced chiral separation of shifts [11].

B1.11.5.5 THE PREDICTION OF CHEMICAL SHIFTS

Enormous numbers of chemical shifts have been recorded, particularly for ^1H and ^{13}C . Many algorithms for the prediction of shifts have been extracted from these, so that the spectra of most organic compounds can be predicted at a useful level of accuracy, using data tables available in several convenient texts [12, 13, 14 and 15]. Alternatively, computer programs are available that store data from 10^4 – 10^5 spectra and then use direct

structure-comparison methods to predict the ^1H and ^{13}C chemical shifts of new species.

Shifts can also be predicted from basic theory, using higher levels of computation, if the molecular structure is precisely known [16]. The best calculations, on relatively small molecules, vary from observation by little more than the variations in shift caused by changes in solvent. In all cases, it is harder to predict the shifts of less common nuclei, because of the generally greater number of electrons in the atom, and also because fewer shift examples are available.

B1.11.6 THE DETECTION OF NEIGHBOURING ATOMS–COUPLINGS

The ^1H NMR spectrum in figure B1.11.2 shows two resonances in the region around 7 ppm, from the two types of ring hydrogens. Each appears as a pair of peaks rather than as a single peak. This splitting into a pair, or ‘doublet’, has no connection with chemical shift, because if the same sample had been studied at twice the magnetic field, then the splitting would have appeared to halve, on the chemical shift scale. However, the same splitting does remain strictly constant on the concealed, frequency scale mentioned previously, because it derives not from B_0 , but instead from a fixed energy of interaction between the neighbouring hydrogen atoms on the ring. Each pair of peaks in the present example is called a doublet: a more general term for such peak clusters is a multiplet. The chemical shift of any symmetrical multiplet is the position of its centre, on the ppm scale, whether or not any actual peak arises at that point. The area of an entire multiplet, even if it is not fully symmetric, obeys the principles of section B1.11.4 above. It follows that the individual peaks in a multiplet may be considerably reduced in intensity compared with unsplit peaks, especially if many splittings are present.

The splittings are called J couplings, scalar couplings or spin–spin splittings. They are also closely related to hyperfine splittings in ESR. Their great importance in NMR is that they reveal interactions between atoms that are chemically nearby and linked by a bonding pathway. The J value of a simple coupling is the frequency difference in hertz between the two peaks produced by the coupling. It is often given by the symbol nJ , where n is the number of bonds that separate the coupled atoms. Thus, in combination with chemical shifts and integrals, they will often allow a chemical structure to be determined from a single ^1H NMR spectrum, even of a previously unknown molecule of some complexity. Their presence also permits a wide range of elegant experiments where spins are manipulated by carefully timed pulses. However, they also complicate spectra considerably if more than a few interacting atoms are present,

-16-

particularly at low applied fields, when the chemical shift separations, converted back to hertz, are not large in comparison with the couplings. Fortunately some of the aforesaid elegant experiments can extract information on the connectivities of atoms, even when the multiplets are too complex or overlapped to permit a peak-by-peak analysis.

B1.11.6.1 COUPLING MECHANISMS

The simplest mechanism for spin–spin couplings is described by the Fermi contact model. Consider two nuclei linked by a single electron-pair bond, such as ^1H and ^{19}F in the hydrogen fluoride molecule. The magnetic moment of ^1H can be either ‘up’ or ‘down’ relative to B_0 , as described earlier, with either possibility being almost equally probable at normal temperatures. If the ^1H is ‘up’ then it will have a slight preferential attraction for the ‘down’ electron in the bond pair, i.e. the one whose magnetic moment lies antiparallel to it, for magnets tend to pair in this way. The effect will be to unpair the two electrons very slightly and, thus, to make the ^{19}F nucleus more likely to be close to the ‘up’ electron and thus slightly favoured in energy, if it is itself ‘down’. The net result is that the ^1H and ^{19}F nuclei gain slightly in energy when they are mutually antiparallel. The favourable and unfavourable arrangements are summarized as follows:

energetically favourable: $H\uparrow e\downarrow\uparrow e\downarrow F$ $H\downarrow e\uparrow\downarrow e\uparrow F$ energy gain $\frac{1}{4}J$
energetically unfavourable: $H\uparrow e\downarrow\uparrow e\uparrow F$ $H\downarrow e\uparrow\downarrow e\downarrow F$ energy loss $\frac{1}{4}J$.

These energy differences then generate splittings as outlined in [figure B1.11.8](#). If the energies of the two spins, here generalized to I and S, in the magnetic field are corrected by the above $\pm \frac{1}{4}J$ quantities, then the transitions will move from their original frequencies of ν_I and ν_S to $\nu_I \pm \frac{1}{2}J$ and $\nu_S \pm \frac{1}{2}J$. Thus, both the I and the S resonances will each be symmetrically split by J Hz. In the case of $^1H^{19}F$, $^1J_{HF} = +530$ Hz. The positive sign applies when the antiparallel nuclear spin configuration is found, and the '1' superscript refers to the number of bonds separating the two spins.

[Figure B1.11.8](#) does not apply accurately in the not uncommon cases when I and S have Larmor frequencies whose separation $\Delta\nu$ is not large compared with J_{IS} . In these cases the two spin states where I and S are antiparallel have very similar energies, so that the coupling interaction mixes their spin states, analogously to the non-crossing rule in UV-visible spectroscopy. As $\Delta\nu$ falls, the peak intensities in the multiplet alter so as to boost the component(s) nearest to the other multiplet, at the expense of the other components, whilst keeping the overall integral of the multiplet constant. This 'roofing' or 'tenting' is an example of a second-order effect on couplings. It is actually useful up to a point, in that it helps the analysis of couplings in a complex molecule, by indicating how they pair off. Some examples are evident in subsequent figures. [Figure B1.11.10](#) for example, shows mutual roofing of the H-6a and H-6b multiplets, and also of H-3 with H-2. Roofing is also seen, more weakly, in [Figure B1.11.9](#), where every multiplet is slightly tilted towards the nearest multiplet with which it shares a coupling. Indeed, it is unusual not to see second-order distortions in 1H NMR spectra, even when these are obtained at very high field.

Figure B1.11.8. Combined energy states for two spins I and S (e.g. 1H and ^{13}C) with an exaggerated representation of how their mutual alignment *via* coupling affects their combined energy.

As $\Delta\nu$ gets even smaller, the outer components of the multiplet become invisibly small. Further splittings may also appear in complex multiplets. In the extreme case that $\Delta\nu = 0$, the splittings disappear altogether, even though the physical coupling interaction is still operative. This is why the methyl resonance in [figure B1.11.3](#) appears as a single peak. It is occasionally necessary to extract accurate coupling constants and chemical shifts from complex, second-order multiplets, and computer programs are available for this.

B1.11.6.2 FACTORS THAT DETERMINE COUPLING CONSTANTS

Because J arises from the magnetic interactions of nuclei, the simplest factor affecting it is the product $\gamma_I\gamma_S$ of the two nuclear magnetogyric ratios involved. For example, $^1J_{DF}$ in $^2H^{19}F$ is 82 Hz, i.e. $^1J_{HF} \times \gamma_D/\gamma_H$. This totally predictable factor is sometimes discounted by quoting the reduced coupling constant $K_{IS} \equiv 4\pi^2 J_{IS}/h\gamma_I\gamma_S$.

A second determining factor in the Fermi contact mechanism is the requirement that the wavefunction of the bonding orbital has a significant density at each nucleus, in order for the nuclear and the electron magnets to interact. One consequence of this is that K correlates with nuclear volume and therefore rises sharply for heavier nuclei. Thus the 1K constants in the XH_4 series with $X = ^{13}C, ^{29}Si, ^{73}Ge, ^{119}Sn$ and ^{207}Pb are respectively +41.3, +84.9, +232, +430 and +938 $N A^{-2} m^{-3}$. Here the average value of $(K/\text{nuclear mass number}) = 3.5 \pm 1$.

-18-

The presence of a spin-spin splitting therefore means that the interacting atomic orbitals must each possess significant s character, because all orbitals other than s have zero density at the nucleus. The $^1J_{CH}$ values for CH_4 , $H_2C=CH_2$ and $HC\equiv CH$ illustrate the dependence of J upon s character. They are respectively +124.9, +156.2 and +249 Hz, and so they correlate unusually precisely with the s characters of the carbon orbitals bonding to H, these being respectively 25, 33.3 and 50%. A coupling also shows that the bond that carries the coupling cannot be purely ionic. A significant J value demonstrates covalency, or at least orbital overlap of some kind.

The next large influence on nJ is the number of bonds n in the bonding pathway linking the two spins and their stereochemistry. When $n > 1$, then there will be at least two electron pairs in the pathway, and J will thus be attenuated by the extent to which one electron pair can influence the next. In simple cases, the insertion of a further electron pair will reverse the sign of J , because parallel electrons in different, interacting orbitals attract each other slightly, following Hund's rules. Thus, for a two-bond pathway, a favoured spin configuration will now be

Some other general rules have been extracted; they come particularly from $^nJ_{HH}$ data, but also have a wider validity in many cases.

- $n = 2$ 2J is often low, because of competing pathways involving different orbitals. A typical value for chemically distinct H atoms in a methylene group is -14 Hz. However, it can rise to zero, or even to a positive value, in $C = CH_2$ moieties.
- $n = 3$ 3J is almost always positive and its magnitude often exceeds that of 2J . It always depends in a predictable way on the dihedral angle ϕ between the outer two of the three bonds in the coupling pathway. Karplus first showed theoretically that 3J varies to a good approximation as $A \cos^2\phi + B \cos\phi$, where A and B are constants, and also that $A \gg B$ [17]. His equation has received wide-ranging

experimental verification. For a typical HCCH pathway, with not particularly electronegative substituents, $A = 13$ Hz and $B = -1$ Hz. This predicts ${}^3J = 14.0$ Hz for $\phi = 180^\circ$ and 2.75 Hz for $\phi = 60^\circ$. Thus, a typical HCCH₃ coupling, where the relevant dihedral angles are 60° (twice) and 180° (once) will average to $(2 \times 2.75 + 14)/3 = 6.5$ Hz, as the C–C bond rotates. Almost all other 3J couplings follow a similar pattern, with 3J being close to zero if $\phi = 90^\circ$, even though the values of A vary widely according to the atoms involved. The pattern may be pictured as a direct, hyperconjugative interaction between the outer bonding orbitals, including their rear lobes. It is only fully effective when these orbitals lie in the same plane. The Karplus equation offers a valuable way of estimating bond angles from couplings, especially in unsymmetrical molecular fragments such as CH–CH₂, where the presence of two 3J couplings eliminates any ambiguities in the values of ϕ .

- $n = 4$ 4J couplings are often too small to resolve. However, they are important in cases where the relevant orbitals are aligned appropriately. If the molecular fragment HC–C=CH has the first CH bond approximately parallel to the C=C π orbital, the resulting hyperconjugative interaction will give rise to an ‘allylic’ coupling of about -2 Hz. A similar coupling arises in a saturated HC–C–CH fragment if the bonds lie approximately in a W configuration. In such cases the rear lobes of the CH bonding orbitals touch, thus offering an extra electronic pathway for coupling. Indeed, all such contacts give rise to couplings, even if the formal bonding pathway is long.

-19-

Although the Fermi contact mechanism dominates most couplings, there are smaller contributions where a nuclear dipole physically distorts an orbital, not necessarily of s type [18]. There are many useful compilations of J and K values, especially for HH couplings (see [9], ch 4, 7–21 and [12, 13, 14 and 15]).

B1.11.6.3 MULTIPLE COUPLINGS

In principle, every nucleus in a molecule, with spin quantum number I , splits every other resonance in the molecule into $2I + 1$ equal peaks, i.e. one for each of its allowed values of m_I . This could make the NMR spectra of most molecules very complex indeed. Fortunately, many simplifications exist.

- As described above, most couplings fall off sharply when the number of separating bonds increases.
- Nuclei with a low isotopic abundance will contribute correspondingly little to the overall spectra of the molecule. Thus, splittings from the 1.1% naturally abundant ${}^{13}\text{C}$ isotope are only detectable at low level in both ${}^1\text{H}$ and ${}^{13}\text{C}$ NMR spectra, where they are called ${}^{13}\text{C}$ sidebands.
- Nuclei with $I > 1/2$ often relax so rapidly that the couplings from them are no longer detected, for reasons analogous to shift averaging by chemical exchange. For example, couplings from Cl, Br and I atoms are invisible, even though these halogens all have significant magnetic moments.
- Chemical exchange will similarly average couplings to zero, if it takes place much faster than the value of the coupling in hertz.
- Selected nuclei can also have their couplings removed deliberately (decoupled) by selective irradiation during the acquisition of the FID.

Despite these simplifications, a typical ${}^1\text{H}$ or ${}^{19}\text{F}$ NMR spectrum will normally show many couplings. [Figure B1.11.9](#) is the ${}^1\text{H}$ NMR spectrum of propan-1-ol in a dilute solution where the exchange of OH hydrogens between molecules is slow. The underlying frequency scale is included with the spectrum, in order to emphasize how the couplings are quantified. Conveniently, the shift order matches the chemical order of the atoms. The resonance frequencies of each of the 18 resolved peaks can be quantitatively explained by the four chemical shifts at the centre of each multiplet, plus just three values of 3J , two of these being in fact almost the same. If the hydrogen types are labelled in chemical order from the methyl hydrogens H₃-3 to the

hydroxyl hydrogen then the three coupling types visibly present are ${}^3J_{23} = 2a$, ${}^3J_{12} = 2b$ and ${}^3J_{1-OH} = 2c$ Hz, with $a \approx b$ because of the strong chemical similarity of all the HCCH bonding pathways. Consider first the methyl resonance H_3-3 , and its interaction with the two equivalent hydrogens $H-2$ and $H-2'$. Each of the three equivalent hydrogens of H_3-3 will first be split into a 1:1 doublet by $H-2$, with peak positions $\delta_3 \pm a$, i.e. a Hz on either side of the true chemical shift δ_3 , reconverted here into frequency units. $H-2'$ will further split each component, giving three peaks with positions $\delta_3 \pm a \pm a$. When all the possible \pm combinations are considered, they amount to peaks at δ_3 (twice) plus $\delta_3 \pm 2a$ (once each) and are conveniently called a (1:2:1) triplet. The OH multiplet is similarly a (1:2:1) triplet with peaks at δ_{OH} (twice) plus $\delta_{OH} \pm 2c$ (once each).

-20-

Figure B1.11.9. Integrated 250 MHz ${}^1\text{H}$ NMR spectrum of dilute propan-1-ol in dimethylsulfoxide solvent. Here, the shift order parallels the chemical order. An expansion of the H_2-1 multiplet is included, as is the implicit frequency scale, also referenced here to TMS = 0.

Figure B1.11.10. 400 MHz ${}^1\text{H}$ NMR spectrum of methyl- α -glucopyranose (structure as in figure B1.11.12)

together with the results of decoupling at H-1 (centre trace) and at H-4 (upper trace).

-21-

Each H-1 hydrogen contributes to a more complex multiplet, with peaks at all combinations of the frequencies $\delta_1 \pm b \pm b \pm c$, thus making a triplet of doublets whose peak positions are $\delta_1 \pm c$ (twice each) and $\delta_1 \pm 2b \pm c$ (once each). Finally, each H-2 hydrogen contributes to the sextet at $\delta_2 = 1.42$ ppm, whose individual components appear at $\delta_2 \pm a \pm a \pm a \pm b \pm b$. If we take $b = a$, then the possible combinations of these frequencies amount to the following peak positions, with their relative heights given in brackets: $\delta_2 \pm 5a$ (1), $\delta_2 \pm 3a$ (5), $\delta_2 \pm a$ (10). Note that the relative intensities follow Pascal's triangle and also that the separation of the outermost line of a multiplet must always equal the sum of the underlying couplings, when only spin-1/2 nuclei are involved.

The same principles apply to couplings from spins with $I > 1/2$, where these are not seriously affected by relaxation. [Figure B1.11.4](#) illustrates a common case. The solvent resonance at 30 ppm is a 1:3:6:7:6:3:1 multiplet arising from the $^{13}\text{C}^2\text{H}_3$ carbons in the solvent deuterioacetone. Each of the three deuterium nuclei splits the carbon resonance into a 1:1:1 triplet, corresponding to the three possible Zeeman states of an $I = 1$ nucleus. Thus the overall peak positions are the possible combinations of $\delta_{\text{C}} + (a \text{ or } 0 \text{ or } -a) + (a \text{ or } 0 \text{ or } -a) + (a \text{ or } 0 \text{ or } -a)$, where the coupling constant a is ~ 20 Hz.

With relatively simple spectra, it is usually possible to extract the individual coupling constants by inspection, and to pair them by size in order to discover what atoms they connect. However, the spectra of larger molecules present more of a challenge. The multiplets may overlap or be obscured by the presence of several unequal but similarly sized couplings. Also, if any chiral centres are present, then the two hydrogens in a methylene group may no longer have the same chemical shift, and in this case they will also show a mutual 2J coupling. Fortunately, several powerful aids exist to meet this challenge: decoupling and a range of multidimensional spectra.

B1.11.6.4 DECOUPLING

Several examples have already been given of resonances that merge because the underlying molecular or spin states interchange more rapidly than their frequency separation. Similar interchanges can also be imposed so as to remove a coupling in a controllable way. One irradiates a selected resonance so as to give its magnetization no preferred direction, within the timescale set by the coupling to be removed. This can be achieved selectively for any resonance removed from others by typically 20 Hz, although multiplets nearly as close as this will unavoidably be perturbed in a noticeable and predictable way by the irradiation process.

[Figure B1.11.10](#) offers an example. It shows the 400 MHz ^1H NMR spectrum of α -1-methylglucopyranose, below two further spectra where ^1H -decoupling has been applied at H-1 and H-4 respectively. The main results of the decouplings are arrowed. Irradiation at the chemical shift position of H-1 removes the smaller of the two couplings to H-2. This proves the saccharide to be in its α form, i.e. with $\phi \approx 60^\circ$ rather than 180° , according to the Karplus relationship given previously. Note that both the H-1 resonance and the overlapping solvent peak are almost totally suppressed by the saturation, caused by the decoupling irradiation. The H-4 resonance is a near-triplet, created by the two large and nearly equal couplings to H-3 and H-5. In both these cases, $\phi \approx 180^\circ$. The spectrum in this shift region is complicated by the methyl singlet and by some minor peaks from impurities. However, these do not affect the decoupling process, beyond being severely distorted by it. Genuine effects of decoupling are seen at the H-3 and the H-5 resonances only.

Single-frequency decoupling is easy and rapidly carried out. However, it may be limited by the closeness of different multiplets. Also, it will not normally be possible to apply more than one frequency of decoupling irradiation at a time. Fortunately, these disadvantages do not apply to the equivalent multidimensional methods.

It is also usually possible to remove all the couplings from a particular isotope, e.g. ^1H , provided that one only wishes to observe the spectrum from another isotope, e.g. ^{13}C . Either the decoupling frequency is noise-modulated to cover the relevant range of chemical shifts, or else the same decoupling is achieved more efficiently, and with less heating of the sample, by using a carefully designed, continuous sequence of composite pulses. [Figure B1.11.4](#) is a ^1H -decoupled ^{13}C spectrum: this is sometimes abbreviated to $^{13}\text{C}\{^1\text{H}\}$. In the absence of decoupling, the resonances would each be split by at least four short- and long-range couplings from ^1H atoms, and the signal-to-noise ratio would drop accordingly. The largest couplings would arise from the directly attached hydrogens. Thus, one might use a ^{13}C NMR spectrum without decoupling to distinguish CH_3 (broadened 1:3:3:1 quartets) from CH_2 (1:2:1 triplets) from CH (1:1 doublets) from C (singlets). However, more efficient methods are available for this, such as the DEPT and INEPT pulse sequences outlined below. Two-dimensional methods are also available if one needs to detect the connectivities revealed by the various ^{13}C - ^1H couplings.

B1.11.6.5 POLARIZATION TRANSFER

Couplings can also be exploited in a quite different way, that lies behind a wide range of valuable NMR techniques. If just one component peak in a multiplet X can be given a non-equilibrium intensity, e.g. by being selectively inverted, then this necessarily leads to large changes of intensity in the peaks of any other multiplet that is linked via couplings to X. [Figure B1.11.11](#) attempts to explain this surprising phenomenon. Part A shows the four possible combined spin states of a $^{13}\text{C}^1\text{H}$ molecular fragment, taken as an example. These are the same states as in [Figure B1.11.8](#), but attention is now drawn to the populations of the four spin states, each reduced by subtracting the 25% population that would exist at very low field, or alternatively at infinite temperature. The figures above each level are these relative differences, in convenient units. The intensity of any one transition, i.e. of the relevant peak in the doublet, is proportional to the difference of these differences, and is therefore proportionally relative to unity for any ^{13}C transition at Boltzmann equilibrium, and 4 for any ^1H transition.

The only alteration in part B is that the right hand ^1H transition has been altered so as to interchange the relevant populations. In practice, this might be achieved either by the use of a highly selective soft pulse, or by a more elaborate sequence of two pulses, spaced in time so as to allow the Larmor precessions of the two doublet components to dephase by 180° . The result is to produce a ^{13}C doublet whose relative peak intensities are 5: -3, in place of the original 1:1. Further, similar manipulations of the ^{13}C spins can follow, so as to re-invert the -3 component. This results in a doublet, or alternatively a singlet after decoupling, that has four times the intensity it had originally. The underlying physical process is called polarization transfer. More generally, any nucleus with magnetogyric ratio γ_A , coupled to one with γ_B , will have its intensity altered by γ_B/γ_A . This gain is valuable if $\gamma_B \gg \gamma_A$. The technique is then called INEPT (insensitive nucleus enhancement by polarization transfer) [19]. It has an added advantage. The relaxation rate of a high- γ nucleus is usually much less than that of a low- γ nucleus, because it has a bigger magnetic moment to interact with its surroundings. In the INEPT experiment, the spin populations of the low- γ nucleus are driven by the high- γ nucleus, rather than by natural relaxation. Hence the repeat time for accumulating the FID is shortened to that appropriate for the high- γ nucleus.

Figure B1.11.11. Polarization transfer from ^1H to ^{13}C (see the text). The inversion of one H transition also profoundly alters the C populations.

The same general methodology can also be applied to edit (for example) a decoupled ^{13}C NMR spectrum into four subspectra, for the CH_3 , CH_2 , CH and C moieties separately. A common variant method called DEPT (distortionless enhancement by polarization transfer) uses non-standard pulse angles, and is a rapid and reliable way for assigning spectra of medium complexity [20].

More generally, note that the application of almost any multiple pulse sequence, where at least two pulses are separated by a time comparable to the reciprocal of the coupling constants present, will lead to exchanges of intensity between multiplets. These exchanges are the physical method by which coupled spins are correlated in 2D NMR methods such as correlation spectroscopy (COSY) [21].

B1.11.7 TWO-DIMENSIONAL METHODS

The remarkable stability and controllability of NMR spectrometers permits not only the precise accumulation of FIDs over several hours, but also the acquisition of long series of spectra differing only in some stepped variable such as an interpulse delay. A peak at any one chemical shift will typically vary in intensity as this series is traversed. All the sinusoidal components of this variation with time can then be extracted, by Fourier transformation of the variations. For example, suppose that the normal 1D NMR acquisition sequence (relaxation delay, 90° pulse, collect FID) $_n$ is replaced by the 2D sequence (relaxation delay, 90° pulse, delay τ - 90° pulse, collect FID) $_n$ and that τ is increased linearly from a low value to create the second dimension. The polarization transfer process outlined in the previous section will then cause the peaks of one multiplet to be modulated in intensity, at the frequencies of any other multiplet with which it shares a coupling.

The resulting data set constitutes a rectangular or square array of data points, having a time axis in both dimensions. This is converted via Fourier transformation in both dimensions, giving the corresponding array of points in a 2D spectrum, with each axis being in δ units for convenience. These are most conveniently plotted as a contour map. In the above example the experiment is COSY-90, '90' referring to the second pulse, and the map should be at least approximately symmetrical about its diagonal. Any off-diagonal or 'cross' peaks then indicate the presence of couplings. Thus, a cross-peak with coordinates (δ_A, δ_B) indicates a coupling that connects the multiplets A and B. The spectrum is normally simplified by eliminating superfluous, mirror-image peaks, either with phase-cycled pulses and appropriate subtractions or by the use of carefully controlled, linear pulsed field gradients. No special equipment is needed in a modern spectrometer, although the data sets are typically 1 Mbyte or larger. The time requirement is only about 16 times that for a 1D spectrum, in favourable cases, and may be less if pulsed field gradients are used.

B1.11.7.1 HOMONUCLEAR COSY SPECTRA

Figure B1.11.12 shows the 2D COSY-45 contour plot of the same α -1-methylglucopyranose compound as in a previous figure. The corresponding 1D spectrum, plotted directly above, is in fact the projection of the 2D spectrum onto the horizontal shift axis. The hydrogen assignments are added underneath the multiplets. The analysis of such a spectrum begins by selecting one peak, identifiable either by its distinctive chemical shift or by mapping its coupling pattern onto the expected pattern of molecular connectivity. Here, the doublet at 4.73 ppm uniquely has the high shift expected when a CH group bears two O substituents. The coupling pattern can now be identified by noting the horizontal and vertical alignments of all the strongest diagonal and off-diagonal resonances. These alignments must be exact, within the limits of the digitization, as the COSY process does not cause any shifts. The H-1 to H-2 correlation exemplifies this precision, in that the cross-peak whose centre has coordinates at δ (3.47, 4.73) is precisely aligned with the centres of the H-2 and H-1 multiplets respectively. The same principle allows one to see that the cross-peak at δ (3.47, 3.59) arises from the (H-2 to H-3) coupling, whereas the more complex multiplet to the right of it must come from the overlap of the (H-3 to H-4) and the (H-5 to H-4) cross-peaks, respectively at δ (3.59, 3.33) and δ (3.56, 3.33). In this way it is possible to distinguish the H-3 and H-5 multiplets, respectively at 3.59 and 3.56 ppm, even though they overlap in the 1D spectrum. This illustrates the power of multidimensional NMR to separate overlapping resonances. In a similar way, the 2D spectrum makes it clear that the OCH_3 resonance at 3.35 ppm has no coupling connection with any other hydrogen in the saccharide, so that its shift overlap with H-4 is purely accidental.

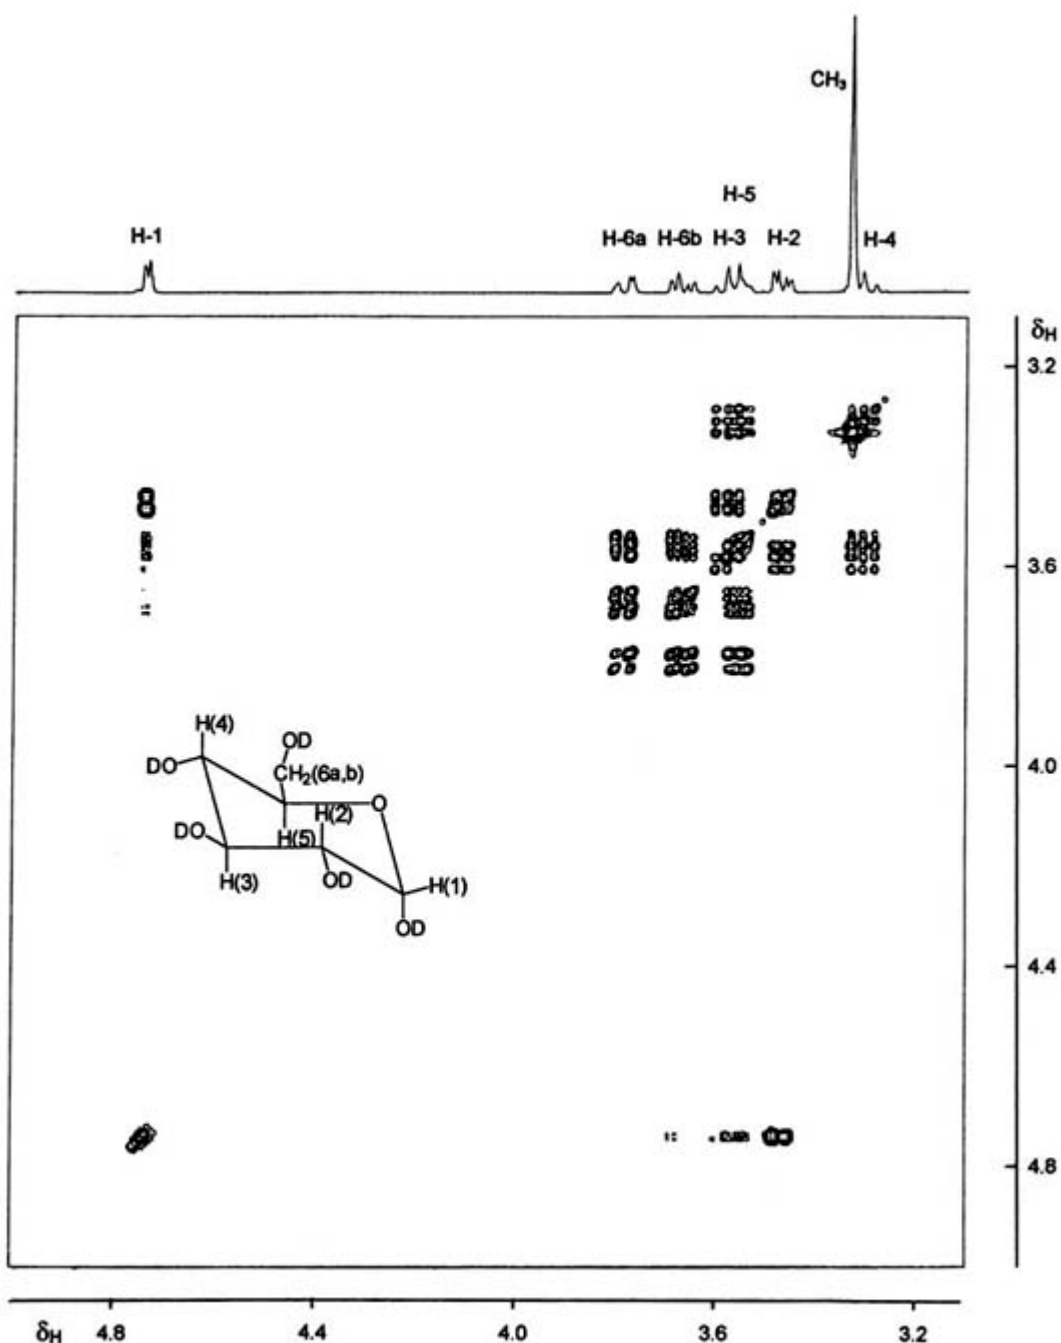

Figure B1.11.12. ^1H - ^1H COSY-45 2D NMR spectrum of methyl- α -glucopyranose (structure shown). The coupling links and the approximate couplings can be deduced by inspection.

Several other features of the figure merit attention. The two hydroxymethyl resonances, H-6a at 3.79 ppm and H-6b at 3.68 ppm, are separated in shift because of the chiral centres present, especially the nearby one at C-5. (One should note that a chiral centre will always break the symmetry of a molecule, just as an otherwise symmetrical coffee mug loses its symmetry whilst grasped by a right hand.) H-5 is thus distinctive in showing three coupling connections, and could be assigned by this alone, in the absence of other information. Also, the (H-6a to H-6b) cross-peak gives the general impression of a tilt parallel to the diagonal, whereas some of the other cross-peaks show the opposite tilt. This appearance of a tilt in the more complex cross-peaks is the deliberate consequence of completing the COSY pulse sequence with a 45° rather than a 90° pulse. It actually arises from selective changes of intensity in the component peaks of the off-diagonal multiplet. The 'parallel'

pattern arises from negative values of the coupling constant responsible for the cross-peak, i.e. the ‘active’ coupling. It therefore usually shows that the active coupling is of 2J or 4J type, whereas an ‘antiparallel’ pattern usually arises from a 3J active coupling.

Another advantage of a COSY spectrum is that it can yield cross-peaks even when the active coupling is not fully resolved. This can be useful for assigning methyl singlets, for example in steroids, and also for exploiting couplings comparable with the troublesomely large linewidths in protein spectra, for example, or the $^{11}\text{B}\{^1\text{H}\}$ spectra of boranes. However, it does also mean that longer-range couplings may appear unexpectedly, such as the weak (H-1 to H-3), (H-1 to H-6b) and (H-6a to H-4) couplings in [figure B1.11.12](#). Their appearance can yield stereochemical information such as the existence of bonding pathways having appropriate conformations, and they are usually recognizable by their comparatively weak intensities.

Many variations of the basic homonuclear COSY experiment have been devised to extend its range. A brief guide to some classes of experiment follows, along with a few of the common acronyms.

- (i) Experiments using pulsed field gradients [23]. These can be very rapid if concentration is not a limiting factor, but they require added equipment and software. Acronym: a prefix of ‘g’.
- (ii) Multiple quantum methods. These employ more complex pulse sequences, with the aim of suppressing strong but uninteresting resonances such as methyl singlets. Acronyms include the letters MQ, DQ, etc. They are also useful in isotope-selective experiments, such as INADEQUATE [24]. For example, the ^{13}C – ^{13}C INADEQUATE experiment amounts to a homonuclear ^{13}C COSY experiment, with suppression of the strong singlets from uncoupled carbons.
- (iii) Extended or total correlation methods. These reveal linked couplings, involving up to every atom in a group, where at least one reasonably large coupling exists for any one member atom. They are valuable for identifying molecular moieties such as individual amino acids in a peptide, for they can remove ambiguities arising from peak overlaps. Acronym: TOCSY (total correlation spectroscopy).
- (iv) Correlations exploiting nuclear Overhauser enhancements (NOEs) in place of couplings, such as NOESY. These are discussed in [section B1.11.8](#).
- (v) Correlations that emphasize smaller couplings. These are simply achieved by the addition of appropriate, fixed delays in the pulse sequence.

Homonuclear techniques such as J -resolved spectroscopy also exist for rotating all multiplets through 90° , to resolve overlaps and also give a 1D spectrum from which all homonuclear couplings have been removed [26].

-27-

The theory of these and other multidimensional NMR methods requires more than can be visualized using magnetization vectors. The spin populations must be expressed as the diagonal elements of a density matrix, which not only has off-diagonal elements indicating ordinary, single-quantum transitions such as those described earlier, but also other off-diagonal elements corresponding to multiple-quantum transitions or ‘coherences’. The pulses and time developments must be treated as operators. The full theory also allows experiments to be designed so as to minimize artefacts [27, 28 and 29].

B1.11.7.2 HETERONUCLEAR CORRELATION SPECTRA

Similar experiments exist to correlate the resonances of different types of nucleus, e.g. ^{13}C with ^1H , provided that some suitable couplings are present, such as $^1J_{\text{CH}}$. It is necessary to apply pulses at both the relevant frequencies and it is also desirable to be able to detect either nucleus, to resolve different peak clusters. Detection through the nucleus with the higher frequency is usually called reverse-mode detection and generally gives better sensitivity. The spectrum will have the two different chemical shift scales along its axes

and therefore will not be symmetrical.

A ^1H (detected)- ^{13}C shift correlation spectrum (common acronym HMQC, for heteronuclear multiple quantum coherence, but sometimes also called COSY) is a rapid way to assign peaks from protonated carbons, once the hydrogen peaks are identified. With changes in pulse timings, this can also become the HMBC (heteronuclear multiple bond connectivity) experiment, where the correlations are made via the smaller $^2J_{\text{CH}}$ and $^3J_{\text{CH}}$ couplings. This helps to assign quaternary carbons and also to identify coupling and, hence, chemical links, where H-H couplings are not available. Similar experiments exist for almost any useful pairing of nuclei: those to ^{15}N are particularly useful in the spectra of suitably labelled peptides. [Figure B1.11.13](#) shows a simple ^{13}C - ^1H shift correlation spectrum of the same saccharide as in the previous two figures, made by exploiting the $^1J_{\text{CH}}$ couplings. The detection was via ^{13}C and so the spectrum has good resolution in the ^{13}C dimension, here plotted as the horizontal axis, but rather basic resolution in the vertical ^1H dimension. The ^1H resolution is nonetheless sufficient to show that C-6 is a single type of carbon attached to two distinct types of hydrogen. Inspection of the ^1H axis shows that the approximate centre of each 2D multiplet matches the shifts in the previous spectra. This affords an unambiguous assignment of the carbons.

Even more complex sequences can be applied for the simultaneous correlation of, for example, ^{15}N shifts with ^1H - ^1H COSY spectra. Because the correlation of three different resonances is highly specific, the chance of an accidental overlap of peaks is greatly reduced, so that very complex molecules can be assigned. Furthermore, the method once again links atoms where no simple H-H couplings are available, such as across a peptide bond. Such 3D NMR methods generate enormous data sets and, hence, very long accumulation times, but they allow the investigation of a wide range of labelled biomolecules.

Figure B1.11.13. ^{13}C - ^1H shift correlation via $^1J_{\text{CH}}$. This spectrum of methyl- α -glucopyranose (structure as in [figure B1.11.12](#)) permits unambiguous ^{13}C assignments once the ^1H assignments have been determined as in [figure B1.11.12](#).

B1.11.8 SPATIAL CORRELATIONS

J couplings are not the only means in NMR for showing that two atoms lie close together. Pairs of atoms, particularly ^1H , also affect each other through their dipolar couplings. Even though the dipolar splittings are averaged away when a molecule rotates isotropically, the underlying magnetic interactions are still the major contributors to the ^1H T_1 . Each pairwise interaction of a particular H_A with any other H_B , separated by a distance r_{AB} in a rigid molecule, will contribute to $1/T_{1A}$ in proportion to $(r_{AB})^{-6}$.

Although it is possible to detect this interaction by the careful measurement of all the T_1 s in the molecule, it may be detected far more readily and selectively, *via* the mutual NOE. When a single multiplet in a ^1H NMR spectrum is selectively saturated, the resulting input of energy leaks to other nuclei, through all the dipolar couplings that are present in the molecule [29]. This alters the intensities and likewise the integrals of their resonances. The A spin of an isolated pair of spins, A and B, in a molecule tumbling fairly rapidly, will have its intensity increased by the multiplicative factor $1 + \gamma_B/2\gamma_A$. This amounts to a gain of 50% when A and B are both ^1H , although it will normally be less in practice, because of the competing interactions of other spins and other relaxation mechanisms. If B is ^1H and A is ^{13}C , the corresponding enhancement is 299%. In this case there need be no competition, for all the ^1H resonances can be saturated simultaneously, using the techniques of broadband decoupling. Also, dipolar coupling usually dominates the relaxation of all carbons bearing hydrogens. The threefold intensity gain is a valuable bonus in $^{13}\text{C}\{^1\text{H}\}$ NMR.

-29-

B1.11.8.1 NOE-DIFFERENCE SPECTRA

Even if the intensity changes are only of the order of 1%, they may nevertheless be reliably detected using difference spectra [30]. Figure B1.11.14 shows an NOE-difference ^1H NMR spectrum of slightly impure aspirin, over a normal spectrum of the same sample. The difference spectrum was obtained by gently saturating the methyl singlet at 2.3 ppm, for a period of 2 s just before collecting the spectrum, and then by precisely subtracting the corresponding spectrum acquired without this pre-irradiation. As the pre-irradiation selectively whitewashes the methyl peak, the result of the subtraction is to create a downwards-going resultant peak. The other peaks subtract away to zero, unless the energy leakage from the pre-irradiation has altered their intensity. In the figure, the four aromatic H resonances to the left subtract to zero, apart from minor errors arising from slight instabilities in the spectrometer. In contrast, the broad OH resonance at 5 ppm in the upper spectrum proves that this hydrogen lies close to the CH_3 group. Thus, aspirin must largely possess the conformation shown on the right. If the left-hand conformation had been significant, then the aromatic H at 7.2 ppm would have received a significant enhancement.

Figure B1.11.14. ^1H NOE-difference spectrum (see the text) of aspirin, with pre-saturation at the methyl resonance, proving that the right-hand conformation is dominant.

NOE-difference spectroscopy is particularly valuable for distinguishing stereoisomers, for it relies solely on internuclear distances, and thus avoids any problems of ambiguity or absence associated with couplings. With smallish molecules, it is best carried out in the above 1D manner, because ~ 2 s are necessary for the transmission of the NOE. The transmission process becomes more efficient with large molecules and is almost optimal for proteins. However, problems can occur with molecules of intermediate size [31]. A 2D version of the NOE-difference experiment exists, called NOESY.

-30-

B1.11.8.2 PROTEIN STRUCTURES

If multidimensional spectra of both COSY and NOESY types can be obtained for a protein, or any comparable structured macromolecule, and if a reasonably complete assignment of the resonances is achieved, then the NOESY data can be used to determine its structure [31, 32 and 33]. Typically, several hundred approximate H–H distances will be found via the NOESY spectrum of a globular protein having mass around 20 000 Da. These can then be used as constraints in a molecular modelling calculation. The resulting structures can compare in quality with those from x-ray crystallography, but do not require the preparation of crystals. Related spectra can also elucidate the internal flexibility of proteins, their folding pathways and their modes of interaction with other molecules. Such information is vital to the pharmaceutical industry in the search for new drugs. It also underpins much biochemistry.

B1.12 NMR of solids

R Dupree and M E Smith

B1.12.1 INTRODUCTION

Solid-state NMR has long been used by physicists to study a wide range of problems such as superconductivity, magnetism, the electronic properties of metals and semiconductors, ionic motion etc. The early experiments mostly used 'wide line' NMR where high resolution was not required but with the development of the technique, particularly the improvements in resolution and sensitivity brought about by magic angle spinning (B1.12.4.3), and decoupling and cross polarization (B1.12.4.4), solid-state NMR has become much more widely used throughout the physical and, most recently, biological sciences. Although organic polymers were the first major widespread application of high-resolution solid-state NMR, it has found application to many other types of materials, from inorganics such as aluminosilicate microporous materials, minerals and glasses to biomembranes. Solid-state NMR has become increasingly multinuclear and the utility of the technique is evidenced by the steady and continued increase in papers that use the technique to characterize materials. There is no doubt that the solid-state NMR spectrometer has become a central piece of equipment in the modern materials physics and chemistry laboratories.

The principal difference from liquid-state NMR is that the interactions which are averaged by molecular motion on the NMR timescale in liquids lead, because of their anisotropic nature, to much wider lines in solids. Extra information is, in principle, available but is often masked by the lower resolution. Thus, many of the techniques developed for liquid-state NMR are not currently feasible in the solid state. Furthermore, the increased linewidth and the methods used to achieve high resolution put more demands on the spectrometer. Nevertheless, the field of solid-state NMR is advancing rapidly, with a steady stream of new experiments forthcoming.

This chapter summarizes the interactions that affect the spectrum, describes the type of equipment needed and the performance that is required for specific experiments. As well as describing the basic experiments used in solid-state NMR, and the more advanced techniques used for distance measurement and correlation, some emphasis is given to nuclei with spin $I > \frac{1}{2}$ since the study of these is most different from liquid-state NMR.

B1.12.2 FUNDAMENTALS

B1.12.2.1 INTERACTION WITH EXTERNAL MAGNETIC FIELDS

NMR is accurately described as a coherent radiofrequency (RF) spectroscopy of the nuclear magnetic energy levels. The physical basis of the technique is the lifting of the degeneracy of the different m_z nuclear spin states through interaction with an external magnetic field, creating a set of energy levels. The total energy separation between these levels is determined by a whole range of interactions. The nuclear spin Hamiltonian has parts corresponding to the experimental conditions, which are termed external, and parts that result from the sample itself, which are called internal. The internal part provides information about the physical and electronic structure of the sample.

-2-

The total interaction energy of the nucleus may be expressed as a sum of the individual Hamiltonians given in equation B1.12.1, (listed in table B1.12.1) and are discussed in detail in several excellent books [1, 2, 3 and 4].

$$H^{\text{TOT}} = H^Z + H^{\text{RF}} + H^{\text{D}} + H^{\text{CS}} + H^{\text{K}} + H^{\text{J}} + H^{\text{P}} + H^{\text{Q(1)}} + H^{\text{Q(2)}} + \dots \quad (\text{B1.12.1})$$

The large static applied magnetic field (B_0) produces the Zeeman interaction ($= -\hbar\omega_0 I_z$, where I_z is the z -component of I (the nuclear spin) with eigenvalues m_z ($-I \leq m_z \leq I$), figure B1.12.1(a) with the nuclear magnetic dipole moment μ ($= \gamma\hbar I$, where γ is the gyromagnetic ratio of the nucleus). The B_0 field is taken to define the z -axis in the laboratory frame and gives an interaction energy of

$$H^Z = \mu B_0 = -\gamma\hbar B_0 m_z = -\hbar\omega_0 m_z \quad (\text{B1.12.2})$$

where ω_0 is the Larmor frequency in angular frequency. In this chapter only the high field limit is considered whereby the nuclear spin states are well described by the Zeeman energy levels, and all the other interactions can be regarded as perturbations of these spin states. Any nucleus that possesses a magnetic moment is technically accessible to study by NMR, thus only argon and cerium of the stable elements are excluded as they possess only even-even isotopes.

Table B1.12.1 Summary of main interactions important to NMR.

H^m	Interaction	T_{ij}	Typical size A_i (Hz)	Comments
H^Z	Zeeman	Unitary B_0	10^7-10^9	Interaction with main magnetic field
H^{RF}	RF	Unitary B_1	10^3-10^5	Interaction with RF field
H^D	Dipolar	D	I 10^3-10^4	Through space spin-spin interaction, axially symmetric traceless tensor
H^{CS}	Chemical shielding	σ	B_0 10^2-10^5	Alteration of the magnetic field by the electrons
H^J	Indirect spin	J	I $1-10^3$	Spin-spin interaction mediated via the bonding electrons through the contact interaction
H^P	Paramagnetic		S 10^2-10^5	Interaction with isolated unpaired electrons
H^K	Knight shift	K	S 10^2-10^5	Interaction with conduction electrons via the contact interaction
H^Q	Quadrupolar	Eq	I 10^3-10^7	Interaction of nuclear quadrupolar moment with the electric field gradient (q) and I twice to produce effectively an I^2 interaction

The resulting spectra show static powder spectra for (b) first-order perturbation for all transitions and (c) second-order broadening of the central transition. (d) The MAS spectrum for the central transition.

-5-

For a spin- $\frac{1}{2}$ nucleus the two m_z values $\pm\frac{1}{2}$ have energies of $\pm\gamma\hbar B_0/2$ giving an energy separation of $\gamma\hbar B_0$. Thermal equilibrium produces a Boltzmann distribution between these energy levels and produces the bulk nuclear magnetization of the sample through the excess population which for a sample containing a total of N spins is $\sim N\gamma\hbar B_0/2kT$. For example for ^{29}Si in an applied magnetic field of 8.45 T the excess in the populations at room temperature is only 1 in 10^5 so that only a small number of the total number of spins contribute to the signal, and this is possibly the greatest weakness of NMR. As the magnetization is directly proportional to the applied magnetic field, sensitivity provides one of the drives to higher applied magnetic fields. The dependence on γ explains why some nuclei are more favoured as the ease with which a nucleus can be observed depends upon the receptivity (R_x)

$$R_x = \gamma^3 C_x I_x (I_x + 1) \quad (\text{B1.12.3})$$

where C_x is the natural abundance of the isotope being considered [3].

In spectroscopy involving electromagnetic (em) radiation both spontaneous and stimulated events can occur. NMR is a relatively low-frequency em spectroscopy so that spontaneous events are very unlikely ($\sim 10^{-22} \text{ s}^{-1}$) and stimulated events therefore dominate. This means that NMR is a coherent spectroscopy so that the excess in population can be made to work in a concerted way. The NMR experiment involves measurement of the energy level separation by application of a time-varying magnetic field \mathbf{B}_1 orthogonal to \mathbf{B}_0 . \mathbf{B}_1 excites transitions (through I_+ and I_- , the conventional spin raising and lowering operators) when its frequency (ω) is close to ω_0 , typically in the RF region of 10 MHz to 1 GHz. The Hamiltonian for this interaction is

$$H^{\text{RF}} = (-\gamma\hbar B_1/2)(I_+ e^{-i\omega t} + I_- e^{+i\omega t}). \quad (\text{B1.12.4})$$

B1.12.2.2 LOCAL INTERACTIONS

In diamagnetic insulating solids spin- $\frac{1}{2}$ nuclei experience a range of interactions that include magnetic dipolar (H^{D}) interaction through space with nearby nuclear magnetic moments, chemical shielding (H^{CS}), modification of the magnetic field at the nucleus due to the surrounding electrons and indirect spin-spin coupling (H^{J})—interaction of magnetic moments mediated by intermediate electron spins. In materials that contain paramagnetic centres the unpaired electrons can interact strongly with the nuclei (H^{P}) and possibly cause very large shifts and severe broadening of the NMR signal. The fluctuating magnetic fields produced by the electron spins can produce very efficient relaxation. Hence, for solids where the nuclei are slowly relaxing and will dissolve paramagnetic ions, small amounts ($\sim 0.1 \text{ mol}\%$) are added to aid relaxation. In materials

containing conduction electrons these can also interact strongly with the nuclear spin via a contact interaction H^K that produces relaxation and a change in resonance position termed the Knight shift, both of which provide important information on the nature of the density of states at the Fermi surface. Nuclei with spin $I > \frac{1}{2}$ are also affected by the electric quadrupole interaction (H^Q), an interaction between the nuclear electric quadrupole moment and the gradient in the electric field at the nucleus. Although this is an electrical interaction it depends on the magnetic quantum number (m_z) so affects the NMR spectrum [2]. The background of the quadrupole interaction is given in the classic paper by Cohen and Reif [5].

All interactions associated with NMR can be expressed as tensors and may be represented by a general expression

-6-

$$H^m = k^m I_i T_{ij}^m A_j^m \quad (\text{B1.12.5})$$

where H^m is one of the component Hamiltonians in equation B1.12.1. For each interaction there is a constant k , a 3×3 second-rank tensor T_{ij} , and then another vector quantity that the spin (I) interacts with: this is either a field or a spin. Normally three numbers are needed to describe a 3×3 tensor relating two vectors and these numbers are usually the isotropic value, the anisotropy and the asymmetry [6]. Their exact definition can vary even though there are conventions that are normally used, so that any paper should be examined carefully to see how the quantities are being defined. Note that the chemical shielding is fundamentally described by the tensor σ although in experiment data it is the chemical shift δ that is normally reported. The shielding and the shift are related by $\delta = 1 - \sigma$ [3, 6].

In a typical isotropic powder the random distribution of particle orientations means the principal axes systems (where the tensor only has diagonal elements) will be randomly distributed in space. In the presence of a large magnetic field, this random distribution gives rise to broadening of the NMR spectrum since the exact resonance frequency of each crystallite will depend on its orientation relative to the main magnetic field.

Fortunately, to first order, all these interactions have similar angular dependences of $(3 \cos^2 \theta - 1 + \eta \sin^2 \theta \cos^2 \varphi)$ where η is the asymmetry parameter of the interaction tensor ($\eta = 0$ for axial symmetry). Lineshapes can provide very important information constraining the local symmetry of the interaction that can often be related to some local structural symmetry.

Of the NMR-active nuclei around three-quarters have $I \geq 1$ so that the quadrupole interaction can affect their spectra. The quadrupole interaction can be significant relative to the Zeeman splitting. The splitting of the energy levels by the quadrupole interaction alone gives rise to pure nuclear quadrupole resonance (NQR) spectroscopy. This chapter will only deal with the case when the quadrupole interaction can be regarded as simply a perturbation of the Zeeman levels.

The electric field gradient is again a tensor interaction that, in its principal axis system (PAS), is described by the three components $V_{x'x'}$, $V_{y'y'}$ and $V_{z'z'}$, where ' indicates that the axes are not necessarily coincident with the laboratory axes defined by the magnetic field. Although the tensor is completely defined by these components it is conventional to recast these into 'the electric field gradient' $eq = V_{z'z'}$, the largest component, and the asymmetry parameter $\eta_Q = |V_{y'y'} - V_{x'x'}|/V_{z'z'}$. The electric field gradient is set up by the charge distribution outside the ion (e.g. Al^{3+}) but the initially spherical charge distribution of inner shells of electrons of an ion will themselves become polarized by the presence of the electrical field gradient to lower their energy in the electric field. This polarization produces an electric field gradient at the nucleus itself of $eq_n = eq(1 - \gamma_\infty)$ where $(1 - \gamma_\infty)$ is the Sternheimer antishielding factor which is a measure of the magnification of eq due to this polarization of the core electron shells [7]. Full energy band structure calculations of electric field gradients show how important the contribution of the electrons on the ion itself are compared to the lattice. The quadrupole Hamiltonian (considering axial symmetry for simplicity) in the laboratory frame, with

θ the angle between the z' -axis of the quadrupole PAS and B_0 , is

$$H^Q = (hC_Q/(8I(2I-1)))[(3\cos^2\theta-1)(3I_z-a)+3\sin\theta\cos\theta(I_+I_+I_-) + (I_+I_-I_z)+3\sin^2\theta/2(I_+^2+I_-^2)] \quad (\text{B1.12.6})$$

where $C_Q = (e^2qQ/h)(1-\gamma_\infty)$ and $a = I(I+1)$. In the limit $H^Z \gg H^Q$ a standard perturbation expansion using the eigenstates of H^Z is applicable. The first-order term splits the spectrum into $2I$ components ([figure B1.12.1 \(a\)](#)) of intensity $|\langle m-1|I_-|m\rangle|^2$ ($\propto a - m(m-1)$) at frequency

-7-

$$\nu_m^{(1)} = (3C_Q/4I(2I-1))(3\cos^2\theta-1)(m_z - 1/2). \quad (\text{B1.12.7})$$

This perturbation can cause the non-central transitions (i.e. $m_z \neq \frac{1}{2}$) to be shifted ([figure B1.12.1\(b\)](#)) sufficiently far from the Larmor frequency such that these transitions become difficult to observe with conventional pulse techniques. This is particularly important for spin-1 nuclei (of which the most important ones are ^2H and ^{14}N) as there is no central transition ($m_z = \frac{1}{2}$) and all transitions are broadened to first order.

Fortunately, for non-integer quadrupolar nuclei for the central transition $\nu_m^{(1)} = 0$ and the dominant perturbation is second order only (equation B1.12.8) which gives a characteristic lineshape ([figure B1.12.1\(c\)](#)) for axial symmetry):

$$\nu_m^{(2)} = (-9C_Q^2/64\nu_0I^2(2I-1)^2)(a-3/4)(1-\cos^2\theta)(9\cos^2\theta-1). \quad (\text{B1.12.8})$$

This angular dependence is different from the first-order perturbations so that the conventional technique of removing linebroadening in solids, MAS (see below), cannot completely remove this interaction at the same time as removing the first-order broadening. Hence, the resolution of MAS spectra from quadrupolar nuclei is usually worse than for spin- $\frac{1}{2}$ nuclei and often characteristic lineshapes are observed. If this is the case, it is usually possible to deduce the NMR interactions C_Q , η and δ_{iso} providing valuable information about the sample.

B1.12.2.3 BASIC EXPERIMENTAL PRINCIPLES OF FT NMR

The essence of NMR spectroscopy is to measure the separation of the magnetic energy levels of a nucleus. The original method employed was to scan either the frequency of the exciting oscillator or to scan the applied magnetic field until resonant absorption occurred. However, compared to simultaneous excitation of a wide range of frequencies by a short RF pulse, the scanned approach is a very time-inefficient way of recording the spectrum. Hence, with the advent of computers that could be dedicated to spectrometers and efficient Fourier transform (FT) algorithms, pulsed FT NMR became the normal mode of operation. Operating at constant field and frequency also produced big advantages in terms of reproducibility of results and stability of the applied magnetic field. In an FT NMR experiment a pulse of RF close to resonance, of duration T_p , is applied to a coil. If the pulse is applied exactly on resonance (i.e. the frequency of the applied em radiation exactly matches that required for a transition) it produces a resultant magnetic field orthogonal to B_0 in the rotating frame which causes a coherent oscillation of the magnetization. The magnetization is consequently tipped by an angle $\theta_p (= \gamma B_1 T_p)$ away from the direction defined by B_0 . After a $\pi/2$ -pulse all the magnetization is in a plane transverse to the direction to B_0 and, hence, is termed transverse magnetization. B_0 exerts a torque on the transverse magnetization which will consequently Larmor precess about B_0 . The rotating magnetization is then providing an alternating flux linkage with the NMR coil that, through Faraday's law of electromagnetic induction, will produce a voltage in the NMR coil. The transverse magnetization

decays through relaxation processes (see chapter B1.13). The observed signal is termed the free induction decay (FID). Adding coherently n FIDs together improves S/N by $n^{1/2}$ compared to a single FID.

In the linear approximation there is a direct Fourier relationship between the FID and the spectrum and, in the great majority of experiments, the spectrum is produced by Fourier transformation of the FID. It is a tacit assumption that everything behaves in a linear fashion with, for example, uniform excitation (or effective RF field) across the spectrum. For many cases this situation is closely approximated but distortions may occur for some of the broad lines that may be encountered in solids. The power spectrum $P(\nu)$ of a pulse applied at ν_0 is given by a sinc^2 function [8]

-8-

$$P(\nu) = [\sin^2 \pi T_p (\nu_0 - \nu)] / (\nu_0 - \nu)^2. \quad (\text{B1.12.9})$$

The spectral frequency range covered by the central lobe of this sinc^2 function increases as the pulselength decreases. For a spectrum to be undistorted it should really be confined to the middle portion of this central lobe (figure B1.12.2). There are a number of examples in the literature of solid-state NMR where the resonances are in fact broader than the central lobe so that the ‘spectrum’ reported is only effectively providing information about the RF-irradiation envelope, not the shape of the signal from the sample itself. The sinc^2 function describes the best possible case, with often a much stronger frequency dependence of power output delivered at the probe-head. (It should be noted here that other excitation schemes are possible such as adiabatic passage [9] and stochastic excitation [10] but these are only infrequently applied.) The excitation/recording of the NMR signal is further complicated as the pulse is then fed into the probe circuit which itself has a frequency response. As a result, a broad line will not only experience non-uniform irradiation but also the intensity detected per spin at different frequency offsets will depend on this probe response, which depends on the quality factor (Q). The quality factor is a measure of the sharpness of the resonance of the probe circuit and one definition is the resonance frequency/halfwidth of the resonance response of the circuit (also $= \omega_0 L/R$ where L is the inductance and R is the probe resistance). Hence, the width of the frequency response at 100 MHz is about 1 MHz. Hence, direct FT-pulse observation of broad spectral lines becomes impractical with pulse techniques for linewidths greater than ~ 200 kHz. For a great majority of NMR studies carried out on nuclei such as ^1H , ^{13}C and ^{29}Si this does not really impose any limitation on their observation. Broader spectral lines can be reproduced by pulse techniques, provided that corrections are made for the RF-irradiation and probe responses but this requires careful calibration. Such corrections have been most extensively used for examining satellite transition spectra from quadrupolar nuclei [11].

Figure B1.12.2. Power distribution for an RF pulse of duration T_p applied at frequency ν_0 .

Another problem in many NMR spectrometers is that the start of the FID is corrupted due to various instrumental deadtimes that lead to intensity problems in the spectrum. The spectrometer deadtime is made up of a number of sources that can be apportioned to either the probe or the electronics. The loss of the initial part of the FID is manifest in a spectrum as a rolling baseline and the preferential loss of broad components of

the spectrum. In the best cases the deadtime is $\leq 2 \mu\text{s}$, but even this can still lead to severe distortion of broad spectral lines. Baseline correction can be achieved by use of either simple spline fits using spectrometer software (including back-prediction) or the use of analytical functions which effectively amount to full-intensity reconstruction. Many spectrometer software packages now contain correction routines, but all such procedures should be used with extreme caution.

-9-

B1.12.3 INSTRUMENTATION

B1.12.3.1 OVERVIEW OF A PULSE FT NMR SPECTROMETER

The basic components of a pulse FT NMR spectrometer are shown schematically in figure B1.12.3. It can be seen that, in concept, a NMR spectrometer is quite simple. There is a high-field magnet, which these days is nearly always a superconducting solenoid magnet that provides the basic Zeeman states on which to carry out the NMR experiment. The probe circuit containing the sample in the NMR coil is placed in the magnetic field. The probe is connected to the transmitter that is gated to form the pulses that produce the excitation. The probe is also connected to the receiver and it requires some careful design to ensure that the receiver that is sensitive to μV does not see any of the large-excitation voltages produced by the transmitter. The relatively simple concept of the experiment belies the extensive research and development effort that has gone into developing the components of NMR spectrometers. Although all components are important, emphasis is placed on three central parts of the spectrometer: namely the magnet, the probe and signal detection.

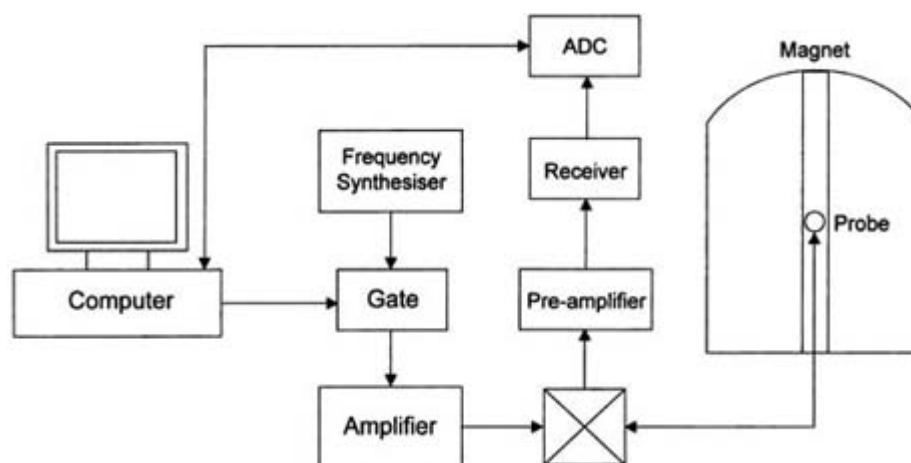

Figure B1.12.3. Schematic representation showing the components of a pulse FT NMR spectrometer.

B1.12.3.2 MAGNETS

Much effort goes into producing ever higher magnetic fields, and the highest currently commercially available for solid-state NMR is 18.8 T. Standard instruments are now considered to be 4.7–9.4 T. The drive for higher fields is based on the increased chemical shift dispersion (in hertz) and the increase in sensitivity via both the Boltzmann factor and higher frequency of operation. For solid-state NMR of half-integer spin quadrupolar nuclei there is the additional advantage that the second-order quadrupolar broadening of the central transition decreases inversely proportionally with B_0 . Superconducting solenoids dominate based on Nb_3Sn or NbTi multifilament wire kept in liquid helium. However, fields and current densities now used are close to the critical limits of these materials demanding improved materials technology [12]. The principle of operation is very simple: a high current is passed through a long coil of wire, with typically 40–100 A of current circulating around several kilometres of wire. This means that the magnet stores significant amounts of energy in its field ($=1/2LI^2$; L is the solenoid's inductance and I is the current flowing) of up to 10 MJ.

A superconducting magnet consists of a cryostat, main coil, superconducting shim set and a means for attaching the current supply to the main coil (figure B1.12.4). The cryostat consists of two vessels for the liquid cryogens, an inner one for helium and the outer one for nitrogen. Then, to insulate these, there are several vacuum jackets with a radiation shield. The aim is to reduce heat leakage to the inner chamber to conserve helium. Superconducting magnets in NMR are usually operated in persistent mode, which means that, after a current is introduced, the start and end of the main coil are effectively connected so that the current has a continuous path within the superconductor and the power supply can then be disconnected. To achieve this the circuits within the cryostat have a superconducting switch. The coil circuits are also designed to cope with a sudden, irreversible loss of superconductivity, termed a quench. There are resistors present (called dump resistors) to disperse the heating effect and prevent damage to the main coil when a quench occurs.

Figure B1.12.4. Construction of a high-field superconducting solenoid magnet.

Higher magnetic fields exist than those used in NMR but the NMR experiment imposes constraints in addition to just magnitude. An NMR spectroscopy experiment also demands homogeneity and stability of the magnetic field. Long-term stability is aided by persistent-mode operation and the drift should be $<2 \times 10^{-7}$ a day. Homogeneity requirements for solid-state NMR experiments are typically up to 2×10^{-9} over a volume of $\sim 1 \text{ cm}^3$. The main coil alone is unable to produce this level of homogeneity so there is also a set of smaller

superconducting coils called cryoshims. The number of these cryoshims depends on the design and also the purpose of the magnet (e.g. solid-state NMR, high-resolution NMR, imaging) but typically varies between three and eight. Although for many wide-line solid-state NMR experiments the homogeneity produced by the cryoshims is sufficient, most commercial spectrometers also have a room-temperature shim set which further improves the homogeneity of the magnetic field. A final consideration for the magnet is the accessible room-temperature bore of the magnet. A standard liquids magnet has a bore of 52 mm diameter. However most solid-state NMR spectroscopists prefer 89 mm as this gives much more room for the probe, allowing the use of larger and more robust electrical components for handling high powers and for accommodating some of the more specialist probe designs (e.g. double angle rotation, dynamic angle spinning (see [section B1.12.4.5](#)) etc).

B1.12.3.3 PROBES

The heart of an NMR spectrometer is the probe, which is essentially a tuned resonant circuit with the sample contained within the main inductance (the NMR coil) of that circuit. Usually a parallel tuned circuit is used with a resonant frequency of $\omega_0 = (LC)^{-1/2}$. The resonant frequency is obviously the most important probe parameter but the input impedance, which should be 50Ω , and Q are also extremely important. Several designs of coil exist each having advantages in specific applications. The traditional coil design, particularly applicable at lower frequencies and for solids, is the conventional solenoid. For external access of large samples, Helmholtz or saddle coils are used, such as are in widespread use for high-resolution liquid-state NMR studies. For large samples, again with external access, birdcage coils are finding increasing uses especially in magnetic resonance imaging. There are competing requirements for the probe which can be characterized in terms of Q ; pulselength ($\propto Q^{-1/2}$), deadtime ($\propto Q$), maximum voltage ($\propto Q$), bandwidth ($\propto Q^{-1}$) and sensitivity ($\propto Q^{1/2}$). A probe cannot be designed that will lead to all these being optimized simultaneously because of their differing Q -dependence so that compromise and focus on the most important aspects for a specific application is required. The probe needs to be constructed from robust electronic components, as they often have to withstand high voltages (many kilovolts).

Often linear circuit analysis is applied but in probes designed for solids, and therefore high-power operation, nonlinear effects can occur. Furthermore, in doubly and triply tuned probes used for decoupling, cross-polarization, and for some of the more sophisticated pulse sequences such as REDOR, TEDOR etc even small voltages generated at the second resonant frequency are unacceptable. They can swamp the NMR signal, given that the coil is part of more than one resonant circuit. Detailed consideration of the design criterion for double-tuned CP-MAS probes has been given [13]. These days, a number of sequences demand triply resonant circuits with two channels tunable over the lower frequency ranges and the third tunable to the high- γ nuclei (e.g. ^1H , ^{19}F).

B1.12.3.4 SIGNAL DETECTION

In addition to the deadtime mentioned earlier, magnetoacoustic ringing (up to 200 μs) can be very significant without careful probe design. Samples that exhibit piezoelectric behaviour can produce very long response times of up to 10 ms. The microvolt NMR signal generated in the coil needs amplification prior to detection and digitization. The first stage is about 30 dB amplification in the preamplifier with the most important characteristic being the noise figure (NF), essentially a measure of the noise added to the signal by the amplifier. Careful consideration is necessary for the production of a low noise figure and rapid recovery from saturation and, again, some compromise is required, with recovery of $<2 \mu\text{s}$. The preamp. should also have good linearity.

The amplified signal is passed to a double-balanced mixer configured as a phase-sensitive detector where the two inputs are the NMR signal (ω_0) and the frequency of the synthesizer (ω_{ref}) with the output proportional to $\cos(\omega_0 - \omega_{\text{ref}})t + \theta) + \cos((\omega_0 + \omega_{\text{ref}})t + \theta)$. The sum frequency is much larger than the total bandwidth of the spectrometer so it is lost, leaving only the difference frequency. Phase-sensitive detection is equivalent to examining the NMR signal in the rotating reference frame and if the frequencies ω_0 and ω_{ref} are equal a constant output is obtained (neglecting relaxation effects). Most modern spectrometers employ two phase-sensitive detectors which have reference signals that differ in phase by 90° , termed quadrature phase-sensitive detection [14]. This scheme can distinguish whether a signal is above or below the reference frequency and allows the transmitter frequency to be placed at the centre of the range of interest, improving pulse power efficiency and signal-to-noise. (This is not possible with a single detector, which can only provide the magnitude of the offset.) Imbalance in the two channels and non- 90° angles between them can give rise to quadrature images and should be minimized in the spectrometer set-up. Phase cycling includes application of different phase pulses and normally four phases 90° apart are available. However, much more sophisticated phase cycles are now required and variable phases can be generated by using a digital synthesizer. In particular, there is increasing demand for much smaller phase shifts than 90° .

The signal is then digitized ready for storage in the computer memory. Digitizers are characterized by the number of bits (usually 12 or 16, determining the dynamic range), the rate of digitization (determining the dwell time) and the size of memory capable of storing the data points. Until very recently the ability to record narrow spectral objects over a broad range of frequencies has been limited, usually by the on-board computer memory, but commercial spectrometers have now addressed this problem.

B1.12.4 EXPERIMENTAL TECHNIQUES

B1.12.4.1 CLASSIFICATION OF NUCLEI

The sensitivity in an NMR experiment is directly proportional to the number of spins, making quantification of the amount of a particular element present straightforward, at least for spin $I = \frac{1}{2}$ nuclei. Furthermore, the large variation in the gyromagnetic ratio, γ , means that, except for pathological cases, the resonant frequencies are sufficiently different from one element to another that there is no possibility of confusing different elements. The ease of obtaining a spectrum, and to a certain extent the type of experiment undertaken, depends upon γ , the nuclear spin and the natural abundance of the isotope concerned. The large variation in γ means that the sensitivity, which is proportional to γ^3 (see [section B1.12.2.1](#)), varies by $>10^4$ from (say) ^1H and ^{19}F which have the largest γ to ^{109}Ag which has one of the smallest. For spin $I = \frac{1}{2}$ nuclei the ability to obtain a useful signal is also dependent on the spin-lattice relaxation time, T_1 , as well as the sensitivity. As the principal cause of relaxation in spin- $\frac{1}{2}$ systems is usually dipolar and thus proportional to (at least) γ^2 , relaxation times can be very long for low-gamma nuclei making experiments still more difficult.

Nuclei with spin $I > \frac{1}{2}$, about three-quarters of the periodic table, have a quadrupolar moment and as a consequence are affected by any electric field gradient present (see [section B1.12.2.2](#)). The lines can be very broad even when techniques such as MAS (see [section B1.12.4.3](#)) are used, thus it is convenient to divide nuclei into groups depending upon ease of observation and likely width of the line. This is done in [table B1.12.2](#) for the most commonly studied elements. These have been divided into six categories: (a) spin $I = \frac{1}{2}$ nuclei which are readily observable, (b) spin $I = \frac{1}{2}$ nuclei which are observable with difficulty because either the isotopic abundance is low, in which case isotopic enrichment is sometimes used (e.g. ^{15}N), or because the γ is very small (e.g. ^{183}W), (c) spin $I = 1$ nuclei where the quadrupolar interaction can lead to very broad lines (d) non-integer spin $I > \frac{1}{2}$ nuclei which are readily observable, (e) non-integer spin $I > \frac{1}{2}$ nuclei which are readily observable only in relatively symmetric environments because the quadrupolar interaction can

strongly broaden the line and (f) those spin $I > \frac{1}{2}$ nuclei whose quadrupole moment is sufficiently large that they can only be observed in symmetric environments where the electric field gradient is small. Of course the boundaries between the categories are not 'rigid'; as technology improves and magnetic fields increase there is movement from (f) to (e) and (e) to (d). In each case the sensitivity at natural abundance relative to ^{29}Si (for which resonance is readily observed) is given. More complete tables of nuclear properties relevant to NMR are given in several books on NMR [1, 2].

-14-

Table B1.12.2 Classification of nuclei according to spin and ease of observation.

Isotope	Sensitivity at natural abundance relative to ^{29}Si	Isotope	Sensitivity at natural abundance relative to ^{29}Si
$I = \frac{1}{2}$			
(a) Readily observable			
^1H	2700	^{113}Cd	3.6
^{13}C	0.48	^{119}Sn	12
^{19}F	2200	^{125}Te	6.0
^{29}Si	1.00	^{195}Pt	9.1
^{31}P	180	^{199}Hg	2.6
^{77}Se	1.4	^{205}Tl	35
^{89}Y	0.32	^{207}Pb	5.6
(b) Observable with difficulty or requiring isotopic enrichment			
$^{15}\text{N}^*$	1.0×10^{-2}	^{109}Ag	0.13
$^{57}\text{Fe}^*$	1.0×10^{-3}	^{183}W	2.8×10^{-2}
^{109}Rh	8.5×10^{-2}		
(c) Integer $I = 1$			
$^2\text{D}^*$	3.9×10^{-3}	^{14}N	2.7
Non-integer $I = \frac{1}{2}$			
(d) Readily observable			
^7Li	730	^{23}Na	250
^9Be	37	^{27}Al	560
^{11}B	360	^{51}V	1030
$^{17}\text{O}^*$	2.9×10^{-2}	^{133}Cs	130
(e) Readily observable only in relatively symmetric environments			
^{25}Mg	0.73	^{59}Co	750
$^{33}\text{S}^*$	4.7×10^{-2}	^{65}Cu	96
^{37}Cl	1.7	^{67}Zn	0.32
^{39}K	1.3	^{71}Ga	150
$^{43}\text{Ca}^*$	2.3×10^{-2}	^{81}Br	133
^{45}Sc	820	^{87}Rb	133
^{55}Mn	470	^{93}Nb	1300
(f) Observable in very symmetric environment			
^{49}Ti	0.44	^{105}Pd	0.68
^{53}Cr	0.23	^{115}In	910

⁶¹ Ni	0.11	¹²¹ Sb	250
⁷³ Ge	0.30	¹²⁷ I	260
⁷⁵ As	69	¹³⁵ Ba	0.89
⁸⁷ Sr	0.51	¹³⁹ La	160
⁹¹ Zr	2.9	²⁰⁹ Bi	380
⁹⁵ Mo	1.4		

* Isotopically enriched.

B1.12.4.2 STATIC BROAD-LINE EXPERIMENTS

Static NMR powder patterns offer one way of characterizing a material, and if spectral features can be observed and the line simulated then accurate determination of the NMR interaction parameters is possible. The simplest experiment to carry out is one-pulse acquisition and despite the effects outlined above that corrupt the start of the time domain signal, the singularities are relatively narrow spectral features and their position can be recorded. The magnitude of the interaction can then be estimated. A common way to overcome deadtime problems is to form a signal with an effective time zero point outside the deadtime, i.e. an echo. There is a huge multiplicity of methods for forming such echoes. Most echo methods are two-pulse sequences, with the classic spin echo consisting of $90^\circ - \tau - 180^\circ$ which refocuses at τ after the second pulse. The echo decay shape is a good replica of the original FID and its observation can be used to obtain more reliable and quantitative information about solids than from the one-pulse experiment.

To accurately determine broad spectral lineshapes from echoes hard RF pulses are preferred for uniform excitation. Often an echo sequence with phase cycling first proposed by Kunwar *et al* [15] has been used, which combines phase cycling to remove quadrature effects and to cancel direct magnetization (the remaining FID) and ringing effects. The rotation produced by the second pulse in the two-pulse echo experiment is not critical. In practice, the best choice is to make the second pulse twice the length of the first, with the actual length a trade-off between sensitivity and uniformity of the irradiation. In recording echoes there is an important practical consideration in that the point of applying the echo is to move the effective $t = 0$ position for the FID to being outside the region where the signal is corrupted. However, in order that phasing problems do not re-emerge, a data sampling rate should be used that is sufficient to allow the effective $t = 0$ point to be accurately defined. If T_2 allows the whole echo (both before and after the maximum, i.e. $t = 0$) to be accurately recorded without an unacceptably large loss of intensity, there is then no need to accurately define the new $t = 0$ position. Fourier transformation of the whole echo (which effectively amounts to integration between $\pm\infty$) followed by magnitude calculation removes phasing errors producing a pure absorption lineshape with the signal-to-noise $\sqrt{2}$ larger than that obtained by transforming from the echo maximum.

Even if echoes are used, there are still difficulties in recording complete broad spectral lines with pulsed excitation. Several approaches have been adopted to overcome these difficulties based on the philosophy that although the line is broad it can be recorded using a series of narrow-banded experiments. One of these approaches is to carry out a spin-echo experiment using relatively weak RF pulses, recording only the intensity of the on-resonance magnetization and repeating the experiment at many frequencies to map out the lineshape. This approach has been successfully used in a series of studies. An example is ⁹¹Zr from the polymorphs of ZrO₂ (figure B1.12.5) where mapping out the lineshape clearly shows differences in NMR interaction [16]. This approach works but is extremely tedious because each frequency step requires accurate retuning of the probe. An alternative is to sweep the main magnetic field. There are several examples of sweeping the main magnetic field for solids dating from the earliest days of NMR but only a limited number reported using superconducting magnets, with a recent example being for ²⁷Al in α -Al₂O₃ [17]. It is now

possible to have a single NMR spectrometer that is capable of both conventional high-resolution spectroscopy and also field sweep operation. As with the stepped-frequency experiment, relatively soft pulses are applied, and although strictly the on-resonance part of the magnetization should be used, it has been shown experimentally that using the spin-echo intensity directly accurately reproduces the lineshape (figure B1.12.6) [18]. Recording the full distortion-free lineshape including the satellite transitions then allows accurate determination of the asymmetry parameter.

-16-

Figure B1.12.5. ^{91}Zr static NMR lineshapes from ZrO_2 polymorphs using frequency-stepped spin echoes.

For quadrupolar nuclei, the dependence of the pulse response on ν_Q/ν_1 has led to the development of quadrupolar nutation, which is a two-dimensional (2D) NMR experiment. The principle of 2D experiments is that a series of FIDs are acquired as a function of a second time parameter (e.g. here the pulse length applied). A double Fourier transformation can then be carried out to give a 2D data set (F_1 , F_2). For quadrupolar nuclei while the pulse is on the experiment is effectively being carried out at low field with the spin states determined by the quadrupolar interaction. In the limits $\nu_Q \ll \nu_1$ and $\nu_Q \gg \nu_1$ the pulse response lies at ν_1 and $(I + \frac{1}{2})\nu_1$ respectively so is not very discriminatory. However, for $\nu_Q \sim \nu_1$ the pulse response is complex and allows C_Q and η to be determined by comparison with theoretical simulation. Nutation NMR of quadrupolar nuclei has largely been limited by the range of RF fields that puts ν_Q in the intermediate region. This approach has been extended by Kentgens by irradiating off-resonance, producing a larger effective nutation field, and matches ν_1 to ν_Q [19].

B1.12.4.3 MAGIC ANGLE SPINNING

All of the anisotropic interactions described in [section B1.12.2](#) are second-rank tensors so that, in polycrystalline samples, lines in solids can be very broad. In liquids, the rapid random molecular tumbling brought about by thermal motion averages the angular dependences to zero, leaving only the isotropic part of the interaction. The essence of the spinning technique is to impose a time dependence on these interactions externally so as to reduce the anisotropic part, which to first order has the same Legendre polynomial, $P_2(\cos \theta)$, dependence for all the interactions, in a similar but not identical manner as in liquids. This time dependence is imposed by rapidly rotating the whole sample container (termed the rotor) at the so-called ‘magic angle’ where $3 \cos^2 \theta = 1$, i.e. $\theta = 54^\circ 44'$. ‘Rapid’ means that the spinning speed should be faster than the homogeneous linewidth. (A spectral line is considered homogeneous when all nuclei can be considered as contributing intensity to all parts of the line, so that the intrinsic linewidth associated with each spin is the same as the total linewidth.) Essentially, this is determined by the dipolar coupling: in proton-rich systems the proton–proton coupling can be >40 kHz, beyond the range of current technology where the maximum commercially available spinning speed is ~ 35 kHz. Fortunately, in most other systems the line is inhomogeneously broadened, i.e. is made up of distinct contributions from individual spins in differently oriented crystallites which merge to give the composite line, the intrinsic width associated with each spin being considerably narrower than the total linewidth. To cause effective narrowing of these lines the spinning rate needs only to exceed the intrinsic linewidth and typically a few kilohertz is sufficient to narrow lines where the chemical shift is the dominant linebroadening mechanism. In [figure B1.12.7](#) both the static and MAS ^{29}Si spectrum of a sample of sodium disilicate ($\text{Na}_2\text{Si}_2\text{O}_7$) crystallized from a glass is shown as an example. Whilst the static spectrum clearly indicates an axial chemical shift powder pattern, it gives no evidence of more than one silicon site. The MAS spectrum clearly shows four resolved lines from the different polymorphs present in the material whose widths are ~ 100 times less than the chemical shift anisotropy.

Note that if the spinning speed is less than the static width then a series of spinning sidebands are produced,

separated from the isotropic line by the spinning speed (these are also visible in figure B1.12.7). For multisite systems, spinning sidebands can make interpretation of the spectrum more difficult and it may be necessary to do experiments at more than one spinning speed in order to determine the isotropic peak and to eliminate overlap between sidebands and main peaks. However, the presence of sidebands can be useful since from the amplitude of the spinning sideband envelope one can deduce the complete chemical tensor, giving additional information about the local site environment [20].

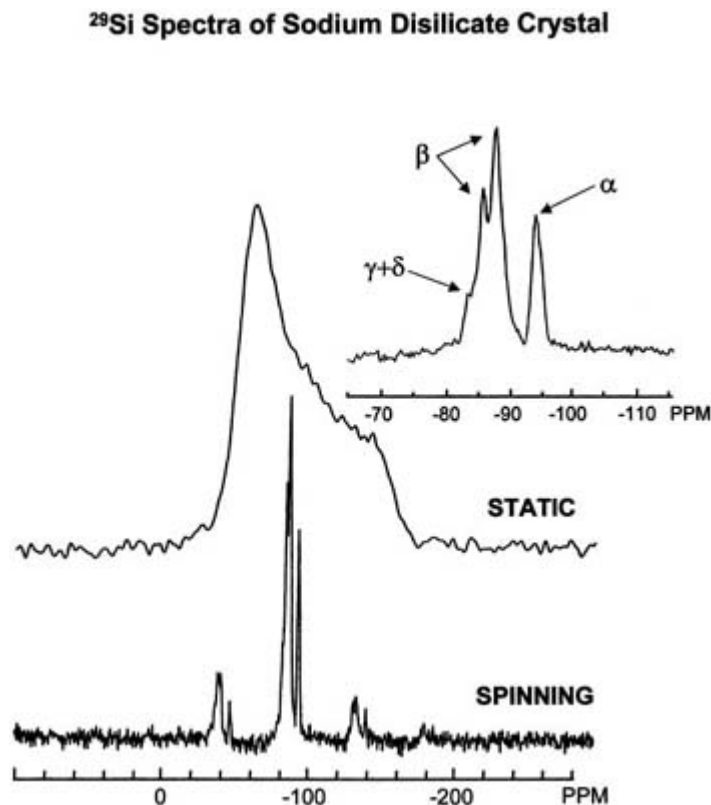

Figure B1.12.7. Static and MAS ²⁹Si NMR spectra of crystalline Na₂Si₂O₅.

The interpretation of MAS experiments on nuclei with spin $I > \frac{1}{2}$ in non-cubic environments is more complex than for $I = \frac{1}{2}$ nuclei since the effect of the quadrupolar interaction is to spread the $\pm m \leftrightarrow \pm(m - 1)$ transition over a frequency range $(2m - 1)\nu_Q$. This usually means that for non-integer nuclei only the $\frac{1}{2} \leftrightarrow -\frac{1}{2}$ transition is observed since, to first order in the quadrupolar interaction, it is unaffected. However, usually second-order effects are important and the angular dependence of the $\frac{1}{2} \leftrightarrow -\frac{1}{2}$ transition has both $P_2(\cos \theta)$ and $P_4(\cos \theta)$ terms, only the first of which is cancelled by MAS. As a result, the line is narrowed by only a factor of ~ 3.6 , and it is necessary to spin faster than the residual linewidth $\Delta\nu_Q$ where

$$\Delta\nu_Q = f(I) \frac{C_Q^2(6 + \eta)^2}{224\nu_0} \quad (\text{B1.12.10})$$

to narrow the line. The resulting lineshape depends upon both C_Q and η and is shown in [figure B1.12.8](#) for several different asymmetry parameters. The centre of gravity of the line does not occur at the isotropic

chemical shift (see [figure B1.12.1\(d\)](#)); there is a quadrupolar shift

$$\nu_{m,\text{cg}}^{(2)} = \frac{3}{40} f(I) \frac{C_Q^2}{\nu_0} \left(1 + \frac{\eta^2}{3} \right). \quad (\text{B1.12.11})$$

If the lineshape can be clearly distinguished, then C_Q , η and δ_{iso} can be readily determined even for overlapping lines, although it should be noted that most computer packages used to simulate quadrupolar lineshapes assume ‘infinite’ spinning speed. Significant differences between the experimental lineshape and simulation can occur if one is far from this limit and caution is required. A further problem for MAS of quadrupolar nuclei is that the angle must be set very accurately (which can be difficult and time consuming with some commercial probes) to obtain the true lineshape of broad lines. In many samples (e.g. glasses and other disordered systems) featureless lines are observed and the centre of gravity must then be used to estimate δ_{iso} and the electric field gradient since

$$\delta_{\text{iso}} = \delta_{\text{cg}} - \frac{3}{40} f(I) \frac{C_Q^2}{\nu_0^2} \left(1 + \frac{\eta^2}{3} \right) \quad (\text{B1.12.12})$$

and a plot of ν_{cg} against $1/\nu_0^2$ will give δ_{iso} and $C_Q^2(1 + \eta^2/3)$. $f(I)$ is the spin-dependent factor $[I(I+1) - 3/4]/I^2(2I-1)^2$ and is given in table B1.12.3.

Table B1.12.3 Spin-dependent factor $f(I)$ for the isotropic second-order quadrupole shift.

<i>I</i>				
$\frac{3}{2}$	$\frac{5}{2}$	$\frac{9}{2}$	$\frac{2}{25}$	$\frac{1}{54}$

Figure B1.12.8. MAS NMR lineshapes from the central transition lineshape for non-integer quadrupole lineshapes with various η_Q ($A = (I(I+1) - 3/4)v_Q^2/v_0$).

The second-order quadrupolar broadening of the $\frac{1}{2} \leftrightarrow -\frac{1}{2}$ transition can be further reduced by spinning at an angle other than 54.7° (VAS), the width being a minimum between $60\text{--}70^\circ$. The reduction is only ~ 2 however, and dipolar and shift anisotropy broadening will be reintroduced, thus VAS has only found limited application.

B1.12.4.4 DECOUPLING AND CROSS-POLARIZATION

In proton-containing systems such as organic materials the dipole–dipole interaction is usually sufficiently large that current spinning speeds are not sufficient to narrow the line. However, in a heteronuclear (I,S) spin system if a large RF magnetic field is applied at the resonance frequency of the spin, I , one wishes to decouple, the magnetization will precess around the effective field in the rotating frame and the average IS dipolar coupling will tend to zero. This technique is most commonly applied to remove the $^1\text{H}\text{--}^{13}\text{C}$ dipolar coupling, but can be used for any system. Decoupling is usually combined with cross-polarization (CP) and the pulse sequence is shown in [figure B1.12.9](#). A 90° pulse is applied to the I spin system and the phase of the RF is then shifted by 90° to spin lock the magnetization in the rotating frame. The S spin system RF is now

turned on with an amplitude such that $\gamma_I B_{1I} = \gamma_S B_{1S}$ i.e. in the rotating frame both spin systems are precessing at the same rate (the Hartmann–Hahn condition) and thus magnetization can be transferred via the flip-flop term in the dipolar Hamiltonian. The length of time that the S RF is on is called the contact time and must be adjusted for optimum signal. Since magnetization transfer is via the dipole interaction, in general the signal from S spin nuclei closest to the I spins will appear first followed by the signal from S spins further away. Thus one use of CP is in spectral editing. However, the main use is in signal enhancement since the S spin magnetization will be increased by (γ_I/γ_S) which for ^1H - ^{13}C is ~ 4 and for ^1H - ^{15}N is ~ 9 . In addition, the S spin relaxation time T_1 is usually much longer than that of the I spin system (because γ is smaller); as a consequence in CP one can repeat the experiment at a rate determined by T_{1I} rather than T_{1S} producing a further significant gain in signal to noise. For spin $I, S = \frac{1}{2}$ systems the equation describing the signal is given by

$$M_0(\text{CP}) = M_0 \left(\frac{\gamma_I}{\gamma_S} \right) \left[\exp \left(- \frac{t}{T_{1\rho I}} \right) - \exp \left(- \left\{ \frac{1}{T_{1\rho S}} + \frac{1}{T_{IS}} \right\} t \right) \right] \quad (\text{B1.12.13})$$

where $T_{1\rho I}$ and $T_{1\rho S}$ are the relaxation times in the rotating frame of the I and S spin systems respectively and T_{IS} , which is dependent upon the strength of the dipole coupling between the I and S spin systems, is the characteristic time for the magnetization of the S spin system to increase via contact with the I spins. Generally, $T_{1\rho S}$ is very much longer than T_{IS} and can be ignored and although $T_{1\rho I}$ is shorter it too is usually much longer than T_{IS} . In this case maximum signal will occur for a contact time $t \sim T_{IS} \ln(T_{IS}/T_{1\rho I})$. If one wishes to do quantitative measurements using CP it is necessary to plot signal amplitude versus contact time and then fit to equation B1.12.13. A typical plot is shown for glycine in [figure B1.12.10](#). It can be seen from the inset that T_{IS} for the CH_2 peak at ~ 40 ppm is much shorter ($20 \mu\text{s}$) than that for the COOH peak at 176 ppm ($570 \mu\text{s}$). Carbon spectra can be very complex. Various pulse sequences have been used to simplify the spectra. The most common is dipolar dephasing, in which there is a delay after the contact time (during which no decoupling takes place) before the signal is acquired. The signal from strongly coupled carbon (e.g. CH_2) will decay rapidly during this time leaving only weakly coupled carbons visible in the spectrum.

-22-

Figure B1.12.10. ^{13}C CP data from the two carbons in glycine as a function of contact time. The signal for short contact times is shown in the inset where the effect of the different $T_{1\rho}$ values can be clearly seen.

-23-

Whilst MAS is effective (at least for spin $I = \frac{1}{2}$) in narrowing inhomogeneous lines, for abundant spin systems with a large magnetic moment such as protons (or fluorine) the homonuclear dipole coupling can be >30 kHz, too strong to be removed by MAS at currently available spinning speeds. Thus there have been many multiple pulse sequences designed to remove homonuclear coupling. When combined with MAS they are called CRAMPS (combined rotation and multiple pulse spectroscopy). The MREV-8 [6] sequence is one of the more commonly used and robust sequences; however, they all require a special probe because of the high powers needed, together with a very well tuned and set up spectrometer. Furthermore, to be effective the period of rotation needs to be much greater than the cycle time of the sequence, thus their use is somewhat restricted.

B1.12.4.5 HIGH-RESOLUTION SPECTRA FROM QUADRUPOLEAR NUCLEI

Although MAS is very widely applied to non-integer spin quadrupolar nuclei to probe atomic-scale structure in solids, such as distinguishing AlO_4 and AlO_6 environments [21], simple MAS about a single axis cannot produce a completely averaged isotropic spectrum. As the second-order quadrupole interaction contains both second-rank ($\propto 3 \cos^2 \theta - 1$ ($P_2(\cos \theta)$)) and fourth-rank ($\propto 35 \cos^4 \theta - 30 \cos^2 \theta + 3$ ($P_4(\cos \theta)$)) terms it can be seen from figure B1.12.11 that spinning at 54.7° can only partially average $35 \cos^4 \theta - 30 \cos^2 \theta + 3$. If a characteristic well defined lineshape can be resolved the NMR interaction parameters can be deduced. Even if overlapping lines are observed, provided a sufficient number of features can be discerned, fitting, especially constrained by field variation, will allow the interactions to be accurately deduced. However, there are still many cases where better resolution from such nuclei would be extremely helpful, and over the last decade or so there have been many ingenious approaches to achieve this. Here, four of the main approaches will be briefly examined, namely satellite transition MAS spectroscopy, double-angle rotation (DOR), dynamic angle spinning (DAS) and multiple quantum (MQ) MAS. The latter three produce more complete averaging of the interactions by imposing more complex time dependences on

the interactions. DOR and DAS do this directly on the spatial coordinates, whereas MQ also manipulates the spin part of the Hamiltonian. For each method the background to producing better-resolution solid-state NMR spectra will be given, and the pros and cons of each detailed. Extensive referencing to general reviews [22, 23 and 24] and reviews of specific techniques is given where more details can be found. Then, by way of illustration, comparison will be made of these methods applied to ^{27}Al NMR of kyanite.

Figure B1.12.11. Angular variation of the second- and fourth-rank Legendre polynomials.

(A) SATELLITE TRANSITION MAS

Physical background. MAS will narrow the inhomogeneously broadened satellite transitions to give a series of sharp sidebands whose intensity envelopes closely follow the static powder pattern so that the quadrupole interaction can be deduced. The work of Samoson [25] gave real impetus to satellite transition spectroscopy by showing that both the second-order quadrupolar linewidths and isotropic shifts are functions of I and m_z . Some combinations of I and m_z produce smaller second-order quadrupolar effects on the satellite lines than for the central transition, thus offering better resolution and more accurate determination of $\delta_{\text{iso, cs}}$. The two cases where there are distinct advantages of this approach over using the central transition are $(\pm\frac{3}{2}, \pm\frac{1}{2})$ for $I = \frac{5}{2}$ and $(\pm\frac{5}{2}, \pm\frac{3}{2})$ for $I = \frac{9}{2}$. ^{27}Al has been the focus of much of the satellite transition work and has been used for a range of compounds including ordered crystalline, atomically disordered and amorphous solids. The work of the group of Jaeger has greatly extended the practical implementation and application of this technique and a comprehensive review is given in [26].

Advantages. The experiment can be carried out with a conventional fast-spinning MAS probe so that it is straightforward to implement. For recording the satellite transition lineshapes it offers better signal-to-noise and is less susceptible to deadtime effects than static measurements. As the effects differ for each m_z value, a single satellite transition experiment is effectively the same as carrying out multiple field experiments on the central transition.

Disadvantages. The magic angle must be extremely stable and accurately set. The spinning speed must show good stability over the duration of the experiment. The probe needs to be accurately tuned and careful correction for irradiation and detection variations with frequency, and baseline effects are necessary. The gain

in resolution only applies to $I = \frac{5}{2}$ and $\frac{9}{2}$.

-25-

(B) DOUBLE ANGLE SPINNING

Physical background. DOR offers the most direct approach to averaging $P_2(\cos \theta)$ and $P_4(\cos \theta)$ terms simultaneously, by making the spinning axis a continually varying function of time [26]. To achieve this, DOR uses a spinning rotor (termed the inner rotor) which moves bodily by enclosing it in a spinning outer rotor, thereby forcing the axis of the inner rotor to describe a complicated but continuous trajectory as a function of time. The effect of this double rotation is to introduce modulation of the second-order quadrupolar frequency of the central transition in the laboratory frame of the form

$$H^{Q(2)}(t) = \frac{hC_Q^2}{8I(2I-1)\nu_0} [A_0(I, m, \eta_Q) + A_1(I, m, \eta_Q)P_2(\cos \beta_1)P_2(\cos \beta_2)F_1(\theta, \phi) + A_2(I, m, \eta_Q)P_4(\cos \beta_1)P_4(\cos \beta_2)F_2(\theta, \phi) + \text{terms } \propto \cos(\omega_1 t + \gamma_2)] \quad (\text{B1.12.14})$$

where β_1 and β_2 are the angles between the outer rotor and the magnetic field and the angle between the axes of the two rotors, respectively, and ϕ and θ describe the orientation of the principal axis system of a crystallite in the inner rotor. ω_1 is the angular frequency of the outer rotor and γ_2 an angle describing the position of the outer rotor in the laboratory frame. More details of the functions A and F can be found by comparison with [equation B1.12.10](#), [equation B1.12.11](#), [equation B1.12.12](#) and [equation B1.12.13](#) in [24]. β_1 and β_2 can be chosen so that $P_2(\cos \beta_1) = 0$ (54.74°) and $P_4(\cos \beta_2) = 0$ (30.56° or 70.15°).

Simulation of the complete DOR spectrum (centreband plus the spinning sidebands) will yield the NMR interaction parameters. However, it is most usual to perform the experiment to give improved resolution and simply quote the measured peak position, which appears at the sum of the isotropic chemical and second-order quadrupole shifts. DOR experiments at more than one applied magnetic field will allow these different isotropic contributions to be separated and hence provide an estimate of the quadrupole interaction. This approach is similar to that using the field variation of the centre of gravity of the MAS centreband ([equation B1.12.12](#)) but has the advantage that the narrower, more symmetric line makes determination of the correct position more precise. For experiments carried out at two magnetic fields where the Larmor frequencies are ν_{01} and ν_{02} for the measured DOR peak positions (in ppm) at the two magnetic fields at $\delta_{\text{dor}1,2}$ then

$$\delta_{\text{iso,cs}} = \frac{\nu_{01}^2 \delta_{\text{dor}1} - \nu_{02}^2 \delta_{\text{dor}2}}{\nu_{01}^2 - \nu_{02}^2} \quad (\text{B1.12.15})$$

and

$$\left[\frac{3(a - \frac{3}{4})}{40I^2(2I-1)^2} \right] C_Q^2 \left(1 + \frac{\eta_Q^2}{3} \right) = \frac{\nu_{01}^2 \nu_{02}^2 (\delta_{\text{dor}1} - \delta_{\text{dor}2})}{\nu_{01}^2 - \nu_{02}^2}. \quad (\text{B1.12.16})$$

Advantages. DOR works well if the quadrupolar interaction is dominant and the sample is highly crystalline, with some extremely impressive gains in resolution. Provided that the correct RF-excitation conditions are employed the spectral information is directly quantitative.

-26-

Disadvantages. The technique requires investment in a specialized, complex probe-head that requires considerable experience to use effectively. The relatively slow rotation speed of the large outer rotor can lead to difficulties in averaging strong homogeneous interactions and produces many closely spaced spectral sidebands. In disordered solids where there is a distribution of isotropic chemical shifts, quite broad sidebands can result that may coalesce at the slow rotation rates used. Currently, the maximum actual spinning speed that can be routinely obtained in the latest system with active computer control of the gas pressures is ~1500 Hz. By the use of synchronous triggering [28] this effectively amounts to a spinning speed of 3 kHz. Undoubtedly the technology associated with the technique will continue to improve leading to increased spinning speeds and thus expanding the application of the technique. Also, the RF coil encloses the whole system, and the filling factor is consequently small leading to relatively low sensitivity. The large coil size also means that the RF generated is quite low and that double tuning for CP is difficult, although such an experiment has been performed.

(C) DYNAMIC ANGLE SPINNING

Physical background. DAS is a 2D NMR experiment where the evolution of the magnetization is divided into two periods and the sample is spun about a different axis during each period [27, 29]. During the first evolution time t_1 the sample is spun at an angle of θ_1 . The magnetization is then stored along the z -axis and the angle of the spinning axis is changed to θ_2 . After the rotor is stabilized (~30 ms) the magnetization is brought into the xy -plane again and a signal is acquired. The second-order quadrupole frequency of an individual crystallite depends on the angle of the spinning axis. So during t_1 the quadrupole frequency will be ν_1 , and ν_2 during t_2 . If ν_2 is of opposite sign to ν_1 the magnetization from the crystallite will be at its starting position again at some time during t_2 . One can choose both angles in such a way that the signals from each individual crystallite will be at the starting position at exactly the same time. In other words, an echo will form and the effect of the second-order quadrupolar broadening is removed at the point of echo formation. To achieve this cancellation to form an echo then

$$P_2(\cos \theta_1) = -k P_2(\cos \theta_2) \quad \text{and} \quad P_4(\cos \theta_1) = -k P_4(\cos \theta_2) \quad (\text{B1.12.17})$$

must both be satisfied where k is the scaling factor. There is a continuous set of solutions for θ_1 and θ_2 , the so-called DAS complementary angles, and each set has a different scaling factor. For these solutions, the second-order quadrupole powder pattern at θ_1 is exactly the scaled mirror image of the pattern at θ_2 and an echo will form at $t_2 = kt_1$. For the combination $\theta_1 = 30.56^\circ$, $\theta_2 = 70.12^\circ$ the $P_4(\cos \theta)$ terms are zero and the scaling factor $k = 1.87$. A practically favoured combination is $\theta_1 = 37.38^\circ$, $\theta_2 = 79.19^\circ$ as the scaling factor $k = 1$ and the spectra are exact mirror images so that an echo will form at $t_1 = t_2$. There are several ways in which the DAS spectra can be acquired; one can acquire the entire echo, which means that the resulting 2D spectrum will be sheared. Some additional processing is then required to obtain an isotropic spectrum in $F1$. The acquisition could also start at the position of the echo so that an isotropic spectrum in $F1$ is obtained directly. A third possibility is to carry the experiment out as a pseudo 1D experiment where only the top of the echo is acquired as a function of t_1 . In this case the isotropic spectrum is acquired directly but there is no saving in the duration of the experiment.

Advantages. Compared to DOR, a small rotor can be used allowing relatively fast spinning speeds; high RF powers can be attained and if the coil is moved with the rotor a good filling factor can be obtained. In the isotropic dimension high-resolution spectra are produced and the second dimension retains the anisotropic information.

Disadvantages. Again, a specialized probe-head is necessary to allow the rotor axis to be changed, usually using a stepper motor and a pulley system. Angle switching needs to be as fast as possible and reproducible.

For an RF coil that changes orientation with the rotor the RF field will vary with the angle and the RF leads need to be flexible and resistant to metal fatigue. A major limitation of the DAS technique is that it cannot be used on compounds with a short t_1 because of the time needed to reorient the spinning axis. If magnetization is lost through t_1 and/or spin diffusion effects the signal can become very weak. This factor has meant that DAS has been most useful on ^{17}O where the dipole–dipole interaction is weak but has not had the impact on NMR of nuclei such as ^{27}Al that it might otherwise have had.

(D) MQMAS

Physical background. Relatively recently (1995) a new experiment emerged that has already had a great impact on solid-state NMR spectroscopy of quadrupolar nuclei [30]. The 2D multiple quantum magic angle spinning (2D MQMAS) experiment greatly enhances resolution of the spectra of half-integer spin quadrupolar nuclei. Basically, this experiment correlates the $(m, -m)$ multiple quantum transition to the $(\frac{1}{2}, -\frac{1}{2})$ transition. The resolution enhancement stems from the fact that the quadrupole frequencies for both transitions are correlated. At specific times the anisotropic parts of the quadrupole interaction are refocused and an echo forms. The frequency of an $(m, -m)$ transition is given by

$$\nu_p = C_0(p)\nu_0^Q - \frac{7}{18}C_4(p)\nu_4^Q(\theta, \phi) \quad (\text{B1.12.18})$$

where $p = 2m$ is the order of the coherence, $p = 1$ for the $(\frac{1}{2}, -\frac{1}{2})$ transition, $p = 3$ for the $(\frac{3}{2}, -\frac{3}{2})$ transition, etc. The coefficients are defined as

$$\begin{aligned} C_0(p) &= p \left(I(I+1) - \frac{3}{4}p^2 \right) \\ C_4(p) &= p \left(18I(I+1) - \frac{34}{4}p^2 - 5 \right). \end{aligned} \quad (\text{B1.12.19})$$

The isotropic part ν_0^Q of the quadrupole frequency is

$$\nu_0^Q = -(\nu_q^2(3 + \eta_q^2))/90\nu_0 \quad [\text{Hz}] \quad (\text{B1.12.20})$$

and the anisotropic part $\nu_4^Q(\theta, \phi)$ is given by

$$\begin{aligned} \nu_4^Q(\theta, \phi) &= (\nu_q^2/112\nu_0) \times [(7/18)(3 - \eta_q \cos 2\phi)^2 \sin^4 \theta \\ &\quad + (2\eta_q \cos 2\phi - 4 - (2/9)\eta_q^2) \sin^2 \theta + (2/45)\eta_q^2 + (4/5)]. \end{aligned} \quad (\text{B1.12.21})$$

Numerous schemes exist that are used to obtain 2D MQMAS spectra [24]. The simplest form of the experiment is when the MQ transition is excited by a single, high-power RF pulse, after which the MQ coherence is allowed to evolve for a time t_1 (figure B1.12.12). After the evolution time, a second pulse is applied which converts the MQ coherence into a $p = -1$ coherence which is observed during t_2 . The signal is then acquired immediately after the second pulse and the echo will form at a time $t_2 = |QA|t_1$. Both pulses are non-selective and will excite all coherences to a varying degree. Selection of the coherences of interest is achieved by cycling the pulse sequence through the appropriate phases. Phase cycles can be easily worked out

by noting that an RF phase shift of ϕ degrees is seen as a phase shift of $p\phi$ degrees for a p -quantum coherence [31]. After a 2D Fourier transformation the resonances will show up as ridges lying along the quadrupole anisotropy (QA) axis. The isotropic spectrum can be obtained by projection of the entire 2D spectrum on a line through the origin ($\nu_1 = \nu_2 = 0$) perpendicular to the QA axis. figure B1.12.12 shows some of the many different pulse sequences and their coherence pathways that can be used for the 2D MQMAS experiment.

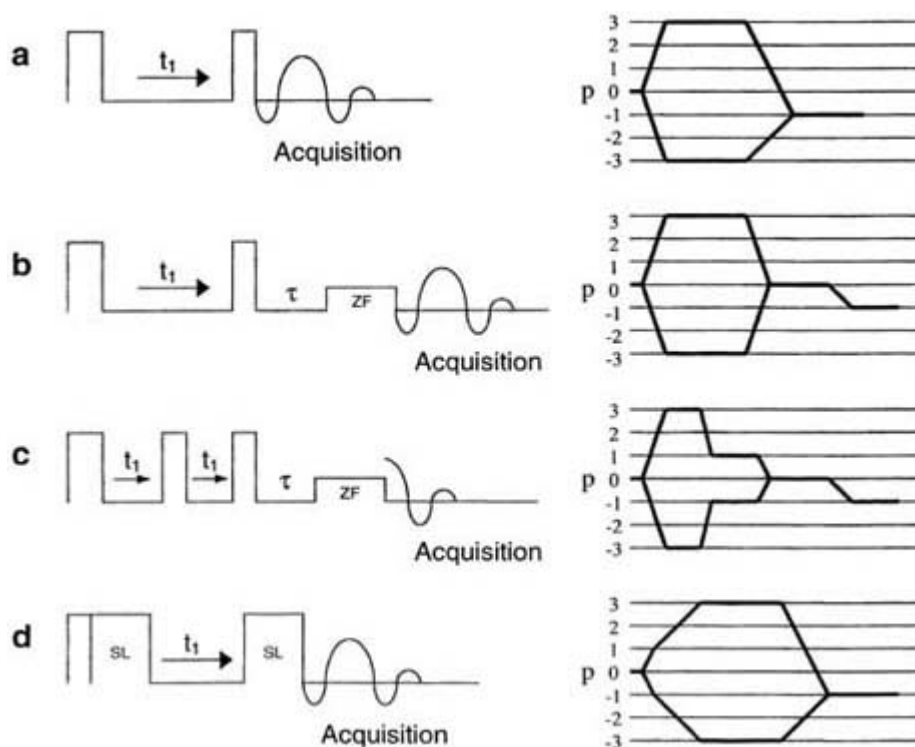

Figure B1.12.12. Pulse sequences used in multiple quantum MAS experiments and their coherence pathways for (a) two-pulse, (b) z-filter, (c) split- t_1 with z-filter and (d) RIACT (II).

The isotropic shift and the quadrupole-induced shift (QIS) can easily be obtained from the data. The QIS is different in both dimensions, however, and is given by

$$\delta_{\text{qis}}^p = \frac{C_0(p)v_0^Q}{p\nu_0} \times 10^6 \quad [\text{in ppm}]. \quad (\text{B1.12.22})$$

-29-

δ_{cg}^p , the position of the centre of gravity with $p = 1$ for the single quantum dimension and $p = \Delta m$ for the multiple quantum dimension, is given by

$$\delta_{\text{cg}}^p = \delta_{\text{iso}} + \delta_{\text{qis}}^p. \quad (\text{B1.12.23})$$

Hence the isotropic shift can be easily retrieved using

$$\delta_{\text{iso}} = \frac{C_0(p)\delta_{\text{cg}}^{p=1} - pC_0(1)\delta_{\text{cg}}^p}{C_0(p) - pC_0(1)} \quad [\text{in ppm}] \quad (\text{B1.12.24})$$

and the isotropic quadrupolar shift by

$$\nu_0^Q = \frac{(\delta_{\text{cg}}^{p=1} - \delta_{\text{cg}}^p)}{C_0(1) - C_0(p)/p} \nu_0 \quad \text{[in Hz].} \quad (\text{B1.12.25})$$

Shearing of the data is performed to obtain isotropic spectra in the $F1$ dimension and to facilitate easy extraction of the 1D slices for different peaks. Shearing is a projection of points that lie on a line with a slope equal to the anisotropy axis onto a line that is parallel to the $F2$ axis [24]. Shearing essentially achieves the same as the split- t_1 experiment or delayed acquisition of the echo. Although sheared spectra may look more attractive, they do not add any extra information and they are certainly not necessary for the extraction of QIS and δ_{iso} values.

Advantages. The experiment can be readily carried out with a conventional probe-head, although the fastest spinning and highest RF powers available are useful. The pulse sequences are relatively easy to set up (compared to DAS and DOR) and the results are usually quite straightforward to interpret in terms of the number of sites and determination of the interactions.

Disadvantages. A researcher new to the subject will be confronted with a large number of schemes for collecting, processing and presenting the data which can be very confusing. The relationship between the measured peak positions and the NMR interaction parameters crucially depends on the processing and referencing conventions adopted. There is one clear distinction between the two main approaches: either the MQ evolution is regarded as having taken place only in the evolution time (t_1), or the period up to the echo is also regarded as being part of the evolution time which is then $(1 + QA)t_1$. A detailed critique of these two approaches and the consequences of adopting each has recently been given by Man [32]. Shearing data introduces an extra processing step, which may introduce artefacts. The key point in determining the quadrupole parameters is the accuracy of measuring the position of the centre of gravity of the resonance. Both the excitation efficiency as well as significant intensity in the spinning sidebands can adversely affect the accuracy of determining the centre of gravity. MQ spectra show a strong dependence on excitation efficiency that is strongly dependent on the value of C_Q relative to the RF field strength. This means that often the spectra are non-quantitative and sites with a large C_Q can be lost completely from the spectrum.

(E) APPLICATION OF HIGH-RESOLUTION METHODS TO ^{27}Al IN KYANITE

Kyanite, a polymorph of Al_2SiO_5 , has four distinct AlO_6 sites. The crystal structure and site geometries (e.g. Al–O bondlengths) are well characterized. The quadrupole interactions vary from 3.6 to 10.1 MHz, providing a good test of the different approaches to achieving high-resolution NMR spectra from quadrupolar nuclei. Both single-crystal studies [33] and NQR [34] have accurately determined the quadrupole interaction parameters. MAS studies of the central transition have been reported from 7 to 18.8 T [35, 36, 37 and 38]. An example of a 17.55 T spectrum is shown in figure B1.12.13(a) along with a simulation of the individual components and their sum. It can be clearly seen that at even this high field there is extensive overlap of the four components. However, many distinct spectral features exist that constrain the simulation and these can be followed as a function of applied magnetic field. As the field is increased the second-order quadrupole effects decrease. Comparing simulations at 4.7 and 9.4 T (figure B1.12.13(b)) the field variation simply scales the width of the spectrum, being a factor of two narrower (in hertz) at the higher field. By extending the simulation to higher fields, 18 T can be seen to be a poor choice as there is considerable overlap of the resonances with virtually no shift dispersion between the sites. 135.3 T would provide a completely resolved spectrum under simple MAS.

Figure continued on next page

Figure B1.12.13. ^{27}Al MAS NMR spectra from kyanite (a) at 17.55 T along with the complete simulation and the individual components, (b) simulation of centreband lineshapes of kyanite as a function of applied magnetic field, and the satellite transitions showing (c) the complete spinning sideband manifold and (d) an expansion of individual sidebands and their simulation.

Satellite transition MAS NMR provides an alternative method for determining the interactions. The intensity envelope of the spinning sidebands are dominated by site A2 (using the crystal structure nomenclature) which has the smallest C_Q , resulting in the intensity for the transitions of this site being spread over the smallest range ($\propto C_Q$), and will have the narrowest sidebands ($\propto C_Q^2/\nu_0$) of all the sites (figure B1.12.13(c)) [37]. The simulation of this envelope provides additional constraints on the quadrupole interaction parameters for this site. Expanding the sidebands (shown for the range 650 to 250 ppm in figure B1.12.13(d)) reveals distinct second-order lineshapes with each of the four sites providing contributions from the $(\pm\frac{1}{2}, \pm\frac{3}{2})$ and $(\pm\frac{3}{2}, \pm\frac{5}{2})$

transitions. The improved resolution provided by the $(\pm\frac{1}{2}, \pm\frac{3}{2})$ transition compared to the central transition is clear. For the A2 site both of the contributing transitions are clearly seen while for the other three only the $(\pm\frac{1}{2}, \pm\frac{3}{2})$ contribution is really observable until the vertical scale is increased by six, which then shows the outer transition for all sites, especially A3. The simulation of all three transitions provides an internal check on the interaction parameters for each site.

DOR provides significantly higher resolution than MAS [37, 39]. At 11.7 T a series of relatively narrow resonances and accompanying sidebands are observed under DOR (figure B1.12.14(a)). The relatively slow spinning speed of the outer rotor results in numerous sidebands and the isotropic line is identified by collecting spectra at several different spinning speeds. If the isotropic position is then collected as a function of B_0 the quadrupole interaction parameters can then be deduced. MQ MAS provides an alternative approach for producing high resolution [38, 40], with the whole 2D data set shown at 9.4 T along with the isotropic projections at 11.7 and 18.8 T (figure B1.12.14(b)) [38]. All three isotropic triple quantum (3Q) projections show only three resolved lines as the NMR parameters from the two sites (A1, A4) with the largest C_Q means that their resonances are superimposed at all fields. This is confirmed by the 9.4 T 3Q data where an RF field of 280 kHz was employed making the data more quantitative: the three resonances with isotropic shifts of 43.0, 21.1 and 8.0 ppm had intensities of 2.1:1.1:1.0 respectively. At 11.7 and 18.8 T the MQ MAS NMR spectra collected are not quantitative since the RF fields to excite the 3Q transitions were not strong enough. For $I = \frac{5}{2}$ the isotropic shifts are $-\frac{10}{17}$ of the value compared to direct MAS at the same field, so MQ data effectively produces results at a 'negative' applied magnetic field thereby more strongly constraining the NMR interaction parameters deduced from isotropic shift against B_0^{-2} plots.

Figure continued on next page

Figure B1.12.14. (a) ^{27}Al DOR NMR spectrum of kyanite at 11.7 T at various spinning speeds and (b) the ^{27}Al MQ MAS NMR spectrum of kyanite at 9.4 T (top) along with the isotropic projections at 11.7 and 18.8 T. (The MQ MAS NMR data are taken from [38] with the permission of Academic Press.)

When ^{27}Al MAS NMR spectra were first collected at moderate B_0 with relatively slow MAS rates (<4 kHz) there was much confusion about the quantitative integrity of such spectra. In fact, provided the correct excitations are employed (i.e. $\nu_1 \gg \nu_r$ and $2\pi\nu_1 T_p \ll 1$) all that is necessary to make MAS NMR spectra quantitative is to know what fraction of the different transitions are contributing to the centreband. In practice this usually amounts to estimating the fraction of the $(\frac{1}{2}, -\frac{1}{2})$ transition that contributes to the centreband, which depends on $\nu_Q^2/\nu_0\nu_r$ [41]. At 17.55 T the intensity distribution between the sites in the centreband was 23%:27%:26%:24% (A1:A2:A3:A4). Once the correction factors are taken into account, within experimental error all sites are equally populated. DAS is not reported for kyanite because of its shortcomings for fast-

relaxing nuclei such as ^{27}Al . The data on kyanite demonstrates how accurately the interaction parameters and intensities can be extracted for quadrupole nuclei by using a combination of advanced techniques.

B1.12.4.6 DISTANCE MEASUREMENTS, DIPOLAR SEQUENCES AND CORRELATION EXPERIMENTS

The dipolar coupling between two nuclei I, S is $(\mu_0/4\pi)(\hbar/2\pi)\gamma_I\gamma_S r_{IS}^{-3}$, thus in systems containing pairs of nuclei measurement of the dipolar coupling will give the distance between them. The simplest pulse sequence for doing this, SEDOR (spin echo double resonance) [2], is shown in [figure B1.12.15\(a\)](#). A normal ‘spin echo’ sequence is applied to spin I which refocuses the heteronuclear dipole coupling and the chemical shift anisotropy producing an echo at 2τ . However, if a 180° pulse is applied to the S spin system it will invert the sign of any IS dipole coupling and reduce the echo intensity. By varying the 180° pulse position a set of difference signals can be used to determine the dipolar coupling and hence the internuclear distance for an isolated spin pair system. The SEDOR sequence is only useful for static samples and the range of distances accessible is restricted by T_2 , however, it can give useful qualitative information in systems where the spins are not isolated pairs.

MAS averages the heteronuclear dipole interaction giving a much increased resolution and increased T_2 . The REDOR (rotational echo double resonance) [42] sequence enables the heteronuclear dipole coupling to be measured for a spinning sample. There are several versions of this experiment; in one ([figure B1.12.15\(b\)](#)) a rotor-synchronized echo is applied to I whilst a series of rotor-synchronized 180° pulses are applied to S . As with SEDOR, the attenuated signal is subtracted from the normal echo signal to determine the REDOR fraction. In suitably labelled systems dipolar couplings as small as 25 Hz have been measured corresponding to a distance of 6.7 Å [43].

TEDOR (transferred echo double resonance) [44, 45] is another experiment for measuring internuclear distances whilst spinning. In this ([figure B1.12.15\(c\)](#)) the S spin is observed. There is first a REDOR sequence on the I spin, the magnetization is then transferred by applying 90° pulses on both spins and this is followed by a REDOR sequence on the S spins. Both REDOR and TEDOR require accurate setting of the 180° pulse and good long-term spectrometer stability to be effective. An advantage of the TEDOR sequence is that there is no background signal from uncoupled spins; however, the theoretical maximum efficiency is 50% giving a reduced signal. Whilst both REDOR and TEDOR can work well for spin $I, S = \frac{1}{2}$ pairs, for quadrupolar nuclei the situation is more complex [24]. The echo sequence must be applied to the quadrupolar nucleus if only one of the pair has spin $I > \frac{1}{2}$ since accurate inversion is rarely possible for spins $> \frac{1}{2}$. A sequence designed specifically for a quadrupolar nucleus is TRAPDOR ([figure B1.12.15\(d\)](#)) in which the dephasing spin is always quadrupolar. One cannot obtain accurate values of the dipolar coupling with this sequence but it can be used to give qualitative information about spatial proximity. There are many other pulse sequences designed to give distance information via the dipole–dipole interaction, most of limited applicability. One, designed specifically for homonuclei, that works well in labelled compounds is DRAMA [46] and a comparison of the more popular homonuclear sequences is given in [47].

Figure B1.12.15. Some double-resonance pulse sequences for providing distance information in solids: (a) SEDOR, (b) REDOR, (c) TEDOR and (d) TRAPDOR. In all sequences the narrow pulses are 90° and the wide pulses 180° . For sequences that employ MAS the number of rotor cycles (N_c) is shown along the bottom.

In liquid-state NMR two-dimensional correlation of spectra has provided much useful information. However, in solids the linewidths (T_2), even under MAS, are usually such that experiments like COSY and INADEQUATE which rely on through-bond J coupling cannot be used (although there are some notable exceptions). The most commonly used heteronuclear correlation (HETCOR) experiments in solids all rely on dipolar coupling and can thus be complicated by less local effects. Nevertheless, they are able to correlate specific sites in the MAS spectrum of one nucleus with sites of the second nucleus which are nearby. The simplest versions of the experiment are just a two-dimensional extension of CP in which the pulse that generates magnetization is separated from the matching pulses by a time which is incremented to give the second dimension. An example of the usefulness of the technique is shown in figure B1.12.16 where the ^1H - ^{31}P correlation of two inorganic hydrated phosphates, (a) brushite and (b) a bone, are shown [48]. In both cases two phosphorus sites that completely overlap in the 1D MAS spectrum are clearly visible in the 2D spectrum.

Figure B1.12.16. ^1H - ^{31}P HETCOR NMR spectra from (a) brushite and (b) bone. (Adapted from [48] with the permission of Academic Press.)

B1.13 NMR relaxation rates

Jozef Kowalewski

B1.13.1 INTRODUCTION

Nuclear magnetic resonance (NMR) spectroscopy deals with the interactions among nuclear magnetic moments (nuclear spins) and between the spins and their environment in the presence of a static magnetic field B_0 , probed by radiofrequency (RF) fields. The couplings involving the spins are relatively weak which results, in particular in low-viscosity liquids, in narrow lines and spectra with a rich structure. The NMR experiments are commonly carried out in the time domain: the spins are manipulated by sequences of RF pulses and delays, creating various types of non-equilibrium spin state, and the NMR signal corresponding to magnetization components perpendicular to B_0 is detected as a function of time (the free induction decay, FID). In terms of the kinetics, the weakness of the interactions results in slow decays (typically milliseconds to seconds) of non-equilibrium states. The recovery processes taking the ensembles of nuclear spins back to equilibrium and some related phenomena, are called *nuclear spin relaxation*. The relaxation behaviour of nuclear spin systems is both an important source of information about the molecular structure and dynamics and a factor to consider in optimizing the design of experiments.

The concept of 'relaxation time' was introduced to the vocabulary of NMR in 1946 by Bloch in his famous equations of motion for nuclear magnetization vector \mathbf{M} [1]:

(B1.13.1)

$$\frac{dM_z}{dt} = \frac{M_0 - M_z}{T_1}$$

$$\frac{dM_{x,y}}{dt} = -\frac{M_{x,y}}{T_2}$$

The phenomenological Bloch equations assume the magnetization component along B_0 (the longitudinal magnetization M_z) to relax exponentially to its equilibrium value, M_0 . The time constant for the process is called the spin–lattice or longitudinal relaxation time, and is denoted T_1 . The magnetization components perpendicular to B_0 (the transverse $M_{x,y}$ magnetization, $M_{x,y}$) are also assumed to relax in an exponential manner to their equilibrium value of zero. The time constant for this process is called the spin–spin or transverse relaxation time and is denoted T_2 . The inverse of a relaxation time is called a relaxation rate.

The first microscopic theory for the phenomenon of nuclear spin relaxation was presented by Bloembergen, Purcell and Pound (BPP) in 1948 [2]. They related the spin–lattice relaxation rate to the transition probabilities between the nuclear spin energy levels. The BPP paper constitutes the foundation on which most of the subsequent theory has been built, but contains some faults which were corrected by Solomon in 1955 [3]. Solomon noted also that a correct description of even a very simple system containing two interacting spins, requires introducing the concept of cross-relaxation, or magnetization exchange between the spins. The subsequent development has been rich and the goal of this entry is to provide a flavour of relaxation theory (section b1.13.2), experimental techniques (section b1.13.3) and applications (section b1.13.4).

-2-

The further reading list for this entry contains five monographs, a review volume and two extensive reviews from the early 1990s. The monographs cover the basic NMR theory and the theoretical aspects of NMR relaxation. The review volume covers many important aspects of modern NMR experiments in general and relaxation measurements in particular. The two reviews contain more than a thousand references to application papers, mainly from the eighties. The number of literature references provided in this entry is limited and, in particular in the theory and experiments sections, priority is given to reviews rather than to original articles.

B1.13.2 RELAXATION THEORY

We begin this section by looking at the Solomon equations, which are the simplest formulation of the essential aspects of relaxation as studied by NMR spectroscopy of today. A more general Redfield theory is introduced in the next section, followed by the discussion of the connections between the relaxation and molecular motions and of physical mechanisms behind the nuclear relaxation.

B1.13.2.1 THE SOLOMON THEORY FOR A TWO-SPIN SYSTEM

Let us consider a liquid consisting of molecules containing two nuclei with the spin quantum number 1/2. We denote the two spins I and S and assume that they are distinguishable, i.e. either belong to different nuclear species or have different chemical shifts. The system of such two spins is characterized by four energy levels and by a set of transition probabilities between the levels, cf. Figure B1.13.1. We assume at this stage that the two spins interact with each other only by the dipole–dipole (DD) interaction. The DD interaction depends on the orientation of the internuclear axis with respect to B_0 and is thus changed (and averaged to zero on a sufficiently long time scale) by molecular tumbling. Taking this motional variation into consideration, it is quite straightforward to use time-dependent perturbation theory to derive transition probabilities between the pairs of levels in Figure B1.13.1. Briefly, the transition probabilities are related to spectral density functions

(*vide infra*), which measure the intensity of the local magnetic fields fluctuating at the frequencies corresponding to the energy level differences in [Figure B1.13.1](#). Solomon [3] showed that the relaxation of the longitudinal magnetization components, proportional to the expectation values of I_z and S_z operators, was related to the populations of the four levels and could be described by a set of two coupled equations:

$$\begin{aligned} \frac{d\langle I_z \rangle}{dt} &= -(W_0 + 2W_{1I} + W_2)(\langle I_z \rangle - I_z^0) - (W_2 - W_0)(\langle S_z \rangle - S_z^0) \\ \frac{d\langle S_z \rangle}{dt} &= -(W_2 - W_0)(\langle I_z \rangle - I_z^0) - (W_0 + 2W_{1S} + W_2)(\langle S_z \rangle - S_z^0) \end{aligned} \quad (\text{B1.13.2})$$

or

$$\begin{aligned} \frac{d\langle I_z \rangle}{dt} &= -\rho_I(\langle I_z \rangle - I_z^0) - \sigma_{IS}(\langle S_z \rangle - S_z^0) \\ \frac{d\langle S_z \rangle}{dt} &= -\sigma_{IS}(\langle I_z \rangle - I_z^0) - \rho_S(\langle S_z \rangle - S_z^0). \end{aligned} \quad (\text{B1.13.3})$$

-3-

I_z^0 and S_z^0 are the equilibrium magnetization for the two spins and ρ^I and ρ^S are the corresponding decay rates (spin–lattice relaxation rates). The symbol σ_{IS} denotes the cross-relaxation rate. The general solutions of [equation B1.13.2](#) or [equation B1.13.3](#) for $\langle I_z \rangle$ or $\langle S_z \rangle$ are sums of two exponentials, i.e. the longitudinal magnetizations in a two-spin system do not follow the Bloch equations. Solomon demonstrated also that the simple exponential relaxation behaviour of the longitudinal magnetization was recovered under certain limiting conditions.

Figure B1.13.1. Energy levels and transition probabilities for an IS spin system. (Reproduced by permission of Academic Press from Kowalewski J 1990 *Annu. Rep. NMR Spectrosc.* **22** 308–414.)

(i) The two spins are identical (e.g. the two proton spins in a water molecule). We then have $W_{1I}=W_{1S}=W^1$ and the spin–lattice relaxation rate is given by:

$$T_1^{-1} = 2(W_1 + W_2). \quad (\text{B1.13.4})$$

(ii) One of the spins, say S , is characterized by another, faster, relaxation mechanism. We can then say that the

S spin remains in thermal equilibrium on the time scale of the I -spin relaxation. This situation occurs in paramagnetic systems, where S is an electron spin. The spin–lattice relaxation rate for the I spin is then given by:

$$\rho_I = T_{1I}^{-1} = W_0 + 2W_1 + W_2. \quad (\text{B1.13.5})$$

(iii) One of the spins, say S again, is saturated by an intense RF field at its resonance frequency. These are the conditions applying for e.g. carbon-13 (treated as the I spin) under broad-band decoupling of protons (S spins). The relaxation rate is also in this case given by equation B1.13.5. In addition, we then observe the phenomenon referred to as the (hetero)nuclear Overhauser enhancement (NOE), i.e. the steady-state solution for $\langle I_z \rangle$ is modified to

$$\langle I_z \rangle_{\text{steady state}} = I_z^0 + \frac{\sigma_{IS}}{\rho_I} S_z^0. \quad (\text{B1.13.6})$$

-4-

B1.13.2.2 THE REDFIELD THEORY

A more general formulation of relaxation theory, suitable for systems with scalar spin–spin couplings (J couplings), is known as the Wangness, Bloch and Redfield (WBR) theory or the Redfield theory [4]. In analogy with the Solomon theory, the Redfield theory is also based on the second-order perturbation theory, which in certain situations (unusual for nuclear spin systems in liquids) can be a limitation. Rather than dealing with the concepts of magnetizations or energy level populations in the Solomon formulation, the Redfield theory is given in terms of density operator (for a general review of the density operator formalism, see ‘Further reading’). Briefly, the density operator describes the average behaviour of an ensemble of quantum mechanical systems. It is usually expressed by expansion in a suitable operator basis set. For the discussion of the IS system above, the appropriate 16-dimensional basis set can e.g. consist of the unit operator, E , the operators corresponding to the Cartesian components of the two spins, $I_x, I_y, I_z, S_x, S_y, S_z$ and the products of the components of I and the components of S . These 16 operators span the Liouville space for our two-spin system. If we concentrate on the longitudinal relaxation (the relaxation connected to the distribution of populations), the Redfield theory predicts the relaxation to follow a set of three coupled differential equations:

$$\frac{d}{dt} \begin{pmatrix} \langle I_z \rangle \\ \langle S_z \rangle \\ \langle 2I_z S_z \rangle \end{pmatrix} = - \begin{pmatrix} \rho_I & \sigma_{IS} & \delta_{I,IS} \\ \sigma_{IS} & \rho_S & \delta_{S,IS} \\ \delta_{I,IS} & \delta_{S,IS} & \rho_{IS} \end{pmatrix} \begin{pmatrix} \langle I_z \rangle - I_z^0 \\ \langle S_z \rangle - S_z^0 \\ \langle 2I_z S_z \rangle \end{pmatrix}. \quad (\text{B1.13.7})$$

The difference compared to [equation B1.13.2](#) or [equation B1.13.3](#) is the occurrence of the expectation value of the $2I_z S_z$ operator (the two-spin order), characterized by its own decay rate ρ_{IS} and coupled to the one-spin longitudinal operators by the terms $\delta_{I,IS}$ and $\delta_{S,IS}$. We shall come back to the physical origin of these terms below.

The matrix on the rhs of equation B1.13.7 is called the relaxation matrix. To be exact, it represents one block of a larger, block-diagonal relaxation matrix, defined in the Liouville space for the two-spin system. The remaining part of the large matrix (sometimes also called the relaxation supermatrix) describes the relaxation of coherences, which can be seen as generalizations of the transverse components of the magnetization vector. In systems without degeneracies, each of the coherences decays exponentially, with its own T_2 . The Redfield theory can be used to obtain expressions for the relaxation matrix elements for arbitrary spin systems and for any type of relaxation mechanism. In analogy with the Solomon theory, also these more general relaxation

rates are expressed in terms of various spectral density functions.

B1.13.2.3 MOLECULAR MOTIONS AND SPIN RELAXATION

Nuclear spin relaxation is caused by fluctuating interactions involving nuclear spins. We write the corresponding Hamiltonians (which act as perturbations to the static or time-averaged Hamiltonian, determining the energy level structure) in terms of a scalar contraction of spherical tensors:

$$H_1(t) = \sum_{q=-j}^j (-1)^q F^{(q)}(t) A^{(-q)}. \quad (\text{B1.13.8})$$

-5-

j is the rank of the tensor describing the relevant interactions, which can be 0, 1 or 2. $A^{(-q)}$ are spin operators and $F^{(q)}(t)$ represent classical functions related to the lattice, i.e. to the classically described environment of the spins. The functions $F^{(q)}(t)$ are, because of random molecular motions, stochastic functions of time. A fluctuating (stochastic) interaction can cause transitions between the energy levels of a spin system (and thus transfer the energy between the spin systems and its environment) if the power spectrum of the fluctuations contains Fourier components at frequencies corresponding to the relevant energy differences. In this sense, the transitions contributing to the spin relaxation and originating from randomly fluctuating interactions, are not really fundamentally different from the transitions caused by coherent interactions with electromagnetic radiation. According to theory of stochastic processes (the Wiener–Khinchin theorem) [5], the power available at a certain frequency, or the spectral density function $J(\omega)$ at that frequency, is obtained as a Fourier transform of a time correlation function (tcf) characterizing the stochastic process. A tcf $G(\tau)$ for a stochastic function of time $F^{(q)}(t)$ is defined:

$$G(\tau) = \langle F^{(-q)}(t) F^{(q)}(t + \tau) \rangle \quad (\text{B1.13.9})$$

with the corresponding spectral density:

$$J(\omega) = \int_{-\infty}^{+\infty} G(\tau) \exp(i\omega\tau) d\tau \quad (\text{B1.13.10})$$

where the symbol $\langle \rangle$ denotes ensemble average. The function in the lhs of equation B1.13.9 is called the auto-correlation function. The prefix ‘auto’ refers to the fact that we deal with an ensemble average of the product of a stochastic function taken at one point in time and the same function at another point in time, the difference between the two time points being τ . In certain situations in relaxation theory, we also need cross-correlation functions, where we average the product of two different stochastic functions, corresponding to different Hamiltonians of [equation B1.13.8](#).

We now come back to the important example of two spin 1/2 nuclei with the dipole–dipole interaction discussed above. In simple physical terms, we can say that one of the spins senses a fluctuating local magnetic field originating from the other one. In terms of the Hamiltonian of [equation B1.13.8](#), the stochastic function of time $F^{(q)}(t)$ is proportional to $Y_{2q}(\theta, \phi)/r_{\text{IS}}^3$, where Y_{2q} is an $l = 2$ spherical harmonic and r_{IS} is the internuclear distance. If the two nuclei are directly bonded, r_{IS} can be considered constant and the random variation of $F^{(q)}(t)$ originates solely from the reorientation of the molecule-fixed internuclear axis with respect to the laboratory frame. The auto-tcf for Y_{2q} can be derived, assuming that the stochastic time dependence can be described by the isotropic rotational diffusion equation. We obtain then:

$$G(\tau) = G(0) \exp(-\tau/\tau_c) \quad (\text{B1.13.11})$$

with the corresponding spectral density:

$$J(\omega) = G(0) \frac{2\tau_c}{1 + \omega^2\tau_c^2}. \quad (\text{B1.13.12})$$

-6-

We call τ_c the correlation time: it is equal to $1/6 D_R$, where D_R is the rotational diffusion coefficient. The correlation time increases with increasing molecular size and with increasing solvent viscosity. [equation B1.13.11](#) and [equation B1.13.12](#) describe the rotational Brownian motion of a rigid sphere in a continuous and isotropic medium. With the Lorentzian spectral densities of [equation B1.13.12](#), it is simple to calculate the relevant transition probabilities. In this way, we can use e.g. [equation B1.13.5](#) to obtain T^{1-1} for a carbon-13 bonded to a proton as well as the corresponding T^{2-} , as a function of the correlation time for a given magnetic field, cf. Figure B1.13.2. The two rates are equal in the region $\omega\tau_c \ll 1$, referred to as the ‘extreme narrowing’. In the extreme narrowing regime, the relaxation rates are independent of the magnetic field and are simply given by a product of the square of an interaction strength constant (the dipole coupling constant, DCC) and the correlation time.

Figure B1.13.2. Spin–lattice and spin–spin relaxation rates (R_1 and R_2 , respectively) for a carbon-13 spin directly bonded to a proton as a function of correlation time at the magnetic fields of 7 and 14 T.

In order to obtain a more realistic description of reorientational motion of internuclear axes in real molecules in solution, many improvements of the tcf of [equation B1.13.11](#) have been proposed [6]. Some of these models are characterized in [table B1.13.1](#). The entry ‘number of terms’ refers to the number of exponential functions in the relevant tcf or, correspondingly, the number of Lorentzian terms in the spectral density function.

-7-

Table B1.13.1 Selected dynamic models used to calculate spectral densities.

Dynamic model	Parameters influencing the spectral densities	Number of terms	Comment	Ref.–
Isotropic rotational diffusion	Rotational diffusion coefficient, $D_R = 1/6 \tau_c$	1	Useful as a first approximation	Further reading
Rotational diffusion, symmetric top	Two rotational diffusion coefficients, D_{\parallel} and D_{\perp} , the angle θ between the symmetry axis and the internuclear axis	3	Rigid molecule, requires the knowledge of geometry	[7]
Rotational diffusion, asymmetric top	Three rotational diffusion coefficients, two polar angles θ and τ	5	Rigid molecule, rather complicated	[8]
Isotropic rotational diffusion with one internal degree of freedom	Rotational diffusion coefficient, D_3 , internal motion rate parameter, angle between the internal rotation axis and the internuclear axis	3	Useful for e.g. methyl groups	[9]
'Model-free'	Global and local correlation times, generalized order parameter, S	2	Widely used for non-rigid molecules	[10]
Anisotropic model-free	D_{\parallel} and D_{\perp} , θ , local correlation time, generalized order parameter, S	4	Allows the interpretation of data for non-spherical, non-rigid molecules	[11]

B1.13.2.4 RELAXATION MECHANISMS

The DD interaction discussed above is just one—admittedly a very important one—among many possible sources of nuclear spin relaxation, collected in [table B1.13.2](#) (not meant to be fully comprehensive). The interactions listed there are often used synonymously with 'relaxation mechanisms' and more detailed descriptions of various mechanisms can be found in 'Further reading'. We can note in [table B1.13.2](#) that one particular type of motion—reorientation of an axis—can cause random variations of many $j = 2$ interactions: DD for different intramolecular axes, CSA, quadrupolar interaction. In fact, all the interactions with the same tensor rank can give rise to the interference or cross-terms with each other. In an important paper by Szymanski *et al* [20], the authors point out that the concept of a 'relaxation mechanism' is more appropriate to use referring to a pair of interactions, rather than to a single one. The role of interference terms has been reviewed by Werbelow [21]. They often contribute to relaxation matrices through coherence or polarization transfer and through higher forms of order or coherence. The relevant spectral densities are of cross-correlation (rather than auto-correlation) type. For example, the off-diagonal δ -terms in the relaxation matrix of [equation B1.13.7](#), connecting the one- and two-spin longitudinal order, are caused by cross-correlation between the DD and CSA interactions, which explains why they are called 'cross-correlated relaxation rates'.

Table B1.13.2 Interactions giving rise to nuclear spin relaxation.

Interaction	Tensor rank	Process causing the random changes	Comment	Ref.
-------------	-------------	------------------------------------	---------	------

Intramolecular dipole-dipole (DD)	2	Reorientation of the inter-nuclear axis	Very common for $I = 1/2$	Further reading
Intermolecular DD	2	Distance variation by translational diffusion	Less common	[12]
Chemical shift anisotropy (CSA)	2	Reorientation of the CSA principal axis	Increases with the square of the magnetic field	[13]
Intramolecular quadrupolar	2	Reorientation of the electric field gradient principal axis	Dominant for $I \geq 1$ (covalently bonded)	[14]
Intermolecular quadrupolar	2	Fluctuation of the electric field gradient, moving multipoles	Common for $I \geq 1$ in free ions in solution	[15]
Antisymmetric CSA	1	Reorientation of a pseudo-vector	Very uncommon	[13]
Spin-rotation	1	Reorientation and time dependence of angular momentum	Small molecules only	[16]
Scalar coupling	0	Relaxation of the coupled spin or exchange	Can be important for T_2	Further reading
Hyperfine interaction (dipolar and scalar)	2,0	Electron relaxation, may be complicated	Paramagnetic systems and impurities	[17–19]

Before leaving the subsection on relaxation mechanisms, I wish to mention the connections between relaxation and chemical exchange (exchange of magnetic environments of spins by a chemical process). The chemical exchange and relaxation determine together the NMR lineshapes, the exchange affects the measured relaxation rates and it can also act as a source of random variation of spin interactions. The relaxation effects of chemical exchange have been reviewed by Woessner [22].

B1.13.3 EXPERIMENTAL METHODS

Relaxation experiments were among the earliest applications of time-domain high-resolution NMR spectroscopy, invented more than 30 years ago by Ernst and Anderson [23]. The progress of the experimental methodology has been enormous and only some basic ideas of the experiment design will be presented here. This section is divided into three subsections. The first one deals with Bloch equation-type experiments, measuring T_1 and T_2 when such quantities can be defined, i.e. when the relaxation is monoexponential. As a slightly oversimplified rule of thumb, we can say that this happens in the case of isolated spins. The two subsections to follow cover multiple-spin effects.

B1.13.3.1 SPIN-LATTICE AND SPIN-SPIN RELAXATION RATES

Measurements of spin-lattice relaxation time, T_1 , are the simplest relaxation experiments. A straight-forward method to measure T_1 is the inversion-recovery experiment, the principle of which is illustrated in [figure B1.13.3](#). The equilibrium magnetization M_0 or $M_z(\infty)$ (cf. [figure B1.13.3\(A\)](#)), directed along B_0 (the z -axis), is first inverted by a 180° pulse (a π -pulse), a RF pulse with the duration τ_{180° and the RF magnetic field B_1 (in the the direction perpendicular to B_0) chosen so that the magnetization is nutated by 180° around the B_1 direction. The magnetization immediately after the 180° pulse is directed along the $-z$ direction (cf. [figure B1.13.3\(B\)](#)) and starts to relax following [equation B1.13.1](#). After a variable delay τ , when the $M_z(\tau)$ has reached the stage depicted in [figure B1.13.3\(C\)](#), a 90° pulse is applied. This pulse nutates the magnetization along the z -axis to the x,y -plane (cf. [figure B1.13.3\(D\)](#)), where it can be detected in the form of a FID. If

required, the experiment can be repeated a number of times to improve the signal-to-noise ratio, waiting for about $5T^1$ (recycle delay) between scans to allow for return to equilibrium. The subsequent Fourier transformation (FT) of the FID gives a spectrum. The experiment is repeated for different values of the delay τ and the measured line intensities are fitted to an exponential expression $S(\tau) = A + B \exp(-\tau / T^1)$. The inversion-recovery experiments are often performed for multiline spectra of low-natural abundance nuclei, such as ^{13}C or ^{15}N , under the conditions of broadband saturation (decoupling) of the abundant proton spins. The proton (S -spin) decoupling renders the relaxation of the I spin of the dipolarly coupled IS -spin system monoexponential; we may say that the decoupling results in 'pseudo-isolated' I spins. An example of a ^{13}C inversion-recovery experiment for a trisaccharide, melezitose, is shown in [figure B1.13.4](#).

-10-

Figure B1.13.3. The inversion-recovery experiment. (Reproduced by permission of VCH from Banci L, Bertini I and Luchinat C 1991 *Nuclear and Electron Relaxation* (Weinheim: VCH).)

-11-

Figure B1.13.4. The inversion-recovery determination of the carbon-13 spin–lattice relaxation rates in melezitose. (Reproduced by permission of Elsevier from Kowalewski J and Mäler L 1997 *Methods for Structure Elucidation by High-Resolution NMR* ed Gy Batta, K E Kövér and Cs Szántay (Amsterdam: Elsevier) pp 325–47.)

NMR spectroscopy is always struggling for increased sensitivity and resolution, as well as more efficient use of the instrument time. To this end, numerous improvements of the simple inversion-recovery method have been proposed over the years. An early and important modification is the so-called fast inversion recovery (FIR) [25], where the recycle delay is made shorter than $5T_1$ and the experiment is carried out under the steady-state rather than equilibrium conditions. A still more time-saving variety, the super-fast inversion recovery (SUFIR) has also been proposed [26].

Several other improvements of the inversion-recovery scheme employ advanced tools of modern NMR spectroscopy: polarization transfer and two-dimensional spectroscopy (see further reading). The basic design of selected pulse sequences is compared with the simple inversion-recovery scheme in figure B1.13.5 taken from Kowalewski and Mäler [24], where references to original papers can be found. The figure B1.13.5(a), where thick rectangular boxes denote the 180° I -spin pulses and thin boxes the corresponding 90° pulses, is a representation of the inversion-recovery sequence with the continuous saturation of the protons. In figure B1.13.5(b), the inverting I -spin pulse is replaced by a series of pulses, separated by constant delays and applied at both the proton and the I -spin resonance frequencies, which creates a more strongly polarized initial I -spin state (the polarization transfer technique). In figure B1.13.5(c), a two-dimensional (2D) NMR technique is employed. This type of approach is particularly useful when the sample contains many heteronuclear IS spin pairs, with different I s and different S s characterized by slightly different resonance frequencies (chemical shifts), resulting in crowded spectra. In a generic 2D experiment, the NMR signal is sampled as a function of two time variables: t_2 is the running time during which the FID is acquired (different

points in the FID have different t_2). In addition, the pulse sequence contains an evolution time t_1 , which is systematically varied in the course of the experiment. The double Fourier transformation of the data matrix $S(t_1, t_2)$ yields a two-dimensional spectrum. In the example of figure B1.13.5(c), the polarization is transferred first from protons to the I spins, in the same way as in figure B1.13.5(b). This is followed by the evolution

time, during which the information on the various I -spin resonance frequencies is encoded. The next period is the analogue of the delay τ of the simple inversion-recovery experiment. The final part of the sequence contains an inverse polarization transfer, from I spins to protons, followed by the proton detection. The resulting 2D spectrum, for a given delay τ , has the proton chemical shifts on one axis and the shifts of the J -coupled I -spin on the other one. We can thus call the experiment the proton– I -spin correlation experiment. This greatly improves the spectral resolution. Spectra with several different τ delays are acquired and the I spin T_1 is determined by fitting the intensity decay for a given peak in the 2D spectrum.

Figure B1.13.5. Some basic pulse sequences for T_1 measurements for carbon-13 and nitrogen-15. (Reproduced by permission of Elsevier from Kowalewski J and Mäler L 1997 *Methods for Structure Elucidation by High-Resolution NMR* ed Gy Batta, K E Kövér and Cs Szántay (Amsterdam: Elsevier) pp 325–47.)

The discussion above is concerned with T_1 experiments under high resolution conditions at high magnetic field. In studies of complex liquids (polymer solutions and melts, liquid crystals), one is often interested to obtain information on rather slow (micro- or nanosecond time scale) motions measuring T_1 at low magnetic fields using the field-cycling technique [27]. The same technique is also invaluable in studies of paramagnetic solutions. Briefly, the non-equilibrium state is created by keeping the sample at a certain, moderately high polarizing field B_0 and then rapidly switching B_0 to another value, at which we wish to measure T_1 . After the variable delay τ , the field is switched again and the signal is detected.

The spin–spin relaxation time, T_2 , defined in the Bloch equations, is simply related to the width $\Delta\nu_{1/2}$ of the Lorentzian line at the half-height: $\Delta\nu_{1/2} = 1/\pi T^2$. Thus, it is in principle possible to determine T_2 by measuring the linewidth. This simple approach is certainly useful for rapidly relaxing quadrupolar nuclei and has also been demonstrated to work for $I=1/2$ nuclei, provided the magnetic field homogeneity is ascertained. The more usual practice, however, is to suppress the inhomogeneous broadening caused by the spread of the magnetic field values (and thus resonance frequencies) over the sample volume, by the spin-echo technique. Such experiments are in general more difficult to perform than the spin–lattice relaxation time measurements. The most common echo sequence, the $90^\circ\text{--}\tau\text{--}180^\circ\text{--}\tau\text{--}\text{echo}$, was originally proposed by Carr and Purcell [28] and modified by Meiboom and Gill [29]. After the initials of the four authors, the modified sequence is widely known as the CPMG method. The details of the behaviour of spins under the spin-echo sequence can be found

in modern NMR monographs (see further reading) and will not be repeated here. We note, however, that complications can arise in the presence of scalar spin–spin couplings.

An alternative procedure for determining the transverse relaxation time is the so-called $T_{1\rho}$ experiment. The basic idea of this experiment is as follows. The initial 90° I -spin pulse is applied with B_1 in the x -direction, which turns the magnetization from the z -direction to the y -direction. Immediately after the initial pulse, the B_1 RF field is switched to the y -direction so that \mathbf{M} and B_1 become collinear. The notation $T_{1\rho}$ (T_1 in the rotating frame) alludes to the fact that the decay of \mathbf{M} along B_1 is similar to the relaxation of longitudinal magnetization along B_0 . The $T_{1\rho}$ in liquids is practically identical to T_2 . The measurements of T_2 or $T_{1\rho}$ can, in analogy with T_1 studies, also utilize the modern tools increasing the sensitivity and resolution, such as polarization transfer and 2D techniques.

B1.13.3.2 CROSS-RELAXATION AND NUCLEAR OVERHAUSER ENHANCEMENT

Besides measuring T_1 and T_2 for nuclei such as ^{13}C or ^{15}N , relaxation studies for these nuclei also include measurements of the NOE factor, cf. [equation B1.13.6](#). Knowing the $T_{1I}^{-1}(\rho_I)$ and the steady-state NOE (measured by comparing the signal intensities in the presence and in the absence of the saturating field), we can derive the cross-relaxation rate, σ_{IS} , which provides an additional combination of spectral densities, useful for e.g. molecular dynamics studies.

The most important cross-relaxation rate measurements are, however, performed in homonuclear networks of chemically shifted and dipolarly coupled proton spins. The subject has been discussed in two books [[30](#), [31](#)]. There is large variety of experimental procedures [[32](#)], of which I shall only mention a few. A simple method to measure the homonuclear NOE is the NOE-difference experiment, in which one measures spectral intensities using low power irradiation at selected narrow regions of the spectrum, before applying the observe pulse. This corresponds to different individual protons acting as the saturated S spins. The difference spectrum is obtained by subtracting the spectrum obtained under identical conditions, but with the irradiation frequency applied in a region without any peaks to saturate. The NOE-difference experiments are most often applied in a semi-quantitative way in studies of small organic molecules.

For large molecules, such as proteins, the main method in use is a 2D technique, called NOESY (nuclear Overhauser effect spectroscopy). The basic experiment [[33](#), [34](#)] consists of three 90° pulses. The first pulse converts the longitudinal magnetizations for all protons, present at equilibrium, into transverse magnetizations which evolve during the subsequent evolution time t_1 . In this way, the transverse magnetization components for different protons become labelled by their resonance frequencies. The second 90° pulse rotates the magnetizations to the $-z$ -direction.

-14-

The interval between the second and third pulse is called the mixing time, during which the spins evolve according to the multiple-spin version of [equation B1.13.2](#) and [equation B1.13.3](#) and the NOE builds up. The final pulse converts the longitudinal magnetizations, present at the end of the mixing time, into detectable transverse components. The detection of the FID is followed by a recycle delay, during which the equilibrium is recovered and by the next experiment, e.g. with another t_1 . After acquiring the 2D data matrix $S(t^1, t^2)$ (for a given mixing time) and the double Fourier transformation, one obtains a 2D spectrum shown schematically in [figure B1.13.6](#). The individual cross-relaxation rates for pairs of spins can be obtained by following the build-up of the cross-peak intensities as a function of the mixing time for short mixing times (the so-called initial rate approximation). For longer mixing times and large molecules, the cross-peaks show up in a large number of positions, because of multiple transfers called spin-diffusion. The analysis then becomes more complicated, but can be handled based on a generalization of the Solomon equation to many spins (the complete relaxation matrix treatment) [[35](#)].

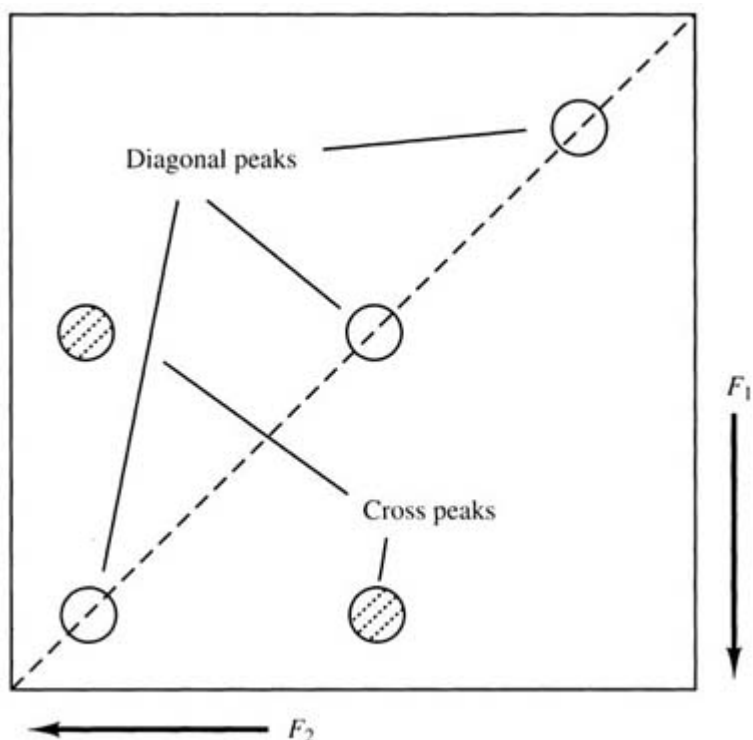

Figure B1.13.6. The basic elements of a NOESY spectrum. (Reproduced by permission of Wiley from Williamson M P 1996 *Encyclopedia of Nuclear Magnetic Resonance* ed D M Grant and R K Harris (Chichester: Wiley) pp 3262–71).

As seen in [equation B1.13.2](#) and [equation B1.13.3](#), the cross-relaxation rate σ_{IS} is given by $W^2 - W^0$, the difference between two transition probabilities. Assuming the simple isotropic rotational diffusion model, each of the transition probabilities is proportional to a Lorentzian spectral density (cf. [equation B1.13.12](#)), taken at the frequency of the corresponding transition. For the homonuclear case, W_2 corresponds to a transition at high frequency ($\omega_1 + \omega_S \approx 2\omega_1$), while W_0 is proportional to a Lorentzian at ($\omega_1 - \omega_S \approx 0$). When the product $\omega_1\tau_c$ is small, W_2 is larger than W_0 and the cross-relaxation rate is positive. When the product $\omega_1\tau_c$ is large, the Lorentzian function evaluated at $2\omega_1$ is much smaller than at zero-frequency and σ_{IS} changes sign. The corresponding NOESY peak intensities in a two-spin

system are shown as a function of the mixing time in figure B1.13.7. Clearly, the intensities of the cross-peaks for small molecules ($\omega^2\tau_c^2 \ll 1$) have one sign, while the opposite sign pertains for large molecules ($\omega^2\tau_c^2 \gg 1$). At a certain critical correlation time, we obtain no NOESY cross-peaks. In such a situation and as complement to the NOESY experiments, one can perform an experiment called ROESY (rotating frame Overhauser effect spectroscopy) [36]. The relation between NOESY and ROESY is similar to that between T_1 and $T_{1\rho}$.

Figure B1.13.7. Simulated NOESY peak intensities in a homonuclear two-spin system as a function of the mixing time for two different motional regimes. (Reproduced by permission of Wiley from Neuhaus D 1996 *Encyclopedia of Nuclear Magnetic Resonance* ed D M Grant and R K Harris (Chichester: Wiley) pp 3290–301.)

B1.13.3.3 CROSS-CORRELATED RELAXATION

Studies of cross-correlated relaxation have received increasing attention during the last decades. The general strategies for creating and detecting different types of spin-ordered state and for measuring the transfer rates have been discussed by Canet [37]. I shall concentrate here on measurements of the DD-CSA interference terms in two-spin systems, the $\delta_{I,IS}$ and $\delta_{S,IS}$ terms in equation B1.13.7. Let us consider a system where the two spins have their resonances sufficiently far apart that we can construct pulses selective enough to manipulate one of them at a time (this is automatically fulfilled for a heteronuclear case; in the homonuclear this requires specially shaped low power RF pulses). One way to measure the longitudinal cross-correlated relaxation rates is to invert one of the spins by a 180° pulse and to detect the build-up of the two-spin order. The two-spin order $\langle 2I_{zSz} \rangle$ is not detectable directly but, if one of the spins is exposed to a 90° pulse, the two-spin order becomes converted into a detectable signal in the form of an antiphase doublet, cf. Figure B1.13.8 (the corresponding one-spin order subjected to a 90° pulse gives rise to an in-phase doublet). To separate the two types of order in a clean way, one can use an RF pulse trick called the double-quantum filter. There are many ways to optimize the above method as well as other schemes to measure the $\langle I_z \rangle$ to $\langle 2I_{zSz} \rangle$ transfer rates. One such scheme uses a set of three selective NOESY experiments, where three 90° pulses strike the spins in the sequence *III*, *SSS* and *IIS* [38]. Another scheme uses an extended sequence of 180° pulses, followed by a detecting pulse [39].

Figure B1.13.8. Schematic illustration of (a) an antiphase doublet, (b) an in-phase doublet and (c) a differentially broadened doublet. The splitting between the two lines is in each case equal to J , the indirect spin–spin coupling constant.

The cross-correlation effects between the DD and CSA interactions also influence the transverse relaxation and lead to the phenomenon known as differential line broadening in a doublet [40], cf. Figure B1.13.8. There is a recent experiment, designed for protein studies, that I wish to mention at the end of this section. It has been proposed by Pervushin *et al* [41], is called TROSY (transverse relaxation optimized spectroscopy) and employs the differential line-broadening in a sophisticated way. One works with the ^{15}N –proton J -coupled spin system. When the system is subjected to a 2D nitrogen–proton correlation experiment, the spin–spin coupling gives rise to four lines (a doublet in each dimension). The differential line broadening results in one of the four lines being substantially narrower than the other ones. Pervushin *et al* [41] demonstrated that the broader lines can be suppressed, resulting in greatly improved resolution in the spectra of large proteins.

B1.13.4 APPLICATIONS

In this section, I present a few illustrative examples of applications of NMR relaxation studies within different branches of chemistry. The three subsections cover one ‘story’ each, in order of increasing molecular size and complexity of the questions asked.

B1.13.4.1 SMALL MOLECULES: THE DUAL SPIN PROBE TECHNIQUE

Small molecules in low viscosity solutions have, typically, rotational correlation times of a few tens of picoseconds, which means that the extreme narrowing conditions usually prevail. As a consequence, the interpretation of certain relaxation parameters, such as carbon-13 T_1 and NOE for proton-bearing carbons, is very simple. Basically, the DCC for a directly bonded CH pair can be assumed to be known and the experiments yield a value of the correlation time, τ_c . One interesting application of the measurement of τ_c is to follow its variation with the site in the molecule (motional anisotropy), with temperature (the correlation

time increases often with decreasing temperature, following an Arrhenius-type equation) or with the composition of solution. The latter two types of measurement can provide information on intermolecular interactions.

Another application of the knowledge of τ_c is to employ it for the interpretation of another relaxation measurement in the same system, an approach referred to as the dual spin probe technique. A rather old, but illustrative, example is the case of *tris*(pentane-2,4-dionato)aluminium(III), $\text{Al}(\text{acac})^3$. Dechter *et al* [42] reported measurements of carbon-13 spin–lattice relaxation for the methine carbon and of the aluminium-27 linewidth in $\text{Al}(\text{acac})^3$ in toluene solution. ^{27}Al is a quadrupolar nucleus ($I=5/2$) and the linewidth gives directly the T_2 , which depends on the rotational correlation time (which can be assumed the same as for the methine CH axis) and the strength of the quadrupolar interaction (the quadrupolar coupling constant, QCC). Thus, the combination of the carbon-13 and aluminium-27 measurements yields the QCC. The QCC in this particular case was also determined by NMR in a solid sample. The two measurements agree very well with each other (in fact, there is a small error in the paper [42]: the QCC from the linewidth in solution should be a factor of 2π larger than what is stated in the article). More recently, Champmartin and Rubini [43] studied carbon-13 and oxygen-17 (another $I=5/2$ quadrupolar nucleus) relaxation in pentane-2,4-dione (Hacac) and $\text{Al}(\text{acac})^3$ in solution. The carbon measurements were performed as a function of the magnetic field. The methine carbon relaxation showed, for both compounds, no field dependence, while the carbonyl carbon T_1 increased linearly with $\frac{2}{\omega_0}$. This indicates the CSA mechanism and allows an estimate of its interaction strength, the anisotropy of the shielding tensor. Also this quantity could be compared with solid state measurements on $\text{Al}(\text{acac})^3$ and, again, the agreement was good. From the oxygen-17 linewidth, the authors obtained also the oxygen-17 QCC. The chemically interesting piece of information is the observation that the QCC changes only slightly between the free acid and the trivalent metal complex.

B1.13.4.2 OLIGOSACCHARIDES: HOW FLEXIBLE ARE THEY?

Oligosaccharides are a class of small and medium-sized organic molecules, subject to intense NMR work. I present here the story of two disaccharides, sucrose and $\alpha\text{-D-Manp-(1}\rightarrow\text{3)-}\beta\text{-D-Glcp-OMe}$ and a trisaccharide melezitose. McCain and Markley [44] published a carbon-13 T_1 and NOE investigation of sucrose in aqueous solution as a function of temperature and magnetic field. At low temperatures, a certain field dependence of the parameters could be observed, indicating that the extreme narrowing conditions might not be fulfilled under these circumstances. Taking the system out of extreme narrowing (which corresponds to correlation times of few hundred picoseconds) renders the relaxation rates field dependent and allows the investigators to ask more profound questions concerning the interaction strength and dynamics. Kovacs *et al* [45] followed up the McCain–Markley study by performing similar experiments on sucrose in a 7:3 molar $\text{D}^2\text{O/DMSO-d}^6$ solvent mixture. The solvent mixture has about four times higher viscosity than water and is a cryo-solvent. Thus, it was possible to obtain the motion of the solute molecule far from the extreme narrowing region and to make a quantitative determination of the effective DCC, in a way which is related to the Lipari–Szabo method [10]. Mäler *et al* [46] applied a similar experimental approach (but extended also to include the T_2 measurements) and the Lipari–Szabo analysis to study the molecular dynamics of melezitose in the same

mixed solvent. Somewhat different dynamic behaviour of different sugar residues and the exocyclic hydroxymethyl groups was reported.

The question of the flexibility (or rigidity) of the glycosidic linkage connecting the different sugar units in oligosaccharides is a hot issue in carbohydrate chemistry. The findings of Mäler *et al* [46] could be interpreted as indicating a certain flexibility of the glycosidic linkages in melezitose. The question was posed more directly by Poppe and van Halbeek [47], who measured the intra- and interresidue proton–proton NOEs and rotating frame NOEs in sucrose in aqueous solution. They interpreted the results as proving the non-rigidity of

the glycosidic linkage in sucrose. Mäler *et al* [48] investigated the disaccharide α -D-Manp-(1 \rightarrow 3)- β -D-Glcp-OMe by a combination of a carbon-13 spin-lattice relaxation study with measurements of the intra- and interresidue proton-proton cross-relaxation rates in a water-DMSO mixture. They interpreted their data in terms of the dynamics of the CH axes, the intra-ring HH axis and the trans-glycosidic HH axis being described by a single set of Lipari-Szabo parameters. This indicated that the inter-residue HH axis did not sense any additional mobility as compared to the other axes. We shall probably encounter a continuation of this story in the future.

B1.13.4.3 HUMAN UBIQUITIN: A CASE HISTORY FOR A PROTEIN

Human ubiquitin is a small (76 amino acid) and well characterized protein. I choose to illustrate the possibilities offered by NMR relaxation studies of proteins [49] through this example. The 2D NMR studies for the proton resonance assignment and a partial structure determination through NOESY measurements were reported independently by Di Stefano and Wand [50] and by Weber *et al* [51]. Schneider *et al* [52] studied a uniformly nitrogen-15 labelled species of human ubiquitin and reported nitrogen-15 T_1 (at two magnetic fields) and NOE values for a large majority of amide nitrogen sites in the molecule. The data were interpreted in terms of the Lipari-Szabo model, determining the generalized order parameter for the amide NH axes. It was thus possible to identify the more flexible and more rigid regions in the protein backbone. Tjandra *et al* [53] extended this work, both in terms of experiments (adding T_2 measurements) and in terms of interpretation (allowing for the anisotropy of the global reorientation, by means of the anisotropic Lipari-Szabo model [10]). This provided a more quantitative interpretation of the molecular dynamics. During the last two years, Bax and coworkers have, in addition, determined the CSA for the nitrogen-15 and proton for most of the amide sites, as well as for the α -carbons, through measurements of the cross-correlated relaxation rates in the nitrogen-15-amide proton or the C_α - H_α spin pairs [54, 55 and 56]. The CSA values could, in turn, be correlated with the secondary structure, hydrogen bond length etc. It is not likely that the ubiquitin story is finished either.

ACKNOWLEDGMENTS

I am indebted to Dr Dan Bergman and Mr Tomas Nilsson for valuable comments on the manuscript.

B1.14 NMR imaging (diffusion and flow)

Ute Goerke, Peter J McDonald and Rainer Kimmich

B1.14.1 INTRODUCTION

Nuclear magnetic resonance imaging and magnetic resonance determinations of flow and diffusion are increasingly coming to the fore as powerful means for characterizing dynamic processes in diverse areas of materials science covering physics, chemistry, biology and engineering. In this chapter, the basic concepts of the methods are introduced and a few selected examples presented to show the power of the techniques. Although flow and diffusion through bulk samples can be measured, they are primarily treated here as parameters to be mapped in an imaging experiment. To that end, imaging is dealt with first, followed by flow and diffusion, along with other contrast parameters such as spin-relaxation times and chemical shift.

The great diversity of applications of magnetic resonance imaging (MRI) has resulted in a plethora of techniques which at first sight can seem bemusing. However, at heart they are built on a series of common

building blocks which the reader will progressively come to recognize. The discussion of imaging is focused very much on just three of these—slice selection, phase encoding and frequency encoding, which are brought together in perhaps the most common imaging experiment of all, the spin warp sequence [1, 2 and 3]. This sequence is depicted in figure B1.14.1. Its building blocks are discussed in the following sections. Blocks for contrast enhancement and parameter selectivity can be added to the sequence.

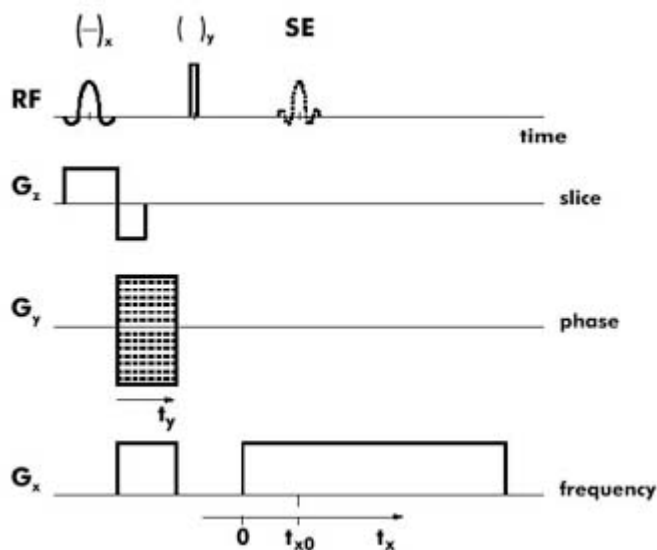

Figure B1.14.1. Spin warp spin-echo imaging pulse sequence. A spin echo is refocused by a non-selective 180° pulse. A slice is selected perpendicular to the z-direction. To frequency-encode the x-coordinate the echo SE is acquired in the presence of the readout gradient. Phase-encoding of the y-dimension is achieved by incrementing the gradient pulse G_y .

B1.14.2 FUNDAMENTALS OF SPATIAL ENCODING

The classical description of magnetic resonance suffices for understanding the most important concepts of magnetic resonance imaging. The description is based upon the Bloch equation, which, in the absence of relaxation, may be written as

$$\frac{d\mathbf{M}(\mathbf{r}, t)}{dt} = \gamma \mathbf{M}(\mathbf{r}, t) \times \mathbf{B}(\mathbf{r}, t).$$

The equation describes the manner in which the nuclear magnetization, \mathbf{M} , at position \mathbf{r} and time t precesses about the magnetic flux density, \mathbf{B} , in which it is found. The constant γ is the magnetogyric ratio of the nuclides under study. The precessional frequency, ω , is given by the Larmor equation,

$$\omega = \gamma B. \tag{B1.14.1}$$

Magnetic resonance imaging, flow and diffusion all rely upon manipulating spatially varying magnetic fields in such a manner as to encode spatial information within the accumulated precession of the magnetization. In

most MRI implementations, this is achieved with three orthogonal, constant, pulsed magnetic field gradients which are produced using purpose built current windings carrying switched currents. The gradient fields are superimposed on the normal static, applied field B_0 . Although the current windings produce gradient fields with components in all directions, for sufficiently high applied flux densities and small enough gradients, it is sufficient to consider only the components in the direction of the applied field, conventionally assigned the z -direction. Accordingly, the gradients are referred to as $G_x = \frac{\partial B_z}{\partial x}$, $G_y = \frac{\partial B_z}{\partial y}$ and $G_z = \frac{\partial B_z}{\partial z}$. The local polarizing field at position \mathbf{r} is then given by

$$\mathbf{B}(\mathbf{r}) = (B_0 + \mathbf{G} \cdot \mathbf{r})\mathbf{u}_z.$$

The Bloch equation is simplified, and the experiment more readily understood, by transformation into a frame of reference rotating at the frequency $\omega_0 = \gamma B_0$ about the z -axis whereupon:

$$\frac{dM'(\mathbf{r}, t)}{dt} = \gamma M'(\mathbf{r}, t) \times (\mathbf{G} \cdot \mathbf{r})\mathbf{u}_z.$$

The transverse magnetization may be described in this frame by a complex variable, m , the real and imaginary parts of which represent the real and imaginary components of observable magnetization respectively:

$$m(\mathbf{r}, t) = M'_x(\mathbf{r}, t) + iM'_y(\mathbf{r}, t).$$

-3-

The components of the Bloch equation are hence reduced to

$$\begin{aligned} \frac{dM'_z(\mathbf{r}, t)}{dt} &= 0 \\ \frac{dm(\mathbf{r}, t)}{dt} &= -i\gamma(\mathbf{G} \cdot \mathbf{r})m(\mathbf{r}, t). \end{aligned}$$

The z -component of the magnetization is constant. The evolution of the transverse magnetization is given by

$$m(\mathbf{r}, t) = m(\mathbf{r}, 0) \exp[-i\Omega(\mathbf{r})t] \tag{B1.14.2}$$

where $\Omega(\mathbf{r}) = \gamma \mathbf{G} \cdot \mathbf{r}$ is the offset frequency relative to the resonance frequency ω_0 . Spin position is encoded directly in the offset frequency Ω . Measurement of the offset frequency forms the basis of the frequency encoding of spatial information, the first building block of MRI. It is discussed further in subsequent sections. In a given time $t = \tau$ the transverse magnetization accumulates a spatially varying phase shift, $\omega(\mathbf{r})\tau$. Measurement of the phase shift forms the basis of another building block, the second encoding technique, phase encoding, which is also further discussed below. However, before proceeding with further discussion of either of these two, we turn our attention to the third key component of an imaging experiment—slice selection.

B1.14.2.1 SLICE SELECTION

A slice is selected in NMR imaging by applying a radio frequency (RF) excitation pulse to the sample in the presence of a magnetic field gradient. This is in contrast to spatial encoding, where the magnetization following excitation is allowed to freely evolve in the presence of a gradient. A simple appreciation of how

slice selection works is afforded by comparing the spread of resonance frequencies of the nuclei in the sample with the frequency bandwidth of the RF pulse. The resonance frequencies of nuclear spins in a sample placed centrally in a magnetic field, B_0 , with a superimposed constant gradient \mathbf{G} vary linearly across the sample between $\omega_0 \pm \gamma G d_s / 2$ where d_s is the dimension of the sample in the gradient direction. To a first approximation, the radio-frequency excitation pulse (of duration t_w and carrier frequency ω_0) contains frequency components in the range $\omega_0 \pm \pi / t_w$. If the pulse bandwidth is significantly less than the spread of frequencies within the sample, the condition for a so called *soft pulse*, then the pulse excites nuclei only in a central slice of the sample, perpendicular to the gradient, where the frequencies match. A slice at a position other than the centre of the sample can be chosen by offsetting the excitation carrier frequency, ω_0 .

A more detailed description of the action of an arbitrary pulse on a sample in a gradient can be obtained from a solution of the Bloch equations, either numerically or using advanced analytic techniques. In general this is complicated since the effective field in the rotating frame is composed not only of the spatially varying gradient field in the z -direction but also the transverse excitation field which, in general, varies with time. What follows is therefore an approximate treatment which nonetheless provides a surprisingly accurate description of many of the more commonly used slice selection pulses [4].

Suppose that a gradient, $\mathbf{G} = G_z \mathbf{u}_z$, is applied in the z -direction. In a local frame of reference rotating about the combined polarizing and gradient fields at the frequency $\omega = \omega_0 + \gamma(\mathbf{G} \cdot \mathbf{r})$, an excitation pulse $\mathbf{B}_1(t)$ applied at the central resonance

-4-

frequency of ω_0 and centred on $t = 0$ is seen to rotate at the offset frequency $\gamma(\mathbf{G} \cdot \mathbf{r})$ and therefore to have components given by

$$B_1(t) \left\{ \cos \left[\gamma(\mathbf{G} \cdot \mathbf{r}) \left(t + \frac{t_w}{2} \right) \right] \mathbf{u}'_x + \sin \left[\gamma(\mathbf{G} \cdot \mathbf{r}) \left(t + \frac{t_w}{2} \right) \right] \mathbf{u}'_y \right\}.$$

The excitation field is the only field seen by the magnetization in the rotating frame. The magnetization precesses about it. Starting from equilibrium ($\mathbf{M}_0 = M_0 \mathbf{u}_z$), transverse components are created and develop according to

$$\frac{d\mathbf{m}(\mathbf{r}, t)}{dt} = i\gamma M'_z(\mathbf{r}, t) B_1(t) \exp \left[-i\gamma(\mathbf{G} \cdot \mathbf{r}) \left(t + \frac{t_w}{2} \right) \right].$$

The simplifying approximation of a linear response is now made, by which it is assumed that rotations about different axes may be decoupled. This is only strictly valid for small rotations, but is surprisingly good for larger rotations too. This means that $M'_z(\mathbf{r}, t) \approx M_0(\mathbf{r})$ constant. Accordingly, at the end of the pulse the transverse magnetization is given by

$$m\left(\mathbf{r}, t = \frac{t_w}{2}\right) \approx i\gamma M_0(\mathbf{r}) \exp\left[-i\gamma(\mathbf{G} \cdot \mathbf{r})\frac{t_w}{2}\right] \int_{-\frac{t_w}{2}}^{+\frac{t_w}{2}} B_1(t) \exp[-i\gamma(\mathbf{G} \cdot \mathbf{r})t] dt. \quad (\text{B1.14.3})$$

The integral describes the spatial amplitude modulation of the excited magnetization. It represents the excitation or slice profile, $g(z)$, of the pulse in real space. As B_1 drops to zero for t outside the pulse, the integration limits can be extended to infinity whereupon it is seen that the excitation profile is the Fourier transform of the pulse shape envelope:

$$g(z) = \gamma \int_{-\infty}^{+\infty} B_1(t) \exp(-i\gamma G_z t z) dt.$$

For a soft pulse with a rectangular envelope

$$B_1(t) = \begin{cases} B_1 & \text{for } -\frac{t_w}{2} \leq t \leq \frac{t_w}{2} \\ 0 & \text{otherwise} \end{cases}$$

-5-

and a carrier frequency resonant at the position $z=z_0$ the excitation profile is sinc shaped. In normalized form, it is:

$$\frac{g(z - z_0)}{g(0)} = \text{sinc}\left[\frac{1}{2\pi}(z - z_0)\gamma G_z t_w\right]$$

where

$$\text{sinc}(x) = \frac{\sin(\pi x)}{\pi x}.$$

A sinc-shape has side lobes which impair the excitation of a distinct slice. Other pulse envelopes are therefore more commonly used. Ideally, one would like a rectangular excitation profile which results from a sinc-shaped pulse with an infinite number of side lobes. In practice, a finite pulse duration is required and therefore the pulse has to be truncated, which causes oscillations in the excitation profile. Another frequently used pulse envelope is a Gaussian function:

$$B_1(t) = B_1(0) e^{-at^2}$$

which produces a Gaussian slice profile:

$$\frac{g(z - z_0)}{g(0)} = e^{-\Omega_{z_0}^2/(4a)}$$

where $\Omega_{z_0} = \gamma G_z(z - z_0)$ and a is a pulse-width parameter. The profile is centred on z_0 at which position the transmitter frequency is resonant. The full width at half maximum of the slice, $\Delta_{1/2}$, is determined by the constant:

$$\Delta z_{1/2} = \frac{4}{\gamma G_z} \sqrt{a \ln 2}.$$

For a given half width at half maximum in the time domain, $\Delta t_{1/2} = 2\sqrt{\frac{\ln 2}{a}}$, the slice width $\Delta z_{1/2}$ decreases with increasing gradient strength G_z .

Closer examination of [equation B1.14.3](#) reveals that, after the slice selection pulse, the spin isochromats at different positions in the gradient direction are not in phase. Rather they are rotated by $i \exp(-i\gamma G_z z \frac{t_w}{2})$ and therefore have a phase $(\gamma G_z z t_w - \pi)/2$. Destructive interference of isochromats at different locations leads to cancellation of the total transverse magnetization.

The dephased isochromats may be refocused by applying one or more RF and trimming gradient pulses after the excitation. In the pulse sequence shown in [figure B1.14.1](#) the magnetization is refocused by a negative trimming z -gradient pulse of the same amplitude, but half the duration as the original slice selection gradient pulse. The trimming gradient causes a precession of the magnetization at every location which exactly compensates that occurring during the initial excitation (save for the constant factor π). A similar effect may be achieved using a (non-selective) 180° pulse and a trimming gradient pulse of the same sign.

B1.14.2.2 FREQUENCY ENCODING

Once a slice has been selected and excited, it is necessary to encode the ensuing NMR signal with the coordinates of nuclei within the slice. For each coordinate (x and y) this is achieved by one of two very closely related means, frequency encoding or phase encoding [1]. In this section we consider the former and in the next, the latter. In the section after that we show how the two are combined in the most common imaging experiment.

As before, we note that the resonance frequency of a nucleus at position \mathbf{r} is directly proportional to the combined applied static and gradient fields at that location. In a gradient $\mathbf{G} = G_x \mathbf{u}_x$, orthogonal to the slice selection gradient, the nuclei precess (in the usual frame rotating at ω_0) at a frequency $\omega = \gamma G_{xx}$. The observed signal therefore contains a component at this frequency with an amplitude proportional to the local spin density. The total signal is of the form

$$S(t_x) = \int_{-\infty}^{+\infty} dx m(x) e^{-i\gamma G_x x t_x}$$

from which it is seen that the spin density in the x -direction is recovered by a Fourier transform of the signal with respect to time

$$m(x) \propto \int dt_x S(t_x) \exp(i\gamma G_x x t_x).$$

In practice, it is generally preferable to create and record the signal in the form of an echo well clear of pulse

ring-down and other artifacts associated with defining the zero of time. This can be done either by first applying a negative gradient lobe followed by a positive gradient—a gradient echo—or by including a 180° inversion pulse between two positive gradients—a spin echo. [Figure B1.14.1](#) demonstrates the spin echo. A trimming x -gradient of duration t_y is placed before the 180° pulse which inverts the phase of the magnetization, so that, with reference to [figure B1.14.1](#).

$$m(\mathbf{r}, t_x) = m(\mathbf{r}, 0) e^{i\gamma G_x x t_y} e^{-i\gamma G_x x t_x}.$$

The maximum signal appears at the echo centre when the exponent disappears for all \mathbf{r} at time $t_x = t_{x0}$. If the magnitude of the read gradient and the corresponding trimming gradient is the same, then $t_{x0} = t_y$. The magnetization profile is obtained by Fourier transforming the echo.

B1.14.2.3 PHASE ENCODING

If a gradient pulse is applied for a fixed evolution time t_y the magnetization is dephased by an amount dependent on the gradient field. The signal phase immediately after the gradient varies linearly in the direction of the gradient. For a y -gradient $\mathbf{G} = G_y \mathbf{u}_y$ of duration t_y as shown in [figure B1.14.1](#) we have:

$$m(\mathbf{r}, G_y) = m(\mathbf{r}, 0) e^{-i\gamma G_y y t_y}$$

-7-

For phase encoding the phase twist is most commonly varied by incrementing G_y in a series of subsequent transients as this results in a constant transverse relaxation attenuation of the signal at the measurement position. The signal intensity as a function of G_y is

$$S(G_y) = \int_{-\infty}^{+\infty} dy m(y) e^{-i\gamma G_y y t_y}.$$

The magnetization profile in the y -direction is recovered by Fourier transformation with respect to G_y .

B1.14.2.4 2D SPIN-ECHO FT IMAGING AND K-SPACE

We now bring all the elements of the imaging experiment together within the typical spin-warp imaging sequence [10] previously depicted in [figure B1.14.1](#). A soft 90° pulse combined with slice-selection gradient G_z excites a slice in the x/y -plane. The spin isochromats are refocused by the negative z -gradient lobe. A subsequent spin echo, SE , is formed by a hard 180° pulse inserted after the slice selection pulse. The G_x -gradient either side of the 180° pulse first dephases and then rephases the magnetization so that an echo forms at twice the time separation, τ , between the two pulses. The x -dimension is encoded by acquiring the echo in the presence of this gradient, often known as a readout gradient. The y -dimension is phase encoded using the gradient G_y which is incremented in subsequently measured transients. The signal intensity S of the echo is the superposition of all the transverse magnetization originating from the excited slice. The acquired data set is described by:

$$S(t_x, G_y) = \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} dx dy m(x, y) e^{-i\gamma G_x x (t_x - t_{x0})} e^{i\gamma G_y y t_y}.$$

The magnetization density is recovered by a two-dimensional Fourier transform of the data with respect to t_x

and G_y .

From a more general point of view, components k_j , $j=x,y,z$ of a wave vector \mathbf{k} which describes the influence of all gradient pulses may be defined as follows: $k_j(t) = \int_0^t \gamma G_j(t') dt'$. For the 2D imaging pulse sequence discussed here, $k_x = \gamma G_x(t_x - t_{x0})$ and $k_y = -\gamma G_y t_y$ (the negative signs result from the inversion pulse). Spatial encoding is the sampling of \mathbf{k} -space and the acquired data set is then:

$$S(k_x, k_y) = \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} dx dy m(x, y) e^{-ik_x x} e^{-ik_y y}.$$

The image, i.e., the spatially resolved distribution of the magnetization $m(x,y)$, is reconstructed by two-dimensional Fourier transformation with respect to k_x and k_y . In the absence of other interactions and encodings discussed below, it represents the spin density distribution of the sample.

There is of course no requirement to confine the slice selection to the z -gradient. The gradients may be used in any combination and an image plane selected in any orientation without recourse to rotating the sample.

-8-

Another frequently used imaging method is gradient-recalled spin-echo imaging (figure B1.14.2). In this method, the 180° pulse of the spin warp experiment is omitted and the first lobe of the G_x gradient is instead inverted. Otherwise the experiment is the same. As the refocusing 180° pulse is omitted, the echo time T_E can be adjusted to be shorter than in the spin-echo version. Therefore gradient-recalled echo and variants of this technique are used when samples with shorter T_2 are to be imaged. On the other hand, this method is more susceptible to off-resonance effects, e.g., due to chemical shift or magnetic field inhomogeneities.

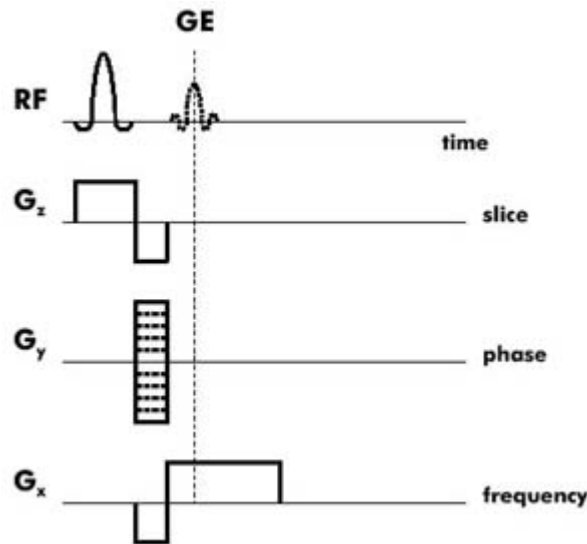

Figure B1.14.2. Gradient-recalled echo pulse sequence. The echo is generated by deliberately dephasing and refocusing transverse magnetization with the readout gradient. A slice is selected in the z -direction and x - and y -dimension are frequency and phase encoded, respectively.

The imaging methods just described require n transients each containing l data points to be acquired so as to construct a two-dimensional image of a matrix of $n \times l$ pixels. Since it is necessary to wait a time of the order of the spin-lattice relaxation time, T_1 , for the spin system to recover between the collection of transients, the total imaging time is in excess of nT_1 for a single average. This may mean imaging times of the order of minutes. The \mathbf{k} -space notation and description of imaging makes it easy to conceive of single transient

imaging experiments in which, by judicious switching of the gradients so as to form multiple echoes, the whole of k -space can be sampled in a single transient.

Techniques of this kind go by the generic title of echo-planar imaging methods [5, 6, 7 and 8] and in the case of full three-dimensional imaging, echo-volumar imaging. A common echo-planar imaging pulse sequence—that for blipped echo-planar imaging—is shown in figure B1.14.3. Slice selection is as before. The alternate positive and negative pulses of x -gradient form repeated gradient echoes as k -space is repeatedly traversed in the positive and negative x -directions. These echoes are used for frequency encoding. The initial negative pulse of y -gradient followed by the much smaller pulses of positive y -gradient ensure that each traverse in the x -direction is for a different value of k_y , starting from an extreme negative value.

-9-

Figure B1.14.3. Echo-planar imaging (EPI) pulse sequence. In analogy to the pure gradient-echo recalled pulse sequence a series of echoes GE1–GE6 is refocused by alternately switching between positive and negative readout gradients. During the readout gradient switching a small phase-encoding gradient pulse (blip) is applied. The spatial phase encoding is hence stepped through the acquired echo train.

In cases where it is not possible to rapidly switch the gradients, frequency-encoded profiles may be acquired in different directions by rotating the gradient and/or sample orientation between transients. The image is reconstructed using filtered back-projection algorithms [9, 10]. The two-dimensional raster of k -space for the spin warp experiment shown in figure B1.14.1 is shown in figure B1.14.4(a) and that for the blipped echo-planar method in figure B1.14.4(b). The raster for back-projection methods is shown in figure B1.14.4(c).

-10-

Figure B1.14.4. k -space representations of the (a) spin-echo imaging pulse sequence in [figure B1.14.1](#), (b) echo-planar imaging sequence in [figure B1.14.3](#) and (c) back-projection imaging. In (a) and (b) the components of the wave vectors k_x and k_y represent frequency and phase encoding, respectively. For back-projection (c) solely a readout gradient for frequency encoding is used. The direction of this gradient is changed stepwise from 0 to 180° in the x/y -plane (laboratory frame) by appropriate superposition of the x - and y -gradient. The related wave vector \mathbf{k}_R then rotates around the origin sampling the k_x/k_y -plane. As the sampled points are not equidistant in k -space, an image reconstruction algorithm different from the two-dimensional Fourier transform has to be used [9, 10].

B1.14.2.5 RESOLUTION

The achievable spatial resolution is limited by several effects. The first is the maximum gradient strength and encoding times available. Bearing in mind [equation B1.14.1](#) and $t_x^{\max} = 1/\Delta f_{\max}$ the pixel size resulting from the Fourier transform of the frequency encoded echo is given by

$$\Delta x = \frac{2\pi}{\gamma G_x t_x^{\max}} \quad (\text{B1.14.4})$$

where t_x^{\max} is the total data acquisition time. The maximum useful encoding time is limited by the transverse relaxation time of the nuclei, T_2 . Therefore the best resolution which can be achieved is of the order of [14]

$$\Delta x^{\text{best}} = \frac{2\pi}{\gamma G_x T_2}. \quad (\text{B1.14.5})$$

A similar result holds for phase encoding where the gradient strength appearing in the expression for the resolution is the maximum gradient strength available. According to these results the resolution can be improved by raising the gradient strength. However, for any spectrometer system, there is a maximum gradient strength which can be switched within a given rise time due to technical limitations. Although modern gradient coil sets are actively shielded to avoid eddy currents in the magnet, in reality systems with pulsed gradients in excess of 1 T m^{-1} are rare. Since the T_2 of many commonly imaged, more mobile, samples is of the order of 10 ms, resolution limits in ^1H imaging are generally in the range one to ten micrometres. At this resolution, considerable signal averaging is generally required in order to obtain a sufficient signal to noise ratio and the imaging time may extend to hours. Moreover, a slice thickness of typically $500 \mu\text{m}$, which is significantly greater than the lateral resolution, is frequently used to improve signal to noise. In solids, T_2 is generally very much shorter than in soft matter and high resolution imaging is not possible without recourse either to sophisticated line narrowing techniques [11], to magic-echo refocusing variants [2] or to very high gradient methods such as stray field imaging [13].

Motion, and in particular diffusion, causes a further limit to resolution [14, 15]. First, there is a physical limitation caused by spins diffusing into adjacent voxels during the acquisition of a transient. For water containing samples at room temperature the optimal resolution on these grounds is about $5 \mu\text{m}$. However, as will be seen in subsequent sections, diffusion of nuclei in a magnetic field gradient causes an additional attenuation of the signal in the time domain. In the presence of a steady gradient, it is $\exp(-\gamma^2 G^2 D t^3/3)$. Hence, the linewidth for spins diffusing in a gradient is of the order of

$$\Delta f_D = 0.6(\gamma^2 G^2 D/3)^{\frac{1}{3}}$$

where D is the diffusion coefficient, so that the best resolution becomes in analogy to the derivation of the equation B1.14.4 and equation B1.14.5

$$\Delta x^{\text{best}} \approx 2.6 \left(\frac{D}{\gamma G} \right)^{\frac{1}{3}} .$$

In practice, internal gradients inherent to the sample resulting from magnetic susceptibility changes at internal interfaces can dominate the applied gradients and lead to strong diffusive broadening just where image resolution is most required. Again the resolution limits tend to be on the ten micrometre scale.

B1.14.3 CONTRASTS IN MR IMAGING

Almost without exception, magnetic resonance ‘images’ are more than a simple reflection of nuclear spin density throughout the sample. They crudely visualize one or more magnetic resonance measurement parameters with which the NMR signal intensity is weighted. A common example of this kind is spin-relaxation-weighted image contrast. Mapping refers to encoding of the value of an NMR measurement parameter within each image pixel and thereby the creation of a map of this parameter. An example is a velocity map. The power of MRI compared to other imaging modalities is the large range of dynamic and microscopic structural contrast parameters which the method can encode, ‘visualise’ and map.

B1.14.3.1 RELAXATION

Transverse relaxation weighting is perhaps the most common form of contrast imposed on a magnetic

resonance image. It provides a ready means of differentiating between more mobile components of the sample such as low viscous liquids which are generally characterized by long T_2 values of the order of seconds and less mobile components such as elastomers, fats and adsorbed liquids with shorter T_2 values of the order of tens of milliseconds [6]. Transverse relaxation contrast is, in fact, a natural consequence of the spin warp imaging technique described in the previous section. As already seen, data are recorded in the form of a spatially encoded spin echo. Only those nuclides in the sample with a T_2 of the order of, or greater than, the echo time, $T_E=2\tau\approx 2t_y$, contribute significantly to the echo signal. Consequently, the image reflects the distribution of nuclides for which $T_2 \geq T_E$. Often, a crude distinction between two components in a sample, one more mobile than the other, is made on the basis of a single T_2 -weighted image in which the echo time is chosen intermediate between their respective T_2 values. For quantitative T_2 -mapping, images are recorded at a variety of echo times and subsequently analysed by fitting single- or multi-modal relaxation decays to the image intensity on a pixel by pixel basis. The fit parameters are then used to generate a true T_2 -map in its own right.

An example of the application of T_2 -weighted imaging is afforded by the imaging of the dynamics of chemical waves in the Belousov–Zhabotinsky reaction shown in [figure B1.14.5](#) [16]. In these images, bright bands correspond to an excess of Mn^{3+} ions with a long T_2 and dark bands to an excess of Mn^{2+} ions with a short T_2 .

-13-

Figure B1.14.5. T_2 -weighted images of the propagation of chemical waves in an Mn^{2+} catalysed Belousov–Zhabotinsky reaction. The images were acquired in 40 s intervals (a) to (f) using a standard spin echo pulse sequence. The slice thickness is 2 mm. The diameter of the imaged pill box is 39 mm. The bright bands

correspond to an excess of Mn^{3+} ions with long T_2 , dark bands to an excess of Mn^{2+} with a short T_2 . (From [16]).

Another powerful contrast parameter is spin–lattice, or T_1 , relaxation. Spin–lattice relaxation contrast can again be used to differentiate different states of mobility within a sample. It can be encoded in several ways. The simplest is via the repetition time, T_R , between the different measurements used to collect the image data. If the repetition time is sufficiently long such that $T_R \gg T_1$ for all nuclei in the sample, then all nuclei will recover to thermal equilibrium between measurements and will contribute equally to the image intensity. However, if the repetition time is reduced, then those nuclei for which $T_R < T_1$ will not recover between measurements and so will not contribute to the subsequent measurement. A steady state rapidly builds up in which only those nuclei with $T_1 \ll T_R$ contribute in any significant manner. As with T_2 -contrast, single images recorded with a carefully selected T_R may be used to select crudely a short T_1 component of a sample.

-14-

The mathematical description of the echo intensity as a function of T_2 and T_1 for a repeated spin-echo measurement has been calculated on the basis that the signal before one measurement cycle is exactly that at the end of the previous cycle. Under steady state conditions of repeated cycles, this must therefore equal the signal at the end of the measurement cycle itself. For a spin-echo pulse sequence such as that depicted in [figure B1.14.1](#) the echo magnetization is given by [17]

$$M_{\text{echo}} = M_0 \frac{[1 - 2 \exp(-\frac{T_R - T_E/2}{T_1}) + \exp(-\frac{T_R}{T_1})] \exp(-\frac{T_E}{T_2})}{1 + \cos \theta \exp(-\frac{T_R}{T_1})} \sin \theta$$

where M_0 is the equilibrium magnetization and θ is the tip angle of the radio-frequency excitation pulse and where it is assumed that there is total dephasing of the magnetization between cycles. Other expressions applicable to other situations are to be found in the literature. In practice, some kind of relaxation-weighting of image contrast is always present and can hardly be avoided.

Other methods to encode T_1 contrast include saturation recovery [18, 19] and T_1 nulling techniques [20]. In the latter, a 180° pulse is applied some time T_0 before the image data acquisition. This pulse inverts the magnetization. In the interval T_0 the magnetization recovers according to $[1 - 2 \exp(-t/T_1)]$ so that at the time of image data excitation it is $[1 - 2 \exp(-T_0/T_1)]$. Nuclei for which $T_0 = 0.693 T_1$ have zero magnetization at this time and so do not contribute to the signal intensity. This method may be used to suppress a large background component in an image, such as that due to bulk water. With saturation recovery, a train of radio-frequency pulses is applied to the sample some time T_{SR} prior to the data acquisition sequence. The train of pulses, which are often applied with ever decreasing spacing between them, serves to saturate the equilibrium magnetization. Only those nuclides for which $T_{SR} < T_1$ recover to equilibrium prior to the image acquisition proper and so only these nuclei contribute to the image intensity. Multiple images recorded as a function of T_{SR} may be used to build a true T_1 -map by fitting a relaxation recovery curve to the data on a pixel by pixel basis. An example of brine in a sandstone core is depicted in [Figure B1.14.6](#)[21]. Both M_0 - and T_1 -maps, which were obtained from fitting with a stretched exponential, clearly show layers in the stone. The spin–lattice relaxation presumably correlates with spatially varying pore sizes and surface relaxivity.

-15-

Figure B1.14.6. T_1 -maps of a sandstone reservoir core which was soaked in brine. (a), (b) and (c), (d) represent two different positions in the core. For T_1 -contrast a saturation pulse train was applied before a standard spin-echo imaging pulse sequence. A full T_1 -relaxation recovery curve for each voxel was obtained by incrementing the delay between pulse train and imaging sequence. M_0 - ((a) and (c)) and T_1 -maps ((b) and (d)) were calculated from stretched exponentials which are fitted to the magnetization recovery curves. The maps show the layered structure of the sample. Presumably T_1 -relaxation varies spatially due to inhomogeneous size distribution as well as surface relaxivity of the pores. (From [21].)

B1.14.3.2 CHEMICALLY RESOLVED IMAGING

In many instances, it is important that some form of chemical selectivity be applied in magnetic resonance imaging so as to distinguish nuclei in one or more specific molecular environment(s). There are many ways of doing this and we discuss here just three. The first option is to ensure that one of the excitation RF pulses is a narrow bandwidth, frequency selective pulse applied in the absence of any gradient [22]. Such a pulse can be made specific to one particular value of the chemical shift and thereby affects only nuclei with that chemical shift. In practice this can be a reasonable method for the specific selection of fat or oil or water in a mixed hydrocarbon/water system.

A higher level of sophistication involves obtaining a full chemical shift spectrum within each image pixel. The chemical information can be encoded either before or after the image encoding. The important requirement is that the spin system is allowed to evolve without gradients and that data are recorded as a function of this chemical shift evolution time. The data can then be Fourier transformed with respect to the evolution time as well as the standard imaging variables so as to yield the spatially resolved chemical shift spectrum. In this respect chemical shift imaging is like a four-dimensional imaging experiment [23]. A post-encoding sequence suitable for this purpose is shown in [figure B1.14.7](#). The chemical shift encoding part—a spin echo in the absence of gradients—comes after the image encoding part—a two-dimensional phase encoding experiment. The 180° pulse refocuses all chemical-shift-induced dephasing occurring during the spatial encoding.

Figure B1.14.7. Chemical shift imaging sequence [23]. Both x - and y -dimensions are phase encoded. Since line-broadening due to acquiring the echo in the presence of a magnetic field gradient is avoided, chemical shift information is retained in the echo.

The third alternative is a more robust, sensitive and specialized form of the first, in that only hydrogen nuclei indirectly spin–spin coupled to ^{13}C in a specific molecular configuration are imaged. In achieving selectivity, the technique exploits the much wider chemical shift dispersion of ^{13}C compared to ^1H . The method involves cyclic transfer from selected ^1H nuclei to indirectly spin–spin coupled ^{13}C nuclei and back according to the sequence

Called CYCLCROP (cyclic cross polarization) [24], the method works by first exciting all ^1H magnetization. Cross polarization pulses are then applied at the specific Larmor frequencies of the ^1H – ^{13}C pair of interest so as to transfer coherence from ^1H to ^{13}C . The transfer pulses must satisfy the Hartmann–Hahn condition

$$\gamma_{\text{C}} B_{1\text{C}} = \gamma_{\text{H}} B_{1\text{H}}$$

$B_{1\text{H}}$ and $B_{1\text{C}}$ are the excitation magnetic field strengths and must be applied for a time of the order of $1/J$ where J is the spin–spin coupling constant. Following magnetization transfer, the ^{13}C magnetization is stored along the z -axis and the remaining ^1H magnetization from other molecular groupings is destroyed by a series of pulses and homospoil gradients. The stored magnetization specific to the coupled ^1H – ^{13}C pair is then returned to the ^1H by a second pair of cross polarization pulses. CYCLCROP chemical selective excitation may replace the initial excitation in a standard

2DFT imaging experiment with the slice selection moved to the 180° pulse in order to yield a ^{13}C edited image. A number of pulse schemes for the cross coupling are known, each with various advantages in terms of low radio-frequency power deposition, tolerance of pulse artifact, breadth of the spectral bandwidth etc. In figure B1.14.8. CYCLCROP has been used to map ^{13}C labelled sucrose in the stem of a castor bean seedling [25]. Its arrival and accumulation are visualized in a series of subsequently acquired ^{13}C -selective images.

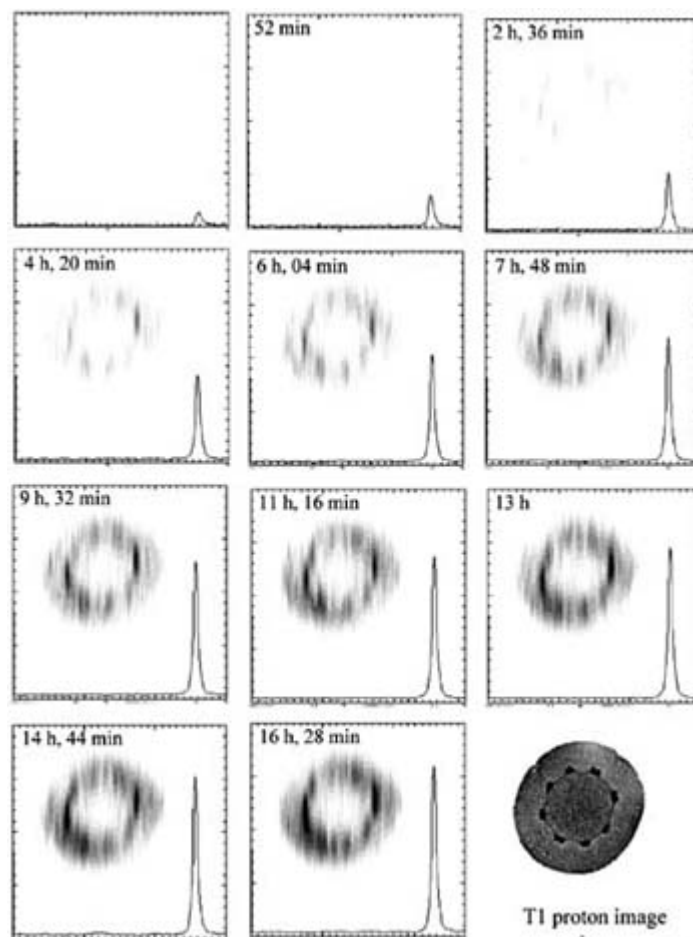

Figure B1.14.8. Time course study of the arrival and accumulation of ^{13}C labelled sucrose in the stem of a castor bean seedling. The labelled tracer was chemically, selectively edited using CYCLCROP (cyclic cross polarization). The first image in the upper left corner was taken before the incubation of the seedling with enriched hexoses. The time given in each image represents the time elapsed between the start of the incubation and the acquisition. The spectrum in the lower right corner of each image shows the total intensity of ^{13}C nuclei. At later times, enriched sucrose is visible in the periphery of the stem. Especially high intensities are detected in the vascular bundles. The last image represents a micrograph of the stem structure showing the position of the vascular bundles (dark features). (From [25]).

B1.14.4 FLOW AND DIFFUSION

NMR is an important technique for the study of flow and diffusion, since the measurement may be made highly sensitive to motion without in any way influencing the motion under study. In analogy to many non-NMR-methods, mass transport can be visualized by imaging the distribution of magnetic tracers as a function of time. Tracers may include paramagnetic contrast agents which, in particular, reduce the transverse relaxation time of neighbouring nuclei and therefore appear as T_2 -contrast in an image. The ^{13}C cross polarization method with enriched compounds may also be used as a tracer experiment. More sophisticated tracer methods include so called ‘tagging’ experiments in which the excitation of nuclei is spatially selective. The spatial evolution of the selected nuclei is followed. This example is discussed in section B1.14.4.5.

Generally, however, the application of tracer methods remains a rarity compared to methods which directly exploit the motion sensitivity of the NMR signal. The detection of motion is based on the sensitivity of the

signal phase to translational movements of nuclei in the presence of magnetic field gradients [26, 27]. Using the large magnetic field gradient in the stray field of superconducting magnets, displacements as small as 10 nm in slowly diffusing polymer melts can be detected. At the other extreme, velocities of the order of $m\ s^{-1}$, such as occur in blood-filled arteries, can be measured.

B1.14.4.1 COHERENT AND STATIONARY FLOW

The displacement of a spin can be encoded in a manner very similar to that used for the phase encoding of spatial information [28, 29 and 30]. Consider a spin j with position $r(t)$ moving in a magnetic field gradient G . The accumulated phase, ϕ_j , of the spin at time t is given by

$$\phi_j(t) = -\gamma \int_0^t G(r') \cdot r_j(t') dt' \tag{B1.14.6}$$

In order to encode displacement as opposed to average position, the gradient is applied in such a manner as to ensure that $\int_0^t G(r') dt' = 0$. Generally, this means applying gradient pulses in bipolar pairs or applying unimodal gradient pairs either side of a 180° RF inversion pulse, with the advantage that the necessary careful balancing of the gradient amplitudes is more straightforward.

We first examine how this works for the case of coherent flow. A typical pulse sequence is shown in [figure B1.14.9](#). This sequence creates a spin echo using two unipolar gradient pulses on either side of a 180° pulse. The duration of each gradient pulse of strength G_v is δ . The centres of the gradient pulses are separated by Δ .

Figure B1.14.9. Imaging pulse sequence including flow and/or diffusion encoding. Gradient pulses $G_{v,D}$ before and after the inversion pulse are supplemented in any of the spatial dimensions of the standard spin-echo imaging sequence. Motion weighting is achieved by switching a strong gradient pulse pair $G_{v,D}$ (see solid black line). The steady-state distribution of flow (coherent motion) as well as diffusion (spatially

incoherent motion) in a sample is encoded by incrementing $G_{v,D}$ (see dashed grey lines). The measured data set then consists of two spatial and a motion-encoded dimension. Velocity and/or diffusion maps can be rendered by three-dimensional Fourier transformation.

Under steady-state flow conditions (coherent motion), a Taylor series can be applied to describe the time-dependent position of the fluid molecules:

$$\mathbf{r}(t) = \mathbf{r}_0 + \mathbf{v}t + \frac{1}{2}\mathbf{a}t^2 + \dots$$

If terms of higher order than linear in t are neglected, the transverse magnetization evolves in the presence of the first bipolar gradient pulse according to (equation B1.14.2 and equation B1.14.6):

$$m(t) = m(0) e^{-i\gamma\mathbf{G}_v \cdot \mathbf{r}_0 t - i\frac{1}{2}\gamma\mathbf{G}_v \cdot \mathbf{v}t^2} \quad 0 \leq t \leq \delta.$$

The phase of the transverse magnetization is inverted by the 180° pulse and the magnetization after the second gradient pulse and therefore at the echo centre is:

-20-

$$\begin{aligned} m(\delta, \Delta) &= m(0) e^{+\gamma\mathbf{G}_v \cdot \mathbf{r}_0 \delta + \gamma\frac{1}{2}\mathbf{G}_v \cdot \mathbf{v}\delta^2} e^{-\gamma\mathbf{G}_v \cdot \mathbf{r}_0[\delta+\Delta] - \gamma\mathbf{G}_v \cdot \mathbf{v}[(\delta+\Delta)^2 - \Delta^2]} \\ &= m(0) e^{-i\gamma\mathbf{G}_v \cdot \mathbf{v}\delta\Delta}. \end{aligned}$$

The echo phase does not depend on the initial position of the nuclei, only on their displacement, $\mathbf{v}\Delta$, occurring in the interval between the gradient pulses. Analysis of the phase of the echo yields a measure of flow velocity in a bulk sample. Spatial resolution is easily obtained by the incorporation of additional imaging gradients. One way of doing this is illustrated in figure B1.14.9. The first part of the experiment is the same flow encoding experiment as just discussed. The velocity-encoded echo is the excitation for the subsequent 2DFT experiment which is as previously discussed. Where both stationary and moving spins are present, these superimpose in the image. A variety of methods exist for separating the two, including cycling the phase of the velocity encoding gradients or making measurements at two or more strengths of the velocity encoding gradient. In the latter, a wave number $\mathbf{k}_v = \gamma\mathbf{G}_v \cdot \mathbf{v}$ can be defined adding an additional dimension to spatial \mathbf{k} -space. Fourier transformation of this dimension directly produces the velocity spectrum of each voxel. As an example, velocity maps of flow through an extruder are shown in figure B1.14.10 [31].

Figure B1.14.10. Flow through an KENICS mixer. (a) A schematic drawing of the KENICS mixer in which the slices selected for the experiment are marked. The arrows indicate the flow direction. Maps of the z -component of the velocity at position 1 and position 2 are displayed in (b) and (c), respectively. (d) and (e) Maps of the x - and the y -velocity component at position 1. The FOV (field of view) is 10 mm. (From [31].)

B1.14.4.2 PULSATING MOTION

Flow which fluctuates with time, such as pulsating flow in arteries, is more difficult to experimentally quantify than steady-state motion because phase encoding of spatial coordinate(s) and/or velocity requires the acquisition of a series of transients. Then a different velocity is detected in each transient. Hence the phase-twist caused by the motion in the presence of magnetic field gradients varies from transient to transient. However if the motion is periodic, e.g., $\mathbf{v}(\mathbf{r}, t) = \mathbf{v}_0 \sin\{\omega_v t + \phi_0\}$ with a spatially varying amplitude $\mathbf{v}_0 = \mathbf{v}_0(\mathbf{r})$, a pulsation frequency $\omega_v = \omega_v(\mathbf{r})$ and an arbitrary phase ϕ_0 , the phase modulation of the acquired data set is described as follows:

$$S(k_x, k_y, k_v) = \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} dx dy dv m(x, y, v) e^{-ik_x x - ik_y y + ik_v v} \sin(\omega_v l_p T_R + \phi_0)$$

where $t = l_p T_R$ is the time at which the l_p th transient is acquired. Since k_y and k_v are 'incremented' for phase encoding in subsequent transients, they are linked to the phase twist caused by $v(t)$ via the parameter l_p . The reconstruction of the dimensions y and v by Fourier transformation is therefore affected, making an interpretation difficult.

Nevertheless, averaging provides information about the motional parameters such as velocity amplitude and

pulsation frequency. If the repetition time, the delay between subsequent transients, is not equal to a multiple of the pulsation period the motion appears to be temporally uncorrelated. In this case, a temporal average over all velocity values is obtained by accumulating a sufficient number of transients. This causes a broad phase distribution resulting in signal attenuation similar to the one caused by diffusion, a spatially incoherent phenomenon. The images provide quantitative information about the distribution of motion and velocity amplitude. The temporal characteristics of the pulsation are detected by omitting phase encoding. Using a gradient pulse pair of constant magnitude for motion weighting the signal phase is then solely a function of the velocity. Since the y determined from the intensity modulation due to the motion in a series of transients.

Figure B1.14.11 shows the application of averaging techniques for the characterization of pulsating motions which start on about the fourth incubation day in quail eggs [32]. Dark areas in the incoherent motion-weighted images in figure B1.14.11 and represent strong motion, white no uncorrelated motion. They are localized at the suspected position of the embryo above the egg yolk which is the black region in the middle of the egg. The signal attenuation strongly depends on the probed velocity component indicating the anisotropic nature of the motion. In figure B1.14.12(a) and (b) a time series of profiles through the region of motion with spatially incoherent motion weighting were acquired before and after the start of pulsations. At the later incubation stage the modulation of the signal intensity due to temporally periodic motion is clearly visible. Fourier transformation (figure B1.14.12(d)) reveals a pulsation frequency of about 0.4 Hz.

Figure B1.14.11. Amplitude-weighted images of (temporally) uncorrelated motions in a quail egg at an incubation period at about 140 h. A standard gradient echo sequence supplemented with strong bipolar gradient pulses for motion weighting was used. A high number of transients ($N_t = 490$) was acquired for each phase-encoding step to adequately average out temporal fluctuation of the motion. The intensity in the images shown corresponds to the signal ratio with and without motion weighting. Light grey shades hence represent no signal attenuation, darker shades strong signal attenuation due to uncorrelated motion. Pixels with signal below the noise level are set black as is the case in the egg yolk (black region in the middle of the egg) due to comparatively short T_2 . The white double arrows indicate the probed velocity component. Both images show signal attenuation due to strong motion in the region above the egg yolk where the embryo presumably is located. Furthermore, the attenuation of the signal appears to be much stronger for the y -velocity component than for the x -component indicating strongly anisotropic motion. The white bar represents 2 mm. (From [32].)

Figure B1.14.12. Study of the temporal fluctuation of motion in a quail egg at the incubation times 119 h and 167 h. Spatial phase encoding of the y -dimension was omitted to increase the rapidity of the imaging experiment. Profiles were obtained by 1D Fourier transformation of echoes which were acquired in the presence of a readout gradient for frequency encoding of the x -coordinate. A strong gradient pulse pair for (spatially) incoherent motion weighting was applied during the evolution period of the magnetization. A series of subsequent single-scan profiles were measured at the two different incubation times 119 h (a) and 167 h (c). Temporal fluctuations of the signal intensity which are not visible in (a) reveal themselves at the later incubation stage. The intensity modulation which was caused by temporally fluctuating motion was analysed by Fourier transformation. The spectra which were calculated from the integral intensities of the pixels between the two dashed lines in (a) and (c) are displayed in (b) and (d) for the two incubation times. The line at 0 Hz is due to the constant baseline offset. The arrows in (d) mark the peak representing a frequency of 0.4 Hz of the pulsating motion. (From [32].)

B1.14.4.3 DIFFUSION AND PSEUDO-DIFFUSION

If magnitude and/or direction of velocity vary on a length scale below spatial resolution, the detected motion is incoherent. (Self-) diffusion certainly falls into this category, but randomly oriented flow is also spatially incoherent. A well known example is the blood flow through brain capillaries, which are smaller than a voxel [33]. Incoherent flow is often referred to as pseudo-diffusion. An apparent diffusion coefficient which can be significantly bigger than the self-diffusion coefficient is then defined. Pulse sequences to measure coherent flow (figure B1.14.9) can also be used for (spatially) incoherent motion although the theory has to be reconsidered at this point [34, 35 and 36].

The observed magnetization in the echo is the superposition of all the spins j at different positions r_j :

$$\begin{aligned} m(T_E) &= \langle m(0) e^{i\gamma G_D \cdot (r_j(\Delta) - r_j(0))\delta} \rangle_j \\ &= \langle m(0) e^{i\varphi_j(t)} \rangle_j. \end{aligned}$$

It is expanded into:

$$m(T_E) = m(0) \sum_j P(\varphi_j) e^{i\varphi_j(t)}$$

where $P(\varphi_j)$ is the probability of phase φ_j . The underlying motional process influences this phase distribution. To demonstrate the principle, the simple case of normal isotropic diffusion will be discussed [27]. The solution of Fick's diffusion equation together with the central limit theorem implies that, for a constant gradient, a Gaussian phase distribution function with a mean squared phase twist $\overline{\varphi^2(t)}$ applies at any instant

$$P(\varphi) = \frac{1}{(2\pi\overline{\varphi^2})^{1/2}} \exp(-\varphi^2/\overline{\varphi^2})$$

leading to the transverse magnetization

$$m(t) = m(0) e^{-\overline{\varphi^2(t)}/2}. \quad (\text{B1.14.7})$$

The relationship between mean squared phase shift and mean squared displacement can be modelled in a simple way as follows: This motion is mediated by small, random jumps in position occurring with a mean interval τ_j . If the jump size in the gradient direction is ϵ , then after n jumps at time $t=n\tau_j$, the displacement of a spin is

$$E(n\tau_j) = \sum_{i=1}^n \epsilon a_i$$

where a_i is a randomly either +1 or -1. Hence, from the relation $\varphi = \gamma G_D \delta E(n\tau_j)$, the phase shift distribution imposed by the diffusion measurement gradients G_D of duration δ is

$$\overline{\varphi^2} = \gamma^2 \delta^2 G_D^2 \epsilon^2 \overline{\left(\sum_{i=1}^n a_i \right)^2}.$$

-25-

The summation averages to n . Using the definition of the diffusion coefficient, $D = \epsilon^2 / (2\tau_j)$, and the diffusion time, $\Delta = n\tau_j$, [equation B1.14.7](#) gives

$$m(t) = m(0) \exp(-\gamma^2 \delta^2 G_D^2 D \Delta).$$

This is the factor by which the echo magnetization is attenuated as a result of diffusion. More elaborate calculations, which account for phase displacements due to diffusion occurring during the application of the gradient pulses yield

$$m(t) = m(0) \exp[-\gamma^2 \delta^2 G_D^2 D (\Delta - \delta/3)].$$

This expression can be used for pulsed field gradient spin-echo experiments and also for spin-echo experiments in which the gradient is applied continuously.

A measure of the echo attenuation within each pixel of an image created using the pulse sequence of [figure B1.14.9](#) perhaps by repeating the experiment with different values of G_D and/or δ , gives data from which a true diffusion map can be constructed [37, 38].

In principle, it is possible to measure both flow and diffusion in a single experiment: the echo is both phase shifted and attenuated. It is also possible to account for the presence of background gradients arising from the sample itself which can be significant. The exact form of the echo in these circumstances has been calculated and the results are to be found in the literature [39, 40, 41 and 42]. Furthermore, in systems in which T_2 is relatively short compared to T_1 , the stimulated echo comprising three 90° pulses can be used instead of a 90° – t – 180° spin-echo sequence [43]. In this case, the fact that the velocity encoding time, Δ , can be made significantly longer outweighs the fact that only half of the magnetization is refocused after the third pulse.

B1.14.4.4 RESTRICTED DIFFUSION PULSED FIELD GRADIENT MICROSCOPY

Diffusometry and spatially resolved magnetic resonance are usefully combined in an alternate technique to imaging which is increasingly coming to the fore. It has been dubbed both q -space microscopy [4] and restricted diffusion pulsed field gradient (PFG) microscopy. The method probes the microstructure of a sample on the micrometre scale—significantly smaller than conventional MRI permits—by measuring the effects of restricted diffusion of a translationally mobile species. The technique yields parameters characteristic of the average structure of the whole sample (the experiment done without spatial resolution) or of the sample within an image pixel (sub-millimetre scale) if the experiment is done in combination with conventional imaging. The method works because of a Fourier relationship which exists between the observed echo attenuation in a pulsed field gradient diffusometry experiment and the propagator, which describes the molecular motion $P(\mathbf{r}; \mathbf{r}', t)$. $P(\mathbf{r}; \mathbf{r}', t)$ is the conditional probability of finding a diffusing spin at location \mathbf{r}' at time t given its initial location, \mathbf{r} . This propagator depends intimately on the microstructure of the sample. Following on from the above analysis, the echo attenuation is

$$E(G_D, \delta, \Delta) = \int_{\mathbf{r}} \rho(\mathbf{r}) \int_{\mathbf{r}'} P(\mathbf{r}; \mathbf{r}', \Delta) \exp[i\gamma\delta G_D \cdot (\mathbf{r} - \mathbf{r}')] d\mathbf{r}' d\mathbf{r}$$

-26-

where $\rho(\mathbf{r})$ is the spin density defined by the microstructure. In the long timescale limit, the diffusing spins sample the whole of the available space and $P(\mathbf{r}; \mathbf{r}', t)$ becomes independent of \mathbf{r} such that

$$P(\mathbf{r}; \mathbf{r}', \infty) = \rho(\mathbf{r}') = \rho(\mathbf{r})$$

then

$$E(G_D, \delta, \infty) = \left| \int_{\mathbf{r}} \rho(\mathbf{r}) \exp[i\gamma\delta(G_D \cdot \mathbf{r})] d\mathbf{r} \right|^2 = |S(\mathbf{q})|^2$$

where $\mathbf{q} = (2\pi)^{-1} \gamma \delta G_D$ and $S(\mathbf{q})$ is a structure factor, defined by the above expression with direct analogies in optics and neutron scattering. Measurement of echo attenuation and hence $S(\mathbf{q})$ and calculations of microstructure have been reported for both model and real systems including porous media and emulsions.

As an example figure B1.14.13 shows the droplet size distribution of oil drops in the cream layer of a decane-in-water emulsion as determined by PFG [45]. Each curve represents the distribution at a different height in the cream with large drops at the top of the cream. The inset shows the PFG echo decay trains as a function of

height and the curves to which the data were fitted using a Stokes-velocity-based model of the creaming process.

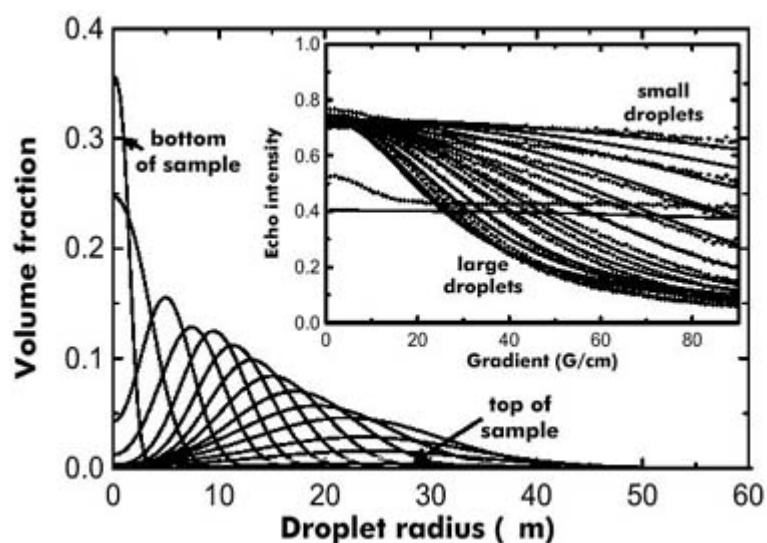

Figure B1.14.13. Derivation of the droplet size distribution in a cream layer of a decane/water emulsion from PGSE data. The inset shows the signal attenuation as a function of the gradient strength for diffusion weighting recorded at each position (top trace = bottom of cream). A Stokes-based velocity model (solid lines) was fitted to the experimental data (solid circles). The curious horizontal trace in the centre of the plot is due to partial volume filling at the water/cream interface. The droplet size distribution of the emulsion was calculated as a function of height from these NMR data. The most intense narrowest distribution occurs at the base of the cream and the curves proceed logically up through the cream in steps of 0.041 cm. It is concluded from these data that the biggest droplets are found at the top and the smallest at the bottom of the cream. (From [45].)

B1.14.4.5 PLANAR TAGGING

A more qualitative means of visualising flows is by ‘multi-plane tagging’ [46, 47]. The principle of tagging experiments is to excite magnetic resonance only in stripes across the image plane and to observe the spatial evolution of these stripes with time (figure B1.14.14). The excitation can be achieved using a comb of radio-frequency pulses each of narrow flip angle applied to a sample in a magnetic field gradient (figure B1.14.15 (a)) [48]. The Fourier transform of this excitation shows distinct maxima occurring at frequency intervals given by the reciprocal of the pulse spacing. The overall excitation bandwidth—which must be sufficient to cover the frequency spread of all nuclei in the sample—is determined by the individual pulse widths, and the sharpness of the maxima by the number of pulses. This frequency response is illustrated in figure B1.14.15(b) from which it is clear how the excitation is achieved. The action of the comb can be understood more qualitatively as follows. Each pulse tips all spins by a small angle. Between the pulses the spins precess by an amount dependent on their position in the gradient. Only at positions where the precessional phases between pulses is equal to $2n\pi$ do the pulses have a cumulative effect in tipping the magnetization through a large angle.

Figure B1.14.14. Pulse sequence for multi-plane tagging. A magnetization saturation grid is prepared in the multi-plane tagging section. After a certain time of flight T_F this grid is imaged using a standard imaging pulse sequence. The motion of tagged spins is visualized by displacements of the grid lines.

-28-

Figure B1.14.15. Preparation of a magnetization grid by means of DANTE pulse trains. The pulse sequence for one-dimensional tagging is shown in (a). As depicted in (b) the spectrum of a pulse train consists of a comb of peaks. To tag spins in certain regions of the sample the DANTE pulse train is applied while a magnetic field gradient G_x is switched. The magnetization is then saturated in planes which are located at equidistant positions corresponding to the spectral peaks of the DANTE pulse train and which are orthogonal to the spatial coordinate $x = \omega / (\gamma G_x)$. A magnetization saturation grid is prepared by subsequently using the sequence (a) with magnetic field gradients in the two directions of the imaging plane coordinates. Saturated spins (bearing transverse magnetization) are visualized as black grid lines in an image. These lines of thickness $\Delta x = 2\pi v_m / (\gamma G_x)$ are separated by $d = 2\pi / (\gamma G_x \tau)$ where τ is the delay from one RF pulse to the next.

Following excitation of this kind, a standard spin warp imaging protocol can be used to create the image. By varying the delay between excitation and image acquisition, flow is visualized by different degrees of distortions of the saturated magnetization grid. An example of a rotating cylinder filled with water–oil mixture is shown in [figure B1.14.16](#) [49].

-29-

Figure B1.14.16. Multi-plane tagging experiment for a 1:1 water (bottom) and oil (top) mixture in the cylinder, which rotates clockwise. The rotation rate was 0.5 rev s^{-1} , and the tagging delay times T_F are (a) 1 ms, (b) 25 ms, (c) 50 ms and (d) 100 ms. The interface between the fluids is clearly shown. The misalignment in the horizontal direction at the interface is caused by chemical shift between water and oil. Flow was mainly detected in a thin layer near the cylinder and a layer along the water–oil interface in the centre that flows to the right. (From [49].)

B1.15 EPR methods

Stefan Weber

B1.15.1 INTRODUCTION

Systems containing unpaired electron spins, such as free radicals, biradicals, triplet states, most transition metal and rare-earth ions and some point defects in solids form the playground for electron paramagnetic resonance, EPR, also called electron spin resonance, ESR, or electron magnetic resonance, EMR. The fundamentals of EPR spectroscopy are very similar to the more familiar nuclear magnetic resonance (NMR) technique. Both deal with interactions of electromagnetic radiation with magnetic moments, which in the case of EPR arise from electrons rather than nuclei. With few exceptions, unpaired electrons lead to a non-vanishing spin of a particle that can be used as a spectroscopic probe. In EPR spectroscopy such molecules are studied by observing the magnetic fields at which they come into resonance with monochromatic electromagnetic radiation. Since species with unpaired electron spins are relatively rare compared to the multitude of species with magnetic nuclei, EPR is less widely applicable than NMR or even optical spectroscopy which has clear advantages with its ability to detect diamagnetic as well as paramagnetic states. What appears to be a drawback, however, can turn into an invaluable advantage, for instance, when selectively studying paramagnetic ions or molecules buried in a large protein environment. With its inherent specificity for those reactants, intermediates or products that carry unpaired electron spins, together with its high spectral resolution, EPR has excelled over many other techniques in, for example, unravelling the primary events of photosynthesis. Similarly, many key intermediates in this process have been identified by

EPR. By appending a paramagnetic fragment—a so-called ‘spin-label’—to a molecule of biological importance, in effect one has acquired a probe to supply data on the interactions and dynamics of biological molecules. Very many systems of biomedical interest have had their structure and function elucidated by application of modern EPR techniques. Also EPR has allowed chemists to probe into the details of reaction mechanisms by using the technique of spin trapping to identify reactive radical intermediates. As one last example of the many successes of EPR the identification of paramagnetic species in insulators and semiconductors is worth mentioning.

More than 50 years after its invention by the Russian physicist Zavoisky (for a review of the EPR history see [1]), advanced EPR techniques presently applied in the above mentioned areas of physics, chemistry and biology include time-resolved continuous wave (CW) and pulsed EPR (Fourier transform (FT) EPR and electron-spin echo (ESE) detected EPR) at various microwave (MW) frequencies and multiple-resonance EPR methods such as electron–nuclear double resonance (ENDOR) and electron–nuclear–nuclear TRIPLE resonance in the case of electron and nuclear transitions and electron–electron double resonance (ELDOR) in the case of different electron spin transitions. High-field/high-frequency EPR and ENDOR have left the developmental stage, and a wide range of significant applications continues to emerge. The range of multi-frequency EPR spectroscopy is now extending from radiofrequencies (RFs) in near-zero fields up to several hundred gigahertz in superconducting magnets or Bitter magnets.

In this article only the most important and frequently applied EPR methods will be introduced. For more extensive treatments of CW and pulsed EPR the reader is referred to some excellent review articles that will be specified in the respective sections of this article. A good starting point for further reading is provided by a number of outstanding textbooks which have been written on the various aspects of EPR in general [2, 3, 4, 5, 6, 7 and 8]. B1.15.2 EPR BACKGROUND

B1.15.2.1 SPINS AND MAGNETIC MOMENTS

Historically, the recognition of electron spin can be traced back to the famous Stern–Gerlach experiment in the early 1920s. Stern and Gerlach observed that a beam of silver atoms was split into two components deflected in different directions when passing through an inhomogeneous magnetic field. The observation could only be explained with the concept of a half-integral angular momentum ascribed to an intrinsic spin of the electron. EPR spectroscopy relies on the behaviour of the electron angular momentum and its associated magnetic moment in an applied magnetic field.

If the angular momentum of a free electron is represented by a spin vector $\mathbf{S}=(S_x, S_y, S_z)$, the magnetic moment μ_S is related to \mathbf{S} by

$$(B1.15.1)$$

where g_e is a dimensionless number called the electron g -factor and $\beta_e = |e|/(2m_e) = 9.2740154 \times 10^{-24} \text{ J T}^{-1}$ is the Bohr magneton; e is the electronic charge, $h/(2\pi)$ is Planck’s constant and m_e is the electron mass. The negative sign in equation (b1.15.1) indicates that, because of the negative charge of the electron, the magnetic moment vector is antiparallel to the spin (since $g_e < 0$). In the quantum theory μ_S and \mathbf{S} are treated as (vector)

operators. Suppose that the angular momentum operator \mathbf{S} is defined in units of \hbar , then \mathbf{S}^2 has the eigenvalues $S(S+1)$, where S is either integer or half integer. The magnitude of the angular momentum itself is given by the square root of the eigenvalue of \mathbf{S}^2 , which is $\hbar\sqrt{S(S+1)}$. Any component of \mathbf{S} (for example S_z) commutes with \mathbf{S}^2 , so that simultaneously eigenvalues of both \mathbf{S}^2 and S_z may be specified, which are $S(S+1)$ and M_S , respectively. M_S has $(2S+1)$ allowed values running in integral steps from $-S$ to $+S$.

Classically, the interaction energy of a magnetic moment μ_S in an applied magnetic field \mathbf{B} is

$$(B1.15.2)$$

For a quantum mechanical system μ_S is replaced by the appropriate operator, equation (b1.15.1) to obtain the Hamiltonian for a free electron in a magnetic field,

$$(B1.15.3)$$

If the magnetic field is B_0 in the z -direction, $\mathbf{B} = (0,0,B_0)$, the scalar product simplifies and the Hamiltonian becomes

$$(B1.15.4)$$

-3-

The eigenvalues of this Hamiltonian are simple, being only multiples $g_e\beta_e B_0$ of the eigenvalues of S_z . Therefore, the allowed energies are $E_{M_S} = g_e\beta_e M_S B_0$. For a simple system of one unpaired electron, $S = \frac{1}{2}$ and $M_S = \pm\frac{1}{2}$, which results in two energy states which are degenerate in zero field and whose energy separation increases linearly with B_0 . This is summarized in figure B1.15.1 where the two states are also labelled with their eigenfunctions $|+\frac{1}{2}\rangle \equiv |\alpha\rangle$ and $|-\frac{1}{2}\rangle \equiv |\beta\rangle$ to indicate the $M_S = +\frac{1}{2}$ and $M_S = -\frac{1}{2}$ eigenstates for $S = \frac{1}{2}$, respectively. The lowest state has $M_S = -\frac{1}{2}$ (since $g_e < 0$), so that the projection of \mathbf{S} along the z -axis, S_z , is antiparallel to the field, but in accordance with physical expectation the z -component of the magnetic moment is parallel to the field (see equation (b1.15.1)). The splitting of the electron spin energy levels by a magnetic field is referred to as the Zeeman effect.

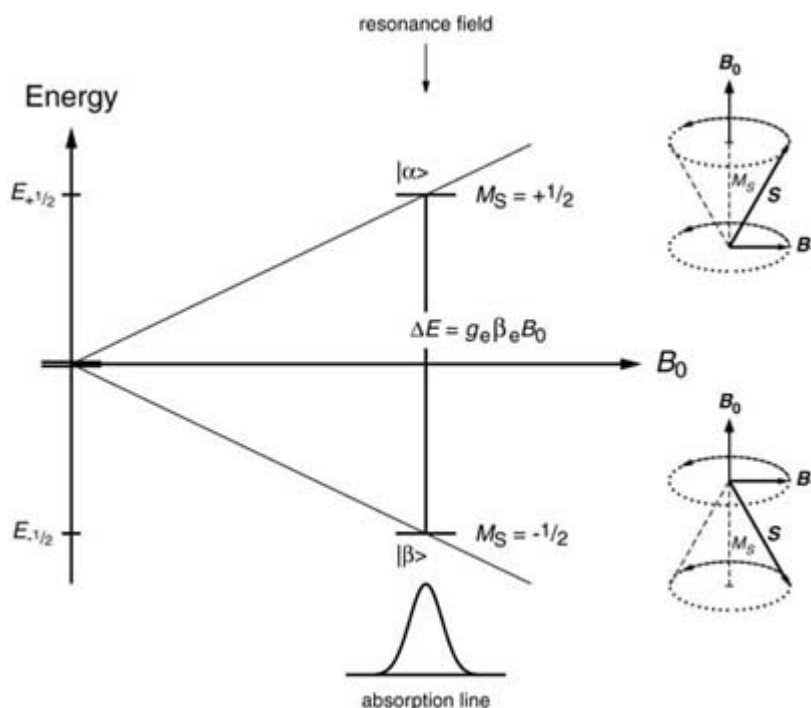

Figure B1.15.1. Energy levels for an electron ($S = \frac{1}{2}$) as a function of the applied magnetic field B_0 . $E_{1/2} = +\frac{1}{2} g_e \beta_e B_0$ and $E_{-1/2} = -\frac{1}{2} g_e \beta_e B_0$ represent the energies of the $M_S = +\frac{1}{2}$ and $M_S = -\frac{1}{2}$ states, respectively.

Under the influence of the external magnetic field \mathbf{B} , the spin \mathbf{S} and the magnetic moment μ_S perform a precessional motion about the axis pointing along the direction of \mathbf{B} . In the absence of additional magnetic fields, the angle between \mathbf{S} and \mathbf{B} does not change and the motion of the spin about the \mathbf{B} axis may be illustrated as cones, as shown on the right-hand side of figure B1.15.1 for the two possible orientations of \mathbf{S} . The z -component of the magnetic moment is sharply defined, while the x - and y -components are not, since they oscillate in the xy -plane. The precession frequency of μ_S and \mathbf{S} about \mathbf{B} is called the Larmor frequency, $\omega_0 = g_e \beta_e B_0 / \hbar$.

-4-

The transition between the two eigenstates can be induced by the application of microwave (MW) radiation with frequency ω and its magnetic field vector linearly polarized in the xy -plane. The oscillating \mathbf{B}_1 -field of this radiation can be formally decomposed into two counter-rotating circularly polarized components, one of which is rotating in the same direction as the Larmor precession of the spins. The other component of the MW field does not interact significantly with the electron spins and can be neglected. If ω is different from ω_0 the precessing magnetic moment will not seriously be affected by \mathbf{B}_1 , for its component in the xy -plane will pass in and out of phase with \mathbf{B}_1 and there will be no resultant interaction. Transitions occur only near the resonance condition of

$$\omega = \omega_0 = g_e \beta_e B_0 / \hbar. \quad (\text{B1.15.5})$$

On exact resonance, μ_S and \mathbf{B}_1 can remain in phase so the precessing magnetic moment experiences a constant field \mathbf{B}_1 in the xy -plane (see figure B1.15.1). It will respond to this by precessing about it with frequency $\omega_1 = g_e \beta_e B_1 / \hbar$.

In the language of quantum mechanics, the time-dependent \mathbf{B}_1 -field provides a perturbation with a nonvanishing matrix element joining the stationary states $|\alpha\rangle$ and $|\beta\rangle$. If the rotating field is written in terms of an amplitude B_1 a perturbing term in the Hamiltonian is obtained

$$\mathcal{H}' = g_e \beta_e B_1 (S_x \cos(\omega t) + S_y \sin(\omega t)). \quad (\text{B1.15.6})$$

The operators S_x and S_y have matrix elements between states $|\alpha\rangle$ and $|\beta\rangle$ or, in general, between states $|M_S\rangle$ and $|M_S \pm 1\rangle$ and consequently induce transitions between levels adjacent in energy.

If $B_1 \ll B_0$ first-order perturbation theory can be employed to calculate the transition rate for EPR (at resonance)

$$W_{\beta \leftarrow \alpha} = \pi \frac{\omega_1^2}{2} \rho(\omega). \quad (\text{B1.15.7})$$

In equation (b1.15.7) $\rho(\omega)$ is the frequency distribution of the MW radiation. This result obtained with explicit evaluation of the transition matrix elements occurring for simple EPR is just a special case of a much more general result, Fermi's golden rule, which is the basis for the calculation of transition rates in general:

$$(\text{B1.15.8})$$

$$W_{M_S \leftarrow M_S+1} = 2\pi |\langle M_S | \mathcal{H}' | M_S + 1 \rangle|^2 \rho(\omega).$$

Using the selection rule for allowed transitions the relative intensity for the transition from the state $|M_S\rangle$ to $|M_S+1\rangle$ is given by

$$W_{M_S \leftarrow M_S+1} \propto (S(S+1) - M_S(M_S+1)). \quad (\text{B1.15.9})$$

-5-

The transition between levels coupled by the oscillating magnetic field \mathbf{B}_1 corresponds to the absorption of the energy required to reorient the electron magnetic moment in a magnetic field. EPR measurements are a study of the transitions between electronic Zeeman levels with $\Delta M_S = \pm 1$ (the selection rule for EPR).

The g -factor for a free electron, $g_e = 2.002\,319\,304\,386(20)$, is one of the most accurately known physical constants. For a magnetic field of 1 T ($= 10^4$ G) the resonance frequency $\omega/(2\pi)$ is 28.024 945 GHz, approximately three orders of magnitude larger than is required for any nuclear resonance (because $\beta_e/\beta_N \approx 1836$). This corresponds to a wavelength of about 10 mm and is in the microwave (MW) region of the electromagnetic spectrum.

B1.15.2.2 THERMAL EQUILIBRIUM, MAGNETIC RELAXATION AND LORENTZIAN LINESHAPE

Application of an oscillating magnetic field at the resonance frequency induces transitions in both directions between the two levels of the spin system. The rate of the induced transitions depends on the MW power which is proportional to the square of $\omega_1 = \gamma_e B_1$ (the amplitude of the oscillating magnetic field) (see [equation \(b1.15.7\)](#)) and also depends on the number of spins in each level. Since the probabilities of upward ($|\beta\rangle \rightarrow |\alpha\rangle$) and downward ($|\alpha\rangle \rightarrow |\beta\rangle$) transitions are equal, resonance absorption can only be detected when there is a population difference between the two spin levels. This is the case at thermal equilibrium where there is a slight excess of spins in the energetically lower $|\beta\rangle$ -state. The relative population of the two-level system in thermal equilibrium is given by the Boltzmann distribution

$$\frac{N_\alpha}{N_\beta} = \exp\left(-\frac{\Delta E}{k_B T}\right) = \exp\left(-\frac{g_e \beta_e B_0}{k_B T}\right) \quad (\text{B1.15.10})$$

where N_α and N_β are the populations of the upper and lower spin states, respectively, ΔE is the energy difference separating the states, k_B is the Boltzmann constant and T is the temperature in Kelvin. The total number of spins is, of course, $N = N_\alpha + N_\beta$.

Computation of the fractional excess of the lower level,

$$\frac{N_\beta - N_\alpha}{N} = \frac{1 - \exp(-g_e \beta_e B_0 / (k_B T))}{1 + \exp(-g_e \beta_e B_0 / (k_B T))} \quad (\text{B1.15.11})$$

yields, for electrons in a magnetic field of 0.3 T at 300 K, a value of 7.6×10^{-4} , while for protons under the same conditions the value is only 1.2×10^{-6} . Thus, at thermal equilibrium, in EPR experiments one can virtually always take any nuclear spin state belonging to the same electron spin state to be equally populated. Because of the slightly larger number of spins occupying the lower energy level, there will be a net absorption of energy which results in an exponential decay of the initial population difference of the spin states. Eventually the levels would be equally populated (the spin system is then said to be saturated) if there were no

radiationless processes that restored the thermal equilibrium distribution of the population by dissipating the energy absorbed by the spin system to other degrees of freedom. These nonradiative transitions between the two states $|\alpha\rangle$ and $|\beta\rangle$ are called spin–lattice relaxation. Spin–lattice relaxation is possible because the spin system is coupled to fluctuating magnetic fields driven by the thermal motions of the surroundings which are at thermal equilibrium. These fluctuations can stimulate spin flips and,

-6-

therefore, this process leads to unequal probabilities of spontaneous transitions $|\alpha\rangle \rightarrow |\beta\rangle$ and $|\beta\rangle \rightarrow |\alpha\rangle$ and unequal populations at thermal equilibrium. In a magnetic resonance experiment one always has a competition between spin–lattice relaxation and the radiation field whose nature is to equalize the population of the levels. Qualitatively, T_1 is the time for the population difference to decay to 1/e of its equilibrium value after the perturbation (which in the case of magnetic resonance is the radiation field) is removed.

A second type of relaxation mechanism, the spin–spin relaxation, will cause a decay of the phase coherence of the spin motion introduced by the coherent excitation of the spins by the MW radiation. The mechanism involves slight perturbations of the Larmor frequency by stochastically fluctuating magnetic dipoles, for example those arising from nearby magnetic nuclei. Due to the randomization of spin directions and the concomitant loss of phase coherence, the spin system approaches a state of maximum entropy. The spin–spin relaxation disturbing the phase coherence is characterized by T_2 .

A result of the relaxation processes is a shortened lifetime of the spin states giving rise to a broadening of the EPR line, which for most magnetic resonance lines dominated by homogeneous linewidth can be written as

$$f(\omega) = \frac{A\gamma M_0 T_2}{1 + \gamma^2 B_1^2 T_1 T_2 + T_2^2 (\omega_0 - \omega)^2}. \quad (\text{B1.15.12})$$

In equation (b1.15.12), M_0 is the z-component of the bulk magnetization vector, $\mathbf{M} = (1/V) \sum_i^N \boldsymbol{\mu}_i$ (unit $\text{J T}^{-1} \text{m}^{-3}$), for an ensemble of N spin magnetic moments at thermal equilibrium (in the absence of any resonant radiation), or in other words the net magnetic moment per unit volume, $\gamma = g_e \beta_e / \hbar$ is the gyromagnetic ratio and A is a proportionality constant to include instrumental factors. The lineshape function $f(\omega)$ has a maximum at $\omega = \omega_0$ and it decreases for high power levels (i.e. for large B_1) and when the spin–lattice relaxation is not fast enough to maintain the population difference. This decrease is called saturation. If the saturation factor s is defined by

$$s = \frac{1}{1 + \gamma^2 B_1^2 T_1 T_2} \quad (\text{B1.15.13})$$

then $f(\omega)$ has the form

$$f(\omega) = \frac{As\gamma M_0 T_2}{1 + sT_2^2 (\omega_0 - \omega)^2}. \quad (\text{B1.15.14})$$

Well below saturation $s \approx 1$, and so the lineshape function becomes

$$f(\omega) = \frac{A\gamma M_0 T_2}{1 + T_2^2 (\omega_0 - \omega)^2}. \quad (\text{B1.15.15})$$

This is the famous Lorentzian function which is very often found for spectra of radicals in solution. In order to determine the relaxation times T_1 and T_2 , a series of EPR spectra is recorded with the MW power varying from a condition of negligible saturation ($B_1^2 \gamma^2 T_1 T_2 \ll 1; s \approx 1$) to one of pronounced saturation ($B_1^2 \gamma^2 T_1 T_2 > 1; s < 1$). T_2 is then calculated from the linewidth below saturation by means of the expression

$$T_2 = \frac{2}{\Delta\omega_{1/2}^0} \quad (\text{B1.15.16})$$

where $\Delta\omega_{1/2}^0$ is the half width at half height of the magnetic resonance absorption line in the limit $B_1 \rightarrow 0$ ($s \rightarrow 1$). For T_1 one obtains

$$T_1 = \frac{\Delta\omega_{1/2}^0}{2} \left(\frac{1/s - 1}{\omega_1^2} \right). \quad (\text{B1.15.17})$$

One of the principal experimental advantages of this method of determining relaxation times is that it may be carried out with standard EPR spectrometers using CW-detected EPR lines [9, 10]. A discussion of more direct measurements of T_1 and T_2 using time-resolved EPR techniques is deferred to a later point (see sections B1.15.4 and B1.15.6.3(b)).

B1.15.2.3 SPIN HAMILTONIAN

To characterize and interpret EPR spectra one needs to obtain transition frequencies and transition probabilities between the $(2S + 1)$ spin states. All interactions of the spins of electrons and nuclei with the applied magnetic field and with each other that lead to energy differences between states with different angular momenta have to be considered. The interactions are expressed in terms of operators representing the spins, with various coupling coefficients for the different interactions. The contributions of all these interactions make up the spin Hamiltonian that will be given in energy units throughout this text. Since, in principle, the spin Hamiltonian has no effect on the spatial part of the electronic wavefunction, the energy of the spin system in a certain state characterized by the quantum numbers M_S and M_I can be derived from the time-independent Schrödinger equation. The EPR spectrum is then interpreted as the allowed transitions between the eigenvalues of the spin Hamiltonian.

(A) ELECTRON ZEEMAN INTERACTION

The first contribution considered here is the electron Zeeman interaction, i.e. the coupling of the magnetic dipole moment of the electron spin to the external magnetic field. For symmetry reasons the electron Zeeman interaction is isotropic for a free electron spin and is characterized by the Zeeman splitting constant g_e . The g -value of an unpaired electron in an atomic or molecular environment is very often different from g_e and may also be anisotropic, i.e. dependent on the orientation of the system relative to the magnetic field \mathbf{B} . The deviation from the spin-only value of the g -factor and the anisotropy result from the contribution of the orbital angular momentum to the total angular momentum of the electron. This phenomenon is called spin-orbit coupling. It leads to an anisotropic electron Zeeman interaction (EZI) which is usually formulated as

$$\mathcal{H}_{\text{EZI}} = \beta_e \mathbf{B} g \mathbf{S} \quad (\text{B1.15.18})$$

where the field and angular momentum vectors are coupled through a symmetric matrix \mathbf{g} of dimension 3×3 . In organic radicals orbital momenta are almost completely quenched by chemical bonding (with the exception of cases where the energies of the two orbitals are nearly degenerate), leading to only small deviations $\Delta g = |g_{ii} - g_e|$, $i=X, Y, Z$ of the principal values of \mathbf{g} from the free-electron value g_e (typically in a range from 10^{-5} to 5×10^{-2}). g -values very different from g_e are expected for first-row transition metal ions and for rare-earth ions where spin-orbit coupling is more complete. The \mathbf{g} -matrix of organic radicals reflects certain features of the electronic wavefunction of the paramagnetic species. The spatial distribution of the orbital carrying the unpaired spin can be influenced by interactions with other molecules, e.g. via hydrogen bonding. Therefore, a determination of the g -values and the orientation of the main axes of \mathbf{g} with respect to the molecular axis frame can give highly specific information on the interaction of the molecule with its surrounding.

(B) ELECTRON SPIN-SPIN INTERACTION

An atom or a molecule with the total spin of the electrons $S = 1$ is said to be in a triplet state. The multiplicity of such a state is $(2S+1)=3$. Triplet systems occur in both excited and ground state molecules, in some compounds containing transition metal ions, in radical pair systems, and in some defects in solids.

For a system with $S = 1$, there are three sublevels characterized by $M_S = \pm 1$ and $M_S = 0$. In contrast to systems with $S = \frac{1}{2}$, these sublevels may not be degenerate in the absence of an external magnetic field (see [figure B1.15.2](#)). The lifting of degeneracy of the spin states at zero field is called zero-field splitting (ZFS) and it is common for systems with $S \geq 1$. For triplet states of organic molecules ($S = 1$) the ZFS arises from the dipolar interaction of the two magnetic moments of the electron spins with each other. The interaction is described by an additional term

$$\mathcal{H}_{\text{ZFS}} = \mathbf{S} \mathbf{D} \mathbf{S} \quad (\text{B1.15.19})$$

that must be included in a spin Hamiltonian when $S \geq 1$. The spin-spin coupling (or ZFS) tensor \mathbf{D} is a symmetric and traceless ($\sum_{i=X,Y,Z} D_{ii} = 0$) second-rank tensor. Therefore, \mathbf{D} can be written in its principal axis frame with only two parameters

$$\mathcal{H}_{\text{ZFS}} = D(S_z^2 - \frac{1}{3}\mathbf{S}^2) + E(S_x^2 - S_y^2) \quad (\text{B1.15.20})$$

where $D \approx \frac{2}{3} D_{ZZ}$ is the axial and $E = \frac{1}{2} (D_{XX} - D_{YY})$ is the rhombic zero-field parameter. One may define an asymmetry parameter $\eta_D = E/D$ of the \mathbf{D} -tensor. The case of $\eta_D = 0$ (or $E = 0$) corresponds to an axially symmetric ZFS tensor ($D_{XX} = D_{YY}$) and two of the states will remain degenerate at zero magnetic field. The ZFS parameters can in general be determined from the EPR spectrum (for $\mathcal{H}_{\text{ZFS}} < \mathcal{H}_{\text{EZI}}$). In liquids the ZFS is averaged out to zero.

Figure B1.15.2. The state energies and corresponding eigenfunctions (high-field labels) as a function of the applied magnetic field B_0 for a system of spin $S = 1$ and $\mathbf{B} \parallel z$, shown for $D > 0$ and $E \neq 0$. The two primary transitions ($\Delta M_S = \pm 1$) are indicated for a constant frequency spectrum. Note that, because $E \neq 0$, the state energies vary nonlinearly with B_0 at low B_0 .

(C) ELECTRON SPIN EXCHANGE INTERACTION

For systems with two unpaired electrons, such as radical pairs, biradicals or triplets, there are four spin states that can be represented by the product functions $|M_{S1}\rangle \otimes |M_{S2}\rangle$, i.e. $|\alpha_1\alpha_2\rangle$, $|\alpha_1\beta_2\rangle$, $|\beta_1\alpha_2\rangle$ and $|\beta_1\beta_2\rangle$, where the subscripts indicate electron spin 1 and electron spin 2, respectively. In a paramagnetic centre of moderate size, however, it is more advantageous to combine these configurations into combination states because, in addition to the dipolar coupling between the spin magnetic moments, there is also an electrostatic interaction between the electron spins, the so-called exchange interaction, which gives rise to an energy separation between the singlet state, $|S\rangle \approx \frac{1}{\sqrt{2}}(|\alpha_1\beta_2\rangle - |\beta_1\alpha_2\rangle)$, and the triplet states ($|T_+\rangle = |\alpha_1\alpha_2\rangle$, $|T_0\rangle \approx \frac{1}{\sqrt{2}}(|\alpha_1\beta_2\rangle + |\beta_1\alpha_2\rangle)$, $|T_-\rangle = |\beta_1\beta_2\rangle$). The magnitude of the (isotropic) exchange interaction can be derived from the overlap of the wavefunctions and is described by the Hamiltonian

$$\mathcal{H}_{EX} = -2JS_1 \cdot S_2 \quad (\text{B1.15.21})$$

-10-

which denotes a scalar coupling between the spins $\mathbf{S}_1 = (S_{1x}, S_{1y}, S_{1z})$ and $\mathbf{S}_2 = (S_{2x}, S_{2y}, S_{2z})$. The energy separation between the $|S\rangle$ and $|T_0\rangle$ wavefunctions is determined by the exchange coupling constant J . For $J > 0$ the singlet state is higher in energy than the $|T_0\rangle$ -state. The observed properties of the system depend on the magnitude of J . If it is zero the two spins behave completely independently and one would have a true biradical. At the other extreme, when J is large the singlet lies far above the triplet and the magnetic resonance properties are solely determined by the interaction within the triplet manifold.

(D) HYPERFINE INTERACTION

The interaction of the electron spin's magnetic dipole moment with the magnetic dipole moments of nearby nuclear spins provides another contribution to the state energies and the number of energy levels, between which transitions may occur. This gives rise to the hyperfine structure in the EPR spectrum. The so-called hyperfine interaction (HFI) is described by the Hamiltonian

$$\mathcal{H}_{\text{HFI}} = \mathbf{SAI} \quad (\text{B1.15.22})$$

where \mathbf{A} is the HFI matrix and $\mathbf{I} = (I_x, I_y, I_z)$ is the vector representation of the nuclear spin. The HFI consists of two parts and therefore, equation (b1.15.22) can be separated into the sum of two terms

$$\mathcal{H}_{\text{HFI}} = \mathbf{SA}^{\text{dip}}\mathbf{I} + a\mathbf{S} \cdot \mathbf{I} \quad (\text{B1.15.23})$$

where the first term describes the anisotropic dipolar coupling through space between the electron spin and the nuclear spin. \mathbf{A}^{dip} is the symmetric and traceless dipolar HFI matrix. In the so-called point-dipole approximation, where both spins are assumed to be located, this part is given by

$$\mathcal{H} = -g\beta_e g_n \beta_n \left[\frac{\mathbf{I} \cdot \mathbf{S}}{r^3} - \frac{3(\mathbf{I}\mathbf{r})(\mathbf{S}\mathbf{r})}{r^5} \right]. \quad (\text{B1.15.24})$$

In equation (b1.15.24), \mathbf{r} is the vector connecting the electron spin with the nuclear spin, r is the length of this vector and g_n and β_n are the g -factor and the Bohr magneton of the nucleus, respectively. The dipolar coupling is purely anisotropic, arising from the spin density of the unpaired electron in an orbital of non-spherical symmetry (i.e. in p, d or f-orbitals) with a vanishing electron density at the nucleus. Since \mathbf{A}^{dip} is traceless the dipolar interactions are averaged out in isotropic fluid solution and only the orientation-independent isotropic coupling represented by the second term in equation (b1.15.23) gives rise to the observed hyperfine coupling in the spectrum. This isotropic contribution is called the (Fermi) contact interaction arising from electrons in s orbitals (spherical symmetry) with a finite probability ($|\psi(0)|^2$) of finding the electron at the nucleus. The general expression for the isotropic hyperfine coupling constant is

$$a = \frac{2\mu_0}{3} g\beta_e g_n \beta_n |\Psi(0)|^2. \quad (\text{B1.15.25})$$

Hence, a measurement of hyperfine coupling constants provides information on spin densities at certain positions in the molecule and thus renders a map of the electronic wavefunction.

The simplest system exhibiting a nuclear hyperfine interaction is the hydrogen atom with a coupling constant of 1420 MHz. If different isotopes of the same element exhibit hyperfine couplings, their ratio is determined by the ratio of the nuclear g -values. Small deviations from this ratio may occur for the Fermi contact interaction, since the electron spin probes the inner structure of the nucleus if it is in an s orbital. However, this so-called hyperfine anomaly is usually smaller than 1%.

(E) NUCLEAR ZEEMAN AND NUCLEAR QUADRUPOLE INTERACTION

While all contributions to the spin Hamiltonian so far involve the electron spin and cause first-order energy shifts or splittings in the EPR spectrum, there are also terms that involve only nuclear spins. Aside from their importance for the calculation of ENDOR spectra, these terms may influence the EPR spectrum significantly in situations where the high-field approximation breaks down and second-order effects become important. The first of these interactions is the coupling of the nuclear spin to the external magnetic field, called the

nuclear Zeeman interaction (NZI). Neglecting chemical shift anisotropies that are usually small and not resolved in ENDOR spectra it can be considered isotropic and written as

$$\mathcal{H}_{\text{NZI}} = -g_n \beta_n \mathbf{B} \cdot \mathbf{I}. \quad (\text{B1.15.26})$$

The negative sign in equation (b1.15.26) implies that, unlike the case for electron spins, states with larger magnetic quantum number have smaller energy for $g_n > 0$. In contrast to the g -value in EPR experiments, g_n is an inherent property of the nucleus. NMR resonances are not easily detected in paramagnetic systems because of sensitivity problems and increased linewidths caused by the presence of unpaired electron spins.

Since atomic nuclei are not perfectly spherical their spin leads to an electric quadrupole moment if $I \geq 1$ which interacts with the gradient of the electric field due to all surrounding electrons. The Hamiltonian of the nuclear quadrupole interactions can be written as tensorial coupling of the nuclear spin with itself

$$\mathcal{H}_{\text{NQI}} = \mathbf{I} \mathbf{P} \mathbf{I} \quad (\text{B1.15.27})$$

where \mathbf{P} is the quadrupole coupling tensor. Comparison with [equation \(b1.15.19\)](#) shows that the NQI can be formally treated in a way analogous to that for the ZFS. In liquids the NQI is averaged out to zero.

(F) THE COMPLETE SPIN HAMILTONIAN

The complete spin Hamiltonian for a description of EPR and ENDOR experiments is given by

$$\mathcal{H} = \mathcal{H}_{\text{EZI}} + \mathcal{H}_{\text{ZFS}} + \mathcal{H}_{\text{EX}} + \mathcal{H}_{\text{HFI}} + \mathcal{H}_{\text{NZI}} + \mathcal{H}_{\text{NQI}}. \quad (\text{B1.15.28})$$

The approximate magnitudes of the terms in equation (b1.15.28) are shown in an overview in [figure B1.15.3](#) (see also [2, 3, 11]).

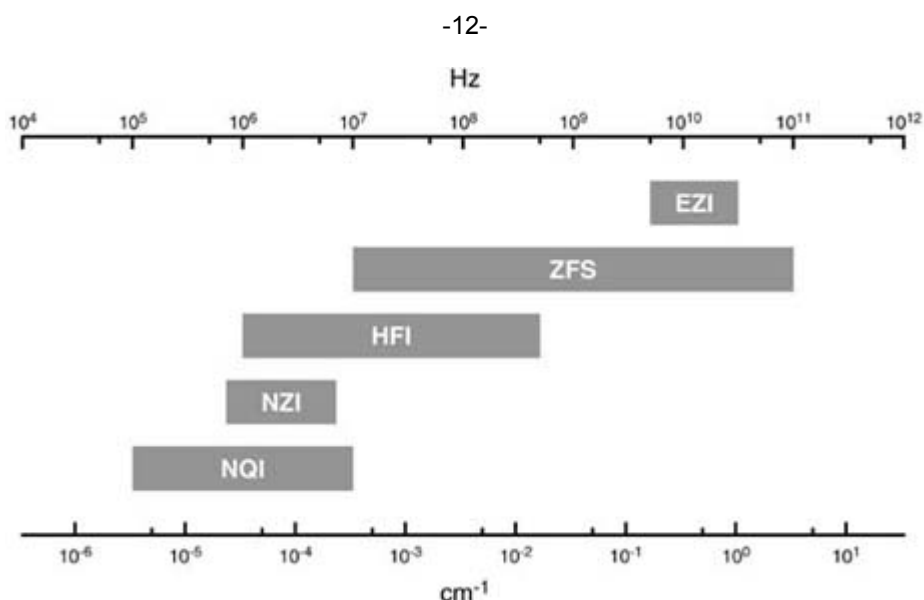

Figure B1.15.3. Typical magnitudes of interactions of electron and nuclear spins in the solid state (logarithmic scale).

B1.15.3 EPR INSTRUMENTATION

A typical CW-detected EPR spectrum is recorded by holding the frequency constant and varying the external magnetic field. In doing so one varies the separation between the energy levels to match it to the quantum of the radiation. Even though magnetic resonance could also be achieved by sweeping the frequency at a fixed magnetic field, high-frequency sources with a broad frequency range and simultaneously low enough noise characteristics have not yet been devised to be practical for frequency-swept EPR.

EPR absorption has been detected from zero magnetic field up to fields as high as 30 T corresponding to a MW frequency of 10^{12} Hz. There are various considerations that influence the choice of the radiation frequency. Higher frequencies, which require higher magnetic fields, give inherently greater sensitivity by virtue of a more favourable Boltzmann factor (see equation (b1.15.11)). However, several factors place limits on the frequency employed, so that frequencies in the MW region of the electromagnetic spectrum remain favoured. One limitation is the sample size; at frequencies around 40 GHz the dimensions of a typical resonant cavity are of the order of a few millimetres, thus restricting the sample volume to about 0.02 cm^3 . The requirement to reduce the sample size roughly compensates for the sensitivity enhancement in going to higher fields and frequencies in EPR. However, the sensitivity advantage persists if only small quantities of the sample are available. This is often the case for biological samples, particularly when single-crystal studies are intended. Second, high frequencies require high magnetic fields that are homogeneous over the sample volume. Sufficiently homogeneous magnetic fields above 2.5 T are difficult to produce with electromagnets. Superconducting magnets are commercially available for magnetic fields up to 22 T, but they are expensive and provide only small room-temperature bores, thus limiting the space available for the resonator. Third, the small size of MW components for high frequencies makes their fabrication technically difficult and costly. These and other factors have resulted in a choice of the frequency region around 10 GHz (usually denominated the X-band region) as the resonance frequency of most commercially available spectrometers. The most common frequency

-13-

bands for high-field/high-frequency EPR are Q-band (35 GHz) and W-band (95 GHz), where the wavelengths are 8 mm and 3 mm, respectively. In order to carry out EPR experiments in larger objects such as intact animals it appears necessary to use lower frequencies because of the large dielectric losses of aqueous samples. At L-band frequencies (1–2 GHz), with appropriate configurations of EPR resonators, whole animals the size of mice can be studied by insertion into the resonator. Table B1.15.1 lists typical frequencies and wavelengths, together with the resonant fields required for resonance of a free electron.

Table B1.15.1 Some frequencies and resonance fields (for $g = 2$) used in EPR.

Typical EPR frequency ν (GHz)	Vacuum wavelength λ (m)	Typical EPR field B_0 (T)	Band designation Frequency (GHz)
1.5	2×10^{-1}	0.054	L 0.39–1.55
3.0	1×10^{-1}	0.107	S 1.55–3.9
6.0	5×10^{-2}	0.214	C 3.9–6.2
9.5	3.2×10^{-2}	0.339	X 6.2–10.9
24	1.2×10^{-2}	0.856	K 10.9–36
36	8.3×10^{-3}	1.285	Q 36–46
50	6.0×10^{-3}	1.784	V 46–56
95	3.2×10^{-3}	3.390	W 56–100
140	2.1×10^{-3}	4.996	D
250	1.2×10^{-3}	8.921	—
360	8.3×10^{-4}	12.846	—
604	5.0×10^{-4}	21.552	—

The components of a typical EPR spectrometer operating at X-band frequencies [3, 4, 6] are shown in [figure B1.15.4](#).

Up to the present the MW radiation has usually been provided by reflex klystrons, which essentially consist of a vacuum tube and a pair of electrodes to produce an electron beam that is velocity modulated by a radio-frequency (RF) electric field. The net effect is the formation of groups or bunches of electrons. Using a reflector the bunched electron beam is turned around and will debunch, giving up energy to the cavity, provided the RF frequency and the beam and reflector voltages are properly adjusted. This will set up one of several stable klystron modes at the cavity frequency f_0 ; the mode corresponding to the highest output of power is usually the one utilized. A typical klystron has a mechanical tuning range allowing the klystron cavity frequency to be tuned over a range of 5–50% around f_0 . The adjustment of the reflector voltage allows one to vary the centre frequency of a given mode over a very limited range of 0.2–0.8%. Often a low-amplitude sine-wave reflector voltage modulation is employed as an integral part of an automatic frequency control (AFC). It is desirable that the klystron frequency be very stable; hence, fluctuations of the klystron temperature or of applied voltages must be minimized and mechanical vibrations suppressed. Klystrons are employed as generators of nearly monochromatic output radiation in the frequency range from 1 to 100 GHz. In commercial EPR spectrometers the klystron normally provides less than 1 W of continuous output power. Increasingly, however, solid-state devices, such as Gunn-effect oscillators and IMPATTs, are superseding klystron tubes.

-14-

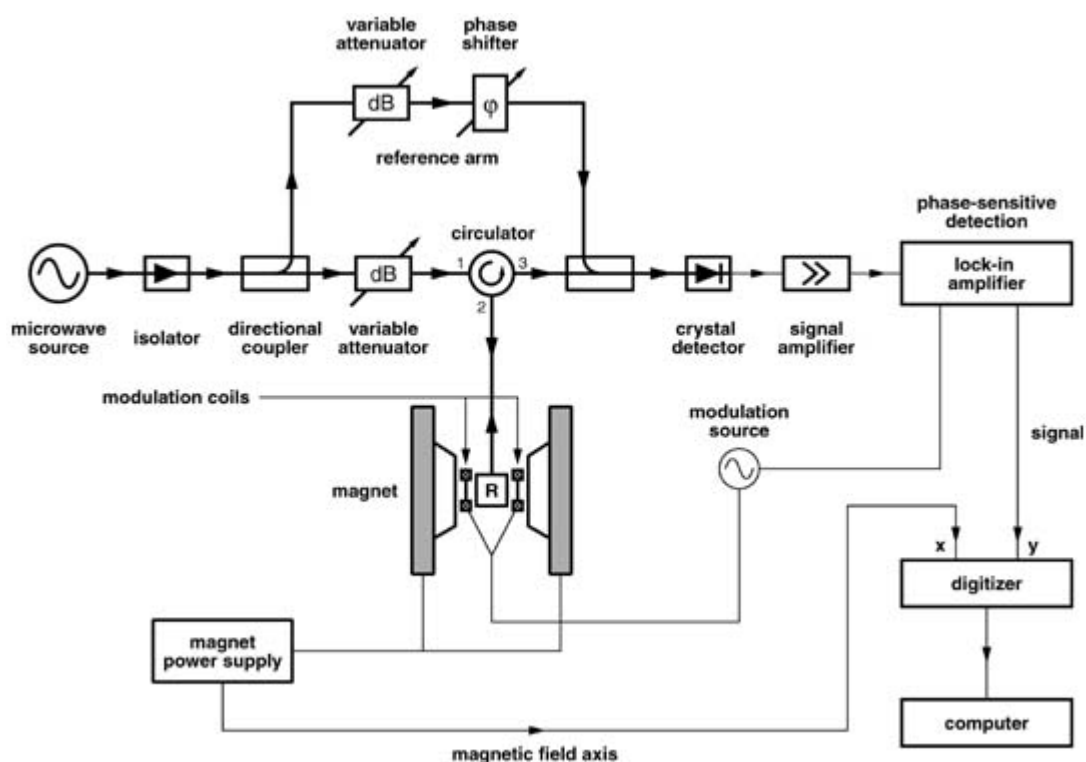

Figure B1.15.4. Block diagram of a typical EPR spectrometer operating at X-band frequencies.

Waveguides are commonly used to transmit microwaves from the source to the resonator and subsequently to the receiver. For not-too-high-frequency radiation (≤ 10 GHz) low-loss MW transmission can also be achieved using strip-lines and coaxial cables. At the output of a klystron an isolator is often used to prevent back-reflected microwaves to perturb the on-resonant klystron mode. An isolator is a microwave-ferrite device that permits the transmission of microwaves in one direction and strongly attenuates their propagation in the other direction. The principle of this device involves the Faraday effect, that is, the rotation of the polarization

planes of the microwaves.

The amount of MW power reaching the sample in the resonator is controlled by a variable attenuator. Like the isolator, the circulator is a non-reciprocal device that serves to direct the MW power to the resonator (port 1 → port 2) and simultaneously allows the signal reflected at resonance to go from the resonator directly to the receiver (port 2 → port 3).

Although achievement of resonance in an EPR experiment does not require the use of a resonant cavity, it is an integral part of almost all EPR spectrometers. A resonator dramatically increases the sensitivity of the spectrometer and greatly simplifies sample access. A resonant cavity is the MW analogue of a RF-tuned *RLC* circuit and many expressions derived for the latter may also be applied to MW resonators. A typical resonant cavity for microwaves is a box or a cylinder fabricated from high-conductivity metal and with dimensions comparable to the wavelength of the radiation. Each particular cavity size and shape can sustain oscillations in a number of different standing wave patterns, called resonator modes. Visual images and mathematical expressions of the distributions of the electric and magnetic field vectors within the cavity can be derived from Maxwell's equations with suitable boundary conditions.

-15-

The locations of the maxima of the \mathbf{B}_1 -field and the \mathbf{E} -field are different depending on the mode chosen for the EPR experiment. It is desirable to design the cavity in such a way that the \mathbf{B}_1 field is perpendicular to the external field \mathbf{B} , as required by the nature of the resonance condition. Ideally, the sample is located at a position of maximum \mathbf{B}_1 , because below saturation the signal-to-noise ratio is proportional to B_1 . Simultaneously, the sample should be placed at a position where the \mathbf{E} -field is a minimum in order to minimize dielectric power losses which have a detrimental effect on the signal-to-noise ratio.

The sharpness of the frequency response of a resonant system is commonly described by a factor of merit, called the quality factor, $Q = \nu / \Delta\nu$. It may be obtained from a measurement of the full width at half maximum $\Delta\nu$, of the resonator frequency response curve obtained from a frequency sweep covering the resonance. The sensitivity of a system (proportional to the inverse of the minimum detectable number of paramagnetic centres in an EPR cavity) critically depends on the quality factor

$$S \propto Q\eta \quad (\text{B1.15.29})$$

where $\eta = \int_0^t \mathbf{G}(t') dt' = \mathbf{0}_{B_1}^2 dV$ is the filling factor. The cavity types most commonly employed in EPR are the rectangular-parallelepiped cavity and the cylindrical cavity. The rectangular cavity is typically operated in a transverse electric mode, TE_{102} , which permits the insertion of large samples with low dielectric constants. It is especially useful for liquid samples in flat cells, which may extend through the entire height of the cavity. In the cylindrical cavity a TE_{011} mode is frequently used because of its fairly high Q -factor and the very strong B_1 along the sample axis.

Microwaves from the waveguide are coupled into the resonator by means of a small coupling hole in the cavity wall, called the iris. An adjustable dielectric screw (usually machined from Teflon) with a metal tip adjacent to the iris permits optimal impedance matching of the cavity to the waveguide for a variety of samples with different dielectric properties. With an appropriate iris setting the energy transmission into the cavity is a maximum and simultaneously reflections are minimized. The optimal adjustment of the iris screw depends on the nature of the sample and is found empirically.

Other frequently used resonators are dielectric cavities and loop-gap resonators (also called split-ring resonators) [12]. A dielectric cavity contains a diamagnetic material that serves as a dielectric to raise the effective filling factor by concentrating the \mathbf{B}_1 field over the volume of the sample. Hollow cylinders machined from fused quartz or sapphire that host the sample along the cylindrical axis are commonly used.

Loop-gap resonators consist of one or a series of cylindrical loops interrupted by at least one or several gaps. Loops and gaps act as inductive and capacitive elements, respectively. With a suitable choice of loop and gap dimensions, resonators operating at different resonance frequencies over a wide range of the MW spectrum can be constructed. Loop-gap resonators typically have low Q -factors. Their broad-bandwidth frequency response, $\Delta\nu$, makes them particularly useful in EPR experiments where high time resolution, $\tau_{\text{res}}=1/(2\pi\Delta\nu)$, because fast signal changes are required. Excellent filling factors, η , may be obtained with loop-gap devices; the high η makes up for the typically low Q to yield high sensitivity (see equation (b1.15.29)), valuable for small sample sizes and in pulsed EPR experiments. Coupling of microwaves into these cavities is most conveniently accomplished by a coupling loop that acts as an antenna. Typically, the distance between the antenna and the loop-gap resonator is varied in order to obtain optimal impedance matching.

When the applied magnetic field is swept to bring the sample into resonance, MW power is absorbed by the sample. This changes the matching of the cavity to the waveguide and some power is now reflected and passes via the circulator to the detector. This reflected radiation is thus the EPR signal.

-16-

The most commonly used detector in EPR is a semiconducting silicon crystal in contact with a tungsten wire, which acts as an MW rectifier. At microwatt powers, crystal detectors are typically non-linear and render a rectified current that is proportional to the MW power (i.e. proportional to B_1^2). In the milliwatt region, the rectified crystal current becomes proportional to the square root of the MW power (i.e. proportional to B_1), and the crystal behaves as a linear detector. In EPR spectroscopy it is preferred to operate the crystal rectifier in its linear regime. However, since the EPR signal is typically rather small, the diode needs to be biased to operate it at higher MW power levels. This can be done by slightly mismatching the cavity to the waveguide in order to increase the MW power back-reflected from the cavity, or by adding microwaves at a constant power level guided through the reference arm (often called the bypass arm) of the spectrometer. The reference arm takes microwaves from the waveguide ahead of the circulator and returns them with adjusted phase and power behind the circulator. When properly adjusted, the reference arm can also be used to detect the in-phase (χ') and out-of-phase (χ'') components of the EPR signal with respect to the phase of the microwaves.

When sweeping the magnetic field through resonance, a crystal detector renders a slowly varying DC signal which is not readily processed and which is superimposed by low-frequency noise contributions. To overcome this, a phase-sensitive detection technique utilizing small-amplitude magnetic field modulation is employed in most EPR spectrometers. Modulation of the magnetic field is achieved by placing a pair of Helmholtz coils on each side of the cavity along the axis of the external magnetic field. An alternating current is fed through them and a small oscillating magnetic field is induced which is superimposed on the external magnetic field. The effect of the modulation is depicted in [figure B1.15.5](#). Provided the amplitude of the modulation field is small compared to the linewidth of the absorption signal, $\Delta B_{1/2}$, the change in MW power at the detector will contain an oscillatory component at the modulation frequency whose amplitude will be proportional to the slope of the EPR line. A lock-in detector compares the modulated EPR signal from the crystal with a reference and only passes the components of the signal that have the proper frequency and phase.

The reference voltage comes from the same frequency generator that produces the field modulation voltage and this causes the EPR signal to pass through while most noise at frequencies other than the modulation frequency is suppressed. As a result of phase-sensitive detection using lock-in amplification one typically obtains the first derivative of the absorption line EPR signal. The application of field modulation, however, can cause severe lineshape distortion: to limit modulation-induced line broadening to below 1% of the undistorted linewidth, $\Delta B_{1/2}$ requires small modulation amplitudes ($B_{\text{mod}} < 0.15 \Delta B_{1/2}$ for Lorentzian lineshapes and $B_{\text{mod}} < 0.3 \Delta B_{1/2}$ for Gaussian lineshapes).

After the signal emerges from the lock-in amplifier it still contains a considerable amount of noise. Most of the noise contributions to the signal can be eliminated by passing the signal through a low-pass filter. The filter time constant is a measure of the cutoff frequency of the filter. If accurate linewidth and g -factor

measurements are intended, one must be careful to employ a sufficiently short response time because lineshape distortions may occur as a result of too intense filtering.

-17-

Figure B1.15.5. Effect of small-amplitude 100 kHz field modulation on the detector output current. The static magnetic field is modulated between the limits B_a and B_b . The corresponding detector current varies between the limits I_a and I_b . The upper diagram shows the recorded 100 kHz signal as a function of B_0 . After [3].

Figure B1.15.6 presents a liquid-phase EPR spectrum of an organic radical measured using a conventional EPR spectrometer like the one depicted in Figure B1.15.4. As is usual, the lines are presented as first derivatives $d\chi''/dB_0$ of the power absorbed by the spins. The spectrum shows a pronounced pattern of hyperfine lines arising from two different groups of protons (see also Figure B1.15.9). The number, spacing and intensity of the lines provides information on the molecular and electronic structure of the molecule carrying the unpaired electron spin. The individual lines have a Lorentzian lineshape with a homogeneous linewidth determined by T_2 . The most common case for inhomogeneously broadened lines giving rise to a Gaussian lineshape is unresolved hyperfine interactions arising from a large number of nonequivalent nuclei and anisotropies of the hyperfine coupling which will persist when recording EPR spectra of radicals in solids.

-18-

Figure B1.15.6. The EPR spectrum of the perinaphtheryl radical in mineral oil taken at room temperature. (A) First derivative of the EPR absorption χ'' with respect to the external magnetic field, B_0 . (B) Integrated EPR spectrum.

EPR has been successfully applied to radicals in the solid, liquid and gaseous phase. Goniometer techniques have been adopted to measure anisotropic magnetic interactions in oriented (e.g. single-crystal) and partially oriented (e.g. film) samples as a function of the sample orientation with respect to the external field. Variable temperature studies can provide a great deal of information about a spin system and its interactions with its environment. Therefore, low-temperature as well as high-temperature EPR experiments can be conducted by either heating or cooling the entire cavity in a temperature-controlled cryostat or by heating or cooling the sample in a jacket inserted into the cavity. Specialized cavity designs have also been worked out to perform EPR studies under specific conditions (e.g. high pressures). Sample irradiation is facilitated through shielded openings in the cavity.

The practical goal of EPR is to measure a stationary or time-dependent EPR signal of the species under scrutiny and subsequently to determine magnetic interactions that govern the shape and dynamics of the EPR response of the spin system. The information obtained from a thorough analysis of the EPR signal, however, may comprise not only the parameters enlisted in the previous chapter but also a wide range of other physical parameters, for example reaction rates or orientation order parameters.

B1.15.4 TIME-RESOLVED CW EPR METHODS

Although EPR in general has the potential to follow the concentration changes of short-lived paramagnetic intermediates, standard CW EPR using field modulation for narrow-band phase-sensitive detection is geared for high sensitivity and correspondingly has only a mediocre time resolution. Nevertheless, transient free radicals in the course of (photo-)chemical processes can be studied by measuring the EPR line intensity of a spectral feature as a function of time at a fixed value of the external magnetic field. Typically, the optimum time response of a commercial spectrometer which uses a CW fixed-frequency lock-in detection is in the order of 20 μs . By use of field modulation frequencies higher than the 100 kHz usually employed in commercial instruments, the time resolution can be increased by about an order of magnitude, which makes this method well suited for the study of transient free radicals on a microsecond timescale.

B1.15.4.1 TRANSIENT EPR SPECTROSCOPY

The time resolution of CW EPR can be considerably improved by removing the magnetic field modulation completely. Rather, a suitably fast data acquisition system is employed to directly detect the transient EPR signal as a function of time at a fixed magnetic field. In transient EPR spectroscopy (TREPR) [13, 14] paramagnetic species (e.g. free radicals, radical pairs, triplets or higher multiplet states) are generated on a nanosecond timescale by a short laser flash or radiolysis pulse and the arising time-dependent signals are detected in the presence of a weak MW magnetic field. For this purpose the standard EPR spectrometer shown in [figure B1.15.4](#) needs to be modified. The components for the field modulation may be removed, and the lock-in amplifier and digitizer are replaced by a fast transient recorder or a digital oscilloscope triggered by a photodiode in the light path of the laser. The response time of such a spectrometer is potentially controlled by the bandwidth of each individual unit. Provided that the MW components are adequately broadbanded and the laser flash is sufficiently short (typically a few nanoseconds), the time resolution can be pushed to the 10^{-8} s range (which is not far from the physical limit given by the inverse MW frequency) if a resonator with a low Q -value (and hence wide bandwidth) is used. Fortunately, the accompanying sensitivity loss (see [equation \(b1.15.29\)](#)) can be compensated to a large extent by using resonators with high filling factors [12]. Furthermore, excellent sensitivity is obtained in studies of photoprocesses where the light-generated paramagnetic species are typically produced in a state of high electron spin polarization (or, in other words, removed from the thermal equilibrium population of the electron spin states). Nevertheless, the EPR time profiles at a fixed magnetic field position are repeatedly measured in order to improve the signal-to-noise ratio by a factor \sqrt{N} , where N is the number of time traces averaged.

Following the pioneering work by Kim and Weissman [15], it has been demonstrated that TREPR works for a broad range of resonance frequencies from 4 GHz (S-band) up to 95 GHz (W-band). As an example the time-dependent EPR signal of the photo-generated triplet state of pentacene in a *para*-terphenyl single crystal obtained by TREPR at X-band is shown in [figure B1.15.7](#). Note that EPR signals taken in direct detection appear in the absorption (or dispersion)

mode, not in the usual derivative form associated with field modulation and phase-sensitive detection. Therefore, positive signals indicate absorptive (A) and negative signals emissive (E) EPR transitions.

Figure B1.15.7. Transient EPR. Bottom: time-resolved EPR signal of the laser-flash-induced triplet state of pentacene in *p*-terphenyl. $B_1=0.085$ mT. Top: initially, the transient magnetization \mathbf{M} is aligned along $\mathbf{B} \parallel z$. In the presence of a MW magnetic field \mathbf{B}_1 the magnetization precesses about $\mathbf{B}_1 \parallel x'$ (rotating frame representation).

The following discussion of the time dependence of the EPR response in a TREPR experiment is based on the assumption that the transient paramagnetic species is long lived with respect to the spin relaxation parameters. When ω_1 is large compared to the inverse relaxation times, i.e. $\omega_1 = \gamma B_1 \gg T_1^{-1}, T_2^{-1}$, or, in other words, for high MW powers, the signal exhibits oscillations with a frequency proportional to the MW magnetic field B_1 . These so-called transient nutations are observed if resonance between an electron spin transition and a coherent radiation field is suddenly achieved. The phenomenon can be understood when viewing the motion of the magnetization vector, \mathbf{M} , in a

reference frame, (x', y', z) , rotating at the frequency ω of the MW field around the static external field ($\mathbf{B}_0 \parallel z$). Hence, in the rotating frame B_1 is a stationary field defined along the x' -axis as indicated in [figure B1.15.7](#). Paramagnetic species are created during the laser flash at $t = 0$ with their spins aligned with the applied magnetic field, which causes an initial magnetization $M_z(0)$ in this direction. This is acted upon by the radiation field at or near resonance, which rotates it to produce an orthogonal component, $M_{y'}(t)$, to which the observed signal is proportional. The signal initially increases as $M_{y'}(t)$ grows under the rotation of \mathbf{M} about \mathbf{B}_1 (at exact resonance) or $\mathbf{B}_0 + \mathbf{B}_1$ (near resonance), but, while the system approaches a new state via oscillations,

M continually decreases under the influence of spin–spin relaxation which destroys the initial phase coherence of the spin motion within the y/z -plane. In solid-state TREPR, where large inhomogeneous EPR linewidths due to anisotropic magnetic interactions persist, the long-time behaviour of the spectrometer output, $S(t)$, is given by

$$S(t) \propto \omega_1 J_0(\omega_1 t) e^{-t/(2T_2)} \quad (\text{B1.15.30})$$

where the oscillation of the transient magnetization is described by a Bessel function $J_0(\omega_1 t)$ of zeroth order, damped by the spin–spin relaxation time T_2 . At low MW powers ($\omega_1^2 T_1 T_2 \ll 1$) an exponential decay of the EPR signal is observed, governed by spin–lattice relaxation

$$S(t) \propto \omega_1 e^{-t/T_1}. \quad (\text{B1.15.31})$$

The rise time of the signals—independent of the chosen MW power—is proportional to the inverse inhomogeneous EPR linewidth. As can be seen from equations (b1.15.30) and (b1.15.31) a measurement of the ω_1 -dependence of the transient EPR signals provides a straightforward method to determine not only the relaxation parameters of the spin system but also the strength of the MW magnetic field B_1 at the sample. Spectral information can be obtained from a series of TREPR signals taken at equidistant magnetic field points covering the total spectral width. This yields a two-dimensional variation of the signal intensity with respect to both the magnetic field and the time axis. Transient spectra can be extracted from such a plot at any fixed time after the laser pulse as slices parallel to the magnetic field axis.

B1.15.4.2 MW-SWITCHED TIME INTEGRATION METHOD (MISTI)

An alternative method to obtain accurate values of the spin–lattice relaxation time T_1 is provided by the TREPR technique with gated MW irradiation, also called the MW-switched time integration method (MISTI) [13, 14]. The principle is quite simple. The MW field is switched on with a variable delay τ after the laser flash. The amplitude of the transient signal plotted as a function of τ renders the decay of the spin-polarized initial magnetization towards its equilibrium value. This method is preferred over the TREPR technique at low MW power (see equation (b1.15.31)) since the spin system is allowed to relax in the absence of any resonant MW field in a true spin–lattice relaxation process. The experiment is carried out by adding a PIN diode MW switch between the MW source and the circulator (see figure B1.15.4, and set between a pair of isolators. Since only low levels of MW power are switched (typically less than 1 W), as opposed to those in ESE and FT EPR, the detector need not be protected against high incident power levels.

As a summary it may be of interest to point out why TREPR spectroscopy and related methods remain important in the EPR regime, even though pulsed EPR methods are becoming more and more widespread. (1) For the case of an inhomogeneously broadened EPR line the time resolution of TREPR compares favourably with pulsed techniques.

(2) The low MW power levels commonly employed in TREPR spectroscopy do not require any precautions to avoid detector overload and, therefore, the full time development of the transient magnetization is obtained undiminished by any MW detection deadtime. (3) Standard CW EPR equipment can be used for TREPR requiring only moderate efforts to adapt the MW detection part of the spectrometer for the observation of the transient response to a pulsed light excitation with high time resolution. (4) TREPR spectroscopy proved to be a suitable technique for observing a variety of spin coherence phenomena, such as transient nutations [16], quantum beats [17] and nuclear modulations [18], that have been useful to interpret EPR data on light-induced spin-correlated radical pairs.

B1.15.5 MULTIPLE RESONANCE TECHNIQUES

In the previous chapters experiments have been discussed in which one frequency is applied to excite and detect an EPR transition. In multiple resonance experiments two or more radiation fields are used to induce different transitions simultaneously [19, 20, 21, 22 and 23]. These experiments represent elaborations of standard CW and pulsed EPR spectroscopy, and are often carried out to complement conventional EPR studies, or to refine the information which can in principle be obtained from them.

B1.15.5.1 ELECTRON–NUCLEAR DOUBLE RESONANCE SPECTROSCOPY (ENDOR)

It was noted earlier that EPR may at times be used to characterize the electronic structure of radicals through a measurement of hyperfine interactions arising from nuclei that are coupled to the unpaired electron spin. In very large radicals with low symmetry, where the presence of many magnetic nuclei results in a complex hyperfine pattern, however, the spectral resolution of conventional EPR is very often not sufficient to resolve or assign all hyperfine couplings. It was as early as 1956 that George Feher demonstrated that by electron–nuclear double resonance (ENDOR) the spectral resolution can be greatly improved [24]. In ENDOR spectroscopy the electron spin transitions are still used as means of detection because the sensitivity of the electron resonance measurement is far greater than that of the nuclear resonance. In brief, an EPR transition is saturated, which leads to a collapse of the observed EPR signal as the corresponding state populations equalize. If one now simultaneously irradiates the spin system with an RF field in order to induce transitions between the nuclear sublevels, the condition of saturation in the EPR transition is lifted as the nuclear sublevel populations shift, and there is a partial recovery of the EPR signal.

ENDOR transitions can be easily understood in terms of a simple system consisting of a single unpaired electron spin ($S=\frac{1}{2}$) coupled to a single nuclear spin ($I=\frac{1}{2}$). The interactions responsible for the various splittings are summarized in the following static Hamiltonian:

$$\mathcal{H} = \mathcal{H}_{EZI} + \mathcal{H}_{NZI} + \mathcal{H}_{HFI} = \beta_e \mathbf{B} g \mathbf{S} - g_n \beta_n \mathbf{B} \cdot \mathbf{I} + \mathbf{S} \mathbf{A} \mathbf{I}. \quad (\text{B1.15.32})$$

The coupling constants of the hyperfine and the electron Zeeman interactions are scalar as long as radicals in isotropic solution are considered, leading to the Hamiltonian

$$\mathcal{H} = g_e \beta_e \mathbf{B} \cdot \mathbf{S} - g_n \beta_n \mathbf{B} \cdot \mathbf{I} + a \mathbf{S} \cdot \mathbf{I}. \quad (\text{B1.15.33})$$

-23-

In the high-field approximation with $\mathbf{B} \parallel z$, the energy eigenvalues classified by the magnetic spin quantum numbers, M_S and M_I , are given by

$$E_{M_S, M_I} = g_e \beta_e B_0 M_S - g_n \beta_n M_I B_0 + a M_S M_I \quad (\text{B1.15.34})$$

where g_n and a may be positive or negative, thus leading to a different ordering of the levels. The energy level diagram for the case $a < 0$ and $|a|/2 < g_n \beta_n B_0$ is shown in figure B1.15.8. Adopting the notation $\hbar \omega_e = g_e \beta_e B_0$ and $\hbar \omega_N = g_n \beta_n B_0$, two EPR transitions are obtained,

$$\omega_{\text{EPR}} = \omega_e \pm a/(2\hbar) \quad (\text{B1.15.35})$$

which obey the selection rule $\Delta M_S = \pm 1$ and $\Delta M_I = 0$. The two ENDOR transitions are

$$\omega_{\text{ENDOR}}^{\pm} = |\omega_n \pm a/(2\hbar)| \quad (\text{B1.15.36})$$

which satisfy the selection rule $\Delta M_S = 0$ and $\Delta M_I = \pm 1$. The absolute value is used in equation (b1.15.36) to take into account the two cases $|a|/(2\hbar) < |\omega_n|$ and $|a|/(2\hbar) > |\omega_n|$. The corresponding ENDOR spectra are shown schematically in figures b1.15.8(B) and (C). Irrespective of the EPR line monitored, two ENDOR lines, separated by $|a|/\hbar$ and centred at $|\omega_n|$, are observed. For $|a|/(2\hbar) > |\omega_n|$ the two ENDOR transitions are given by $|a|/(2\hbar) \pm |\omega_n|$: again, two lines are observed; however, separated by $2|\omega_n|$ and centred at $|a|/(2\hbar)$.

-24-

Figure B1.15.8. (A) Left side: energy levels for an electron spin coupled to one nuclear spin in a magnetic field, $S = I = \frac{1}{2}$, $g_n > 0$, $a < 0$, and $|a|/(2\hbar) < \omega_n$. Right side: schematic representation of the four energy levels with $|\pm\pm\rangle \equiv |M_S = \pm\frac{1}{2}, M_I = \pm\frac{1}{2}\rangle$. $|+-\rangle \equiv 1$, $|++\rangle \equiv 2$, $|--\rangle \equiv 3$ and $| -+\rangle \equiv 4$. The possible relaxation paths are characterized by the respective relaxation rates W . The energy levels are separated horizontally to distinguish between the two electron spin transitions. Bottom: ENDOR spectra shown when $|a|/(2\hbar) < |\omega_n|$ (B) and when $|\omega_n| < |a|/(2\hbar)$ (C).

For the simple system discussed above the advantages of performing double resonance do not become so

apparent: two lines are observed using either method, EPR or ENDOR. The situation dramatically changes when there are i groups of nuclei present, each group consisting of n_i magnetically equivalent nuclei with nuclear spin quantum number I_i , each one coupling to the unpaired electron spin with the hyperfine constant a_i . While the EPR spectrum will consist

-25-

of $\pi_i(2n_i I_i + 1)$ lines, for each group of equivalent nuclei, no matter how many nuclei there are or what their spin quantum number is, there will still be only two ENDOR lines separated by $|a_i|$ or $2\omega_{Ni}$. Hence, with increasing number of groups of nuclei the number of ENDOR lines increases only in an additive way. Since the ENDOR spectral lines are comparable in width to EPR lines, the reduced number of lines in the ENDOR spectrum results in a much greater effective resolution. Therefore, accurate values of the hyperfine couplings may be obtained from an ENDOR experiment even under conditions where the hyperfine pattern is not resolved in the EPR spectrum. In addition, ENDOR spectra become easier to interpret when there are nuclei with different magnetic moments involved. Their ENDOR lines normally appear in different frequency ranges and, from their Larmor frequencies, these nuclei can be immediately identified. ENDOR is also a well justified method when anisotropic hyperfine and nuclear quadrupole (for nuclei with $I \geq 1$) couplings in solids are to be measured. As an example, the ENDOR spectrum of the perinaphtheryl radical in liquid solution is depicted in figure B1.15.9 (see also figure B1.15.6 for a comparison with the CW EPR spectrum).

Figure B1.15.9. The ENDOR spectrum of the perinaphtheryl radical in mineral oil taken at room temperature. $|a_{\bigcirc}^H|/h = 17.68$ MHz and $|a_{\square}^H|/h = 5.12$ MHz are the hyperfine coupling constants for the protons in the position \bigcirc and \square , respectively. $|a_{\bigcirc}^H|/(g\beta_e) = 0.631$ mT and $|a_{\square}^H|/(g\beta_e) = 0.183$ mT.

The ENDOR experiment is performed at a constant external magnetic field by applying MW and RF fields in a continuous fashion. This technique is called CW ENDOR spectroscopy. The design of an ENDOR spectrometer differs only slightly from a basic CW or pulsed EPR spectrometer. A coil located around the sample tube within the resonant EPR cavity is used as an element in a RF transmitter circuit and is the source of a RF field. The basic elements of the RF circuit include a low-power signal source or sweeper and a high-power amplifier to produce an RF output signal that can be scanned over a wide frequency range (e.g. for proton ENDOR at X-band from approximately 4 to 30 MHz) at a power level up to 1 kW. To carry out an ENDOR experiment, the magnetic field B_0 is set at the resonance of one of the observed EPR transitions.

Then, the MW power is increased in order to partially saturate the EPR transition. The degree of saturation is provided by the saturation factor s defined earlier (see [equation \(b1.15.13\)](#)).

-26-

Finally, a strong RF oscillating field of varying frequency is applied to induce and saturate a transition within the nuclear sublevels. When the resonance condition for nuclear transitions is fulfilled, the saturated EPR transition can be desaturated by the ENDOR transition provided both transitions have energy levels in common. This desaturation of the EPR transition is detected as a change in the EPR absorption at characteristic frequencies ω_{ENDOR} , and constitutes the ENDOR response.

Phenomenologically, the ENDOR experiment can be described as the creation of alternative relaxation paths for the electron spins, which are excited with microwaves. In the four-level diagram of the $S=I=\frac{1}{2}$ system described earlier (see [figure B1.15.8](#)) relaxation can occur via several mechanisms: W_{1e} and W_{1n} describe the relaxation rates of the electron spins and nuclear spins, respectively. W_{x1} and W_{x2} are cross-relaxation rates in which electron and nuclear spin flips occur simultaneously. Excitation, for example, of the EPR transition $|-\rangle \leftrightarrow |+\rangle$ (i.e. $4 \leftrightarrow 2$) will equalize the population of both levels, 4 and 2, if the direct relaxation (characterized by the relaxation rate W_{1e}^{24}) cannot compete with the transitions induced by the resonant microwaves.

Simultaneous application of an RF field at a frequency corresponding to the $|+\rangle \leftrightarrow |-\rangle$ (i.e. $2 \leftrightarrow 1$) transition then opens a relaxation path via W_{1e}^{13} and W_{1n}^{34} or, more directly, via W_{x1} . The extent to which these relaxation bypasses can compete with the direct W_{1e}^{24} route controls the degree of desaturation of the EPR line, and, therefore, determines the ENDOR signal intensity, which, consequently, does not generally reflect the number of contributing nuclei (in contrast to EPR and NMR). The signal intensity observed depends very critically on the balance between the various relaxation rates and the magnitude of the MW and RF fields, B_1 and B_2 , respectively. Additional parameters to be varied in order to optimize the ENDOR signal-to-noise ratio are the radical concentration, the solvent viscosity and the temperature. The amplitude of ENDOR signals is furthermore influenced by the enhancement effect which occurs because the nucleus does not only experience the time-dependent magnetic field B_2 at the RF, but also an additional magnetic field component (the hyperfine field) due to the magnetic moment of the electron. Therefore, the effective field at the nucleus can be described as

$$B_2^{\text{eff}} = \kappa B_2 \quad (\text{B1.15.37})$$

where κ is the hyperfine enhancement factor. For isotropic HFI $\kappa = |1 - M_{\text{Sa}} / (\hbar \omega_N)|$. The hyperfine enhancement is one reason for the different intensities of the individual lines of an ENDOR line pair; at the same RF power the high-frequency line is usually more intense than the low-frequency one. Another reason for asymmetrical ENDOR line patterns is the effectiveness of the cross-relaxation paths: W_{x1} is in general different from W_{x2} , thus leading to an asymmetrical relaxation network and, as a consequence, to unequal signal intensities. In spectra of single crystals, powders and noncrystalline solids, however, the enhancement factor is governed by different hyperfine tensor components. This often leads to unexpected intensity patterns within ENDOR line pairs.

Despite the increased resolution of ENDOR compared to EPR, some restrictions concerning the information contents of ENDOR spectra persist: (1) unlike EPR, the relative signal intensities of ENDOR line pairs belonging to different groups of nuclei do not give any indication of the relative number of nuclei belonging to the individual groups; (2) the ENDOR spectrum does not give the sign of the hyperfine couplings, that is, one does not know which ENDOR transition belongs to which electron spin state. Both problems are addressed in triple resonance, which can be seen as an extension to ENDOR spectroscopy. Therefore, triple resonance experiments are very often carried out in order to supplement ENDOR data.

B1.15.5.2 ELECTRON–NUCLEAR–NUCLEAR TRIPLE RESONANCE

A refinement of the ENDOR experiment is electron–nuclear–nuclear triple resonance, now commonly denoted TRIPLE. In TRIPLE experiments one monitors the effect of a simultaneous excitation of two nuclear spin transitions on the level of the EPR absorption. Two versions, known as special TRIPLE (ST) and general TRIPLE (GT), are routinely performed on commercially available spectrometers.

(A) SPECIAL TRIPLE (ST)

The special TRIPLE technique [25, 26] is used for hyperfine couplings $|a|/(2h) < |\omega_N|$. In a typical experiment, RF is generated at two frequencies: one is fixed at the free nuclear frequency ω_N appropriate to the sort of nuclei under scrutiny and the second is swept. These two frequencies are multiplied to obtain the sum and the difference frequencies, $\omega_N \pm \omega_{RF2}$, which are used to irradiate the sample. The experiment can be understood using the energy level and relaxation scheme of figure B1.15.8. Both ENDOR transitions, ω_{ENDOR}^{\pm} (i.e. transitions $3 \leftrightarrow 4$ and $1 \leftrightarrow 2$), associated with the same nucleus are simultaneously excited. In cases of vanishing cross-relaxation the second saturating RF field enhances the efficiency of the relaxation bypass, thus increasing the signal intensity, particularly in cases where W_N is the rate-limiting step (because $W_n \ll W_c$). A second advantage of ST resonance over ENDOR is that when both RF fields are sufficiently strong to completely saturate nuclear transitions the EPR desaturation becomes independent of W_N . Consequently, the line intensities are no longer determined by the relaxation behaviour of the various nuclei, but rather reflect the number of nuclei involved in the transition. Finally, ST also has the advantage of higher resolution because the effective saturation of nuclear transitions results in smaller observed linewidths compared to ENDOR.

(B) GENERAL TRIPLE (GT)

In a general TRIPLE (GT) experiment one particular ENDOR transition is pumped with the first RF while the second RF is scanned over the whole range of nuclear resonances [27]. Therefore, nuclear transitions of different sets of nuclei of the same kind or of different kinds are saturated simultaneously and the effect on the ENDOR transitions for all the hyperfine couplings in the system is measured. Clearly, ST is included within GT. From the characteristic intensity changes of the high-frequency and low-frequency signals compared with those of the ENDOR signals the relative signs of the hyperfine coupling constants can easily be determined.

B1.15.5.3 ELECTRON–ELECTRON DOUBLE RESONANCE (ELDOR)

ELDOR is the acronym for electron–electron double resonance. In an ELDOR experiment [28] one observes a reduction in the EPR signal intensity of one hyperfine transition that results from the saturation of another EPR transition within the spin system. ELDOR measurements are still relatively rare but the experiment is firmly established in the EPR repertoire.

With help of the four-level diagram of the $S=I=\frac{1}{2}$ system (see figure B1.15.8) two common ways for recording ELDOR spectra will be illustrated. In frequency-swept ELDOR the magnetic field is set at a value that satisfies the resonance condition for one of the two EPR transitions, e.g. $4 \leftrightarrow 2$, at the fixed observe klystron frequency, ω_{obs} . The pump klystron is then turned on and its frequency, ω_{pump} , is swept. When the pump frequency passes through the value

that satisfies the resonance condition of the $3 \leftrightarrow 1$ transition, there is a decrease in the signal at the frequency ω_{obs} which constitutes the ELDOR signal. In field-swept ELDOR the pumping and observing MW frequencies are held fixed at predetermined values and the magnetic field is swept through the region of resonance. ELDOR experiments are technically more difficult than ENDOR: simultaneous EPR in one magnetic field for two different transitions requires irradiation simultaneously at two MW frequencies. That is, one requires a resonator tunable to two MW frequencies separated by a multiple of the hyperfine coupling. The development of loop-gap and split-ring resonators has, because of their wide bandwidth and the feasibility of high filling factors, made ELDOR a truly practical technique.

To analyse ELDOR responses, the reduction of the observed EPR transition at ω_{obs} is expressed quantitatively in terms of the ELDOR reduction factor

$$R = \frac{I(\omega_{\text{pump}} = 0) - I(\omega_{\text{pump}})}{I(\omega_{\text{pump}} = 0)} \quad (\text{B1.15.38})$$

where $I(\omega_{\text{pump}}=0)$ is the observed EPR intensity with pump power off, and $I(\omega_{\text{pump}})$ is the intensity with pump power on. The ELDOR technique is very sensitive to the various relaxation mechanisms involved. For the $S=I=\frac{1}{2}$ system R may be expressed in terms of the six relaxation rates between the four energy levels that are indicated in [figure B1.15.8](#). With the assumption $W_e^{13}=W_e^{24}=W_e$ and $W_N^{12}=W_N^{34}=W_N$ the ELDOR reduction factor is given by

$$R = \frac{W_n^2 - W_{x1} W_{x2}}{W_c(2W_n + W_{x1} + W_{x2}) + (W_n + W_{x1})(W_n + W_{x2})} \quad (\text{B1.15.39})$$

which shows that the ELDOR response will be a reduction if $W_N^2 > W_{x1} W_{x2}$. If modulation of dipolar hyperfine couplings is the dominant relaxation mechanism, this condition can be fulfilled for dilute radical concentrations at low temperatures. At high concentrations or sufficiently high temperatures, Heisenberg spin exchange or chemical exchange, which tends to equalize the population of all spin levels, is the dominant ELDOR mechanism.

ELDOR has been employed to study a number of systems such as inorganic compounds, organic compounds, biologically important compounds and glasses. The potential of ELDOR for studying slow molecular motions has been recognized by Freed and coworkers [29, 30].

B1.15.6 PULSED EPR SPECTROSCOPY

By far the greatest advantage of pulsed EPR [31, 32] lies in its ability to manipulate the spin system nearly at will and, thus, to measure properties that are not readily available from the CW EPR spectra. Nevertheless, EPR has long remained a domain of CW methods. In contrast to the rapid development of pulsed NMR spectroscopy, the utilization of the time domain in EPR took a much longer time, even though the underlying principles are essentially the same. There are several reasons for this slow development of pulsed EPR. (1) The large energies involved in electron spin interactions (see [figure B1.15.3](#)) can give rise to spectral widths of the order of 10–25% of the carrier frequency

(at X-band) as opposed to the ppm scale which applies to NMR. Consequently, with the exception of some organic radicals in solution and a few defect centres in single crystals, it is technically impossible to excite the

entire EPR spectrum by a pulse of electromagnetic radiation. (2) CW EPR records derivatives of absorption spectra by using magnetic field modulation in a range between 10 kHz and 100 kHz, a method that takes advantage of narrowband detection at the modulation frequency (see [figure B1.15.5](#)) and of better resolution of the derivative as compared to the absorption lineshape (see [figure B1.15.6](#)). Calculating the derivative from the absorption lineshape obtained with pulsed methods results in a decrease in the signal-to-noise ratio. For these reasons, CW EPR is typically more sensitive than pulsed EPR at a given resolution. (3) Finally, the fact that electron spin relaxation times are orders of magnitudes shorter than the nuclear spin relaxation times encountered in NMR makes the technology required to perform pulsed EPR experiments much more demanding.

In recent years, however, enormous progress has been made and with the availability of the appropriate MW equipment pulsed EPR has now emerged from its former shadowy existence. Fully developed pulse EPR instrumentation is nowadays commercially available [31, 33].

The practical goal for pulsed EPR is to devise and apply pulse sequences in order to isolate pieces of information about a spin system and to measure that information as precisely as possible. To achieve this goal it is necessary to understand how the basic instrumentation works and what happens to the spins during the measurement.

B1.15.6.1 PULSES AND THEIR EFFECTS

For an understanding of pulsed excitation of spin ensembles it is of fundamental importance to realize that radiation pulses actually contain ranges of frequencies: A burst of monochromatic microwaves at frequency ω_{MW} and of pulse duration t_p translates into a frequency spectrum of the pulse that has field components at all frequencies. The amplitude of the field drops off as one moves away from the carrier frequency ω_{MW} according to $B_1(\omega) \propto B_1 \sin(\omega_{\text{MW}t_p})/(\omega_{\text{MW}t_p})$. The excitation bandwidth of a specific pulse depends only on the pulse duration, t_p .

The effect of an MW pulse on the macroscopic magnetization can be described most easily using a coordinate system (x', y', z) which rotates with the frequency ω_{MW} about the z -axis defined by the applied field \mathbf{B} . Initially, the net magnetic moment vector \mathbf{M} is in its equilibrium position oriented parallel to the direction of the strong external field. In the rotating frame, \mathbf{B}_1 is a stationary field, which is assumed to be oriented parallel to the x' -axis of the rotating coordinate system. The result of applying a short intense MW pulse is to rotate the magnetization \mathbf{M} about the axis defined by \mathbf{B}_1 , i.e. the x' -axis, through the flip angle $\theta = \gamma_e B_1 t_p = \omega_1 t_p$, expressed in radians. When the duration of the MW radiation at a given MW power level is just long enough to flip \mathbf{M} into the $x'y'$ -plane, the pulse is defined as a $\pi/2$ -pulse. Immediately after the cessation of the pulse, \mathbf{M} has been rotated with its magnitude unaltered (if relaxation phenomena are negligible during the excitation pulse) to an orientation perpendicular to \mathbf{B}_1 at angle θ with respect to $B_0 \parallel z$. After this perturbation the system is then allowed to return to its equilibrium, or, after an appropriate delay, additional pulses with specific flip angles and phases are applied to further manipulate the spin system. With suitable apparatus, that is, the detection system aligned in the direction of the y' -axis of the rotating axis system, the temporal behaviour of the y' -component of the magnetization can be followed. The normalized FT of the function $M_{y'}(t)$ provides the lineshape which is analogous to that obtained from CW EPR experiments under nonsaturating conditions.

B1.15.6.2 INSTRUMENTATION

The design of a pulsed EPR spectrometer depends heavily on the required pulse length and pulse power which in turn are mainly dictated by the relaxation times of the paramagnetic species to be studied, but also by the type of experiment performed. When pulses of the order of a few nanoseconds are required (either to compete

with the relaxation times or to excite a broad spectral range) not only is high MW power needed to fulfill the condition $\gamma_e B_1 t_p = \pi/2$, but also the whole design of such a high power spectrometer becomes much more complex and the construction is more expensive. In most of today's pulsed EPR spectrometers the MW pulses are formed on a low-power level by fast switching diodes after the CW source. These low-power pulses are then fed into a pulsed high-power MW amplifier (typically a travelling-wave tube amplifier) capable of giving the requisite high power up to a few kW. The amplified pulses are then directed into a resonant cavity to excite the EPR transitions of the system. The MW power in the resonator grows as $[1 - \exp(-\omega_{MW}t/Q)]$ and decays as $\exp(-\omega_{MW}t/Q)$ in response to a square, resonant pulse. An important consideration in a pulsed EPR spectrometer is the detection deadtime, or how soon after a pulse the signal $M_{y'}(t)$ can be measured. Typically, the deadtime is taken to be the time when ringing from the resonator equals thermal noise. The choice of an appropriate resonator for pulsed EPR experiments is therefore always influenced by the conflicting demands for a short deadtime and good sensitivity: a low quality factor Q for bandwidth coverage and fast instrumental response should be combined with concentrated MW fields for short pulses and high filling factor, the latter in partial compensation for the loss in sensitivity in favour of fast time resolution. The spin system responds to the exciting MW pulses by producing a signal at a later time when the incident pulses are off. A low-noise amplifier amplifies the signal to a level well above the noise floor of the detector. Standard Schottky barrier diodes can be used as detectors up to a bandwidth of 5 MHz. For broader bandwidths, multiplying mixers can be employed to downconvert the signal from the sample to a video signal centred at zero frequency. (The mixer output is the sum or the difference of two input frequencies and the signal amplitudes are proportional to the input amplitudes.) A quadrature mixer has two inputs, one for the signal and one for a reference from the master MW oscillator. Its two outputs are in quadrature with each other: one is out of phase by 90° and the other in phase with the pulse phase. Quadrature detection means that, unlike the case in other spectrometers, the reference arm needs no phase shifter since the phase of the recorded signal can be adjusted digitally by taking a linear combination of the two quadrature components. Typically, the low-noise MW amplifier and the mixer detector are very sensitive to high-power reflections from the cavity and, therefore, have to be protected during the excitation pulse. A gated PIN-diode switch in front of the amplifier strongly attenuates the input of the detection system during the excitation pulses and, therefore, avoids saturation or permanent damage.

B1.15.6.3 PULSE EPR METHODS

(A) FOURIER TRANSFORM EPR (FT EPR)

All operating principles are the same as in FT NMR. A single short and intense MW pulse (typically a $\pi/2$ -pulse along x') is applied to flip the magnetizations into the $x'y'$ -plane of the rotating frame (see [figure B1.15.10\(A\)](#)). The induced signal proportional to $M_{y'}$, will decay due to transverse relaxation or sample inhomogeneities. This process is called free induction decay (FID). The complete spectrum is obtained without the need of a field sweep via FT of the FID. Under most conditions, the FT EPR spectrum measured using a single excitation pulse corresponds exactly to the CW EPR spectrum. Today's state-of-the-art pulsed EPR spectrometers feature $\pi/2$ -pulse lengths of $t_p \approx 5$ ns or less, corresponding to an excitation bandwidth of roughly 200 MHz. Therefore, FT EPR is applicable to not too wide spectral patterns consisting of narrow lines (as typical for free radicals in solution) with long enough T_2 so that the

FID does not die away before the deadtime has elapsed. In the case of inhomogeneously broadened EPR lines (as typical for free radicals in solids) the dephasing of the magnetizations of the individual spin packets (which all possess slightly different resonance frequencies) will be complete within the detection deadtime and, therefore, the FID signal will usually be undetectable.

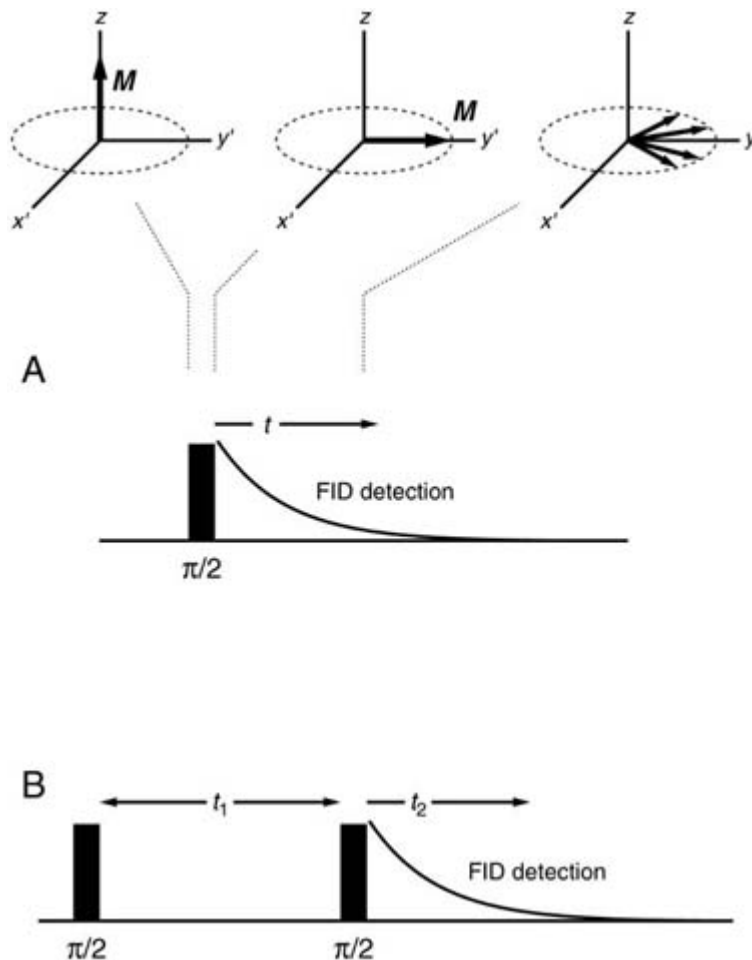

Figure B1.15.10. FT EPR. (A) Evolution of the magnetization during an FT EPR experiment (rotating frame representation). (B) The COSY FT EPR experiment.

In complete analogy to NMR, FT EPR has been extended into two dimensions. Two-dimensional correlation spectroscopy (COSY) is essentially subject to the same restrictions regarding excitation bandwidth and detection deadtime as was described for one-dimensional FT EPR. In 2D-COSY EPR a second time dimension is added to the FID collection time by a preparatory pulse in front of the FID detection pulse and by variation of the evolution time between them (see figure B1.15.10(B)). The FID is recorded during the detection period of duration t_2 , which begins with the second $\pi/2$ -pulse. For each t_1 the FID is collected, then the phase of the first pulse is advanced by 90° , and a second set of FIDs is collected. The two sets of FIDs, whose amplitudes oscillate as functions of t_1 , then undergo a two-dimensional complex Fourier transformation, generating a spectrum over the two frequency variables ω_1 and ω_2 .

The peaks along the leading diagonal $\omega_1 = \omega_2$ correspond to the usual absorption spectrum, whereas the cross-peaks (peaks removed from the diagonal) provide evidence for cross-correlations.

(B) ELECTRON-SPIN ECHO (ESE) METHODS

Under conditions where the rapid decay of the FID following a single excitation pulse is governed by inhomogeneous broadening the dephasing of the individual spin packets in the $x'y'$ -plane can be reversed by the application of a second MW pulse in an ESE experiment (see figure B1.15.11) [34]. As before, the experiment begins with the net electron spin magnetization \mathbf{M} aligned along the magnetic field direction z . At the end of the first $\pi/2$ -pulse, which is applied at the Larmor precession frequency ω_0 , with the amplitude B_1

pointing along the x' -direction, the net magnetic moment is in the equatorial plane. Immediately, the magnetization starts to decay as different spin packets precess about z at their individual Larmor frequencies $\omega_i \neq \omega_0$. In the rotating frame the contributions of different spin packets to the magnetization MD_y , appear to fan out as shown in [figure B1.15.11\(A\)](#) : viewed in the laboratory frame some spins would appear to precess faster ($\omega_i > \omega_0$) and some slower ($\omega_i < \omega_0$) than the average. As a result, the FID decays rapidly and after a short time there is no detectable signal. From this FID an echo can be generated by means of a second MW pulse, applied at time τ after the first pulse. The second pulse is just long enough to turn the magnetization vectors through 180° about the x' -axis. The original precession frequencies and the directions of rotation of the individual components will remain unaltered and, therefore, the magnetizations will rotate toward each other in the $x'y'$ -plane until they refocus after the same time τ into a macroscopic magnetic moment along the $-y'$ -axis. At this point the spin alignment produces a microwave field B_1 in the cavity corresponding to an emission signal that is referred to as an echo [34].

As the spins precess in the equatorial plane, they also undergo random relaxation processes that disturb their movement and prevent them from coming together fully realigned. The longer the time τ between the pulses the more spins lose coherence and consequently the weaker the echo. The decay rate of the two-pulse echo amplitude is described by the phase memory time, T_M , which is the time span during which a spin can remember its position in the dephased pattern after the first MW pulse. T_M is related to the homogeneous linewidth of the individual spin packets and is usually only a few microseconds, even at low temperatures.

The two-pulse sequence $\pi/2-\tau-\pi-\tau$ is not the only sequence which leads to the formation of an echo. A pulse sequence which has proven to have particular value consists of three $\pi/2$ -pulses as depicted in [figure B1.15.11\(B\)](#). In this three-pulse sequence with pulse intervals τ and T a so-called stimulated echo is formed after an interval τ following the third pulse. The mechanism of formation of the stimulated echo is a little more complicated than that of the primary echo and the reader is referred to some excellent review articles [32, 35, 36] for a comprehensive discussion of this topic. Here it is sufficient to mention that with the second $\pi/2$ -pulse the y' -components of the dephased magnetization pattern are temporarily stored in the $x'z'$ -plane where they remain during the waiting time T . The third MW pulse brings the M_z magnetizations back into the $x'y'$ -plane, where they continue their time evolution and give rise to the stimulated echo at time τ after the third pulse. The characteristic time of the three-pulse echo decay as a function of the waiting time T is much longer than the phase memory time T_M (which governs the decay of a two-pulse echo as a function of τ), since the phase information is stored along the z -axis where it can only decay via spin–lattice relaxation processes or via spin diffusion.

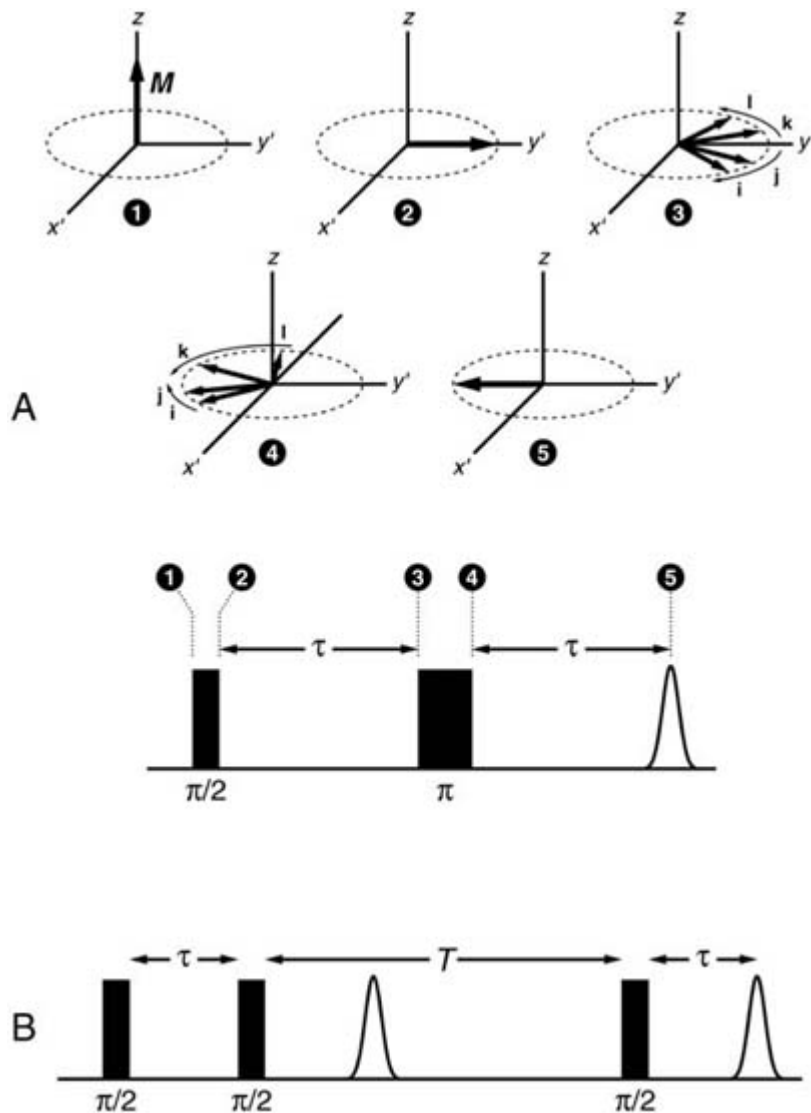

Figure B1.15.11. Formation of electron spin echoes. (A) Magnetization of spin packets i, j, k and l during a two-pulse experiment (rotating frame representation). (B) The pulse sequence used to produce a stimulated echo. In addition to this echo, which appears at τ after the third pulse, all possible pairs of the three pulses produce primary echoes. These occur at times 2τ , $2(\tau+T)$ and $(\tau+2T)$.

In electron-spin-echo-detected EPR spectroscopy, spectral information may, in principle, be obtained from a Fourier transformation of the second half of the echo shape, since it represents the FID of the refocused magnetizations, however, now recorded with much reduced deadtime problems. For the inhomogeneously broadened EPR lines considered here, however, the FID and therefore also the spin echo, show little structure. For this reason, the amplitude of the echo is used as the main source of information in ESE experiments. Recording the intensity of the two-pulse or three-pulse echo amplitude as a function of the external magnetic field defines electron-spin-echo- (ESE-)

detected EPR spectroscopy. Such a field-swept ESE spectrum is similar to the conventional CW EPR spectrum except for the fact that the lines appear in absorption and not in the more familiar first derivative form.

ESE-detected EPR spectroscopy has been used advantageously for the separation of spectra arising from different paramagnetic species according to their different echo decay times. Furthermore, field-swept ESE

spectroscopy is superior to conventional CW EPR when measuring very broad spectral features. This is because the field modulation amplitudes used in CW EPR to detect the first derivative of the signal are often too small compared to the width of the EPR line, so that the gradient of the absorption signal becomes very small. Such features are either invisible in CW EPR or obscured by baseline drifts, while they can be well distinguished in the absorption spectra with ESE-detected EPR.

In electron spin echo relaxation studies, the two-pulse echo amplitude, as a function of the pulse separation time τ , gives a measure of the phase memory relaxation time T_M from which T_2 can be extracted if T_1 -effects are taken into consideration. Problems may arise from spectral diffusion due to incomplete excitation of the EPR spectrum. In this case some of the transverse magnetization may leak into adjacent parts of the spectrum that have not been excited by the MW pulses. Spectral diffusion effects can be suppressed by using the Carr–Purcell–Meiboom–Gill pulse sequence, which is also well known in NMR. The experiment involves using a sequence of π -pulses separated by 2τ and can be denoted as $[\pi/2-(\tau-\pi-\tau\text{-echo})_n]$. A series of echoes separated by 2τ is generated and the decay in their amplitudes is characterized by T_M .

The other important (spin–lattice) relaxation time T_1 is accessible with the help of an additional preparation, e.g. an inversion (i.e. a π -pulse) or saturation pulse (a single long pulse or a chain of short $\pi/2$ -pulses) placed with a variable delay time T in front of a two-pulse ESE sequence. The T_1 -information is then extracted from the dependence of the echo amplitude on the interval T . Experiments of this type are generally called ‘inversion recovery’ or ‘saturation recovery’ experiments. In principle T_1 can also be estimated from the amplitude of the stimulated echo, as the z -magnetization relaxes towards thermal equilibrium during the variable pulse delay time T . Here, inaccuracies in measuring T_1 may again originate from spectral diffusion and the interaction between the electron spin and the nuclear spins which can affect the amplitude of the echo.

The electron-spin echo envelope modulation (ESEEM) phenomenon [37, 38] is of primary interest in pulsed EPR of solids, where anisotropic hyperfine and nuclear quadrupole interactions persist. The effect can be observed as modulations of the echo intensity in two-pulse and three-pulse experiments in which τ or T is varied. In liquids the modulations are averaged to zero by rapid molecular tumbling. The physical origin of ESEEM can be understood in terms of the four-level spin energy diagram for the $S = I = \frac{1}{2}$ model system introduced earlier to describe ENDOR (see [figure B1.15.8](#)). So far, however, only isotropic hyperfine couplings have been considered, leading to an EPR spectrum of this system that comprises the two allowed transitions $1 \leftrightarrow 3$ and $2 \leftrightarrow 4$ with $\Delta M_S = \pm 1$ and $\Delta M_I = 0$. The situation is different for the case where the hyperfine couplings are anisotropic and, in particular, of the same order of magnitude as the nuclear Zeeman couplings. Because of the anisotropic nature of the interactions, the energy levels of the spin system are modified and the nuclear spin states are mixed. As a consequence, the transitions $1 \leftrightarrow 4$ and $2 \leftrightarrow 3$ involving a simultaneous nuclear spin transition (both forbidden for the isotropic case) are now also allowed to some extent. In [figure B1.15.12\(A\)](#) the evolution of this spin system in a two-pulse echo experiment (see [figure B1.15.11\(A\)](#)) is considered. Since there are four transitions, there are four components of the magnetization to keep track of. For simplicity, only the magnetizations of two transitions, ω_{24} and ω_{14} (labelled \mathbf{a} and \mathbf{f} , respectively), originating from the same nuclear spin level in the lower electron spin manifold, are considered. By applying sufficiently short MW pulses both allowed and forbidden transitions are excited simultaneously. After the first $\pi/2$ -pulse, the two sets of electrons

are precessing at two different frequencies separated by the nuclear frequency. If spin packet \mathbf{a} is on resonance ($\omega_{24} = \omega_{MW}$), its component of the magnetization is fixed in the rotating frame, whereas the magnetization component \mathbf{f} precesses with frequency $\omega_{14} - \omega_{MW} = \omega_{12}$. After the time τ , the π -pulse inverts the vector \mathbf{a} into the $-y'$ -direction, and at the same time, because of the branching of transitions, gives rise to a new component \mathbf{f}' . The effect of the π -pulse on the magnetization component \mathbf{f} is a rotation about x' by 180° and the formation of a component \mathbf{a}' according to the ratio of the transition probabilities for allowed and forbidden transitions. \mathbf{a} and \mathbf{a}' will remain unaltered in the rotating frame (because they are on resonance),

whereas the two vectors \mathbf{f} and \mathbf{f}' continue to precess with the off-resonance frequency ω_{12} . At time τ , \mathbf{f} will refocus with \mathbf{a} at the $-y'$ -axis to form an echo, but the vectors \mathbf{a}' and \mathbf{f}' will not contribute, because they are no longer oriented along $-y'$. This results in a reduction of the echo intensity at time τ . The component \mathbf{f}' will only contribute to the echo if, in time τ , it precesses an integral number of times in the $x'y'$ -plane. Therefore, the echo amplitude oscillates in proportion to $\cos(\omega_{12}\tau)$. The same holds for any combination of transitions with energy levels in common. Therefore, one expects the echo intensity to oscillate not only with the nuclear frequencies ω_{12} and ω_{34} but also with the sum and the difference of these frequencies. By FT of the echo envelope an ENDOR-like spectrum is obtained. The amplitudes of the modulation frequencies are determined by the depth parameter $k=4I_a I_f / (B\omega_N / (\omega_{12}\omega_{34}))^2$, where I_a and I_f denote the intensities of the allowed and forbidden transitions, respectively. B/ω_N is a measure of the anisotropy of the hyperfine coupling tensor. Large modulation amplitudes are expected for $\omega_{12}, \omega_{34} \rightarrow 0$. This is in contrast to ENDOR spectroscopy, where the enhancement factor and, therefore, the ENDOR line intensities, decrease for small nuclear transition frequencies. For small hyperfine coupling constants $\omega_{12} \approx \omega_{34} \approx \omega_N$ and $k \propto (B/\omega_N)^2$. Again in contrast to ENDOR, the ESEEM modulation depth will increase for nuclei with smaller γ_n .

The stimulated (three-pulse) echo decay may also be modulated, but only by the nuclear frequencies ω_{12} and ω_{34} and not by their sum and difference frequencies. The qualitative reason for this is that the first pulse generates modulation at the nuclear frequencies; the second pulse additionally incorporates the sum and difference frequencies and the third pulse causes interference of the sum and difference frequencies to leave only the ENDOR frequencies. Apart from the depth parameter k the modulation amplitudes of the ENDOR frequencies ω_{12} and ω_{34} are determined by $\sin^2(\omega_{34}\tau/2)$ and $\sin^2(\omega_{12}\tau/2)$, respectively. As a consequence, so-called blind spots can occur. For example, if ω_{34} is an integral multiple of π , i.e. $\tau=2\pi n/\omega_{34}$, then the modulation at ω_{12} is completely suppressed. Therefore, the dependence on the response on τ should also be examined.

The main advantage of the three-pulse ESEEM experiment as compared to the two-pulse approach lies in the slow decay of the stimulated echo intensity determined by T_1 , which is usually much longer than the phase memory time T_M that limits the observation of the two-pulse ESE.

More sophisticated pulse sequences have been developed to detect nuclear modulation effects. With a five-pulse sequence it is theoretically possible to obtain modulation amplitudes up to eight times greater than in a three-pulse experiment, while at the same time the unmodulated component of the echo is kept close to zero. A four-pulse ESEEM experiment has been devised to greatly improve the resolution of sum-peak spectra.

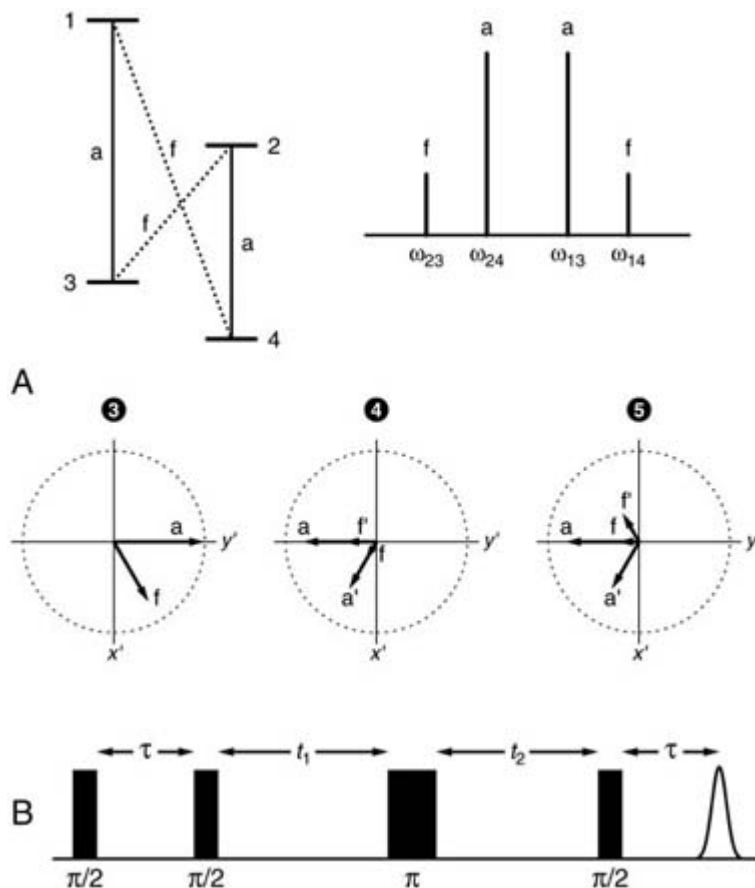

Figure B1.15.12. ESEEM spectroscopy. (A) Top: energy level diagram and the corresponding stick spectrum for the two allowed (**a**) and two forbidden (**f**) transitions. Bottom: time behaviour of the magnetization of an allowed (**a**) spin packet and a forbidden (**f**) spin packet during a two-pulse ESE sequence (see [figure B1.15.11 \(A\)](#)). (B) The HYSORE pulse sequence.

In the 2D three-pulse ESEEM technique both the time intervals $t_1 = \tau$ and $t_2 = T$ of a stimulated echo sequence are independently increased in steps (see [figure B1.15.11\(B\)](#)) [39]. If the spacing between the first two pulses, τ , is varied over a sufficiently broad range, blind spots, which caused problems in one-dimensional spectra, do not arise in this 2D ESEEM method. Combination cross peaks arising from couplings with several inequivalent nuclei can be used to determine the relative signs of the hyperfine splittings. A disadvantage of the 2D three-pulse ESEEM technique is that the echo intensities decay at different rates along the two time axes, with T_M -relaxation along the t_1 -axis and T_1 -relaxation along the t_2 -axis. As a result, the linewidths in the two frequency dimensions can differ by orders of magnitude.

An alternative 2D ESEEM experiment based on the four-pulse sequence depicted in [figure B1.15.12\(B\)](#) has been proposed by Mehring and coworkers [40]. In the hyperfine sublevel correlation (HYSORE) experiment, the decay of the echo intensity as a function of t_1 is governed by T_1 -relaxation, whereas the echo decay along the t_2 -axis is

determined by the T_2 -relaxation of the nuclei. Since both relaxation processes are fairly slow, the resolution along both frequency dimensions is much increased compared to the 2D three-pulse ESEEM experiment. In the HYSORE experiment, too, the positions of the cross-peaks can be used to determine the relative signs of the hyperfine coupling constants.

The ESEEM methods are best suited for the measurement of small hyperfine couplings, e.g. for the case of

nuclear spins with small magnetic moment. Larger hyperfine interactions can be measured best by pulsed versions of ENDOR spectroscopy. These methods will be introduced as a final application of the pulsed excitation scheme introduced earlier. Pulsed ENDOR methods are double-resonance techniques wherein, at some particular time in an ESE pulse sequence, a RF pulse is applied that is swept in frequency to match resonance with the hyperfine-coupled nuclei. The typical pulse schemes for the most commonly used versions of pulsed ENDOR, termed Mims- [41] and Davies-type [42] ENDOR to acknowledge those who originally introduced them, are depicted in [figure B1.15.13](#). In both experiments the ENDOR effect is manifested in a change of the ESE intensity when the RF field is on nuclear resonance. The ENDOR spectrum can thus be recorded by detecting the echo amplitude as a function of the frequency of the RF pulse.

The Davies-ENDOR technique is based on an inversion recovery sequence (see [figure B1.15.13\(A\)](#)). The experiment starts by interchanging the populations of levels 1 and 3 of one of the EPR transitions of the $S=I=\frac{1}{2}$ model spin system by means of a first selective MW π -pulse (with a strength $|\omega_1| \ll |A|/\hbar$). Neglecting relaxation during the time span T , a two-pulse ESE sequence performed after time $t=T$ produces an echo which is inverted with respect to a two-pulse ESE applied to the same spin system at thermal equilibrium. When, during the time span T , a selective RF π -pulse is applied, the two-pulse ESE will disappear as soon as the RF field is on resonance with one of the two transitions $1\leftrightarrow 2$ or $3\leftrightarrow 4$. This is because the populations of the nuclear sublevels are interchanged by the RF pulse, which simultaneously equalizes the populations of the on-resonant EPR transition. The ENDOR effect will not be observable if the preparation pulse (i.e. MW pulse 1) and/or the two-pulse ESE sequence are non-selective.

Mims ENDOR involves observation of the stimulated echo intensity as a function of the frequency of an RF π -pulse applied between the second and third MW pulse. In contrast to the Davies ENDOR experiment, the Mims-ENDOR sequence does not require selective MW pulses. For a detailed description of the polarization transfer in a Mims-type experiment the reader is referred to the literature [43]. Just as with three-pulse ESEEM, blind spots can occur in ENDOR spectra measured using Mims' method. To avoid the possibility of missing lines it is therefore essential to repeat the experiment with different values of the pulse spacing τ . Detection of the echo intensity as a function of the RF frequency and τ yields a real two-dimensional experiment. An FT of the τ -domain will yield cross-peaks in the 2D-FT-ENDOR spectrum which correlate different ENDOR transitions belonging to the same nucleus. One advantage of Mims ENDOR over Davies ENDOR is its larger echo intensity because more spins due to the nonselective excitation are involved in the formation of the echo.

Pulsed ENDOR offers several distinct advantages over conventional CW ENDOR spectroscopy. Since there is no MW power during the observation of the ESE, klystron noise is largely eliminated. Furthermore, there is an additional advantage in that, unlike the case in conventional CW ENDOR spectroscopy, the detection of ENDOR spin echoes does not depend on a critical balance of the RF and MW powers and the various relaxation times. Consequently, the temperature is not such a critical parameter in pulsed ENDOR spectroscopy. Additionally the pulsed technique permits a study of transient radicals.

Figure B1.15.13. Pulsed ENDOR spectroscopy. (A) Top: energy level diagram of an $S=I=\frac{1}{2}$ spin system (see also [figure B1.15.8\(A\)](#)). The size of the filled circles represents the relative population of the four levels at different times during the (3+1) Davies ENDOR sequence (bottom). (B) The Mims ENDOR sequence.

More advanced pulsed techniques have also been developed. For a review of pulsed ENDOR techniques the reader is referred to [\[43, 44 and 45\]](#).

B1.15.7 HIGH-FIELD EPR SPECTROSCOPY

Since its discovery in 1944 by Zavoisky, EPR has typically been performed at frequencies below 40 GHz. This limitation was a technical one, but recent developments in millimetre and submillimetre wave frequency technology and magnetic field technology have enabled the exploration of ever higher EPR frequencies [\[46, 47 and 48\]](#). High-field/high-frequency EPR spectroscopy has a number of inherent advantages [\[47\]](#). (1) The spectral resolution of g -factor differences and anisotropies greatly improves since the electron Zeeman interaction scales linearly with the magnetic field (see [equation \(b1.15.18\)](#)). If paramagnetic centres with different g -values or different magnetic sites of rather similar g -values are present, the difference in the spectral field positions of the resonances is proportional to the MW frequency ω

$$\Delta B_0 = \frac{\hbar\omega}{\beta_c} \left(\frac{1}{g_1} - \frac{1}{g_2} \right). \quad (\text{B1.15.40})$$

Even for a single radical the spectral resolution can be enhanced for disordered solid samples if the inhomogeneous linewidth is dominated by unresolved hyperfine interactions. Whereas the hyperfine line broadening is not field dependent, the anisotropic \mathbf{g} -matrix contribution scales linearly with the external field. Thus, if the magnetic field is large enough, i.e. when the condition

$$\frac{\Delta g}{g_{\text{iso}}} B_0 > B_{1/2}^{\text{HFI}} \quad (\text{B1.15.41})$$

is fulfilled, the powder spectrum is dominated by the anisotropic \mathbf{g} -matrix. equation (b1.15.41) may be considered as the high-resolution condition for solid-state EPR spectra, to be fulfilled only at high enough B_0 . From [figure B1.15.14](#) one sees that for a nitroxide spin label in a protein this is fulfilled almost completely at 95 GHz, but not at 10 GHz. In the case of well resolved g -anisotropy the extension to high-field ENDOR and ESEEM has the additional advantage of providing single-crystal-like hyperfine information when transitions are excited at field positions where only specific orientations of the \mathbf{g} -matrix with respect to the external magnetic field contribute to the spectrum. (2) Relaxation times become longer for many systems at higher frequencies. (3) Particularly in studies of small samples, high-field/high-frequency EPR is typically more sensitive compared to EPR at X-band frequencies, by virtue of the increased Boltzmann factor (see [equation \(b1.15.10\)](#)). (4) For high-spin systems with zero-field splittings larger than the MW quantum it is impossible to observe all EPR transitions. Here, higher-frequency experiments are essential for recording the whole spectrum. (5) At high frequencies it becomes possible to violate the high-temperature approximation with standard cryogenic systems. This effect can be exploited to gain information on the absolute sign of parameters of the spin Hamiltonian.

Figure B1.15.14. Comparison of 95.1 GHz (A) and 9.71 GHz (B) EPR spectra for a frozen solution of a nitroxide spin label attached to insulin measured at 170 K.

Disadvantages of high-field/high-frequency EPR are mainly technical ones due to the limited availability of MW components operating at millimetre and submillimetre wavelengths and the high costs of spectrometer development. Furthermore, low-frequency EPR will not be completely superseded by high-field/high-frequency EPR because some experiments that rely on the violation of the high-field approximation no longer work when increasing the EPR frequency. The largest disadvantages occur in studies of proton interactions, where ESEEM is a convenient tool at X-band but cannot be used at W-band frequencies and above because of too small modulation depths for most systems. Nevertheless, these drawbacks are outweighed by the advantages to such an extent that high-field/high-frequency EPR methods will become more and more widespread as one overcomes the technical hurdles.

The early high-field/high-frequency EPR spectrometers were developed mostly on the basis of klystron MW generators. In the past few years, however, solid-state MW sources such as Gunn oscillators or IMPATT diodes were applied more frequently. To improve their mediocre frequency stability they need to be phase locked to a low-frequency stable reference source. If frequencies higher than approximately 150 GHz are required, the output frequency of the solid-state MW generator can be multiplied in a Schottky diode harmonic generator (multiplication factors between 2 and 5). To generate even higher frequencies up to 1 THz more exotic high-power pulsed and CW tube sources such as gyrotrons, extended interaction oscillators

(EIOs), backward wave oscillators (BWOs) or magnetrons are available. Their spectral characteristics may be favourable; however, they typically require highly stabilized high-voltage power supplies. Still higher frequencies may be obtained using far-infrared gas lasers pumped for example by a CO_2 laser [49].

All the waveguide elements become very small at high frequencies as compared to the standard X-band or even Q-band. This produces high losses up to several decibels per metre due to waveguide imperfections. Therefore, if millimetre and submillimetre waves have to be transmitted over long (and straight) distances, oversized or corrugated waveguides are normally used because of their smaller ohmic losses. Corrugated waveguides have narrow grooves, each a quarter-wavelength deep, cut into the guide walls. The effect of the grooves is to destructively average the **E** field near the wall surface which cannot now have a non-zero component perpendicular to the surface. To couple to a resonant cavity, however, these waveguides need to be tapered back to the fundamental-mode waveguide. Very recently developed EPR spectrometers operating at 130 GHz [50], 250 GHz [51] and 360 GHz [52] (see [figure B1.15.15](#) for waveguides for millimetre-wave transmission for the most part. Instead quasi-optic techniques are used [53]. Once millimetre-waves have been converted into Gaussian beams by means of corrugated feedhorns they can be transported and manipulated in free space using quasi-optical elements such as lenses (constructed from Teflon or high-density polyethylene) and off-axis mirrors. The losses in these elements are virtually negligible.

The mechanical specifications of cavities for millimetre waves are highly demanding regarding cavity dimensions, cavity surfaces and precision of coupling mechanisms due to the reduced dimensions at millimetre wavelengths. Furthermore, with increasing MW frequency resonators become more and more difficult to handle. Therefore, high-field/high-frequency EPR measurements are very often carried out without a cavity with the sample placed directly in a transmission waveguide. From the point of view of absolute sensitivity, however, small-volume cavities are evidently preferable. Typically used cavities for millimetre- and submillimetre-wave EPR are multi-mode Fabry–Pérot resonators [54] consisting of a confocal or semiconfocal arrangement of two mirrors placed at a particular distance apart. Fabry–Pérot resonators have been used successfully in the reflection and the transmission mode. A typical Fabry–Pérot resonator is extremely sensitive to displacements of the mirrors by as little as 0.1 μm . Also, the mechanical isolation of the cavity from the modulation coils has to be improved compared to lower frequency designs because of the larger modulation amplitudes and increased interaction forces with the larger static field.

Figure B1.15.15. High-field/high-frequency EPR spectrometer operating at 360.03 GHz b1.15.52. Microwaves at 360.03 GHz are produced by frequency multiplication of the output of a Gunn oscillator and are then passed into a corrugated feedhorn to set up a fundamental Gaussian beam. Refocusing and redirection of the beam is accomplished using off-axis mirrors. The microwaves then travel through a corrugated waveguide and are coupled into a Fabry–Perot-type open cavity. Incident linearly polarized microwaves and circularly polarized EPR signals emitted from the resonator are separated by a wiregrid polarizer. Heterodyne phase-sensitive detection of the EPR signal is achieved in a subharmonic mixer using microwaves of 180.62 GHz to produce a 1.21 GHz intermediate frequency signal which is further down-converted in a quadrature mixer. All MW sources are phase locked to one common reference oscillator.

Many different sorts of millimetre-wave detectors have been developed, each offering its own combination of advantages and drawbacks. For convenience, they may be divided into two general categories: bolometers and mixers (heterodyne detectors). A bolometer is a device which responds to a change in temperature produced when it absorbs incident radiation. The noise figure of an He-cooled bolometer is excellent; however, its small bandwidth limits its application to CW EPR experiments. Heterodyne detection systems transfer a signal band from a high frequency to a lower frequency where low-noise amplifiers are available. This is accomplished, for example, in a mixer by overlaying the signal with a monofrequent and stable local oscillator (LO) frequency to produce a (difference) intermediate frequency (IF) in the lower GHz range. With increasing frequency, however, the Schottky barrier diodes used in mixers become very sensitive to static electricity and mechanical stress, thus limiting their reliability.

Pulsed, or time-domain, EPR spectrometers have also been developed at higher frequencies up to 140 GHz [55, 56]. They are generally low-power units with characteristically long pulse lengths (typically 50 ns for a $\pi/2$ -pulse) due to the limited MW powers available at millimetre wavelengths and the lack of fast-switching

pulse-forming devices at these frequencies. In general, all the experiments outlined in the previous section can be performed, however, with the even more severe restriction to limited excitation bandwidths. Nevertheless, pulsed EPR performed at high frequencies has clear advantages when the poor orientation selection at low frequencies prevents the study of spectral anisotropies of the ESE decay, for example in relaxation measurements. As an example, figure B1.15.16 depicts the decay of a two-pulse ESE of a quinone radical as a function of the external magnetic field. Clearly, the echo decay governed by T_2 is different for selected field positions in the spectrum. This T_2 anisotropy can be analysed in terms of anisotropic motional processes of the radical in its molecular environment. Due to the low g -anisotropy (as is typical in biomolecules) this experiment would not have been successful at lower frequencies.

Figure B1.15.16. Two-pulse ESE signal intensity of the chemically reduced ubiquinone-10 cofactor in photosynthetic bacterial reaction centres at 115 K. MW frequency is 95.1 GHz. One dimension is the magnetic field value B_0 ; the other dimension is the pulse separation τ . The echo decay function is anisotropic with respect to the spectral position.

B1.16 Chemically-induced nuclear and electron polarization (CIDNP and CIDEP)

Elizabeth J Harbron and Malcolm D E Forbes

B1.16.1 INTRODUCTION

Chemically-induced spin polarization was one of the last truly new physical phenomena in chemistry to be discovered and explained during this century. So unusual were the observations and so ground-breaking the theoretical descriptions that, over a very short time period, the chemist's way of thinking about free radical reactions and how to study them was fundamentally changed. After the earliest experimental reports of unusual phases of electron paramagnetic resonance (EPR) (1963) [1] and nuclear magnetic resonance (NMR) (1967) [2, 3 and 4] transitions in thermal, photolytic and radiolytic reactions involving free radical intermediates, it took several years of theoretical development before the idea of the radical pair mechanism (RPM) was put forward to explain the results [5, 6, 7, 8 and 9]. Gradually, the theory was tested and improved, and additional polarization mechanisms were discovered. The overall physical picture has stood the test of time and now both chemically-induced dynamic nuclear polarization (CIDNP) and its electron analogue (CIDEP) are well understood. The phenomena are exploited by many researchers who are trying to understand the kinetic and magnetic properties (and the links between them) of free radicals, biradicals and radical ion pairs in organic photochemistry, as well as photosynthetic reaction centres and other biologically relevant systems. The high structural resolution of NMR and EPR spectroscopies, combined with recent advances in fast data collection instrumentation and high powered pulsed lasers, has made time-resolved CIDNP and CIDEP experiments some of the most informative in the modern physical chemistry arsenal.

In spectroscopy it is common for transitions to be observed as absorptive lines because the Boltzmann distribution, at equilibrium, ensures a higher population of the lower state than the upper state. Examples where emission is observed, which are by definition non-equilibrium situations, are usually cases where excess population is created in the higher level by infusing energy into the system from an external source. For example, steady-state emission spectroscopy is used to measure fluorescence or phosphorescence from the excited states of organic molecules. The technique requires excitation to the upper energy levels first, then what is observed is a spontaneous emission. Another example is the laser, which is pumped with an external source such as a flash lamp or an electric arc to ensure a population inversion, and stimulated emission then occurs from the upper state upon absorption of another photon. What makes the non-Boltzmann NMR and EPR populations observed in CIDNP and CIDEF experiments so unusual is that *nuclear-spin dependent* chemical reactions (homolytic bond-breaking or forming) are responsible for the process. While it usually requires energy to break the bond, once it is broken the mixing of spin wavefunctions in the resulting radical pair, which will be described in detail in the following, is all that is necessary to make some NMR and EPR transitions appear with enhanced absorption (greater intensity than Boltzmann would predict) or even in emission (higher population in the excited state). The overall phase and magnitude of the polarization is dependent on the nuclear spin projections of the nuclei (usually, but not always, protons) near the free radical site of the molecules in question. For this reason, it is easy to see why a suitable theoretical description of CIDNP took a long time to evolve. The idea that the nuclear spin-state energy level differences, which are much smaller than kT at room temperature, could be responsible for different chemical reaction rates was a revolutionary and somewhat controversial one. As more and

-2-

more experiments were performed to support this idea, it rapidly gained acceptance and, in fact, helped connect the solution dynamics of small molecules to spin quantum mechanics in a very natural and informative fashion.

We make one important note here regarding nomenclature. Early explanations of CIDNP invoked an Overhauser-type mechanism, implying a dynamic process similar to spin relaxation; hence the word ‘dynamic’ in the CIDNP acronym. This is now known to be incorrect, but the acronym has prevailed in its infant form.

The general phenomena of CIDNP and CIDEF are presented in figure B1.16.1 and [figure B1.16.2](#). Figure B1.16.1 shows work by Roth *et al* [10] on radical cation structure in which the bottom trace is a ‘dark’ spectrum and the top trace is the CIDNP spectrum [10]. [Figure B1.16.2](#) shows CIDEF spectra of radicals formed by decomposition of a fluorinated polymer initiator [11]. The NMR spectra in figure B1.16.1 and the EPR spectra in [figure B1.16.2](#) can be recognized as spin-polarized by the presence of lines in emission and enhanced absorption. The origin of the CIDNP and CIDEF phenomena will be explored and explained in the following, and we will return to these examples for further analysis once the theory behind them is understood.

Part A is the A/E RPM spectrum obtained upon direct photolysis; part B is the E/A RPM spectrum obtained upon triplet sensitization of this reaction using benzophenone.

B1.16.2 CIDNP

B1.16.2.1 SPIN HAMILTONIAN

CIDNP involves the observation of diamagnetic products formed from chemical reactions which have radical intermediates. We first define the geminate radical pair (RP) as the two molecules which are born in a radical reaction with a well defined phase relation (singlet or triplet) between their spins. Because the spin physics of the radical pair are a fundamental part of any description of the origins of CIDNP, it is instructive to begin with a discussion of the radical-pair spin Hamiltonian. The Hamiltonian can be used in conjunction with an appropriate basis set to obtain the energetics and populations of the RP spin states. A suitable Hamiltonian for a radical pair consisting of radicals 1 and 2 is shown in equation (B1.16.1) below [12].

$$\hat{H}_{\text{RP}} = \beta_e \hbar^{-1} B_0 (g_1 \hat{S}_{1z} + g_2 \hat{S}_{2z}) + \hat{S}_1 \cdot \sum_j a_j \hat{I}_j + \hat{S}_2 \cdot \sum_k a_k \hat{I}_k - J \left(\frac{1}{2} + 2\hat{S}_1 \cdot \hat{S}_2 \right) \quad (\text{B1.16.1})$$

-4-

The first term describes the electronic Zeeman energy, which is the interaction of the magnetic field with the two electrons of the radical pair with the magnetic field, B_0 . The two electron spins are represented by spin operators \hat{S}_{1z} and \hat{S}_{2z} . In this expression, g is the g factor, which is the chemical shift of the unpaired electrons. The other variables in the first term are constants: β_e is the Bohr magneton, and \hbar is Planck's constant divided by 2π . The second term in the Hamiltonian describes the hyperfine interaction between each radical and the nuclei on that radical, where \hat{S} is again the electron spin operator, \hat{I} is the nuclear spin operator, and a_j and a_k are the hyperfine coupling constants. The hyperfine constants describe the coupling between electronic and nuclear spins; coupling between an electron and a proton is designated a_{H} . For most carbon-centred alkyl free radicals, a_{H} for an electron and a proton on the same carbon is negative in sign while a_{H} for a proton β to an electron is positive. The sign of the hyperfine coupling constant will become an important issue in the analysis of CIDNP data below.

The final term in the radical pair Hamiltonian is the exchange interaction (J) between the unpaired electrons. This interaction is a scalar quantity that describes the coupling of the angular momenta of two radicals which are in close proximity. Its magnitude decreases exponentially with increasing inter-radical distance as shown by equation (B1.16.2), where J_0 is the exchange interaction at the point of closest contact, r_0 ; r is the inter-radical distance; and λ is a fall-off parameter generally accepted to be approximately 1 \AA^{-1} for isotropic solutions. The exchange interaction should not be confused with the quantum mechanical term exchange integral, although the two are related [13].

$$J = J_0 e^{-\lambda(r-r_0)}. \quad (\text{B1.16.2})$$

The exchange interaction results in an energy splitting between the singlet and triplet states of the RP as shown in figure B1.16.3 which shows a plot of the RP energy levels versus the inter-radical separation. The S and T levels shown in the lower part of the figure are in the absence of an external magnetic field. When an external field is applied, the triplet level is split into T_+ , T_0 and T_- , as shown in the upper inset. At the high magnetic fields at which most CIDNP experiments are conducted, T_+ and T_- are far away from S and can be neglected in what is known as the high-field approximation.

-5-

Figure B1.16.3. Energy levels versus inter-radical separation for a radical pair. The lower part of the figure shows the S and T levels in the absence of an external magnetic field while the inset shows the splitting of the triplet levels in the presence of a magnetic field, B_0 .

When the inter-radical distance is very small, J is large, and S and T_0 are far apart and cannot mix. This is called the ‘exchange region’ as the electron spins are constrained by the exchange interaction to remain in their respective spin states. As the radicals diffuse apart, J rapidly falls to zero, and the S and T_0 levels become degenerate and are allowed to mix. If the radicals diffuse back to the region of large J , they must again be in either the S or T_0 state, but some of the RPs which were formerly in one spin state will now be in the other. This phenomenon is known as intersystem crossing; it is a process critical to the understanding of CIDNP and will be explained in greater detail below.

B1.16.2.2 MECHANISM OF INTERSYSTEM CROSSING

Vector representations of the radical pair spin states, shown in [figure B1.16.4A](#), help to explain how intersystem crossing occurs in RPs. The vector diagrams show the magnitude of the spin angular momentum vector and its z component (parallel to B_0) for each of the two spins in the RP. Because the x and y components of spin are unspecified, each spin vector can be thought to precess around a cone. When considering only the influence of the interaction of the electron chemical shift with the magnetic field, the frequency of electron precession is given by the expression for the Larmor frequency, equation (B1.16.3). Additional interactions, such as electron–nuclear hyperfine couplings, must be added to or subtracted from the Larmor frequency in order to determine the actual precessional frequency of a given electron;

$$\omega = g\beta_e\hbar^{-1}B_0. \quad (\text{B1.16.3})$$

As mentioned previously, a geminate RP in close contact is constrained by the exchange interaction to remain in its initial spin state, S or T_0 , and vector representations of these states are shown in [figure B1.16.4A](#). The exchange interaction prevents the two spins in the RP from precessing independently; so long as they precess at the same frequency, the two spins will remain in the same mutual orientation. Once the radicals have diffused to the region where J is zero, however, they are free to precess independently of one another. At this point, differences in g factor and/or hyperfine interaction will cause the radicals to precess at different

frequencies. This difference in precessional frequencies is given by Q , as shown in equation (B1.16.4), where m_{1i} and m_{2j} are the nuclear magnetic quantum numbers for each member of the RP, respectively, and the other variables were defined previously;

$$\omega_1 - \omega_2 = 2Q = (g_1 - g_2)\beta_v\hbar^{-1}B_0 + \sum a_{1i}m_{1i} - \sum a_{2j}m_{2j}. \quad (\text{B1.16.4})$$

Eventually, the two spins will fall out of step with one another and will oscillate between the S state, intermediate states, and the T_0 state. An intermediate state is shown in region II of the vector diagram and can be described as a coherent superposition of the S and T_0 states with the coefficients c_S and c_T delineating the amount of S and T_0 'character'. If the radicals diffuse back together to the region of large J , the RP is again required to be in either the S or T_0 state. The squares of the coefficients c_S and c_T will determine the probability that the RP will jump to the S or T_0 state at this inter-radical distance. Some RPs will now be in a different spin state than they were initially and are said to have undergone intersystem crossing, as mentioned above. While S - T_0 mixing occurs when the radicals in a RP are in the $J=0$ region, the fact that intersystem crossing has occurred cannot be determined unless they diffuse back together and are forced by the exchange interaction to be in the S or T_0 state.

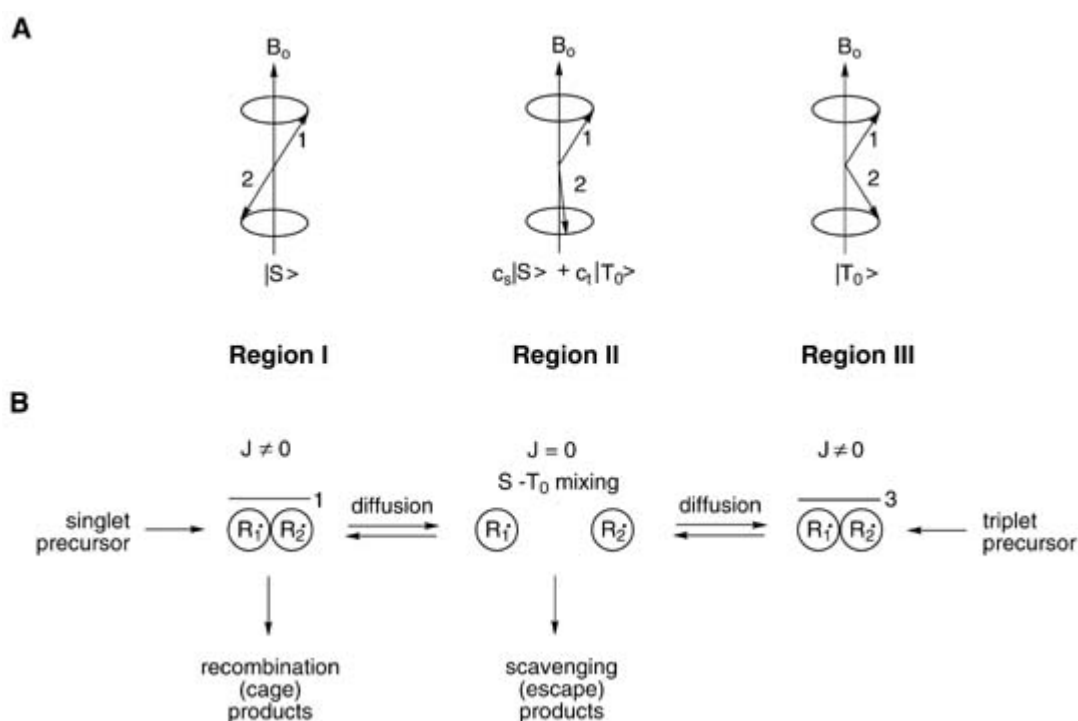

Figure B1.16.4. Part A is the vector representations of the S state, an intermediate state, and the T_0 state of a radical pair. Part B is the radical reaction scheme for CIDNP.

By examining the expression for Q (equation (B1.16.4)), it should now be clear that the nuclear spin state influences the difference in precessional frequencies and, ultimately, the likelihood of intersystem crossing, through the hyperfine term. It is this influence of *nuclear* spin states on *electronic* intersystem crossing which will eventually lead to non-equilibrium distributions of nuclear spin states, i.e. spin polarization, in the products of radical reactions, as we shall see below.

B1.16.2.3 RADICAL REACTION SCHEME

A general reaction scheme for CIDNP is shown in [figure B1.16.4B](#), where the radical dynamics in each region

correspond to the vector diagram for that region shown in [figure B1.16.4A](#). A geminate RP is formed from a singlet or triplet precursor through bond cleavage or an electron transfer reaction. Thermal reactions proceed from the singlet state while photochemical reactions tend to occur from the triplet state; certain species, such as azo compounds, react from the singlet in photochemical reactions [14]. The RP is always formed in the same spin state as its precursor because the RP-forming reaction must conserve angular momentum. For the vast majority of reactions, recombination of singlet RPs is allowed while recombination of triplet RPs is forbidden. While there are exceptions [15], we will consider triplet RPs to be incapable of recombination throughout this explanation. It should also be noted that [figure B1.16.4B](#) shows radical-forming reaction pathways for both singlet and triplet RPs for the purpose of illustration, but it is to be understood that most radical-forming reactions occur from either a singlet (left side) or triplet (right side) precursor but not both.

The geminate RPs in [figure B1.16.4B](#) are indicated by a bar with the spin multiplicity. It is common to speak of geminate RPs as being in a ‘cage’, and this notion is central enough to our discussion of CIDNP to merit some discussion. The idea of the cage effect in radical chemistry stems from early work by Franck and Rabinowitch [16] in which they noted that radicals have an increased probability of recombination in solution as compared to the gas phase. While the term ‘cage’ may encourage one to picture a rigid ensemble of solvent molecules, the cage effect does not describe the influence of a static entity and is actually somewhat difficult to define.

While all agree that the cage is a concept critical to CIDNP, different researchers vary somewhat in their definition of it. Turro *et al* [17] conceive of a RP as guest and a solvent cage as host in an extremely short-lived ‘collision complex’ with a lifetime of about 10^{-11} s. Salikhov *et al* [12] define the cage as a region of effective recombination of two radicals in a RP. They note that radicals may diffuse to the second or third coordination sphere and still come back together to give products. Accordingly, the cage effect describes a twofold influence of condensed media: the two radicals in a RP are not only in close contact for a longer period of time than they would be in the gas phase but are also more likely to re-encounter one another after diffusing apart. Goetz [18] describes the same effects in more abstract terms. He writes of the cage as a region of time and states that two radicals are in the cage so long as they have not lost each other for good. If two radicals in a RP diffuse apart but re-encounter, then they can be said to have been in the cage the entire time. If the same two radicals do not re-encounter, then they are said to have escaped the cage. These different perspectives on the cage are not meant to confuse the reader but are rather intended to present the general idea while conveying the complexity and importance of the concept in CIDNP.

Returning to [figure B1.16.4](#) if the RP is initially in the singlet state, some of the geminate RPs will recombine in the cage in what are called *cage* or *recombination* products. In addition to the reformed radical precursor, recombination products can also include products from disproportionation reactions which occur in cage. A few singlet RPs may escape the cage instead of recombining; as mentioned before, triplet RPs cannot recombine, so they will also escape.

-8-

Escaped radicals diffuse to region II, where J is negligible, and may undergo $S-T_0$ mixing as described previously. From region II, the radicals may follow any of three different pathways.

- (1) The radicals may re-encounter one another following $S-T_0$ mixing. As they diffuse together into the region of large J , the radicals are again constrained to be in either the S or the T_0 state. Some fraction of RPs will have undergone intersystem crossing.
- (2) An individual radical from the RP may encounter a radical from a different RP to form what are known as random RPs or F pairs. F pairs which happen to be in the singlet state have a high probability of recombining, so the remaining F pairs will be in the triplet state. Consequently, the initial condition for F pairs is the triplet state in nearly all cases.

- (3) An individual radical from the RP may be scavenged by a solvent or another chemical species to form diamagnetic products. Because the products are formed following escape from the cage, they are known as *escape* or *scavenging* products.

B1.16.2.4 RADICAL PAIR MECHANISM: NET EFFECT

We have introduced the RP spin Hamiltonian, the mechanism of nuclear spin selective intersystem crossing, and the reaction scheme for RPs has been explained. We now possess all the tools we need to explain qualitatively how nuclear spin polarization arises and manifests itself in a CIDNP spectrum. The RPM may appear in a CIDNP spectrum as a *net effect*, a *multiplet effect*, or a combination of both. The net effect is observed when the g factor difference between radicals R_1 and R_2 (Δg) in a radical pair is large compared with the hyperfine interaction. The simplest example involves a RP with just one hyperfine interaction, as shown in [figure B1.16.5](#). In this example we will set the following conditions: (1) the RP is initially a singlet; (2) the hyperfine coupling constant (a_H) is negative; and (3) the g factor for R_1 is greater than that for R_2 . The recombination product is formed by in-cage recombination of R_1 and R_2 , and a scavenging product is formed by the abstraction of, say, a halogen atom from the solvent following escape from the cage. The scavenging product is formed primarily from escaped triplet RPs although it should be noted that escaped singlets could also form the same product.

Figure B1.16.5. An example of the CIDNP net effect for a radical pair with one hyperfine interaction. Initial conditions: $g_1 > g_2$; a_H negative; and the RP is initially singlet. Polarized nuclear spin states and schematic NMR spectra are shown for the recombination and scavenging products in the boxes.

In this simple case, there are just two nuclear spin states, α and β . Equation (1.16.5) shows the calculation of the difference in electron precessional frequencies, Q , for nuclear spin states α (equation (B1.16.5a)) and β (equation (B1.16.5b)).

$$2Q = \Delta g \beta_e \hbar^{-1} B_0 + \left(\frac{1}{2}\right)a_H \quad (\text{B1.16.5a})$$

$$2Q = \Delta g \beta_c \hbar^{-1} B_0 + \left(\frac{1}{2}\right) a_H \quad (\text{B1.16.5b})$$

Since Δg is positive and a_H is negative, Q is larger for the β state than for the α state. Radical pairs in the β nuclear spin state will experience a faster intersystem crossing rate than those in the α state with the result that more RPs in the β nuclear spin state will become triplets. The end result is that the scavenging product, which is formed primarily from triplet RPs, will have an excess of spins in the β state while the recombination product, which is formed from singlet RPs, will have an excess of α nuclear spin states.

Relative populations for the α and β states are indicated by the thickness of the lines in the diagrams at the bottom of figure B1.16.5 and the corresponding CIDNP spectrum is shown below each level diagram. The signal for the recombination product, with its excess of α spins, will be in enhanced absorption. This enhanced absorption is distinguished from a typical NMR absorptive signal by its abnormal intensity, which may be as much as 1000 times

-10-

greater than a NMR signal from a Boltzmann population difference. The scavenging product, with its excess of β spins, appears in emission in the CIDNP spectrum. Herein lies an extremely important feature of CIDNP: cage and escape products have opposite phases of polarization. It should be straightforward to see that changing the sign of a_H in the previous example would change the values of Q and would ultimately result in a flipping of the phase of the polarization. A rule for predicting the phase of the polarization for each product will be presented with the next example.

A slightly more complex system exhibiting the RPM net effect is presented in figure B1.16.6 [19]. In this case, radicals R_1 and R_2 each have one hyperfine coupling, so the two protons in the recombination product originate from different radicals. The four nuclear spin states and allowed transitions for the product are shown in figure B1.16.6A along with the NMR spectrum in the absence of spin polarization. Again, we must set some initial conditions for this CIDNP example: the RP is initially in the triplet state, both hyperfine coupling constants are positive and g_1 is greater than g_2 . The values shown on each level in figure B1.16.6B are representative of the absolute values of Q for each nuclear spin state and are proportional to the populations of those states. The phase of each transition can be determined by subtracting the Q value of the upper level from that of the lower. For transitions 1 and 2, this value is $2a_1(\Delta g)$, which is positive and yields absorptive transitions. For transitions 3 and 4, the value $[-2a_2(\Delta g)]$ results in emission transitions. A stick plot of the CIDNP spectrum is shown in the figure. For the CIDNP net effect, each line within a multiplet will always have the same phase.

Figure B1.16.6. An example of CIDNP net effect for a radical pair with two hyperfine interactions. Part A shows the spin levels and schematic NMR spectrum for unpolarized product. Part B shows the spin levels and schematic NMR spectrum for polarized product. Populations are indicated on each level. Initial conditions: $g_1 > g_2$; $a_1 > 0$; $a_2 > 0$; spins on different radicals; the RP is initially triplet.

-11-

The phase of a transition in a CIDNP spectrum can be determined using rules developed by Kaptein [20]. The rule for the net effect is shown in equation (B1.16.6). For each term, the sign (+ or -) of that value is inserted, and the final sign determines the phase of the polarization: plus is absorptive and minus is emissive. The variables are defined in the caption to figure B1.16.7.

$$\Gamma_{\text{net}} = \mu \epsilon \Delta g_i a_i \quad \Gamma_{\text{mult}} = \mu \epsilon a_i a_j J_{ij} \sigma_{ij}$$

$\begin{array}{l} + = A \\ - = E \end{array}$
 $\begin{array}{l} + = E/A \\ - = A/E \end{array}$

Figure B1.16.7. Kaptein's rules for net and multiplet RPM of CIDNP. The variables are defined as follows: $\mu = +$ for RP formed from triplet precursor or F pairs and $-$ for RP formed from singlet precursor. $\epsilon = +$ for recombination (or disproportionation)/cage products and $-$ for scavenge/escape products. $\sigma_{ij} = +$ if nuclei i and j were on the same radical and $-$ if nuclei i and j were on different radicals. $\Delta g_i = \text{sign of } (g_1 - g_2)$. $a = \text{sign of hyperfine interaction}$. $J_{ij} = \text{sign of exchange interaction}$.

$$\Gamma_{\text{net}} = \mu \epsilon \Delta g_i a_i \quad (\text{B1.16.6})$$

Kaptein's rule is applied below to each transition in the example in figure B1.16.6. It is important to choose Δg correctly: Δg is equal to $g_1 - g_2$ where g_1 describes the radical containing the nucleus of interest (often a proton) while g_2 is the other radical in the RP. The rule correctly predicts absorptive phase for NMR transitions 1 and 2 and emissive for NMR transitions 3 and 4.

for 1 and 2: $\Gamma_{\text{net}} = (+)(+)(+)(+) = + = A$

for 3 and 4: $\Gamma_{\text{net}} = (+)(+)(-)(+) = - = E$.

B1.16.2.5 RADICAL PAIR MECHANISM: MULTIPLY EFFECT

The other RPM polarization pattern observed in CIDNP spectra is called the multiplet effect. In contrast to the net effect, the multiplet effect occurs when the hyperfine interactions are large compared with Δg . This is best explained by example, and the radical pair for a hypothetical case is shown in [figure B1.16.8](#). We note that only the recombination product will be considered here. Both radicals are identical and have two protons with hyperfine coupling, H_1 and H_2 . The initial conditions for this example are that Δg is zero; the nuclear spin-spin coupling constant, J_{12} is positive; a_1 is negative; a_2 is positive; the RP is initially a singlet; and the nuclear spins are both on the same radical. Values proportional to Q are again shown on each nuclear spin level in [figure B1.16.8](#). Because Δg is zero, the Zeeman term in the equation for Q is zero and, therefore, the value of Q is proportional to the magnitude and the sign of the sum or difference of the hyperfine coupling constants, as shown in [figure B1.16.8](#). Assuming that a_1 and a_2 are roughly equal in magnitude but opposite in sign, it should be clear that the $\alpha\alpha$ and $\beta\beta$ nuclear spin states will have very small Q values while $\alpha\beta$ and $\beta\alpha$ will have larger Q values. Accordingly, $\alpha\beta$ and $\beta\alpha$ will intersystem cross from singlet to triplet more quickly, and these levels will be depleted by escape from the cage relative to the $\alpha\alpha$ and $\beta\beta$ levels. The remaining populations are indicated by the width of the bars in the bottom of [figure B1.16.8](#), and the transitions from more populated levels to less populated ones are shown. As shown in the stick plot CIDNP spectrum, the lines of each multiplet alternate in phase. Because the first line is emissive and the second line is absorptive, this pattern is called E/A for emissive/absorptive.

-12-

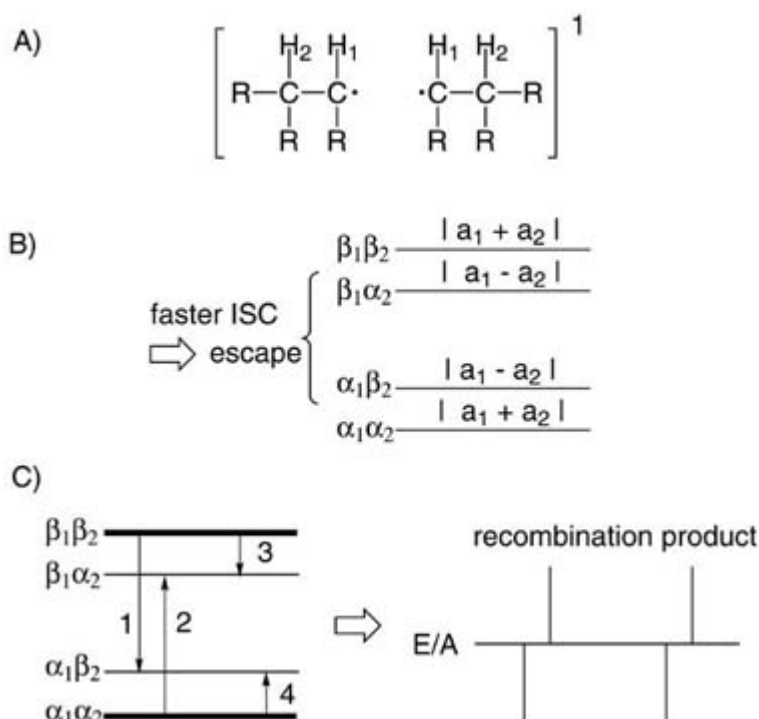

Figure B1.16.8. Example of CIDNP multiplet effect for a symmetric radical pair with two hyperfine interactions on each radical. Part A is the radical pair. Part B shows the spin levels with relative Q values indicated on each level. Part C shows the spin levels with relative populations indicated by the thickness of each level and the schematic NMR spectrum of the recombination product.

Kaptein's rule for the multiplet effect is useful for predicting the phase of each transition, and it is similar to

but has more variables than the rule for the net effect. The variables in equation (B1.16.7) are defined in [figure B1.16.7](#). A final sign of plus predicts E/A phase while minus predicts A/E.

$$\Gamma_{\text{mult}} = \mu \epsilon a_i a_j J_{ij} \sigma_{ij}. \quad (\text{B1.16.7})$$

The application of Kaptein's rule to the example in [figure B1.16.8](#) is shown below, and it correctly predicts E/A multiplets.

$$\Gamma_{\text{mult}} = (-)(+)(-)(+)(+)(+) = + = \text{E/A}.$$

One of the most attractive features of the CIDNP multiplet effect is that it allows determination of the sign of the J coupling, which is often difficult to do by other methods.

-13-

B1.16.2.6 EXAMPLES OF CIDNP

While the stick plot examples already presented show net and multiplet effects as separate phenomena, the two can be observed in the same spectrum or even in the same NMR signal. The following examples from the literature will illustrate 'real life' uses of CIDNP and demonstrate the variety of structural, mechanistic, and spin physics questions which CIDNP can answer.

Roth *et al* [10] have used CIDNP to study the structures of vinylcyclopropane radical cations formed from precursors such as sabinene (**1**).

The radical cation of **1** ($\mathbf{1}^{\cdot+}$) is produced by a photo-induced electron transfer reaction with an excited electron acceptor, chloranil. The major product observed in the CIDNP spectrum is the regenerated electron donor, **1**. The parameters for Kaptein's net effect rule in this case are that the RP is from a triplet precursor (μ is +), the recombination product is that which is under consideration (ϵ is +) and Δg is negative. This leaves the sign of the hyperfine coupling constant as the only unknown in the expression for the polarization phase. Roth *et al* [10] used the phase and intensity of each signal to determine the relative signs and magnitudes of the hyperfine coupling constant for each proton in $\mathbf{1}^{\cdot+}$. Signals in enhanced absorption indicated negative hyperfine coupling constants while emissive signals indicated positive hyperfines.

The CIDNP spectrum is shown in [figure B1.16.1](#) from the introduction, top trace, while a dark spectrum is shown for comparison in [figure B1.16.1](#) bottom trace. Because the sign and magnitude of the hyperfine coupling constant can be a measure of the spin density on a carbon, Roth *et al* [10] were able to use the relative spin density of each carbon to determine that the structure of the radical cation $\mathbf{1}^{\cdot+}$ is a delocalized one, shown below. This example demonstrates the use of CIDNP to determine the signs and relative

magnitudes of the hyperfine coupling constants and to assign the structure of an intermediate.

-14-

In a case involving both net and multiplet effects, Goetz and Sartorius [21] studied the photoreaction of triethylamine with various triplet sensitizers containing carbonyl functionalities. In a two-step process, the amine (DH) first transfers an electron to the excited sensitizer and forms the aminium cation DH^+ . The aminium cation is then deprotonated to form a neutral α -aminoalkyl radical (D^{\cdot}), which can go on to form products. In this example, triethylamine (DH) was reacted with a variety of sensitizers, and N,N-diethylvinylamine was the polarized product which was studied. N,N-diethylvinylamine can be formed by two different pathways. If the deprotonation step occurs in cage, H^+ is transferred to the sensitizer, and polarization in the product arises from a neutral radical pair, $AH^{\cdot}D^{\cdot}$. If the deprotonation step occurs out of cage, then H^+ will be abstracted by free amine; in this case, polarization is formed from a radical ion pair, $A^{\cdot-}DH^+$. The goal of this work was to determine the intermediates leading to N,N-diethylvinylamine; does the deprotonation step occur in cage or out of cage?

The radical cation and neutral radical derived from triethylamine are shown below.

$DH^{\cdot+}$ has only one non-negligible hyperfine, $a_{H\alpha} = +19.0$ G while D^{\cdot} has two significant hyperfines, $a_{H\alpha} = -13.96$ G and $a_{H\beta} = +19.24$ G. Clearly, these two radicals will lead to very different polarizations in the CIDNP spectrum of both cage and escape products.

Figure B1.16.9 shows background-free, pseudo-steady-state CIDNP spectra of the photoreaction of triethylamine with (a) anthroquinone as sensitizer and (b) and (c) xanthone as sensitizer. Details of the pseudo-steady-state CIDNP method are given elsewhere [22]. In trace (a), no signals from the β protons of products 1 (recombination) or 2 (escape) are observed, indicating that the products observed result from the radical ion pair. Traces (b) and (c) illustrate a useful feature of pulsed CIDNP: net and multiplet effects may be separated on the basis of their radiofrequency (RF) pulse tip angle dependence [23]. Net effects are shown in trace (b) while multiplet effects can

be seen in (c). Both traces show signals from the β protons of products 1 and 2, indicating that these products were formed from a neutral radical pair intermediate. It was ultimately determined that the time scale of the deprotonation step relative to the lifetime of the radical ion pairs determined whether products were formed from radical ion pairs or from neutral radical pairs. The energetics of the system varied with the sensitizer, and results were compiled for a variety of sensitizers. This example illustrates the very common application of CIDNP as a mechanistic tool.

Figure B1.16.9. Background-free, pseudo-steady-state CIDNP spectra observed in the photoreaction of triethylamine with different sensitizers ((a), anthraquinone; (b), xanthone, CIDNP net effect; (c), xanthone, CIDNP multiplet effect, amplitudes multiplied by 1.75 relative to the centre trace) in acetonitrile- d_3 . The structural formulae of the most important products bearing polarizations (1, regenerated starting material; 2, N,N-diethylvinylamine; 3, combination product of amine and sensitizer) are given at the top; R denotes the sensitizer moiety. The polarized resonances of these products are assigned in the spectra. Reprinted from [21].

In an extension of traditional CIDNP methods, Closs and co-workers developed time-resolved CIDNP (TR-CIDNP) in the late 1970s [24, 25 and 26]. The initial time-resolved experiments had a time resolution in the

microsecond range [24], but a nanosecond method was later developed [27]. A typical pulse sequence for time-resolved CIDNP involves a series of saturation pulses to remove background signals from equilibrium polarization followed by a laser pulse to form the radical pairs. After a preset delay time, τ , after the laser flash, a RF pulse is applied, and the FID of the product is acquired. Further details of this experiment are given in [26].

The first application of the time-resolved CIDNP method by Closs and co-workers involved the Norrish 1 cleavage of benzyl phenyl ketone [24, 25]. Geminate RPs may recombine to regenerate the starting material while escaped RPs may form the starting ketone (2), bibenzyl (3), or benzil (4), as shown below.

Closs *et al* [25] plotted the polarizations versus time of the starting ketone (2, trace B, emissive signal) and the bibenzyl escape product (3, trace A, absorptive signal), as shown in figure B1.16.10. Ketone 2 can be formed either by recombination of geminate pairs or the reaction of F pairs; in either case, the polarization will be emissive. At the earliest delay time (1 μs), the emissive signal of 2 is already present while no polarization from F pairs is apparent because there has not been sufficient time for the diffusion of radicals to occur. At later delay times, both absorptive and emissive polarizations grow until they reach a maximum. In order to demonstrate that much of the emissive polarization was due to production of 2 from F pairs, a thiol scavenger was added to trap the escaped benzoyl radicals. As shown in trace C, the emissive polarization is constant from the earliest delay time when the scavenger is present, indicating that much of the emissive polarization from geminate pairs is constant, while that from F pairs grows in with time. This was the first instance in which polarization from F pairs was shown to enhance the polarization of geminate products. In addition to establishing the utility of the time-resolved CIDNP method, this experiment was the first to demonstrate that polarization from cage and escape products could be separated based on the time scale of its production.

-17-

Figure B1.16.10. Intensity of CH_2 resonance as a function of delay time in A dibenzyl, B deoxybenzoin, and C deoxybenzoin in presence of thiol scavenger. Reprinted from [25].

While the earliest TR-CIDNP work focused on radical pairs, biradicals soon became a focus of study. Biradicals are of interest because the exchange interaction between the unpaired electrons is present throughout the biradical lifetime and, consequently, the spin physics and chemical reactivity of biradicals are markedly different from radical pairs. Work by Morozova *et al* [28] on polymethylene biradicals is a further example of how this method can be used to separate net and multiplet effects based on time scale [28]. [Figure B1.16.11](#) shows how the cyclic precursor, 2,12-dihydroxy-2,12-dimethylcyclododecanone, cleaves upon 308 nm irradiation to form an acyl-ketyl biradical, which will be referred to as the primary biradical since it is formed directly from the cyclic precursor. The acyl-ketyl primary biradical decarbonylates rapidly ($k_{CO} \geq 5 \times 10^7 \text{ s}^{-1}$) to form a bis-ketyl biradical, which will be referred to as the secondary biradical. Both the primary and secondary biradicals can form a number of diamagnetic products, as shown in [Figure B1.16.11](#).

Figure B1.16.11. Biradical and product formation following photolysis of 2,12-dihydroxy-2,12-dimethylcyclododecanone. Reprinted from [28].

In the TR-CIDNP spectrum, the methyl protons of products IV, V, and VI, formed from the secondary biradical, show a combination of net and multiplet polarizations. Morozova *et al* [28] measured separately the time dependence of the net and multiplet polarizations for this group of protons, and the results are shown in [figure B1.16.12](#) and [figure B1.16.13](#) respectively. Clearly, the net and multiplet polarizations develop on different time scales; while the net polarization is constant after approximately 1 μs , the multiplet polarization takes much longer to evolve. It was determined that this difference arises because the net polarization in these products of the secondary biradical is actually inherited from the primary biradical, while the multiplet polarization is generated in the secondary biradical. If chemical transformation (decarbonylation in this case) is fast compared with the rate of intersystem crossing, then a secondary biradical or radical pair may inherit polarization from its precursor. This is known as the *memory effect* in CIDNP, and this work was the first report of the memory effect in biradicals. The polarization inherited from the primary biradical is net because $\Delta g > 0$ in the primary biradical; because the secondary biradical is symmetric, $\Delta g = 0$, and only multiplet polarization can be generated. It was also determined in this study that the kinetics of the net effect reflect the decay of the T_0 level while the multiplet effect corresponds to the decay of the T_+ and T_- levels; the reasons for these observations are beyond the scope of this presentation, but the interested reader is directed to the references for additional details.

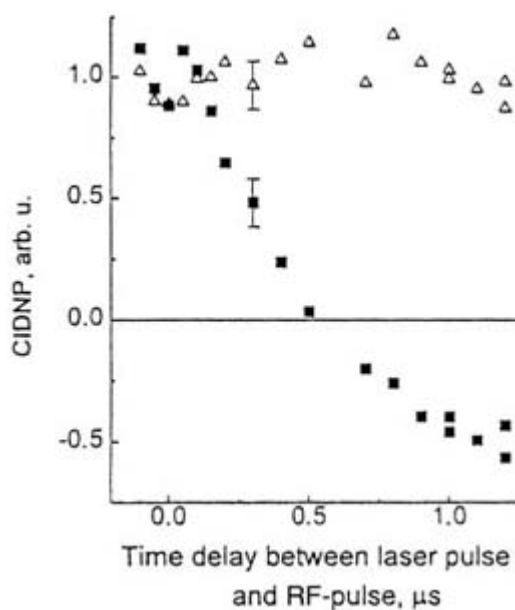

Figure B1.16.12. Experimental kinetics of the CIDNP net effect: (Δ) for the aldehyde proton of the products II and III of primary biradical; (\blacksquare) for the $\text{CH}_3\text{CH}(\text{OH})$ protons of the products IV, V, and VI of secondary biradical. Reprinted from [28].

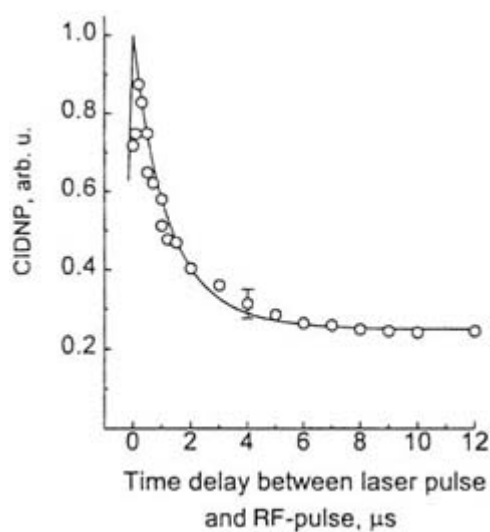

Figure B1.16.13. Kinetics of the CIDNP multiplet effect: (full curve) the calculated CIDNP kinetics for the product of disproportionation of bis-ketyl biradical; (O) experimental kinetics for the $\text{CH}_3\text{CH}(\text{OH})$ protons of the products IV, V and VI of the secondary biradical. Reprinted from [28].

B1.16.3 CIDEP

As the electron counterpart to CIDNP, CIDEP can provide different but complementary information on free radical systems. Whereas CIDNP involves the observation of diamagnetic products, the paramagnetic

intermediates themselves are observed in CIDEP studies. Unlike CIDNP, CIDEP does not require chemical reaction for the formation of polarization, as we shall see below. In addition to the RPM, three other mechanisms may produce electron polarization: the triplet mechanism (TM), the radical-triplet pair mechanism (RTPM) and the spin-correlated radical pair (SCRIP) mechanism. Some of these mechanisms provide information which can lead directly to the structural identification of radical intermediates while all of them supply data which may be used to elucidate mechanisms of radical reactions.

Experimentally, the observation of CIDEP is difficult but not impossible using a commercial steady-state EPR spectrometer with 100 kHz field modulation [29]. The success of this particular experiment requires large steady-state concentrations of radicals and rather slow spin relaxation, as the time response of the instrument is, at best, 10 μ s. Therefore, the steady-state method works well for only a limited number of systems and generally requires a very strong CW lamp for irradiation. The time response can be shortened if the radicals are produced using a pulsed laser and the 100 kHz modulation is bypassed. The EPR signal is then taken directly from the preamplifier of the microwave bridge and passed to a boxcar signal averager [30] or transient digitizer [31]. At the standard X-band frequency the time response can be brought down to about 60 ns in this fashion. In this case the overall response becomes limited by the resonant microwave cavity quality factor [32]. At higher frequencies such as Q-band, the time response can be limited by laser pulse width or preamplifier rise time (< 10 ns) [33]. Using the boxcar or digitizer method, CIDEP is almost always observable, and this so-called time-resolved (CW) EPR spectroscopy is the method of choice for many practitioners. The ‘CW’ in the name is used to indicate that the microwaves are always on during the experiment, even during the production of the radicals, as opposed to pulsed microwave methods such as electron-spin-echo or Fourier-transform (FT) EPR. Significant advantages in sensitivity with similar time response are available with FT-EPR, but there are also disadvantages in terms of the spectral width of the excitation that limit the application of this technique [34]. The TR (CW) method is the most facile and cost effective method for the observation of complete EPR spectra exhibiting CIDEP on the sub-microsecond time scale.

B1.16.3.1 RADICAL PAIR MECHANISM

The RPM has already been introduced in our explanation of CIDNP. The only difference is that for the electron spins to become polarized, product formation from the geminate RP is not required. Rather, in a model first introduced by Adrian, so-called ‘grazing encounters’ of geminate radical pairs are all that is required [35]. Basically the RP must diffuse from a region where the exchange interaction is large to one where it is small, then back again. The spin wavefunction evolution that mixes the S and T_0 electronic levels in the region of small J leads to unequal populations of the S and T_0 states in the region of large J . The magnitude of the RPM CIDEP is proportional to this population difference.

-21-

As for CIDNP, the polarization pattern is multiplet (E/A or A/E) for each radical if Δg is smaller than the hyperfine coupling constants. In the case where Δg is large compared with the hyperfines, net polarization (one radical A and the other E or *vice versa*) is observed. A set of rules similar to those for CIDNP have been developed for both multiplet and net RPM in CIDEP (equation (B1.16.8) and equation (B1.16.9)) [36]. In both expressions, μ is positive for triplet precursors and negative for singlet precursors. J is always negative for neutral RPs, but there is evidence for positive J values in radical ion reactions [37]. In equation (B1.16.8), $\Gamma_{\text{mult}} = +$ predicts E/A while $\Gamma_{\text{mult}} = -$ predicts A/E. For the net effect in equation (B1.16.9), $\Gamma_{\text{net}} = +$ predicts A while $\Gamma_{\text{net}} = -$ predicts E.

$$\Gamma_{\text{mult}} = -J\mu \quad (\text{B1.16.8})$$

$$\Gamma_{\text{net}} = +J\Delta g\mu. \quad (\text{B1.16.9})$$

Because the number of grazing encounters is a function of the diffusion coefficient, CIDEP by the RPM mechanism is a strong function of the viscosity of the solvent and, in general, the RPM becomes stronger with increasing viscosity. Pedersen and Freed [39] have developed analytical techniques for the functional form of the viscosity dependence of the RPM.

A typical example of RPM multiplet effects is shown in [figure B1.16.2](#). Upon 308 nm laser irradiation, the O–O bond of a fluorinated peroxide dimer is cleaved to yield two radicals plus CO₂ as shown in [figure B1.16.2](#). The radical signal is split into a doublet by the α -fluorine atom, and each line in the doublet is split into a quartet by the adjacent CF₃ group (although not all lines are visible in these spectra). The A/E pattern of the spectrum in [figure B1.16.2A](#) indicates that the RP is formed from a singlet precursor. When benzophenone, a triplet sensitizer, is added to the system, the precursor becomes a triplet, and the polarization pattern is now E/A, as shown in [figure B1.16.2B](#). These spectra demonstrate the utility of RPM CIDEP in determining the spin multiplicity of the precursor.

B1.16.3.2 TRIPLET MECHANISM

A second mechanism of CIDEP is the triplet mechanism (TM) [40, 41]. As the name implies, this polarization is generated only when the RP precursor is a photoexcited triplet state. The polarization is produced during the intersystem crossing process from the first excited singlet state of the molecular precursor. It should be noted that this intersystem crossing, which will be explained in detail later, is to be distinguished from that described for RPs described above. Because the TM polarization is present before the triplet reacts to produce the RP, its phase is either net E or net A for both radicals. The origin of the polarization is as follows: in the intersystem crossing process, which is dominated by spin–orbit interactions, the most suitable basis set is one where the canonical orientations of the triplet state are represented. An example is shown in [figure B1.16.14](#) where the directions of the triplet T_x , T_y , and T_z basis functions for naphthalene are indicated in their usually defined orientations. These are also sometimes called the ‘zero-field’ basis functions. As the electrons undergo the intersystem crossing process, these are the orbital directions they ‘see’. This is called the molecular frame of reference.

Figure B1.16.14. Top, the canonical axes for triplet naphthalene. The z-axis is directed out of the plane of the paper. Bottom, energy levels and relative populations during the CIDEP triplet mechanism process. See text

for further details.

Because the spin–orbit interaction is anisotropic (there is a directional dependence of the ‘view’ each electron has of the relevant orbitals), the intersystem crossing rates from S_1 to each triplet level are different. Therefore, unequal populations of three triplet levels results. The T_x , T_y and T_z basis functions can be rewritten as linear combinations of the familiar α and β spin $\frac{1}{2}$ functions and, consequently, they can also be rewritten as linear combinations of the high-field RP spin wavefunctions T_+ , T_0 and T_- , which we have already described above. The net polarization generated in the zero-field basis is carried over to the high-field basis set and, consequently, the initial condition for the geminate RP is that the population of the triplet levels is not strictly equal ($\frac{1}{3}$ each). Exactly which triplet level is overpopulated depends on the sign of the zero-field splitting parameter D in the precursor triplet state. A representative energy level diagram showing the flow of population throughout the intersystem crossing, RP and free radical stages is shown in figure B1.16.14.

The absolute magnitude of the TM polarization intensity is governed by the rate of rotation of the triplet state in the magnetic field. If the anisotropy of the zero-field states is very rapidly averaged (low viscosity), the TM is weak. If the experiment is carried out in a magnetic field where the Zeeman interaction is comparable with the D value and the molecular tumbling rate is slow (high viscosity), the TM is maximized. Additional requirements for a large TM polarization are: (1) the intersystem crossing rates from S_1 to T_x , T_y and T_z must be fast relative to the RP production step, and (2) the spin relaxation time in the excited triplet state should not be too short in order to ensure a large TM polarization. An example of the triplet mechanism from work by Jent *et al* [42] is shown in figure B1.16.15. Upon laser flash photolysis, dimethoxyphenylacetophenone (DMPA, **5**) forms an excited singlet and undergoes fast intersystem crossing and subsequent photocleavage of the triplet to form radicals **6** and **7** as shown below.

-23-

Radical **7** can subsequently fragment to form methyl radical (**8**) and methylbenzoate (**9**).

Figure B1.16.15. TREPR spectrum after laser flash photolysis of 0.005 M DMPA (**5**) in toluene. (a) 0.7 μ s, 203 K, RF power 10 mW; O, lines $\cdot\text{CH}_3$ (**8**), spacing 22.8 G; \bullet , benzoyl (**6**), remaining lines due to (**7**). (b) 2.54 μ s, 298 K, RF power 2 mW to avoid nutations, lines of **7** only. Reprinted from [42].

Contradictory evidence regarding the reaction to form **8** and **9** from **7** led the researchers to use TREPR to investigate the photochemistry of DMPA. Figure B1.16.15A shows the TREPR spectrum of this system at 0.7 μs after the laser flash. Radicals **6**, **7** and **8** are all present. At 2.54 μs , only **7** can be seen, as shown in figure B1.16.15B. All radicals in this system exhibit an emissive triplet mechanism. After completing a laser flash intensity study, the researchers concluded that production of **8** from **7** occurs upon absorption of a second photon and not thermally as some had previously believed.

B1.16.3.3 RADICAL-TRIPLET PAIR MECHANISM

In the early 1990s, a new spin polarization mechanism was postulated by Paul and co-workers to explain how polarization can be developed in transient radicals in the presence of excited triplet state molecules (Blättler *et al* [43], Blättler and Paul [44], Goudsmit *et al* [45]). While the earliest examples of the radical-triplet pair mechanism (RTPM) involved emissive polarizations similar in appearance to triplet mechanism polarizations, cases have since been discovered in which absorptive and multiplet polarizations are also generated by RTPM.

Polarization obtained by RTPM is related to the RPM in that diffuse encounters are still required, but differs in that it involves the interaction of a photoexcited triplet state with a doublet state radical. When a doublet state (electron spin $\frac{1}{2}$) radical is present in high concentration upon production of a photoexcited triplet, the doublet and triplet interact to form new quartet and doublet states. When the two species find themselves in regions of effective exchange ($|J| > 0$), a fluctuating dipole–dipole interaction (D) induces transitions between states, leading to a population redistribution that is non-Boltzmann, i.e. CIDEP. This explanation of RTPM is only valid in regions of moderate viscosity. If the motion is too fast, the assumption of a static ensemble will break down. The resulting polarization is either net E or net A depending on the sign of J (there is no dependence on the sign of D). This mechanism may also be observable in reactions where a doublet state radical produced by photolysis and unreacted triplets might collide. For this to happen, the triplet lifetimes, radical–triplet collision frequencies and triplet spin relaxation rates need to be of comparable time scales.

Figure B1.16.16 shows an example of RTPM in which the radical species is TEMPO (**10**), a stable nitroxide radical, while the triplet state is produced by photoexcitation of benzophenone (**11**) [45].

Figure B1.16.16. TREPR spectrum of TEMPO radicals in 1,2-epoxypropane solution with benzophenone, 1 μ s after 308 nm laser flash. Reprinted from [45].

-25-

The three-line spectrum with a 15.6 G hyperfine reflects the interaction of the TEMPO radical with the nitrogen nucleus ($I = 1$); the benzophenone triplet cannot be observed because of its short relaxation times. The spectrum shows strong net emission with weak E/A multiplet polarization. Quantitative analysis of the spectrum was shown to match a theoretical model which described the size of the polarizations and their dependence on diffusion.

B1.16.3.4 SPIN CORRELATED RADICAL PAIR MECHANISM

The fourth and final CIDEP mechanism results from the observation of geminate radical pairs when they are still interacting, i.e. there is a measurable dipolar or exchange interaction between the components of the RP at the time of measurement. It is called the spin correlated radical pair (SCRCP) mechanism and is found under conditions of restricted diffusion such as micelle-bound RPs [46, 47] or covalently linked biradicals [48] and also in solid state structures such as photosynthetic reaction centres [49] and model systems [50]. In this mechanism additional lines in the EPR spectrum are produced due to the interaction. If the D or J value is smaller than the hyperfines, then the spectrum is said to be first order, with each individual hyperfine line split by $2J$ or $2D$ into a doublet. The most unusual and immediately recognizable feature of the SCRCP mechanism with small interactions is that each component of the doublet receives an opposite phase. For triplet precursors and negative J values, which is the common situation, the doublets are E/A. The level diagram in figure B1.16.17 shows the origin of the SCRCP polarization for such a system, considering only one hyperfine line.

Figure B1.16.17. Level diagram showing the origin of SCRCP polarization.

When the J or D coupling exceeds the hyperfine couplings, the spectrum becomes second order and is much more complex. Lines are alternating with E or A phase, and, if J or D becomes even larger or becomes comparable with the Zeeman interaction, a net emission appears from $S-T$ mixing. In second-order spectra the J coupling must be extracted from the spectrum by computer simulation. In terms of line positions and relative intensities, these spectra have a direct analogy to NMR spectroscopy: the first-order spectrum is the equivalent of the AX NMR problem (two sets of doublets), while the second-order spectrum is analogous to the AB ('roof' effect, intermediate J values) or AA' (convergence of lines, large J values) nuclear spin system [51].

-26-

The SCRCP polarization pattern can be complicated by other factors: chemical reaction can deplete the middle energy levels in Scheme Y as they have the most singlet character and are thus more likely to react upon encounter. Spin relaxation via either correlated (dipole-dipole) or uncorrelated (g factor or hyperfine anisotropy) mechanisms can also redistribute populations on the TREPR time scale [52]. The most important relaxation mechanism is that due to modulation of the exchange interaction caused by conformational motion which changes the inter-radical distance on the EPR time scale. Here both the T_1 and T_2 relaxation processes are important [53]. Interestingly, J modulation is also the process by which RPM is produced, and recently it has been demonstrated that at certain viscosities, both RPM and SCRCP polarization patterns can be observed simultaneously in both micellar [54] and biradical-type RPs [55]. The presence of SCRCP polarization in biradicals has enabled much information to be obtained regarding weak electronic couplings in flexible systems as a function of molecular structure, solvent, and temperature [56, 57, 58 and 59]. The spin polarization observed in EPR spectra of photosynthetic reaction centres has also proven informative in relating structure to function in those systems, especially in comparing structural parameters measured magnetically to those found by other methods such as x-ray crystallography [60].

Most observations of SCRCP have been from triplet precursors, but Fukuju *et al* [61] have observed singlet-born SCRCP upon photolysis of tetraphenylhydrazine in sodium dodecyl sulfate (SDS) micelles. The tetraphenylhydrazine (**12**) cleaves to form two diphenylamino (DPA) radicals, as shown below.

Figure B1.16.18 shows TREPR spectra of this system in SDS micelles at various delay times. The A/E/A/E pattern observed at early delay times is indicative of a singlet-born SCRCP. Over time, a net absorptive

component develops and, eventually, the system inverts to an E/A/E/A pattern at late delay times. The long lifetime of this SCRIP indicates that the DPA radicals are hydrophobic enough that they prefer to remain in the micelle rather than escape. The time dependence of the spectra can be described by a kinetic model which considers the recombination process and the relaxation between all states of the RP. The reader is directed to the reference for further details.

Figure B1.16.18. TREPR spectra observed after laser excitation of tetraphenylhydrazine in an SDS micelle at room temperature. Reprinted from [61].

B1.16.3.5 FURTHER EXAMPLES OF CIDEP

While each of the previous examples illustrated just one of the electron spin polarization mechanisms, the spectra of many systems involve polarizations from multiple mechanisms or a change in mechanism with delay time.

Work by Koga *et al* [62] demonstrates how the polarization mechanism can change upon alteration of the chemical environment. Upon laser flash photolysis, excited xanthone abstracts a proton from an alcohol solvent, cyclohexanol in this case. The xanthone ketyl radical ($\cdot\text{XnH}$) and the alcoholic radical ($\cdot\text{ROH}$) exhibit E/A RPM polarization with slight net emission, as shown in [figure B1.16.19\(a\)](#). Upon addition of HCl to the cyclohexanol solution, the same radicals are observed, but the polarization is now entirely an absorptive triplet mechanism, as shown in [figure B1.16.19 \(b\)](#). It was determined that both H^+ and Cl^- or HCl molecules must be present for this change in mechanism to occur, and the authors postulated that the formation of a charge transfer complex between xanthone and HCl in their ground state might be responsible for the observed change in polarization. This curious result demonstrates how a change in the CIDEP mechanism can yield information about chemical changes which may be occurring in the system.

Figure B1.16.19. (a) CIDEP spectrum observed in the photolysis of xanthone (1.0×10^{-2} M) in cyclohexanol at room temperature. The stick spectra of the ketyl and cyclohexanol radicals with RPM polarization are presented. (b) CIDEP spectrum after the addition of hydrochloric acid (4.1 vol%; HCl 0.50 M) to the solution above. The stick spectra of the ketyl and cyclohexanol radicals with absorptive TM polarization are presented. The bold lines of the stick spectra of the cyclohexanol radical show the broadened lines due to ring motion of the radical. Reprinted from [62].

Utilizing FT-EPR techniques, van Willigen and co-workers have studied the photoinduced electron transfer from zinc tetrakis(4-sulfonatophenyl)porphyrin (ZnTPPS) to duroquinone (DQ) to form ZnTPPS^{3-} and DQ^- in different micellar solutions [34, 63]. Spin-correlated radical pairs [$\text{ZnTPPS}^{3-} \dots \text{DQ}^-$] are formed initially, and the SCRPs lifetime depends upon the solution environment. The ZnTPPS^{3-} is not observed due to its short T_2 relaxation time, but the spectra of DQ^- allow for the determination of the location and stability of reactant and product species in the various micellar solutions. While DQ is always located within the micelle, the location of ZnTPPS and free DQ^- depends upon the micellar environment.

Figure B1.16.20 shows spectra of DQ^- in a solution of TX100, a neutral surfactant, as a function of delay time. The spectra are qualitatively similar to those obtained in ethanol solution. At early delay times, the polarization is largely TM while RPM increases at later delay times. The early TM indicates that the reaction involves ZnTPPS triplets while the A/E RPM at later delay times is produced by triplet excited-state electron transfer. Calculation of relaxation times from spectral data indicates that in this case the ZnTPPS porphyrin molecules are in the micelle, although some may also be in the hydrophobic mantle of the micelle. Further, lineshape and polarization decay analyses indicate that free DQ^- radicals move from the micelle into the aqueous phase. The lack of observation of spin-correlated radical pairs indicates that they have dissociated prior to data acquisition. Small out-of-phase signal contributions at the earliest delay times show that the radical pair lifetime in TX100 solution is approximately 100 ns.

FT-EPR spectra of the ZnTPPS/DQ system in a solution of cetyltrimethylammonium chloride (CTAC), a cationic surfactant, are shown in figure B1.16.21. As in the TX100 solution, both donor and acceptor are associated with the micelles in the CTAC solution. The spectra of DQ^- at delays after the laser flash of less than 5 μs clearly show polarization from the SCRPs mechanism. While SCRPs were too short-lived to be observed in TX100 solution, they clearly have a long lifetime in this case. Van Willigen and co-workers

determined that the anionic radicals ZnTPPS^{3-} and DQ^- remain trapped in the cationic micelles, i.e. an electrostatic interaction is responsible for the extremely long lifetime of the $[\text{ZnTPPS}^{3-} \dots \text{DQ}^-]$ spin-correlated radical pair. The spectrum at delay times greater than $5 \mu\text{s}$ is again due to free DQ^- . Linewidth analysis and relaxation time calculations indicate that the free DQ^- remains trapped in the cationic micelles. These results demonstrate the use of the CIDEP mechanisms in helping to characterize the physical environments of free radicals. In both cases shown here, spectral analysis allowed a determination of the lifetime of the initial SCRPs and the location of the porphyrin and the free DQ^- .

Figure B1.16.20. FTEPR spectra of photogenerated DQ^- in TX100 solution for delay times between laser excitation of ZnTPPS and microwave pulse ranging from 20 ns to 11 μs . The central hyperfine line ($M = 0$) is at ≈ -4.5 MHz. Reprinted from [63].

Figure B1.16.21. FTEPR spectra photogenerated DQ^- in CTAC solution for delay times between laser excitation of ZnTPPS and microwave pulse ranging from 50 ns to 10 μ s. The central hyperfine line ($M = 0$) is at ≈ 7 MHz. Reprinted from [63].

Figure B1.16.22 shows a stick plot summary of the various CIDEP mechanisms and the expected polarization patterns for the specific cases detailed in the caption. Each mechanism clearly manifests itself in the spectrum in a different and easily observable fashion, and so qualitative deductions regarding the spin multiplicity of the precursor, the sign of J in the RP and the presence or absence of SCRPs can immediately be made by examining the spectral shape. Several types of quantitative information are also available from the spectra. For example, if the molecular structure of one or both members of the RP is unknown, the hyperfine coupling constants and g -factors can be measured from the spectrum and used to characterize them, in a fashion similar to steady-state EPR. Sometimes there is a marked difference in spin relaxation times between two radicals, and this can be measured by collecting the time dependence of the CIDEP signal and fitting it to a kinetic model using modified Bloch equations [64].

Figure B1.16.22. Schematic representations of CIDEP spectra for hypothetical radical pair $\cdot\text{CH}_3 + \cdot\text{R}$. Part A shows the A/E and E/A RPM. Part B shows the absorptive and emissive triplet mechanism. Part C shows the spin-correlated RPM for cases where $J \ll a_H$ and $J \gg a_H$.

If the rate of chemical decay of the RP is desired, the task is complex because the majority of the CIDEP signal decays via relaxation pathways on the 1–10 μs time scale, as opposed to chemical reaction rates which are nominally about an order of magnitude longer than this. There are two ways around this problem. The first is to use a transient digitizer or FT-EPR and signal average many times to improve the signal-to-noise ratio at long delay times where chemical reaction dominates the decay trace. The second is to return to the steady-state method described above and run what is called a ‘kinetic EPR’ experiment, where the light source is suddenly interrupted and the EPR signal decay is collected over a very long time scale. The beginning of the trace may contain both relaxation of CIDEP intensity as well as chemical decay; however, the tail end of this trace should be dominated by the chemical reaction rates. Much use has been made of kinetic EPR in measuring free radical addition rates in polymerization reactions [65, 66].

From SCRIP spectra one can always identify the sign of the exchange or dipolar interaction by direct examination of the phase of the polarization. Often it is possible to quantify the absolute magnitude of D or J by computer simulation. The shape of SCRIP spectra are very sensitive to dynamics, so temperature and viscosity dependencies are informative when knowledge of relaxation rates of competition between RPM and SCRIP mechanisms is desired. Much use of SCRIP theory has been made in the field of photosynthesis, where structure/function relationships in reaction centres have been connected to their spin physics in considerable detail [67, 68].

B1.17.1 INTRODUCTION

The electron microscope (EM) was developed in the 1930s primarily as an imaging device which exceeded the resolution power of the light microscope by several orders of magnitude. With the evolution towards dedicated instruments designed to answer specific structural and analytical questions, electron microscopy (EM) has grown into a heterogeneous field of electron beam devices. These allow the study of the interaction of electrons with the sample, which can subsequently be interpreted as information about object structure or chemical composition. Therefore, EM must be compared to other high-resolution diffraction methods, such as x-ray or neutron scattering, or to spectroscopic techniques such as electron spin resonance spectroscopy (ESR) and nuclear magnetic resonance spectroscopy (NMR). More recent, non-diffractive techniques include scanning tunnelling microscopy (STM) and atomic force microscopy (AFM) (for a detailed discussion see [chapter B1.19](#)).

All these methods are used today to obtain structural and analytical information about the object (see also the specific chapters about these techniques). In the case of structural studies, x-ray crystallography is the method of choice if suitable three-dimensional (3D) crystals of the object are available. In fact, x-ray crystallography has provided a vast number of atomic structures of inorganic compounds or organic molecules. The main advantage of EM, however, is the possibility of directly imaging almost any sample, from large biological complexes consisting of many macromolecules down to columns of single atoms in a solid material. With modern instruments and applying specific preparation techniques, it is even possible to visualize beam-sensitive organic material at molecular resolution (of the order of 3–4 Å). Imaging at atomic resolution is almost routine in material science. Today, some challenges remain, including the combination of sub-Ångström resolution with chemical analysis and the ability to routinely reconstruct the complete 3D spatial structure of a given sample.

The history of EM (for an overview see [table B1.17.1](#)) can be interpreted as the development of two concepts: the electron beam either illuminates a large area of the sample ('flood-beam illumination', as in the typical transmission electron microscope (TEM) imaging using a spread-out beam) or just one point, i.e. focused to the smallest spot possible, which is then scanned across the sample (scanning transmission electron microscopy (STEM) or scanning electron microscopy (SEM)). In both situations the electron beam is considered as a matter wave interacting with the sample and microscopy simply studies the interaction of the scattered electrons.

1995	Zach proves the concept of a corrected LVSEM	Zach (1995) [10]
1998	Haider and colleagues prove the concept of the TEM spherical aberration corrector	Haider <i>et al</i> (1998) [55]

In principle, the same physico-chemical information about the sample can be obtained from both illumination principles. However, the difference of the achievable spatial resolutions of both illumination principles illustrates the general difference of the two approaches. Spatial resolution in the case of flood-beam illumination depends on the point spread function (PSF) of the imaging lens and detector system and—for a typical TEM sample—on the interference effects representing phase shifts of the scattered electron wave. In general, resolution is described as a global phenomenon. For the scanned beam, all effects are local and confined to the illuminated spot. Thus, spatial resolution of any event is identical to the achievable spot diameter. Therefore, all steps in the further development of EM involve either the improvement of the PSF (either by improving sample preparation, imaging quality of the electron lenses, or improving spatial resolution of the electron detection devices) or the improvement of the spot size (by minimizing the size of the electron source using a field emission gun (FEG) and by improving the imaging quality of the electron lenses).

In general, EM using a focused beam provides higher spatial resolution if the spot size of the scanning beam is smaller than the delocalization of the event studied: consider, for example, inelastic scattering events which for signal-to-noise ratio (SNR) reasons can be imaged in energy filtering TEMs (EFTEM) at 1–2 nm resolution. In a dedicated STEM with an FEG electron source, a localization of the inelastic event comparable

to the actual probe size of e.g. 2 Å can be expected. Moreover, this effect is enhanced by the electron detectors used in TEM and S(T)EM. For scanned-beam microscopy, detectors do not resolve spatial information, instead they are designed for highest detection quantum efficiency (DQE almost ideal). Such an ideal detection has only recently been reached for TEM by the use of slow-scan charge-coupled device (ssCCD) cameras or imaging plates (IP). However, their spatial resolution is only moderate, compared to conventional, electron-sensitive photographic material.

-4-

For several reasons, such as ease of use, cost, and practicability, TEM today is the standard instrument for electron diffraction or the imaging of thin, electron-transparent objects. Especially for structural imaging at atomic level (spatial resolution of about 1 Å) the modern, aberration-corrected TEM seems to be the best instrument. SEM provides the alternative for imaging the surface of thick bulk specimens. Analytical microscopy can either be performed using a scanning electron probe in STEM and SEM (as for electron probe micro-analysis (EPMA), energy-dispersive x-ray spectroscopy (EDX) and electron energy loss spectroscopy (EELS)) or energy-selective flood-beam imaging in EFTEM (as for image-EELS and electron spectroscopic imaging (ESI)). The analytical EM is mainly limited by the achievable probe size and the detection limits of the analytical signal (number of inelastically scattered electrons or produced characteristic x-ray quanta). The rest of this chapter will concentrate on the structural aspects of EM. Analytical aspects are discussed in more detail in specialized chapters (see, for example, [B1.6](#)).

It is interesting to note the analogy of developments in light microscopy during the last few decades. The confocal microscope as a scanning beam microscope exceeds by far the normal fluorescence light microscope in resolution and detection level. Very recent advances in evanescent wave and interference microscopy seem to promise to provide even higher resolution ([B1.18](#)).

EM has been used in a wide variety of fields, from material sciences to cell and structural biology or medical research. In general, EM can be used for any high-resolution imaging of objects or their analytical probing. Modern instrumentation of STEM and SEM provides high-resolution instruments capable of probe sizes, in the case of TEM, of a few Ångström or sub-Ångström information limit. However, specimen properties and sample preparation limit the achievable resolution. Typical resolution obtained today range from atomic detail for solid materials, molecular detail with resolution in the order of 3–5 Å for crystalline biological samples, and about 1–2 nm for individual particles without a certain intrinsic symmetry. Recent publications on the different aspects of EM include Williams and Carter ([\[1\]](#), general text covering all the modern aspects of EM in materials science), the textbooks by Reimer ([\[2,3 and 4\]](#), detailed text about theory, instrumentation, and application), or—for the most complete discussion of all electron-optical and theoretical aspects—Hawkes and Kasper [\[5\]](#). Additional research papers on specialized topics are referenced in text.

B1.17.2 INTERACTION OF ELECTRONS WITH MATTER AND IMAGING OF THE SCATTERING DISTRIBUTION

The interaction of electrons with the specimen is dominated by the Coulomb interaction of charged particles. For a summary of possible charge–charge interactions see [figure B1.17.1](#). Elastic scattering by the Coulomb potential of the positively charged atomic nucleus is most important for image contrast and electron diffraction. This scattering potential is well localized, leads to large scattering angles and yields high-resolution structural information from the sample. In contrast, interactions with the atomic electrons lead to an energy loss of the incident electron by the excitation of different energy states of the sample, such as phonon excitation, plasmon excitation or inner-shell ionization (see [table B1.17.2](#)). Inelastic scattering processes are not as localized as the Coulomb potential of the nucleus, leading to smaller scattering angles (inelastic forward scattering), and are in general not used to obtain high-resolution structural information. Instead, inelastic scattering provides analytical information about the chemical composition and state of the sample.

Table B1.17.2. Electron–specimen interactions.

	Elastic scattering	Inelastic scattering
Where	Coulomb potential of nucleus	At atomic shell electrons
Scattering potential	Localized	Less localized
Scattering angles $E = 100 \text{ keV}$	Large ($> 10 \text{ mrad}$)	Smaller ($< 10 \text{ mrad}$)
Application	High-resolution signal (TEM, STEM) Back-scattering of electrons (BSE signal in SEM)	Analytical signal (TEM, STEM, SEM) Emission of secondary electrons (SE signal in SEM)
Used effects		Phonon excitation (20 meV–1 eV) Plasmon and interband excitations (1–50 eV) Inner-shell ionization ($\Delta E =$ ionization energy loss) Emission of x-ray (continuous/characteristic, analytical EM)

The ratio of elastically to inelastically scattered electrons and, thus, their importance for imaging or analytical work, can be calculated from basic physical principles: consider the differential elastic scattering cross section

$$\frac{d\sigma_{el}}{d\Omega} = \frac{4Z^2 R^4 (1 + E/E_0)}{a_H^2} \frac{1}{[1 + (\theta/\theta_0)^2]} \quad (\text{B1.17.1})$$

with the characteristic screening angle $\theta_0 = \lambda/(2\pi R)$ where θ denotes the scattering angle, E is the electron energy, E_0 the electron rest energy, $+eZ$ is the charge of the nucleus, $R = a_H Z^{1/3}$, and $a_H = 0.0529 \text{ nm}$ is the Bohr radius. Compare this to the inelastic differential scattering cross section

$$\frac{d\sigma_{incl}}{d\Omega} = \frac{\lambda^4 (1 + E/E_0)^2}{4\pi^4 a_H^2} \frac{Z \left\{ 1 - \frac{1}{[1 + (\theta/\theta_0)^2]} \right\}}{(\theta^2 + \theta_E^2)^2} \quad (\text{B1.17.2})$$

with the characteristic inelastic scattering angle $\theta_E = \Delta E/E \cdot (E+E_0)/(E+2E_0)$ for a given energy loss ΔE .

For large scattering angles, $\theta \gg \theta_0, \theta_E$ the ratio

$$\frac{d\sigma_{\text{inel}}/d\Omega}{d\sigma_{\text{el}}/d\Omega} = \frac{1}{Z} \quad (\text{B1.17.3})$$

-6-

only depends on the atomic number Z , whereas for small angles θ

$$d\sigma_{\text{inel}}/d\Omega > d\sigma_{\text{el}}/d\Omega \quad (\text{B1.17.4})$$

for all Z . The total scattering cross sections are found by integrating the above equations [6]

$$\nu = \frac{\sigma_{\text{inel}}}{\sigma_{\text{el}}} \approx \frac{26}{Z} \quad (\text{B1.17.5})$$

or experimentally [7]

$$\nu \approx \frac{18}{Z}. \quad (\text{B1.17.6})$$

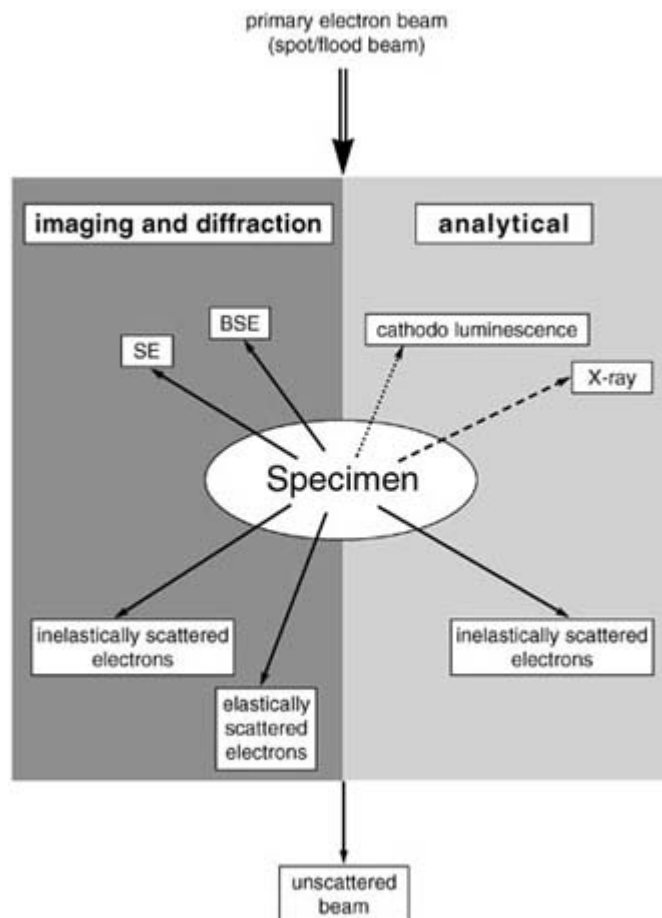

Figure B1.17.1. Schema of the electron specimen interactions and their potential use for structural and analytical studies.

Equation (B1.17.1), Equation (B1.17.2), Equation (B1.17.3), Equation (B1.17.4), Equation (B1.17.5) and Equation (B1.17.6) indicate that inelastic scattering is most important for light atoms, whereas elastic scattering dominates for large scattering angles and heavy atoms. Therefore, the high resolution image contrast—given by electrons scattered to large angles—for TEM and STEM is dominated by the elastic scattering process. Inelastically scattered electrons are treated either as background, or separated from the elastic image by energy-dispersive spectrometers.

In the case of SEM, both elastic and inelastic processes contribute to image contrast: elastic scattering to large angles (multiple elastic scattering resulting in a large scattering angle) produces backscattered electrons (BSE), which can be detected above the surface of the bulk specimen. Inelastic collisions can excite atomic electrons above the Fermi level, i.e. more energy is transferred to the electron than it would need to leave the sample. Such secondary electrons (SE) are also detected, and used to form SEM images. As will be discussed in B1.17.4 (specimen preparation), biological material with its light atom composition is often stained or coated with heavy metal atoms to increase either the elastic scattering contrast in TEM or the BSE signal in SEM. Unstained, native biological samples generally produce only little image contrast.

Inelastic scattering processes are not used for structural studies in TEM and STEM. Instead, the signal from inelastic scattering is used to probe the electron-chemical environment by interpreting the specific excitation of core electrons or valence electrons. Therefore, inelastic excitation spectra are exploited for analytical EM.

Next we will concentrate on structural imaging using only elastically scattered electrons. To obtain the structure of a scattering object in TEM it is sufficient to detect or image the scattering distribution. Consider the scattering of an incident plane wave $\psi_0(\mathbf{r}) \equiv 1$ on an atomic potential $V(\mathbf{r})$. The scattered, outgoing wave will be described by the time-independent Schrödinger equation. Using Green's functions the wave function can be written as

$$\psi(\mathbf{r}) = \exp(i\mathbf{k}\mathbf{r}) - \frac{m}{2\pi\hbar^2} \int \frac{\exp(i\mathbf{k}|\mathbf{r} - \mathbf{r}'|)}{|\mathbf{r} - \mathbf{r}'|} V(\mathbf{r}')\psi(\mathbf{r}') d\mathbf{r}' \quad (\text{B1.17.7})$$

where \mathbf{k} denotes the initial wave vector, m is equal to the electron mass. For large distances from the scattering centre $r \gg r'$. This can be approximated by

$$\psi(\mathbf{r}) = \exp(i\mathbf{k}\mathbf{r}) + f(\theta) \frac{\exp(ikr)}{r} \quad (\text{B1.17.8})$$

where θ denotes the scattering angle.

In this approximation, the wave function is identical to the incident wave (first term) plus an outgoing spherical wave multiplied by a complex scattering factor

$$f(\theta) = |f(\theta)| \exp(i\eta(\theta)) \quad (\text{B1.17.9})$$

which can be calculated as

$$f(\theta) = -\frac{m}{2\pi\hbar^2} \int \exp(ik'\mathbf{r}') V(\mathbf{r}') \psi(\mathbf{r}') d\mathbf{r}' \quad (\text{B1.17.10})$$

where $\mathbf{k}' = k\mathbf{r}'/r$. For a weak potential $V(\mathbf{r})$ it is possible to use the first Born approximation, i.e. $\psi(\mathbf{r}')$ in equation (B1.17.10) can be replaced by the incident wave resulting in:

$$f(\theta) = -\frac{m}{2\pi\hbar^2} \int \exp(i(\mathbf{k} - \mathbf{k}')\mathbf{r}') V(\mathbf{r}') d\mathbf{r}'. \quad (\text{B1.17.11})$$

This equation describes the Fourier transform of the scattering potential $V(\mathbf{r})$. It should be noted that, in the Born approximation the scattering amplitude $f(\theta)$ is a real quantity and the additional phase shift $\eta(\theta)$ is zero. For atoms with high atomic number this is no longer true. For a rigorous discussion on the effects of the different approximations see [2] or [5].

In a diffraction experiment a quantity $|F(\mathbf{S})|^2$ can be measured which follows from equation (B1.17.8) and equation (B1.17.9) in Fourier space as

$$F(\mathbf{S}) = \delta_0 + i|f(\mathbf{S})| \exp(i\eta(\mathbf{S})) \quad (\text{B1.17.12})$$

where $\mathbf{S} = \mathbf{k} - \mathbf{k}'$ denotes the scattering vector. Combining equation (B1.17.11) and equation (B1.17.12) leads to the conclusion that in a diffraction experiment the squared amplitude of the Fourier transform of the scattering potential $V(\mathbf{r})$ is measured. Similar formulae can be deduced for whole assemblies of atoms, e.g. macromolecules, resulting in the molecular transform instead of simple atomic scattering factors (for an introduction to the concept of molecular transforms see e.g. [8]). Such measurements are performed in x-ray crystallography, for example. To reconstruct the original scattering potential $V(\mathbf{r})$ it is necessary to determine the phases of the structure amplitudes to perform the reverse Fourier transform. However, if lenses are available for the particles used as incident beam—as in light and electron microscopy—a simple microscope can be built: the diffracted wave is focused by an objective lens into the back focal plane, where the scattered and unscattered parts of the wave are separated. Thus, the objective lens can simply be understood as a Fourier transform operator. In a subsequent imaging step by one additional lens, the scattered and unscattered waves are allowed to interfere again to form a direct image of the scattering potential. This can be understood as a second Fourier transform of the scattering factor (or molecular transform) recovering the spatial distribution of the scattering centres. The small angular scattering distribution of only 10–20 mrad results in a complication in the case of EM. The depth of focus is very large, i.e. it is not possible to recalculate the 3D distribution of the scattering potential but only its 2D projection along the incident beam. All scattering distributions, images, or diffraction patterns are always produced by the 2D projecting transmission function of the actual 3D object. Using a variety of tomographic data collections it is then possible to reconstruct the true 3D object (see below).

The above theory can also be applied to STEM, which records scattering distributions as a function of the scanning probe position. Images are then obtained by plotting the measured scattering intensities (i.e. in the case of the elastic scattering, the direct measurement of the scattering factor amplitudes) according to the probe position. Depending on the signal used, this leads to a conventional elastic dark-field image, or to STEM phase-contrast images [9].

In the case of the scanning electron microscope (SEM), images are formed by recording a specific signal resulting from the electron beam/specimen interaction as a function of the scanning probe position. Surface structures are generally described with the SE (secondary electron) signal. SEs are produced as a consequence

of inelastic events. They have very low energies and, therefore, can leave the specimen and contribute to the imaging signal only when created very close to the specimen surface. The escape depth for the secondary electrons depends on the material. It is relatively large (tens of nanometres) for organic and biological material and small for heavy metals (1–3 nm). High-resolution topographic information (limited mainly by the diameter of the scanning electron beam) requires that the source of the signal is localized very close to the specimen surface. In the case of organic materials this localization can be achieved by a very thin metal coating (W, Cr, Pt; thickness = approximate SE escape depth).

The BSE signal is also frequently used for imaging purposes. BSE are electrons of the primary beam (scanning probe) that have been elastically or inelastically scattered in the sample. Their energy depends on their scattering history. When scattered from the surface, they may have lost no or very little energy and provide high topographic resolution. When multiply scattered inside the sample they may have lost several keV and transfer information from a large volume. This volume depends on the material as well as on the energy of the primary beam. BSE produce SE when passing through the SE escape zone. These SE are, however, not correlated with the position of the scanning probe and contribute a background noise which can obscure the high resolution topographic SE signal produced at the point of impact of the primary beam. The interpretation of high-resolution topographic images therefore depends on optimized handling of specimen properties, energy of the electron probe, metal coating and sufficient knowledge of the signal properties.

The discussion of electron–specimen interactions shows that, for a given incident electron dose, a certain quantity of resulting scattered electrons and secondary electrons or photons is produced. The majority of energy transfer into the specimen leads to beam damage and, finally, to the destruction of the sample structure. Therefore it is desirable to simultaneously collect as much information from the interactions as possible. This concept could lead to an EM instrument based on the design of a STEM but including many different detectors for the elastic dark field, phase contrast, inelastically scattered electrons, BSE, SE, and EDX. The complexity of such an instrument would be enormous. Instead, specific instruments developed in the past can coarsely be categorized as TEM for structural studies on thin samples, STEM for analytical work on thin samples and SEM for analytical and surface topography studies.

B1.17.3 INSTRUMENTATION

B1.17.3.1 ELECTRON BEAM INSTRUMENTS

The general instrumentation of an EM very much resembles the way an ordinary, modern light microscope is built. It includes an electron beam forming source, an illumination forming condenser system and the objective lens as the main lens of the microscope. With such an instrumentation, one forms either the conventional bright field microscope with a large illuminated sample area or an illumination spot which can be scanned across the sample. Typical electron sources are conventional heated tungsten hairpin filaments, heated LaB₆, or CeB₆-single-crystal electron emitters, or—as the most sophisticated source—FEGs. The latter sources lead to very coherent electron beams, which are necessary to obtain high-resolution imaging or very small electron probes.

Modern EMs use electromagnetic lenses, shift devices and spectrometers. However, electrostatic devices have always been used as electron beam accelerators and are increasingly being used for other tasks, e.g. as the objective lens (LVSEM, [10]).

EM instruments can be distinguished by the way the information, i.e. the interacting electrons, is detected. [Figure B1.17.2](#) shows the typical situations for TEM, STEM, and SEM. For TEM the transmitted electron beam of the brightfield illumination is imaged simply as in an light microscope, using the objective and

projective lenses as conventional imaging system. Combining such TEMs with energy-dispersive imaging elements (filters, spectrometers; see [14]) the modern generation of EFTEMs has been introduced in the last decade. In the case of STEM, the transmitted electrons are not again imaged by lenses, instead the scattered electrons are directly recorded by a variety of detectors. For SEM, the situation is similar to that of STEM. However, only the surface of a bulk specimen is scanned and the resulting backscattered or secondary electrons are recorded by dedicated detectors.

As a special development in recent years, SEMs have been designed which no longer necessitate high vacuum (environmental SEM, ESEM; variable pressure SEM, VPSEM). This development is important for the imaging of samples with a residual vapour pressure, such as aqueous biological or medical samples, but also samples in materials science (wet rock) or organic chemistry (polymers).

-11-

Figure B1.17.2. Typical electron beam path diagrams for TEM (a), STEM (b) and SEM (c). These schematic diagrams illustrate the way the different signals can be detected in the different instruments.

B1.17.3.2 ELECTRON DETECTORS IN TEM, STEM, AND SEM

Detectors in EM can be categorized according to their different spatial resolution or in relation to the time it takes to actually see and process the signal (real-time/on-line capability).

Historically, TEM—as an offspring of the electron oscillograph—uses a fluorescent viewing screen for the direct observation of impinging electrons by green fluorescent light. The spatial resolution of such screens is of the order of 30–50 μm . Coupled to a TV camera tube and computer frame-grabber cards, fluorescent screens are still used for the real-time recording of the image. Often the cameras are combined with silicon intensifier targets (SIT), which allows

-12-

the detection of single electrons. This is of special importance for the study of beam-sensitive samples. In general, the spatial resolution of such combinations is very poor and dynamic range of the signal is limited to about 256 grey levels (8 bit).

The most common electron detector for TEM has been photographic emulsion. Its silver halide particles are sensitive to high-energy electrons and record images at very high resolution (grain size smaller than 10 μm) when exposed to the electron beam in the TEM. The resolution recorded on film depends on the scattering volume of the striking electron. For typical electron energies of 100–200 keV, its lateral spread is 10–20 μm . The dynamic range of photographic film is up to 4000 grey levels (12 bit). The most important advantage of film is its large detector size combined with high resolution: with a film size of $6 \times 9 \text{ cm}^2$, up to 10^7 image points can be recorded.

A recent development is the adaptation of IP to EM detection. IPs have been used for detecting x-rays, which generate multiple electron–electron hole pairs in a storage layer of BaFBr:Eu^{2+} . The pairs are trapped in Eu–F centres and can be stimulated by red light to recombine, thereby emitting a blue luminescent signal. Exposing IPs to high energetic electrons also produces electron–electron hole pairs. Scanning the IP with a red laser beam and detecting the blue signal via a photo-multiplier tube results in the readout of the latent image. The large detector size and their extremely high dynamic range of more than 10^7 makes IPs the ideal detector for electron diffraction.

The only on-line detector for TEM with moderate-to-high spatial resolution is the slow-scan CCD camera. A light-sensitive CCD chip is coupled to a scintillator screen consisting of plastic, an yttrium–aluminium garnet (YAG) crystal, or phosphor powder. This scintillator layer deteriorates the original resolution of the CCD chip elements by scattering light into neighbouring pixels. Typical sizes of chips at present are 1024×1024 or 2048×2048 pixels of $(19\text{--}24 \mu\text{m})^2$; the achievable dynamic range is about 10^5 grey levels.

For all the detectors with spatially distinct signal recording, the numeric pixel size (such as scanning pixel size for photographic film and IP, or chip-element size for ssCCD) must be distinguished from the actual obtainable resolution. This resolution can be affected by the primary scattering process of electrons in the detecting medium, or by the scattering of a produced light signal or a scanning light spot in the detecting medium. Therefore, a point signal is delocalized, mathematically described by the PSF. The Fourier transform of the PSF is called the modulation transfer function (MTF), describing the spatial frequency response of the detector. Whereas the ideal detector has a $\text{MTF} = 1$ over the complete spatial frequency range, real detectors exhibit a moderate to strong fall-off of the MTF at the Nyquist frequency, i.e. their maximal detectable spatial resolution. In addition to spatial resolution, another important quantity characterizing a detector is the detection quantum efficiency (DQE). It is a measure of the detector noise and gives an assessment for the detection of single electrons.

For all TEM detectors the ssCCD has the best DQE. Depending on the scintillator, it is in the range of $\text{DQE} = 0.6 - 0.9$, comparable to IPs which show a DQE in the order of 0.5–0.8. The DQE of photographic emulsion is strongly dependent on electron dose and does not exceed $\text{DQE} = 0.2$. For a complete and up-to-date discussion on TEM electron detectors see the special issue of *Microscopy Research and Technique* (vol 49, 2000).

In SEM and STEM, all detectors record the electron current signal of the selected interacting electrons (elastic scattering, secondary electrons) in real time. Such detectors can be designed as simple metal-plate detectors, such as the elastic dark-field detector in STEM, or as electron-sensitive PMT. For a rigorous discussion of SEM detectors see [3].

-13-

Except for the phase-contrast detector in STEM [9], STEM and SEM detectors do not track the position of the recorded electron. The spatial information of an image is formed instead by assigning the measured electron current to the known position of the scanned incident electron beam. This information is then mapped into a 2D pixel array, which is depicted either on a TV screen or digitalized in a computer.

For the parallel recording of EEL spectra in STEM, linear arrays of semiconductor detectors are used. Such detectors convert the incident electrons into photons, using additional fluorescent coatings or scintillators in the very same way as the TEM detectors described above.

B1.17.4 SPECIMEN PREPARATION

The necessity to have high vacuum in an electron beam instrument implies certain constraints on the specimen. In addition, the beam damage resulting from the interaction of electrons with the specimen (radiation damage) requires specific procedures to transfer the specimen into a state in which it can be analysed. During these procedures, which are more elaborate for organic than for inorganic solid-state materials, structural and compositional aspects of the specimen may be altered and consequently the corresponding information may be misleading or completely lost. It must be mentioned here that the EM is only the tool to extract information from the specimen. As well as having its own physical problems (CTF, beam damage, etc) it is—like any other microscopy—clearly not capable of restoring information that has been lost or altered during specimen preparation.

Specimens for (S)TEM have to be transparent to the electron beam. In order to get good contrast and resolution, they have to be thin enough to minimize inelastic scattering. The required thin sections of organic materials can be obtained by ultramicrotomy either after embedding into suitable resins (mostly epoxy- or methacrylate resins [11]) or directly at low temperatures by cryo-ultramicrotomy [12].

Ultramicrotomy is sometimes also used to produce thin samples of solid materials, such as metals [13] which are, however, preferentially prepared by chemical- or ion-etching (see [1]) and focused ion beam (FIB) techniques [14].

Bulk specimens for SEM also have to resist the impact of the electron beam instrument. While this is generally a minor problem for materials science specimens, organic and aqueous biological samples must be observed either completely dry or at low enough temperatures for the evaporation/sublimation of solvents and water to be negligible. Internal structures of aqueous biological samples can be visualized by cryosectioning or cryofracturing procedures [15,16]. Similar procedures are used in the preparation of polymers and composites [17]. Fracturing and field-ion beam procedures are used to expose internal structures of semiconductors, ceramics and similar materials.

The preparation of biological specimens is particularly complex. The ultrastructure of living samples is related to numerous dynamic cellular events that occur in the range of microseconds to milliseconds [18]. Interpretable high-resolution structural information (e.g. preservation of dimensions, or correlation of the structural detail with a physiologically or biochemically controlled state) is therefore obtained exclusively from samples in which life has been stopped very quickly and with a sufficiently high time resolution for the cellular dynamics [19]. Modern concepts for specimen preparation therefore try to avoid traditional, chemical

fixation as the life-stopping step because it is comparatively slow (diffusion limited) and cannot preserve all cellular components. Cryotechniques, often in

-14-

combination with microscopy at low temperatures, are used instead. Very high cooling rates ($> 10\,000\text{ K s}^{-1}$) are required to prevent the formation and growth of ice crystals, which would affect the structural integrity. Such high cooling rates, at the same time, result in a rapid arrest of the physiological events, i.e. produce a very high temporal resolution (microseconds to milliseconds) [20], in capturing dynamic processes in the cell [21,22].

Despite the drawbacks of chemical-fixation based procedures [23,24], most of our current knowledge on biological ultrastructure relies on this approach. In contrast to cryopreparative procedures, chemical fixation does not require special skills and instrumentation.

Cryoimmobilization procedures that lead to vitrification (immobilization of the specimen water in the amorphous state) are the sole methods of preserving the interactions of the cell constituents, because the liquid character of the specimen water is retained (reviewed in [25]).

Vitrification at ambient pressure requires very high cooling rates. It can be accomplished by the 'bare grid' approach for freezing thin ($> 100\text{ nm}$) aqueous layers of suspensions containing isolated macromolecules, liposomes, viruses, etc. This technique was used to produce [figure B1.17.6](#). It has developed into a powerful tool for structural biology, now providing subnanometre resolution of non-crystalline objects [26,27]. The bare-grid technique permits imaging of macromolecules in functional states with sufficient resolution to allow the correlation with atomic data from x-ray diffraction of crystals [28,29] (see also *Journal of Structural Biology*, vol 125, 1999).

High-pressure freezing is at present the only practicable way of cryoimmobilizing larger non-pretreated samples [30,32]. At a pressure of 2100 bars, about the 10-fold greater thickness can be vitrified, as compared to vitrification at ambient pressure [33] and a very high yield of adequately frozen specimens (i.e. no detectable effects of ice crystal damage visible after freeze substitution) has been demonstrated by TEM of suspensions of micro-organisms, as well as for plant and animal tissue, provided that the thickness of the aqueous layer did not exceed $200\text{ }\mu\text{m}$.

Biological material, immobilized chemically or by rapid freezing, must be transferred into an organic solvent that is compatible with the most frequently used hydrophobic resins. Chemically fixed materials are dehydrated in graded series of alcohol or acetone at room temperature. The ice of the frozen sample is dissolved at low temperature by a freeze-substitution process [34]. For TEM, the samples are embedded in resin [11], for SEM they are dried, most frequently by the critical-point drying technique, which avoids deleterious effects of the surface tension of the solvents. Dehydration and complete drying results in non-isotropic shrinkage of biological materials.

The information that can be extracted from inorganic samples depends mainly on the electron beam/specimen interaction and instrumental parameters [1], in contrast to organic and biological materials, where it depends strongly on specimen preparation.

For analytical SEM and non-destructive imaging (e.g. semiconductor, critical-dimension measurements (CD) and other quality control) adequate electron energies have to be selected in order to minimize charging up of the specimen. For high-resolution imaging of surfaces using the SE signal, the signal source often must be localized at the specimen surface by a thin metal coating layer [35].

B1.17.5 IMAGE FORMATION AND IMAGE CONTRAST

Whereas electron optics, sample preparation and the interaction of electrons with the sample follow a common set of rules for all different kinds of EM (TEM, STEM, SEM), the image formation and image contrast in EM images is very technique-specific. In general, analytical imaging is distinguished from structural imaging, the latter being further classified either into the imaging of the projected 2D scattering potential for TEM and STEM or into the topographical imaging of a surface in SEM. The complete understanding of the electron–sample interaction and the increasingly better understanding of the sample preparation and reconstruction of the object from image contrast allows a quantitative interpretation of EM data. The electron microscope has evolved, over a long period, from a simple imaging microscope to a quantitative data collection device.

B1.17.5.1 IMAGING OF PROJECTED STRUCTURE—THE CONTRAST TRANSFER FUNCTION (CTF) OF TEM

The discussion of the electron–specimen interaction has already provided the necessary physical principles leading to amplitude and phase changes of the scattered electron wave. Consider again the elastic scattering as described by [equation \(B1.17.1\)](#). In STEM the elastic scattering is measured by an angular detector, integrating over all electrons scattered to high angles (see [figure B1.17.3\(a\)](#)). For thin samples, the measured image contrast can be directly interpreted as the spatial distribution of different atomic composition. It corresponds to the pointwise measurement of the sample’s scattering factor amplitude (see [equation \(B1.17.9\)](#))

$$f_{\text{int}} = \int_{\theta_{\text{det. min}}}^{\theta_{\text{det. max}}} \int_0^{2\pi} f(\theta) \, d\varphi \, d\theta \quad (\text{B1.17.13})$$

where θ denotes the scattering angle, constrained by the geometry of the angular detector; φ denotes the azimuthal angle. According to the properties of the elastic scattering distribution ([equation \(B1.17.1\)](#)), the detected signal for a given detection angle interval depends strongly on the atomic number Z of the scattering atom. This results in different contrast for different atomic composition (Z -contrast). With a different, position selective, detector it is also possible to measure the phase part of the scattering factor. The geometry of these detectors is illustrated in [figure B1.17.3\(b\)](#) [9].

Figure B1.17.3. STEM detectors: (a) conventional bright and dark-field detectors, electrons are detected according to their different scattering angles, all other positional information is lost; (b) positional detector as developed by Haider and coworkers (Haider *et al* 1994).

It should be noted again that STEM provides lateral spatial discrimination of the 2D projected sample by the scanning of a point-like electron beam. Spatial resolution is thereby given by the focus of the incident beam, which is at present limited to a typical diameter of a few Ångströms. Modern TEM, using the very coherent electron wave of a FEG and higher electron energies (see B1.17.3.1), delivers higher resolution, i.e. its information limit can be improved into the sub-Ångström regime. However, the correspondence of image contrast and scattering factor $f(\theta)$ (equation (B1.17.9)) is more complicated than in STEM. In TEM, image contrast can be understood either by interference effects between scattered and unscattered parts of the electron wave, or by simple removal of electrons scattered to higher angles (scattering contrast). The latter is important for imaging of strongly scattering objects consisting of heavy metal atoms. Electrons scattered to high angles are easily removed by a circular aperture (see figure B1.17.4(a)). Elastically scattered electrons not removed by such an aperture can form interference patterns with the unscattered part of the incident electron wave (see figure B1.17.4(b)). Such interference patterns lead to either diffraction patterns or images of the sample, depending on the imaging conditions of the microscope. Therefore, any wave aberrations of the electron wave, both by the imaged sample (desired signal) and by lens aberrations or defocused imaging, result in a change of image

contrast. Mathematically, this behaviour is described by the concept of contrast transfer in spatial frequency space (Fourier space of image), modelled by the CTF.

Figure B1.17.4. Visualization of image contrast formation methods: (a) scattering contrast and (b) interference contrast (weak phase/weak amplitude contrast).

In the simplest case of bright-field imaging, the CTF can easily be deduced: the elastically scattered electron wave can be described using a generalized phase shift Φ_{gen} by

$$\psi_{\text{scattered}}(\mathbf{r}) = \psi_0(\mathbf{r}) \exp(i\Phi_{\text{gen}}(\mathbf{r})) \quad (\text{B1.17.14})$$

where

$$\exp(i\Phi_{\text{gen}}(\mathbf{r})) = \exp(i\varphi_{\text{el}}(\mathbf{r}) + \mu_{\text{el}}(\mathbf{r})) \quad (\text{B1.17.15})$$

and $\varphi_{\text{el}}(\mathbf{r})$ and $\mu_{\text{el}}(\mathbf{r})$ denote the elastic phase and amplitude contrast potential. In the notation of [equation \(B1.17.15\)](#), $\varphi_{\text{el}}(\mathbf{r})$ denotes a positive phase potential whereas $\mu_{\text{el}}(\mathbf{r})$ denotes a negative absorption potential. Assuming a weak phase/weak amplitude object—compared to the unscattered part of the electron wave—the generalized phase shift can be reduced to

$$\exp(i\Phi_{\text{gen}}(\mathbf{r})) = 1 + i\varphi_{\text{el}}(\mathbf{r}) + \mu_{\text{el}}(\mathbf{r}). \quad (\text{B1.17.16})$$

After propagation into the back focal plane of the objective lens, the scattered electron wave can be expressed in terms of the spatial frequency coordinates k as

$$\tilde{\psi}_{\text{scattered}}(\mathbf{k}) = (\delta(\mathbf{k}) + i\tilde{\varphi}_{\text{el}}(\mathbf{k}) + \tilde{\mu}_{\text{el}}(\mathbf{k})) \times \exp(-iW(\mathbf{k})). \quad (\text{B1.17.17})$$

Here $W(\mathbf{k})$ denotes the wave aberration

$$W(\mathbf{k}) = \frac{\pi}{2}(C_s\lambda^3k^4 - 2\Delta z\lambda k^2) \quad (\text{B1.17.18})$$

with the objective lens spherical aberration C_s , the electron wave length λ and the defocus Δz . It should be noted that, in the above formulae, the effect of inelastic scattering is neglected. For a rigorous discussion of image contrast, including inelastic scattering, see [36].

In the usual approximation of the object as a weak phase/weak amplitude object, this scattered wave can be used to calculate the intensity of the image transform as

$$\tilde{I}(\mathbf{k}) = \tilde{\psi}_{\text{scattered}}(\mathbf{k}) \otimes \tilde{\psi}_{\text{scattered}}^*(\mathbf{k}). \quad (\text{B1.17.19})$$

Calculating the convolution using equation (B1.17.17) and regrouping the terms yields the final equation for the image transform:

$$\tilde{I}(\mathbf{k}) = \delta(\mathbf{k}) - 2 \times (\tilde{\varphi}_{\text{el}}(\mathbf{k})) \sin(W(\mathbf{k})) + \tilde{\mu}_{\text{el}}(\mathbf{k}) \cos(W(\mathbf{k})). \quad (\text{B1.17.20})$$

The power spectrum of the image $PS(\mathbf{k})$ is then given by the expectation value $\langle \tilde{I}(\mathbf{k}) \times \tilde{I}(\mathbf{k}) \rangle$, normally calculated as the squared amplitude of the image transform. More detailed discussions of the above theory are found in [1,2].

In the conventional theory of elastic image formation, it is now assumed that the elastic atomic amplitude scattering factor is proportional to the elastic atomic phase scattering factor, i.e.

$$\tilde{\mu}_{\text{el}}(\mathbf{k}) = -A(\mathbf{k})\tilde{\varphi}(\mathbf{k}) \equiv -A\tilde{\varphi}_{\text{el}}(\mathbf{k}). \quad (\text{B1.17.21})$$

The factor A has been measured for a variety of samples, indicating that the approximation can be applied up to quasi-atomic resolution. In the case of biological specimens typical values of A are of the order of 5–7%, as determined from images with a resolution of better than 10 Å [37,38]. For an easy interpretation of image contrast and a retrieval of the object information from the contrast, such a combination of phase and amplitude information is necessary.

Figure B1.17.5 shows typical examples of the CTF for weak phase, weak amplitude or combined samples. The resulting effect on image contrast is illustrated in Figure B1.17.6, which shows image averages of a protein complex embedded in a vitrified aqueous layer recorded at different defocus levels. The change in contrast and visible details is clear, but a direct interpretation of the image contrast in terms of object structure is not possible. To reconstruct the imaged complex, it is necessary to combine the information from the different images recorded with different defocus levels. This was first suggested by Schiske [39] and is normally applied to high-resolution images in materials science or biology. Such correction procedures are necessary to rectify the imaging aberrations from imperfect electron-optical systems, which result in a delocalized contrast of object points. In recent years, improvements of the electron-optical lenses have been made, and high-resolution imaging with localized object contrast will be possible in the future (see B1.17.5.3

and [figure B1.17.9](#)). It should be noted that any high-resolution interpretation of an EM image strongly depends on the correction of the CTF. In high-resolution TEM in materials science, sophisticated methods for this correction have been developed and are often combined with image simulations, assuming a certain atomic model structure of the sample. Three mainstream developments in this field are: (1) the use of focal series and subsequent image processing [[40,41](#)], (2) electron holography [[42,43](#) and [44](#)] and (3) the development of corrected TEMs, which prohibit contrast delocalization (see [B1.17.5.3](#)).

-20-

Figure B1.17.5. Examples of CTFs for a typical TEM (spherical aberration $C_s = 2.7$ mm, 120 keV electron energy). In (a) and (b) the idealistic case of no signal decreasing envelope functions [[77](#)] are shown. (a) Pure phase contrast object, i.e. no amplitude contrast; two different defocus values are shown (Scherzer focus of 120 nm underfocus (solid curve), 500 nm underfocus (dashed curve)); (b) pure amplitude object (Scherzer focus of 120 nm underfocus); (c) realistic case including envelope functions and a mixed weak

amplitude/weak phase object (500 nm underfocus).

-21-

Figure B1.17.6. A protein complex (myosin S1 decorated filamentous actin) embedded in a vitrified ice layer. Shown is a defocus series at (a) 580 nm, (b) 1130 nm, (c) 1700 nm and (d) 2600 nm underfocus. The pictures result from averaging about 100 individual images from one electron micrograph; the decorated filament length shown is 76.8 nm.

B1.17.5.2 IMAGING OF SURFACE TOPOLOGY

SEMs are ideally suited to study highly corrugated surfaces, due to the large depth of focus. They are generally operated with lower beam energies (100 eV–30 keV) in order to efficiently control the volume in which the electron beam interacts with the sample to produce various specific signals (see [figure B1.17.1](#) for imaging and compositional analysis. Modern SEM instruments (equipped with a field emission electron source) can scan the sample surface with a beam diameter of 1 nm or smaller, thus providing high-resolution structural information that can complement the information obtained from atomic force microscopy (AFM). In contrast to AFM, which directly provides accurate height information in a limited range, quantitative assessment of the surface topography by SEM is possible by measuring the parallax of stereo pairs [45].

High-resolution topographic information is obtained by the secondary-electron signal (SE 1, see [figure B1.17.7](#) produced at the point of impact of the primary beam (PE). The SE 1 signal alone is related to the position of the scanning beam. It depends on the distance the primary beam travels through the SE escape zone, where it releases secondary electrons that can leave the specimen surface, i.e. it depends on the angle of impact of the primary beam (see [figure B1.17.7](#)). The high-resolution topographic signal is obscured by other SE signals (SE 2, SE 3, [figure B1.17.7](#)) that are created by BSE (electrons of the primary beam, multiply scattered deeper inside the specimen) when they leave the specimen and pass through the SE escape zone (SE 2) and hit the pole pieces of the objective lens and/or the walls of the specimen chamber (SE 3). Additional background signal is produced by the primary beam striking the objective lens aperture.

-22-

Figure B1.17.7. (a) Classification of the secondary electron signals. High-resolution topographic information is obtained by the SE 1 signal. It might be obscured by SE 2 and SE 3 signals that are created by the conversion of BSE. d : SE escape depth, R : range out of which BSE may leave the specimen. (b) SE signal intensity, $R > d$: the SE 1 signal depends on the angle of impact of the electron beam (PE). SE 1 can escape from a larger volume at tilted (B) surfaces and edges (C) than at orthogonal surfaces (A).

High-resolution topographic imaging by secondary electrons therefore demands strategies (instrumentation, specimen preparation [35] and imaging conditions) that aim at enhancing the SE 1 signal and suppressing the background noise SE signals (e.g. [46]). Basically, the topographic resolution by SE 1 depends on the smallest spot size available and on the SE escape zone, which can be up to 100 nm for organic materials and down to 1–2 nm for metals.

Non-conductive bulk samples, in particular, are frequently rendered conductive by vacuum coating with metals using sputter or evaporation techniques. The metal coating should be of uniform thickness and significantly thinner than the smallest topographic details of interest. Metal coating provides the highest resolution images of surface details. It may, however, irreversibly destroy the specimen. An example of such a metal-coated sample is shown in [figure B1.17.8](#).

Figure B1.17.8. Iron oxide particles coated with 4 nm of Pt in an m-planar magnetron sputter coater (Hermann and Müller 1991). Micrographs were taken in a Hitachi S-900 ‘in-lens’ field emission SEM at 30,000 primary magnification and an acceleration voltage of 30 kV. Image width is 2163 nm.

SEM with low acceleration voltage (1–10 kV) (LVSEM) can be applied without metal coating of the sample, e.g. for quality control purposes in semiconductor industries, or to image ceramics, polymers or dry biological samples. The energy of the beam electrons (the acceleration voltage) should be selected so that charge neutrality is approached, i.e. the amount of energy that enters the sample also leaves the sample in the form of SE and BSE. Modern SEM instruments, equipped with FEGs provide an adequate spot size, although the spot size increases with decreasing acceleration voltage. The recent implementation of a cathode lens system [47] with very low aberration coefficients will allow the surfaces of non-metal coated samples at beam energies of only a few electronvolts to be imaged without sacrificing spot size. New contrast mechanisms and new experimental possibilities can be expected.

The fact that electron beam instruments work under high vacuum prohibits the analysis of aqueous systems, such as biological materials or suspensions, or emulsions without specimen preparation as outlined above. These preparation procedures are time consuming and are often not justified in view of the only moderate resolution required to solve a specific practical question (e.g. to analyse the grain size of powders, bacterial colonies on agar plates, to study the solidification of concrete, etc). Environmental SEM (ESEM) and ‘high-pressure SEM’ instruments are equipped with differentially pumped vacuum systems and Peltier-cooled specimen stages, which allow wet samples to be observed at pressures up to 5000 Pa [48]. Evaporation of water from the specimen or condensation of water onto the specimen can thus be efficiently controlled. No metal coating or other preparative steps are needed to control charging of the specimen since the interaction of the electron beam with the gas molecules in the specimen chamber produces positive ions that can compensate surface charges. ‘High-pressure SEM’, therefore, can study insulators without applying a conductive coating. The high gas pressure in the vicinity of the specimen leads to a squirting of the electron beam. Thus the resolution-limiting spot size achievable on the specimen surface depends on the acceleration voltage, the gas pressure, the scattering cross section of the gas and the distance the electrons have to travel through the high gas pressure zone [49]. High-pressure SEM and ESEM is still under development and the scope of applications is expanding. Results to date consist mainly of analytical and low-resolution images (e.g. [50]).

B1.17.5.3 MODERN DEVELOPMENTS OF INSTRUMENTS AFFECTING IMAGE CONTRAST AND RESOLUTION

As was discussed above, the image contrast is significantly affected by the aberrations of the electron-optical

lenses. The discussion on the CTF showed that the broadening PSF of the TEM delocalizes information in an TEM image. This necessitates additional techniques to correct for the CTF, in order to obtain interpretable image information. Furthermore, it was discussed that the resolution of STEM and SEM depends on the size of the focused beam, which is also strongly dependent on lens aberrations. The leading aberrations in state-of-the-art microscopes are the spherical and chromatic aberrations in the objective lens. Correction of such aberrations was discussed as early as 1947, when Scherzer suggested the correction of electron optical lenses [51], but it was not until 1990 that a complete concept for a corrected TEM was proposed by Rose [52]. It was in the last decade that prototypes of such corrected microscopes were presented.

The first corrected electron-optical SEM was developed by Zach [10]. For low-voltage SEM (LVSEM, down to 500 eV electron energy instead of the conventional energies of up to 30 keV) the spot size is extremely large without aberration correction. Combining C_s and C_c correction and an electrostatic objective lens, Zach showed that a substantial improvement in spot size and resolution is possible. The achievable resolution in a LVSEM is now of the order of 1–2 nm. More recently, Krivanek and colleagues succeeded in building a C_s corrected STEM [53,54].

The construction of an aberration-corrected TEM proved to be technically more demanding: the point resolution of a conventional TEM today is of the order of 1–2 Å. Therefore, the aim of a corrected TEM must be to increase the resolution beyond the 1 Å barrier. This implies a great number of additional stability problems, which can only be solved by the most modern technologies. The first C_s corrected TEM prototype was presented by Haider and coworkers [55]. Figure B1.17.9 shows the improvement in image quality and interpretability gained from the correction of the spherical aberration in the case of a materials science sample.

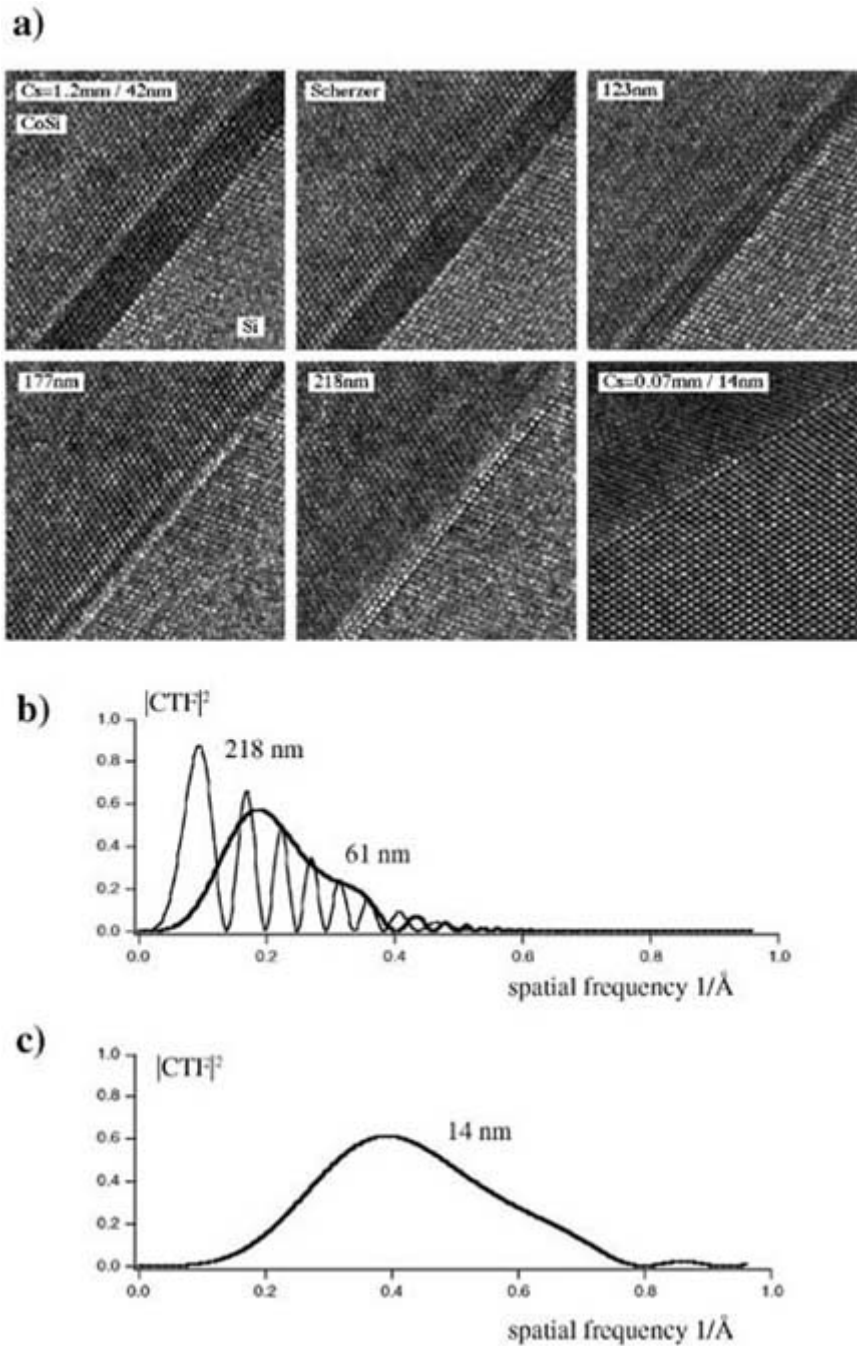

Figure B1.17.9. A CoSi grain boundary as visualized in a spherical-aberration-corrected TEM (Haider *et al* 1998). (a) Individual images recorded at different defocus with and without correction of C_s ; (b) CTFs in the case of the uncorrected TEM at higher defocus; (c) CTF for the corrected TEM at only 14 nm underfocus. Pictures by courtesy of M Haider and Elsevier.

The field of corrected microscopes has just begun with the instruments discussed above. The progress in this field is very rapid and proposals for a sub-Ångström TEM (SATEM) or even the combination of this instrument with a corrected energy filter to form a sub-electronvolt/sub-Ångström TEM (SESAM) are underway.

B1.17.6 ANALYTICAL IMAGING, SPECTROSCOPY, AND MASS MEASUREMENTS

For a detailed discussion on the analytical techniques exploiting the amplitude contrast of inelastic images in ESI and image-EELS, see [chapter B1.6](#) of this encyclopedia. One more recent but also very important aspect is the quantitative measurement of atomic concentrations in the sample. The work of Somlyo and colleagues [56], Leapman and coworkers [57,58], and Door and Gängler [59] introduce techniques to convert measured intensities of inelastically scattered electrons directly into atomic concentrations.

For bio-medical or cell-biological samples, in particular, this provides a direct measurement of physiological ion concentrations. The main disadvantage of such methods is the almost unavoidable delocalization of free ions and the resulting change in concentration during sample preparation steps. The discussed rapid freezing and the direct observation of samples without any chemical treatment provides a very good compromise for organic samples. In materials science, delocalization does not seem to pose a major problem.

Another specialized application of EM image contrast is mass measurement. Using the elastic dark-field image in the STEM or the inelastic image in the EFTEM, a direct measurement of the scattering mass can be performed. For reviews on this technique see [60,61].

B1.17.7 3D OBJECT INFORMATION

EM images are always either 2D projections of an interaction potential (see equation (B1.17.11) and equation (B1.17.12)) or a surface topology encoded in grey levels of individual image points (image contrast). The aim of EM image processing is to reconstruct the 3D object information from a limited number of such projections. This problem does not arise for all applications of EM. Very often in materials science the sample is prepared in such a way that one single projection image contains all the information necessary to answer a specified question. As an example, consider [figure B1.17.9](#) which shows a Co–Si interface. The orientation of the sample is chosen to give a perfect alignment of atoms in the direction of the grain boundary. Imaging at atomic resolution allows the direct interpretation of the contrast as images of different atoms. One single exposure is, in principle, sufficient to collect all the information needed. It should be noted here again that this is only true for the spherical-aberration, C_s corrected EM with its non-oscillating CTF (bottom right panel in [figure B1.17.9\(a\)](#)). As is obvious from the Co–Si interface ([figure B1.17.9\(a\)](#)) finite C_s imaging) and the defocus series of the biological sample ([figure B1.17.6](#)) more than one image has to be combined for conventional EMs. However, such a direct interpretation of one projected image to obtain the 3D structure information works only for samples that are ordered crystallographically at the atomic level. For other samples it is necessary to combine projections from different angles. Such samples are unique, non-crystallographic structures, e.g. structural defects in materials science, cellular compartments in cell biology, or macromolecules (protein complexes or single biological molecules) in high-resolution molecular imaging.

The generalized problem has been solved by tomography. In EM it is possible to tilt the sample along an axis which is perpendicular to the electron beam (single-axis tomography, see [figure B1.17.10](#)). If the sample can withstand a high cumulative electron dose, then an unlimited number of exposures at different defocus values and tilting angles can be recorded. If kinematical scattering theory can be applied (single elastic scattering, compare [equation \(B1.17.8\)](#)), then it is possible to correct all the effects of the CTF and each corrected projection image at one particular tilting angle corresponding to a section of the Fourier-transformed scattering potential [equation \(B1.17.11\)](#) and [equation \(B1.17.12\)](#). The combination of information from different tilting angles provides the determination of the structure factors in the complete 3D Fourier space. Finally, a simple mathematical inverse Fourier-transform produces a complete 3D reconstructed object. A

geometric equivalent of the projection and reconstruction process is found in the sectioning of the Ewald-sphere with the 3D Fourier-transform of the scattering potential. For an introduction to the concepts of the Ewald-sphere and Fourier techniques in structure determination see [62].

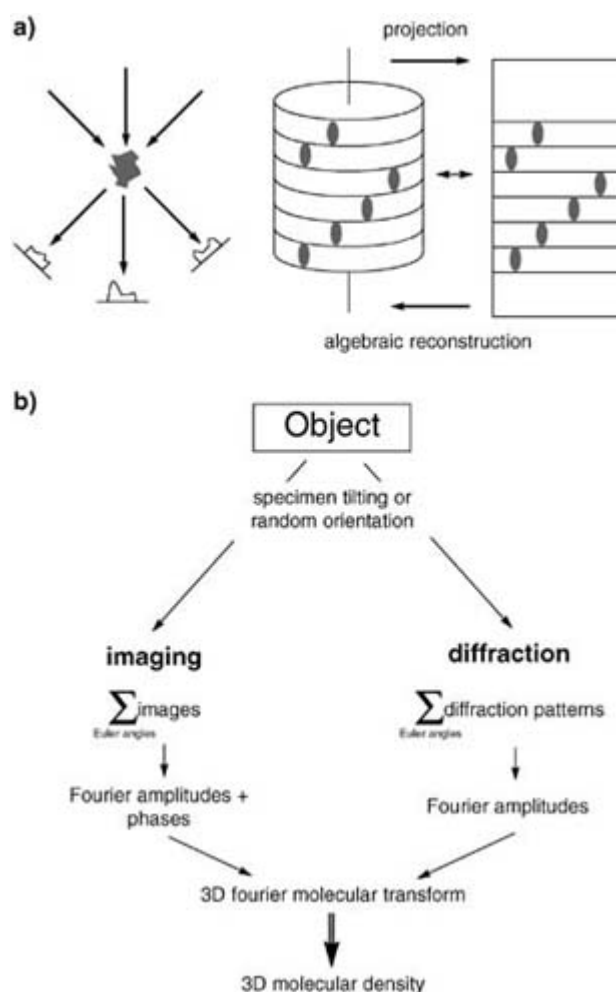

Figure B1.17.10. Principles of 3D reconstruction methods. (a) Principle of single axis tomography: a particle is projected from different angles to record corresponding images (left panel); this is most easily realized in the case of a helical complex (right panel). (b) Principle of data processing and data merging to obtain a complete 3D structure from a set of projections.

The basic reconstruction algorithms involved are mathematically well known and are well established [63]. A variety of concepts has evolved for single- and multi-axis tomography, combining projection information, calculating 3D object densities either with Fourier- or real-space algorithms (see figure B1.17.10 which shows some examples of the geometry used for the single- and multi-axis tomography). For a complete reference to the methods used see Frank [64] and the special issue of *Journal of Structural Biology* (vol 120, 1997).

The main disadvantage of the tomographic approach is the beam-induced destruction of the sample. In practice, one can record only a limited number of images. Therefore, it is not possible to correct the CTF completely or to obtain an infinite sampling of the projection angles from only one specimen. Two major approaches are used today: the single- and double-axis tomography of one individual object (e.g. cell organelles, see Baumeister and coworkers [65]) and, second, the imaging of many identical objects under different projection angles (see [64]; random conical tilt, angular reconstitution).

For single-axis tomography, with its limited number of images and the subsequent coarse sampling in reciprocal Fourier space, only a moderate resolution can be expected. For chemically fixed samples with high image contrast from heavy atom staining it is possible to obtain a resolution of about 4 nm ([66], reconstruction of the centrosome). For native samples, true single-axis tomography without averaging over different samples results in even lower resolution. Today, sophisticated EM control software allows a fully automatic collection of tilted images [67], making single-axis tomography a perfect reconstruction tool for unique objects.

If many identical copies of the object under study are available, other procedures are superior. They rely on the fact that the individual molecules are oriented with respect to the incident electron beam. Such a situation is found mainly for native ice-embedded samples (compare the paragraph about preparation). In ice layers of sufficient thickness, no special orientation of the molecule is preferred. The obtained projection images from one, untilted image can then be classified and aligned in an angular reconstitution reconstruction process. By averaging large numbers of projection images, it is possible to correct for CTF effects [68] and to obtain an almost complete coverage of reciprocal Fourier space. If—for some reason—the object still shows a limited number of preferred orientations, an additional tilting of the sample again gives complete coverage of possible projection angles (random conical tilt method). Both methods have been successfully applied to many different biological samples (for an overview, see [64]).

An important point for all these studies is the possible variability of the single molecule or single particle studies. It is not possible, *a priori*, to exclude ‘bad’ particles from the averaging procedure. It is clear, however, that high structural resolution can only be obtained from a very homogeneous ensemble. Various classification and analysis schemes are used to extract such homogeneous data, even from sets of mixed states [69]. In general, a typical resolution of the order of 1–3 nm is obtained today.

The highest resolutions of biological samples have been possible for crystalline samples (electron crystallography). 2D crystals of membrane proteins and one cytoskeletal protein complex have been solved at the 3–4 Å level combining imaging and electron diffraction, as pioneered by Henderson and coworkers [70,71 and 72], also see [figure B1.17.11](#). Icosahedral virus particles are reconstructed from images to 8–9 Å resolution [26,27], allowing the identification of alpha helices. Compared to single particles, these samples give much higher resolution, in part because much higher numbers of particles are averaged, but it is also possible that a crystallization process selects for the uniformity of the crystallizing object and leads to very homogeneous ensembles.

Figure B1.17.11. Reconstructed density of an α,β -tubulin protein dimer as obtained from electron crystallography (Nogales *et al* 1997). Note the appearance of the β -sheets ((a), marked B) and the α -helices ((b), marked H) in the density. In particular the right-handed α -helix H6 is very clear. Pictures by courtesy of E Nogales and Academic Press.

For electron crystallography, the methods to obtain the structure factors are comparable to those of conventional x-ray crystallography, except that direct imaging of the sample is possible. This means that both electron diffraction and imaging can be used, i.e. structure amplitudes are collected by diffraction, structure factor phases by imaging. For a general overview in the structure determination by electron crystallography, see [73]. The 3D structure of the sample is obtained by merging diffraction and imaging data of tilt series from different crystals. It is, therefore, a form of tomography adapted for a diffracting object.

Even though it is easy to get the phase information from imaging, in general, imaging at the desired high resolution (for structure determination work of the order of 3–4 Å) is very demanding. Specialized instrumentation (300 kV, FEG, liquid He sample temperature) have to be used to avoid multiple scattering, to allow better imaging (less imaging aberrations, less specimen charging which would affect the electron beam) and to reduce the effects of beam damage.

B1.17.8 TIME-RESOLVED AND *IN SITU* EM STUDIES: VISUALIZATION OF DYNAMICAL EVENTS

As a result of the physical conditions in electron microscopes such as the high vacuum, the high energy load on the sample by inelastic scattering, or the artificial preparation of the sample by sectioning or thinning, it has become customary to think about samples as static objects, precluding the observation of their native structural changes during a reaction. In some studies, however, the dynamics of reactions have been studied for biological systems as well as in

materials science. *In situ* microscopy was widely used in materials science in the 1960s and 1970s, when, for example, metal foils were studied, heated up in the EM, and reactions followed in a kind of time-lapse

microscopy [74]. In recent years, similar experiments have been performed on semiconductors and ceramics, and a general new interest in *in situ* microscopy has developed.

Time-resolved EM in biological systems is a comparatively new and limited field. Simple time-lapse fixation of different samples of a reacting biological tissue has long been used, but the direct, temporal monitoring of a reaction was developed only with the invention of cryo-fixation techniques. Today, time-lapse cryo-fixation studies can be used in the case of systems with slow kinetics, i.e. reaction times of the order of minutes or slower. Here, samples of a reacting system are simply taken in certain time intervals and frozen immediately. For the study of very fast reactions, two approaches have been developed that couple the initiation of the reaction and the fixation of the system on a millisecond time scale. The reaction itself can be started either by a rapid mixing procedure [75] or by the release of a masked reaction partner photolysing caged compounds (see figure B1.17.12 [76]. For a review of time-resolved methods used in biological EM, see [19].

Figure B1.17.12. Time-resolved visualization of the dissociation of myosin S1 from filamentous actin (see also figure B1.17.6). Shown are selected filament images before and after the release of a nucleotide analogue (AMPPNP) by photolysis: (a) before flashing, (b) 20 ms, (c) 30 ms, (d) 80 ms and (e) 2 s after flashing. Note the change in obvious order (as shown by the diffraction insert in (a)) and the total dissociation of the complex in (e). The scale bar represents 35.4 nm. Picture with the courtesy of Academic Press.

B1.18 Microscopy: light

H Kiess

B1.18.1 INTRODUCTION

Light microscopy is of great importance for basic research, analysis in materials science and for the practical control of fabrication steps. When used conventionally it serves to reveal structures of objects which are otherwise invisible to the eye or magnifying glass, such as micrometre-sized structures of microelectronic devices on silicon wafers. The lateral resolution of the technique is determined by the wavelength of the light

and the objective of the microscope. However, the quality of the microscopic image is not solely determined by resolution; noise and lack of contrast may also prevent images of high quality being obtained and the theoretical resolution being reached even if the optical components are ideal. The working range of the light microscope in comparison to other microscopic techniques is depicted schematically in table B1.18.1. Clearly, the light microscope has an operating range from about half a micrometer up to millimetres, although recent developments in improving resolution allow the lower limit to be pushed below half a micrometer.

Table B1.18.1 Overview of working ranges of various microscopic techniques (in μm).

Light microscope	0.5 \leftrightarrow 1000
Scanning electron microscope	0.05 \leftrightarrow 1000
Transmission electron microscope	0.001 \leftrightarrow 10
Scanning probe microscope	0.0001 \leftrightarrow 100

Microscopes are also used as analytical tools for strain analysis in materials science, determination of refractive indices and for monitoring biological processes *in vivo* on a microscopic scale etc. In this case resolution is not necessarily the only important issue; rather it is the sensitivity allowing the physical quantity under investigation to be accurately determined.

Light microscopy allows, in comparison to other microscopic methods, quick, contact-free and non-destructive access to the structures of materials, their surfaces and to dimensions and details of objects in the lateral size range down to about 0.2 μm . A variety of microscopes with different imaging and illumination systems has been constructed and is commercially available in order to satisfy special requirements. These include stereo, darkfield, polarization, phase contrast and fluorescence microscopes.

-2-

The more recent scanning light microscopes are operated in the conventional and/or in the confocal mode using transmitted, reflected light or fluorescence from the object. Operation in the confocal mode allows samples to be optically sectioned and 3D images of objects to be produced—an important aspect for imaging thick biological samples. The breakthrough for confocal microscopes was intimately connected with the advent of computers and data processing. The conventional microscope is then replaced by a microscopic *system* comprising the microscope, the scanning, illumination and light detection systems, the data processor and computer.

This overview will first deal with the optical aspects of conventional microscopes and the various means to improve contrast. Confocal microscopy, which in the last decade has become an important tool, especially for biology, is discussed in the final section.

B1.18.2 MAGNIFICATION, RESOLUTION AND DEPTH OF FOCUS

B1.18.2.1 MAGNIFICATION

Microscopes are imaging systems and, hence, the image quality is determined by lens errors, by structures in the image plane (e.g., picture elements of CCD cameras) and by diffraction. In addition, the visibility of objects with low contrast suffers from various noise sources such as noise in the illuminating system (shot noise), scattered light and by non-uniformities in the recording media. Interest often focuses on the achievable resolution, and discussions on limits to microscopy are then restricted to those imposed by diffraction (the so-called Abbe limit), assuming implicitly that lenses are free of errors and that the visual system or the image sensors are ideal. However, even under these conditions the Abbe limit of the resolution may not be reached if the contrast is insufficient and noise is high.

Before discussing the limits imposed by diffraction and the influence of contrast and noise on resolution, it is important to recall the basic principle of the light microscope: The objective lens provides a magnified real image of the object in the focal plane of the eyepiece. This image is then focused by the eyepiece onto the retina of the eye and is seen by the observer as a virtual image at about 25 cm distance, the normal distance for distinct vision (figure B1.18.1). The object is illuminated by the light of a lamp, either from below through the stage of the object holder if the object is transparent, or from the top if the object is non-transparent and reflecting. Organic objects containing fluorescent molecules are often investigated with an illuminating light beam that causes the sample to fluoresce. The exciting light is ‘invisible’ and the object is imaged and characterized by the emitted light.

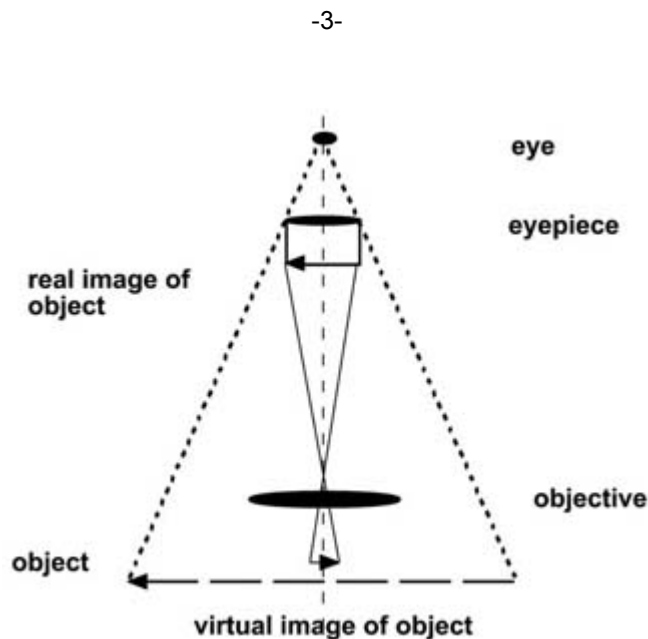

Figure B1.18.1. Light rays and imaging lenses in the microscope. The illumination system is not included. The real image is seen by the eye as a virtual image at 25 cm distance, the normal distance for distinct vision.

The magnification $M_{\text{microscope}}$ achievable by a microscope is the ratio of the scales of the virtual image and of the object. It can be easily seen from figure B1.18.1 that this ratio is given by

$$M_{\text{microscope}} = M_{\text{obj}} M_{\text{eyepiece}}$$

M_{obj} is the scale of magnification by the objective under the geometric conditions given by the microscope and $M_{\text{eyepiece}} = \ell / f_{\text{eyepiece}}$ is the magnification by the eyepiece, with the focal length f_{eyepiece} and $\ell = 25$ cm, the normal distance for distinct vision. The objectives are marked with the scale of magnification (e.g. 40:1) by the manufacturer and similarly, the eyepiece by its magnification under the given conditions (e.g. 5 \times). Multiplication of both numbers gives the magnification of the microscope. For practical reasons the magnification of the objective is not so high as to resolve all the details in the real image with the naked eye.

The magnification is rather chosen to be about $500 A_{\text{obj}}$ to $1000 A_{\text{obj}}$, where A_{obj} is the numerical aperture of the objective (see the next section) The eyepiece is then necessary to magnify the real image so that it can conveniently be inspected.

B1.18.2.2 LATERAL RESOLUTION: DIFFRACTION LIMIT

The performance of a microscope is determined by its objective. It is obvious that details of the object that are not contained in the real image (figure B1.18.1) cannot be made visible by the eyepiece or lens systems, whatever quality or magnification they may have. The performance is defined here as the size of the smallest lateral structures of the object that can be resolved and reproduced in the image. To fully assess resolution *and* image fidelity, the modulation transfer function of the imaging system has to be known (or for scanning microscopes more conveniently the point spread function). The resolution is then given by the highest lateral frequency of an object which can just be transmitted by the optical system.

-4-

Alternatively, one may consider the separation of two structure elements in the plane of the object, which are just discernible in the image [1, 2 and 3]. Since an exact correlation exists between the pattern generated by the object in the exit pupil of the objective and the image, the limit on the resolution can be estimated simply. If the diffracted beams of zeroth and \pm first order are collected by the lens, then an image of low fidelity of the structure, with the zeroth order only a grey area, is obtained. Hence, the limit to resolution is given whenever the zeroth- and first-order beams are collected (figure B1.18.2). If the diffracted light enters a medium of refractive index n , the minimal discernible separation a_{min} of two structure elements is given by $n \sin \alpha = \lambda/a_{\text{min}}$. The expression $n \sin \alpha$ can be called the numerical aperture of the diffracted beam of first order which, for microscopes, is identical to the numerical aperture A_{obj} of the objective lens. The numerical aperture of a lens is the product of the refractive index of the medium in front of the objective and of the sine of half of the angle whose vertex is located on the optical axis and being the starting point of a light cone of angle α which is just collected by the lens.

Figure B1.18.2. Diffraction figure of a grating: If only the zeroth-order beam were collected by the lens, only a bright area would be visible without any structure indicating the presence of the grating. If the zeroth- and \pm first-order beams are collected, as indicated in the figure, the grating can be observed, albeit with incomplete object fidelity.

The smallest resolvable structure is thus $a_{\text{min}} = \lambda/A_{\text{obj}}$. If, in addition, the aperture of the illumination system is taken into account, one finds:

$$a_{\text{min}} = \lambda/(A_{\text{obj}} + A_{\text{ill}}).$$

The highest resolution is obtained if $A_{\text{ill}} = A_{\text{obj}}$. In this case a_{min} equals about half the wavelength used for the illumination divided by the numerical aperture. Using blue or ultraviolet light for illumination, a_{min} can reach values of 0.2 to 0.15 μm with a numerical aperture of the microscope of about 0.9.

The diffraction limit for resolution does not imply that objects of dimensions smaller than a_{\min} are not detectable. Single light-emitting molecules or scattering centres of atomic dimensions can be observed even though their size is below the resolution. For their detectability it is required that the separation of the centres is greater than the resolution and that the emitted signal is sufficiently high to become detectable by a light-sensitive device. Microscopy, for which these assumptions are fulfilled, has sometimes been called ultramicroscopy.

-5-

B1.18.2.3 CONTRAST, NOISE AND RESOLUTION

The resolution limited by diffraction assumes that illumination and contrast of the object are optimal. Here we discuss how noise affects the discernibility of small objects and of objects of weak contrast [4]. Noise is inherent in each light source due to the statistical emission process. It is, therefore, also a fundamental property by its very nature and limits image quality and resolution, just as diffraction is also responsible for the fundamental limit. Light passing through a test element in defined time slots Δt will not contain the same number of photons in a series of successive runs. This is due to the stochastic emission process in the light source. Other sources of noise, such as inhomogeneities of recording media, will not be considered here.

It is assumed that the image can be divided up into a large number of picture elements, whose number will be of the order of 10^6 . If the contrast due to a structure in the object between two adjacent elements is smaller than the noise-induced fluctuations, the structure cannot be discerned, even if diffraction would allow this. Similarly, if the statistical excursion of the photon number in one or several of the elements is larger than or equal to the signal, then the noise fluctuations might be taken as true signals and lead to misinterpretations.

If viewed in transmission, the background brightness B_b is higher than the light B_o transmitted by an absorbing object. The contrast can then be defined as $C = (B_b - B_o)/B_o$ with $B_b \geq B_o \geq 0$ and $1 \geq C \geq 0$. It has been shown that density of photons R (photons cm^{-2}) required to detect the contrast C is

$$R = Nk^2/C^2.$$

Here, N is the density of picture elements (cm^{-2}); if N is high, the resolution is high, requiring, however, an increase of photon density over images with lower resolution. Also, low contrast requires greater photon density than high contrast in order to overcome false signals by noise fluctuations of adjacent picture elements. The factor k reflects the random character of the photons (noise) and has to be chosen so as to protect against misinterpretations caused by noisy photon flux. k depends somewhat on how well the image should be freed from noise-induced artefacts, a reasonable value being $k = 5$.

A summary of the diffraction- and noise-induced limitations of the resolution is qualitatively depicted in [figure B1.18.3](#). With noise superimposed, the rectangular structure depicted in [figure B1.18.3\(a\)](#) becomes less defined with decreasing spacing and width of the rectangles. In [figure B1.18.3\(b\)](#), an assumed modulation transfer function of an objective is shown: that is, the light intensity in the image plane as a function of spatial frequency obtained by an object which sinusoidally modulates the transmitted light intensity. At low spatial frequencies, the amplitude is independent of frequency; at higher frequencies it drops linearly with increasing frequency. The root mean square (rms) noise, due to the statistical nature of the light, increases with spatial frequency. The intersection of the rms noise with the modulation transfer function gives the frequency at which noise becomes equal to ($k = 1$) or 1/25th ($k = 5$) of the signal. At high contrast, the decrease in image amplitude is usually determined by diffraction; at lower contrast, noise is predominant.

-6-

Figure B1.18.3. (a) Rectangular structure with noise superimposed: in the left half of the graph the rectangular structure is recognizable; in the right half, with the narrower spacing the rectangular structure would barely be recognizable without the guiding lines in the figure. (b) Modulation transfer function for a sinusoidal signal of constant amplitude as a function of frequency: at low frequency the amplitude of the transfer function is independent of the frequency. However, beyond a certain frequency the amplitude decreases with increasing frequency. This drop corresponds to a limitation of the resolution by diffraction. Noise increases with frequency and the crossings with the transfer function indicate where noise limits the resolution. At a contrast of 30% this cutoff frequency is exclusively determined by noise at point A; at 100% contrast the amplitude of the signal drops before the final signal is cut off at point B by noise. For $k = 5$, the noise at the crossing is 1/25th of the signal; for $k = 1$, it is equal to the signal.

Under appropriate contrast and high light intensity, the resolution of planar object structures is diffraction limited. Noise in the microscopic system may also be important and may reduce resolution, if light levels and/or the contrasts are low. This implies that the illumination of the object has to be optimal and that the contrast of rather transparent or highly reflecting objects has to be enhanced. This can be achieved by an appropriate illumination system, phase- and interference-contrast methods and/or by data processing if electronic cameras (or light sensors) and processors are available. Last but not least, for low-light images, efforts can be made to reduce the noise either by averaging the data of a multitude of images or by subtracting the noise. Clearly, if the image is inspected by the eye, the number of photons, and hence the noise, are determined by the integration time of the eye of about 1/30 s; signal/noise can then only be improved, if at all possible, by increasing the light intensity. Hence, electronic data acquisition and processing can be used advantageously to improve image quality, since integration times can significantly be extended and noise suppressed.

B1.18.2.4 DEPTH OF FOCUS

The depth of focus is defined as how far the object might be moved out of focus before the image starts to become blurred. It is determined (i) by the axial intensity distribution which an ideal object point suffers by imaging with the objective (point spread function), (ii) by geometrical optics and (iii) by the ability of the eye to adapt to different distances. In case (iii), the eye adapts and sees images in focus at various depths by successive scanning. Obviously, this mechanism is inoperative for image sensors and will not be considered here. The depth of focus caused by spreading the light intensity in axial direction (i) is given by

-7-

$$t_{\text{PSF}} = n\lambda / (A)^2$$

with n the refractive index, λ the wavelength of the light and A the numerical aperture.

The focal depth in geometrical optics is based on the argument that ‘points’ of a diameter smaller than 0.15 mm in diameter cannot be distinguished. This leads to a focal depth of

$$t_{GO} = 0.15n / (AM_{\text{microscope}}).$$

The total depth of focus is the sum of both. It increases with the wavelength of the light, depends on the numerical aperture and the magnification of the microscope. For $\lambda = 550$ nm, a refractive index of 1 and a numerical aperture of 0.9, the depth of focus is in the region of $0.7 \mu\text{m}$; with a numerical aperture of 0.4 it increases to about $5 \mu\text{m}$. High-resolution objectives exclude the observation of details in the axial direction beyond their axial resolution. This is true for conventional microscopy, but not for scanning confocal microscopy, since optical sectioning allows successive layers in the bulk to be studied. Similarly, the field of view decreases with increasing resolution of the objective in conventional microscopy, whereas it is independent of resolution in scanning microscopy.

B1.18.3 CONTRAST ENHANCEMENT

In transmission microscopy, a transparent object yields low contrast. Molecular biological samples may be dyed in order to enhance contrast. However, this is in many cases neither possible nor desirable for various reasons, meaning that the object is only barely visible in outline and with practically no contrast. Similarly, if inorganic samples are to be investigated which are composites of materials of practically equal indices of refraction, the different components can only be distinguished in the microscope with great difficulty. This is all equally true for reflected light microscopy: the visibility and resolution of microscopic images suffer, if contrast is low. In order to cope with this, different illumination techniques are applied in order to enhance the contrast.

B1.18.3.1 KÖHLER'S BRIGHT-FIELD ILLUMINATION SYSTEM

Köhler's illumination system [5], which allows the field of view to be precisely illuminated, is schematically depicted in [figure B1.18.4](#). The object is illuminated through a substage: the filament of a lamp is imaged by a collector lens into the focal plane of the condenser, where the condenser iris is located. Light from each point in the condenser iris passes through the object as a parallel beam inclined to the axis of the microscope at an angle depending on the position of the point in the iris. The parallel beams come to a focus at corresponding points in the focal plane of the objective. The collector iris allows the area illuminated in the object plane to be varied. The condenser iris is the aperture of the illumination and its opening should be adjusted to the aperture of the objective lens and contrast properties of the object: if the apertures are equal, the highest resolution is achieved; if the illumination aperture is reduced, the contrast is enhanced. In practice, the aperture of the condenser is in most cases chosen to be smaller than the aperture of the objective lens in order to improve contrast.

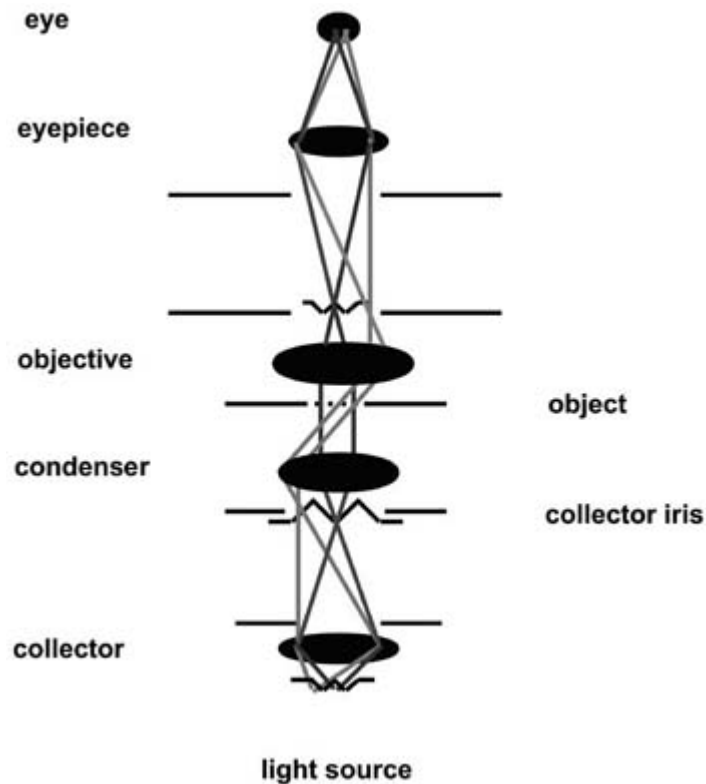

Figure B1.18.4. The most frequently used illumination system in bright-field microscopy.

B1.18.3.2 ENHANCED CONTRAST BY DARK-FIELD ILLUMINATION

Dark-field microscopy utilizes only those light beams from the condenser that have an aperture greater than that of the objective. This is in contrast to Köhler's illumination principle, where care is taken to adjust the aperture of the condenser by an iris to become equal to or smaller than that of the objective. A ring-type diaphragm is used to allow light beams to pass the condenser lens at an aperture greater than that of the objective lens. This is shown schematically in [figure B1.18.5](#). In this arrangement, no direct light beams pass through the objective but only those which are diffracted or scattered by the object. If the direct light beam is blocked out, the background appears black instead of bright, thus increasing the contrast. Special condensers have been designed for dark-field illumination. Dark-field illumination has often been used in reflection.

Figure B1.18.5. Dark-field illumination: the aperture of the objective is smaller than the aperture of the beams allowed by the annular diaphragm.

B1.18.3.3 ZERNIKE'S PHASE CONTRAST MICROSCOPY

Phase contrast microscopy [6, 7] is more sophisticated and universal than the dark-field method just described. In biology, in particular, microscopic objects are viewed by transmitted light and phase contrast is often used. Light passing through transparent objects has a different phase from light going through the embedding medium due to differences in the indices of refraction. The image is then a so-called phase image in contrast to an amplitude image of light absorbing objects. Since the eye and recording media in question respond to the intensity (amplitude) of the light and not to changes of the light phase, phase images are barely visible unless means are taken to modify the interference of the diffracted beams. The diffraction pattern of a phase grating is like that of an amplitude grating except that the zeroth-order beam is especially dominant in intensity. Zernike realized that modification of the zeroth-order beam will change the character of the image very effectively, by changing its phase and its intensity. For each object, depending on its character concerning the phase and amplitude, a 'Zernike diaphragm' (i.e. a diaphragm that affects the phase and the amplitude of the zeroth-order beam) can be constructed with an appropriate absorption and phase shift, which allows the weak-contrast image of the object to be transformed into an image of any desired contrast.

The principle of phase contrast microscopy is explained by [figure B1.18.6](#). The object is assumed to be a linear phase grating. The diaphragm is annular, which means that only a small fraction of the diffracted light is covered by the Zernike diaphragm, as indicated in the figure for the first-order beams. In general, the Zernike diaphragm shifts the phase of the zeroth order by $\pi/2$ with respect to the diffracted beams. Since the intensity of the diffracted beams is much lower than that of the direct beam, the intensity of the zeroth-order beam is usually attenuated by adding an absorbing film. Clearly, all these measures indicate that images of high contrast cannot be combined with high intensity using this technique; a compromise between both has to be found depending on the requirements. The image fidelity of phase contrast imaging depends, therefore, on the width and light absorption of the Zernike diaphragm, in addition to the size and optical path difference created by the object under study and, finally, on the magnification.

Figure B1.18.6. Schematic representation of Zernike's phase contrast method. The object is assumed to be a relief grating in a transparent material of constant index of refraction. Phase and amplitude are varied by the Zernike diaphragm, such that an amplitude image is obtained whose contrast is, in principle, adjustable.

At this point it is worth comparing the different techniques of contrast enhancements discussed so far. They represent spatial filtering techniques which mostly affect the zeroth order: dark field microscopy, which eliminates the zeroth order, the Schlieren method (not discussed here), which suppresses the zeroth order and one side band and, finally, phase contrast microscopy, where the phase of the zeroth order is shifted by $\pi/2$ and its intensity is attenuated.

B1.18.3.4 INTERFERENCE MICROSCOPY

As already discussed, transparent specimens are generally only weakly visible by their outlines and flat areas cannot be distinguished from the surroundings due to lack of contrast. In addition to the phase contrast techniques, light interference can be used to obtain contrast [8, 9].

Transparent, but optically birefringent, objects can be made visible in the polarizing microscope if the two beams generated by the object traverse about the same path and are brought to interfere. In the case of optically isotropic bodies, the illuminating light beam has to be split into two beams: one that passes through the specimen and suffers phase shifts in the specimen which depend on the thickness and refraction index, and a second beam that passes through a reference object on a separate path (see figure B1.18.7). By superposing the two beams, phase objects appear in dark-bright contrast.

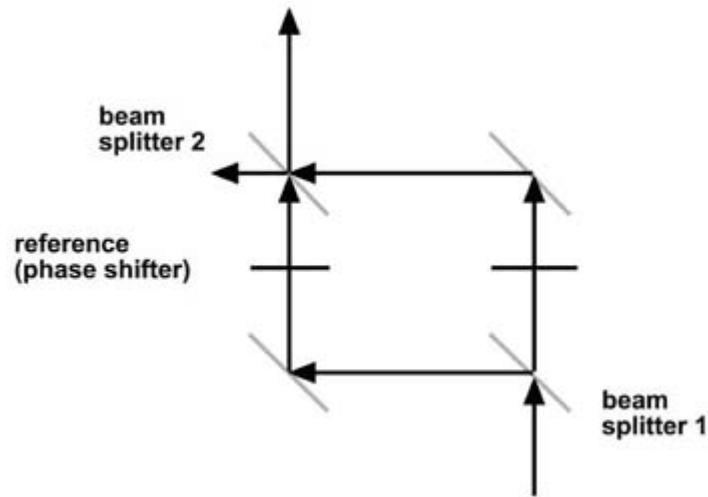

Figure B1.18.7. Principle for the realization of interference microscopy. The illuminating beam is split by beamsplitter 1 before passing the object so that the reference beam is not affected by the object. The separated beams interfere behind beamsplitter 2.

The differential interference contrast method utilizes the fact that, using a Wollaston prism, linearly polarized light can be split into two light beams of perpendicular polarization (figure B1.18.8). Since they are slightly parallel shifted, the two beams pass through the object at positions having different thickness and/or refractive index. The splitting of the beams is chosen to be sufficiently small not to affect the resolution. They are brought together again by a second Wollaston prism, and pass through the analyser. Since the beams are parallel and their waves planar in the object plane, the beams in the image plane are also parallel and the waves planar. Hence, the interference of the beams does not give rise to interference lines but to contrast, whose intensity depends on the phase difference caused by small differences of the refractive index. The image appears as a relief contrast which can be modified by changing the phase difference: for example, by moving the Wollaston prism perpendicularly to the optical axis.

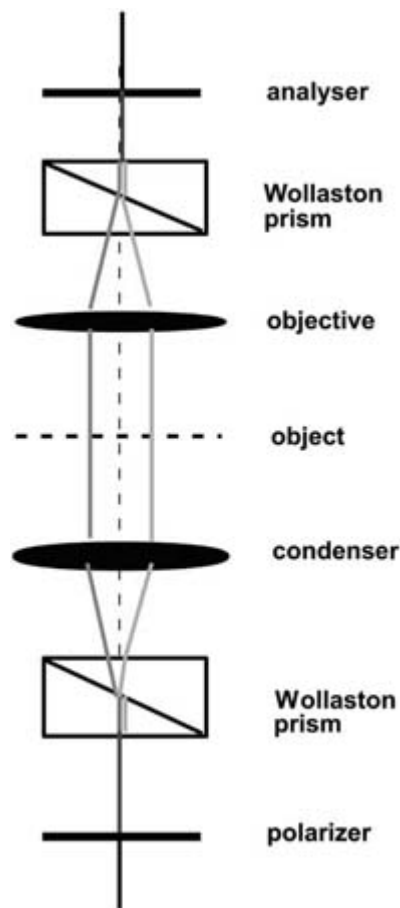

Figure B1.18.8. Differential interference contrast: the light beam is split into two beams by a Wollaston prism. The two beams pass the object at closely spaced positions and give, after interference, a contrast due to the phase difference.

The interpretation of such images requires some care, because the appearance of a relief structure may be misleading; it does not necessarily mean that the surface or thickness of the object is relief-like. Obviously, such a relief may also appear if samples are homogeneously thick, but composed of elements of different indices of refraction. Also, edges of the object may be missed if they are inappropriately oriented with respect to the polarization direction of the beams.

Interference microscopy is also possible in reflection. The surface structure of highly reflecting objects such as metals or metallized samples is frequently investigated in this way. Using multiple-beam interference [10], surface elevations as small as a few nanometres in height or depth can be measured. This is due to the fact that the interference lines become very sharp if the monochromaticity of the light and the number of interfering beams are high.

B1.18.3.5 FLUORESCENCE MICROSCOPY

Fluorescence microscopy has been a very popular method of investigating biological specimens and obtaining contrast in otherwise transparent organic objects. The samples are stained with fluorescent dyes and illuminated with light capable of exciting the dye to fluoresce. The wavelength of the emitted light is Stokes-shifted to wavelengths longer than that of the primary beam. Since the quantum efficiency (the ratio of the numbers of emitted to exciting photons) of the dyes is often low and since the light is emitted in all directions, the image is of low intensity. Nevertheless, this technique allows images of high contrast and of high signal-

to-noise ratio to be obtained. The principle of fluorescence microscopy is illustrated in figure B1.18.9 for the epifluorescence microscope. The primary excitation does not in principle directly enter the detector and thus provides the desired contrast between stained and unstained areas, which appear completely dark. It is obvious from the very nature of the preparation technique that, in addition to morphological structures, chemical and physicochemical features of the sample can be revealed if the dyes adsorb only at special chemical sites.

Figure B1.18.9. Epifluorescence microscope: the object is excited from the top and the fluorescent light is emitted in all directions, as indicated by the multitude of arrows in the object plane. The fluorescent light within the aperture of the objective gives rise to the image, showing that much of the fluorescent light is lost for imaging.

B1.18.4 SCANNING MICROSCOPY

In scanning microscopy, the object is successively scanned by a light spot, in contrast to conventional microscopy in which the entire object field is processed simultaneously. Thus, scanning represents a serial (and conventional microscopy a parallel) processing system. The requirements for the optical lenses are relaxed for the scanning microscope, because the whole field of view is no longer imaged at once, but the price that is paid is the need for reconstruction of the image from a set of data and the required precision for the scanning.

A point light source is imaged onto the specimen by the objective and the transmitted light collected by the collector lens and detected by a broad-area detector; in the case of reflection microscopy, the objective lens also serves simultaneously as a collector (see figure B1.18.10). The resolution is solely determined by the objective lens, because the collector has no imaging function and only collects the transmitted light. The

scanning is assumed in [figure B1.18.10](#) to be based on the mechanical movement of the sample through the focal point of the objective. In this case, off-axis aberrations of the objective are avoided, the area to be imaged is not limited by the field of view of the objective and the image properties are identical and only determined by the specimen. The drawback of stage movement is the lower speed compared with beam scanning and the high mechanical precision required for the stage. Beam scanning allows the image to be reconstructed from the serially available light intensity data of the spots in real time [11, 12]. If a framestore is available, the image can be taken, stored, processed if desired and displayed. Processing of the electrical signal offers advantages. There is, for example, no need to increase contrast by stopping down the collector lens or by dark-field techniques which, in contrast to electronic processing, modify the resolution of the image.

Scanning gives many degrees of freedom to the design of the optical system and the confocal arrangement is one of the most prominent, having revolutionized the method of microscopic studies, in particular of biological material. Since confocal microscopy has in recent years proved to be of great importance, it is discussed in some detail here.

-15-

Figure B1.18.10. Scanning microscope in reflection: the laser beam is focused on a spot on the object. The reflected light is collected and received by a broad-area sensor. By moving the stage, the object can be scanned point by point and the corresponding reflection data used to construct the image. Instead of moving the stage, the illuminating laser beam can be used for scanning.

B1.18.5 CONFOCAL SCANNING MICROSCOPY

B1.18.5.1 PRINCIPLE AND ADVANTAGES OF CONFOCAL MICROSCOPY

The progress that has been achieved by confocal microscopy [13, 14, 15 and 16] is due to the rejection of

object structures outside the focal point, rejection of scattered light and slightly improved resolution. These improvements are obtained by positioning pointlike diaphragms in optically conjugate positions (see [figure B1.18.11](#)). The rejection of structures outside the focal point allows an object to be optically sectioned and not only images of the surface are obtained by scanning but also of sections deep in a sample, so that three-dimensional microscopic images can be prepared as well as images of sections parallel to the optical axis. Therefore, internal structures in biological specimens can be made visible on a microscopic scale without major interference with the biological material by preparational procedures (fixation, dehydration etc) and without going through the painstaking procedure of mechanical sectioning. In addition, time-dependent studies of microscopic processes are possible. Obviously, there is a price to be paid:

-16-

Confocal microscopy requires serial data acquisition and processing and hence comprises a complete system whose cost exceeds that of a conventional microscope.

Figure B1.18.11. Confocal scanning microscope in reflection: the pinhole in front of the detector is in a conjugate position to the illumination pinhole. This arrangement allows the object to be optically sectioned. The lens is used to focus the light beam onto the sample and onto the pinhole. Thus, the resulting point spread function is sharpened and the resolution increased.

Figure B1.18.11 shows the basic arrangement of a confocal instrument. The important points are more easily presented for the reflection microscope, although everything also applies to transmission if modified appropriately. The broad-area detector is replaced by a point detector implemented by a pinhole placed in front of the detector at the conjugate position to the pinhole on the illumination side. This arrangement ensures that only light from the small illuminated volume is detected and light that stems from outside the focal plane is strongly reduced in intensity. This is illustrated in [figure B1.18.12](#) where a reflecting object is assumed to be below the focal plane: only a small fraction of the reflected light reaches the detector, since it is shielded by the pinhole. The intensity drops below detection threshold and no image can be formed.

-17-

Figure B1.18.12. Illustration that only light reflected from object points in the focal plane contributes to the image. If the light is reflected from areas below the focal plane, only a small fraction can pass through the pinhole so that light from those areas does not contribute to the image. The pinhole in front of the detector is exaggerated in size for the sake of presentation.

B1.18.5.2 OPTICAL SECTIONING, SMALLEST SLICE THICKNESS AND AXIAL RESOLUTION

The fact that only points in the focal plane contribute to the image, whereas points above or below do not, allows optical sectioning. Thus, the object can be imaged layer by layer by moving them successively into the focal plane. For applications, it is important how thin a slice can be made by optical sectioning. A point-like object imaged by a microscope has a finite volume [13] which is sometimes called voxel, in analogy to pixel in two dimensions. Its extension in the axial direction determines the resolution in this direction (z) and the smallest thickness of a layer that can be obtained by optical sectioning. The intensity variation of the image of a point along the optical axis for the confocal arrangement is given by

$$I(u) = \{\sin(u/4)/u/4\}^4$$

with $u = (8\pi/\lambda) z \sin^2(\alpha/2)$. λ is the wavelength of the light, and $n \sin \alpha$ is the numerical aperture of the lens. The function $I(u)$ is zero at $u = \pi, 2\pi \dots$. If we take the spread of the function $I(u)$ between $u = \pm \pi$ as the smallest slice thickness t , one obtains

$$t = \lambda/(4 \sin^2 \alpha/2).$$

The slice thickness is proportional to the wavelength of the light and a function of the aperture angle. For $\lambda = 0.5 \mu\text{m}$, the slice thickness is about $0.25 \mu\text{m}$ for $\alpha = \pi/2$. Obviously, the point spread function serves also to

determine the smallest separation that two points in the axial direction may have in order to be resolved. If the Rayleigh criterion is applied—intensity between the image points to be half of the intensity at maximum—then the resolution is in the range of 0.15–0.2 μm .

B1.18.5.3 RANGE OF DEPTH FOR OPTICAL SECTIONING

The greatest depth at which a specimen can be optically sectioned is also of interest. This depth is limited by the working distance of the objective, which is usually smaller for objectives with greater numerical aperture. However, the depth imposed by the working distance of the objective is rarely reached, since other mechanisms provide constraints as well. These are light scattering and partial absorption of the exciting and emitted light, in the case of fluorescence microscopy. The exciting beam is partially absorbed by fluorophores until it reaches the focused volume. Hence, less light is emitted from a focused volume that is deep in the bulk of a sample. Thus, the intensity of the light reaching the detector decreases with increasing depth, so that for image formation laser power and/or integration time would have to be increased. Though technically possible, both cannot be increased beyond thresholds at which the samples, especially biological materials, are damaged.

B1.18.5.4 LATERAL RESOLUTION

The extension of the voxel in a radial direction gives information on the lateral resolution. Since the lateral resolution has so far not been discussed in terms of the point spread function for the conventional microscope, it will be dealt with here for both conventional and confocal arrangements [13]. The radial intensity distribution in the focal plane (perpendicular to the optical axis) in the case of a conventional microscope is given by

$$I_m(v) = (2J_1(v)/v)^2$$

with $v = (2\pi/\lambda)rn \sin \alpha$, λ is the wavelength of the light, r is the radial coordinate, $n \sin \alpha$ is the numerical aperture, and $J_1(v)$ is the first-order Bessel function of the first kind. Zero intensity is at $v = 1.22 \pi, 2.23\pi, 3.42\pi \dots$

For the confocal arrangement in transmission, the objective and the collector are used for imaging; in reflection the objective is used twice. Therefore, the radial intensity distribution in the image is the square of that of the conventional microscope:

$$I_{\text{conf}}(v) = (2J_1(v)/v)^4.$$

$I_{\text{conf}}(v)$ has the same zero points as $I_m(v)$. However, in the confocal case the function is sharpened and the sidelobes are suppressed. The light intensity distributions for the conventional and the confocal case are depicted in [figure B1.18.13](#). If the Rayleigh criterion for the definition of resolution is applied, one finds that the lateral resolution in

the confocal case is improved in comparison with conventional microscopy: obviously, the sharpened function in the confocal case allows two closely spaced points at smaller separation to be distinguished.

Figure B1.18.13. The point spread function in the confocal arrangement (full square) is sharpened in comparison with the conventional arrangement (full diamond). Therefore, the resolution is improved.

B1.18.5.5 CONTRAST ENHANCEMENT AND PRACTICAL LIMITS TO CONFOCAL ONE-PHOTON-EXCITATION FLUORESCENCE MICROSCOPY

The methods to improve contrast described for conventional microscopy can also be applied to confocal microscopy [17]. However, because the images are obtained by scanning and data processing, the tools of image manipulation are also advantageously utilized to improve image quality. Nevertheless, all these methods have their limitations, as will be explained in the following example. Biological studies are often made with fluorescence. Usually the fluorophore is excited by one photon from the ground state to the excited state; the ratio of the number of photons emitted by the fluorophore to the number of exciting photons is, as a rule, significantly below one. Therefore, the number of photons collected per voxel is low, depending on the density of fluorophores, on the exciting light intensity and on the scan rate. The density of fluorophores is, in general, determined by the requirements of the experiment and cannot be significantly varied. In order to increase the signal, the scan rate would have to be lowered, and the number of scans and the exciting light intensity increased. However, extended exposure of the dyes leads to bleaching in the whole cone of illumination and hence to the number of layers to be sectioned. The number of layers is even more reduced if, in addition to bleaching the fluorophore, the excitation produces toxic products that modify or destroy the properties of

living cells or tissues. Lasers could, in principle, supply higher light intensities, but saturation of emission of the dyes additionally limits the applicable power. In these circumstances, real improvement can only be reached if the voxel at the focal point could exclusively be excited by the incident light.

B1.18.5.6 CONFOCAL MICROSCOPY WITH MULTIPHOTON-EXCITATION FLUORESCENCE

Usually a fluorophore is excited from its ground to its first excited state by a photon of an energy which corresponds to the energy difference between the two states. Photons of smaller energy are generally not absorbed. However, if their energy amounts to one-half or one-third (etc) of the energy difference, a small probability for simultaneous absorption of two or three (etc) photons exists since the energy condition for absorption is fulfilled. However, due to this small probability, the photon density has to be sufficiently high if two-, three- or n -photon absorption is to be observed [18]. In general, these densities can only be achieved by lasers of the corresponding power and with appropriate pulse width, since absorption by multiphoton processes increases with the n th power of the photon density (figure B1.18.14).

Figure B1.18.14. Schematic representation of the increase of absorption with photon density for two- and three-photon absorption.

One-photon excitation has limitations due to the unwanted out-of-focus fluorophore absorption and bleaching, and light scattering. These drawbacks can be circumvented if multiphoton excitation of the fluorophore is used. Since it increases with the n th power of the photon density, significant absorption of the exciting light will only occur at the focal point of the objective where the required high photon density for absorption is reached. Consequently, only

-21-

fluorescent light will be emitted from a volume element whose size will be determined by the intensity and power law dependence of the exciting radiation. Though confocal arrangement is not needed, it was shown that, in the confocal arrangement, the effective point spread function is less extended and, hence, the resolution improved [19, 20].

Thus, multiphoton excitation eliminates unwanted out-of-focus excitation, unnecessary phototoxicity and bleaching. However, efficient power sources are required and, since the efficiency of multiphoton excitation is usually low, the times needed to generate images are increased.

MICROSCOPY?

As light microscopy has many advantages over other microscopic techniques, the desire is to overcome the limit due to the extension of the point spread function or to reduce the emitting volume by multiphoton excitation. One proposal was made on the basis of fluorescence microscopy [21]. As discussed, in fluorescence microscopy, molecules are excited to emit light which is then used to form the microscopic image. If the exciting light is imaged onto a small volume of the sample, light emitted from this volume determines the spatial resolution (i.e. both in depth and the lateral direction). If the light-emitting volume can be reduced, resolution will be improved. This is achievable, in principle, by stimulated emission: if the stimulated emission rate is higher than the fluorescence decay and slower than the decay rate of intrastate vibrational relaxation, the emitting volume in the focal region shrinks. Estimates predict a resolution of 0.01–0.02 μm for continuous illumination of 1 mW and picosecond excitations of 10 MW cm^{-2} at a rate of 200 kHz. If this idea can be reduced into practice, the diffraction limit would be overcome. The high resolution combined with the advantages of light microscopy over other microscopic methods would indeed represent a major breakthrough in this field.

B1.19 Scanning probe microscopies

Nicholas D Spencer and Suzanne P Jarvis

B1.19.1 INTRODUCTION

The development of the scanning tunnelling microscope (STM) [1] was a revelation to the scientific community, enabling surface atomic features to be imaged in air with remarkably simple apparatus. The STM earned Binnig and Rohrer the Nobel prize for physics in 1986, and set the stage for a series of scanning probe microscopies (SPMs) based on a host of different physical principles, many of the techniques displaying nanometre resolution or better.

The methods have in turn launched the new fields of nanoscience and nanotechnology, in which the manipulation and characterization of nanometre-scale structures play a crucial role. STM and related methods have also been applied with considerable success in established areas, such as tribology [2], catalysis [3], cell biology [4] and protein chemistry [4], extending our knowledge of these fields into the nanometre world; they have, in addition, become a mainstay of surface analytical laboratories, in the worlds of both academia and industry.

Central to all SPMs (or ‘local probe methods’, or ‘local proximal probes’ as they are sometimes called) is the presence of a tip or sensor, typically of less than 100 nm radius, that is rastered in close proximity to—or in ‘contact’ with—the sample’s surface. This set-up enables a particular physical property to be measured and imaged over the scanned area. Crucial to the development of this family of techniques were both the ready availability of piezoelements, with which the probe can be rastered with subnanometre precision, and the highly developed computers and stable electronics of the 1980s, without which the operation of SPMs as we know them would not have been possible.

A number of excellent books have been written on SPMs in general. These include the collections edited by Wiesendanger and Güntherodt [5] and Bonnell [6] as well as the monographs by Wiesendanger [7], DiNardo [8] and Colton [9].

B1.19.2 SCANNING TUNNELLING MICROSCOPY

B1.19.2.1 PRINCIPLES AND INSTRUMENTATION

Tunnelling is a phenomenon that involves particles moving from one state to another through an energy barrier. It occurs as a consequence of the quantum mechanical nature of particles such as electrons and has no explanation in classical physical terms. Tunnelling has been experimentally observed in many physical systems, including both semiconductors [10] and superconductors [11].

In STM, a sharp metal tip [12] is brought within less than a nanometre of a conducting sample surface, using a piezoelectric drive (figure B1.19.1). At these separations, there is overlap of the tip and sample wavefunctions at the

-2-

gap, resulting in a tunnelling current of the order of nanoamps when a bias voltage ($\pm 10^{-3}$ –4 V) is applied to the tip [13]. The electrons flow from the occupied states of the tip to the unoccupied states in the sample, or *vice versa*, depending on the sign of the tip bias. The current is exponentially dependent on the tip–sample distance [14],

$$I = C\rho_t\rho_s e^{-s\sqrt{\phi}} \quad (\text{B1.19.1})$$

where s is the sample–tip separation, ϕ is a parameter related to the barrier between the sample and the tip, ρ_t is the electron density of the tip, ρ_s is the electron density of the sample and C , a constant, is a linear function of voltage. The exponential dependence on distance has several very important consequences. Firstly, it enables the local tip–sample spacing to be controlled very precisely ($< 10^{-2}$ Å) by means of a feedback loop connected to the z -piezo, using the tunnelling current as a control parameter. Secondly, it means that despite the fact that the tip may be many tens of nanometres in radius, the effective radius—through which most of the tunnelling takes place—is of atomic dimensions, yielding subnanometre spatial resolution. This tip may be rastered over an area that can range from hundredths of square nanometres to hundreds of square microns, and the surface topography—or more specifically the spatial distribution of particular electronic states—may thereby be imaged. Imaging (which may be done in air, in vacuum, or even under liquids) may be achieved either by monitoring the tunnelling current, in order to maintain a constant tip–sample separation and displaying the z -voltages as a function of x and y position, or by simply rastering the tip above the surface at a constant height, and plotting the tunnelling current on the z -axis. The former is known as *constant-current mode*, the latter as *constant-height mode* (figure B1.19.2). While constant-current mode is more stable for relatively rough surfaces, it is also somewhat slower than constant-height mode, because of its reliance on the feedback system, which sets a limit on the maximum scan speed.

Figure B1.19.1. Principle of operation of a scanning tunnelling microscope. The x - and y -piezodrives scan the tip across the surface. In one possible mode of operation, the current from the tip is fed into a feedback loop that controls the voltage to the z -piezo, to maintain constant current. The line labelled z -displacement shows the tip reacting both to morphological and chemical (i.e. electronic) inhomogeneities. (Taken from [213].)

-3-

Figure B1.19.2. The two modes of operation for scanning tunnelling microscopes: (a) constant current and (b) constant height. (Taken from [214], figure 1.)

The image obtained in a STM experiment is conventionally displayed on the computer screen as grey scales or false colour, with the lightest shades corresponding to peaks (or highest currents) and darkest shades corresponding to valleys (or lowest currents). With such graphic methods of data display, it is particularly tempting to interpret atomic-scale STM images as high-resolution topographs. However, it must be remembered that only electrons near the Fermi energy contribute to the tunnelling current, whereas all electrons contribute to the surface charge density. Since topography can reasonably be defined as a contour of constant surface charge density [15], STM images are intrinsically different from surface topographs.

In addition to its strong dependence on tip-sample separation, the tunnelling current is also dependent on the electron density of states (DOS) of both tip and sample (equation B1.19.1). This dependence can be exploited to produce a map of the local DOS under the tip by varying the applied voltage and measuring the tunnelling current. Both occupied and unoccupied electronic states can be probed by this method, which is known as scanning tunnelling spectroscopy (STS) [16]. The traditional method of mapping DOS is to use ultraviolet photoelectron spectroscopy (UPS) to measure occupied states and inverse photoemission spectroscopy (IPS) to measure empty states. However, it is important to remember that these data do not correspond exactly to those derived from STS measurements. Firstly, the STS spectrum is a convolution of tip and sample properties (a potential problem, should the tip become contaminated during the experiment). Secondly, since states near the upper edge of the energy range investigated see a lower barrier than those near the lower end, they contribute a greater tunnelling current, so that sensitivity to occupied states falls off with increasing energy below the Fermi level. Thirdly, STS is a much more surface- (and above-surface-) sensitive technique than UPS or IPS, meaning that surface electronic states contribute far more to the STS spectrum. This also means that the sensitivity to s, p, and d states is different in STS, due to the different degrees to which the electron density associated with these states extends out of the surface.

-4-

(A) SEMICONDUCTORS

STM found one of its earliest applications as a tool for probing the atomic-level structure of semiconductors. In 1983, the 7×7 reconstructed surface of Si(111) was observed for the first time [17] in real space; all previous observations had been carried out using diffraction methods, the 7×7 structure having, in fact, only been hypothesized. By capitalizing on the spectroscopic capabilities of the technique it was also proven [18] that STM could be used to probe the electronic structure of this surface (figure B1.19.3).

Figure B1.19.3. STM images of Si(111)-(7×7) measured with (a) -2 V and (b) $+2$ V applied to the sample. (Taken from [18], figure 1.)

A complete STS spectrum of the 7×7 reconstructed Si(111) surface displays remarkable correlation with the corresponding UPS and IPS spectra [19] (figure B1.19.4), showing the potential value of this approach. The high spatial resolution of the STS technique has also been demonstrated using a silicon surface containing impurity atoms [20] (figure B1.19.5), where the absence or presence of a band gap over *an individual atom* shows whether it belongs, respectively, to the silicon or to a metallic impurity.

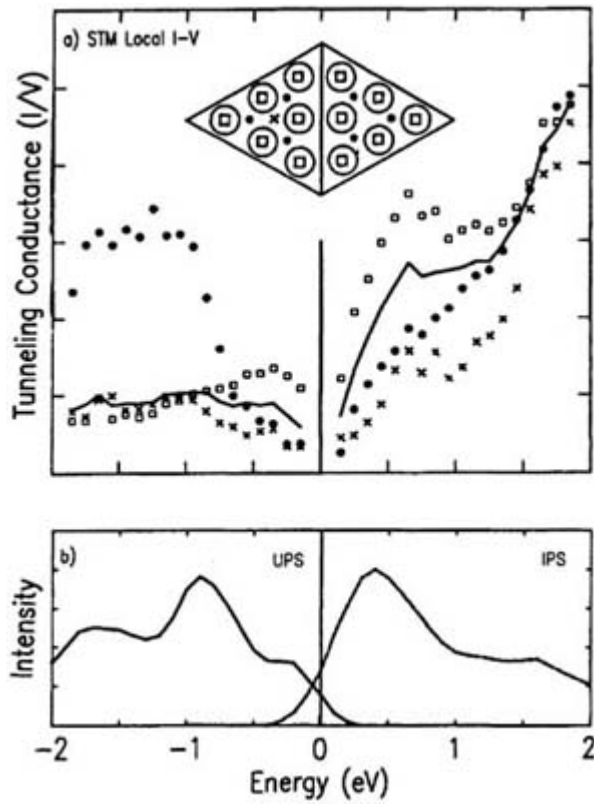

Figure B1.19.4. (a) Local conductance STS measurements at specific points within the Si(111)-(7 × 7) unit cell (symbols) and averaged over whole cell. (b) Equivalent data obtained by ultraviolet photoelectron spectroscopy (UPS) and inverse photoemission spectroscopy (IPS). (Taken from [19], figure 2.)

-6-

Figure B1.19.5. Tunnelling $I-V$ curves acquired across a defect on Si(100). Away from the defect a bandgap can be seen. Over the defect itself, the bandgap disappears, suggesting that it possesses metallic character.

This analysis was performed with spatial resolution of better than 1 nm. (Taken from [20], figure 2 and figure 6.)

Chemical reactions of ammonia with the silicon surface have also been clearly observed using STS [21], where the disappearance of the π and π^* states characteristic of the clean surface coincides with the formation of Si–H antibonding states corresponding to the dissociation of the ammonia on the Si surface.

Other semiconductors have also proved to be a fruitful ground for STM investigation. Zheng *et al* [22] have used the spatial resolution and electronic state sensitivity of STM to spatially display the electronic characteristics of single Zn impurity atoms in Zn-doped GaAs, both in filled and empty states, which show spherical and triangular symmetry, respectively. Upon imaging a number of Zn-induced features, a variety of different heights were recorded, corresponding to the depth of the impurity atoms within the sample. Thus STM was used to probe both the chemical nature and the 3D spatial location of the impurity atoms—an achievement that would have been inconceivable before the advent of STM.

STM has not as yet proved to be easily applicable to the area of ultrafast surface phenomena. Nevertheless, some success has been achieved in the direct observation of dynamic processes with a larger timescale. Kitamura *et al* [23], using a high-temperature STM to scan single lines repeatedly and to display the results as a time-*versus*-position pseudoimage, were able to follow the diffusion of atomic-scale vacancies on a heated Si(001) surface in real time. They were able to show that vacancy diffusion proceeds exclusively in one dimension, along the dimer row.

-7-

(B) METALS

STM has been applied with great success to the study of metals and adsorbate–metal systems [24]. This has naturally brought the technique into the mainstream of surface science, where structural information at the atomic level could previously only be obtained via diffraction methods such as low-energy electron diffraction (LEED) [25]. The STM can also provide a level of electronic information and visualization of the quantum mechanical behaviour of electrons that is unavailable from other methods: the images of copper and silver surfaces obtained by the groups of Eigler [26] and Avouris [27], showing standing waves produced by the defect-induced scattering of the 2D electron gas in surface states, bear eloquent testament to this (figure B1.19.6).

Figure B1.19.6. Constant current 50 nm × 50 nm image of a Cu(111) surface held at 4 K. Three monatomic steps and numerous point defects are visible. Spatial oscillations (electronic standing waves) with a

periodicity of ~ 1.5 nm are evident. (Taken from [26], figure 1.)

Surface reconstructions have been observed by STM in many systems, and the technique has, indeed, been used to confirm the ‘missing row’ structure in the 1×2 reconstruction of Au(110) [28]. As the temperature was increased within 10 K of the transition to the disordered 1×1 phase (700 K), a drastic reduction in domain size to ~ 20 – 40 Å (i.e. less than the coherence width of LEED) was observed. In this way, the STM has been used to help explain and extend many observations previously made by diffraction methods.

STM studies of simple adsorbates on metal surfaces have proved challenging, partly due to the significant mobility of most small species on metals at room temperature, which therefore generally necessitates low-temperature operation. Additionally, since adsorbates can change the local density of states in the metal surface, particular care must be taken not to interpret STM images of adsorbate–metal systems as simple topographs, but rather to capitalize on the technique’s capability for observing unoccupied and occupied energy states. In this way, the bond between adsorbate and substrate can be investigated on a local level, subject to the restrictions on energy range mentioned above. By observing the electronic changes in the neighbourhood of an adsorption site, much can be learned about the range over which chemical bonds can act and influence each other.

-8-

Metal surfaces in motion have also been characterized by STM, one of the clearest examples being the surface diffusion of gold atoms on Au(111) [29] (figure B1.19.7). Surface diffusion of adsorbates on metals can be followed [30] provided that appropriate cooling systems are available, and STM has been successfully employed to follow the 2D dendritic growth of metals on metal surfaces [31].

Figure B1.19.7. A series of time-lapse STM topographic images at room temperature showing a 40 nm \times 40 nm area of Au(111). The time per frame is 8 min, and each took about 5 min to scan. The steps shown are one atomic unit in height. The second frame shows craters left after tip–sample contact, which are two and three atoms deep. During a 2 h period the small craters have filled completely with diffusing atoms, while the large craters continue to fill. (Taken from [29], figure 1.)

(C) ORGANIC SURFACES

The operation of the STM depends on the conduction of electrons between tip and sample. This means, of course, that insulating samples are, in general, not accessible to STM investigations. Nevertheless, a large body of work [32] dealing with STM characterization of thin organic films on conducting substrates is now in

the literature, and the technique provides local structural and electronic information that is essentially inaccessible by any other method.

STM of thin organic layers involves the tunnelling of current between the tip and the conducting substrate, underneath the organic layer. By choosing the tunnelling parameters appropriately [32] ($\approx 0.3\text{--}1\text{ V}$, $0.05\text{--}1\text{ nA}$ for adsorbate, $0.1\text{--}0.3\text{ V}$, $0.3\text{--}10\text{ nA}$ for substrate), the method can be used to image either the substrate or the adsorbate—or both simultaneously, if a suitable voltage programme is used—repeating each line scanned at both voltages. There is some evidence that the tip can damage the organic layer during the imaging process [33]. The precise mechanism by which insulating molecules are imaged remains a topic of much discussion. Although single organic molecules have been successfully imaged by STM [34], the majority of STM studies of organic species has concerned a single monolayer of molecules deposited by evaporation, or by self-assembly, or by Langmuir–Blodgett techniques [35]. Often these images corroborate what had already been deduced from painstaking LEED investigations: an example is the imaging of co-adsorbed arrays of benzene and mobile CO, as seen by Ohtani *et al* [36].

-9-

One class of large molecules that was investigated relatively early was liquid crystals [37, 38], and in particular the group 4-*n*-alkyl-4'-cyanobiphenyl (*m*CB). These molecules form a highly crystalline surface adlayer, and STM images clearly show the characteristic shape of the molecule (figure B1.19.8).

Figure B1.19.8. (a) STM image ($5.7\text{ nm} \times 5.7\text{ nm}$) of 10-alkylcyanobiphenyl on graphite; (b) model showing the packing of the molecules. The shaded and unshaded segments represent the alkyl tails and the cyanobiphenyl head groups, respectively. (Taken from [38], figure 2.)

The self-assembly of alkanethiols on gold has been an important topic in surface chemistry over the last few years [39] and STM has contributed significantly to our understanding of these systems. In particular, the

formation of etch pits on the surface of Au(111) following treatment with alkanethiols is a phenomenon that was first observed by STM [40]. The segregation of thiols of different molecular weight or functionality is proving to be a relevant issue in their application. Stranick *et al* [41] have used STM to show the segregation of thiols with only very slight molecular differences into domains of size 10–100 Å and their subsequent coalescence.

The STM study of biological macromolecules has also been an area of great activity, and the imaging of DNA has been one of the challenges of the STM technique [42] (figure B1.19.9). The elimination of artifacts has been a major issue in this story, and the work of Beebe *et al* [43] showing that ‘DNA-like’ structures were to be seen on the surface of clean graphite (HOPG) substrates was something of a milestone (figure B1.19.10).

-10-

Figure B1.19.9. Plasmid DNA (pUC18) on mica imaged by STM at high resolution. The inset is a cut-out of a zoomed-in image taken immediately after the overview. (Taken from [42], figure 2.)

Figure B1.19.10. These images illustrate graphite (HOPG) features that closely resemble biological molecules. The surface features not only appear to possess periodicity (A), but also seem to meander across the HOPG steps (B). The average periodicity was 5.3 ± 1.2 nm. Both images measure 150 nm × 150 nm. (Taken from [43], figure 4.)

Other biomolecules imaged have included all DNA bases [44], polysaccharides [45] and proteins [46, 47]. In many cases there is strong evidence that the imaging process is facilitated by the presence of ultrathin (conducting) water films on the surface of the sample [48, 49 and 50].

Lastly, STM has also been applied to the molecular-level imaging of polymer structures. In some cases these materials were deposited by Langmuir–Blodgett techniques [51], and in some cases by *in situ* polymerization [52]. Fujiwara *et al* [51] have used molecular dynamics simulations to interpret the images obtained from STM experiments. The combined use of these two techniques is proving to be a very powerful tool for understanding the conformation of polymer films on surfaces. They showed that the individual polyimide strands observed were aligned parallel to the deposition direction of the Langmuir–Blodgett film.

(D) ELECTROCHEMISTRY

The molecular-level observation of electrochemical processes is another unique application of STM [53, 54]. There are a number of experimental difficulties involved in performing electrochemistry with a STM tip and substrate, although many of these have been essentially overcome in the last few years.

If the scanning tip is to be involved in electrochemical reactions, it is important to remember that at micrometre separations (i.e. when the tip is too far from the substrate for tunnelling to occur), the faradaic current is given by the equation [54]: $I_f \approx 4nFD_O C_O r$, where D_O is the diffusion coefficient of a particular species, F is Faraday's constant, C_O is the concentration of the species in solution, r is the radius of a disc of area equal to the effective exposed area of the tip and n is the number of electrons involved in the reaction. The total tip current, I , when the separation is small enough for tunnelling to occur, is given by $I = I_f + I_t$, where I_t is the tunnelling current, which is virtually independent of the total tip area exposed. In order to minimize I_f so as to be able to perform meaningful STM experiments, the exposed tip must be made as small as possible, and a plethora of techniques has been developed [53] for insulating all but the very end of the tip.

Several designs for STM electrochemical cells have appeared in the literature [55]. In addition to an airtight liquid cell and the tip insulation mentioned above, other desirable features include the incorporation of a reference electrode (e.g. Ag/AgCl in saturated KCl) and a bipotentiostat arrangement, which allows the independent control of the two working electrodes (i.e. tip and substrate) [56] (figure B1.19.11).

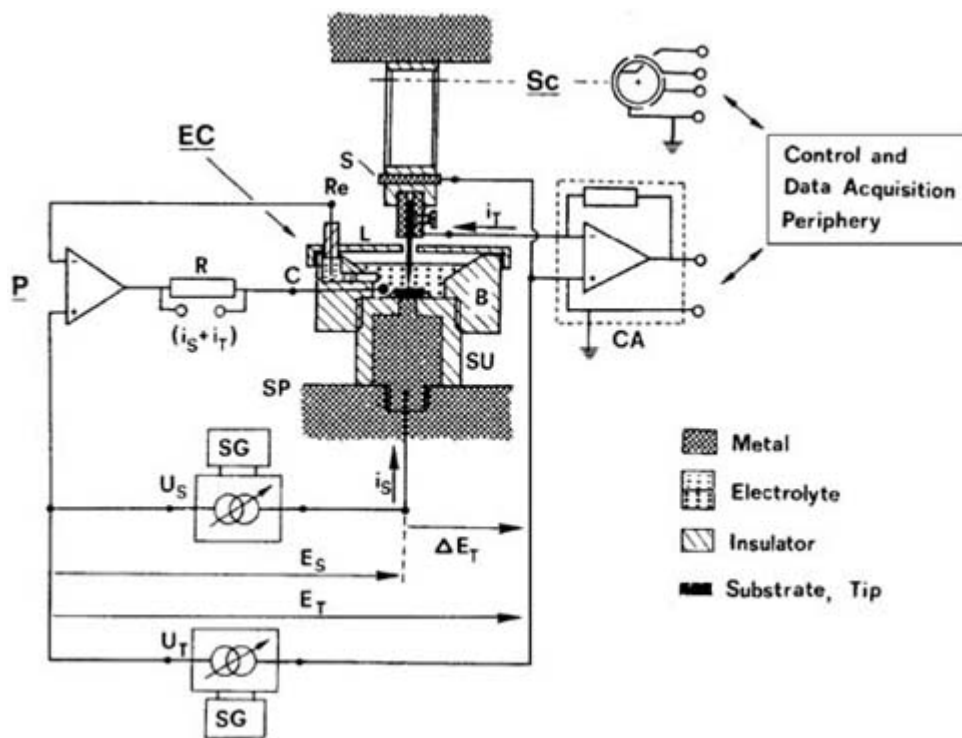

Figure B1.19.11. Schematic presentation of a potentiostatic STM system, with individual potential control of substrate and tip. Piezoelectric single-tube scanner *Sc* with titanium spacer plate *S*; electrochemical cell *EC* consisting of plexiglass beaker *B* with Pt counterelectrode *C* and Ag/AgCl reference electrode *Re* in 0.1 M NaCl; plexiglass lid *L*; PTFE support unit *SU* with epoxy-sealed substrate, mounted on support plate *SP*. Low-noise potentiostat *P* with low-impedance voltage units U_S and U_T , both equipped with low-pass filter and signal generator *SG*; precision resistor *R* for measuring $(i_S + i_T)$; low-noise current amplifier *CA* for measuring i_T . (Taken from [56], figure 1.)

Examining electrodes and how they change under conditions of electrochemical reaction has been a major part of the electrochemical STM work performed until now. Many studies have revealed changes in surface reconstructions on silver and gold electrodes during electrochemical reactions [57], as well as increasing or decreasing surface roughness, depending on the conditions and electrolyte employed. Another field of activity has been the monitoring of metal deposition on electrodes [58], which is, of course, of tremendous practical importance. Since STM can image both periodic and non-periodic structures, it is of great utility, both in determining the geometric relationships between deposited metal and substrate, as well as in assessing the role of steps and defects in the deposition process [57].

Corrosion is another economically significant process that can be investigated on a molecular level, thanks to electrochemical STM. In addition to a number of academically interesting studies of systems such as the selective dissolution of copper from Cu–Au alloys [59], STM has also been used to investigate the properties of iron and steel under a variety of conditions designed to induce either passivation, corrosion, or electrochemical anodization [60, 61]. In the case of corrosion, STM has been used to monitor the growth of magnetite crystallites on the surface of the sample as it is taken through several successive cyclic voltammograms [61].

The technique of scanning electrochemical microscopy (SECM) [62] uses the same apparatus as in electrochemical STM, but instead of measuring tunnelling currents, the reaction $O + ne \rightarrow R$ (where *O* and *R*

are oxidized and reduced species, respectively) is followed, by measuring the Faradaic current, I_f , at distances further from the substrate than those at which tunnelling will readily occur. The current, I_f , at distances far from the substrate surface, corresponds to the hemispherical diffusion of O to the tip surface (figure B1.19.12). As the tip nears the surface, this current is perturbed, either by hindered diffusion (lower current) or by reoxidation of R on the surface (higher current). The conductivity, potential, and electrochemical activity will therefore all influence I_f , which can thus be used to produce an electrochemical image of the surface—if plotted as a function of x and y —as the tip is rastered over the surface. The technique has been used to image metals, polymers, biological materials and semiconductors.

Figure B1.19.12. Basic principles of SECM. (a) With ultramicroelectrode (UME) far from substrate, diffusion leads to a steady-state current, i_T, ∞ . (b) UME near an insulating substrate. Hindered diffusion leads to $i_T < i_T, \infty$. (c) UME near a conductive substrate. Positive feedback leads to $i_T > i_T, \infty$. (Taken from [62], figure 2.)

(E) CATALYSIS

It has long been the goal of many catalytic scientists to be able to study catalysts on a molecular level under reaction conditions. Since the vast majority of catalytic reactions take place at elevated temperatures, the use of STM for such *in situ* catalyst investigations was predicated upon the development of a suitable STM reaction cell with a heating stage. This has now been done [3] by McIntyre *et al*, whose cell-equipped STM can image at temperatures up to 150 °C and in pressures ranging from ultrahigh vacuum up to several atmospheres. The set-up has been used for a number of interesting studies. In one mode of operation [63] (figure B1.19.13(a)), a Pt–Rh tip was first used to image clusters of carbonaceous species formed on a clean Pt(111) surface by heating a propylene adlayer to 550 K, and later to catalyze

the rehydrogenation of the species (in a propylene/hydrogen atmosphere) at room temperature. The catalytic activity of the tip was induced by applying a voltage pulse, which presumably cleaned the surface of deactivating debris (figure B1.19.13(b)).

Figure B1.19.13. (a) Three STM images of a Pt(111) surface covered with hydrocarbon species generated by exposure to propene. Images taken in constant-height mode. (A) after adsorption at room temperature. The propylidyne ($\equiv\text{C}-\text{CH}_2-\text{CH}_3$) species that formed was too mobile on the surface to be visible. The surface looks similar to that of the clean surface. Terraces (~ 10 nm wide) and monatomic steps are the only visible features. (B) After heating the adsorbed propylidyne to 550 K, clusters form by polymerization of the C_xH_y fragments. The clusters are of approximately round shape with a diameter equal to the terrace width. They form rows covering the entire image in the direction of the step edges. (C) Rows of clusters formed after heating to 700 K. At this higher temperature, the carbonaceous clusters are more compact and slightly smaller in size, as they evolve to the graphitic form when H

-15-

is lost completely. (b) The catalytic action of the STM Pt-Rh tip on a surface covered by carbonaceous clusters, as in figure B1.19.13(a). (B) Imaging was performed in 1 bar of a propene (10%) and hydrogen (90%) mixture at room temperature. (A) Carbon clusters were imaged in the top third of the image while the tip was inactive. A voltage pulse of 0.9 V was applied to the position marked P, leaving a mound of material 1.5 nm high. This process produced a chemically active Pt-Rh tip, which catalyzed the removal of all clusters in the remaining two-thirds of the image. Only the lines corresponding to the steps are visible. This image was illuminated from a near-incident angle to enhance the transition region where the tip was switched to its active state. (B) While the tip was in this catalytically active state, another area was imaged, and all of the clusters were again removed. (C) A slightly larger image of the area shown in (B) (centre square of this image), obtained after the tip was deactivated, presumably by contamination. The active-tip lifetime was of the order of minutes. (Taken from [63], figure 1 and figure 2.)

(F) STM AS A SURFACE MODIFICATION METHOD

Within a few years of the development of STM as an imaging tool, it became clear that the instrument could also find application in the manipulation of individual or groups of atoms on a surface [64]. Perhaps the most dramatic image originated from Eigler and Schweizer [65], who manipulated single physisorbed atoms of xenon on a Ni(110) surface, held at liquid helium temperature (figure B1.19.14). The tip–Xe distance was reduced (by raising the setpoint for the tunnelling current) until the tip–sample interaction became strong enough for the tip to be able to pick up the atom. After being moved to the desired location, the atom was removed by reversing the procedure. Using a similar experimental set-up, Crommie *et al* [66] have managed to shape the spatial distribution of electrons on an atomic scale, by building a ring of 48 iron adatoms (a ‘quantum corral’) on a Cu(111) surface, which confines the surface-state electrons of the copper by virtue of the scattering effect of the Fe atoms (figure B1.19.15). STS measurements of the local densities of states for the confined electrons correspond to the expected values for a ‘particle-in-a-box’, where the box is round and two-dimensional. In a similar way, Yokoyama *et al* [67] formed a pair of long straight chains of Al on the Si(001)-c(4 × 2) surface to create well defined 1D quantum wells. The electrons in the Π^* surface states can propagate only in the dimer-row direction of Si(001)-c(4 × 2) because of nearly flat dispersion in the perpendicular direction. The STM/STS measurements of the standing-wave patterns and their discrete energy levels could be interpreted according to the ‘1D particle-in-a-box model’. This technique shows considerable promise for the further investigation of confined electrons and waveguides. There are numerous other means for moving atoms in surfaces, including voltage-pulsing techniques, which show promise as potential lithographic methods for silicon [68].

Figure B1.19.14. A sequence of STM images taken during the construction of a patterned array of xenon atoms on a Ni(100) surface. Grey scale is assigned according to the slope of the surface. The atomic structure of the nickel surface is not resolved. Each letter is 5 nm from top to bottom. (Taken from [65], figure 1.)

Figure B1.19.15. Spatial image of the eigenstates of a quantum corral. 48-atom Fe ring constructed on a Cu (111) surface. Average diameter of ring is 14.3 nm. The ring encloses a defect-free region of the surface. (Taken from [66], figure 2.)

Finally, a technique that combines chemical vapour deposition (CVD) with STM has been devised by Kent *et al* [69]. The CVD gas used was iron pentacarbonyl, which is known to decompose under electron bombardment. Decomposition between tip and sample was found to occur at bias voltages above 5 V, forming iron clusters as small as 10 nm in diameter on the Si(111) substrate. Of particular practical interest is that arrays of 20 nm diameter dots have been shown to be magnetic, presenting a whole new range of possibilities for high-density data storage, as well as providing a convenient laboratory for nanometre-scale experiments in quantum magnetism.

B1.19.3 FORCE MICROSCOPY

B1.19.3.1 PRINCIPLES

(A) BACKGROUND

A major limitation of the scanning tunnelling microscope is its inability to analyse insulators, unless they are present as ultrathin films on conducting substrates. Soon after the development of the STM, work started on the development of an equivalent nanoscale microscope based on force instead of current as its imaging parameter [70]. Such an instrument would be equally adept at analysing both conducting and insulating samples. Moreover, the instrument already existed on a micro- and macro-scale as the stylus profilometer [71]; this is typically used to measure surface roughness in one dimension, although it had been extended into a three-dimensional imaging technique, with moderate resolution (0.1 μm lateral and 1 nm vertical), by Teague *et al* [72].

The concept that Binnig and co-workers [73] developed, which they named the atomic force microscope (AFM, also known as the scanning force microscope, SFM), involved mounting a stylus on the end of a cantilever with a spring constant, k , which was lower than that of typical spring constants between atoms. This sample surface was then rastered below the tip, using a piezo system similar to that developed for the STM, and the position of the tip monitored [74]. The sample position (z -axis) was altered in an analogous way to STM, so as to maintain a constant displacement of the tip, and the z -piezo signal was displayed as a function of x and y coordinates (figure B1.19.16). The result is a force map, or image of the sample's surface [75], since displacements in the tip can be related to force by Hooke's Law, $F = -kz$, where z is the cantilever displacement. In AFM, the displacement of the cantilever by the sample is very simply considered to be the result of long-range van der Waals forces and Born repulsion between tip and sample. However, in most practical implementations, meniscus forces and contaminants often dominate the interaction with interaction lengths frequently exceeding those predicted [76]. In addition, an entire family of force microscopies has been developed, where magnetic, electrostatic, and other forces have been measured using essentially the same instrument.

Figure B1.19.16. Schematic view of the force sensor for an AFM. The essential features are a tip, shown as a rounded cone, a spring, and some device to measure the deflection of the spring. (Taken from [74], figure 6.)

(B) AFM INSTRUMENTATION

The first AFM used a diamond stylus, or 'tip' attached to a gold-foil cantilever, and much thought was given to the choice of an appropriate k -value [73]. While on the one hand a soft spring was necessary (in order to obtain the maximum deflection for a given force), it was desirable to have a spring with a high resonant frequency (10–100 kHz) in order to avoid sensitivity to ambient noise. The resonant frequency, f_0 , is given by the equation

$$f_0 = (1/2\pi)\sqrt{k/m_0}$$

where m_0 is the effective mass loading the spring. Thus, as k is reduced to soften the spring, the mass of the cantilever must be reduced in order to keep the k/m_0 ratio as large as possible. Nowadays, cantilevers and integrated tips are

routinely microfabricated out of silicon or silicon nitride. Typical dimensions of a cantilever are of the order

of $1 \times 10 \times 100 \mu\text{m}^3$ [77], the exact dimensions depending on the intended use. Cantilevers designed to operate in contact with the surface, in a similar way to a surface profilometer, have low spring constants (usually less than 1 N m^{-1}) and correspondingly low resonant frequencies. Such levers are often fabricated in a V-shape configuration (figure B1.19.17), which makes for a greater stability towards lateral motion. If the tip is to come into hard contact with the surface, high-aspect-ratio tips are often desirable, with, typically, a radius of curvature of 10–30 nm. It is interesting to note that since experiments are generally carried out with contact forces on the order of nanonewtons, contact pressures in these experiments can be in the gigapascal range. In a stylus profilometer, the force exerted on the sample is some five orders of magnitude greater, but it is exerted over a larger contact area, leading to pressures in the tens of megapascals.

Figure B1.19.17. Commercially produced, microfabricated, V-shaped Si_3N_4 cantilever and tip for AFM (Taken from [215].)

When the lever is intended for use with the tip separated from the surface, the lever stiffness is usually greater than 10 N m^{-1} with a high resonant frequency. In this case, more care is taken to prepare tips with small radii of curvature—sometimes as low as 2 nm. However, in reality, most experiments are performed with tips of unknown radii or surface composition, apart from rare cases where the AFM has been combined with field ion microscopy [78] or a molecule or nanotube of known dimensions and composition has been attached to the tip [79]. It is likely that in most AFMs, microasperities and contaminants mediate the contact.

Detection of cantilever displacement is another important issue in force microscope design. The first AFM instrument used an STM to monitor the movement of the cantilever—an extremely sensitive method. STM detection suffers from the disadvantage, however, that tip or cantilever contamination can affect the instrument's sensitivity, and that the topography of the cantilever may be incorporated into the data. The most common methods in use today are optical, and are based either on the deflection of a laser beam [80], which has been bounced off the rear of the cantilever onto a position-sensitive detector (figure B1.19.18), or on an interferometric principle [81].

Figure B1.19.18. Schematic of an atomic force microscope showing the optical lever principle.

Lateral resolution in AFM is usually better than 10 nm and, by utilizing dynamic measurement techniques in ultrahigh vacuum, true atomic resolution can be obtained [82]. In hard contact with the surface, the atomic-scale structure may still appear to be present, but atomic-scale defects will no longer be visible, suggesting that the image is actually averaged over several unit cells. The precise way in which this happens is still the subject of debate, although the ease with which atomic periodicity can be observed with layered materials is probably due to the Moiré effect suggested by Pethica [83]. In this case a periodic image is formed by the sliding of planes directly under the tip caused by the lateral tip motion as the force varies in registry with unit lattice shear.

A further issue that should be considered when interpreting AFM images is that they are convolutions of the tip shape with the surface (figure B1.19.19). This effect becomes critical with samples containing ‘hidden’ morphology (or ‘dead zones’) on the one hand (such as deep holes into which the tip does not fit, or the underside of spherical features), or structure that is comparable in size to that of the tip on the other. While the hidden morphology cannot be regenerated, there have been several attempts to deconvolute tip shape and dimensions from AFM images (‘morphological restoration’) [84]. Some of these methods involve determining tip parameters by imaging a known sample, such as monodisperse nanospheres [85] or faceted surfaces [86]. Another approach is to analyse the AFM image as a whole, extracting a ‘worst case’ tip shape from common morphological features that appear in the image [87].

Figure B1.19.19. Examples of inaccessible features in AFM imaging. L corresponds to the AFM tip. The dotted curves show the image that is recorded in the case of (a) depressions on the underside of an object and (b) mounds on the top surface of an object. $M \cdot L$ and $M \oslash L$ correspond to convolutions of the surface features with the tip shape. (Taken from [85], figure 2.)

As with STM, the AFM can be operated in air, in vacuum or under liquids, providing a suitable cell is provided. Liquid cells (figure B1.19.20) are particularly useful for the examination of biological samples.

Figure B1.19.20. Cross section of an AFM fluid cell. (Taken from [216], figure 1.)

Analogously to STM, the image obtained in a force microscopy experiment is conventionally displayed on the computer screen as grey scales or false colour, with the lightest shades corresponding to peaks (or highest forces) and darkest shades corresponding to valleys (or lowest forces).

(C) FORCES IN AFM

Although imaging with force microscopy is usually achieved by means of rastering the sample in close proximity to the tip, much can be learned by switching off the x - and y -scanning piezos and following the deflection of the cantilever as function of sample displacement, from large separations down to contact with the surface, and then back out to large separations. The deflection–displacement diagram is commonly known as a ‘force curve’ and this technique as

‘force spectroscopy’, although strictly speaking it is displacement that is actually measured, and further processing [88], reliant on an accurate spring constant, is necessary in order to convert the data into a true force–distance curve. In order to obtain sensitive force curves, it is preferable to make dynamic force-gradient measurements with the force and energy being found by integration [89] or alternatively to measure frequency shift of the cantilever resonant frequency as a function of displacement. This method has become particularly popular in combination with non-contact mode AFM (see below). Although with this method it is not straightforward to relate frequency shifts to forces, it appears to be a promising technique for distinguishing between materials on the nanometre scale [90].

As the tip is brought towards the surface, there are several forces acting on it. Firstly, there is the spring force due to the cantilever, F_S , which is given by $F_S = -kz$. Secondly, there are the sample forces, which, in the case of AFM, may comprise any number of interactions including (generally attractive) van der Waals forces, chemical bonding interactions, meniscus forces or Born (‘hard-sphere’) repulsion forces. The total force

gradient as the tip approaches the sample is the convolution of spring and sample force gradients, or

$$\frac{\partial F}{\partial D} = \frac{k(\partial^2 U / \partial D^2)}{k + \partial^2 U / \partial D^2}$$

where U is the sample potential and D the tip–sample separation. If the spring constant of the cantilever is comparable to the gradient of the tip–surface interaction, then at some point where $\partial^2 U / \partial D^2$ (negative for attraction) equals k , the total force gradient becomes instantaneously infinite, and the tip jumps towards the sample [91] (figure B1.19.21). This ‘jump to contact’ is analogous to the jump observed when two attracting magnets are brought together. The kinetic energy involved is often sufficient to damage the tip and sample, thus reducing the maximum possible resolution during subsequent imaging. Once a jump to contact occurs, the tip and sample move together (neglecting sample deformation for the time being) until the direction of sample travel is reversed. The behaviour is almost always hysteretic, in that the tip remains in contact with the sample due to adhesion forces, springing back to the equilibrium position when these have been exceeded by the spring force of the cantilever. The adhesion forces add to the total force exerted on the sample, and are often caused by tip contamination. It has been found that pretreating the tip in ozone and UV light, in order to remove organic contamination, reduces the adhesion observed, and improves image quality [92]. Image quality can also be enhanced by tailoring the imaging medium (i.e. in a liquid cell) to have a dielectric constant intermediate between those of the tip and the sample. This leads to a small, repulsive van der Waals force, which eliminates the jump to contact, and has been shown to improve resolution in a number of cases [93, 94], probably due to the fact that the tip is not damaged during the approach. It should be noted that the jump to contact may also be eliminated if a stiff cantilever is chosen, such that k , the force constant of the cantilever, is greater than $\partial^2 U / \partial D^2$ at all separations. This condition for jump-to-contact is insufficient if the stiffness of the cantilever is artificially enhanced using feedback [95] or if dynamic measurements are made [96, 97].

Since the AFM is commonly used under ambient conditions, it must be borne in mind that the sample is likely to be covered with multilayers of condensed water. Consequently, as the tip approaches the surface, a meniscus forms between tip and surface, introducing an additional attractive capillary force. Depending on the tip radius, the magnitude of this force can be equal to or greater than that of the van der Waals forces and is observed clearly in the approach curve [98]. In fact, this effect has been exploited for the characterization of thin liquid lubricant films on surfaces [95]. The capillary forces may be eliminated by operation in ultrahigh vacuum, provided both tip and sample are baked, or, most simply, by carrying out the experiment under a contamination-free liquid environment, using a liquid cell [99].

Figure B1.19.21. A plot of cantilever displacement as a function of tip sample separation during approach and retraction with an AFM. Note the adhesive forces upon retraction from the surface.

(D) NON-CONTACT AFM

Non-contact AFM (NC-AFM) imaging is now a well established true-atomic-resolution technique which can image a range of metals, semiconductors and insulators. Recently, progress has also been made towards high-resolution imaging of other materials such as C_{60} , DNA and polypropylene. A good overview of recent progress is the proceedings from the First International Conference on NC-AFM [100].

Most NC-AFMs use a frequency modulation (FM) technique where the cantilever is mounted on a piezo and serves as the resonant element in an oscillator circuit [101, 102]. The frequency of the oscillator output is instantaneously modulated by variations in the force gradient acting between the cantilever tip and the sample. This technique typically employs oscillation amplitudes in excess of 20 nm peak to peak. Associated with this technique, two different imaging methods are currently in use: namely, fixed excitation and fixed amplitude. In the former, the excitation amplitude to the lever (via the piezo) is kept constant, thus, if the lever experiences a damping close to the surface the actual oscillation amplitude falls. The latter involves compensating the excitation amplitude to keep the oscillation amplitude of the lever constant. This mode also readily provides a measure of the dissipation during the measurement [100].

Although both methods have produced true-atomic-resolution images it has been very problematic to extract quantitative information regarding the tip–surface interaction as the tip is expected to move through the whole interaction potential during a small fraction of each oscillation cycle. For the same reason, it has been difficult to conclusively identify the imaging mechanism or the minimum tip–sample spacing at the turning point of the oscillation.

Many groups are now trying to fit frequency shift curves in order to understand the imaging mechanism, calculate the minimum tip–sample separation and obtain some chemical sensitivity (quantitative information on the tip–sample interaction). The most common methods appear to be perturbation theory for considering the lever dynamics [103], and quantum mechanical simulations to characterize the tip–surface interactions [104]. Results indicate that the

interaction curve measured as a function of frequency shift does not correspond directly to the force gradient as first believed.

(E) INTERMITTENT CONTACT AFM

A further variation is intermittent contact mode or ‘TappingMode’ [105] (TappingMode® is a trademark of Digital Instruments, Santa Barbara, CA.), where the tip is oscillated with large amplitudes (20–100 nm) near its resonant frequency, and the amplitude used to control the feedback loop. The system is adjusted so that the tip contacts the sample once within each vibrational cycle. Since the force on the sample in this mode is both small (<5 nN) and essentially normal to the surface, it is far less destructive than contact AFM, with its inherently large shear forces. This is of great importance when imaging biological materials; a further development of the intermittent-mode AFM, which allows it to be operated under *liquids* [106], extends the possibilities in this area even further.

(F) MAGNETIC FORCE MICROSCOPY

Magnetic forces may be exploited for the imaging of samples containing magnetic structure. Resolutions as high as 10 nm have been reported [107]. The central modification of the AFM needed to perform magnetic force microscopy (MFM) is the use of a magnetic tip, which often consists of an electrochemically etched ferromagnetic material, or a non-magnetic tip that has been coated with a magnetic thin film [108]. The experiment is run in non-contact mode, with the tip some 10 nm away from the surface. Detection at long range helps distinguish between magnetic and non-magnetic interactions. Greater sensitivity is obtained when the cantilever is oscillated and magnetic force gradients detected by changes in the resonant frequency as the tip approaches the magnetic surface. The method is unique in its ability to image magnetic structure in surfaces (figure B1.19.22) [109], which lies at the heart of magnetic data storage technology.

Figure B1.19.22. Magnetic force microscopy image of an 8 μm wide track on a magnetic disk. The bit transitions are spaced every 2 μm along the track. Arrows point to the edges of the DC-erased region. (Taken from [109], figure 7.)

(G) LATERAL FORCE MICROSCOPY

Lateral force microscopy (LFM) has provided a new tool for the investigation of tribological (friction and wear) phenomena on a nanometre scale [110]. Alternatively known as friction force microscopy (FFM), this variant of AFM focuses on the lateral forces experienced by the tip as it traverses the sample surface, which

correspond to the local coefficients of dynamic friction. LFM can therefore provide a frictional map of the surface with sub-nanometre resolution. It therefore has the potential to reveal chemical differences between regions of similar morphology, virtually down to the atomic scale.

The LFM method is an inherently contact-mode technique, and can be performed with an AFM, provided that there is some means of measuring the lateral tip displacement. Mate *et al* [111] were the first to modify their AFM in order to detect lateral forces and to observe frictional behaviour on the atomic scale. Their detection system was interferometric, and their cantilever and tip consisted of a shaped tungsten wire. Later developments using the laser beam-deflection method [112, 113] with two sets of position-sensing detectors (figure B1.19.23), enabled both lateral and normal forces to be measured simultaneously. Clearly, these two sets of forces are not entirely independent, since a lateral force will be felt as the tip is scanned over a step, for example, irrespective of the frictional coefficient at the step. However, by measuring the lateral force as the tip is scanned in both directions along the same line (producing a ‘friction loop’, figure B1.19.24), and subtracting one trace from the other, the frictional information can be separated from the purely morphological.

Figure B1.19.23. Principle of simultaneous measurement of normal and lateral (torsional) forces. The intensity difference of the upper and lower segments of the photodiode is proportional to the z-bending of the cantilever. The intensity difference between the right and left segments is proportional to the torsion, t , of the force sensor. (Taken from [110], figure 2.)

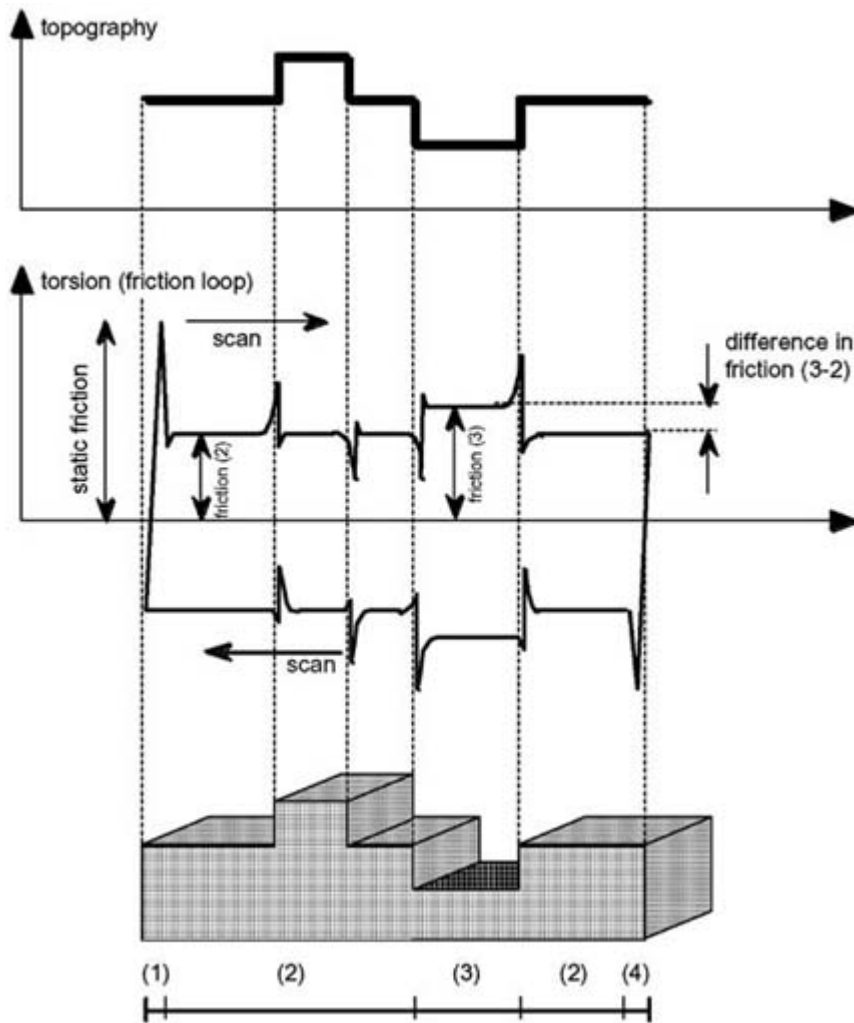

Figure B1.19.24. Friction loop and topography on a heterogeneous stepped surface. Terraces (2) and (3) are composed of different materials. In regions (1) and (4), the cantilever sticks to the sample surface because of static friction F_{ST} . The sliding friction is t_1 on part (2) and t_3 on part 3. In a torsional force image, the contrast difference is caused by the relative sliding friction, $\Delta F_{SL} = t_1 - t_3$. Morphological effects may be distinguished from frictional ones by their non-inverted behaviour upon scanning in the opposite direction. (Adapted from [110], figure 2.)

(H) MECHANICAL IMAGING WITH FORCE MICROSCOPY

In AFM, the relative approach of sample and tip is normally stopped after ‘contact’ is reached. However, the instrument may also be used as a nanoindenter, measuring the penetration depth of the tip as it is pressed into the surface of the material under test. Information such as the elastic modulus at a given point on the surface may be obtained in this way [114], although producing enough points to synthesize an elastic modulus image is very time consuming.

Pulsed-force mode AFM (PFM-AFM) is a method introduced for fast mapping of local stiffness and adhesion with lower required data storage than recording force–distance curves at each point on the x – y plane [115]. A sinusoidal or triangular modulation is applied between the tip and sample (either *via* lever or sample piezo) at a lower frequency than that of either the piezo or cantilever resonance frequency. Tip and sample then come

into contact for part of each oscillation cycle. The deflection signal of the cantilever is put into sample-and-hold circuits. The peak displacement of the lever during the approach cycle is usually chosen for the feedback signal to the piezo, in order to maintain a constant force during scanning. Other sampling points can be chosen at any arbitrary timings within one cycle depending on the required property. For example, the local stiffness can be calculated from the slope obtained from subtracting the sample-and-hold signals at two different points on the linear part of the deflection–displacement curve. The adhesion force can be calculated from the difference between the largest negative deflection signal and the zero-deflection point.

Another method developed for imaging mechanical properties is ultrasonic force microscopy [116] (UFM). This technique involves carrying out contact AFM while oscillating the sample at high frequency: typically 200–700 kHz, chosen to be above the highest tip–sample resonance. If operating in the purely contact mode (i.e. if the tip does not leave the surface), the amplitude of the tip oscillations is determined by the elastic modulus of the tip–sample system, independent of the spring stiffness of the cantilever. The technique can be thought of as a fast-indentation system, and it samples a volume that has a radius some ten times the indentation depth. The overall spatial resolution is typically a few nanometres.

B1.19.3.2 APPLICATIONS OF FORCE MICROSCOPY

(A) INORGANIC SURFACES

True atomic resolution has been obtained on a wide range of inorganic surfaces including metals, semiconductors and insulators. Initially, imaging concentrated on Si (111) 7×7 as a means of demonstrating the true-atomic-resolution imaging capability of the technique [81]. Even with such a well understood surface, surprising results were obtained in the form of additional contrast revealed between different surface atoms. In the case of Erlandsson *et al* [117] their results showed that centre adatoms appeared to be 0.13 Å higher than the corner adatoms. They suggest that the additional contrast may be due to variation in chemical reactivity of the adatoms or to tip-induced, atomic relaxation effects reflecting the stiffness of the surface lattice (figure B1.19.25). Nakagiri *et al* [118] also saw additional contrast in their images of Si(111) 7×7 . However, they observed the six atoms in one half of the unit cell to be brighter than in the other half. The two halves correspond to faulted and unfaulted halves of the unit cell according to the dimer–adatom stacking fault model [119]. At present they are not able to distinguish which atoms correspond to which half. The fact that this additional contrast varied depending on the precise experimental technique used indicates that different imaging mechanisms could be responsible as a result of the different tip material or height of the tip with respect to the surface.

Of particular interest are those surfaces where AFM has provided complementary information or revealed surface structure which could not be obtained by STM. One obvious application is the imaging of insulators such as NaCl(001) [120]. In this case it was possible to observe point defects and thermally activated atomic jump processes, although it was not possible to assign the observed maxima to anion or cation.

Another area where AFM has provided new information is the imaging of metal oxides such as TiO₂ [121, 122]. Although the surface of TiO₂(110) is observable with STM, only NC-AFM was able to image the bridging oxygen rows which are the outermost atoms on the surface (figure B1.19.26). True-atomic-resolution imaging is still a relatively recent development and the full power of the technique in imaging insulators such as Al₂O₃ or SiO₂ has yet to be demonstrated.

-29-

Figure B1.19.26. Highly resolved, non-contact AFM image of the TiO₂(110)-(1 × 1) surface (8.5 × 8.5 nm²) with a single step. The two-dimensional order of the bright spots (0.65 × 0.3 nm²) reproduces the alignment of the bridging oxygen atoms. (Taken from [121], figure 3.)

Even without atomic resolution, AFM has proved its worth as a technique for the local surface structural determination of a number of bio-inorganic materials, such as natural calcium carbonate in clam and sea-urchin shells [123], minerals such as mica [124] and molybdenite [125] as well as the surfaces of inorganic crystals, such as silver bromide [126] and sodium decatungstocerate [127]. This kind of information can prove invaluable in the understanding of phenomena such as biomineralization, the photographic process or catalysis, where the surface crystallography, especially the presence of defects and superstructures, can play an important role, but is difficult to determine by other methods. AFM has the considerable advantage that it can be used to examine powdered samples, either pressed into a pellet, if the contact mode is employed, or loosely dispersed on a surface, if intermittent or non-contact AFM is available.

AFM has also provided insights into the growth of metal clusters and films on mica. In the case of palladium [128], for example, it was found that clusters in the 50 nm range exhibited truncated triangular shapes. Epitaxial growth of silver on a mica surface [129] is seen to depend in a complex way on both substrate temperature and film thickness (figure B1.19.27), with island morphology giving way to channels, which become holes and then networks as the film thickness increases, the changes progressing more gradually as the substrate temperature is increased. The issue of surface roughness of silver films is central to the technique of surface-enhanced Raman spectroscopy, and AFM has been used to characterize films produced for this

purpose [130]. AFM possesses a considerable advantage over electron microscopy in this kind of application, in that it can, if calibrated, automatically yield *quantitative* morphological and roughness data [131].

Figure B1.19.27. AFM topographic images ($7 \times 7 \mu\text{m}^2$) of 20 epitaxial Ag films on mica prepared at five substrate temperatures (75, 135, 200, 275, and 350 °C) and four film thicknesses (50, 110, 200, and 300 nm) using metal deposition rates of 0.1 to 0.2 nm s⁻¹. The vertical RMS and peak-to-valley roughness are indicated for each image. (Taken from [129], figure 1.)

(B) ORGANIC SURFACES

AFM has been used to image several surfaces of organic crystals—such as tetracene [132] and pyrene [133]—and has produced images that can be compared to the unit cells expected from previous x-ray crystallographic studies. In the case of tetracene, the surface is merely a truncation of that expected from the bulk data. However, in the case of pyrene, where the bulk consists of dimer pairs, a surface reconstruction is evident in the AFM image, corresponding to the presence of monomer species. Reconstructions are common phenomena in metal surfaces, where LEED has frequently been used to detect them [25]. LEED has scarcely been used to analyse organic crystal surfaces, however, due to problems associated with charging and/or degradation of the sample in an electron beam. AFM nicely fills this gap in the surface analytical arsenal.

The overwhelming majority of AFM studies on organic surfaces has concerned organic thin films on inorganic substrates and, in particular, those deposited *via* Langmuir–Blodgett or self-assembly processes [35]. These films

have been an active research area for several years, frequently serving as models for complex systems, such as membranes. Thin organic films are also being developed for their nonlinear optical properties, as microlithographic resists and as sensor components [32].

Two Langmuir–Blodgett film systems that have been much studied by AFM are the calcium and barium arachidates, adsorbed as double layers on a silicon substrate, which has been pretreated so as to be hydrophobic [32]. These structures are formed by dipping the silicon into an arachidate film on a water trough and then removing the substrate again through the film. Repeating the process simply adds another double layer to the structure. As with organic crystals, more traditional surface-structure-determining approaches are often too destructive to allow analysis of systems such as these; possibly the most important and unique aspect of AFM in this context is that it is a *local probe*, and therefore capable of showing the enormous variety of defects in the films, both on a microscale (pores and islands in the films) and a nanoscale [134, 135] (twinning, defects and complexities in molecular packing) (figure B1.19.28). This topic has been dealt with at length by Frommer in her excellent review article [32].

Figure B1.19.28. Molecular-scale image (2 nm × 20 nm) of a barium arachidate bilayer. Image was produced by averaging six images, but without filtering data. (Taken from [135], figure 1.)

Self-assembly of long-chain alkanethiols on the Au(111) surface has been studied by a number of different techniques including AFM, and it has been consistently shown that the molecules form a commensurate ($\sqrt{3} \times \sqrt{3}$)R30° structure. AFM studies can also provide additional information on the mechanical properties of the organic layers [136], which are interesting in that they serve as a model system for lubricants [137]. Above a critical applied load of 280 nN for the C₁₈ thiols, it has been found that the monolayers were disrupted, and that the subsequent image corresponded to that of the Au(111) substrate. However, on reducing the load to substantially below the critical value, the surface apparently healed, and the characteristic periodicity of the thiol overlayer returned. The exact way in which this phenomenon occurs is not completely understood [138]. Possibilities include displacement of the thiols by the tip, binding of the thiols to the tip, or desorption of the thiols into a liquid phase.

(C) POLYMER SURFACES

AFM is contributing significantly to our understanding of the surface structure of polymers, both on a microscale and on a molecular level. Segregation in the surface of block copolymers and polymer blends is often critical in determining technologically important properties, such as wettability or biocompatibility. It is also often difficult to image by optical or electron microscopy. AFM, on the other hand, offers a method for scrutinizing these materials down to the molecular level, without the need for surface preparation. AFM's ability to operate in a liquid environment makes it particularly useful in analysing polymers for medical applications, since these materials are designed to function surrounded by body fluids, which can influence the surface microstructure and nanostructure.

Several studies have concerned the microstructure of lamellae in materials such as the block copolymers polystyrene-*block*-poly-2-vinylpyridine [139] and polystyrene-*block*-polybutadiene [140], as well as single crystals of poly-*para*-xylylene [139], and reveal features (such as intersecting lamellae (figure B1.19.29)) that had not been previously observed.

Figure B1.19.29. AFM image of polystyrene/polybutadiene copolymer, showing lamellar structure. (Taken from [140], figure 1.)

LFM has also proved useful in the examination of polymer blends, since its ability to image effective frictional coefficients imparts a certain chemical sensitivity to the method [141]. A novel approach to discrimination between components of a polymer blend was adopted by Feldman *et al* [142], who used the low-refractive-index liquid, perfluorodecalin, as a medium for measurement of tip-polymer 'pull-off', thereby enhancing the London component of the Hamaker constant, improving the signal-to-noise ratio of the measurement. Using the same medium for lateral force (frictional) imaging, a striking contrast reversal was found between polystyrene and PMMA blend components, when the tip surface was changed from (hydrocarbon-covered) gold to silica (figure B1.19.30).

Figure B1.19.30. Height and friction images of a spin-cast polystyrene-poly(methyl methacrylate) blend obtained with (a) gold and (b) silica probes under perfluorodecalin. Note the reversal of frictional contrast and the high spatial resolution. (Taken from [142], figure 7.)

On the molecular level, spectacular AFM images have been obtained for a number of systems. In the case of isotactic polypropylene, for example, Snétiy and Vancso [143] have succeeded in imaging individual methyl groups on the polymer chain, and distinguishing between left- and right-handed helices in the crystalline *i*-polypropylene matrix (figure B1.19.31). The same group has also used AFM to image the phenylene groups in poly(*p*-phenyleneterephthalamide) fibres, and have used this data to show the existence of a new polymorphic form that had previously only been suggested by computer simulations.

Figure B1.19.31. AFM image of a 2.7 nm × 2.7 nm area of a polypropylene surface, displaying methyl groups and right- and left-handed helices. (Taken from [143], figure 10.)

(D) BIOLOGICAL SURFACES

The AFM is now firmly established as a unique tool for the *in situ* investigation of biological surfaces [144], whether these be biomolecules, cell structures, or even viruses [145]. Often, a successful immobilization strategy has been key to successful imaging of the biological surface [146].

Lured by the promise of a new way to sequence the genetic code, and the prospect of nanomanipulation of nucleic acids, investigators have produced a plethora of papers in the area of AFM imaging of DNA. Notable among these is the work of Bustamente *et al* [147], who developed one of the first reproducible methods for imaging nucleic acids. Their approach involved three important components: (1) the use of extremely sharp tips [148] (radius of curvature ≈ 10 nm), which are prepared by electron-beam deposition of a carbon whisker on the tip apex in an electron microscope [149], (2) the use of mica substrates that have been ion-exchanged with magnesium, in order to promote interaction with the phosphate groups on the DNA and (3) careful control of the relative humidity [150] (or operation under liquids), in order to prevent tip-induced sample movement. Using this approach, and imaging under 2-propanol, high-resolution images of plasmid DNA have been obtained [151] (figure B1.19.32), and the molecules dissected by momentarily increasing the AFM force [152]. Single- and double-stranded DNA [153] and RNA-polymerase-DNA complexes [154] have also been imaged using this approach, the helical pitch of the DNA deciphered [155], AFM used to determine local chirality of the DNA supercoiling [156] and even individual base pairs resolved [157].

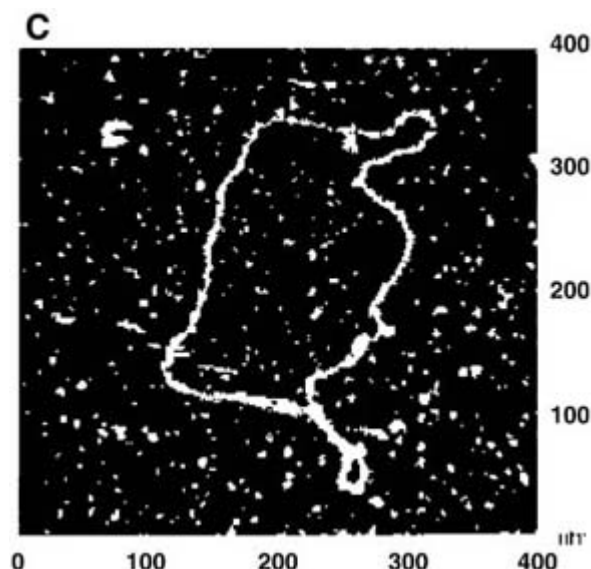

Figure B1.19.32. AFM image of Blue Script II plasmid (400 nm × 400 nm) in propanol, taken with ‘super tip’, prepared by carbon deposition on normal tip in SEM, followed by ion milling. (Taken from [152], figure 1.)

Proteins have also been investigated extensively by AFM. Radmacher *et al* [158] monitored height changes in an adsorbed layer of lysozyme using intermittent-contact AFM, as the enzyme was exposed to a substrate molecule. The height changes were variously interpreted as due to conformational adaptations of the lysozyme, or to the different height of the enzyme–substrate complex. Many other proteins have been imaged, using various immobilization methods, and this area has been comprehensively reviewed in the literature [159]. Among the highest-resolution (<1 nm) examples have been those of Müller *et al* [160], who have studied the inner surface of the hexagonally packed intermediate (HPI) layers of cell envelope proteins, such as those in the bacterium *Deinococcus radiodurans*, where protein conformational changes can be observed (figure B1.19.33). AFM has also provided a new window into the channels present in the surfaces of living cells, and Lal *et al* [161] have imaged the channels formed when the responsible cell proteins (porins) are reconstituted as crystalline arrays. The resolution obtained was such that individual polar head groups of the lipid molecules could be discerned. Several mechanical studies on proteins using AFM have also been reported, notably the hysteretic unfolding of the giant muscle protein, titin, reported by Rief *et al* [162], where the importance of this protein as a ‘strength reservoir’ during muscle stretching was demonstrated for the first time.

Figure B1.19.33. Conformational changes of the inner surface of an HPI layer. (a) The protruding cores are clearly visible, with some pores in an open conformation and others in an obstructed conformation. (b) Area shown in panel a imaged 5 min later. Some pores that were open earlier are now closed (circles), while closed ones have opened during this time interval (squares). Units were aligned and divided into two classes. The class averages exhibit a plugged (c) and an open hexamer (d). The difference map (g) represents the modulus of the height difference between the sixfold-symmetrized class averages ((e) and (f)). The full grey-level range corresponds to a vertical distance of 6 nm ((a) and (b)) and 3 nm ((c) to (f)). (Taken from [160], figure 3.)

In the area of cell and cell-structure imaging, AFM offers an advantage over optical and scanning electron microscopies in that it permits high-resolution imaging of living cells, and even the observation of dynamic phenomena. Henderson *et al* [163] observed the motion of filamentous actin in living glial cells (i.e., structures beneath the plasma membrane were imaged), and even performed nanosurgery on the cell with the AFM tip. Brandow *et al* [164] also cut into lipid membranes on a graphite surface using deliberately high force from the AFM tip, and found that the membranes healed themselves after sufficient time, but that the healing could be accelerated by rubbing the AFM tip perpendicular to the cut with a controlled force. The same group was also able to manipulate living glial cells [165] and even peel them away from a surface, if the normal force was appropriate. Thus, depending on the amount of force applied, the AFM could be used to cut, anneal, peel or image the sample.

Several groups have focused on the biochemical receptor–ligand interaction, measuring forces between individual molecular binding pairs, such as biotin and streptavidin [166, 167]. One approach involves coating the tip with either receptor or ligand, the sample with the complementary molecule, and then carefully monitoring tip–sample separation after contact. If the cantilever stiffness is appropriately chosen, the force–distance curve during separation appears to be ‘quantized’ in units corresponding to a single molecular-pair interaction. Lee *et al* [168] have also demonstrated and measured the interaction between single complementary strands of DNA base pairs using AFM. Several other examples of ligand–receptor interactions have been summarized in a review by Bongrand [169].

Due to its sensitivity to small forces and its ability to operate in liquids, the AFM has opened up a new avenue of investigation into colloidal systems. A frequently used approach, developed by Ducker *et al* [170], involves the cementing of a colloidal-sized particle onto an AFM cantilever in place of the usual tip, and then monitoring interactions with some appropriate flat surface, or even another colloidal particle [171], under a variety of conditions. Larson *et al* [172] used this technique to investigate the interactions between a titania (rutile) particle ($\approx 9 \mu\text{m}$ diameter) and a rutile single-crystal surface under various conditions of pH and ionic strength. From their experiments they were able to measure the van der Waals interaction between rutile surfaces directly, and to calculate the non-retarded Hamaker constant for the system. Biggs *et al* have applied a similar approach to the venerable subject of gold colloid stability [173], by immobilizing a $\sim 6 \mu\text{m}$ gold sphere on a cantilever and measuring its interaction with a polished gold plate under solutions containing combinations of gold, citrate, chloride and a number of other ions of relevance to the colloid system. The authors were able to demonstrate the presence of a repulsive interaction between the gold surfaces due to adsorbed citrate or chloride; they showed that citrate adsorbed preferentially, and succeeded in measuring the surface potential of the gold as a function of anion concentrations.

(F) TRIBOLOGY

Force microscopy, and lateral (or frictional) force microscopy in particular, are having a tremendous impact in tribology—the science and technology of friction, wear, and lubrication. The interaction between moving surfaces (the central issue in tribology) is thought to consist of separate interactions between the many peaks in one surface with the many peaks in the countersurface. These peaks are known as asperities. It is this mode of interaction that leads to Amontons' empirical 'law' of friction (this law is generally attributed to Amontons, although initially observed by Leonardo da Vinci a century earlier), $F = \mu N$, where F is the frictional force, N is the normal force, and μ is the coefficient of friction. Notable by its absence in this equation is the *apparent* contact area between the two sliding bodies. In fact, as one might intuitively believe, the *actual* contact area, A , between the asperities is all-important, and the frictional force is proportional to A . However, A , in turn, increases in proportion to the normal force [174], (both due to 'flattening' of the asperities by the load and the creation of new load-bearing asperities, as the higher asperities are flattened) so that A can be cancelled out of the resulting equation, leaving behind only the measurable quantities, F and N . The importance of AFM in fundamental tribology research is that the AFM measurement can be thought of as a single asperity contact, i.e. the fundamental interaction in frictional behaviour.

Carpick *et al* [84] used AFM, with a Pt-coated tip on a mica substrate in ultrahigh vacuum, to show that if the deformation of the substrate and the tip–substrate adhesion are taken into account (the so-called JKR model [175] of elastic adhesive contact), then the frictional force is indeed proportional to the contact area between tip and sample. However, under these single-asperity conditions, Amontons' law does not hold, since the 'statistical' effect of more asperities coming into play no longer occurs, and the contact area is not simply proportional to the applied load.

Mate *et al* [111], who pioneered LFM, used their instrument to show atomic-scale structure in the frictional force between a tungsten tip and surface graphite atoms. In fact, what these authors observed was stick–slip behaviour: an effect normally associated with macroscopic phenomena, such as the vibration induced in a violin string by the bow, or the squealing of an automobile's brakes. They also found that the frictional coefficient varied slightly with applied load, i.e. a deviation from Amontons' law. The same group went on to study mica surfaces [124], where a similar stick–slip behaviour was observed, the frictional coefficient varying with the unit cell periodicity of the mica cleavage plane (figure B1.19.34). Hu *et al* [176] examined mica surfaces by LFM using silicon nitride tips, and found that above

normal loads of 10 nN, Amontons' law was obeyed, while at low loads, deviations from linearity were observed. They also showed that friction decreased substantially as a function of humidity, decreasing by an order of magnitude under liquid water, but was essentially invariant with scanning direction across the mica surface. Wear was also observed by these authors, who found that a threshold load value needed to be exceeded before layer-by-layer wear was initiated. Below this value, even multiple scans were not found to produce visible damage to the surface. A similar effect was observed for the system AgBr on NaCl(001) (SiO₂-coated tip) by Lüthi *et al* [177], where a wear onset was observed at around 14 nN. Interestingly, frictional coefficients were measured over a range of loads in this latter work and the μ measured on NaCl was found to be an order of magnitude lower than that measured on AgBr.

Figure B1.19.34. Cantilever deflection and corresponding frictional force in the x -direction as a function of sample position as a mica sample is scanned back and forth under a tungsten tip. (Taken from [124], figure 2.)

Numerous groups have applied LFM to address the issue of friction on thin organic films. These systems serve as useful models for the important macroscopic tribological issue of boundary lubrication. Overney *et al* [178] used LFM to examine mixed Langmuir–Blodgett films of perhydro arachidic acid and partially fluorinated carboxylic acid that had been transferred onto a silicon surface as a bilayer system, using poly(4-vinyl-N-methylpyridinium) as a counteraction. The images clearly showed a difference in frictional coefficient between the two components, which segregated into submicron domains. Surprising, however, was the observation that the apparent frictional coefficient on the fluorinated component was a factor of four higher than that measured on the non-fluorinated one. The authors attributed this to the greater shear strength of fluorinated films, although more recent measurements using LB-deposited straight-chain acids of different lengths [179] suggest that the length of the molecule itself has a significant effect on mechanical properties, and therefore on the frictional coefficients measured.

Kim *et al* [180], using specially synthesized, end-functionalized alkanethiols, investigated mechanisms of friction by producing gold-supported monolayers containing varying quantities of various bulky endgroups. They found that the differences in friction were apparently due to differences in the size of the terminal groups, larger terminal groups (whether F-containing or not) giving rise to increasing interactions that provided pathways for energy dissipation, and therefore higher frictional losses.

The issues of the correlation of adhesion and of viscoelastic relaxation with friction are currently being investigated using AFM and LFM. Although friction does not correlate with the adhesion energy between two

surfaces, there is increasing evidence that it is proportional to adhesion *hysteresis* [181]: i.e., the energy dissipated during the making and breaking of an adhesive bond. Marti *et al* [189] have shown that the adhesion hysteresis measured during force-curve measurements (Si_3N_4 tip) on silica and alumina surfaces under electrolytes is proportional to the LFM friction force measurements made under the same conditions. Haugstad *et al* [182] characterized fundamental aspects of friction on polymer surfaces by measuring frictional force on a gelatin film as a function of scanning frequency, i.e. velocity. The friction was found to increase at lower velocities, which can be explained by the onset of rubbery-state-type molecular relaxations, the viscoelastic dissipation correlating with frictional dissipation. Following intensive scanning at a particular site on the gelatin surface, a high-friction ‘signature’ could be observed in subsequent LFM measurements, and was explained by the perturbative effect of the previous frictional measurement. In this case, the LFM images were providing a map of molecular relaxation across the film.

(G) MEASUREMENT OF MECHANICAL PROPERTIES

The technological importance of thin films in such areas as semiconductor devices and sensors has led to a demand for mechanical property information for these systems. Measuring the elastic modulus for thin films is much harder than the corresponding measurement for bulk samples, since the results obtained by traditional indentation methods are strongly perturbed by the properties of the substrate material. Additionally, the behaviour of the film under conditions of low load, which is necessary for the measurement of thin-film properties, is strongly influenced by surface forces [75]. Since the force microscope is both sensitive to surface forces and has extremely high depth resolution, it shows considerable promise as a technique for the mechanical characterization of thin films.

A striking example of the use of the AFM as an indenter is provided by Burnham and Colton [184] (figure B1.19.35), where the differences (at <100 nm indentation) between the plastic behaviour of gold at $20 \mu\text{N}$ load and the elastic behaviour of graphite and elastomer at lower loads are clearly observable. The importance of surface forces in measuring mechanical properties at low load has been demonstrated by Salmeron *et al* [184], who showed that tip-sample adhesion can seriously perturb hardness measurements, not only for clean surfaces, but also for those covered by a layer of contamination. These authors also suggested that initial passivation of the surface (e.g., by sulfidation) might be an effective approach to overcoming these artefacts.

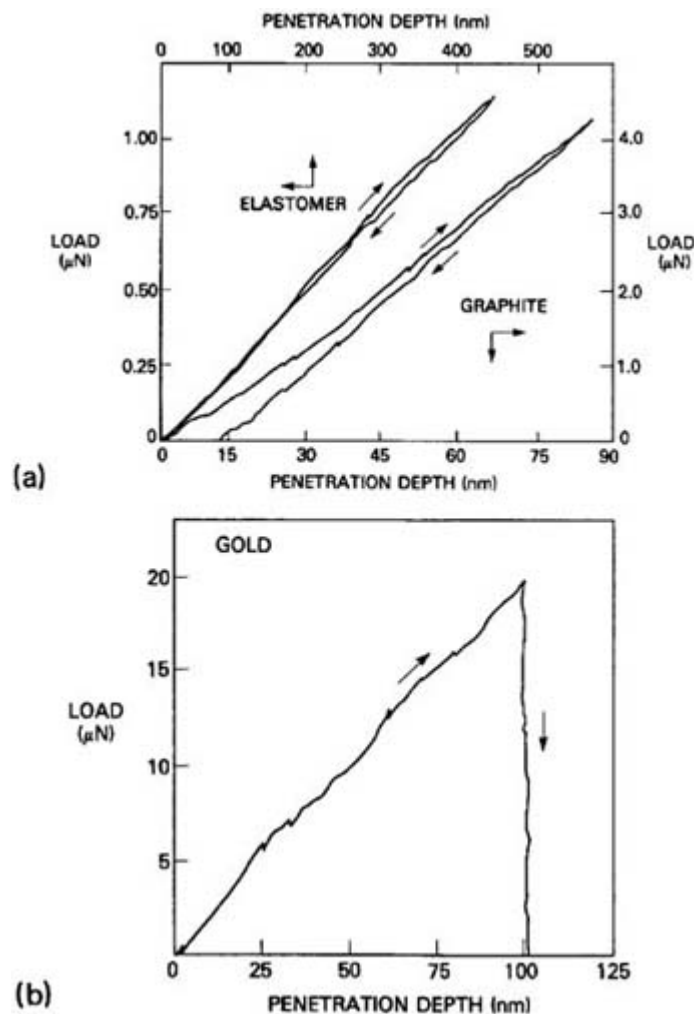

Figure B1.19.35. Experimental nanoindentation curves obtained with the AFM showing the loading and unloading behaviour of (a) an elastomer and highly oriented pyrolytic graphite and (b) a gold foil. (Taken from [183], figure 4.)

(H) CHEMICAL IMAGING

The imaging of surfaces according to chemical species is immensely useful in understanding the mechanisms of many complex technological systems on a fundamental level. Over the past two decades, Auger electron spectroscopy, x-ray photoelectron spectroscopy and secondary ion mass spectroscopy have been extended into surface-sensitive chemical imaging methods [185]; nowadays the use of such techniques for troubleshooting has become virtually routine in the semiconductor industry, and has contributed significantly to our knowledge of catalyst systems, corrosion mechanisms and many other areas. However, these methods are not universally applicable since they are limited in spatial resolution (especially for insulating samples) and require the sample to be analysed in a vacuum. A chemically sensitive scanning force microscopy that could image the distribution of chemical species on an insulating surface with nanometre resolution under ambient conditions, or even under liquids, is therefore a highly desirable goal, and many research groups are active in this area.

A promising approach, still in the early stages of development, involves the functionalization of the AFM tip.

In many cases this has been limited to the demonstration of the sensitivity of force curves to the chemical species present on the surface—a necessary first step for the development of an imaging methodology. Akari *et al* [186] have functionalized a gold-coated tip with COOH-terminated long-chain hydrocarbons, using a self-assembled monolayer procedure; they have shown that the contrast is considerably enhanced over that of the uncoated tip, when imaging a patterned mixed monolayer consisting of CH₃- and COOH-terminated molecules of similar length.

LFM coupled with tip functionalization is a potentially important chemical imaging technique, since the tip functionality can be tailored so as to produce maximum contrast (i.e. maximum difference in frictional coefficient) between different chemical species on the surface. Frisbie *et al* [187] have examined a patterned surface of COOH and CH₃ groups, and have shown that the pattern could be readily imaged by a COOH- or CH₃-coated tip (figure B1.19.36) running in LFM mode, since the imaged frictional coefficients depended on the particular tip–surface species interaction. A potential pitfall with this technique is that both local chemistry and local mechanical properties, due to differences in molecular packing, contribute to the imaging contrast. This problem was elegantly sidestepped by McKendry *et al* who investigated chiral discrimination by chemical force microscopy [188]. In this case the interaction between the tip and surface can be changed without alteration of the mechanical properties or wetting energies of tip or surface. The chemical force microscope proved to be sufficiently sensitive to permit discrimination between enantiomers of simple chiral molecules in a friction image with more quantitative differences being obtained from adhesion force or ‘pull-off’ force histograms.

Figure B1.19.36. Image of the frictional force distribution of a pattern consisting of areas of CH₃-terminated and areas of COOH-terminated molecules attached to gold-coated silicon. The tip was also functionalized in (a) with CH₃ species and in (b) with COOH species. The bright regions correspond to the higher friction force, which in (a) is observed on the CH₃ areas and in (b) on the COOH areas. (Taken from [187], figure 3.)

One potentially powerful approach to chemical imaging of oxides is to capitalize on the tip–surface interactions caused by the surface charge induced under electrolyte solutions [189]. The sign and the amount of the charge induced on, for example, an oxide surface under an aqueous solution is determined by the pH and ionic strength of the solution, as well as by the isoelectric point (IEP) of the sample. At pH values above the IEP, the charge is negative; below this value,

the charge is positive. The same argument applies to a Si₃N₄ tip (normally an oxynitride at the surface), so

that at every pH, either an attractive or a repulsive electrostatic tip–sample force will be superimposed upon the forces that are normally encountered in AFM (figure B1.19.37). By varying the pH and determining the value at which the charges switch sign, the IEP of the sample may be determined. Since this value is characteristic for a particular oxide, and the sample area probed is on the nanometre-squared scale, this appears to be a promising direction for the high-resolution chemical imaging of mixed oxide, oxide-covered alloy [190] or even protein [191] surfaces.

Figure B1.19.37. Normal force versus tip–sample distance curves for a Si_3N_4 tip on a SiO_2 surface under 1 mM NaCl solution at pH 4 and pH 9. (Taken from [189], figure 2.)

Finally, Berger *et al* [192] have developed a technique whereby an array of force curves is obtained over the sample surface (‘force-curve mapping’), enabling a map of the tip–sample adhesion to be obtained. The authors have used this approach to image differently oriented phase domains of Langmuir–Blodgett-deposited lipid films.

B1.19.4 SCANNING NEAR-FIELD OPTICAL MICROSCOPY AND OTHER SPMS

Since the invention of the scanning tunnelling microscope, many other related techniques have been developed that combine the principles of piezo positioning with a feedback system, but rely on a surface interaction other than electron tunnelling or force sensing in order to produce images. The overwhelming majority of these scanning techniques are still in the very early stages of development and, in contrast to STM and AFM, have as yet revealed little that could not be better determined by other methods. Nevertheless, this is an area with tremendous promise, and a selection of these methods is therefore described below.

B1.19.4.1 SCANNING NEAR-FIELD OPTICAL MICROSCOPY

Of the methods described in this section, scanning near-field optical microscopy (SNOM or NSOM) is the closest to being able to provide useful information that is unobtainable by other means. Indeed, this technique has already been made available as a commercial instrument. A detailed review of SNOM has been written by Pohl [193].

While the spatial resolution in classical microscopy is limited to approximately $\lambda/2$, where λ is the optical wavelength (the so-called Abbé Limit [194], $\sim 0.2 \mu\text{m}$ with visible light), SNOM breaks through this barrier by monitoring the *evanescent* waves (of high spatial frequency) which arise following interaction with an

object, rather than the *propagating* waves (of low spatial frequency), which are observed under far-field conditions. While the field intensity of propagating waves decays with the well known inverse-square dependence on distance from the source, evanescent waves decay much more rapidly, with an inverse-fourth power relationship. This means that the evanescent waves are almost completely damped out within a few nanometres of the source, and play no part in far-field (i.e. classical) optical measurements. Synge [195] was the first to discuss the possibility of exceeding the Abbé limit, as long ago as 1928, and suggested that by scanning a nanometre-sized aperture over the surface of the sample, a resolution higher than $\lambda/2$ could be obtained. This is analogous to the use of a stethoscope by a physician, where spatial information can be obtained with a resolution far greater than the acoustical wavelength [196]. This forms the basis of SNOM. In 1972, Ash *et al* [197] were able to show that this principle could indeed be demonstrated for microwave wavelengths (3 cm), but SNOM with visible light was not developed until the 1980s, when the technologies surrounding the STM became available.

The design of the SNOM in the first experiments consisted of a minute aperture, formed by a metallized glass fibre tip, which was rastered across a sample that was illuminated by a laser beam from behind (figure B1.19.38). The tip was maintained at a constant distance from the sample by using the tip-sample tunnelling current in a feedback loop. The resolution obtained was 25 nm ($\lambda/20$) [196, 198]. Subsequent variations to the experimental set-up have included the use of force interactions to maintain tip-sample separation [199] (enabling the imaging of insulators), as well as operation in transmission mode [200]. Recent applications have included the detection and spectroscopy of single molecules [201], where spectral differences corresponding to the different chemical environments of individual molecules can be discerned, and the orientation of each molecular dipole determined. In general, the combination of high lateral resolution in the optical near-field and spectroscopic information has been restricted to fluorescence and luminescence experiments. Recently, vibrational spectroscopy in the optical near-field has also been attempted [202, 203, 204 and 205] with surface-enhanced Raman scattering in particular, appearing to be a promising method for obtaining spectral, spatial and chemical information of molecular adsorbates with subwavelength lateral resolution. This has been implemented in illumination mode, where the incident light emerges from the fibre probe, to obtain surface-enhanced Raman spectra from single Ag colloid nanoparticles [206]. Raman chemical imaging on a scale of 100 nm has also been demonstrated by Deckert *et al* on dye-labelled DNA. On the nanometre scale a strong dependence of the enhanced Raman signal on substrate morphology is expected. It is therefore particularly useful to correlate near-field Raman spectra with topographic information on a nanoscale, as in the experiment of Zeisel *et al* [207] who investigate the near-field surface-enhanced Raman spectroscopy of dye molecules adsorbed on silver island films.

Figure B1.19.38. Schematic of a scanning near-field optical microscope (SNOM). (Taken from [196], figure 2.)

B1.19.4.2 SCANNING NEAR-FIELD ACOUSTIC MICROSCOPY (SNAM)

This corresponds to the physician's stethoscope case mentioned above, and has been realized [208] by bringing one leg of a resonating 33 kHz quartz tuning fork close to the surface of a sample, which is being rastered in the x - y plane. As the fork-leg nears the sample, the fork's resonant frequency and therefore its amplitude is changed by interaction with the surface. Since the behaviour of the system appears to be dependent on the gas pressure, it may be assumed that the coupling is due to hydrodynamic interactions within the fork-air-sample gap. Since the fork tip-sample distance is approximately $200\ \mu\text{m}$ ($\sim\lambda/20$), the technique is sensitive to the near-field component of the scattered acoustic signal. $1\ \mu\text{m}$ lateral and $10\ \text{nm}$ vertical resolutions have been obtained by the SNAM.

B1.19.4.3 SCANNING THERMAL PROFILER (STP)

This technique involves the scanning of a heated thermocouple tip above the surface of the sample (figure B1.19.39). Since the heat loss from the tip is highly dependent on the tip-sample spacing, the temperature of the tip can be used as a control parameter to monitor sample morphology and/or thermal properties [209]. The lateral resolution obtained with this method is of the order of $0.1\ \mu\text{m}$, with a vertical resolution of about $3\ \text{nm}$. The temperature sensitivity of the tip is $\sim 0.1\ \text{mK}$. An advantage of the technique is that morphology can be imaged at distances approximately equal to the desired lateral resolution.

Figure B1.19.39. Schematic of the thermocouple probe in a scanning thermal profiler. The probe is supported on a piezoelectric element for modulation of tip–sample distance at frequency ω_1 and to provide positioning. The AC thermal signal at ω_1 is detected, rectified, and sent to the feedback loop, which supplies a voltage to the piezostack to maintain the average tip–sample spacing constant. (Taken from [209], figure 1.)

An extension of this technique, known as scanning thermal microscopy [210] (S_{Th}M) combines the thermal profiling technique with modulated-temperature differential scanning calorimetry, by applying a sinusoidal modulation to the tip temperature. Using this technique, the spatial distribution of thermal properties of materials (such as conductivity and diffusivity) can be monitored, and subsurface features imaged (since the penetration depth of the evanescent temperature wave is frequency-dependent). Additionally, local calorimetric analysis can be used to probe thermally activated near-surface processes, such as glass transitions, melting, crystallization or cure reactions. The technique has been used to great effect with polymer blends, where imaging contrast is caused by differences in the thermal properties of the individual components.

B1.19.4.4 SCANNING ION CONDUCTANCE MICROSCOPY (SICM)

This method relies on the simple principle that the flow of ions into an electrolyte-filled micropipette as it nears a surface is dependent on the distance between the sample and the mouth of the pipette [211] (figure B1.19.40). The probe height can then be used to maintain a constant current flow (of ions) into the micropipette, and the technique functions as a non-contact imaging method. Alternatively, the height can be held constant and the measured ion current used to generate the image. This latter approach has, for example, been used to probe ion flows through channels in membranes. The lateral resolution obtainable by this method depends on the diameter of the micropipette. Values of 200 nm have been reported.

Figure B1.19.40. The scanning ion-conductance microscope (SICM) scans a micropipette over the contours of a surface, keeping the electrical conductance through the tip of the micropipette constant by adjusting the vertical height of the probe. (Taken from [211], figure 1.)

B1.19.4.5 SCANNING MICROPIPETTE MOLECULE MICROSCOPY (SMMM)

The apparatus involved in this method is related to that of SICM, except that the micropipette is blocked by a permeable polymer plug, and connected to the inlet of a differentially pumped quadrupole mass spectrometer [212] (figure B1.19.38). Unlike most other scanning techniques, SMMM relies on a light microscope for positioning. Nevertheless, it is a unique spatially resolved sampling method for desorbing surface species under solution, and has numerous potential applications in biology and medicine. The diffusion of water through pores in a polymer membrane has been followed by using the set-up in figure B1.19.41 where diffusing HDO is converted to HD (with the unambiguous mass of 3 amu) prior to mass spectrometric detection by means of a uranium reduction furnace.

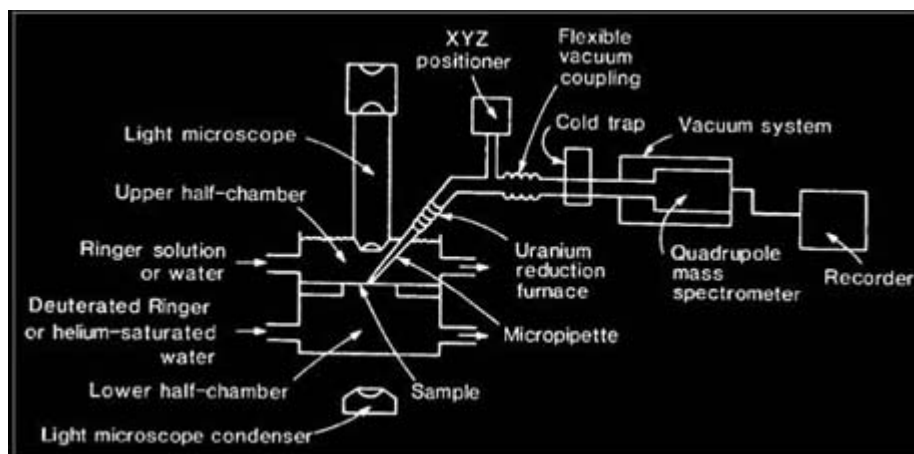

Figure B1.19.41. Schematic of the scanning micropipette molecule microscope. (Taken from [212], figure 1.)

STM and its many related methods have opened new windows onto the nanometre-scale world. Within a short period of time, SPMs have become common fixtures, not only in surface science laboratories, but also in research groups working in areas as diverse as ceramics, polymers, cell biology, robotics, catalysis, and tribology. Clearly this trend will continue, as the concept of the proximal probe becomes combined with more and more of the macroscale analytical tools that we know today. It is also clear that the nanoscale chemical analysis of surfaces by means of SPM will become increasingly viable, with biological surfaces providing some of the most challenging and potentially fruitful analytical problems. Other suggested applications of SPMs are as high-density information storage systems, as selective molecular manipulators and as aids in microsurgery. With the field barely into its second decade, the technological and scientific possibilities of the SPM approach are immense.

B1.20 The surface forces apparatus

Manfred Heuberger

B1.20.1 INTRODUCTION

Compared with other direct force measurement techniques, a unique aspect of the surface forces apparatus (SFA) is to allow *quantitative measurement of surface forces and intermolecular potentials*. This is made possible by essentially three measures: (i) well defined contact geometry, (ii) high-resolution interferometric distance measurement and (iii) precise mechanics to control the separation between the surfaces.

It is remarkable that the roots of the SFA go back to the early 1960s [1]. Tabor and Winterton [2] and Israelachvili and Tabor [3] developed it to the current state of the art some 15 years before the invention of the more widely used atomic force microscope (AFM) (see [chapter B1.19](#)).

Although only a few dozen laboratories worldwide are actively practising the SFA technique, it has produced many notable findings and a fundamental understanding of surface forces [4]. These are applicable to various research fields such as polymer science [5, 6, 7, 8, 9 and 10], thin-film rheology [11, 12, 13 and 14], biology [15, 16, 17 and 19], liquid crystals [20, 21 and 22], food sciences [12, 23, 24], molecular tribology [9, 14, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34 and 35] and automotive tribology [36]—to name just a few. Numerous experimental extensions of the SFA technique have been developed to take advantage of the unique experimental set-up.

One of the most important extensions is the measurement of lateral forces (friction). Friction measurements have accompanied the SFA technique since its early beginnings in the Cavendish laboratory in Cambridge [37] and a variety of different lateral force measurements are practised throughout the SFA community.

B1.20.2 PRINCIPLES

B1.20.2.1 DIRECT FORCE MEASUREMENT

The measurement of surface forces calls for a rigid apparatus that exhibits a high force sensitivity as well as distance measurement and control on a subnanometre scale [38]. Most SFAs make use of an optical interference technique to measure distances and hence forces between surfaces. Alternative distance measurements have been developed in recent years—predominantly capacitive techniques, which allow for faster and simpler acquisition of an *averaged* distance [11, 39, 40] or even allow for simultaneous dielectric loss measurements at a confined interface.

The predominant method of measuring forces is to detect the proportional deflection of an elastic spring. The proportionality factor is commonly called the *spring constant* and, in the SFA, may range from some 10 N m^{-1} to some 100 kN m^{-1} . It is essential that the apparatus frame and surface compliance be at least 1000 times stiffer than the force-measuring spring. In a typical SFA, one of the two surfaces is attached to the force-measuring spring, while the other surface is rigidly mounted to the apparatus frame. In this set-up, shown

schematically in figure B1.20.1 a set of at least three parameters must be controlled or measured simultaneously for a direct force measurement.

Figure B1.20.1. Direct force measurement via deflection of an elastic spring—essential design features of a direct force measurement apparatus.

The accurate and absolute measurement of the distance, D , between the surfaces is central to the SFA technique. In a typical experiment, the SFA controls the base position, z_3 , of the spring and simultaneously measures D , while the *spring constant*, k , is a known quantity. Ideally, the simple relationship $\Delta F(D) = k\Delta(D - z_3)$ applies. Since surface forces are of limited range, one can set $F(D = \infty) = 0$ to obtain an absolute scale for the force. Furthermore, $\delta F(D = \infty)/\delta D \approx 0$ so that one can readily obtain a calibration of the distance control at large distances relying on an accurate measurement of D . Therefore, D and F are obtained at high accuracy to yield $F(D)$, the so-called *force versus distance curve*.

Most interferometric SFAs allow one to measure the distance, D , as a function of a selected lateral dimension, x' , which can be used to obtain information about the entire contact geometry. Knowledge of the contact geometry, together with the assumption that the underlying intermolecular forces are additive, allows the *intermolecular potential* $W(D)$ to be deduced from the measured $F(D)$ using the so-called *Derjaguin approximation* [4, 41]. For the idealized geometry of an undeformed sphere of radius R on a flat:

$$(B1.20.1)$$

where R becomes an effective radius $R' = (R, R_2)^{0.5}$ for the case of two cylinders (SFA) with radii R_1 and R_2 .

-3-

In accordance with [equation \(B1.20.1\)](#), one can plot the so-called *surface force parameter*, $P = F(D) / 2\pi R$, versus D . This allows comparison of different direct force measurements in terms of intermolecular potentials $W(D)$, i.e. independent of a particular contact geometry. Figure B1.20.2 shows an example of the attractive van der Waals force measured between two curved mica surfaces of radius $R \approx 10$ mm.

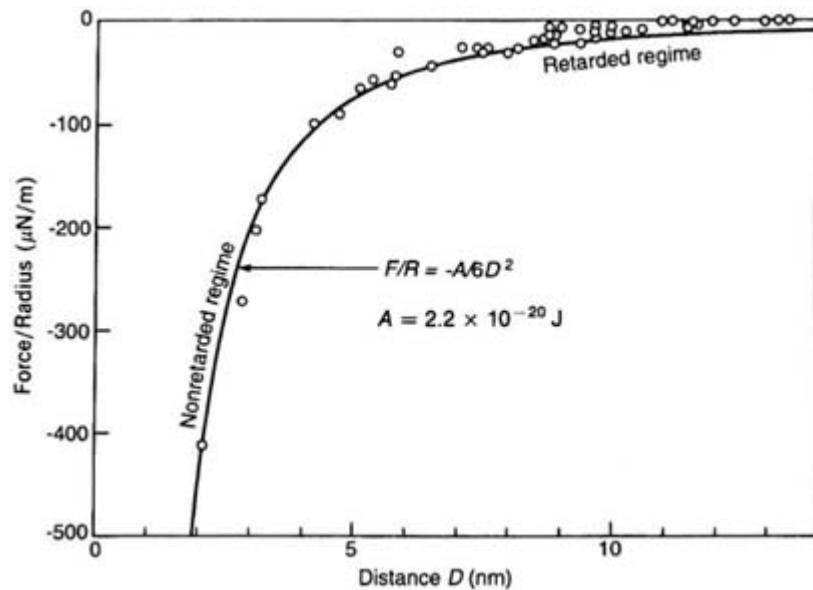

Figure B1.20.2. Attractive van der Waals potential between two curved mica surfaces measured with the SFA. (Reproduced with permission from [4], figure 11.6.)

An alternative way of measuring $F(D)$ is to control forces using magnetic fields instead of controlling

distances [42, 43]. An electronically controlled current through one or more coils creates a magnetic gradient, which exerts a force on the force-measuring spring. The surfaces are allowed to equilibrate at a distance, D , which is then measured. This alternative set-up allows one to measure $D(F)$ instead of $F(D)$ allowing for a true equilibrium force measurement.

B1.20.2.2 SAMPLE PREPARATION

Well defined contact geometry and absolute cleanliness are crucial factors for a successful SFA experiment. Therefore, two curved sheets of mica are brought into contact in crossed-cylinder geometry.

The sample preparation of these mica sheets is a delicate process that requires some experience and often takes 1–2 days prior to an SFA experiment. Through successive cleaving, one has to prepare 1–5 μm thick and uniform sheets of mica. Mica is a natural material that is available in different qualities [44].

Each newly cleaved mica surface is very clean. However, it is known that mica has a strong tendency to spontaneously adsorb particles [45] or organic contaminants [46], which may affect subsequent measurements. The mica sheets are cut into 10 mm \times 10 mm sized samples using a hot platinum wire, then laid down onto a thick and clean 100 mm \times 100 mm mica *backing sheet* for protection. On the backing sheet, the mica samples can be transferred into a vacuum chamber for thermal evaporation of typically 50–55 nm thick silver mirrors.

-4-

It was the idea of Winterton [2] to glue the otherwise fragile mica sheets onto polished *silica discs* to give them better mechanical stability, especially for friction experiments. The glue layer determines the final surface compliance of the silica/glue/mica stack which is typically around 4×10^{10} Pa. The use of mica samples from the same original sheet guarantees that the interferometer will be perfectly symmetrical (see section (b1.20.2.3)).

The silica discs that now hold the back-silvered mica samples are finally mounted into the SFA so that the cylinder axes are crossed and the clean mica surfaces are facing each other.

B1.20.2.3 MULTIPLE BEAM INTERFEROMETRY

The absolute measurement of the distance, D , between the surfaces is central to the SFA technique. In *interferometric* SFAs, it is realized through an optical method called multiple beam interferometry (MBI), which has been described by Tolansky [47].

A 50 nm film of metal (silver) is deposited onto the atomically smooth mica sheets. White light with a coherence length of some 10 μm is directed normally through the mica sheets to illuminate the contact zone. The mica–silver interfaces have a reflectivity of typically 97% and form an optical resonator. A constructive interference occurs for light that has a wavelength equal to half the optical distance between the mirrors. This resonance is called *interference fringe of chromatic order* $N = 1$. The larger the optical distance, the more this resonance shifts towards the red end of the spectrum. In analogy to an organ pipe, one also observes harmonic fringes at higher frequencies which are identified with integer numbers $N = 2, 3, \dots$. The emerging light from the silver/mica/mica/silver interferometer is focused onto the slit of an imaging spectrograph for further analysis. The light selected to enter the spectrograph entrance slit corresponds to a one-dimensional cut through the illuminated contact zone. The distance information along this (linear) dimension is maintained and the exit plane of the imaging spectrograph displays the interference pattern as a function of a position x' . Typically, one uses fringes in the visible spectrum ($15 < N < 35$) for distance measurements in the SFA, but other near-visible wavelengths can equally be employed. Generally, the distance resolution of MBI decreases linearly with increasing N and longer wavelengths used.

Because the mica surfaces are curved, the optical distance between the mirrors is a function of the lateral dimension, x' , i.e. $T = T(x')$. Therefore, the wavelength of a given fringe becomes itself a function of x' . Since the chromatic order, N , is invariant within a given fringe, these fringes are commonly called fringes of equal chromatic order (FECO) (see [figure B1.20.3.](#))

-5-

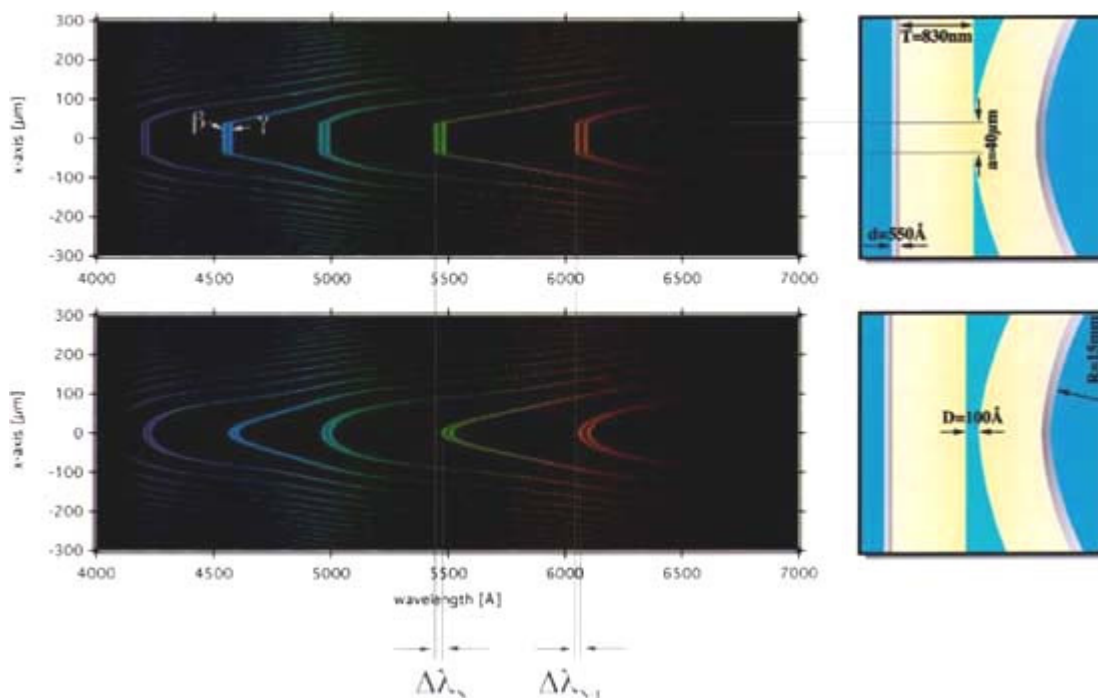

Figure B1.20.3. FECO allow optical distances in the SFA to be measured at subnanometre resolution. The FECOs depicted here belong to a symmetric, three-layer interferometer. The elastically deformed contact region appears as flattened fringes in the upper graph (vertical part). Once the surfaces are separated to a distance D in a medium of index n , the wavelength shifts are measured to calculate D and n . Since mica is birefringent, one can observe β and γ components for each fringe. To simplify data evaluation, birefringence can be suppressed using polarizing filters after the interferometer.

The problem of calculating surface separations from a given FECO pattern is in general far more complex than it may seem at first sight. The main reason is the fact that the refractive index is different for each of the different layers in the interferometer. For the simplest case of two mica surfaces in contact, surrounded by a medium, one has to solve for a one-layer interferometer inside the contact area and for a three-layer interferometer outside the contact area—that is where light travels partially through the medium. The analytical treatment of a three-layer interferometer is considerably simplified if the two mica sheets have exactly the same thickness, i.e. when the interferometer is *symmetric*. Based on the work of Hunter *et al* [48], Israelachvili [49] has derived the first useful analytical expressions and methodology for the symmetrical three-layer interferometer in the SFA. Clarkson [50] extended MBI with a numerical analysis of asymmetric three-layer interferometers by applying the multilayer matrix method [51]. Later, Horn *et al* [52] derived useful analytical expressions for the asymmetric interferometer.

Nonetheless, the symmetric interferometer remains very useful, because there, the wavelengths of fringes with *even* chromatic order, N , strongly depend on the refractive index, n_3 , of the central layer, whereas fringes with *odd* chromatic order are almost insensitive to n_3 . This lucky combination allows one to measure the thickness as well as the refractive index of a layer between the mica surfaces independently and simultaneously [49].

To simplify FECO evaluation, it is common practice to experimentally filter out one of the components by the use of a linear polarizer after the interferometer. Mica birefringence can, however, be useful to study thin films of birefringent molecules [49] between the surfaces. Rabinowitz [53] has presented an eigenvalue analysis of birefringence in the multiple beam interferometer.

Partial reflections at the inner optical interfaces of the interferometer lead to so-called *secondary* and *tertiary* fringe patterns as can be seen from figure B1.20.4. These additional FECO patterns become clearly visible if the reflectivity of the silver mirrors is reduced. Methods for analysis of such secondary and tertiary FECO patterns were developed to extract information about the topography of non-uniform substrates [54].

Figure B1.20.4. Cross-sectional sideview of a symmetric, three-layer interferometer illustrating the origin of primary, secondary, tertiary and gap FECOs. (Reproduced with permission from [54].)

In the *symmetric*, three-layer interferometer, only even-order fringes are sensitive to refractive index and it is possible to obtain spectral information of the confined film by comparison of the different intensities of odd- and even-order fringes. The absorption spectrum of thin dye layers between mica was investigated by Müller and Mächtle [55, 56] using this method.

Instead of an absorbing dye layer between the mica, Levins *et al* [57] used thin metallic films and developed a method for FECO analysis using an extended spectral range.

The preparation of the reflecting silver layers for MBI deserves special attention, since it affects the optical properties of the mirrors. Another important issue is the optical phase change [58] at the mica/silver interface, which is responsible for a wavelength-dependent shift of all FECOs. The phase change is a function of silver layer thickness, T , especially for $T < 40$ nm [54]. The roughness of the silver layers can also have an effect on the resolution of the distance measurement [59, 60].

Another interesting extension of the FECO technique, using a capillary droplet of mercury as the second mirror, was developed by Horn *et al* [61]. The light from this special interferometer is analysed in reflection,

which yields an inverted FECO pattern.

Every property of an interface that can be optically probed can, in principle, be measured with the SFA. This may include information obtainable from absorption spectroscopy [55], fluorescence, dichroism, birefringence, or nonlinear optics [43], some of which have already been realized.

B1.20.2.4 COMMON DESIGNS AND ATTACHMENTS

Israelachvili and Adams [62] designed one of the first SFAs, known as the Mk I, in the mid-1970s. Later, Israelachvili developed the Mk II [63, 64], which is based on the Mk I but has improved mechanics—in particular, a double cantilever spring to avoid surface tilt upon deflection (force), as well as a number of new attachments for a variety of different experimental set-ups. The Mk I and Mk II designs served as basis for further versions. More recent and improved versions include the Mk III developed by Israelachvili [65], as well as the circular steel Mk IV developed by Parker *et al* [66] and the circular glass SFA designed by Klein [67]. Some of the most common designs are schematically reproduced in [figure B1.20.5](#).

Figure B1.20.5. A selection of common SFA designs: SFA Mk I [62], SFA Mk II [64], SFA Mk III [65], SFA Mk IV [66], capacitive SFA [11], fibre-optic SFA [43]. Figures reproduced with permission from indicated references.

A considerable number of experimental extensions have been developed in recent years. Luckham *et al* [5] and Dan [68] review examples of dynamic measurements in the SFA. Studying the visco-elastic response of surfactant films [69] or adsorbed polymers [7, 9] promises to yield new insights into molecular mechanisms of frictional energy loss in boundary-lubricated systems [28, 70].

The measurement of lateral forces (friction and shear) in the SFA has recently been reviewed by Kumacheva

[32]. To measure friction and shear response, one has to laterally drive one surface and simultaneously measure the response of a lateral spring mount. A variety of versions have been devised. Lateral drives are often based on piezoelectric or bimorph deflection [13, 71] or DC motor drives, whereas the response can be measured via strain gauges, bimorphs, capacitive or optical detection.

Another promising extension uses x-rays to probe the structure of confined molecules [72].

In summary, the SFA is a versatile instrument that represents a unique platform for many present and future implementations. Unlike any other experimental technique, the SFA yields quantitative insight into molecular dimensions, structures and dynamics under confinement.

B1.20.3 APPLICATIONS

This section deals with some selected examples of typical SFA results, collected from various research areas. It is not meant to be a comprehensive review, rather a brief glance at the kind of questions that can be addressed with the SFA.

The earliest SFA experiments consisted of bringing the two mica sheets into contact in a controlled atmosphere (figure B1.20.6) or (confined) liquid medium [14, 27, 73, 74 and 75]. Later, a variety of surfactant layers [76, 77], polymer surfaces [5, 9, 10, 13, 68, 78], polyelectrolytes [79], novel materials [80] or biologically relevant molecular layers [15, 19, 81, 85 and 86] or model membranes [84, 87, 88] were prepared on the mica substrate. More recently, the SFA technique has also been extended to thick layers of other materials, such as silica [73, 89], polymer [10], as well as metals [59] and metal oxides [90, 91].

-10-

Figure B1.20.6. Short-range adhesion of a mica–mica contact as a function of the relative crystallographic orientation of the mica surfaces, measured in a dry nitrogen atmosphere. With permission from [94].

B1.20.3.1 MEASURING SHORT-RANGE SOLVATION AND HYDRATION FORCES

The measurement of surface forces out-of-plane (normal to the surfaces) represents a central field of use of the SFA technique. Besides the ubiquitous van der Waals dispersion interaction between two (mica) surfaces

in dry air ([figure B1.20.2](#)) and [figure B1.20.6](#), there is a wealth of other surface forces arising when the surfaces are brought into contact in a liquid medium. Many of these forces result from the specific properties of the liquid medium and originate from a characteristic ordering or reorientation of atoms or molecules—processes which are often entropy driven.

The well defined contact geometry and the ionic structure of the mica surface favours observation of *structural* and *solvation forces*. Besides a monotonic entropic repulsion one may observe superimposed periodic force modulations. It is commonly believed that these modulations are due to a metastable layering at surface separations below some 3–10 molecular diameters. These diffuse layers are very difficult to observe with other techniques [92]. The periodicity of these *oscillatory forces* is regularly found to correspond to the characteristic molecular diameter. [Figure B1.20.7](#) shows a typical measurement of solvation forces in the case of ethanol between mica.

Figure B1.20.7. The solvation force of ethanol between mica surface. The inset shows the full scale of the experimental data. With permission from [75].

In the case of water, these forces are called *hydration forces* [93, 94]. The behaviour of water close to surfaces has attracted considerable attention due to its importance in the understanding of colloidal and biological interactions. Water seems to be a molecule of remarkable intermolecular interactions [95], mainly due to its capability to form hydrogen bonds. A number of aspects of water have been vigorously debated using results obtained with the SFA technique. These include the apparent viscosity in ultra-thin confined films [73] or the structure of water near surfaces, which is believed to give rise to *hydrophilic repulsion* or *hydrophobic attraction* [96, 97], or, indeed, the very origin of hydration forces and oscillatory forces [93].

B1.20.3.2 MEASURING LONG-RANGE DLVO-TYPE INTERACTIONS

In a given aqueous electrolyte there is a certain population of hydrated ions and counterions. In addition, many surfaces, including mica, exhibit a net charge in aqueous solution. Counterions are known to form a diffuse screening layer near a charged molecule, particle or surface with roughly exponentially decreasing concentration into the solution. The characteristic decay length of this *double layer* is called the *Debye length* and decreases with increasing ionic strength. This double layer gives rise to an entropically driven,

exponentially decreasing surface force, the so-called *double-layer repulsion*. Before the discovery of short-range forces (see above), it was commonly accepted that surface forces in liquid media could always be decomposed into an attractive dispersion component (van der Waals) and a repulsive double-layer force. These two forces are combined in the well known Derjaguin–Landau, Verwey–Overbeck (DLVO) theory and a number of systems have been measured in the SFA to confirm the predictions of this theory. Figure B1.20.8 shows results obtained in aqueous solutions of NaCl on silica surfaces. The ranges of the observed long-range repulsion forces are in good agreement with the DLVO theory. The inset nicely demonstrates the effect of the monotonic short-range forces described in [section \(b1.20.3.1\)](#). As a contrast to the results obtained on silica surfaces, [figure B1.20.9](#) schematically displays the measured DLVO-type forces between mica surfaces in aqueous electrolytes. The main differences are that the monotonic hydration (solvation) force is dependent on the salt concentration and that there are oscillatory forces superimposed. On the mica surface, the monotonic hydration force hence seems to be mainly the result of the presence of hydrated ions in the double-layer, whereas the silica surface is strongly hydrophilic and hence ‘intrinsically’ hydrated [94].

Figure B1.20.8. DLVO-type forces measured between two silica glass surfaces in aqueous solutions of NaCl at various concentrations. The inset shows the same data in the short-range regime up to $D = 10$ nm. The repulsive deviation at short range (< 2 nm) is due to a monotonic solvation force, which seems not to depend on the salt concentration. Oscillatory surface forces are not observed. With permission from [73].

Figure B1.20.9. Schematic representation of DLVO-type forces measured between two mica surfaces in aqueous solutions of KNO_3 or KCl at various concentrations. The inset reveals the existence of oscillatory and monotonic structural forces, of which the latter clearly depend on the salt concentration. Reproduced with permission from [94].

B1.20.3.3 MEASURING BIOLOGICAL INTERACTIONS

Interactions between macromolecules (proteins, lipids, DNA, . . .) or biological structures (e.g. membranes) are considerably more complex than the interactions described in the two preceding paragraphs. The sum of all biological interactions at the molecular level is the basis of the complex mechanisms of *life*. In addition to computer simulations, direct force measurements [98], especially the surface forces apparatus, represent an invaluable tool to help understand the molecular interactions in biological systems.

Proteins can be physisorbed or covalently attached to mica. Another method is to immobilise and orient them by specific binding to receptor-functionalized planar lipid bilayers supported on the mica sheets [15]. These surfaces are then brought into contact in an aqueous electrolyte solution, while the pH and the ionic strength are varied. Corresponding variations in the force-versus-distance curve allow conclusions about protein conformation and interaction to be drawn [99]. The local electrostatic potential of protein-covered surfaces can hence be determined with an accuracy of ± 5 mV.

A typical force curve showing the specific avidin–biotin interaction is depicted in figure B1.20.10. The SFA revealed the strong influence of hydration forces and membrane undulation forces on the specific binding of proteins to membrane-bound receptors [81].

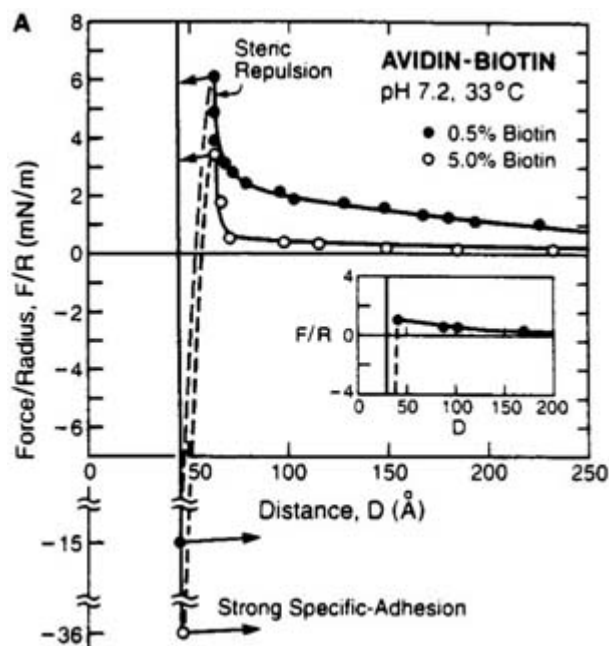

Figure B1.20.10. Typical force curve for a streptavidin surface interacting with a biotin surface in an aqueous electrolyte of controlled pH. This result demonstrates the power of specific protein interactions. Reproduced with permission from [81].

Direct measurement of the interaction potential between tethered ligand (biotin) and receptor (streptavidin) have been reported by Wong *et al* [16] and demonstrate the possibility of controlling range and dynamics of specific biologic interactions *via* a flexible PEG-tether.

The adhesion and fusion mechanisms between bilayers have also been studied with the SFA [88, 100]. Kuhl *et al* [17] found that solutions of short-chained polymers (PEG) could produce a short-range depletion attraction between lipid bilayers, which clearly depends on the polymer concentration (figure B1.20.11). This *depletion attraction* was found to induce a membrane fusion within 10 minutes that was observed, in real-time, using FECO fringes. There has been considerable progress in the preparation of fluid membranes to mimic natural conditions in the SFA [87], which promises even more exciting discoveries in biologically relevant areas.

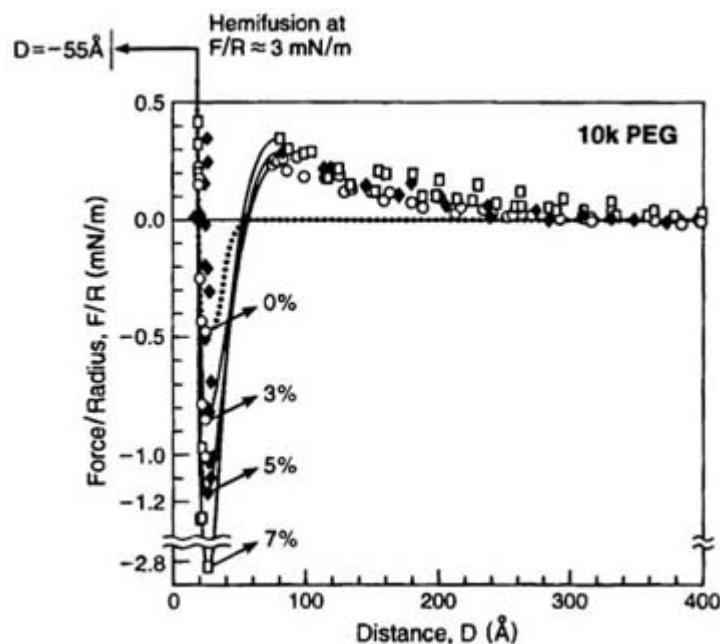

Figure B1.20.11. Force curves of DMPC/DPPE (dimyristoyl phosphatidylcholine and dipalmitoyl phosphatidylethanolamine) bilayers across a solution of PEG at different concentrations. Clearly visible is a concentration-dependent depletion attraction, with permission from [17].

B1.20.3.4 MEASUREMENTS IN MOLECULAR TRIBOLOGY

Using friction attachments (see section (b1.20.2.4)), many remarkable discoveries related to thin-film and boundary lubrication have been made with the SFA. The dynamic aspect of confined molecules at a sliding interface has been extensively investigated and the SFA had laid the foundation for *molecular tribology* long before the AFM technique was available.

The often-cited Amontons' law [101, 102] describes friction in terms of a friction coefficient, which is, *a priori*, a material constant, independent of contact area or dynamic parameters, such as sliding velocity, temperature or load. We know today that all of these parameters can have a significant influence on the magnitude of the measured friction force, especially in thin-film and boundary-lubricated systems.

Using the SFA technique, it could be demonstrated that there is an intimate relationship between adhesion hysteresis and friction [28, 29, 68, 77]. Both processes dissipate energy through non-equilibrium mechanisms at the interface [30]. Friction can be represented as a sum of two terms, one adhesion related and the other load-related. It was recently shown with the SFA that, in the absence of adhesion, the load related portion linearly depends on the load and not necessarily on the *real contact area*, as commonly believed [25]. [Figure B1.20.12](#) nicely illustrates this finding.

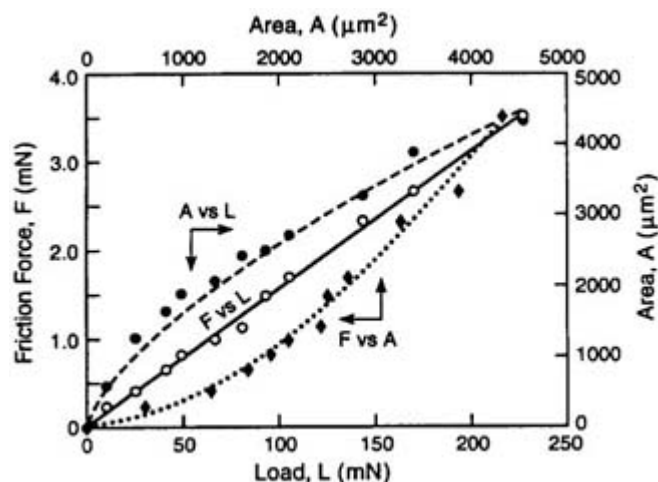

Figure B1.20.12. Measured friction force, F , and real contact area, A , against externally applied load, L , for two molecularly smooth mica surfaces sliding in 0.5 M KCl solution, i.e. in the absence of adhesion, with permission from [25].

A traditional subject of discussion is the phenomenon of intermittent friction, also called *stick – slip* friction [35]. It is thought that interfacial molecules can switch between different dynamic states, namely between a solid-like and a liquid-like state [103]. It was also found that liquids become oriented [7] and solid-like, when confined in a narrow gap. A diffuse layering of the trapped molecules may occur (see also section (B1.20.3.1)). The ordering mechanisms are particularly susceptible to the shape of the molecules and can spur substantial history and time effects, as illustrated in figure B1.20.13. Molecules in such ordered arrangements no longer behave as liquids and exhibit, for example, a finite yield stress [8]. When sliding above a critical speed, however, intermittent friction often disappears and the interface remains liquid-like at all times. This dynamic phenomenon, which occurs in the absence of hydrodynamic lubrication, is due to a time effect at the molecular level. Furthermore, on molecular layers of surfactants it was observed that, at even higher speeds, the system can enter a *superkinetic* regime with vanishingly small friction forces [70], as depicted in figure B1.20.14. In this high-speed regime, mechanisms of molecular entanglement are too slow to dissipate energy. New findings point out a more complex behaviour of such systems in terms of multiple relaxation mechanisms at the molecular interface [77]. It has also been shown experimentally [28] and by molecular dynamics simulation [104] that there is a potential to control interfacial dynamics with subnanometre out-of-plane excitations to achieve ultralow friction at arbitrarily slow sliding velocities.

Figure B1.20.13. Temporal development of intermittent friction following commencement of sliding. The shape of the molecules has a great influence on history and time effects in the system. Reproduced with permission from [34].

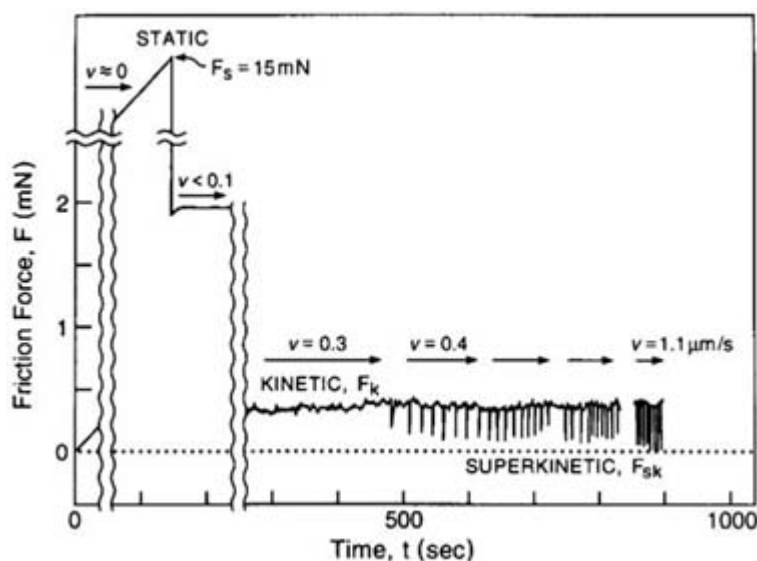

Figure B1.20.14. Dynamic friction at different velocities of DHDAA-coated mica (DHDAA = dihexadecyldimethylammonium acetate). Reproduced with permission from [70].

Polymer-bearing surfaces have also attracted considerable attention in view of their particular friction properties and underlying mechanisms. Klein *et al* [9] have demonstrated the possibility of achieving ultra-low friction on surfaces covered with polymer brushes. Figure B1.20.15 displays the strong lubricating effect, which is due to a very fluid layer at the interface between polymer and solvent—a layer that remains fluid even under high compression. Accompanying molecular dynamics simulations [105] suggest that a dynamic disentanglement of the polymer chains is responsible for the observed reduction in friction.

Figure B1.20.15. Shear force as a function of time for (a) bare mica in toluene and (b) polystyrene-covered mica in toluene. Reproduced with permission from [9].

B1.21 Surface structural determination: diffraction methods

Michel A Van Hove

B1.21.1 INTRODUCTION

Diffraction methods have provided the large majority of solved atomic-scale structures for both the bulk materials and their surfaces, mainly in the crystalline state. Crystallography by diffraction tends to filter out defects and focus on the periodic part of a structure. By adding contributions from very many unit cells, diffraction gives results that are, in effect, averaged over space and time. This is excellent for investigating stable states of solid matter as they occur in well crystallized samples; some forms of disorder can also be analysed reasonably well. Diffraction, however, is much less appropriate for examining inhomogeneous and time-dependent events such as transition states and pathways in chemical reactions.

For bulk structural determination (see [chapter B1.9](#)), the main technique used has been x-ray diffraction (XRD). Several other techniques are also available for more specialized applications, including: electron diffraction (ED) for thin film structures and gas-phase molecules; neutron diffraction (ND) and nuclear magnetic resonance (NMR) for magnetic studies (see [chapter B1.12](#) and [chapter B1.13](#)); x-ray absorption fine structure (XAFS) for local structures in small or unstable samples and other spectroscopies to examine local structures in molecules. Electron microscopy also plays an important role, primarily through imaging (see [chapter B1.17](#)).

At surfaces, the primary challenge is to obtain the desired surface sensitivity. Ideally, one wishes to gain structural information about those atomic layers which differ in their properties from the underlying bulk material. This means in practice extracting the structure of the first few monolayers, i.e. atoms within about 5–10 Å (0.5–1 nm) of the vacuum above the surface. The above-mentioned bulk methods, if applied unchanged, do not easily provide sensitivity to this very thin slice of matter. The challenge becomes even greater when dealing with an interface between two materials, including solid/liquid and solid/gas interfaces. A number of mechanisms are available to obtain surface sensitivity on the required depth scale. We shall describe some of them in the next section, with emphasis on the solid/vacuum interface.

However, it is necessary to first discuss the meaning of ‘diffraction’, because this concept can be interpreted in several ways. After these fundamental aspects are dealt with, we will take a statistical and historical view of the field. It will be seen that many different diffraction methods are available for surface structural determination.

It will also be useful to introduce concepts of two-dimensional ordering and the corresponding nomenclature used to characterize specific structures. We can then describe how the surface diffraction pattern relates to the ordering and, thus, provides important two-dimensional structural information.

We will, in the latter part of this discussion, focus only on those few methods that have been the most productive, with low-energy electron diffraction (LEED) receiving the most attention. Indeed, LEED has been the most successful surface structural method in two quite distinct ways. First, LEED has become an almost universal characterization

technique for single-crystal surfaces: the diffraction pattern is easily imaged in real time and is very helpful in monitoring the state of the surface in terms of the ordering and, hence, also density, of adsorbed atoms and molecules. Second, LEED has been quite successful in determining the detailed atomic positions at a surface (e.g., interlayer distances, bond lengths and bond angles), especially for ordered structures. This relies primarily on simulating the intensity (current) of diffracted beams as a function of electron energy in order to fit assumed model structures to measured data. Because of multiple scattering, such simulation and fitting is a very different and much more difficult task than looking at a diffraction pattern. We will close with a

description of the state of the art and an outlook on the future of the field.

B1.21.2 FUNDAMENTALS OF SURFACE DIFFRACTION METHODS

B1.21.2.1 DIFFRACTION

(A) DIFFRACTION AND STRUCTURE

Diffraction is based on wave interference, whether the wave is an electromagnetic wave (optical, x-ray, etc), or a quantum mechanical wave associated with a particle (electron, neutron, atom, etc), or any other kind of wave. To obtain information about atomic positions, one exploits the interference between different scattering trajectories among atoms in a solid or at a surface, since this interference is very sensitive to differences in path lengths and hence to relative atomic positions (see [chapter B1.9](#)).

It is relatively straightforward to determine the *size and shape of the three- or two-dimensional unit cell* of a periodic bulk or surface structure, respectively. This information follows from the *exit directions* of diffracted beams relative to an incident beam, for a given crystal orientation: measuring those exit angles determines the unit cell quite easily. But no *relative positions* of atoms within the unit cell can be obtained in this manner. To achieve that, one must measure *intensities* of diffracted beams and then computationally analyse those intensities in terms of atomic positions.

With XRD applied to bulk materials, a detailed structural analysis of atomic positions is rather straightforward and routine for structures that can be quite complex (see [chapter B1.9](#)): *direct methods* in many cases give good results in a single step, while the resulting atomic positions may be refined by iterative fitting procedures based on simulation of the diffraction process.

With ED, by contrast, the task is more complicated due to *multiple scattering* of the electrons from atom to atom (see [chapter B1.17](#)). Such multiple scattering is especially strong at the relatively low energies employed to study surfaces. This dramatically restricts the application of direct methods and strongly increases the computational cost of simulating the diffraction process. As a result, an iterative *trial-and-error fitting* is the method of choice with ED, even though it can be a slow process when many trial structures have to be tested.

Also, the result of any diffraction-based trial-and-error fitting is not necessarily unique: it is always possible that there exists another untried structure that would give a better fit to experiment. Hence, a multi-technique approach that provides independent clues to the structure is very fruitful and common in surface science: such clues include chemical composition, vibrational analysis and position restrictions implied by other structural methods. This can greatly restrict the number of trial structures which must be investigated.

(B) NON-PERIODIC STRUCTURES

Diffraction is not limited to periodic structures [1]. Non-periodic imperfections such as defects or vibrations, as well as sample-size or domain effects, are inevitable in practice but do not cause much difficulty or can be taken into account when studying the ordered part of a structure. Some other forms of disorder can also be handled quite well in their own right, such as *lattice-gas* disorder in which a given site in the unit cell is randomly occupied with less than 100% probability. At surfaces, lattice-gas disorder is very common when atoms or molecules are adsorbed on a substrate. The local adsorption structure in the given site can be studied in detail.

(C) NON-PLANAR INITIAL WAVES

More fundamental is the distinction between planar and spherical initial waves. In XRD, for instance, the incident x-rays are well described by plane waves; this is generally true of probes that are aimed at the sample from macroscopic distances, as is the case also in most forms of ED and ND. However, there are techniques in which a wave is generated locally within the sample, for instance through emission of an x-ray (by fluorescence) or an electron (by photoemission) from a sample atom. In such *point-source emission*, the wave which performs the useful diffraction initially has a spherical rather than planar character; it is centred on the nucleus of an atom, with a rapidly decaying amplitude as it travels away from the emitting site. (Depending on the excitation mechanism, this initial wave need not be spherically symmetrical, but may also have an angular variation, as given by spherical harmonics, for instance, or combinations thereof.)

This spherical outgoing wave can diffract only from atoms that are near to the emitting atom, mainly those atoms within a distance of a few atomic diameters. In these circumstances, the crystallinity of the sample is of less importance: the diffracting wave sees primarily the *local* atomic-scale neighbourhood of the emitting atoms. As long as the same local neighbourhood predominates everywhere in the sampled part of the surface, information about the structure of that neighbourhood can be extracted. It also helps very much if the local neighbourhood has a constant orientation, so that the experiment does not average over a multitude of orientations, since these tend to average out diffraction effects and thus wash away structural information.

(D) VARIETY OF DIFFRACTION METHODS

From the above descriptions, it becomes apparent that one can include a wide variety of techniques under the label ‘diffraction methods’. [Table B1.21.1](#) lists many techniques used for surface structural determination, and specifies which can be considered diffraction methods due to their use of wave interference ([table B1.21.1](#) also explains many technique acronyms commonly used in surface science). The diffraction methods range from the classic case of XRD and the analogous case of LEED to much more subtle cases like XAFS (listed as both SEXAFS (surface extended XAFS) and NEXAFS (near-edge XAFS) in the table).

-4-

Table B1.21.1. Surface structural determination methods. The second column indicates whether a technique can be considered a diffraction method, in the sense of relying on wave interference. Also shown are statistics of surface structural determinations, extracted from the Surface Structure Database [[14](#)], up to 1997. Counted here are only ‘detailed’ and complete structural determinations, in which typically the experiment is simulated computationally and atomic positions are fitted to experiment. (Some structural determinations are performed by combining two or more methods: those are counted more than once in this table, so that the columns add up to more than the actual 1113 structural determinations included in the database.)

Surface structural determination method	Diffraction method?	Number of structural determinations	Percentage of structural determinations
LEED	yes	751	67.5
IS (including LEIS, MEIS and HEIS for low-, medium- and high-energy ion scattering)	no	102	9.2

PD (covers a variety of other acronyms, like ARPEFS, ARXPD, ARXPS, ARUPS, NPD, OPD, PED)	yes	88	7.9
SEXAFS	yes	67	6.0
XSW	yes	52	4.7
XRD (also GIXS, GIXD)	yes	40	3.6
TOF-SARS (time-of-flight scattering and recoiling spectrometry)	no	13	1.2
NEXAFS (also called XANES)	yes	11	1.0
RHEED	yes	10	0.9
LEPD	yes	5	0.4
HREELS	yes	4	0.4
MEED	yes	3	0.3
AED	yes	3	0.3
SEELFS (surface extended energy loss fine structure)	yes	2	0.2
TED	yes	1	0.1
AD	yes	1	0.1
STM	no	1	0.1

XAFS is a good example of less obvious diffraction [2, 3]. In XAFS, an electron is emitted by an x-ray locally within the sample. It propagates away as a spherical wave, which is allowed to back-scatter from neighbouring atoms to the emitter atom. The back-scattered electron wave interferes at the emitting atom with the emitted wave, thereby modulating the probability of the emitting process itself when the energy (wavelength) is varied: as one cycles through constructive and destructive interferences, the emission probability oscillates with a period that reflects the interatomic distances. This emission probability is, however, measured through yet another process (e.g., absorption of the incident x-rays, or emission of other x-rays or other electrons), which oscillates in synchrony with the interference. Thus, the structure-determining diffraction is in such a case buried relatively deeply in the overall process, and does not closely resemble the classic plane-wave diffraction of XRD.

B1.21.2.2 SURFACE SENSITIVITY

There are several approaches to gain the required surface sensitivity with diffraction methods. We review several of these here, emphasizing the case of solid/vacuum interfaces; some of these also apply to other interfaces.

(A) SHORT MEAN FREE PATH

One obvious method to obtain surface sensitivity is to choose probes and conditions that give shallow penetration. This can be achieved through a short *mean free path* λ , i.e. a short average distance until the probe (e.g., x-ray or electron) is absorbed by energy loss or is otherwise removed from the useful diffraction channels. For typical x-rays, λ is of the order of micrometres in many materials, which is too large compared to the desired surface thickness [4]. But for electrons of low kinetic energies, i.e. $E \approx 10\text{--}1000$ eV, the mean free path λ is of the order of 5–20 Å [5]. The mean free path has a minimum in the 100–200 eV range, with larger mean free paths existing both below and above this range.

Such ideal low mean free paths are the basis of LEED, the technique that has been used most for determining surface structures on the atomic scale. This is also the case of photoelectron diffraction (PD): here, the mean free path of the emitted electrons restricts sensitivity to a similar depth (actually double the depth of LEED, since the incident x-rays in PD are only weakly attenuated on this scale).

(B) GRAZING INCIDENCE AND/OR EMERGENCE

Another approach to limit the penetration of the probe into the surface region is to use *grazing incidence* and/or *grazing emergence*; this works for those probes that already have a reasonably small mean free path λ . A grazing angle θ (measured from the surface normal, i.e., θ close to 90°) then allows the probe to penetrate to a depth of only about $\lambda \cos(\theta)$. This approach is used primarily for higher-energy electrons above about 1000 eV in a technique called reflection high-energy electron diffraction (RHEED) [6].

With XRD, however, the mean free path is still too long to make this approach practical by itself [4]: as an example, to obtain even 100 Å penetration, one would typically need to use a grazing angle of about 0.05° , which is technically extremely demanding. The penetration depth is proportional to the grazing angle of incidence at such small angles, so that a ten times smaller penetration depth requires a further tenfold reduction in grazing angle. In addition, such small grazing angles require samples with a flatness that is essentially impossible to achieve, in order that the x-rays see a flat surface rather than a set of ridges that shadow much of the surface.

-6-

(C) TOTAL EXTERNAL REFLECTION

In XRD, surface sensitivity can, however, be achieved through another phenomenon [4]: *total external reflection*. This also occurs at grazing angles of incidence, giving rise to the technique acronym of GIXS for grazing-incidence x-ray scattering. At angles within approximately 0.5° of $\theta = 90^\circ$, x-rays cannot penetrate by refraction into materials: the laws of optics imply that the wave velocity of refracted waves in the material would have to be larger than the speed of light under those circumstances, which is impossible for propagating waves. Instead, the incident wave is totally reflected. However, this is accompanied by a shallow penetration of waves that decay exponentially into the bulk while propagating parallel to the surface. Under such conditions, the decay length into the surface is of the order of 10–30 Å, as desired. This penetration depth depends on the material and not on the wavelength of the x-rays. Note that total external reflection does not require vacuum: it can occur at various kinds of interfaces, depending on the relative optical constants of the phases in contact.

(D) HIGH-SURFACE AREA MATERIALS

None of the above methods is sufficient for neutrons, however. Neutrons penetrate matter so easily that the only effective approach is to use materials with a very high surface-to-volume ratio. This can be accomplished with small particles and exfoliated graphite, for instance, but the technique has essentially been abandoned in surface studies [7, 8].

(E) SUPERLATTICE DIFFRACTION

One further method for obtaining surface sensitivity in diffraction relies on the presence of two-dimensional *superlattices* on the surface. As we shall see further below, these correspond to periodicities that are different from those present in the bulk material. As a result, additional diffracted beams occur (often called fractional-order beams), which are uniquely created by and therefore sensitive to this kind of surface structure. XRD, in particular, makes frequent use of this property [4]. Transmission electron diffraction (TED) also has used this property, in conjunction with ultrathin samples to minimize bulk contributions [9].

(F) HYBRID METHODS

As we have seen, the electron is the easiest probe to make surface sensitive. For that reason, a number of hybrid techniques have been designed that combine the virtues of electrons and of other probes. In particular, electrons and photons (x-rays) have been used together in techniques like PD [10] and SEXAFS (or EXAFS, which is the high-energy limit of XAFS) [2, 11]. Both of these rely on diffraction by electrons, which have been excited by photons. In the case of PD, the electrons themselves are detected after emission out of the surface, limiting the depth of ‘sampling’ to that given by the electron mean free path.

(G) ELEMENTAL AND CHEMICAL-STATE RESOLUTION

With some techniques, another mechanism can give high surface sensitivity, namely *elemental resolution* through spectroscopic filtering of emitted electrons or x-rays. In this approach, one detects, by setting an energy window, only those electrons or x-rays that are emitted by a particular kind of atom, since each electronic level produces a line at a particular energy given by the level energy augmented by the excitation energy.

-7-

Thus, if a ‘foreign’ element is present only at the surface, one can detect a signal that only comes from that element and, therefore, only from the surface. Given sufficient energy resolution, one can even differentiate electrons coming from the same atoms in different bonding environments: e.g., in the case of a clean surface, atoms of the outermost layer *versus* bulk atoms [10]. This *chemical-state resolution* is due to the fact that electronic levels are shifted by bonding to other atoms, resulting in different emitted lines from atoms in different bonding situations.

Elemental and chemical-state resolution affords the possibility of detecting only a monolayer or even a fraction of a monolayer. This approach is prevalent in PD and in methods based on x-ray fluorescence.

It is also used in SEXAFS [11]: as we have seen, photoexcited electrons are back-reflected to the photoemitting atoms, thereby modulating the x-ray absorption cross-section through electron wave interference, after which a secondary electron or ion or fluorescent x-ray is ejected from the surface and finally detected. This latter ejection process provides surface sensitivity, through the electronic mean free path or the shallowness of ionic emission. However, elemental and chemical-state selection by energy filtering is essentially universal here, and again can give monolayer resolution with emission from foreign surface atoms different from the bulk atoms.

A similar device can be applied to a form of x-ray diffraction called the x-ray standing wave (XSW) method [12, 13], as detected by fluorescence. Here, x-ray waves reflected from bulk atomic planes form a standing wave pattern near the surface. The maxima and minima of this standing wave pattern can be arranged to fall at different locations on the atomic scale, by varying the energy and incidence angles. Thereby, the induced fluorescence varies with the location of those maxima and minima. Since the fluorescence is element specific, one can thus determine positions of foreign surface atoms relative to the extended bulk lattice (it remains

difficult, however, to locate those substrate atoms that are close to the fluorescing surface atoms, because they are drowned by the bulk signal).

B1.21.3 STATISTICS OF FULL STRUCTURAL DETERMINATIONS

Many methods have been developed to determine surface structure: we have mentioned several in the previous section and there are many more. To get an idea of their relative usage and importance, we here examine historical statistics. We also review the kinds of surface structure that have been studied to date, which gives a feeling for the kinds of surface structures that current methods and technology can most easily solve. This will provide an overview of the range of surfaces for which detailed surface structures are known, and those for which very little is known.

As source of information we use the Surface Structure Database [14], a critical compilation of surface structures solved in detail, covering the period to the end of 1997. It contains 1113 structural determinations with, on average, two determinations for each structure: thus there are approximately 550 distinct solved structures available.

In terms of individual techniques, [table B1.21.1](#) lists the breakdown totalled over time, counting from the inception of surface structural determination in the early 1970s. It is seen that LEED has contributed altogether about 67% of all structural determinations included in the database. The annual share of LEED was 100% until 1978, and has generally remained over 50% since then. In 1979 other methods started to produce structural determinations, especially PD, ion scattering (IS) and SEXAFS. XRD and then XSW started to contribute results in the period 1981–3.

-8-

As the table shows, a host of other techniques have contributed a dozen or fewer results each. It is seen that diffraction techniques have been very prominent in the field: the major diffraction methods have been LEED, PD, SEXAFS, XSW, XRD, while others have contributed less, such as NEXAFS, RHEED, low-energy position diffraction (LEPD), high-resolution electron energy loss spectroscopy (HREELS), medium-energy electron diffraction (MEED), Auger electron diffraction (AED), SEELFS, TED and atom diffraction (AD). The major non-diffraction method is IS, which is described in [chapter B1.23](#).

The database provides interesting perspectives on the evolution of surface structural determination since its inception around 1970. Not surprisingly, there is a clear temporal trend toward more complex and more diverse materials, such as compound substrates, alloyed bimetallic surfaces, complex adsorbate-induced relaxations and reconstructions, epitaxial and pseudomorphic growth, alkali adsorption on semiconductor and transition metal substrates, and molecular adsorbates as well as co-adsorbates on metal surfaces. The complexity of some solved structures has grown to about 100 times that of the earliest structures. The range of structure types can also be gauged, for instance, from the list of substrate lattice categories included in the SSD database: bcc, CdCl₂, CdI₂, corundum, CsCl, CuAu I, Cu₃Au, diamond, fcc, fluorite, graphite, hcp, hexagonal, NaCl, perovskite, rutile, spinel, wurtzite, zincblende, 2H–MoS₂, 2H–NbSe₂ and 6H–SiC.

Nonetheless, when counting all structures solved over time, one finds a strong predominance of studies in certain narrow categories, as exhibited by the following uneven statistics:

- fcc metals far outdistance any other substrate lattice type, with 60% of the total;
- the diamond lattice (C, Si and Ge) forms the next most numerous lattice category, about 10%, followed by the bcc (9%) and hcp (7%) lattices;
- elemental solids (with or without foreign adsorbates) form 85% of the substrates examined, the rest being metallic alloys (7%) or other compounds (8%);

- the surfaces of *non-reconstructed* elemental metal substrates (with or without adsorbates) constitute about 77% of the results; the remainder are *reconstructed*, i.e. have undergone a substantial structural change from the ideal termination of the bulk lattice, involving bond breaking and/or bond making;
- looking at electronic properties, metals again dominate heavily, with 81% of the total, followed by semiconductors (16%), insulators (3%) and semimetals (less than 1%);
- atomic overlayers comprise about 54% of all types of adsorption, as opposed to interstitial (1%) or substitutional (5%) underlayers, molecular overlayers (10%), multilayers (9%) or mixes of these adsorption modes.

There is much room for further study of various important categories of materials: one prominent example is oxides and other compounds (carbides, nitrides, . . .); another is all types of adsorption on oxides and other compounds.

However, recent advances in techniques will ensure further diversification and complexification of solved surface structures. The present maturity of techniques will thus increasingly allow the analysis of structures chosen for their practical interest rather than for their simplicity.

B1.21.4 TWO-DIMENSIONAL ORDERING AND NOMENCLATURE

In diffraction, the degree and kind of structural ordering is an important consideration, since the diffraction reflects those structural properties. As a result, diffraction methods are ideal for characterizing the degree and type of ordering that a surface exhibits. In particular, at surfaces, LEED has always been a favourite tool for ‘fingerprinting’ a particular state of ordering of a surface, enhancing experimental reproducibility. It is therefore useful to first briefly examine the forces that are responsible for the variety of ordering types that occur at surfaces. Then, we can introduce standard notation to succinctly describe specific forms of ordering that occur at surfaces.

B1.21.4.1 TWO-DIMENSIONAL ORDERING

A large number of ordered surface structures can be produced experimentally on single-crystal surfaces, especially with adsorbates [15]. There are also many disordered surfaces. Ordering is driven by the interactions between atoms, ions or molecules in the surface region. These forces can be of various types: covalent, ionic, van der Waals, etc; and there can be a mix of such types of interaction, not only within a given bond, but also from bond to bond in the same surface. A surface could, for instance, consist of a bulk material with one type of internal bonding (say, ionic). It may be covered with an overlayer of molecules with a different type of intramolecular bonding (typically covalent); and the molecules may be held to the substrate by yet another form of bond (e.g., van der Waals).

Strong adsorbate–substrate forces lead to *chemisorption*, in which a chemical bond is formed. By contrast, weak forces result in *physisorption*, as one calls non-chemical ‘physical’ adsorption.

The balance between these different types of bonds has a strong bearing on the resulting ordering or disordering of the surface. For adsorbates, the relative strength of adsorbate–substrate and adsorbate–adsorbate interactions is particularly important. When adsorbate–substrate interactions dominate, well ordered overlayer structures are induced that are arranged in a *superlattice*, i.e. a periodicity which is closely related to that of the substrate lattice: one then speaks of *commensurate* overlayers. This results from the tendency for each adsorbate to seek out the same type of *adsorption site* on the surface, which means that all adsorbates attempt to bond in the same manner to substrate atoms.

An example of commensurate overlayers is provided by atomic sulfur chemisorbed on a Ni (100) surface: all S atoms tend to adsorb in the *fourfold coordinated hollow sites*, i.e. each S atom tries to bond to four Ni atoms. At typical high coverages and moderate temperatures, this results in an ordered array of S atoms on the Ni (100) surface. However, high temperatures will disorder such overlayers; also, this layer may be kinetically disordered during its formation, as a result of gradual addition of sulfur atoms before they manage to order. The same is often true of molecular adsorption. Although intramolecular bonding can be strong enough to keep an adsorbed molecular species intact despite its bonding to the substrate, there is usually only a relatively weak mutual interaction among adsorbed molecular species.

Relatively strong adsorbate–adsorbate interactions have a different effect: the adsorbates attempt to first optimize the bonding between them, before trying to satisfy their bonding to the substrate. This typically results in close-packed overlayers with an internal periodicity that it is not matched, or at least is poorly matched, to the substrate lattice. One thus finds well ordered overlayers whose periodicity is generally not closely related to the substrate lattice: this leads

-10-

to so-called *incommensurate* overlayers. Such behaviour is best exemplified by very cohesive overlayers like graphite sheets or oxide thin films that adopt their own preferred lattice constant regardless of the substrate material on which they are adsorbed.

B1.21.4.2 COVERAGE AND MONOLAYER DEFINITIONS

It is useful to define the terms *coverage* and *monolayer* for adsorbed layers, since different conventions are used in the literature. The surface coverage measures the two-dimensional density of adsorbates. The most common definition of coverage sets it to be equal to one monolayer (1 ML) when each two-dimensional surface unit cell of the unreconstructed substrate is occupied by one adsorbate (the adsorbate may be an atom or a molecule). Thus, an overlayer with a coverage of 1 ML has as many atoms (or molecules) as does the outermost single atomic layer of the substrate.

However, many adsorbates cannot reach a coverage of 1 ML as defined in this way: this occurs most clearly when the adsorbate is too large to fit in one unit cell of the surface. For example, benzene molecules normally lie flat on a metal surface, but the size of the benzene molecule is much larger than typical unit cell areas on many metal surfaces. Thus, such an adsorbate will saturate the surface at a lower coverage than 1 ML; deposition beyond this coverage can only be achieved by starting the growth of a second layer on top of the first layer.

It is thus tempting to define the first saturated layer as being one monolayer, and this often done, causing some confusion. One therefore also often uses terms like *saturated monolayer* to indicate such a single adsorbate layer that has reached its maximal two-dimensional density. Sometimes, however, the word ‘saturated’ is omitted from this definition, resulting in a different notion of monolayer and coverage. One way to reduce possible confusion is to use, for contrast with the saturated monolayer, the term *fractional monolayer* for the term that refers to the substrate unit cell rather than the adsorbate size as the criterion for the monolayer density.

B1.21.4.3 TWO-DIMENSIONAL CRYSTALLOGRAPHIC NOMENCLATURE

(A) MILLER INDICES

Single-crystal surfaces are characterized by a set of Miller indices that indicate the particular crystallographic orientation of the surface plane relative to the bulk lattice [5]. Thus, surfaces are labelled in the same way that atomic planes are labelled in bulk x-ray crystallography. For example, a Ni (111) surface has a surface plane

that is parallel to the (111) crystallographic plane of bulk nickel. Thus, the Ni (111) surface exposes a hexagonally close-packed layer of atoms, given that nickel has a face-centred close-packed (fcc) cubic bulk lattice, see [figure B1.21.1 a](#)). Some authors use the more correct notation $\{111\}$ instead of (111), as is common in bulk crystallography to emphasize that the (111) plane is only one of several symmetrically equivalent plane orientations, like $(11\bar{1})$, $(\bar{1}11)$, etc. The $\{111\}$ notation implicitly includes all such equivalent planes.

-11-

figure continued on next page.

-12-

Figure B1.21.1. Atomic hard-ball models of low-Miller-index bulk-terminated surfaces of simple metals with face-centred close-packed (fcc), hexagonal close-packed (hcp) and body-centred cubic (bcc) lattices: (a) fcc (111)–(1 × 1); (b) fcc(100)–(1 × 1); (c) fcc(110)–(1 × 1); (d) hcp(0001)–(1 × 1); (e) hcp(10-10)–(1 × 1), usually written as hcp(10 $\bar{1}$ 0)–(1 × 1); (f) bcc(110)–(1 × 1); (g) bcc(100)–(1 × 1) and (h) bcc(111)–(1 × 1). The atomic spheres are drawn with radii that are smaller than touching-sphere radii, in order to give better depth views. The arrows are unit cell vectors. These figures were produced by the software program BALSAC [35].

Figure B1.21.1 shows a number of other clean unreconstructed low-Miller-index surfaces. Most surfaces studied in surface science have low Miller indices, like (111), (110) and (100). These planes correspond to relatively close-packed surfaces that are atomically rather smooth. With fcc materials, the (111) surface is the densest and smoothest, followed by the (100) surface; the (110) surface is somewhat more ‘open’, in the sense that an additional atom with the same or smaller diameter can bond directly to an atom in the *second* substrate layer. For the hexagonal close-packed (hcp) materials, the (0001) surface is very similar to the fcc (111) surface: the difference only occurs deeper into the surface, namely in the fashion of stacking of the hexagonal close-packed monolayers onto each other (ABABAB... *versus* ABCABC..., in the convenient layer-stacking notation). The hcp (10 $\bar{1}$ 0) surface resembles the fcc (110) surface to some extent, in that it also

presents open troughs between close-packed rows of atoms, exposing atoms in the second layer. With the body-centred cubic (bcc) materials, the (110) surface is the densest and smoothest, followed by the (100) surface; in this case, the (111) surface is rather more open and atomically ‘rough’.

(B) HIGH-MILLER-INDEX OR STEPPED SURFACES

The atomic structures of high-Miller-index surfaces are composed of *terraces*, separated by *steps*, which may have *kinks* in them [5]. Examples are shown in figure B1.21.2. Thus, the (755) surface of an fcc crystal consists of (111) terraces, six atoms deep (from one step to the next), separated by straight steps of (100) orientation and of single-atom height. The fcc (10,8,7) has ‘kinks’ in its step edges, i.e. the steps themselves are not straight. The steps and kinks provide a degree of roughness that can be very important as sites for chemical reactions or for nucleation of crystal growth.

The step notation [5, 16] compacts the terrace/step information into the general form $w(h_t k_t l_t) \times (h_s k_s l_s)$. Here $(h_t k_t l_t)$ and $(h_s k_s l_s)$ are the Miller indices of the terrace plane and the step plane, respectively, while w is the number of atoms that are counted in the width of the terrace, including the step-edge atom and the in-step atom. Thus, the fcc (755) surface can be denoted by $6(111) \times (100)$, since its terraces are six atoms in depth. A kinked surface, like fcc (10,8,7), can also be approximately expressed in this form: the step plane $(h_s k_s l_s)$ is a stepped surface itself, and thus has higher Miller indices than the terrace plane. However, the step notation does not exactly tell us the relative location of adjacent steps, and it is not entirely clear how the terrace width w should be counted. A more complete microfacet notation is available to describe kinked surfaces generally [5].

-14-

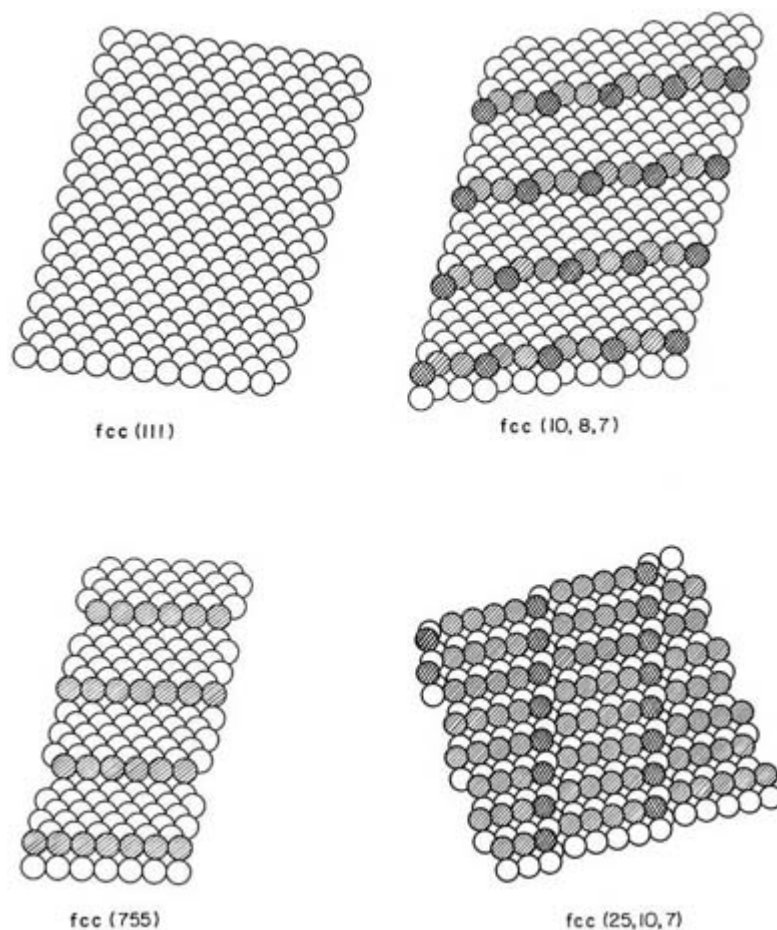

Figure B1.21.2. Atomic hard-ball models of ‘stepped’ and ‘kinked’ high-Miller-index bulk-terminated surfaces of simple metals with fcc lattices, compared with an fcc(111) surface: fcc(755) is stepped, while fcc

(10,8,7) and fcc(25,10,7) are 'kinked'. Step-edge atoms are shown singly hatched, while kink atoms are shown cross-hatched.

-15-

(C) SUPERLATTICES

Many surfaces exhibit a different periodicity than expected from the bulk lattice, as is most readily seen in the diffraction patterns of LEED: often additional diffraction features appear which are indicative of a *superlattice*. This corresponds to the formation of a new two-dimensional lattice on the surface, usually with some simple relationship to the expected 'ideal' lattice [5]. For instance, a layer of adsorbate atoms may occupy only every other equivalent adsorption site on the surface, in both surface dimensions. Such a lattice can be labelled (2×2) : in each surface dimension the repeat distance is doubled relative to the ideal substrate. In this example, the unit cell of the original bulk-like surface is magnified by a factor of two in both directions, so that the new surface unit cell has dimensions (2×2) relative to the original unit cell. For instance, an oxygen overlayer on Pt (111), at a quarter-monolayer coverage, is observed to adopt an ordered (2×2) superlattice: this can be denoted as Pt (111) + (2×2) -O, which provides a compact description of the main crystallographic characteristics of this surface. This particular notation is that of the Surface Structure Database [14]; other equivalent notations are also common in the literature, such as Pt (111)-(2 × 2)-O or Pt (111) 2×2 -O.

This (2×2) notation can be generalized. First, it can take on the form $(m \times n)$, where the numbers m and n are two independent stretch factors for the two unit cell vectors. These numbers are often integers, but need not be. In addition, this new stretched unit cell can be rotated by any angle about the surface normal: this is denoted as $(m \times n) R\alpha^\circ$, where α is the rotation angle in degrees [5, 17, 18 and 19]; the suffix $R\alpha^\circ$ is omitted when $\alpha = 0$, as is the case for Pt (111) + (2×2) -O. This *Wood notation* [5, 19] allows the original unit cell to be stretched and rotated; however, it conserves the angle between the two unit cell vectors in the plane of the surface, therefore not allowing 'sheared' unit cells.

As a particular case, a surface may be given the Wood notation (1×1) , as in Ni (111)-(1 × 1): this notation indicates that the two-dimensional unit cell of the surface has the same size as the two-dimensional unit cell of the bulk (111) layers. Thus, an ideally terminated bulk lattice without overlayers or reconstructions will carry the label (1×1) .

The Wood notation can be generalized somewhat further, by adding either the prefix 'c' for centred, or the prefix 'p' for primitive. For instance, one may have a c (2×2) unit cell or a p (2×2) unit cell, the latter often abbreviated to (2×2) because it is identical to it. In a centred unit cell, the centre of the cell is an exact copy of the corners of the cell; this makes the cell non-primitive, i.e. it is no longer the smallest cell that, when repeated periodically across the surface, generates the entire surface structure. Nonetheless, the centred notation is often used because it can be quite convenient, as the next example will illustrate.

-16-

The c (2×2) unit cell can also be written as $(\sqrt{2} \times \sqrt{2})R45^\circ$. Here, the original unit vectors of the (1×1) structure have both been stretched by factors $\sqrt{2}$ and then rotated by 45° . Thus, sulfur on Ni (100) forms an ordered half-monolayer structure that can be labelled as Ni (100) + c (2×2) -S or, equivalently, Ni (100) + $(\sqrt{2} \times \sqrt{2}) R45^\circ$ -S. The c (2×2) notation is clearly easier to write and also easier to convert into a geometrical model of the structure, and hence is the favoured designation.

A more general notation than Wood's is available for all kinds of unit cells, including those that are sheared, so that the superlattice unit cell can take on any shape, size and orientation. It is the *matrix notation*, defined

as follows [5]. We connect the unit cell vectors \mathbf{a}' and \mathbf{b}' of the superlattice to the unit cell vectors \mathbf{a} and \mathbf{b} of the substrate by the general relations

$$\mathbf{a}' = m_{11}\mathbf{a} + m_{12}\mathbf{b}$$

$$\mathbf{b}' = m_{21}\mathbf{a} + m_{22}\mathbf{b}.$$

The coefficients m_{11} , m_{12} , m_{21} and m_{22} define the matrix $\mathbf{M} = \begin{pmatrix} m_{11} & m_{12} \\ m_{21} & m_{22} \end{pmatrix}$, which serves to denote the superlattice. The (1×1) , (2×2) and $c(2 \times 2)$ lattices are then denoted respectively by the matrices $\mathbf{M} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$, $\mathbf{M} = \begin{pmatrix} 2 & 0 \\ 0 & 2 \end{pmatrix}$ and $\mathbf{M} = \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}$. This allows the Ni (100) + $c(2 \times 2)$ -S structure to be also written as Ni(100)+ $\begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}$ -S. Clearly, this notation is not as intuitive and compact as the $c(2 \times 2)$ Wood notation. However, when the Wood notation is not capable of a clear and compact notation, use of the matrix notation is necessary. Thus, a structure characterized by a matrix like $\mathbf{M} = \begin{pmatrix} 4 & -3 \\ 2 & 5 \end{pmatrix}$ could not be described in the Wood notation.

In LEED experiments, the matrix \mathbf{M} is determined by visual inspection of the diffraction pattern, thereby defining the periodicity of the surface structure: the relationship between surface lattice and diffraction pattern will be described in more detail in the next section.

A superlattice is termed *commensurate* when all matrix elements m_{ij} are integers. If at least one matrix element m_{ij} is an irrational number (not a ratio of integers), then the superlattice is termed *incommensurate*. A superlattice can be incommensurate in one surface dimension, while commensurate in the other surface dimension, or it could be incommensurate in both surface dimensions.

A superlattice can be caused by adsorbates adopting a different periodicity than the substrate surface, or also by a reconstruction of the clean surface. In [figure B1.21.3](#) several superlattices that are commonly detected on low-Miller-index surfaces are shown with their Wood notation.

figure continued on next page.

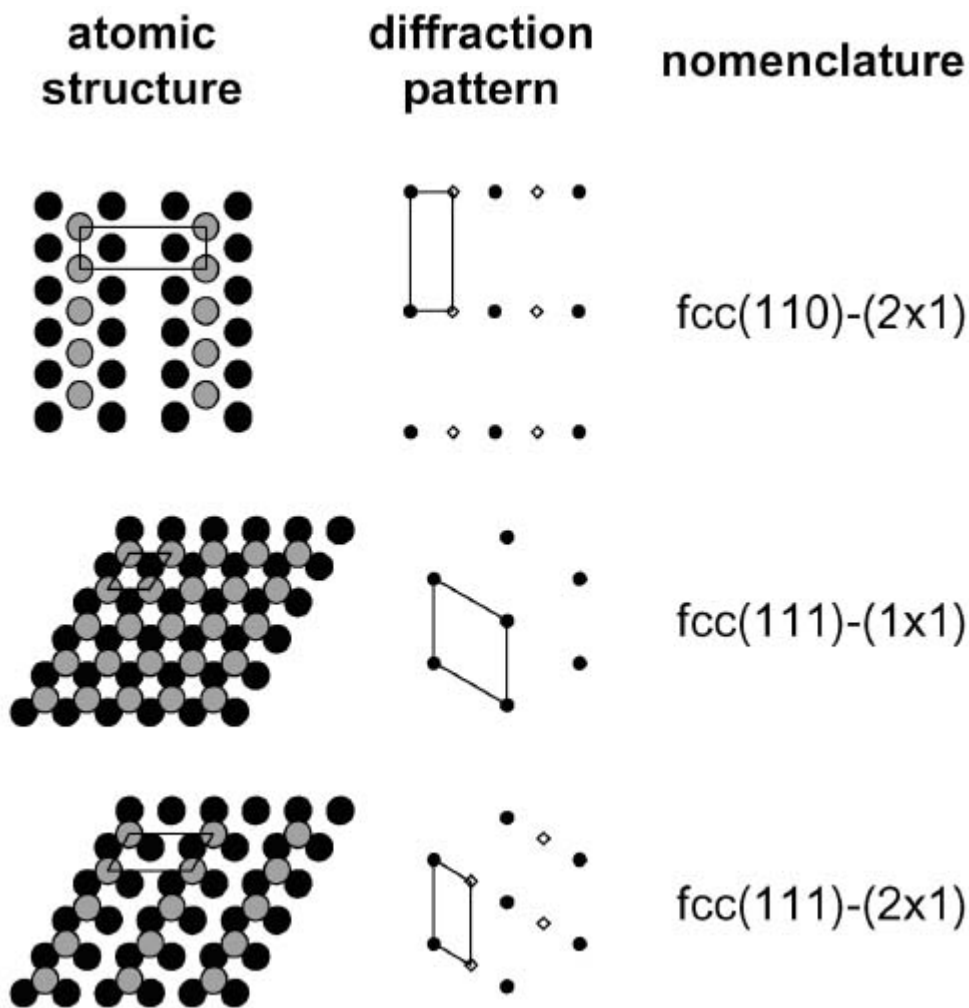

Figure B1.21.3. ‘Direct’ lattices (at left) and corresponding reciprocal lattices (at right) of a series of commonly occurring two-dimensional superlattices. Black circles correspond to the ideal (1 × 1) surface structure, while grey circles represent adatoms in the direct lattice (arbitrarily placed in ‘hollow’ positions) and open diamonds represent fractional-order beams in the reciprocal space. Unit cells in direct space and in reciprocal space are outlined.

B1.21.5 SURFACE DIFFRACTION PATTERN

The diffraction pattern observed in LEED is one of the most commonly used ‘fingerprints’ of a surface structure. With XRD or other non-electron diffraction methods, there is no convenient detector that images in real time the corresponding diffraction pattern. Point-source methods, like PD, do not produce a convenient spot pattern, but a diffuse diffraction pattern that does not simply reflect the long-range ordering.

So it is essential to relate the LEED pattern to the surface structure itself. As mentioned earlier, the diffraction pattern does not indicate relative atomic positions within the structural unit cell, but only the size and shape of that unit cell. However, since experiments are mostly performed on surfaces of materials with a known crystallographic bulk structure, it is often a good starting point to assume an ideally terminated bulk lattice; the actual surface structure will often be related to that ideal structure in a simple manner, e.g. through the creation of a superlattice that is directly related to the bulk lattice.

In this section, we concentrate on the relationship between diffraction pattern and surface lattice [5]. In direct analogy with the three-dimensional bulk case, the *surface lattice* is defined by two vectors \mathbf{a} and \mathbf{b} parallel to the surface (defined already above), subtended by an angle γ ; \mathbf{a} and \mathbf{b} together specify one unit cell, as illustrated in figure B1.21.4. Within that unit cell atoms are arranged according to a *basis*, which is the list of atomic coordinates within that unit cell; we need not know these positions for the purposes of this discussion. Note that this unit cell can be viewed as being infinitely deep in the third dimension (perpendicular to the surface), so as to include all atoms below the surface to arbitrary depth.

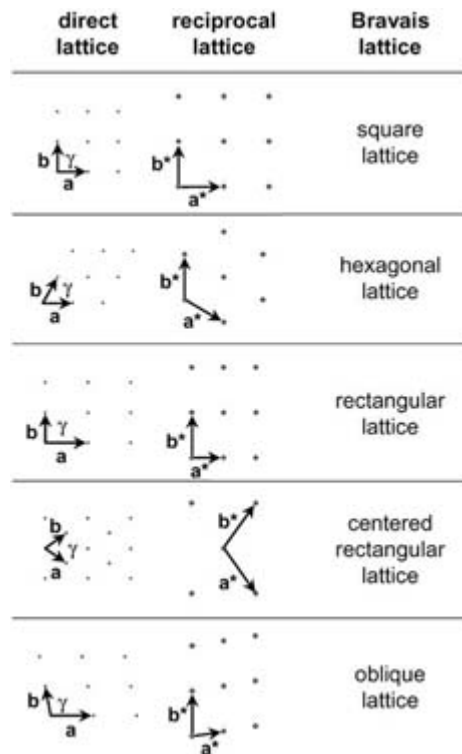

Figure B1.21.4. ‘Direct’ lattices (at left) and reciprocal lattices (middle) for the five two-dimensional Bravais lattices. The reciprocal lattice corresponds directly to the diffraction pattern observed on a standard LEED display. Note that other choices of unit cells are possible: e.g., for hexagonal lattices, one often chooses vectors \mathbf{a} and \mathbf{b} that are subtended by an angle γ of 120° rather than 60° . Then the reciprocal unit cell vectors also change: in the hexagonal case, the angle between \mathbf{a}^* and \mathbf{b}^* becomes 60° rather than 120° .

There are several special shapes of the surface lattice, forming the five two-dimensional Bravais lattices shown in [figure B1.21.4](#). The Bravais lattices form the complete list of possible lattices. They are characterized by unit cell vectors of equal length (in the case of the square and hexagonal lattices) and/or a subtended angle of 90° or 60° (for the square, rectangular and hexagonal lattices) or by completely general values (for the oblique lattice). The rectangular lattice comes in two varieties: primitive and centred. The centred lattice has the particularity that its atomic basis is duplicated: each atom is reproduced by displacement through the vector $1/2 (\mathbf{a} + \mathbf{b})$. The main value of the centred rectangular lattice is its convenience: it is easier to think in terms of the rectangle (with duplicated basis) than to think of the rhombus with arbitrary angle γ . One could also centre any of the other lattices, but one would only produce another instance of a square, rectangular or oblique lattice, i.e. nothing more convenient.

The diffraction of low-energy electrons (and any other particles, like x-rays and neutrons) is governed by the translational symmetry of the surface, i.e. the surface lattice. In particular, the directions of emergence of the diffracted beams are determined by conservation of the linear momentum parallel to the surface, $\hbar \mathbf{k}_\parallel$. Here \mathbf{k}

denotes the wavevector of the incident plane electron wave that represents the incoming electron beam. This conservation can occur in two ways. After the diffractive scattering, the parallel component of the momentum $\hbar\mathbf{k}'_{\parallel}$ can be equal to that of the incident electron beam, i.e. $\hbar\mathbf{k}'_{\parallel} = \hbar\mathbf{k}_{\parallel}$; this corresponds to *specular* (mirror-like) reflection, with equal polar angles of incidence and emergence with respect to the surface normal, and with a simple reversal of the perpendicular momentum $\hbar\mathbf{k}'_{\perp} = -\hbar\mathbf{k}_{\perp}$.

Alternatively, the electron can exchange parallel momentum with the lattice, but only in well defined amounts given by vectors $\hbar\mathbf{g}$ that belong to the *reciprocal lattice* of the surface. That is, the vector \mathbf{g} is a linear combination of two reciprocal lattice vectors \mathbf{a}^* and \mathbf{b}^* , with integer coefficients. Thus, $\mathbf{g} = h\mathbf{a}^* + k\mathbf{b}^*$, with arbitrary integers h and k (note that all the vectors \mathbf{a} , \mathbf{b} , \mathbf{a}^* , \mathbf{b}^* and \mathbf{g} are parallel to the surface). The reciprocal lattice vectors \mathbf{a}^* and \mathbf{b}^* are related to the ‘direct-space’ lattice vectors \mathbf{a} and \mathbf{b} through the following non-transparent definitions, which also use a vector \mathbf{n} that is perpendicular to the surface plane, as well as vectorial dot and cross products:

$$\mathbf{a}^* = 2\pi \left(\frac{\mathbf{b} \times \mathbf{n}}{\mathbf{a} \cdot (\mathbf{b} \times \mathbf{n})} \right) \quad \text{and} \quad \mathbf{b}^* = 2\pi \left(\frac{\mathbf{n} \times \mathbf{a}}{\mathbf{b} \cdot (\mathbf{n} \times \mathbf{a})} \right).$$

These two equations are a special case of the corresponding three-dimensional definition, common in XRD, with the surface normal \mathbf{n} replacing the third lattice vector \mathbf{c} .

[Figure B1.21.4](#) illustrates the ‘direct-space’ and reciprocal-space lattices for the five two-dimensional Bravais lattices allowed at surfaces. It is useful to realize that the vector \mathbf{a}^* is always perpendicular to the vector \mathbf{b} and that \mathbf{b}^* is always perpendicular to \mathbf{a} . It is also useful to notice that the length of \mathbf{a}^* is inversely proportional to the length of \mathbf{a} , and likewise for \mathbf{b}^* and \mathbf{b} . Thus, a large unit cell in direct space gives a small unit cell in reciprocal space, and a wide rectangular unit cell in direct space produces a tall rectangular unit cell in reciprocal space. Also, the hexagonal direct-space lattice gives rise to another hexagonal lattice in reciprocal space, but rotated by 90° with respect to the direct-space lattice.

-21-

The reciprocal lattices shown in [figure B1.21.3](#) and [figure B1.21.4](#) correspond directly to the diffraction patterns observed in LEED experiments: each reciprocal-lattice vector produces one and only one diffraction spot on the LEED display. It is very convenient that the hemispherical geometry of the typical LEED screen images the reciprocal lattice without distortion; for instance, for the square lattice one observes a simple square array of spots on the LEED display.

One of the spots in such a diffraction pattern represents the specularly reflected beam, usually labelled (00). Each other spot corresponds to another reciprocal-lattice vector $\mathbf{g} = h\mathbf{a}^* + k\mathbf{b}^*$ and is thus labelled (hk) , with integer h and k .

When a superlattice is present, additional spots arise in the diffraction pattern, as shown in [figure B1.21.3](#) in terms of the reciprocal lattice: again, each reciprocal lattice point corresponds to a spot in a diffraction pattern. This can be easily understood from the fact that a larger unit cell in direct space imposes a smaller unit cell in reciprocal space. For instance, a (2×1) superlattice has a unit cell doubled in length in one surface direction relative to the (1×1) lattice, i.e. \mathbf{a} is replaced by $2\mathbf{a}$. According to the above equations, this has no effect on \mathbf{b}^* , but halves \mathbf{a}^* . This is equivalent to allowing h to be a half-integer in $\mathbf{g} = h\mathbf{a}^* + k\mathbf{b}^*$, thus doubling the number of spots in the diffraction pattern. These additional spots are therefore often called half-order spots in the (2×1) case, or fractional-order spots in the general case.

With some practice, one can easily recognize specific superlattices from their LEED pattern. Otherwise, one can work through the above equations to connect particular superlattices to a given LEED pattern. A number

of examples are given and discussed in some detail in [5]. A discussion can also be found there of the special case of stepped and kinked surfaces.

B1.21.6 DIFFRACTION PATTERN OF DISORDERED SURFACES

Many forms of disorder in a surface structure can be recognized in the LEED pattern. The main manifestations of disorder are *broadening* and *streaking* of diffraction spots and *diffuse* intensity between spots [1].

Broadening of spots can result from thermal diffuse scattering and island formation, among other causes. The thermal effects arise from the disorder in atomic positions as they vibrate around their equilibrium sites; the sites themselves may be perfectly crystalline.

Islands occur particularly with adsorbates that aggregate into two-dimensional assemblies on a substrate, leaving bare substrate patches exposed between these islands. Diffraction spots, especially fractional-order spots if the adsorbate forms a superlattice within these islands, acquire a width that depends inversely on the average island diameter. If the islands are systematically anisotropic in size, with a long dimension primarily in one surface direction, the diffraction spots are also anisotropic, with a small width in that direction. Knowing the island size and shape gives valuable information regarding the mechanisms of phase transitions, which in turn permit one to learn about the adsorbate–adsorbate interactions.

-22-

Lattice-gas disorder, in which adatoms occupy a periodic lattice of equivalent sites with a random occupation probability, produces diffuse intensity distributions between diffraction spots. For complete disorder, one observes such diffuse intensity throughout the diffraction pattern. If there is order in one surface direction, but disorder in the other, one observes streaking in the diffraction pattern: the direction of the streaks corresponds to the direction in which disorder occurs. In principle, the diffuse intensity distribution can be converted into a direct-space distribution, including a pair-correlation function between occupied sites, e.g. by Fourier transformation. However, the diffuse intensity is too much affected by other diffraction effects (like multiple scattering) to be very useful in this manner. It nonetheless can be interpreted in terms of local structure, i.e. bond lengths and angles, by a procedure that is very similar to the multiple-scattering modelling for solving structures in full detail [20].

LEED has found a strong competitor for studying surface disorder: scanning tunnelling microscopy, STM (see [chapter B1.20](#)). Indeed, STM is the ideal tool for investigating irregularities in periodic surface structures. LEED (as any other diffraction method) averages its information content over macroscopic parts of the surface, giving only statistical information about disorder. By contrast, STM can provide a direct image of individual atoms or defects, enabling the observation of individual atomic behaviour. By observing a sufficiently large area, STM can also provide statistical information, if desired.

B1.21.7 FULL STRUCTURAL DETERMINATION

In the previous sections we have emphasized the two-dimensional information available through the diffraction pattern observed in LEED. But, as mentioned before, one can extract the detailed atomic positions as well, including interlayer spacings, bond lengths, bond angles, etc. Here we sketch how this more complete structural determination is accomplished. We focus on the case of LEED, since this method has produced by far the most structural determinations [5, 17, 18, 21]. The procedures employed to analyse PD data are in fact very similar to those for LEED, in many details. With XRD, the kinematic (single-scattering) nature of the

problem makes the analysis simpler, but still considerable for complex structures: there also, a trial-and-error search for the solution is common.

To obtain spacings between atomic layers and bond lengths or angles between atoms, it is necessary to measure and analyse the *intensity* of diffraction spots. This is analogous to measuring the intensity of XRD reflections.

The measurement of LEED spot intensities is nowadays mostly accomplished by digitizing the image recorded by a video camera that observes the diffraction pattern, which is visibly displayed on a fluorescent screen within an ultra-high vacuum system [22]. The digitized image is then processed by computer to give the integrated spot intensity, after removal of the background. This is repeated for different incident electron energies. Thereby, the intensity of each spot is obtained as a function of the incident electron energy, resulting in an *IV curve* (intensity–voltage curve) for each spot. Computer codes for this purpose are available, and are normally packaged together with the required hardware [23]. The resulting IV curves form the experimental database to which theory can fit the atomic structure. It typically takes between minutes and an hour to accumulate such a database, once the sample has been prepared.

Since ED by a surface is a complicated process, there is no routine method available to *directly* and accurately extract atomic positions from the experimental data. Direct holographic methods have been proposed [24], but have not yet

-23-

become routine methods, and in any case they yield only approximate atomic positions (with uncertainties on the scale of 0.2–0.5 Å) and work only for relatively simple structures; when they do work they have to be followed up by refinement using the same trial-and-error approach that we discuss next.

A detailed structural determination proceeds by modelling the full multiple scattering of the electrons that are diffracted through the surface structure. The multiple scattering means that an electron can bounce off a succession of atoms in an erratic path before emerging from the surface. Various theoretical and computational methods are available to treat this problem to any degree of precision: a compromise between precision and computing expense must be struck, with progress moving toward higher precision, even for more complex structures.

The modelling of the multiple scattering requires input of all atomic positions, so that the *trial-and-error approach* must be followed: one guesses reasonable models for the surface structure, and tests them one by one until satisfactory agreement with experiment is obtained. For simple structures and in cases where structural information is already known from other sources, this process is usually quite quick: only a few basic models may have to be checked, e.g. adsorption of an atomic layer in hollow, bridge or top sites at positions consistent with reasonable bond lengths. It is then relatively easy to refine the atomic positions within the best-fit model, resulting in a complete structural determination. The refinement is normally performed by some form of *automated steepest-descent optimization*, which allows many atomic positions to be adjusted simultaneously [21]. Computer codes are also available to accomplish this part of the analysis [25]. The trial-and-error search with refinement may take minutes to hours on current workstations or personal computers.

In more complex cases, and when little additional information is available, one must test a larger number of possible structural models. The computational time grows rapidly with complexity, so that it may take hours to check a single model. More time-consuming, however, is often the human factor in guessing what are reasonable models to test. This is a much more difficult problem, which is the issue of finding the ‘global optimum’, not just a ‘local optimum’. At present, several approaches to *global optimization* are being examined, such as *simulated annealing* [26] and *genetic algorithms* [27]. In any event, these will require larger amounts of computer time, since a wide variety of surface models must be tested in such a global

search.

B1.21.8 PRESENT CAPABILITIES AND OUTLOOK

Surface crystallography started in the late 1960s, with the simplest possible structures being solved by LEED [14]. Such structures were the clean Ni (111), Cu(111) and Al(111) surfaces, which are unreconstructed and essentially unrelaxed, i.e. very close to the ideal termination of the bulk shown in [figure B1.21.1 a](#)): typically, only one unknown structural parameter was fitted to experiment, namely the spacing between the two outermost atomic layers.

Progress in experiment, theory, computational methods and computer power has contributed to the capability to solve increasingly complex structures [28, 29]. [Figure B1.21.5](#) quantifies this progress with three measures of complexity, plotted logarithmically: the achievable two-dimensional unit cell size, the achievable number of fit parameters and the achievable number of atoms per unit cell per layer: all of these measures have grown from 1 for simple clean metal

-24-

surfaces, like Ni (111) (see [Figure B1.21.1 \(a\)](#)), to about 50–100 in the case of the reconstructed Si(111)–(7 × 7) surface, the most complicated structure examined to date [30] (note that the basic model which solved the Si(111)–(7 × 7) surface was mainly derived from another diffraction study, using TED [9]). All these measures thus exhibit a progression by about two orders of magnitude over less than 25 years.

Figure B1.21.5. Evolution with time of the complexity of structural determination achievable with LEED. The unit cell area is measured relative to the unit cell area of the simple (1 × 1) structures studied in the early days: thus a ($n \times n$) superstructure (due to reconstruction and/or adsorption) has a unit cell size of n^2 . A (7 × 7) structure gives a complexity of 49 on this scale. The number of fit parameters measures the number of coordinates fitted to experiment in any given structure: a value of 1 was typical of many early determinations, when only one interlayer spacing was fitted to experiment. The Si(111)–(7 × 7) structure has over 100 fit parameters, if one allows only those structural changes in the top two double layers and the adatom layer that maintain the $p3m1$ symmetry of the substrate. The number of atoms per unit cell refers to so-called composite layers, which are groups of closely spaced layers: this number dramatically affects computation time in multiple-scattering methods. It has grown from 1 in the simplest structures to about 100 in the Si(111)×(7 × 7) structure.

Figure B1.21.6, figure B1.21.7, figure B1.21.8 and figure B1.21.9 show several of the more complex structures solved by LEED in recent years. They exhibit various effects observed at surfaces:

- clustering of adatoms in Re(0001) – $(2\sqrt{3} \times 2\sqrt{3})R30^\circ-6S$ [31], see figure B1.21.6
- hollow-site adsorption and adsorbate-induced relaxations of substrate atoms both in Re(0001)– $(2\sqrt{3} \times 2\sqrt{3})R30^\circ-6S$ [31] and in Mo (100) – $c(4 \times 2)-3S$ [32], see figure B1.21.7
- adsorbate-induced reconstruction as well as substitutional adsorption in Cu(100)– $(4 \times 4)-10Li$ [33], see figure B1.21.8 note that this is the most complex surface structural determination by LEED to date, involving far more adjustable structural parameters than were fitted in the Si(111) – (7×7) structure [30];
- compound ionic surface with a large bulk unit cell and very large surface relaxations in $Fe_3O_4(111)$ [34], see figure B1.21.9

-25-

Further progress towards solving more complex surface structures is possible. The biggest challenge on the computational and theoretical side is the identification of the globally optimum structure. Holographic and other methods have not yet provided a convenient way to accomplish this, and would actually fail with structures that have the complexity of Cu(100) – $(4 \times 4)-10Li$ and Si(111) – (7×7) . Global-search algorithms, like simulated annealing and genetic algorithms, may provide workable, if perhaps not cheap, solutions.

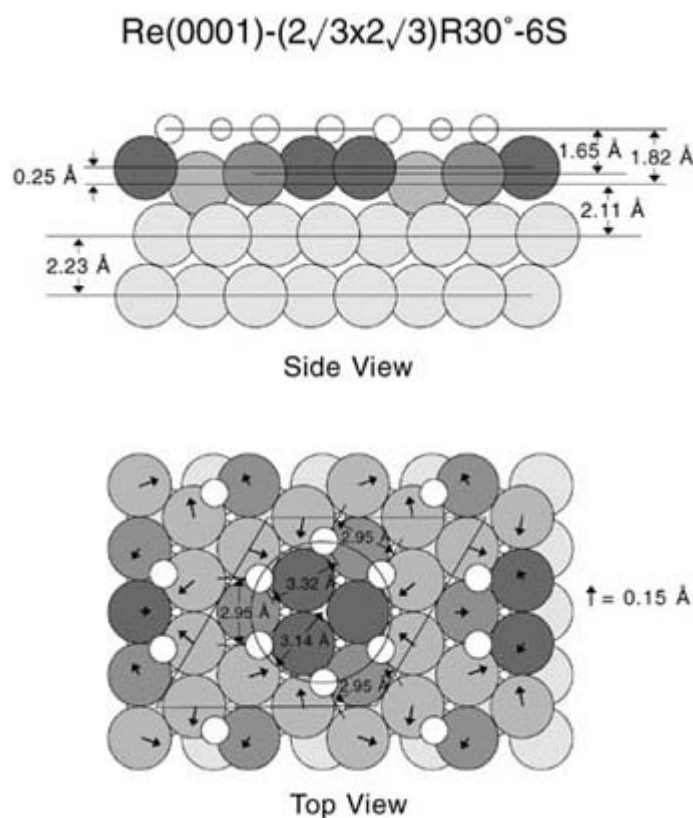

Figure B1.21.6. Side and top views of the best-fit structure of the Re(0001)– $(2\sqrt{3} \times 2\sqrt{3})R30^\circ-6S$ surface structure (with a half-monolayer coverage of sulfur), as determined by LEED [31]. A $(2\sqrt{3} \times 2\sqrt{3})R30^\circ$ unit cell is outlined in the top view. Sulfur atoms are drawn as small open circles, Re atoms as large grey circles. Sulfur–sulfur distances in a ring of six alternate between 2.95 and 3.32 Å, expanded from the unrelaxed distance between hollow sites of 2.75 Å. Arrows represent lateral relaxations in the topmost metal layer, with the scale of displacements indicated by the lone arrow on the right. The bulk interlayer spacing in Re(0001) is 2.23 Å. Shades of grey identify atoms that are equivalent by symmetry in the sulfur and outermost rhenium layers. The darkest-grey rhenium atoms forming a triangle within a sulfur ring are pulled out of the surface by the adsorbed sulfur, relative to the lighter-grey rhenium atoms in the same layer.

Mo(100)-c(4x2)-3S

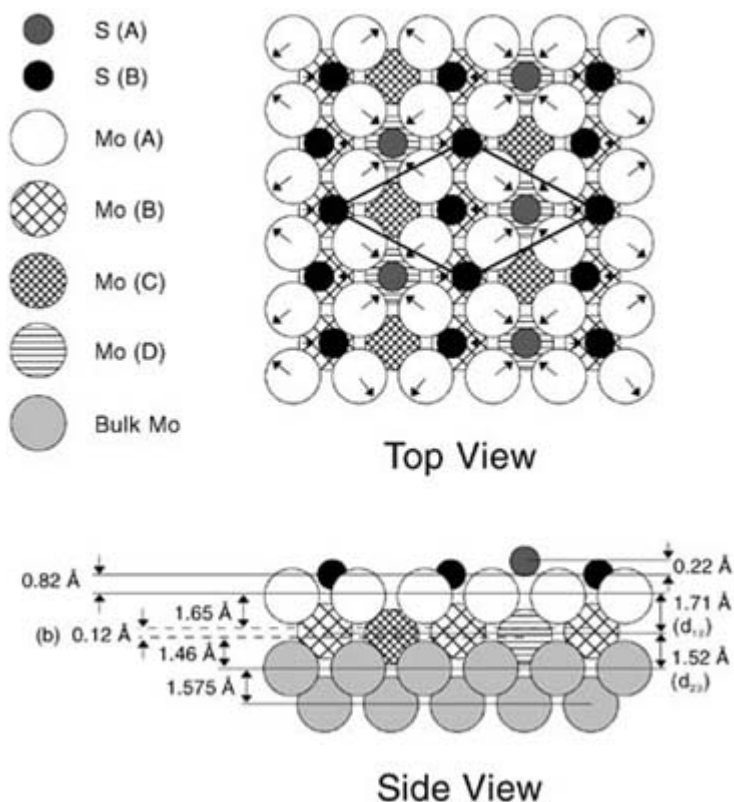

Figure B1.21.7. Top and side views of the best-fit structure of the Mo(100)-c(4 × 2)-3S surface structure (with a 3/4-monolayer coverage of sulfur), as determined by LEED [32]. A c(4 × 2) unit cell is outlined in the top view. The sulfur sizes (small black and dark grey circles) have been reduced from covalent for clarity, while the molybdenum atoms (large circles) are drawn with touching radii. The same cross-hatching has been assigned to molybdenum atoms that are equivalent by symmetry in the topmost two metal layers. Two-thirds of the sulfur atoms are displaced away from the centre of the hollow sites in which they are bonded: these displacements by 0.13 Å are drawn exaggerated. Arrows in the top view also indicate the directions and relative magnitudes of molybdenum atom displacements (these substrate atoms are drawn in their undisplaced positions, except for the buckling seen in the second molybdenum layer in the side view). The bulk interlayer spacing in Mo(100) is 1.575 Å.

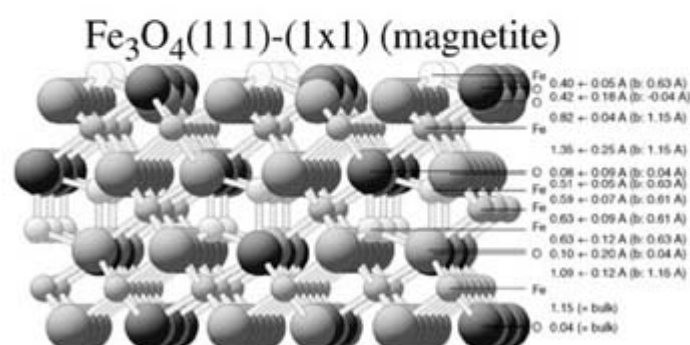

Figure B1.21.8. Perspective view of the structure of the Cu(100)–(4 × 4)–10Li surface structure (with a 10/16-monolayer coverage of lithium), as determined by LEED [33]. The atoms are drawn with radii that are reduced by about 15% from covalent radii. The surface fragment shown includes four (4 × 4) unit cells. Lithium atoms are shown as larger spheres. In each unit cell, four lithium atoms (dark grey) form a flat-topped pyramid (as outlined): the lithium atoms rest in hollow sites on a 3 × 3 base of nine Cu atoms (lighter grey). Around each pyramid 12 lithium atoms occupy substitutional sites, i.e. have taken the place of Cu atoms: these lithium atoms are shown linked by an octagon. Since the lithium atoms are about 15% larger than the copper atoms that they replace, fewer lithium atoms can fit in the troughs evacuated by the copper atoms; thus, they do not fill the troughs completely, and leave a hole at each intersection between troughs (e.g. at the exact centre of the fragment). The lightest-grey atoms underneath are the bulk Cu(100) termination: some small local distortions in the atomic positions are also detected by LEED there. This and the following figure were produced with the SARCH/LATUSE/PLOT3D/BALSAC software, available from the author.

Top view

Side view

$\text{Fe}_3\text{O}_4(111)-(1 \times 1)$ (magnetite)

Figure B1.21.9. Perspective side and top view of the best-fit structure of $\text{Fe}_3\text{O}_4(111)$, as determined by LEED [34]. A unit cell is outlined in the top view, in which all atoms are drawn with nearly touching radii, while smaller radii are used in the side view. This iron oxide was grown as an ultrathin film on a Pt(111) substrate, in order to prevent electrical charging of the surface. The free surface is at the top end of the side view, exposing 1/4 monolayer of ‘external’ iron ions (shown as small light-grey circles in both views). Large circles represent oxygen ions, forming hexagonally close-packed layers. In each such layer, one-fourth of the oxygen ions (drawn in darkest grey) is not coplanar with the others: in particular, in the outermost oxygen layer, these ions are raised outward by a large amount (0.42 Å, compared to 0.04 Å in the opposite direction in the bulk). Small circles below the surface represent iron ions in tetrahedral or octahedral interstitial positions between the O layers: the lightest-grey of these are in tetrahedral positions. Interlayer spacings as determined by LEED are given at the right with error bars and with corresponding bulk values in parentheses.

On the experimental side, a larger measured database is required than is commonly available to determine the large number of structural parameters to be fitted. For instance, LEED calculations for the $\text{Si}(111) - (7 \times 7)$ surface have been attempted to fit the many tens of unknown structural parameters; however, the amount of experimental data was insufficient for the task, resulting in a multitude of locally-optimum structures, without the ability to discriminate between them. Increasing the database size can be achieved by extending the energy range to higher energies, or by acquiring data at a number of different incidence directions: either way, the calculations become disproportionately more time-consuming, because the computing effort rises quickly

with energy and non-symmetrical off-normal incidence directions.

ACKNOWLEDGMENTS

Professor K Hermann is gratefully thanked for the images in [figure B1.21.1](#) which were produced with the program BALSAC [35].

B1.22 Surface characterization and structural determination: optical methods

Francisco Zaera

B1.22.1 INTRODUCTION

As discussed in more detail elsewhere in this encyclopaedia, many optical spectroscopic methods have been developed over the last century for the characterization of bulk materials. In general, optical spectroscopies make use of the interaction of electromagnetic radiation with matter to extract molecular parameters from the substances being studied. The methods employed usually rely on the examination of the radiation absorbed,

emitted or scattered by a system, and may be based on simple linear optical processes, resonance transitions and/or nonlinear processes. Molecular spectroscopy probes energy transitions at all levels, from the excitation of spins in the radiofrequency range (NMR), to rotational (microwave), vibrational (infrared) and electronic valence (visible–UV) and core (x-rays) excitations. Additional diffraction- and polarization-based techniques provide structural information and laser-based pump–probe methods allow for the study of molecular dynamics down to the femtosecond time scale.

In spite of the wide range of applications of optical techniques for the study of bulk samples, however, they have so far found only limited use in the characterization of surfaces. One of the main reasons for this is the fact that it is quite difficult to discriminate optical signals originating from the surface from those arriving from the bulk of a given material. To illustrate this problem, imagine a typical metal sample consisting of a cube one centimetre long on each side. At a density of approximately 10 g cm^{-3} , this represents about 0.1 moles (for molybdenum, to pick an example), or approximately 6×10^{22} atoms, and of those about 1×10^{16} , that is, only one in six million atoms, are on the surface of the cube. This means that if one wants to selectively characterize a surface phenomenon, one would need to develop a technique with a large dynamic range (of at least seven orders of magnitude) and/or the ability to discriminate between signals from surface and bulk elements.

Moreover, with the advent of relatively cheap vacuum technologies over the past decades, physicists have been able to develop a large number of alternative particle-based (electrons, ions, atoms) techniques capable of selectively probing solid surfaces. Most particles interact strongly with matter, and therefore cannot penetrate deeply into the substance being probed. Consequently, whatever information can be obtained from the interactions of those particles with solid samples, it must be related to the properties of the surface. The same argument does not work as well with optical techniques, because photons penetrate through most substances to depths comparable to their wavelength, microns in the case of IR radiation. In order to overcome this difficulty, alternative ways have been devised to gain surface sensitivity with optical spectroscopies. Among them are the following:

- (1) Increasing the surface-to-bulk ratio of the sample to be studied. This is easily done in the case of highly porous materials, and has been exploited for the characterization of supported catalysts, zeolites, sol-gels and porous silicon, to mention a few.
- (2) Taking advantage of the intrinsic physical and chemical differences of surfaces introduced by the discontinuity of the bulk environment. Specifically, most solids display specific structural relaxations and reconstructions, surface

-2-

phonons and surface electronic states easy to discriminate from those of the bulk. A clearer surface specificity is introduced in the study of adsorbates by the uniqueness of the molecules present at the interface.

- (3) Taking advantage of the symmetry changes induced by the presence of a surface. Many nonlinear techniques rely on the fact that the surface breaks the centrosymmetrical nature of the bulk. The use of polarized light can also discriminate among dipole moments in different orientations.
- (4) Illuminating the sample at grazing angles. The penetration depth of photons depends on the cosine of the incidence angle and, therefore, can be reduced by this procedure. Although such an approach has limited use, it has been successfully employed in a few instances, such as for x-ray diffraction experiments.

The power of optical spectroscopies is that they are often much better developed than their electron-, ion- and atom-based counterparts, and therefore provide results that are easier to interpret. Furthermore, photon-based techniques are uniquely poised to help in the characterization of liquid–liquid, liquid–solid and even solid–solid interfaces generally inaccessible by other means. There has certainly been a renewed interest in the use of optical spectroscopies for the study of more ‘realistic’ systems such as catalysts, adsorbates, emulsions, surfactants, self-assembled layers, etc.

In this chapter we review some of the most important developments in recent years in connection with the use of optical techniques for the characterization of surfaces. We start with an overview of the different approaches available to the use of IR spectroscopy. Next, we briefly introduce some new optical characterization methods that rely on the use of lasers, including nonlinear spectroscopies. The following section addresses the use of x-rays for diffraction studies aimed at structural determinations. Lastly, passing reference is made to other optical techniques such as ellipsometry and NMR, and to spectroscopies that only partly depend on photons.

B1.22.2 IR SPECTROSCOPY

Perhaps the optical technique most used for surface characterization has been infrared (IR) spectroscopy. The reason for this may very well be because the vibrational modes identified by the interaction of IR radiation with matter are among the most specific and thus the most informative for chemical characterization. Not only can vibrational frequencies be easily identified with specific localized vibrational groups within a molecule (metal-adsorbate vibrations, O-H stretches, C-C-C deformation modes, etc), but they also depend strongly on the local environment in which the probed moiety is placed [1, 2]. The use of IR spectroscopy was greatly enhanced by the development of Fourier-transform (FTIR) spectrometers in the early 1970s, an event that brought about an enormous improvement in performance in terms of sensitivity, acquisition time, dynamic range and ease of data processing (spectra ratioing in particular) over the conventional scanning apparatus; this made the extension of IR spectroscopy to difficult systems quite feasible. The several experimental approaches pursued for the implementation of IR spectroscopy in surface studies include straight transmission, diffuse reflectance, reflection-absorption, attenuated total reflectance and emission. Each of these is discussed in some detail below.

-3-

B1.22.2.1 TRANSMISSION IR SPECTROSCOPY

The most common use of spectroscopy in general is in its transmission mode, and this was the first method employed for surface characterization as well. The pioneering work of Terenin *et al* on porous glasses [3] and of Eischens and others on chemisorption over supported metals [4] has already been reviewed in the past [5, 6]. Extensive studies have been carried out since on the characterization of catalysts upon chemisorption of many reactants, from simple molecules such as carbon and nitrogen oxides to hydrocarbons and other complex species [7, 8]. In a recent use of transmission IR absorption to surface problems, the reactivity of silicon towards water and other gases was addressed by first creating highly reproducible porous surfaces by the controlled etching of silicon single crystals [9]. Unfortunately, the general application of transmission IR spectroscopy to surface studies faces some significant limitations, in particular the need for high-surface-area solids (which usually have quite heterogeneous and ill characterized surfaces) and the restricted range of frequencies available away from the regions where the solid absorbs (above 1300 cm⁻¹ for silica, 1050 cm⁻¹ for alumina, 1200 cm⁻¹ for titania, 800 cm⁻¹ for magnesia).

B1.22.2.2 DIFFUSE-REFLECTANCE IR SPECTROSCOPY

Another useful technique for the IR characterization of surfaces in powders is diffuse-reflectance IR spectroscopy (DRIFTS) [10]. In the past, the challenge in using this approach has been in the development of efficient optics to collect the diffuse reflected radiation from the sample once illuminated with a focused IR beam, but nowadays this problem has been solved, and several cell designs are available commercially for this endeavour [11]. DRIFTS has, in theory, several advantages over conventional transmission arrangements. First, loose powders can be used without the need to press them into pellets, thus avoiding any sample distortions due to severe physical treatments, allowing for better exposures of the surface to adsorbates, and

avoiding losses in the high-frequency range due to light scattering. Second, band intensities in the DRIFTS mode can be as much as four times more intense than in the transmission mode, possibly because of the potential multiple internal reflection of the light in the vicinity of the surface before its emergence towards the detector. Lastly, DRIFTS is better for opaque samples than transmission IR spectroscopy, although the diffuse reflectance may still be low in spectral regions where the absorptivity of the substrate is high. On the negative side, there is a potential lack of reproducibility in the intensities of the DRIFTS bands because of variations in scattering coefficients with cell geometry and sample-loading procedure. Furthermore, diffuse-reflectance spectroscopy suffers from the same key limitation in transmission IR spectroscopy, namely, it requires high-surface-area samples, and therefore provides average spectra only from many types of surface local ensembles and adsorption sites.

The use of DRIFTS for the characterization of surfaces has to date been limited, but has recently been used for applications in fields as diverse as sensors development [12], soils science [13], forensic chemistry [14], corrosion [15], wood science [16] and art [17]. Given that there is in general no reason for preferring transmission over diffuse reflectance in the study of high-area powder systems, DRIFTS is likely to become much more popular in the near future.

B1.22.2.3 REFLECTION–ABSORPTION IR SPECTROSCOPY

The best way to perform IR spectroscopy studies on small samples is in the reflection–absorption (RAIRS) or attenuated total-reflectance (ATR) modes, which work best for opaque and transparent substrates, respectively. RAIRS has in fact become the method of choice for the study of adsorbates on well characterized metal samples, including single crystals. The first attempt to obtain spectra from adlayers on bulk metal samples was that of Pickering and Eckstrom, who in 1959 looked at the adsorption of carbon monoxide and hydrogen on metal films by using a multiple reflection technique with an incoming beam at close to normal incidence to the surface [18]. It soon became clear that better spectra could be obtained by using glancing incidence angles instead [19], and that the gain from using multiple reflection was not worth the complications connected with the required experimental set-up (the optimum number of reflections usually varies between 3 and 10, and results in signal intensity increases of only about 30–50% compared to those from single reflection) [20]. The theory for IR radiation reflection at metal surfaces was later developed by Greenler, who proved that only the p-polarized component of the incident beam is capable of strong interaction with adsorbates on metals, and that interference between that component of the incident and reflected rays sets an intense standing field at the surface which can yield an intensity enhancement of a factor of up to 25 compared to that from the perpendicularly polarized photons [21]. Many surface scientists have since taken advantage of these properties to perform reflection–absorption measurements of monolayers on solid metals [22, 23 and 24]. Even though the initial RAIRS experiments were carried out with molecules with large dynamic moments such as CO (in order to take advantage of their large absorption cross sections), recent FTIR developments have led to the possibility of detecting submonolayer quantities of species like hydrocarbons with much weaker signals on single crystals of less than 1 cm² area [25].

A recent example of the usefulness of RAIRS for the characterization of supported catalyst surfaces is given in [figure B1.22.1](#) which displays spectra obtained for a mixture of carbon and nitrogen monoxides coadsorbed on different palladium surfaces [26]. Both CO and NO stretching frequencies are quite sensitive to their adsorption sites, so they can be used to probe local surface sites by determining adsorption geometries in an analogous way as in organometallic discrete complexes. In this example, signals can be easily seen for the two-fold coordination of both CO and NO on Pd(100) surfaces and for three-fold, bridge and atop coordination of CO on Pd(111). The peaks from adsorption on single crystals are used as signatures for the different planes in palladium particles, so an estimate can be obtained on the relative abundance of (100) *versus* (111) sites available on the supported-metal system.

On metals in particular, the dependence of the radiation absorption by surface species on the orientation of the electrical vector can be fully exploited by using one of the several polarization techniques developed over the past few decades [27, 28, 29 and 30]. The idea behind all those approaches is to acquire the p-to-s polarized light intensity ratio during each single IR interferometer scan; since the adsorbate only absorbs the p-polarized component, that spectral ratio provides absorbance information for the surface species exclusively. Polarization-modulation methods provide the added advantage of being able to discriminate between the signals due to adsorbates and those from gas or liquid molecules. Thanks to this, RAIRS data on species chemisorbed on metals have been successfully acquired *in situ* under catalytic conditions [31], and even in electrochemical cells [32].

-5-

Figure B1.22.1. Reflection-absorption IR spectra (RAIRS) from palladium flat surfaces in the presence of a 1×10^{-6} Torr 1:1 NO:CO mixture at 200 K. Data are shown here for three different surfaces, namely, for Pd (100) (bottom) and Pd(111) (middle) single crystals and for palladium particles (about 500 Å in diameter) deposited on a 100 Å thick SiO₂ film grown on top of a Mo(110) single crystal. These experiments illustrate how RAIRS titration experiments can be used for the identification of specific surface sites in supported catalysts. On Pd(100) CO and NO each adsorbs on twofold sites, as indicated by their stretching bands at about 1970 and 1670 cm⁻¹, respectively. On Pd(111), on the other hand, the main IR peaks are seen around 1745 cm⁻¹ for NO (on-top adsorption) and about 1915 cm⁻¹ for CO (threefold coordination). Using those two spectra as references, the data from the supported Pd system can be analysed to obtain estimates of the relative fractions of (100) and (111) planes exposed in the metal particles [26].

The polarization dependence of the photon absorbance in metal surface systems also brings about the so-called surface selection rule, which states that only vibrational modes with dynamic moments having components perpendicular to the surface plane can be detected by RAIRS [22, 23 and 24]. This rule may in some instances limit the usefulness of the reflection technique for adsorbate identification because of the reduction in the number of modes visible in the IR spectra, but more often becomes an advantage thanks to the simplification of the data. Furthermore, the relative intensities of different vibrational modes can be used to estimate the orientation of the surface moieties. This has been particularly useful in the study of self-

assembled and Langmuir–Blodgett monolayers, where RAIRS data have been unique in providing information on the orientation of the hydrocarbon chains [33]. Figure B1.22.2 shows an example in which RAIRS was used to determine a collective change in adsorption geometry for alkyl halides on metal single crystals as the surface coverage is increased past the half-monolayer [34].

-6-

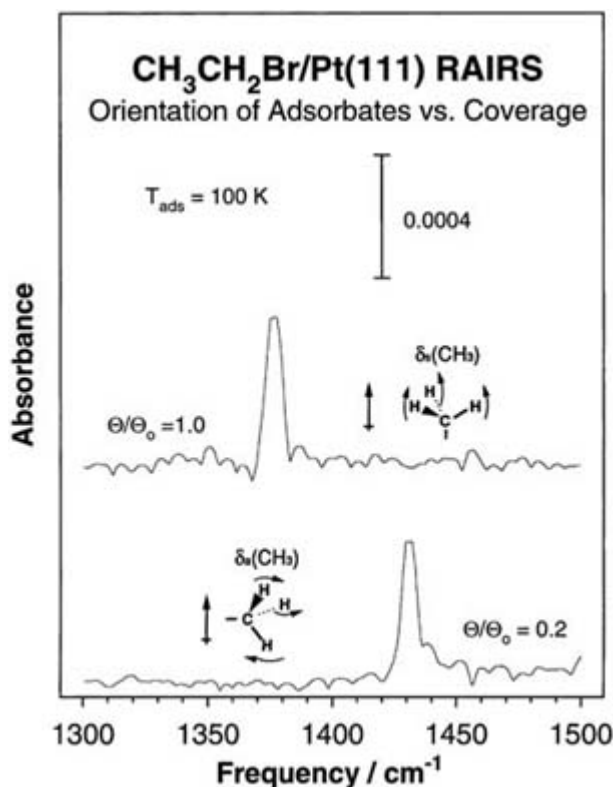

Figure B1.22.2. RAIRS data from molecular ethyl bromide adsorbed on a Pt(111) surface at 100 K. The two traces shown, which correspond to coverages of 20% and 100% saturation, illustrate the use of the RAIRS surface selection rule for the determination of adsorption geometries. Only one peak, but a different one, is observed in each case: while the signal detected at low coverages is due to the asymmetric deformation of the terminal methyl group (1431 cm^{-1}), the feature corresponding to the symmetric deformation (1375 cm^{-1}) is the one seen at high coverages instead. Given that only vibrations with dynamic dipole moments perpendicular to the surface are visible with this technique, it is concluded that a flat adsorption geometry prevails at low coverages but that a collective rearrangement of the adsorbates to a standing-up configuration takes place at about half-saturation [34].

The use of RAIRS has recently been extended from its regular mid-IR characterization of adsorbates on metals into other exciting and promising directions. For one, changes in optics and detectors have allowed for an extension of the spectral range towards the far-IR region in order to probe substrate–adsorbate vibrations [35]. The use of intense synchrotron sources in particular looks quite promising for the detection of such weak modes [36]. Thanks to the speed with which Fourier-transform spectrometers can acquire complete IR spectra, kinetic studies of surface reactions can be carried out as well. To date this has only been done in a few cases, usually for reactions that take seconds or more to occur [37], but the advent of step scanners promises the availability of time resolutions of 10^{-8} s or better in the near future [38]. In terms of the lifetime of the vibrational excitations themselves, this can in some instances be estimated from IR absorption line shapes. Because of the efficient coupling between the vibrations of adsorbate and phonons and other electronic surface states, the former are generally short-lived, and therefore yield IR absorption bands several wavenumbers wide. Nevertheless, bands as narrow as 0.7 cm^{-1} have been observed in some cases [39]. Finally, the use of RAIRS is not limited to metal surfaces. Although the surface selection rules change

significantly for non-metal surfaces, they can still be used to obtain orientational information for adsorbates on transparent substrates, as recently demonstrated in the elegant study by Hoffmann *et al* on the adsorption of long-chain hydrocarbons on silicon (figure B1.22.3) [40], and even for the analysis of air–liquid interfaces [41]. There are many clear new directions still unexplored for the use of RAIRS in surface characterization studies.

Figure B1.22.3. RAIRS data in the C–H stretching region from two different self-assembled monolayers, namely, from a monolayer of dioctadecylsulfide (ODS) on gold (bottom), and from a monolayer of octadecyltrichlorosilane (OTS) on silicon (top). Although the RAIRS surface selection rules for non-metallic substrates are more complex than those which apply to metals, they can still be used to determine adsorption geometries. The spectra shown here were, in fact, analysed to yield the tilt (α) and twist (β) angles of the molecular chains in each case with respect to the surface plane (the resulting values are also given in the figure) [40].

B1.22.2.4 ATTENUATED TOTAL REFLECTANCE IR SPECTROSCOPY

In 1960, Harrick demonstrated that, for transparent substrates, absorption spectra of adsorbed layers could be obtained using internal reflection [42]. By cutting the sample in a specific trapezoidal shape, the IR beam can be made to enter through one end, bounce internally a number of times from the flat parallel edges, and exit the other end without any losses, leading to high adsorption coefficients for the species adsorbed on the external surfaces of the plate (higher than in the case of external reflection) [24]. This is the basis for the ATR technique.

In recent years, ATR has been used primarily in connection with the characterization of semiconductor surfaces. For instance, ATR studies have led to the detailed mapping of the complex series of reconstructions that silicon surfaces follow upon thermal treatment and/or hydrogen exposures [43]. Surface electronic excitations have been studied with this technique as well; see, for instance, the pioneering work of McCombe *et al* on the characterization of inter-subband optical transitions in silicon MOS field-effect transistors (figure B1.22.4) [44]. One interesting additional extension of the use of multiple internal reflection to the characterization of non-transparent samples was discussed by Bermudez, who suggested that the sensitivity to adsorbates in IR-reflection spectroscopy can be enhanced by burying a metal layer beneath the surface of a dielectric material [45].

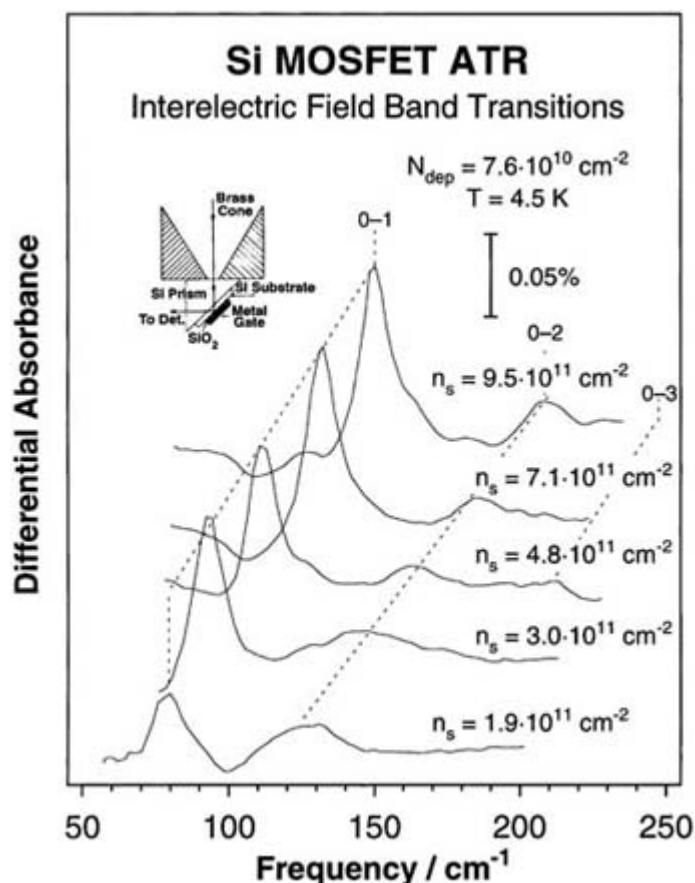

Figure B1.22.4. Differential IR absorption spectra from a metal–oxide silicon field-effect transistor (MOSFET) as a function of gate voltage (or inversion layer density, n_s , which is the parameter reported in the figure). Clear peaks are seen in these spectra for the 0–1, 0–2 and 0–3 inter-electric-field subband transitions that develop for charge carriers when confined to a narrow ($<100 \text{ \AA}$) region near the oxide–semiconductor interface. The inset shows a schematic representation of the attenuated total reflection (ATR) arrangement used in these experiments. These data provide an example of the use of ATR IR spectroscopy for the probing of electronic states in semiconductor surfaces [44].

B1.22.2.5 OTHER SURFACE IR SPECTROSCOPY ARRANGEMENTS

There have been a few other experimental set-ups developed for the IR characterization of surfaces. Photoacoustic (PAS), or, more generally, photothermal IR spectroscopy relies on temperature fluctuations caused by irradiating the sample with a modulated monochromatic beam: the acoustic pressure wave created in the gas layer adjacent to the solid by the adsorption of light is measured as a function of photon wavelength

in order to determine the absorption spectra [11]. It has sometimes been thought that PAS is more surface sensitive than DRIFTS, but in fact that depends on the specific optical and thermal properties of the material being studied. In emission spectrometry (EMS), the IR radiation emitted by the sample is directly collected and analysed. The detection of the (non-monochromatized) IR radiation from thin films has recently been combined with molecular beam techniques in order to perform differential microcalorimetric measurements on adsorption processes [46]. Finally, the sample itself can be used as the detector of IR radiation. None of these techniques have found much use in surface studies to date.

B1.22.3 LASER-BASED SPECTROSCOPIES

Although the development of a large variety of lasers with different spectral ranges, intensities and temporal resolutions has led to the surge of many new optical characterization techniques, most of those have yet to make a large impact in surface science. As discussed above, the signals from surfaces are often weak and hard to differentiate from those from the bulk, and this is particularly troublesome in nonlinear techniques which rely on the absorption of more than one photon. Furthermore, the increase of the laser power to levels where signal intensities are no longer an issue may lead to damaging of the substrate. In spite of these limitations, some laser-based methods have already been developed for surface-characterization studies.

B1.22.3.1 RAMAN SPECTROSCOPY

Perhaps the best known and most used optical spectroscopy which relies on the use of lasers is Raman spectroscopy. Because Raman spectroscopy is based on the inelastic scattering of photons, the signals are usually weak, and are often masked by fluorescence and/or Rayleigh scattering processes. The interest in using Raman for the vibrational characterization of surfaces arises from the fact that the technique can be used *in situ* under non-vacuum environments, and also because it follows selection rules that complement those of IR spectroscopy.

Regular Raman has been employed mainly for the characterization of high-surface-area solids [47]. Specifically, a good methodology has been developed for the determination of bond orders, bond lengths and local geometries in many metal oxides used for catalysis. [Figure B1.22.5](#) illustrates this point by displaying some examples where the Raman vibrational signals for metal–oxygen single and double bonds as well as for oxygen–metal–oxygen deformations were used to determine the structure of a number of supported and highly dispersed transition-metal oxides [48].

Figure B1.22.5. *In situ* Raman spectra from a family of transition-metal oxides dispersed on high-surface-area alumina substrates. Three distinct regions can be differentiated in these spectra, namely, the peaks around 1000 cm^{-1} , which are assigned to the stretching frequency of terminal metal–oxygen double bonds, the features about 900 cm^{-1} , corresponding to metal–oxygen stretches in tetrahedral coordination sites, and the low-frequency ($<400\text{ cm}^{-1}$) range associated with oxygen–metal–oxygen deformation modes. Data such as these can be used to determine the nature and geometry of supported oxides as a function of metal loading and subsequent treatment [48].

In an interesting development in Raman spectroscopy, Fleischmann *et al* noticed in 1974 that there is a significant enhancement in the Raman signal intensities from solid surfaces if the substrate is comprised of small silver particles [49]. The same phenomenon has since been observed with copper, silver, gold, lithium, sodium, potassium, indium, platinum and rhodium, and has become the basis for surface-enhanced Raman spectroscopy (SERS) [50, 51]. The reasons for this enhancement are still not completely clear, but have been recognized to be the result of a combination of effects, including a surface electromagnetic field enhancement (in particular when illuminating rough samples with photons of energies near those of localized plasmons) and a chemical enhancement due to the change of polarizability in molecules when interacting with surfaces [52].

Since its initial development, SERS has been used for the surface characterization of a good number of systems. One important extension to the use of SERS has been in the determination of surface geometries. Figure B1.22.6 shows

an example of the SERS C–H stretching frequency data used to determine the different chemisorption geometries of 2-butanol and 2-butanethiol on silver electrodes [53]. Notice that, being an optical technique, SERS works quite well in solid–liquid interfaces. On the other hand, the need for signal enhancement normally limits the use of SERS to a handful of metals and/or to samples with rough surfaces.

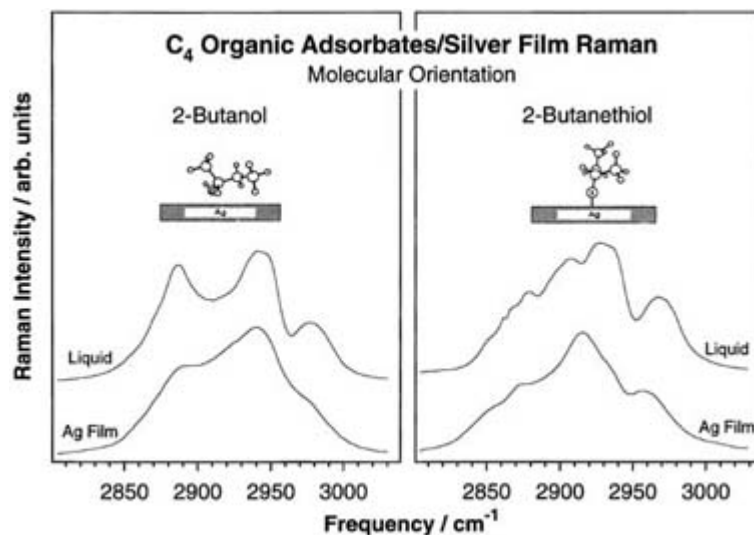

Figure B1.22.6. Raman spectra in the C–H stretching region from 2-butanol (left frame) and 2-butanethiol (right), each either as bulk liquid (top traces) or adsorbed on a rough silver electrode surface (bottom). An analysis of the relative intensities of the different vibrational modes led to the proposed adsorption structures depicted in the corresponding panels [53]. This example illustrates the usefulness of Raman spectroscopy for the determination of adsorption geometries, but also points to its main limitation, namely the need to use rough silver surfaces to achieve adequate signal-to-noise levels.

Another recent development in the use of Raman spectroscopy for the characterization of surfaces has been the employment of UV light for the initial excitation of the sample [54]. The advantage of UV over conventional Raman spectroscopy is twofold: (1) since the normal Raman scattering cross sections are proportional to the fourth power of the scattered light frequency, the use of higher-energy photons significantly increases the signal intensity and (2) by using UV light the spectral range is moved away from that where fluorescence de-excitation is observed. This allows for the Raman characterization of virtually any high-surface-area sample, including opaque solids such as black carbon. Unfortunately, UV-Raman spectroscopy is still not commercially available.

B1.22.3.2 OTHER NONLINEAR OPTICAL TECHNIQUES

Other nonlinear optical spectroscopies have gained much prominence in recent years. Two techniques in particular have become quite popular among surface scientists, namely, second harmonic (SHG) [55] and sum-frequency (SFG) [56] generation. The reason why both SHG and SFG can probe interfaces selectively without being overwhelmed by the signal from the bulk is that they rely on second-order processes that are electric-dipole forbidden in centrosymmetric media; by breaking the bulk symmetry, the surface places the molecular species in an environment where their second-order nonlinear susceptibility, the term responsible for the absorption of SHG and SFG signals, becomes non-zero.

In SHG the sample is illuminated with light of a single colour and the component at twice the initial frequency is filtered from the emitted light and analysed. Because these experiments usually involve near-IR or visible–UV photons, SHG most often probes electronic transitions. In fact, SHG has often been used as a way to measure changes in work function or localized electrostatic surface potentials. When using polarized light, SHG can also be used to determine the geometrical alignment of polar molecules at interfaces and, by sweeping the incident photon energy, spectroscopic information can be obtained on molecular orbital energies as well. Figure B1.22.7 shows an example of the latter for the case of rhodamine 6G [55]. This figure also shows a clever extension of the technique as a microscope to provide spatial information on adsorbates.

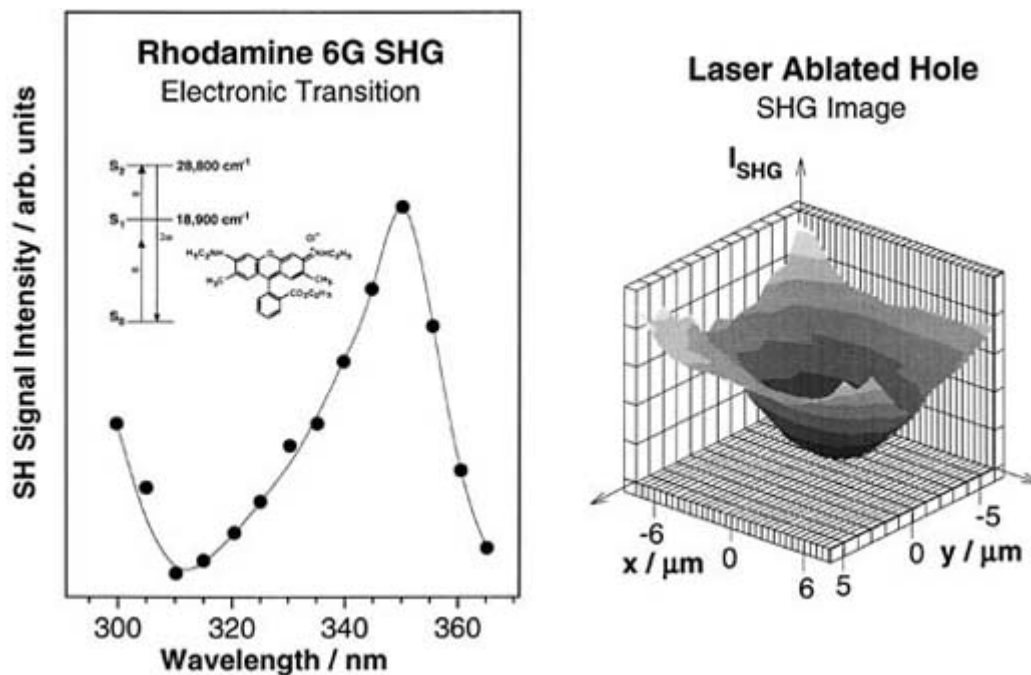

Figure B1.22.7. Left: resonant second-harmonic generation (SHG) spectrum from rhodamine 6G. The inset displays the resonant electronic transition induced by the two-photon absorption process at a wavelength of approximately 350 nm. Right: spatially resolved image of a laser-ablated hole in a rhodamine 6G dye monolayer on fused quartz, mapped by recording the SHG signal as a function of position in the film [55]. SHG can be used not only for the characterization of electronic transitions within a given substance, but also as a microscopy tool.

By combining two beams on the surface, one of visible or IR fixed frequency and a second, of variable energy in the IR region, resonance absorption can be measured by detecting the intensity of the outgoing light resulting from the addition of the two incident beams as a function of the photon energy of the variable laser. The net effect of this SFG is the acquisition of vibrational absorption spectra for surface species where signals are seen only for the modes active in both IR and Raman. Vibrational information can be obtained with SFG for almost any interface as long as lasers are available to cover the frequency range of interest and the bulk materials are transparent to the laser light. Also, as with many of the other techniques described above, orientational information can be obtained with SFG as well. Figure B1.22.8 displays data demonstrating that an increase in the concentration of acetonitrile dissolved in water leads to a collective molecular orientation change at the air/water interface [57].

Figure B1.22.8. Sum-frequency generation (SFG) spectra in the $\text{C}\equiv\text{N}$ stretching region from the air/aqueous acetonitrile interfaces of two solutions with different concentrations. The solid curve is the IR transmission spectrum of neat bulk CH_3CN , provided here for reference. The polar acetonitrile molecules adopt a specific orientation in the air/water interface with a tilt angle that changes with changing concentration, from 40° from the surface normal in dilute solutions (molar fractions less than 0.07) to 70° at higher concentrations. This change is manifested here by the shift in the $\text{C}\equiv\text{N}$ stretching frequency seen by SFG [57]. SFG is one of the very few techniques capable of probing liquid/gas, liquid/liquid, and even liquid/solid interfaces.

There are a few other surface-sensitive characterization techniques that also rely on the use of lasers. For instance surface-plasmon resonance (SPR) measurements have been used to follow changes in surface optical properties as a function of time as the sample is modified by, for instance, adsorption processes [58]. SPR has proven useful to image adsorption patterns on surfaces as well [59].

B1.22.3.3 TIME-RESOLVED PUMP-PROBE EXPERIMENTS

The dynamics of fast processes such as electron and energy transfers and vibrational and electronic de-excitations can be probed by using short-pulsed lasers. The experimental developments that have made possible the direct probing of molecular dissociation steps and other ultrafast processes in real time (in the femtosecond time range) have, in a few cases, been extended to the study of surface phenomena. For instance, two-photon photoemission has been used to study the dynamics of electrons at interfaces [60]. Vibrational relaxation times have also been measured for a number of modes such as the O–H stretching in silica and the C–O stretching in carbon monoxide adsorbed on transition metals [61]. Pump-probe laser experiments such as these are difficult, but the field is still in its infancy, and much is expected in this direction in the near future.

B1.22.4 X-RAY DIFFRACTION AND X-RAY ABSORPTION

Because x-rays are particularly penetrating, they are very useful in probing solids, but are not as well suited for the analysis of surfaces. X-ray diffraction (XRD) methods are nevertheless used routinely in the characterization of powders and of supported catalysts to extract information about the degree of crystallinity and the nature and crystallographic phases of oxides, nitrides and carbides [62, 63]. Particle size and dispersion data are often acquired with XRD as well.

One way to obtain surface sensitivity in XRD experiments with crystalline samples is to illuminate the substrate at glancing angles. Under normal conditions, x-rays projected onto the sample at incident angles of less than 10° still penetrate to a depth of 10 μm or more but, beyond a critical angle, x-ray photons are completely reflected from the surface and light propagation into the solid is *via* a rapidly attenuating evanescent wave, and this renders the x-ray probe quite surface sensitive [64]. There are several inherent difficulties in implementing grazing-angle XRD experiments, which require focusing high-intensity x-rays onto surfaces at angles of the order of 0.1° , but recent experiments have proved the usefulness of this technique in providing interesting information on the structure of robust surfaces such as oxides, nitrides, silicides and other thin films.

A related technique that also relies on the interference of x-rays for solid characterization is extended x-ray absorption fine structure (EXAFS) [65, 66]. Because the basis for EXAFS is the interference of outgoing photoelectrons with their scattered waves from nearby atoms, it does not require long-range order to work (as opposed to diffraction techniques), and provides information about the local geometry around specific atomic centres. Unfortunately, EXAFS requires the high-intensity and tunable photon sources typically available only at synchrotron facilities. Further limitations to the development of surface-sensitive EXAFS (SEXAFS) have come from the fact that it requires technology entirely different from that of regular EXAFS, involving in many cases ultrahigh-vacuum environments and/or photoelectron detection. One interesting advance in SEXAFS came with the design by Stöhr *et al* of fluorescence detectors for the x-rays absorbed by the surface species of small samples; that allows for the characterization of well defined systems such as single crystals under non-vacuum conditions [67]. Figure B1.22.9 shows the S K-edge x-ray absorption data obtained for a $(2 \times 2)\text{S-Ni}(100)$ overlayer using their original experimental set-up. This approach has since been extended to the analysis of lighter atoms (C, O, F) on many different substrates and under atmospheric pressures [68].

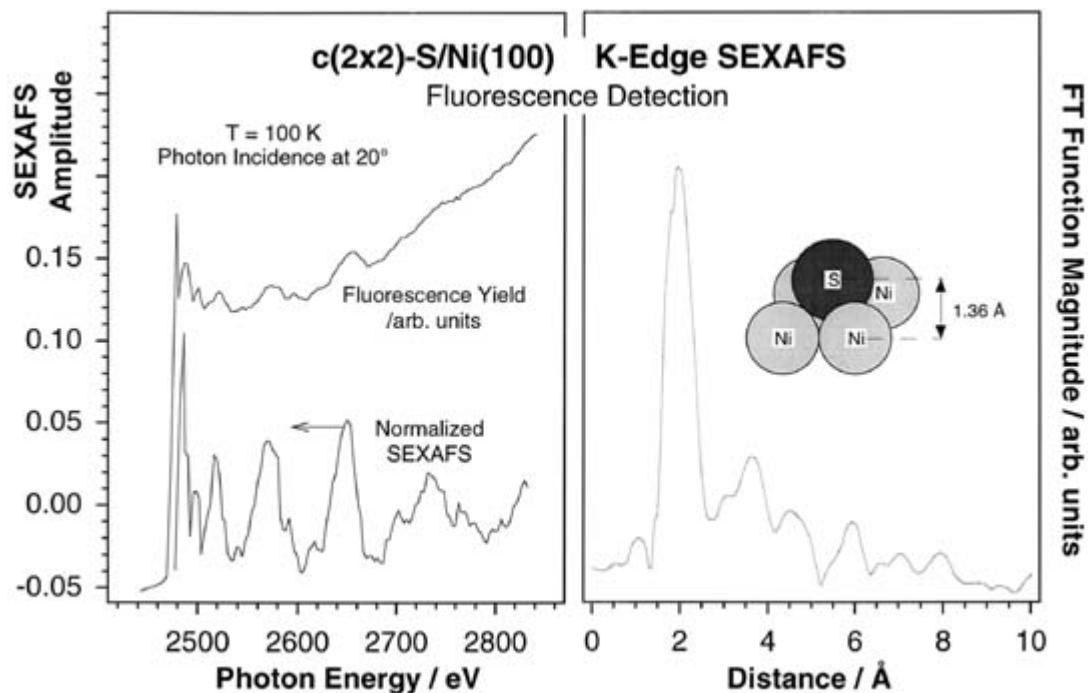

Figure B1.22.9. Fluorescence-yield, surface-extended x-ray absorption fine structure (FY-SEXAFS) spectra for the S K-edge of a $c(2 \times 2)$ ordered monolayer of sulfur atoms adsorbed on a Ni(100) surface. The upper trace in the left panel corresponds to the raw data obtained at an incident photon angle of 20° from the surface plane, while the bottom trace displays the background-subtracted and normalized SEXAFS oscillations calculated from the original spectrum. The right panel, which corresponds to the Fourier-transformed SEXAFS data, provides information on both the Ni–S bond length (2.22 \AA) and the Ni near-neighbour coordination number around each sulfur atom (4) [67]. Because EXAFS relies on the interference of an outgoing photoelectron with its own scattering from nearby atoms, it provides local geometry information without requiring long-range order. This example also illustrates the high sensitivity of the technique (these experiments were carried out with a 1 cm^2 area single crystal). The use of fluorescence detection allows for the extension of this type of study to samples in non-vacuum environments [68].

Soon after the development of EXAFS it was recognized that the signal near the x-ray absorption edge is quite complex and provides information on electronic transitions from atomic core levels to valence bands and/or molecular orbitals [69]. The analysis of that signal constitutes the basis for a technique named near-edge x-ray absorption fine structure (NEXAFS, or XANES). The shape of the x-ray absorption spectra near the absorption edge has long been used as an empirical fingerprint for the local chemical environment of oxides and other supported catalysts, but newer developments allow for the extraction of a more detailed picture of the nature and geometrical arrangement of adsorbates from those data. This is possible thanks in great part to the combination of the polarized nature of synchrotron radiation and the simplicity of the electronic transition dipoles for absorption from core levels [70]. [Figure B1.22.10](#) displays an example where the geometry of vinyl moieties adsorbed on Ni(100) surfaces was determined by using NEXAFS [71].

Figure B1.22.10. Carbon K-edge near-edge x-ray absorption (NEXAFS) spectra as a function of photon incidence angle from a submonolayer of vinyl moieties adsorbed on Ni(100) (prepared by dosing 0.2 l of ethylene on that surface at 180 K). Several electronic transitions are identified in these spectra, to both the pi (284 and 286 eV) and the sigma (>292 eV) unoccupied levels of the molecule. The relative variations in the intensities of those peaks with incidence angle can be easily converted into adsorption geometry data; the vinyl plane was found in this case to be at a tilt angle of about 65° from the surface [71]. Similar geometrical determinations using NEXAFS have been carried out for a number of simple adsorbate systems over the past few decades.

B1.22.5 OTHER OPTICAL TECHNIQUES

A few additional optical techniques need to be mentioned in this review. As discussed above, these are by and large well known spectroscopies for the study of bulk samples; it is only their extension to the study of surfaces what has not been realized to its fullest potential yet.

B1.22.5.1 OTHER UV-VISIBLE OPTICAL TECHNIQUES

Spectroscopies such as UV-visible absorption and phosphorescence and fluorescence detection are routinely used to probe electronic transitions in bulk materials, but they are seldom used to look at the properties of surfaces [72]. As with other optical techniques, one of the main problems here is the lack of surface discrimination, a problem that has sometime been bypassed by either using thin films of the materials of interest [73, 74], or by using a reflection detection scheme. Modulation of a parameter, such as electric or magnetic fields, stress, or temperature, which affects the optical properties of the sample and detection of the AC component of the signal induced by such periodic changes, can also be used to achieve good surface sensitivity [75]. This latter approach is the basis for techniques such as surface reflectance spectroscopy, reflectance difference spectroscopy/reflectance anisotropy spectroscopy, surface photoadsorption

spectroscopy and surface differential reflectivity [76, 77 and 78]. Early optical characterization studies of solid surfaces were instrumental in the detection and characterization of intrinsic surface electronic states due to the uniqueness of the interface environments. Ellipsometry is also a mature technique often used to obtain film thickness and other optical properties [79].

One interesting new field in the area of optical spectroscopy is near-field scanning optical microscopy, a technique that allows for the imaging of surfaces down to sub-micron resolution and for the detection and characterization of single molecules [80, 81]. When applied to the study of surfaces, this approach is capable of identifying individual adsorbates, as in the case of oxazine molecules dispersed on a polymer film, illustrated in figure B1.22.11 [82]. Absorption and emission spectra of individual molecules can be obtained with this technique as well, and time-dependent measurements can be used to follow the dynamics of surface processes.

B1.22.5.2 MAGNETIC RESONANCE

NMR has developed into a powerful analytical technique in the past decades, and has been used extensively in the characterization of a great number of chemical systems. Its extension to the study of surfaces, however, has been hampered by the need of large samples because of its poor sensitivity. On the other hand, the development of magic-angle-spinning NMR (MAS-NMR) and the extension of NMR to many nuclei besides hydrogen have opened the doors for the use of that technique to many solids. For instance, MAS ^1H NMR has been quite useful in the research on Brønsted acidity in oxides [83]. Also, the study of zeolites with NMR is now practically routine: the chemical shifts in ^{29}Si NMR data are easily interpreted in terms of the number of aluminium atoms next to a given silicon centre, and the position of the ^{27}Al peaks provides information on the coordination number and geometry of the aluminium atoms [84]. ^{129}Xe NMR has been used to probe both the local environment inside porous materials [83] and heterogeneities in adsorbates [85]. Dynamic studies on the thermal conversion of adsorbates on transition metal catalysts have been performed as well [86].

Other magnetic measurements of catalysts include electron paramagnetic resonance and magnetic susceptibility. Although those are not as common as NMR, they can be used to look at the properties of paramagnetic and ferromagnetic samples. Examples of these applications can be found in the literature [87, 88].

-18-

Figure B1.22.11. Near-field scanning optical microscopy fluorescence image of oxazine molecules dispersed on a PMMA film surface. Each protuberance in this three-dimensional plot corresponds to the detection of a single molecule, the different intensities of those features being due to different orientations of the molecules. Sub-diffraction resolution, in this case on the order of a fraction of a micron, can be achieved by the near-field scanning arrangement. Spectroscopic characterization of each molecule is also possible. (Reprinted with permission from [82]. Copyright 1996 American Chemical Society.)

B1.22.5.3 SPECTROSCOPIES WHICH RELY ONLY IN PART ON PHOTONS

A number of surface-sensitive spectroscopies rely only in part on photons. On the one hand, there are techniques where the sample is excited by electromagnetic radiation but where other particles ejected from the sample are used for the characterization of the surface (photons in; electrons, ions or neutral atoms or moieties out). These include photoelectron spectroscopies (both x-ray- and UV-based) [89, 90 and 91], photon stimulated desorption [92], and others. At the other end, a number of methods are based on a particles-in/photons-out set-up. These include inverse photoemission and ion- and electron-stimulated fluorescence [93, 94]. All these techniques are discussed elsewhere in this encyclopaedia.

B1.23 Surface structural determination: particle scattering methods

J Wayne Rabalais

B1.23.1 INTRODUCTION

The origin of scattering experiments has its roots in the development of modern atomic theory at the beginning of this century. As a result of both the Rutherford experiment on the scattering of alpha particles (He nuclei) by thin metallic foils and the Bohr theory of atomic structure, a consistent model of the atom as a small massive nucleus surrounded by a large swarm of light electrons was confirmed. Following these developments, it was realized that the inverse process, namely, analysis of the scattering pattern of ions from crystals, could provide information on composition and structure. This analysis is straightforward because the kinematics of energetic atomic collisions is accurately described by classical mechanics. Such scattering occurs as a result of the mutual Coulomb repulsion between the colliding atomic cores, that is, the nucleus plus core electrons. The scattered primary atom loses some of its energy to the target atom. The latter, in turn, recoils into a forward direction. The final energies of the scattered and recoiled atoms and the directions of their trajectories are determined by the masses of the pair of atoms involved and the closeness of the collision. By analysis of these final energies and angular distributions of the scattered and recoiled atoms, the elemental composition and structure of the surface can be deciphered.

Low-energy (1–10 keV) ion scattering spectrometry (ISS) had its beginning as a modern surface analysis technique with the 1967 work of Smith [1], which demonstrated both surface elemental and structural analysis. Over the next twenty years, it was clearly demonstrated [2, 3, 4, 5 and 6] that direct surface structural information could be obtained from ISS. Most of the early workers used electrostatic analysers to measure the kinetic energies of the scattered ions. There are two problems with this technique. (i) It analyses only the scattered ions; these are typically only a very small fraction (<5%) of the total scattered flux. Thus, high primary ion doses are required for spectral acquisition which are potentially damaging to the surface and adsorbate structures. (ii) Neutralization probabilities are a function of the ion beam incidence angle α with the surface and the azimuthal angle δ along which the ion beam is directed. This is not a simple behaviour since the probabilities depend on the distances of the ion to specific atoms. As a result, it is difficult to separate scattering intensity changes due to neutralization effects from those due to structural effects. The use of alkali primary ions [7] which have low neutralization probabilities leads to higher scattering intensities and pronounced focusing effects, however, the contamination of the sample surface by the reactive alkali ions is a potential problem with this method. Buck and co-workers [8], who had been developing time-of-flight (TOF) methods for ion scattering since the mid 1970s, used TOF methods for surface structure analysis in 1984 and demonstrated the capabilities and high sensitivity of the technique when both neutrals and ions are detected simultaneously. A TOF spectrometer system with a long flight path for separation of the scattered and recoiled particles and continuous variation of the scattering θ and recoiling ϕ angles was developed in 1990 [9]. This coupling of TOF methods with detection of both scattered and recoiled particles led to the development of TOF scattering and recoiling spectrometry (TOF-SARS) as a tool for structural analysis [10]. A large, time-gated, position-sensitive microchannel plate detector was used in 1997 to obtain images of the scattered and recoiled particles, leading to the development of scattering and recoiling imaging spectrometry (SARIS) [11]. Several research groups [12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23 and 24] throughout the world are now engaged in surface structure determinations using some form of low-keV ISS.

This section will concentrate on TOF-SARS and SARIS, for it is felt that these are the techniques that will be most important in future applications. Also, emphasis will be placed on surface structure determinations rather than surface elemental analysis, because TOF-SARS and SARIS are capable of making unique contributions in the area of structure determination. The use of TOF methods and large-area position-sensitive detectors has led to a surface crystallography that is sensitive to all elements, including the ability to directly detect hydrogen adsorption sites. TOF detection of both neutrals and ions provides the high sensitivity necessary for non-destructive analysis. Detection of atoms scattered and recoiled from surfaces in simple collision sequences, together with calculations of shadowing and blocking cones, can now be used to make direct

measurements of interatomic spacings and adsorption sites within an accuracy of less than 0.1 Å.

B1.23.2 BASIC PHYSICS UNDERLYING KEV ION SCATTERING AND RECOILING

There are two basic physical phenomena which govern atomic collisions in the keV range. First, repulsive interatomic interactions, described by the laws of classical mechanics, control the scattering and recoiling trajectories. Second, electronic transition probabilities, described by the laws of quantum mechanics, control the ion–surface charge exchange process.

B1.23.2.1 KINEMATICS OF ION–SURFACE COLLISIONS AND ELEMENTAL ANALYSIS

The dynamics of ion surface scattering at energies exceeding several hundred electronvolts can be described by a series of binary collision approximations (BCAs) in which only the interaction of one energetic particle with a solid atom is considered at a time [25]. This model is reasonable because the interaction time for the collision is short compared with the period of phonon frequencies in solids, and the interaction distance is shorter than the interatomic distances in solids. The BCA simplifies the many-body interactions between a projectile and solid atoms to a series of two-body collisions of the projectile and individual solid atoms. This can be described with results from the well known two-body central force problem [26].

Within the BCA, the trajectories of energetic particles on the surface become a series of linear motion segments between neighbouring atoms. Both the scattered and recoiled atoms have high, discrete kinetic energy distributions. The simplest case of ion–surface scattering phenomena is quasi-single scattering (QSS), which represents the case of one large-angle deflection that is preceded and/or followed by a few small deflections. [Figure B1.23.1](#) shows an example of QSS. This typically produces a sharp scattering peak whose energy is near that of the theoretical single-collision energy. The energies of scattered and recoiled particles in single scattering (SS) can be derived from the laws of conservation of energy and momentum. The energy E_s of a projectile scattered from a stationary target is given as

-3-

$$E_s = E_0 \{ (\cos \theta \pm (A^2 - \sin^2 \theta)^{1/2})^2 / (1 + A)^2 \} \quad (\text{B1.23.1})$$

where $A = M_t/M_p$, and E_0 , M_t , and M_p are the initial energy of the projectile and the mass of the target and the projectile, respectively. If the mass of the impinging particle is less than or equal to that of the target atom then $A \geq 1$, and only the positive sign is used. If the scattering angle is chosen as 90° , equation (B1.23.1) can be simplified to

$$\frac{E_s}{E_0} = \frac{A - 1}{A + 1} \quad (\text{B1.23.2})$$

Solving for M_t yields

$$M_t = M_p \frac{1 + B}{1 - B} \quad (\text{B1.23.3})$$

where $B = E_s/E_0$. If the mass of the impinging particle is greater than that of the target atom, $M_p > M_t$, and both signs are used in the equation. The energy of the scattered particle is then found to be a double-valued function of the scattering angle θ , i.e. there are two E_s for each θ . For the case of $A < 1$, the maximum SS scattering angle is

$$\theta_{\max} = \sin^{-1} A. \quad (\text{B1.23.4})$$

For angles greater than θ_{\max} , only multiple scattering can occur.

The energy of scattered or recoiled ions can be measured directly by means of an electrostatic energy analyser. If the TOF method is used, the relation between scattering energy E_s and TOF t_s is expressed as

$$E_s = \frac{1}{2} M_s v_s^2 = \frac{1}{2} M_s \left(\frac{d_{\text{tof}}}{t_s} \right)^2 \quad (\text{B1.23.5})$$

and

$$t_s = d_{\text{tof}} \sqrt{\frac{M_s}{2E_s}} \quad (\text{B1.23.6})$$

where d_{tof} is the flight distance of the scattered atom.

Figure B1.23.1. (a) Two-body collision of a projectile of mass M_p and kinetic energy E_0 approaching a stationary target of mass M_t with an impact parameter p . (b) Quasi-single scattering and direct recoiling with

incident angle α and exit angle β , based on the BCA.

The intensity of SS I_i from an element i in the solid angle $\Delta\Omega$ is proportional to the initial beam intensity I_0 , the concentration of the scattering element N_i , the neutralization probability P_i , the differential scattering cross section $d\sigma(\theta)/d\Omega$, the shadowing coefficient $f_{si}(\alpha, \delta_{in})$ and the blocking coefficient $f_{bi}(\alpha, \delta_{out})$ for the i th component on the surface:

$$I_i \approx I_0 N_i P_i f_{si} f_{bi} \frac{d\sigma}{d\Omega} \Delta\Omega. \quad (\text{B1.23.7})$$

Similar to QSS, direct recoil (DR) of surface atoms produces energetic atoms that have a relatively narrow velocity distribution. DR particles are those species which are recoiled from the surface layers as a result of a direct collision of the primary ion. They escape from the surface with little energy loss through collisions with neighbouring atoms. The energy E_r of a DR surface atom can be expressed as

$$E_r = E_0 \{4A \cos^2 \phi\} / (1 + A)^2. \quad (\text{B1.23.8})$$

-5-

From geometry considerations, DR is observed only in the forward-scattering direction for which $\phi < 90^\circ$. A similar expression as [equation \(B1.23.7\)](#) is applicable for recoiling intensity evaluation. All elements, including hydrogen, can be analysed by either scattering, recoiling, or both techniques. TOF peak identification of QSS and DR is straightforward using the equations above.

B1.23.2.2 SHADOW CONES, BLOCKING CONES, AND STRUCTURAL ANALYSIS

A simple interpretation based on the BCA yields some important concepts for ion scattering and recoiling: shadow cones and blocking cones. As shown in [figure B1.23.2\(a\)](#) scattering of ions by a target atom produces a region in which no ion can penetrate behind the target atom. This region is called a shadow cone. The cone dimensions can be evaluated from known interatomic distances in experiments. [figure B1.23.2\(b\)](#) shows the normalized ion flux density across the shadow cone. There is zero flux density inside of the shadow cone and unit flux density far outside of the cone. Highly focused ion flux density appears at the boundary of the cone. This anisotropic distribution of ion flux after interaction with a target atom is the basis of ISS structural determinations. If a neighbouring atom lies inside the shadow cone (A in (a)), it cannot be scattered or recoiled. If it is well away from the cone (C), the cone has no effect on the intensity. When it lies in the focusing region (B), enhanced intensity scattering and/or recoiling intensity is observed. TOF-SARS measures the intensity change due to the shadow cone effect on neighbouring atoms as a function of incident beam direction.

Trajectories of ions interacting with an additional target atom (blocking atom) after scattering from the initial target atom (scattering atom) produce a hollow region behind the blocking atom called a blocking cone ([figure B1.23.2\(c\)](#)). It can be regarded as an interaction of a target atom (blocking atom) with ions emitted from an adjacent point ion source (scattering atom). A shadow cone is different because it originates from the interaction with ions from an infinitely distant point ion source (ion source in the ion beam line). Unlike a shadow cone, a blocking cone diverges with a measurable blocking cone angle ξ . The closer the blocking atom is to the scattering atom, the larger is the angle of divergence. In traditional ISS, the variation of the interactions of both shadowing and blocking cones are measured. It is possible to minimize the effect of blocking cones by a judicious choice of scattering geometry. Blocking cones are, however, inevitable, especially for scattering trajectories from deep subsurface layers.

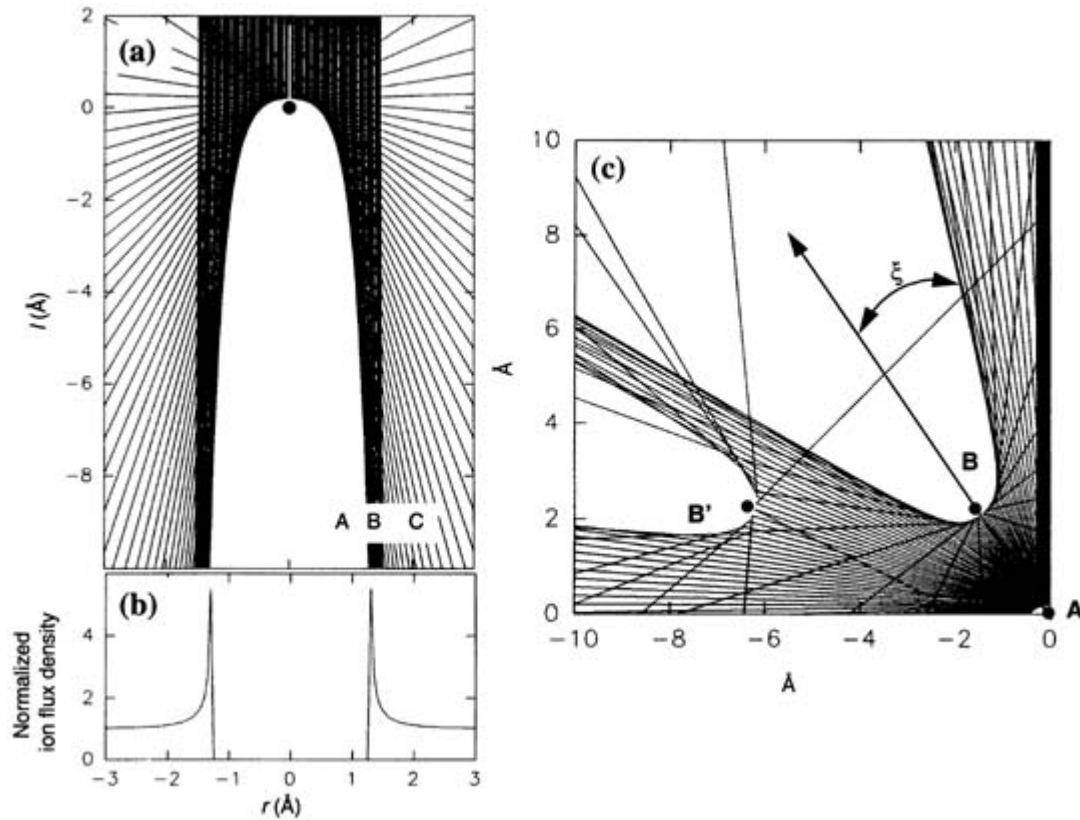

Figure B1.23.2. (a) Shadow cone of a stationary Pt atom in a 4 keV Ne^+ ion beam, appearing with the overlapping of ion trajectories as a function of the impact parameter. The initial position of the target atom that recoils in the collision is indicated by a solid circle. (b) Plot of the normalized ion flux distribution density across the shadow cone in (a). The flux density changes from 0 inside the shadow cone, to much greater than ~ 1 in the focusing region, converging to 1 away from the shadow cone edge. (c) Blocking cones of Pt atoms (B, B') cast by 4 keV Ne^+ ions scattered from another Pt atom (A). Note the different blocking angles of the two blocking atoms, which is due to the differences in the interatomic spacings between the scattering and blocking atoms.

Considering a large number of ions with parallel trajectories impinging on a target atom, the ion trajectories are bent by the repulsive potential such that there is an excluded volume, called the shadow cone, in the shape of a paraboloid formed behind the target atom as shown in [figure B1.23.3\(a\)](#). Ion trajectories do not penetrate into the shadow cone, but instead are concentrated at its edges much as rain pours off an umbrella. Atoms located inside the cone behind the target atom are shielded from the impinging ions. Similarly, if the scattered ion or recoiling atom trajectory is directed towards a neighbouring atom, that trajectory will be blocked. For a large number of scattering or recoiling trajectories, a blocking cone will be formed behind the neighbouring atom into which no particles can penetrate, as shown in [figure B1.23.3\(b\)](#). The dimensions of the shadowing and blocking cones can be determined experimentally from scattering measurements along crystal azimuths for which the interatomic spacings are accurately known.

Figure B1.23.3. Schematic illustrations of backscattering with shadowing and direct recoiling with shadowing and blocking.

B1.23.2.3 SCATTERING AND RECOILING ANISOTROPY CAUSED BY SHADOWING AND BLOCKING CONES

When an isotropic ion fluence impinges on a crystal surface at a specific incident angle α , the scattered and recoiled atom flux is anisotropic. This anisotropy is a result of the incoming ion's eye view of the surface, which depends on the specific arrangement of atoms and the shadowing and blocking cones. The arrangement of atoms controls the atomic density along the azimuths and the ability of ions to channel, that is, to penetrate into empty spaces between atomic rows. The cones determine which nuclei are screened from the impinging ion flux and which exit trajectories are blocked, as depicted in figure B1.23.3. By measuring the ion and atom flux at specific scattering and recoiling angles as a function of ion beam incident α and azimuthal δ angles to the surface, structures are observed which can be interpreted in terms of the interatomic spacings and shadow cones from the ion's eye view.

(A) TIME OF FLIGHT SCATTERING AND RECOILING SPECTROMETRY (TOF-SARS)—SHADOW CONE BASED EXPERIMENT

In TOF-SARS [9], a low-keV, monoenergetic, mass-selected, pulsed noble gas ion beam is focused onto a sample surface. The velocity distributions of scattered and recoiled particles are measured by standard TOF methods. A channel electron multiplier is used to detect fast (>800 eV) neutrals and ions. This type of detector has a small acceptance solid angle. A fixed angle is used between the pulsed ion beam and detector directions with respect to the sample as shown in figure B1.23.4. The sample has to be rotated to measure ion scattering

and recoiling anisotropy as a function of the incident angle (α) and azimuthal angle (δ) of the incident beam. Since the sample rotation changes both the incident beam direction and the detector direction, the spectra are affected by both shadow cones and blocking cones. In order to reduce blocking cone effects for simpler interpretations, high-angle scattering is preferred. Elemental analyses are achieved by converting the velocity distributions into energy distributions and relating those to the masses of the target atoms through the kinematic relationship that describes classical scattering and recoiling (equation (B1.23.1) and equation (B1.23.8)). Structural analyses are achieved by monitoring the scattered and recoiled particles as a function of both beam incident angle α and crystal azimuthal angle δ . The anisotropic features in these α - and δ -scans are interpreted by means of shadow cone and blocking cone analyses. It requires several hours to collect data needed to construct a contour map of intensities as a function of both α and δ . Moreover, the experimental geometry is restricted to fixed scattering angles and in-plane scattering and recoiling trajectories.

(B) SCATTERING AND RECOILING IMAGING SPECTROMETRY (SARIS)—BLOCKING CONE BASED EXPERIMENT

In an ideal SARIS system [11], it would be desirable to measure the velocity distributions of all the energetic particles scattered and recoiled from a sample surface in a short time period. This concept requires a hemispherical, time-resolving, position-sensitive detector which covers all of the solid angle space above the sample surface. Implementation of this concept is not currently feasible. If data collection time is unimportant, a point detector as described above, such as a channel electron multiplier mounted on a flexible goniometer which allows movement of the detector over a large solid angle, can be used to collect TOF spectra. In order to compromise the size of detector with data collection time, a hybrid configuration can be used. This is a large, time-resolving, position-sensitive microchannel plate detector mounted on a triple-axis UHV goniometer. This instrument makes it possible to capture scattering and recoiling intensity distributions without changing the incident beam direction. It gives a great advantage in comparison of experimental results with those of computer simulations. The large-area detector provides the intensity distribution over a limited solid angle. Since the optimum detector position and flight distance for a specific experiment are variable, the detector has to be moved around to cover a large solid angle, and to compromise TOF resolution with the detector acceptance solid angle.

Figure B1.23.4. Schematic diagram of TOF scattering and recoiling spectrometry (TOF-SARS) illustrating the plane of scattering formed by the ion beam, sample and detector. TOF spectra (a) are collected with fixed

positions of the ion beam, sample and detector. In order to measure the incident angle (α) or azimuthal angle (δ) intensity variation of a peak in a TOF spectrum, the sample is rotated about an axis that goes through its normal or through its plane, respectively. Such α and δ intensity variations of a peak are shown in (b) and (c).

B1.23.3 INSTRUMENTATION

The basic requirements [9] for low-energy ion scattering are an ion source, a sample mounted on a precision manipulator, an energy or velocity analyser and a detector as shown in [figure B1.23.5](#). The sample is housed in an ultra-high vacuum (UHV) chamber in order to prepare and maintain well defined clean surfaces. The UHV prerequisite necessitates the use of differentially pumped ion sources. Ion scattering is typically done in a UHV chamber which houses other surface analysis techniques such as low-energy electron diffraction (LEED), x-ray photoelectron spectroscopy (XPS) and Auger electron spectroscopy (AES). The design of an instrument for ion scattering is based on the type of analyser to be used. An electrostatic analyser (ESA) measures the kinetic energies of ions while a TOF analyser measures the velocities of both ions and fast neutrals.

-10-

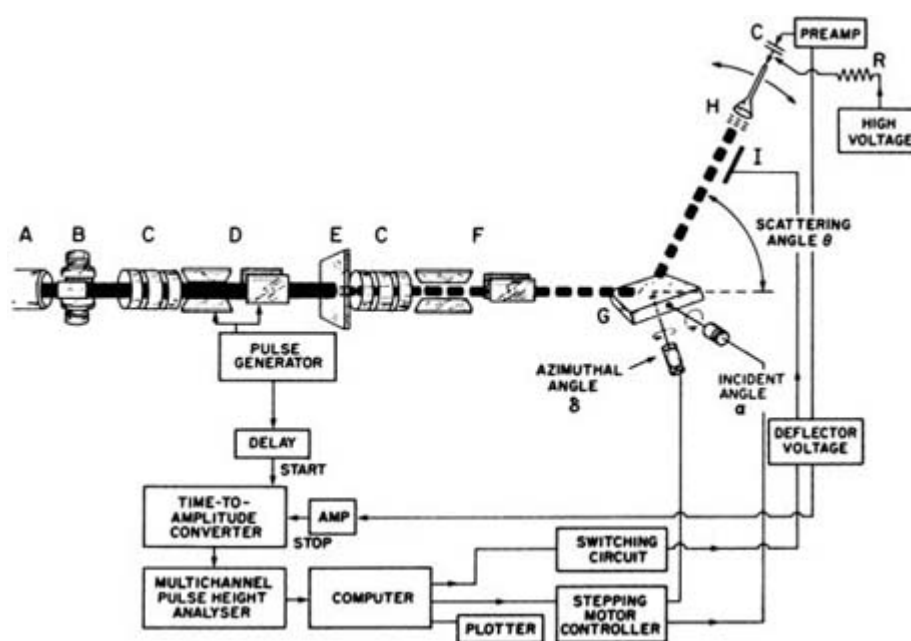

Figure B1.23.5. Schematic illustration of the TOF-SARS spectrometer system. A = ion gun, B = Wien filter, C = Einzel lens, D = pulsing plates, E = pulsing aperture, F = deflector plates, G = sample, H = electron multiplier detector with energy prefilter grid and I = electrostatic deflector.

B1.23.3.1 ION SOURCE AND BEAM LINE

The critical requirements for the ion source are that the ions have a small energy spread, there are no fast neutrals in the beam and the available energy is 1–10 keV. Both noble gas and alkali ion sources are common. For TOF experiments, it is necessary to pulse the ion beam by deflecting it past an aperture. A beam line for such experiments is shown in [figure B1.23.5](#) it is capable of producing ion pulse widths of ≈ 15 ns.

B1.23.3.2 ANALYSERS

An ESA provides energy analysis of the ions with high resolution. A TOF analyser provides velocity analysis

of both fast neutrals and ions with moderate resolution. In an ESA the energy separation is made by spatial dispersion of the charged particle trajectories in a known electrical field. ESAs were the first analysers used for ISS; their advantage is high-energy resolution and their disadvantages are that they analyse only ions and have poor collection efficiency due to the necessity for scanning the analyser. A TOF analyser is simply a long field-free drift region. It has the advantage of high efficiency since it collects both ions and fast neutrals simultaneously in a multichannel mode; its disadvantage is only moderate resolution.

B1.23.3.3 DETECTORS

The most common detectors used for TOF-SARS are continuous dynode channel electron multipliers which are capable of multiplying the signal pulses by 10^6 – 10^7 . They are sensitive to both ions and fast neutrals. Neutrals with

-11-

velocities $\gtrsim 10^6$ cm s⁻¹ are detected with the same efficiency as ions. Since the cones of these detectors are usually less than 1 cm² and the TOF flight paths are of the order of ~1 m, the acceptance solid angles of such detectors are very small. Incident and azimuthal angle scans are made by rotating the sample with the detector at a fixed position.

SARIS overcomes the limitations of small-area detectors by using a large, time-resolving, position-sensitive microchannel plate (MCP) detector and TOF methods to capture images of both ions and fast neutrals that are scattered and recoiled from a surface. Due to the large solid angle subtended by the MCP, atoms that are scattered and recoiled in both planar and non-planar directions are detected simultaneously. For example, with a 75 × 95 mm MCP situated at a distance of 16 cm from the sample, it spans a solid angle of ~0.3 sr corresponding to an azimuthal range of ~26°. Using a beam current of ~0.1 nA cm⁻², the four images required to make up a 90° azimuthal range can be collected in ~2 min with a total ion dose of ~10¹¹ ions cm⁻². The time gating of the MCP provides resolution of the scattered and recoiled atoms into time frames as short as 10 ns, thereby providing element-specific spatial-distribution images. These SARIS images contain features that are sharply focused into well defined patterns as a function of both space and time by the crystal structure of the target sample. If the MCP is mounted on a goniometer that provides both horizontal and vertical rotation and translation away from the sample, it is possible to change the solid angle of collection and the flight path length.

B1.23.4 COMPUTER SIMULATION METHODS

It is extremely helpful to use classical ion trajectory simulations in order to visualize the ion trajectories to improve the understanding of ion behaviour in the surface region and to provide a systematic method for surface structure determination. Such simulations are based on the BCA in which the trajectories of the energetic particles are assumed to be a series of straight lines corresponding to the asymptotes of the scattering trajectories due to sequential binary collisions. The BCA has been proven to be valid for the keV range of energies.

B1.23.4.1 BINARY COLLISION APPROXIMATION

Atom–surface interactions are intrinsically many-body problems which are known to have no analytical solutions. Due to the shorter de Broglie wavelength of an energetic ion than solid interatomic spacings, the energetic atom–surface interaction problem can be treated by classical mechanics. In the classical mechanical

framework, the problem becomes a set of Newtonian equations of motion [26] for i th particle in an N -body problem.

$$\mathbf{F}_i = m_i \frac{d^2 \mathbf{r}_i}{dt^2} = -\nabla \Phi(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_N). \quad (\text{B1.23.9})$$

The summation of pair-wise potentials is a good approximation for molecular dynamics calculations for simple classical many-body problems [27]. It has been widely used to simulate hyperthermal energy (>1 eV) atom–surface scattering:

$$\mathbf{F}_i \approx - \sum_j^{N, i \neq j} \nabla \Phi(\mathbf{r}_i, \mathbf{r}_j). \quad (\text{B1.23.10})$$

-12-

As the kinetic energy involved in the system goes higher, the interaction of energetic particles is more and more localized near the nuclei. When the interaction distance is much smaller than interatomic distances in the system, the BCA is valid:

$$\mathbf{F}_i \approx -\nabla \Phi(\mathbf{r}_i, \mathbf{r}_j) \quad j = \text{the nearest neighbour of } i. \quad (\text{B1.23.11})$$

In the BCA, each collision process is regarded as an isolated event. Ion–solid interactions are approximated by a series of two-body interactions which are reduced to one-body problems in the centre-of-mass (CM) coordinates. The projectile is assumed to converge to the asymptote after a collision before interacting with the next collision partner. In the central force one-body problem, evaluation of scattering integrals and time integrals replaces the time-consuming numerical integration of a set of differential equations.

B1.23.4.2 SCATTERING INTEGRAL AND TIME INTEGRAL

Once atom–surface scattering is reduced to the BCA, one can calculate the energy relationship between two particles involved in scattering with a known scattering angle and the laws of conservation of energy and momentum as shown in section B1.23.2.1. The scattering angle as a function of impact parameter necessitates evaluation of the scattering integrals. The scattering angle, χ in the CM coordinate system, and the CM energy E , are given by

$$\chi = \pi - 2 \int_{r_0}^{\infty} \frac{p \, dr}{r^2} \left(1 - \frac{V(r)}{E} - \frac{p^2}{r^2} \right)^{-1/2} \quad (\text{B1.23.12})$$

where

$$E = \frac{A}{1+A} E_0. \quad (\text{B1.23.13})$$

$A = M_t/M_p$, p is impact parameter and r_0 is the distance of closest approach (apsis) of the collision pair. The transformations from the CM coordinates (scattering angle χ) to the laboratory coordinates with the scattering angle θ for the primary particle and ϕ for the recoiled surface atoms is given by

$$\tan \theta = \frac{A \sin \chi}{1 + A \cos \chi} \quad (\text{B1.23.14})$$

and

$$\tan \phi = \frac{\sin \theta}{1 - \cos \chi}. \quad (\text{B1.23.15})$$

-13-

For accurate ion trajectory calculation in the solid, it is necessary to evaluate the exact positions of the intersections of the asymptotes (Δ_1, Δ_2) of the incoming trajectory and that of the outgoing trajectories of both the scattered and recoiled particles in a collision. The evaluation of these values requires time integrals and the following transformation equations:

$$t = \sqrt{r_0^2 - p^2} - \int_{r_0}^{\infty} \left\{ \left(1 - \frac{V(r)}{E_r} - \frac{p^2}{r^2} \right)^{-1/2} \left(1 - \left(\frac{p^2}{r^2} \right) \right)^{-1/2} \right\} dr \quad (\text{B1.23.16})$$

$$\Delta_1 = \frac{t + (A - 1)p \tan \frac{1}{2}\chi}{1 + A} \quad (\text{B1.23.17})$$

$$\Delta_2 = \frac{p}{\tan \phi} - \Delta_1. \quad (\text{B1.23.18})$$

Numerical integration methods are widely used to solve these integrals. The Gauss–Muhler method [28] is employed in all of the calculations used here. This method is a Gaussian quadrature [29] which gives exact answers for Coulomb scattering.

B1.23.4.3 POTENTIAL FUNCTION

One of the most important issues in simulation of energetic atom–surface scattering is the determination of the interaction potential between the colliding atoms. In the low-keV energy region, electrons have a screening effect on the Coulomb interaction of nuclei so that the actual nuclear charges affecting the trajectories are less than the atomic numbers (Z) of the atoms involved. This screening effect decreases the potential $V(r)$ by an amount which is expressed as a screening function $\Phi(r)$. The form of the potential function is

$$V(r) = \frac{Z_1 Z_2 e^2}{r} \Phi(r). \quad (\text{B1.23.19})$$

The $\Phi(r)$ can be expressed in various forms [30], e.g. the Bohr, Born–Mayer, Thomas–Fermi–Firsov and Moliere models, as well as the ‘universal potential’ of Ziegler, Biersack and Littmark known as the ZBL potential [31]. The ZBL potential function is expressed as

$$\Phi(r) = 0.1818 e^{-3.2/ar} + 0.5099 e^{0.9423/ar} + 0.2802 e^{0.4029/ar} + 0.02817 e^{0.2016/ar} \quad (\text{B1.23.20})$$

where the screening length $a = (0.8853 C_F a_0 / (Z_1^{0.23} + Z_2^{0.23}))$, a_0 is Bohr radius (0.53 Å), Z_1, Z_2 are the atomic numbers of the atoms involved and C_F is a screening constant for adjusting the screening length to calibrate the potential to experimental scattering data. The ZBL potential provides good agreement between simulated

and experimental results.

-14-

B1.23.4.4 GENERAL DESCRIPTION OF SIMULATION PROGRAM

Classical ion trajectory computer simulations based on the BCA are a series of evaluations of two-body collisions. The parameters involved in each collision are the type of atoms of the projectile and the target atom, the kinetic energy of the projectile and the impact parameter. The general procedure for implementation of such computer simulations is as follows. All of the parameters involved in the calculation are defined: the surface structure in terms of the types of the constituent atoms, their positions in the surface and their thermal vibration amplitude; the projectile in terms of the type of ion to be used, the incident beam direction and the initial kinetic energy; the detector in terms of the position, size and detection efficiency; the type of potential functions for possible collision pairs.

After defining the input parameters, the calculation of the trajectories of an incident ion begins with a randomly chosen initial entrance point on the surface. The next step is to find the first collision partner. Taking advantage of the symmetry of the crystal structure, one can list the positions of surface atoms within a certain distance from the projectile. The atoms are sorted in ascending order of the scalar product of the interatomic vector from the atom to the projectile with the unit velocity vector of the projectile. If the collision partner has larger impact parameter than a predefined maximum impact parameter (p_{\max}), it is discarded. If a partner has a shorter impact parameter than p_{\max} , the evaluation of the collision is initiated by converting three-dimensional information, such as the positions of the projectile and the target atom and the velocity of the projectile, into the parameters necessary to calculate the expressions for the impact parameter and the relative energy. After the equations are solved with these parameters, the values are converted back to three-dimensional information to search for a new collision partner with a new set of parameters calculated in the previous collision. This procedure is repeated until the kinetic energy of the projectile falls below a predefined cutoff energy or it ejects from the surface. If it is necessary to follow recoiled particles, they are regarded as new projectiles in subsequent collisions. After finishing a trajectory calculation, a new calculation starts with a new randomly chosen entrance point. Millions of trajectory calculations with different initial impact parameters are carried out in order to compare the results with those of experiments. In order to increase the speed of the calculation, a precalculated table of scattering angle and scattered energy as a function of impact parameter and kinetic energy is used. A two-dimensional spline method is used to interpolate a scattering angle and energy from the table.

(A) CRYSTAL MODELS WITH THERMAL VIBRATION INCLUSION

The lattice atoms in the simulation are assumed to vibrate independently of one another. The displacements from the equilibrium positions of the lattice atoms are taken as a Gaussian distribution, such as

$$\rho(x) = \frac{1}{\sqrt{2\pi}\sigma} e^{-\Delta x^2/2\sigma^2} \quad (\text{B1.23.21})$$

where σ^2 and Δx are the variance and the displacement from the lattice equilibrium position, respectively. The variance of the distribution can be expressed as [32]

$$\sigma^2 = \overline{\Delta x^2} = \frac{2h^2T}{4\pi^2mk\Theta_D^2} \quad (\text{B1.23.22})$$

where Θ_D is the Debye temperature. The Box–Muller method [29] is used for generating random deviates with a Gaussian distribution.

(B) COMPARISON OF SIMULATED AND EXPERIMENTAL DATA

A systematic comparison of two sets of data requires a numerical evaluation of their likeliness. TOF-SARS and SARIS produce one- and two-dimensional data plots, respectively. Comparison of simulated and experimental data is accomplished by calculating a one- or two-dimensional reliability (R) factor [33], respectively, based on the R -factors developed for LEED [34]. The R -factor between the experimental and simulated data is minimized by means of a multiparameter simplex method [33].

B1.23.5 ELEMENTAL ANALYSIS FROM SCATTERING AND RECOILING

TOF-SARS and SARIS are capable of detecting all elements by either scattering, recoiling or both techniques. TOF peak identification is straightforward by converting equation (B1.23.1) and equation (B1.23.8) to the flight times of the scattered t_s and recoiled t_r particles as

$$t_s = L(M_1 + M_2)/(2M_1 E_0)^{1/2} \{ \cos + [(M_2/M_1)^2 - \sin^2 \theta]^{1/2} \} \quad (\text{B1.23.23})$$

and

$$t_r = L(M_1 + M_2)/(8M_1 E_0)^{1/2} \cos \phi \quad (\text{B1.23.24})$$

where L is the flight distance, that is, the distance from target to detector. Collection of neutrals plus ions results in scattering and recoiling intensities that are determined by elemental concentrations, shadowing and blocking effects and classical cross sections. The main advantage of TOF-SARS for surface compositional analyses is its extreme surface sensitivity as compared to the other surface spectrometries, i.e. mainly XPS and AES. Indeed, with a correct orientation and aperture of the shadow cone, the first monolayer can be probed selectively. At selected incident angles, it is possible to delineate signals from specific subsurface layers. Detection of the particles independently of their charge state eliminates ion neutralization effects. Also, the multichannel detection requires primary ion doses of only $\approx 10^{11}$ ions cm^{-2} or $\approx 10^{-4}$ ions/surface atom for spectral acquisition; this ensures true static conditions during analyses.

Examples of typical TOF spectra obtained from 4 keV Ar^+ impinging on a $\text{Si}\{100\}$ surface with chemisorbed H_2O and H_2 are shown in figure B1.23.6 [35]. Peaks due to Ar scattering from Si and recoiled H, O and Si are observed. The intensities necessary for structural analysis are obtained by integrating the areas of fixed time windows under these peaks.

Figure B1.23.6. TOF spectra of a Si{100} surface with chemisorbed H₂O (left) and clean Si (right). Peaks due to scattered Ar and recoiled H, O, and Si are observed. Conditions: 4 keV Ar⁺, scattering angle $\theta = 28^\circ$, incident angle $\alpha = 8^\circ$.

While qualitative identification of scattering and recoiling peaks is straightforward, quantitative analysis requires relating the scattered or recoiled flux to the surface atom concentration. The flux of scattered or recoiled atoms is dependent on several parameters as detailed in [equation \(B1.23.7\)](#). Compositional analyses by TOF-SARS and ISS have been applied in different areas of surface science, mainly in situations where the knowledge of the uppermost surface composition (first monolayer) is crucial. Some of these areas are as follows: gas adsorption, surface segregation, compounds and polymer blends, surface composition of real supported catalysts, surface modifications due to preferential sputtering by ion beams, diffusion, thin film growth and adhesion.

B1.23.6 STRUCTURAL ANALYSIS FROM TOF-SARS

The atomic structure of a surface is usually not a simple termination of the bulk structure. A classification exists based on the relation of surface to bulk structure. A *bulk truncated* surface has a structure identical to that of the bulk. A *relaxed* surface has the symmetry of the bulk structure but different interatomic spacings. With respect to the first and second layers, *lateral relaxation* refers to shifts in layer registry and *vertical relaxation* refers to shifts in layer spacings. A *reconstructed* surface has a symmetry different from that of the bulk symmetry. The methods of structural analysis will be delineated below.

B1.23.6.1 SCATTERING VERSUS INCIDENT ANGLE SCANS

When an ion beam is incident on an atomically flat surface at grazing angles, each surface atom is shadowed by its neighbouring atom such that only forwardscattering (FS) is possible; these are large impact parameter (p) collisions.

As α increases, a critical value $\alpha_{c,sh}^i$ is reached each time the i th layer of target atoms moves out of the shadow cone allowing for large-angle backscattering (BS) or small- p collisions as shown in [figure B1.23.3](#). If the BS intensity I_{RC} is monitored as a function of α , steep rises [36] with well defined maxima are observed when the

focused trajectories at the edge of the shadow cone pass close to the centre of neighbouring atoms. This is illustrated for scattering of Ne^+ from a Pt(110) surface in figure B1.23.7. From the shape of the shadow cone, i.e. the radius (R) as a function of distance (l) behind the target atom (figure B1.23.3)), the interatomic spacing (δ) can be directly determined from the I_{BS} versus α plots. For example, by measuring $\alpha_{c,sh}^1$ along directions for which specific crystal azimuths are aligned with the projectile direction and using $d = r/\sin \alpha_{c,sh}^1$, one can determine interatomic spacings in the first atomic layer. The first–second layer spacing can be obtained in a similar manner from $\alpha_{c,sh}^2$ measured along directions for which the first- and second-layer atoms are aligned, providing a measure of the vertical relaxation in the outermost layers.

Figure B1.23.7. Scattering intensity versus incident angle α scans for 2 keV Ne^+ incident on $(1 \times 2)\text{-Pt}\{110\}$ at $\theta = 149^\circ$ along the $\langle \bar{1}10 \rangle$, $\langle 001 \rangle$ and $\langle \bar{1}12 \rangle$ azimuths. A top view of the (1×2) missing-row Pt $\{110\}$ surface along with atomic labels is shown. Cross-section diagrams along the three azimuths illustrating scattering trajectories for the peaks observed in the scans are shown on the right.

B1.23.6.2 SCATTERING VERSUS AZIMUTHAL ANGLE Δ SCANS

Fixing the incident beam angle and rotating the crystal about the surface normal while monitoring the backscattering intensity provides a scan of the crystal azimuthal angles δ [37]. Such scans reveal the periodicity of the crystal structure. For example, one can obtain the azimuthal alignment and symmetry of the outermost layer by using a low α value such that scattering occurs from only the first atomic layer. With higher α values, similar information can be obtained for the second atomic layer. Shifts in the first–second layer registry can be detected by carefully monitoring the $\alpha_{c,sh}^2$ values for second-layer scattering along directions near those azimuths for which the second-layer atoms are expected, from the bulk structure, to be

directly aligned with the first-layer atoms. The $\alpha_{c,sh}^2$ values will be maximum for those δ values where the first- and second-layer neighbouring atoms are aligned.

When the scattering angle θ is decreased to a forward angle ($<90^\circ$), both shadowing effects along the incoming trajectory and blocking effects along the outgoing trajectory contribute to the patterns. The blocking effects arise because the exit angle $\beta = \theta - \alpha$ is small at high α values. Surface periodicity can be read directly from these features [37], as shown in figure B1.23.8 for Pt{110}. Minima are observed at the δ positions corresponding to alignment of the beam along specific azimuths. These minima are a result of shadowing and blocking along the close-packed directions, thus providing a direct reading of the surface periodicity.

Figure B1.23.8. Scattering intensity of 2 keV Ne^+ versus azimuthal angle δ scans for Pt{110} in the (1×2) and (1×3) reconstructed phases. Scattering angle $\theta = 28^\circ$ and incident angle $\alpha = 6^\circ$.

Azimuthal scans obtained for three surface phases of Ni{110} are shown in figure B1.23.9 [38]. The minima observed for the clean and hydrogen-covered surfaces are due only to Ni atoms shadowing neighbouring Ni atoms, whereas for the oxygen-covered surface minima are observed due to both O and Ni atoms shadowing neighbouring Ni atoms. Shadowing by H atoms is not observed because the maximum deflection in the Ne^+ trajectories caused by H atoms is less than 2.8° .

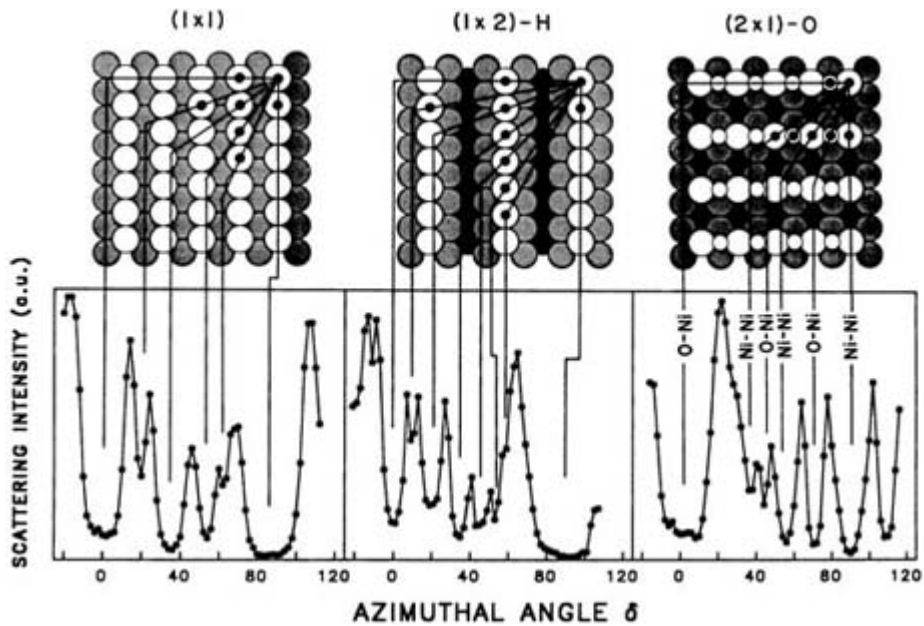

Figure B1.23.9. Scattering intensity of 4 keV Ne^+ versus azimuthal angle δ for a $\text{Ni}\{110\}$ surface in the clean (1×1) , (1×2) -H missing row, and (2×1) -O missing row phases. The hydrogen atoms are not shown. The oxygen atoms are shown as small open circles. O–Ni and Ni–Ni denote the directions along which O and Ni atoms, respectively, shadow the Ni scattering centre.

B1.23.7 STRUCTURAL ANALYSIS FROM SARIS

An example of the SARIS experimental arrangement is shown in [figure B1.23.10](#) [39, 40 and 41]. The velocity distributions of scattered and recoiled ions plus fast neutrals are measured by analysing the positions of the particles on the detector along with their correlated TOF from sample to detector. The detector is gated so that it can be activated in windows of several microseconds duration, which are appropriate for TOF collection of specific scattered or recoiled particles. These windows are divided into 255 time frames with the time duration of 16.7 ns for each frame. Good statistics are obtained in a total acquisition time of ~ 1 min. The image ordinate represents particle exit angles (β) and the abscissa represents the crystal azimuthal angles (δ), i.e. an image in (β, δ) -space.

Figure B1.23.10. Schematic diagram of a scattering and recoiling imaging spectrometer (SARIS). A large-area ($95 \times 75 \text{ mm}^2$), time-resolving, position-sensitive microchannel plate (MCP) detector captures a large

solid angle of the scattering and recoiling particles. A triple-axis UHV goniometer moves the MCP inside the vacuum chamber in order to vary the scattering angle, the distance from detector to sample, the TOF resolution and the acceptance solid angle of the detector.

B1.23.7.1 INTERACTION OF 4 KEV AR WITH PT{111}

(A) AR SCATTERING

The time-resolved images of Ar scattering [33] from Pt{111} of figure B1.23.11 correspond to selected frames of scattered Ar atoms with the azimuthal angle of the incident beam aligned along $\langle\bar{1}\bar{1}2\rangle$. The overall scattering intensity is maximal at 1.17 μs (3.54 keV) for the scattered Ar atoms, corresponding to SS as predicted by the BCA. The two intense spots at 1.17 μs result from the scattering from a first-layer Pt atom and focusing of the scattered beam by an ‘atomic lens’ formed by neighbouring first-layer Pt atoms (2, 3, 4 in figure B1.23.11). The intense spots are at small β since most of the Ar atoms are scattered and focused by first-layer Pt atoms. Focused high- β scattering usually arises from subsurface collisions.

-21-

Figure B1.23.11. Above: selected time-resolved SARIS images of 4 keV Ar^+ scattering from Pt{111} along $\langle\bar{1}\bar{1}2\rangle$. Below: view of Pt{111} surface along $\langle\bar{1}\bar{1}2\rangle$ showing Ar^+ scattering from a first-layer Pt atom (1) and splitting into two focused beams by an ‘atomic lens’ formed by neighbouring first-layer Pt atoms (2, 3, 4).

(B) PT RECOILING

The images of recoiled Pt atoms [33] by 4 keV Ar^+ are shown in figure B1.23.12. With increasing TOF, the recoil Pt images change from diffuse, to a focused recoil spot at $\beta \sim 25^\circ$ and, finally, to movement of this spot to a higher β that is partially off the MCP. This focused recoil is observed along the $0^\circ \langle\bar{2}11\rangle$ and $60^\circ \langle\bar{1}\bar{1}2\rangle$ azimuths but not along the $30^\circ \langle\bar{1}01\rangle$ and $90^\circ \langle 0\bar{1}1\rangle$ azimuths. The diffuse images at short TOF, e.g. 3.77 μs , correspond to recoil of Pt atoms from the first layer. These recoils have more isotropic distributions and higher energies because there are no atoms above them by which they can be blocked. At longer TOF, e.g. 4.57 μs , the focused recoil is due to Pt atoms from the second layer which have been focused by an ‘atomic lens’ created by first-layer atoms (figure B1.23.12)). The second-layer Pt atom can either be recoiled directly into the atomic lens or it can scatter from the neighbouring aligned third-layer atom into the atomic lens.

Figure B1.23.12. Above: selected time-resolved SARIS images of 4 keV Ar⁺ recoiling Pt atoms from Pt {111} along $\langle\bar{1}\bar{1}2\rangle$. Below: view of Pt{111} surface along $\langle\bar{1}\bar{1}2\rangle$ showing a focused second-layer Pt recoil trajectory (atoms 1–4 form a focusing ‘atomic lens’).

B1.23.7.2 INTERACTION OF 4 KEV HE WITH PT{111}

A series of time-resolved He scattering images [33] taken as a function of azimuthal angle is shown in [figure B1.23.13](#). The crystal was rotated about its surface normal by 3° for each image. Each image is taken from a 16.7 ns frame corresponding to the QSS TOF. The same intensity scale was used for all of the frames. The observed images are rich in features which change in position and intensity as a function of azimuthal angle. The regions of low intensity correspond to the positions of the centres of the blocking cones; these regions have mainly circular or oval shapes with distortions caused by other overlapping blocking cones. The regions of high intensity correspond to the positions of intersection or near-overlap of blocking cones; atom trajectories are highly focused along the edges of the cones.

Figure B1.23.13. A series of 20 time-resolved SARIS frames for 4 keV He^+ scattering from $\text{Pt}\{111\}-(1 \times 2)$ taken every 3° of rotation about the azimuthal angle δ , starting with $\delta = 0^\circ$ as the $\langle 211 \rangle$ azimuth and 60° as the $\langle \bar{1}\bar{1}2 \rangle$ azimuth. Each frame represents a 16.7 ns window centred at the TOF corresponding to QSS as predicted by the BCA. The abscissa is the crystal azimuthal angle (δ) and the ordinate is the particle exit angle (β).

The images at $\delta = 0^\circ$ and 60° along the $\langle 211 \rangle$ and $\langle \bar{1}\bar{1}2 \rangle$ azimuths, respectively, are symmetrical about a vertical line through the centre of the frame, as is the crystal structure along these azimuths as shown in [figure B1.23.14](#). The shifts in the positions and sizes of the blocking cones can be monitored as the azimuthal angle δ is rotated away from the symmetrical 0° or 60° directions. There are large variations in the intensities as a function of δ , with the highest intensities being observed along the directions $\delta = 22\text{--}32^\circ$ and $56\text{--}60^\circ$. These high-intensity features result from focusing of ions onto second-layer atoms by the shadow cones of first-layer atoms. The first-layer atoms are symmetrical; however, the second-layer atoms are in sites which are asymmetrical with respect to the first layer, resulting in non-planar scattering trajectories. Very intense features in asymmetrical positions are observed at higher exit angles. These intense features correspond to semichanneling in asymmetrical channels. Semichannels are ‘valleys’ in surfaces through which scattered ions are guided. Along $\langle \bar{1}01 \rangle$ the first-layer atoms form the ‘walls’ and the second-layer atoms form the ‘floor’ of the semichannel. However, the second-layer rows are not centred in the bottom of the channel, resulting in an asymmetrical channel. As a result, the scattered atom trajectories are bent and focused along directions determined by the asymmetry of the channel.

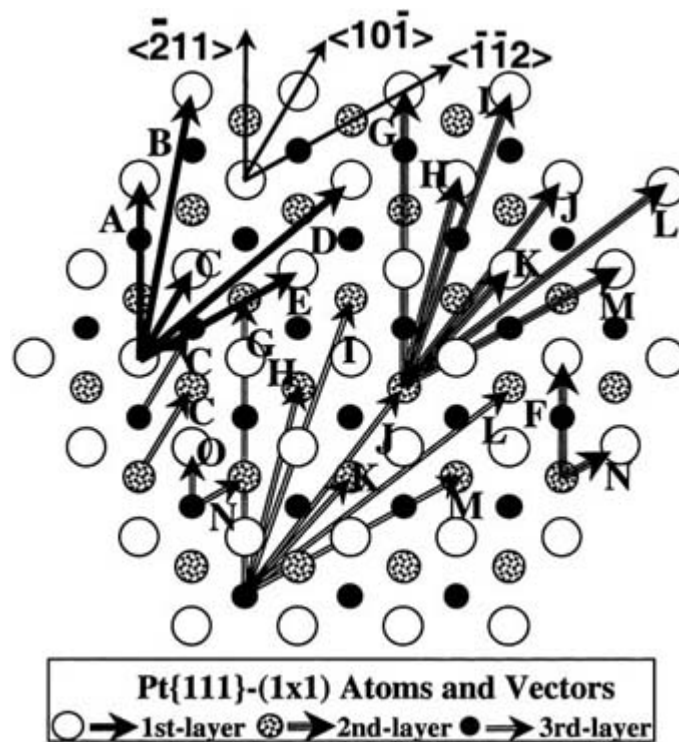

Figure B1.23.14. Schematic illustration of the Pt{111}-(1 × 1) surface. Arrows are drawn to indicate the nearest-neighbour first–first-, second–first-, and third–first-layer interatomic vectors.

The frames along the 0° $\langle \bar{2}11 \rangle$ and 60° $\langle \bar{1}\bar{1}2 \rangle$ azimuths in figure B1.23.13 were selected to compare with those of blocking cone analyses and classical ion trajectory simulations. The arrangement of the first-layer atoms is identical along both of these azimuths; however, the second- and third-layer atoms have a different arrangement with respect to the first-layer atoms. The atoms scattered from second- and third-layer atoms experience a different arrangement of blocking cones on their exit from the surface. The positions of the blocking cones were calculated [39] from the interatomic vectors of figure B1.23.14 and the critical blocking angles or sizes of the cones were calculated with the method described in section B1.23.4. The results are shown in figure B1.23.15. The blocking of scattering trajectories from n th-layer atoms by their neighbouring n th-layer atoms are observed at low β since these atoms are all in the same plane. This first/first-layer atom scattering contributes most of the intensity at low β . The arcs corresponding to the edges of the blocking cones (figure B1.23.15) resulting from the vectors A , B , D and E in figure B1.23.14 occur at $\beta \sim 10^\circ$. The features at higher β correspond to scattering trajectories from second- and third-layer atoms that are blocked and focused by first-layer atoms. The cones resulting from the vectors F , G and O along $\langle \bar{2}11 \rangle$ and M and N along $\langle \bar{1}\bar{1}2 \rangle$ are due to scattering trajectories from second- and third-layer atoms that are blocked by first-layer atoms along these symmetrical directions. These are centred along the azimuths and are directed to higher β values for shorter interatomic spacings. Blocking cones due to the vectors H , I , K and L result from second- and third-layer scattering and are observed at δ values off of the 0° and 60° directions due to non-planar scattering trajectories.

Figure B1.23.15. Experimental images (left), simulated images (right) and blocking cone analyses (centre) for He^+ scattering along the $\langle \bar{2}11 \rangle$ and $\langle \bar{1}\bar{1}2 \rangle$ azimuths. For the calculated blocking cones, first–first, first–second, and first–third layer interactions are identified by dash-dot, solid, and dotted lines, respectively. The scattering parameters are: scattering angle (with respect to incident beam direction) $\theta = 45^\circ$; beam incident angle (with respect to surface plane) $\alpha = 28^\circ$; exit angle of scattered particles along detector normal (relative to surface plane) $\beta = 17^\circ$; flight path to detector (along the detector normal)= 15.5 cm. Angular space subtended by MCP is 27° of crystal azimuthal angle δ and 33° of particle exit angle β .

(A) QUANTITATIVE ANALYSIS

Quantitative analyses can be achieved by using the scattering and recoiling imaging code (SARIC) simulation and minimization of the R -factor [33] (section B1.23.4.4) between the experimental and simulated images as a function of the structural parameters. The SARIC was used to generate simulated images of 4 keV He^+ scattering from bulk-terminated $\text{Pt}\{111\}$ as a function of the first–second interlayer spacing d . Anisotropic thermal vibrations with an amplitude of 0.1 Å were included in the model. A two-dimensional reliability, or R , factor, based on the differences between the experimental and simulated patterns, was calculated as a function of the deviation d of the first–second interlayer spacing from the bulk value. The plots shown in figure B1.23.16 exhibit minima at $d_{\min} = -0.005$ and $+0.005$ Å for the $\langle \bar{1}\bar{1}2 \rangle$ and $\langle \bar{2}11 \rangle$ azimuths, respectively. The optimized simulated images corresponding to d_{\min} are shown in figure B1.23.16, rightmost frames; there is good agreement between these simulated and experimental images. The R -factors are sensitive to changes in the interlayer spacing at the level of 0.01 Å. Based on these data, we conclude that the $\text{Pt}\{111\}$ surface is bulk terminated with the first–second layer spacing within ± 0.01 Å, or 0.4%, of the 2.265 Å bulk spacing. This sensitivity is less than the uncertainty due to the thermal vibrations because SARIS samples the average positions of lattice atoms.

Figure B1.23.16. Plots of the two-dimensional R -factors as a function of the deviation (d) of the first–second interlayer spacing from the bulk value. The experimental and simulated images along the $\langle \bar{2}11 \rangle$ and $\langle \bar{1}\bar{1}2 \rangle$ azimuths of [figure B1.23.15](#) were used in the comparison.

B1.23.8 ION–SURFACE ELECTRON EXCHANGE

One of the unsolved problems in the interaction of low-energy ions with surfaces is the mechanism of charge transfer and prediction of the charge composition of the flux of scattered, recoiled and sputtered atoms. The ability to collect spectra of neutrals plus ions and only neutrals provides a direct measure of scattered and recoiled ion fractions. SARIS images can provide electronic transition probability contour maps which are related to surface electron density and reactivity along the various azimuths.

Ion–surface electron transition probabilities are determined by electron tunnelling between the valence bands of the surface and the atomic orbitals of the ion [42]. Such transition probabilities are highest for close distances of approach. Since TOF-SARS is capable of directly measuring the scattered and recoiled ion fractions, it provides an excellent method for studying ion–surface charge exchange. For simplicity, electron exchange [43] between ions or atoms and surfaces can be discussed in terms of two regions: (i) along the incoming and outgoing trajectories where the particle is within Ångstroms of the surface and (ii) in the close atomic encounter where the core electron orbitals of the collision partners overlap. In region (i), the dominating processes are resonant and Auger electron tunnelling transitions, both of which are fast ($\tau < 10^{-15}$ s). Since the work functions of most solids are lower than the ionization potentials of most gaseous atoms, keV scattered and recoiled species are predominately neutrals as a result of electron capture from the solid. In region (ii), as the interatomic distance R decreases, the atomic orbitals (AOs) of the separate atoms of atomic number Z_1 and Z_2 evolve into molecular orbitals (MOs) of a quasimolecule and finally into the AO of the ‘united’ atom of atomic number ($Z_1 + Z_2$). As R decreases, a critical distance is reached where electrons are promoted into higher-energy MOs because of electronic repulsion and the Pauli exclusion principle. This can result in collisional reionization of neutral species. The fraction of species scattered and recoiled as ions is sensitive to atomic structure through changes in electron density along the trajectories. A direct method for measuring the spatial dependence of charge transfer probabilities with atomic-scale resolution has been developed using the method of DR ion fractions [43]. The data demonstrate the need for an improved understanding of how atomic energy levels shift and broaden near surfaces.

These types of measurements, combined with theoretical modelling, can provide a detailed microscopic map of the local reactivity of the surface as well as electron tunnelling rates within the surface unit cell. This information is of crucial importance for the understanding of various impurity-induced promotion and

poisoning phenomena in catalysis and electron-density maps from scanning tunnelling microscopy.

B1.23.9 ROLE OF SCATTERING AND RECOILING AMONG SURFACE SCIENCE TECHNIQUES

Scattering and recoiling contribute to our knowledge of surface science through (i) elemental analysis, (ii) structural analysis and (iii) analysis of electron exchange probabilities. We will consider the merits of each of these three areas.

B1.23.9.1 ELEMENTAL ANALYSIS

There are two unique features of scattering and recoiling spectrometry: (1) sensitivity to the outermost atomic layer of a surface and (2) sensitivity to surface hydrogen. Using an ESA, it is possible to resolve ions scattered from all elements of mass greater than carbon. The TOF technique is sensitive to all elements, including hydrogen, although it has limited mass resolution. For general qualitative and quantitative surface elemental analyses, XPS and AES remain the techniques of choice.

B1.23.9.2 STRUCTURAL ANALYSIS

The major role of TOF-SARS and SARIS is as surface structure analysis techniques which are capable of probing the positions of all elements with an accuracy of $\lesssim 0.1$ Å. They are sensitive to short-range order, i.e. individual interatomic spacings that are < 10 Å. They provide a direct measure of the interatomic distances in the first and subsurface layers and a measure of surface periodicity in real space. *One of its most important applications is the direct determination of hydrogen adsorption sites by recoiling spectrometry [12, 41].* Most other surface structure techniques do not detect hydrogen, with the possible exception of He atom scattering and vibrational spectroscopy.

TOF-SARS and SARIS are complementary to LEED, which probes long-range order, minimum domain size of 100–200 Å and provides a measure of surface and adsorbate symmetry in reciprocal space. Coupling TOF-SARS, SARIS and LEED provides a powerful combination for surface structure investigations. The techniques of medium- and high- (Rutherford backscattering) energy ion scattering only sample subsurface and bulk structure and are not as surface sensitive as TOF-SARS.

B1.23.10 LOW-ENERGY SCATTERING OF LIGHT ATOMS

Atomic and molecular beams of light atoms such as He, H and H₂ formed from supersonic nozzle beam sources typically have kinetic energies of 20 to 100 meV [44]. Scattering of such low-energy light atoms from surfaces is predominantly elastic. Coherently scattered waves from regularly spaced surface atoms can interfere with each other, giving rise to well known diffraction phenomena. Such hyperthermal atoms have classical turning points that are

typically about 3 Å above the centres of the outermost atomic layer of the surface. The diffraction data probe the outer regions of the atom–surface potential. This information is usually expressed as a corrugation function. Structural information such as bond angles and lengths is obtained by calculating the potential or corrugation function from assumed geometries [44].

The basic components of an apparatus for such atom scattering consist of a UHV scattering chamber equipped with a supersonic atomic and molecular beam source, a sample manipulator and a rotating mass spectrometer. Cryogenic sample temperatures are usually used in order to reduce the vibrational amplitudes of the surface atoms. Data are obtained from the in-plane and out-of-plane diffraction intensity distributions as a function of scattering angle. A set of corrugation parameters is derived from this data. These parameters can be calculated from a first principles approach based on a proportionality relation between the atom–surface interaction potential and the surface charge density. Such diffraction experiments of thermal He atoms coupled with theoretical simulations of the data have been shown to be a very useful structural tool for studying adsorption on surfaces. The method is extremely surface-sensitive, is capable of providing adsorption site information and is one of the few techniques that can detect surface hydrogen.

B1.23.11 SUMMARY

Emphasis in this chapter has been placed on the physical concepts and structural applications of TOF-SARS and SARIS. These techniques are now established as surface structural analysis methods that will have a significant impact in areas as diverse as thin-film growth, catalysis, hydrogen embrittlement and penetration of materials, surface reaction dynamics and analysis of interfaces. Surface crystallography is evolving from the classical concept of a static surface and the question of ‘Where do atoms sit?’ to the concept of a dynamically changing surface. The development of large-area detectors with rapid acquisition of scattering and recoiling structural images, as described in B1.23.7, will provide a technique for capturing time-resolved snapshots of such dynamically changing surfaces.

B1.24 Rutherford backscattering, resonance scattering, PIXE and forward (recoil) scattering

C C Theron, V M Prozesky and J W Mayer

B1.24.1 INTRODUCTION

The use of million electron volt (MeV) ion beams for materials analysis was instigated by the revolution in integrated circuit technology. Thin planar structures were formed in silicon by energetic ion implantation of dopants to create electrical active regions and thin metal films were deposited to make interconnections between the active regions. Ion implantation was a new technique in the early 1960s and interactions between metal films and silicon required analysis. For example, the number of ions implanted per square centimetre (ion dose) and thicknesses of metal layers required careful control to meet the specifications of integrated circuit technology. Rutherford backscattering spectrometry (RBS) and MeV ion beam analysis were developed in response to the needs of the integrated circuit technology. In turn integrated circuit technology provided the electronic sophistication used in the instrumentation in ion beam analysis. It was a synergistic development of analytical tools and the fabrication of integrated circuits.

Rutherford backscattering spectrometry is the measurement of the energies of ions scattered back from the surface and the outer microns (1 micron = 1 μm) of a sample. Typically, helium ions with energies around 2 MeV are used and the sample is a metal coated silicon wafer that has been ion implanted with about a

monolayer (10^{15} ions cm^{-2}) of electrically active dopants such as arsenic. Only moderate vacuum levels (about 10^{-4} Pa) are required so that sample exchange is rapid allowing the analysis of the number of implanted atoms per square centimetre and their distribution in depth to be carried out in periods of about 15 minutes or less. The sample is not damaged structurally during the analysis and therefore Rutherford backscattering spectrometry is considered non-destructive. This is in contrast to surface sensitive techniques such as Auger electron spectroscopy where surface erosion by sputtering is required for depth analysis. One of the strong features of Rutherford backscattering spectrometry is that the scattering cross sections are well known so that the analysis is quantitative. In other analytical techniques, such as secondary ion mass spectrometry (SIMS), the cross sections are not well defined. The relative ion yields can vary over three orders of magnitude depending on the nature of the surface. Rutherford backscattering has been a convenient way to calibrate secondary ion mass spectrometry, which in turn is more sensitive to the detection of trace elements than Rutherford backscattering. The two techniques are thus complementary.

Ion beam analysis grew out of nuclear physics research on cross sections and reaction products involved in atomic collisions. In this work million volt accelerators were developed and used extensively. As the energies of the incident particles increased, the lower energy accelerators became available for use in solid state applications. The early nuclear physics research used magnetic spectrometers to measure the energies of the particles. This analytical procedure was time consuming and the advent of the semiconductor nuclear particle detector allowed simultaneous detection of all particle energies. It was an energy dispersive spectrometer. The semiconductor detector is a Schottky barrier (typically a gold film on silicon) or shallow diffused p-n junction with the active region defined by the high electric field in the depletion layer. The active region extends tens of microns below the surface of the detector so that in almost every application the penetration of the energetic particles is confined within the active region. The response of the detector is linear with the energy of the particles providing a true particle energy spectrometer.

-2-

Analysis of ion implanted layers and metal-silicon interactions was carried out with Rutherford backscattering at 2.0 MeV energies and with semiconductor nuclear particle detectors for several years. Rutherford backscattering became well established and was utilized in materials analysis in industrial and university laboratories across the world. The importance of hydrogen and its influence in solid state chemistry led to the development of forward scattering in which one measures the energy of the recoiling hydrogen atom. The helium ion is heavier than that of hydrogen so that by tilting the sample it is possible to measure the recoil energy of the emerging hydrogen, again with a nuclear particle detector. In other words, the modification to the Rutherford backscattering spectrometry target chamber geometry was only to tilt the target and to move the detector. These forward recoil techniques have of course become more sophisticated with use of heavy incident ions and detectors which measure both the energy and the mass of the recoiling particles ($\Delta E - E$ or time of flight detector).

Analysis of silicon is an almost ideal experimental situation because the masses of most implanted atoms and metal layers exceed that of silicon. In Rutherford backscattering the mass of the atom must be greater than that of the silicon target to separate the energy signals of the target atom from those of the silicon spectrum. Oxygen is an exception. It is lighter than silicon and also is ubiquitous in surface and interface layers. The analysis of oxygen, and also carbon and nitrogen, are carried out in the same experimental chamber as used in Rutherford backscattering, but the energy of the incident helium ions is increased to energies where there are resonances in the backscattering cross sections. These resonances increase the yield of the scattered particle by nearly two orders of magnitude and provide high sensitivity to the analysis of oxygen and carbon in silicon. The use of these high energies, 3.04 MeV for the helium-oxygen resonance, is called resonance scattering and the word Rutherford is inappropriate for a descriptor.

By inserting a semiconductor x-ray detector into the analysis chamber, one can measure particle induced x-rays. The cross section for particle induced x-ray emission (PIXE) is much greater than that for Rutherford backscattering and PIXE is a fast and convenient method for measuring the identity of atomic species within

the outer microns of the sample surface. The energy resolution in helium ion Rutherford backscattering spectrometry does not allow discrimination between the signals from high atomic number (high Z) elements close to each other in the periodic table. With conventional semiconductor detectors one cannot distinguish between gold and tungsten, for example, whereas the ion induced x-ray energies are easily distinguished for the two high Z elements. PIXE, then, becomes another tool in the MeV ion analysis chamber and only requires the addition of a x-ray detector system.

The dimensions of the incident ion beam are typically 1 mm across the width of the incident beam impinging on the sample surface. This dimension can be easily obtained using slits in the beam handling system. The beam diameter can be reduced by orders of magnitude by using quadrupole or electrostatic lenses to focus the ion beam to diameters of about one micron on the sample surface. The beam is then rastered across the surface to provide a visual image of the surface with micron resolution. In this work the large cross sections for PIXE are important, because sample analysis can be performed without sample damage caused by the high current density of incident ions.

This overview covers the major techniques used in materials analysis with MeV ion beams: Rutherford backscattering, channelling, resonance scattering, forward recoil scattering, PIXE and microbeams. We have not covered nuclear reaction analysis (NRA), because it applies to special incident-ion–target-atom combinations and is a topic of its own [1, 2].

B1.24.2 RUTHERFORD BACKSCATTERING SPECTROMETRY (RBS)

The discussion of Rutherford backscattering spectrometry starts with an overview of the experimental target chamber, proceeds to the particle kinematics that determine mass identification and depth resolution, and then provides an example of the analysis of a silicide.

B1.24.2.1 TARGET CHAMBER

Figure B1.24.1 shows the placement of the sample and detectors in the target chamber. The sample is located so that its surface is on an axis of rotation of a goniometer so that the beam position does not shift across the sample as the sample is tilted with respect to the incident ion beam. The backscattering detector is mounted as close to the incident beam as possible so that the average backscattering angle, θ , is close to 180° , typically 170° , with a detector solid angle of about 3–5 milliradians (msr). In some cases annular detectors are used with the incident beam passing through the centre of the detector aperture in order to provide larger analysis solid angles. The sample is rotated to glancing angle geometries when the forward scattering detector is used. Typically a thin foil is placed in front of the detector to block the helium ions while allowing the hydrogen ions to pass through with only minimal energy loss. The stopping power (energy loss) of MeV helium ions is ten times that of the recoiling hydrogen ions. As shown in [section B1.24.8](#) below, the forward scattering detector system can be augmented to include a $\Delta E - E$ detector to allow identification of the ion mass as well as energy. The x-ray detector is placed so that the active region is in full view of the sample surface bombarded with the incident ions.

Figure B1.24.1. Schematic diagram of the target chamber and detectors used in ion beam analysis. The backscattering detector is mounted close to the incident beam and the forward scattering detector is mounted so that, when the target is tilted, hydrogen recoils can be detected at angles of about 30° from the beam direction. The x-ray detector faces the sample and receives x-rays emitted from the sample.

-4-

For conventional backscattering spectrometry with helium ions, the energy resolution of the semiconductor particle detector is typically 15 kiloelectron volts (keV). This resolution can be improved to 10 keV with special detectors and detector cooling. The output signal, which is typically millivolts in pulse height, is processed by silicon integrated circuit electronics and provides an energy spectrum in terms of number of particles versus energy. It is often displayed as particles versus channel number as the energy scale is divided into channels which must be calibrated to give the energy scale. The calibration between the measured particle energy and the channel number is independent of the ion energy and sample analysed and only depends on the semiconductor detector and associated electronics response to the energy of the ion beams.

The vacuum requirements in the target chamber are relatively modest (10^{-4} Pa) and are comparable to those in the accelerator beam lines. All that is required is that the ion beam does not lose energy on its path to the sample and that there is minimal deposition of contaminants and hydrocarbons on the surface during analysis.

B1.24.2.2 KINEMATICS

In ion beam analysis the incident particle penetrates into the silicon undergoing inelastic collisions, predominantly with target electrons, and loses energy as it penetrates to the end of its range. The range of 2.5 MeV helium ions is about 10 microns in silicon; the range of comparable energy protons is about ten times that of the helium ions (the range of 3 MeV hydrogen is about 100 microns in silicon). During the penetration of the helium ions, a small fraction undergo elastic collisions with the target atom to give the backscattering signal.

Figure B1.24.2 is a schematic representation of the geometry of an elastic collision between a projectile of mass M_1 and energy E_0 with a target atom of mass M_2 initially at rest. After collision the incident ion is scattered back through an angle θ and emerges from the sample with an energy E_1 . The target atom after collision has a recoil energy E_2 . There is no change in target mass, because nuclear reactions are not involved and energies are non-relativistic.

Figure B1.24.2. A schematic representation of an elastic collision between a particle of mass M_1 and energy E_0 and a target atom of mass M_2 . After the collision the projectile and target atoms have energies of E_1 and E_2 respectively. The angles θ and ϕ are positive as shown. All quantities refer to the laboratory frame of reference.

The ratio of the projectile energies for $M_1 < M_2$ is given by

$$K = \frac{E_1}{E_0} = \left[\frac{(M_2^2 - M_1^2 \sin^2 \theta)^{1/2} + M_1 \cos \theta}{M_2 + M_1} \right]^2. \quad (\text{B1.24.1})$$

-5-

The energy ratio, called the kinematic factor $K = E_1/E_0$, shows that the energy after scattering is determined by the masses of the incident particle and target atoms and the scattering angle. For a direct backscattering through 180° the energy ratio has its lowest value given by

$$\frac{E_1}{E_0} = \left(\frac{M_2 - M_1}{M_2 + M_1} \right)^2. \quad (\text{B1.24.2})$$

For incident helium ions ($M_1 = 4$) at $E_0 = 2.0$ MeV the energy E_1 of the backscattered particle for silicon ($M_2 = 28$) is 1.12 MeV and for palladium ($M_2 = 106$) the energy is 1.72 MeV.

The energy E_2 transferred to the target atom has a general relation given by

$$\frac{E_2}{E_0} = \frac{4M_1M_2}{(M_1 + M_2)^2} \cos^2 \phi \quad (\text{B1.24.3})$$

and at $\theta = 180^\circ$ the energy E_2 transferred to the target atom has its maximum value given by

$$\frac{E_2}{E_0} = \frac{4M_1M_2}{(M_1 + M_2)^2}. \quad (\text{B1.24.4})$$

In collisions where $M_1 = M_2$ at $\theta = 180^\circ$ the incident particle is at rest after the collision, with all the energy transferred to the target atom. For 2.0 MeV helium ions colliding with silicon the recoil energy E_2 is 0.88 MeV and from palladium is 0.28 MeV.

The ability to identify different mass species depends on the energy resolution of the detector which is typically 15 keV full width at half maximum (FWHM). For example, silver has a mass $M_2 = 108$ and tin has a mass $M_2 = 119$. The difference between $K_{\text{Ag}} = 0.862$ and $K_{\text{Sn}} = 0.874$ is 0.012. For 2 MeV helium ions the

difference in backscattering energy is 24 keV which is well outside the range of the detector resolution, indicating that signals from Ag and Sn on the surface can be resolved. The difference between gold and tungsten K values is 0.005, and at 2 MeV energies one would not resolve the signals between gold and tungsten. With Rutherford backscattering and conventional detectors with energy resolution of 15 keV one can resolve the signals from and identify the elements of masses up to 100. One can resolve isotopes up to a mass of around 60. For example, all the silicon isotopes can be identified.

B1.24.2.3 SCATTERING CROSS SECTION

The identity of target elements is established by the energy of the scattered particles after an elastic collision. The number of atoms per unit area, N_S , is found from the number Q_D of detected particles (called the yield, Y) for a given number Q of particles incident on the target. The connection is given by the scattering cross section $\sigma(\theta)$ by

$$Y = Q_D = \sigma(\theta)\Omega Q N_S. \quad (\text{B1.24.5})$$

-6-

This is shown schematically in figure B1.24.3. In the simplest approximation the scattering cross section σ is given by

$$\sigma(\theta) = \left(\frac{Z_1 Z_2 e^2}{4E} \right)^2 \frac{1}{\sin^4 \theta/2}, \quad (\text{B1.24.6})$$

the scattering cross section originally derived by Rutherford. For 2 MeV helium ions incident on silver, $Z_2 = 47$ at 180° , the cross section is $2.89 \times 10^{-24} \text{ cm}^2$ or 2.89 barns where the barn = 10^{-24} cm^2 . The distance of closest approach is about $7 \times 10^{-4} \text{ \AA}$ which is smaller than the K-shell radius of silver (10^{-2} \AA). This means that the incident helium ion penetrates well within the innermost radius of the electrons so that one can use an unscreened Coulomb potential for the scattering. The distance of closest approach is sufficiently large that penetration into the nuclear core does not occur and one neglects nuclear reactions.

Figure B1.24.3. Layout of a scattering experiment. Only primary particles that are scattered within the solid angle Ω spanned by the solid state detector are counted.

The cross sections are sufficiently large that one can detect sub-monolayers of most heavy mass elements on silicon. For example, the yield of 2.0 MeV helium ions from 10^{14} cm^{-2} silver atoms (approximately one-tenth of a monolayer) is 800 counts for a current of 100 nanoamperes for 15 minutes and detector area of 5 msr.

This represents a large signal for a small number of atoms on the surface. With care, 10^{-4} monolayers of gold on silicon can be detected.

B1.24.2.4 DEPTH SCALE

Light ions such as helium lose energy through inelastic collision with atomic electrons. In backscattering spectrometry, where the elastic collision takes place at depth t below the surface, one considers the energy loss along the inward path and on the outward path as shown in [figure B1.24.4](#). The energy loss on the way in is weighted by the kinematic factor and the total is

$$\Delta E = \Delta t \left(K \frac{dE}{dx} \Big|_{\text{in}} + \frac{1}{|\cos \theta|} \frac{dE}{dx} \Big|_{\text{out}} \right) = \Delta t [S] \quad (\text{B1.24.7})$$

-7-

where dE/dx is the rate of energy loss with distance and $[S]$ is the energy loss factor. An example illustrating the influence of depth on analysis is given in [figure B1.24.5](#) which shows two thin gold layers on the front and back of a nickel film. The scattering from gold at the surface is clearly separated from gold at the back layer. The energy width between the gold signals is closely equal to that of the energy width of the nickel signal. This signal is nearly square shaped because nickel exists from the front to the back surface. The depth scales are determined from energy loss values, which are given in tabular form as a function of energy [1, 2]. It is often expressed as a stopping cross section in terms of $(1/N) dE/dx$, which gives values in eV cm^2 . The depth resolution is given by dividing the detector resolution by the energy loss factor. For 2 MeV helium in silicon one might expect a depth resolution of about 200 Å for 180° scattering geometries. This can be reduced to values of about 50 Å for glancing incident and exit angles. These values of depth resolution degrade as the particle penetrates into the sample and energy straggling becomes a factor.

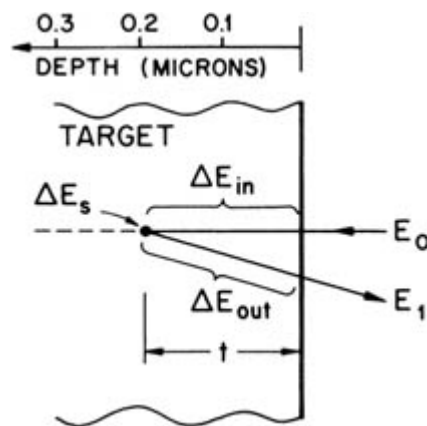

Figure B1.24.4. Energy loss components for a projectile that scatters from depth t . The particle loses energy ΔE_{in} via inelastic collisions with electrons along the inward path. There is energy loss ΔE_S in the elastic scattering process at depth t . There is energy lost to inelastic collisions ΔE_{out} along the outward path. For an incident energy E_0 the energy of the exiting particle is $E_1 = E_0 - \Delta E_{\text{in}} - \Delta E_S - \Delta E_{\text{out}}$.

-8-

Figure B1.24.5. Backscattering spectrum of a thin Ni film (950 Å) with near monolayers ($\approx 30 \times 10^{15}$ at cm^{-2}) of Au on the front and back surfaces of the Ni film. The signals from the front and back layers of Au are shown and are separated in energy from each other by nearly the same energy width as the Ni signal.

B1.24.2.5 SIMULATION

Rutherford backscattering spectra can be analysed by use of some of the available analysis programs. Programs such as RUMP and GISA provide a layer-by-layer signal for multielement targets [3, 4, 5]. These programs include detector resolution, energy straggling and individual isotopes, and can also be applied to forward recoil spectrometry for detection of light elements. These programs also include provisions for enhanced cross section for light elements such as carbon and oxygen.

B1.24.2.6 SILICIDE FORMATION

An example of Rutherford backscattering spectrometry of the formation of PtSi is shown in figure B1.24.6 for the case where the original Pt layer has reacted to form Pt₂Si. The backscattering signals at the high energy end near 1.8 MeV represent Pt at the surface of the sample. The plateau extends downward in energy to 1.7 MeV where there is a step down to the signals from Pt in Pt₂Si. In the Pt signal the contribution from Pt₂Si is shown shaded. In the Si portion of the spectrum the signal steps upward around 1.0 MeV and represents the silicon in the Pt₂Si. The second step represents the Si signal from the Si substrate. In this case, the signals from the unreacted Pt, the Pt and Si in Pt₂Si and the Si in the substrate are clearly identified and can be used to specify the thickness and composition of the silicide layer.

Figure B1.24.6. Backscattering spectrum of a layer of Pt on Si that has been thermally heated so that approximately half the Pt has been consumed in the formation of Pt_2Si , the first stage in the reaction of Pt with Si. In the spectrum the signals from Si have been multiplied by a factor of three for visibility, because the atomic number of Si (14) is much less than that of Pt (78). In the spectrum the signals from Pt are in the region of 1.6–1.8 MeV. The higher energy corresponds to scattering from unreacted Pt and the step around 1.7 MeV corresponds to the transition from Pt to Pt_2Si . The signal at 1.6 MeV corresponds to the back interface of the Pt_2Si in contact with silicon. The silicon signal in the energy range from about 0.9–1.0 MeV corresponds to the Si in the Pt_2Si . At lower energies the spectrum represents signals from the Si substrate.

B1.24.3 IN SITU REAL-TIME RBS

The essentially non-destructive nature of Rutherford backscattering spectrometry, combined with the its ability to provide both compositional and depth information, makes it an ideal analysis tool to study thin-film, solid-state reactions. In particular, the non-destructive nature allows one to perform *in situ* RBS, thereby characterizing both the composition and thickness of formed layers, without damaging the sample. Since only about two minutes of irradiation is needed to acquire a Rutherford backscattering spectrum, this may be done continuously to provide a real-time analysis of the reaction [6].

There are two main applications for such real-time analysis. The first is the determination of the chemical reaction kinetics. When the sample temperature is ramped linearly with time, the data of thickness of formed phase together with ramped temperature allows calculation of the complete reaction kinetics (that is, both the activation energy and the pre-exponential factor) from a single sample [6], instead of having to perform many different temperature ramps as is the usual case in differential thermal analysis [7, 8, 9, 10 and 11]. The second application is in determining the

contribution that each of the elements in the reaction couple makes to the overall atomic transport across the forming layer. For this purpose, thin, inert markers (analogous to the thin wires used by Kirkendall [12, 13]) are inserted into the layers to establish a reference frame within which to measure the contribution of each element's flux to the overall growth. Without the use of a real-time analysis technique, one must rely on the

use of different samples, which, although nominally identical, do not necessarily behave identically since many of these reactions depend critically on the exact conditions at the interfaces between the layers. On the other hand, if analysis can be performed on a single sample, small changes in the position of the marker can then confidently be interpreted. Examples of these two applications are presented below.

B1.24.3.1 PT-SI

When a thin (about 3000 Å) layer of Pt is deposited onto a Si wafer and then heated, the first phase that forms at the interface between Pt and Si is Pt₂Si. After all the Pt has been consumed, the newly formed Pt₂Si layer reacts with the Si to form PtSi, which is stable in contact with excess Si. No further reaction is observed.

Figure B1.24.7 shows the progress of this reaction as the temperature is ramped linearly at a rate of 1°C min⁻¹. At time zero, the signal between 1.5 and 1.9 MeV is from the unreacted Pt layer, whereas the signal from the Si wafer appears below about 0.9 MeV. The signal from the Si has been magnified by a factor of three to compensate for the differences in cross sections between Pt (Z = 78) and Si (Z = 14).

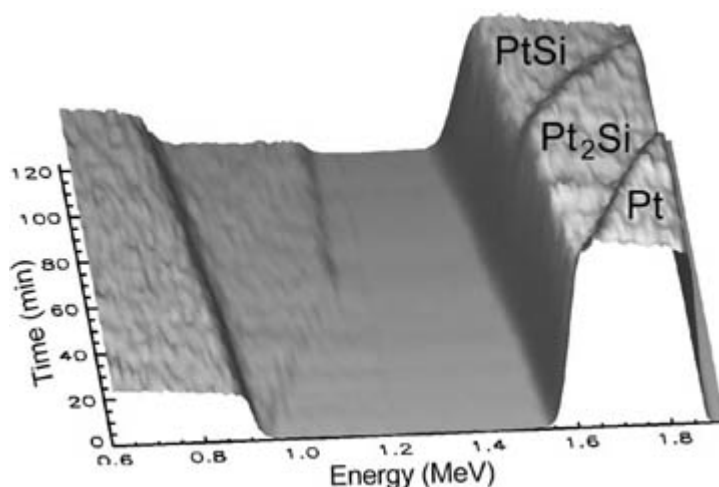

Figure B1.24.7. A three-dimensional plot of backscattering signal versus time for a Pt film deposited onto Si and heated at a rate of 1 °C min⁻¹. At time zero, the Pt signal shows a square-topped energy distribution. As time progresses and the sample is heated, a step appears in the Pt signal, indicating the formation of the first phase Pt₂Si. At longer times a second step appears, indicating the formation of the second phase PtSi after all the Pt has been consumed. The energy widths of the Pt signals give the thickness of the formed phases. The heights of the Pt signals, relative to those from Si, give the composition of the phases.

After 60 minutes of annealing, all the Pt has reacted to form Pt₂Si. Almost immediately thereafter the reaction between Pt₂Si and Si to form PtSi starts and after a further 60 minutes all the Pt₂Si has reacted, resulting in a stable PtSi film on Si. The data of silicide thickness versus ramped temperature can be plotted in reduced form in an Arrhenius-like plot to give the activation energy [6, 14].

B1.24.3.2 PD₂SI ON CRSI₂

When a thin film structure of Si(100)/Pd/Cr (see figure B1.24.8(a) is heated to 300 °C, the Pd quickly reacts with the Si to form Pd₂Si (b). Upon further heating the Cr reacts with the Si to form CrSi₂ on top of the Pd₂Si. The required silicon can either be supplied directly by the diffusion of Si atoms from the crystalline substrate (c) or by Pd₂Si dissociation followed by Pd diffusion (d). The motion of a thin Ta marker embedded in the Pd₂Si layer is used to distinguish between these two mechanisms. In (c) there is no movement of the marker relative to the Pd₂Si layer, while in (d) the marker moves towards the Pd₂Si / CrSi₂ interface.

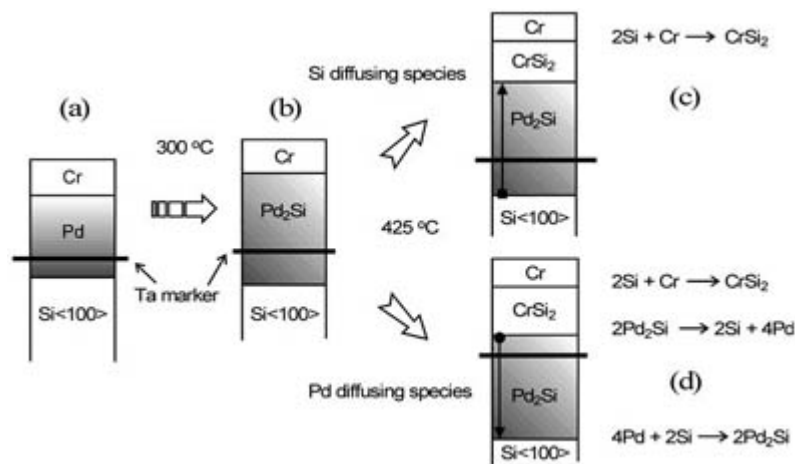

Figure B1.24.8. Schematic diagram of the reaction of Pd/Cr layers on (100) Si with a Ta marker placed inside the Pd layer. When the sample (a) is heated to 300°C, the Pd reacts with the Si to form Pd₂Si (b). Upon further heating Cr reacts with Si to form CrSi₂ on top of Pd₂Si. The required Si can either be supplied directly by the diffusion of Si atoms from the crystalline substrate (c) or by Pd₂Si dissociation followed by Pd diffusion (d). The motion of a thin Ta marker, embedded in the Pd₂Si layer, is used to distinguish between these two mechanisms. In (c) there is no movement of the marker relative to the Pd₂Si layer, while in (d) the marker moves towards the Pd₂Si/CrSi₂ interface.

In figure B1.24.9 the *in situ*, real-time, RBS spectrum of the formation of CrSi₂ on Pd₂Si at 425°C is shown. The Ta marker embedded in the Pd₂Si layer shifts to lower energies during CrSi₂ formation in agreement with the prediction for the case of Si diffusion (c). In the figure, the element from which backscattering has taken place has been underlined [14].

-12-

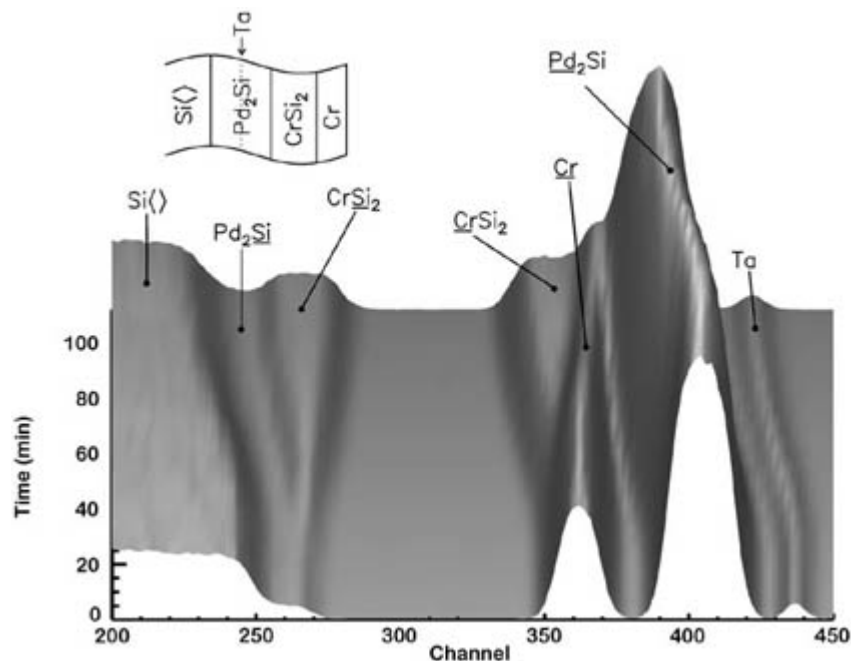

Figure B1.24.9. *In situ*, real-time, backscattering spectrum of the formation of CrSi₂ on Pd₂Si at 425°C. The structure is shown in the inset. The elements underlined represent the origin of the signal; the Si signal in CrSi₂ is around channel 260 and the Cr signal from CrSi₂ appears around channel 350. The Ta marker embedded in the Pd₂Si layer shifts to lower energy during CrSi₂ formation indicating that Si diffusion through

the Pd₂Si layer has occurred as indicated in diagram (c) of [figure B1.24.8](#).

B1.24.4 CHANNELLING

If the sample is mounted on a goniometer so that the crystal axis or planes of a single crystal sample, such as silicon, are aligned within about 0.1 or 0.5 degrees, the crystal lattice can steer the trajectories of incident ions penetrating the crystal [15, 16]. This steering of the incident energetic beam is known as ‘channelling’ as the atomic rows and planes are guides that steer the energetic ions along the channels between rows and planes. The channelled ions do not closely approach the lattice atoms with the result that the backscattering yield can be reduced 100-fold (an aligned spectrum compared to that when the incident ions are misaligned from the lattice atoms gives a random spectrum). Channelling measurements can determine the amount of lattice disorder in which displaced atoms are located within the channels and hence accessible to backscattering collisions with the channelled ions. Channelling can also be used to measure the number of impurity atoms located sufficiently far from substitutional lattice sites that they are accessible to backscattering from the channelled ions.

Channelling phenomena were studied before Rutherford backscattering was developed as a routine analytical tool. Channelling phenomena are also important in ion implantation, where the incident ions can be steered along the lattice planes and rows. Channelling leads to a deep penetration of the incident ions to depths below that found in the normal, near Gaussian, depth distributions characterized by non-channelled energetic ions. Even today, implanted channelled

-13-

ions are of concern when one attempts to form shallow junctions in ion implantation of integrated circuit structures. Channelling effects can be overcome if the silicon crystal is amorphized by a prior implantation of silicon or germanium atoms.

Figure B1.24.10 shows schematically a random and aligned spectrum for MeV helium ions incident on silicon. The aligned spectrum is characterized by a peak at the high energy end of the spectrum. The peak represents ions scattered from the outermost layer of atoms directly exposed to the incident beam. This peak is called the ‘surface peak’. Behind the surface peak, at lower energies, the aligned spectrum drops to a value of 1/40th of the silicon random spectrum indicating that nearly 98% of the incident ions are channelled and do not make close impact collisions with the lattice atoms. The rise in the aligned spectrum at lower energies represent the ions that are deflected from the steering by the lattice atoms and can then collide in close impact collisions with the lattice atoms and hence directly contribute to the backscattering spectra.

Figure B1.24.10. Random and aligned (channelled) backscattering spectrum from a single crystal sample of silicon. The aligned spectrum has a peak at the high energy end of the Si signal. This peak represents helium

ions scattered from the outer layers of Si that are exposed to the incident beam. The yield behind the peak is 1/40 th of the random yield because the Si atoms are shielded from close encounter elastic collisions from the ion beam that is channelled along the axial rows of the Si crystal.

The application of channelling to Rutherford backscattering spectrometry is used to determine the amount of damage in ion-implanted crystal and the lattice location of ion-implanted dopant atoms. One of the important contributions of channelling to integrated circuit technology is the analysis of amorphous layer formation during ion implantation and its subsequent reanneal at temperatures near 550°C, approximately half the melting temperature of silicon (1414°C). [Figure B1.24.11](#) shows a channelling spectrum in a silicon sample, where the outer 4200 Å of the silicon were converted into an amorphous layer by implantation of silicon atoms at liquid nitrogen temperatures [17]. In the spectrum of the as-implanted sample, marked '0 minutes', the yield of the silicon spectra matches that of the random spectra at energies of around 1 to 1.1 MeV. This shows that the implanted amorphous layer has atoms that are displaced from the underlying single crystal silicon. The silicon signal at 0 minutes shows a decrease at around 0.9 MeV. This decrease represents the fraction of channelled ions in the silicon lattice. The yield does not drop to the non-implanted level because the incident helium atoms suffer multiple collisions penetrating through the amorphous layer and their angular distribution is broadened well beyond the critical angle for channelling. The critical angle for channelling of 1 MeV helium ions along the <100> axis of silicon at room temperature is 0.63 degrees. As the sample is

-14-

thermally annealed at temperatures above 500°C, the amorphous layer reorders epitaxially on the silicon substrate. The rear edge of the amorphous spectrum moves towards the surface such that after 30 minutes half of the layer has recrystallized. The yield from the single-crystal silicon behind the implanted layer decreases since fewer of the incident ions suffer multiple collisions sufficient to make their angular distribution exceed that of the critical angle. Finally, after 60 minutes annealing, almost all the implanted layer is recrystallized and one is left with a surface peak slightly greater than that in the non-implanted case.

Figure B1.24.11. The backscattering yield from an Si sample that has been implanted with Si atoms to form an amorphous layer. Upon annealing this amorphous layer recrystallizes epitaxially leading to a shift in the amorphous/single-crystal interface towards the surface. The aligned spectra have a step between the amorphous and crystal substrate which shifts towards the surface as the amorphous layer epitaxially recrystallizes on the Si.

Channelling only requires a goniometer to include the effect in the battery of MeV ion beam analysis techniques. It is not as commonly used as the conventional backscattering measurements because the lattice location of implanted atoms and the annealing characteristics of ion implanted materials is now reasonably well established [18]. Channelling is used to analyse epitaxial layers, but even then transmission electron microscopy is used to characterize the defects.

B1.24.5 RESONANCES

At 2 MeV energies the incident helium ion does not penetrate through the barrier around the nucleus. At higher energies and for lighter target atoms such as carbon, nitrogen and oxygen, the helium ion can penetrate and resonances in the cross sections lead to enhanced backscattering yields. This allows one to investigate these target atoms within silicon and even higher mass substrates.

An example of the oxygen resonance cross section is shown in figure B1.24.12 which displays the cross section *versus* energy [19]. The resonance that occurs at 3.04 MeV shows a strong peak. This results in a peak in the backscattering spectra as shown in figure B1.24.13 for 3.05 MeV He⁴ incident on an LaCaMnO₃ film on an LaAlO₃ substrate. In the analysis one increases the energy of the beam to move the resonance to increasing depths.

Carbon also has a resonance in its cross section leading to a 100-fold increase in the backscattering signal. This resonance has been very convenient for analysing 1% carbon in silicon-germanium films. The resonance for nitrogen is not as pronounced and has not been used extensively.

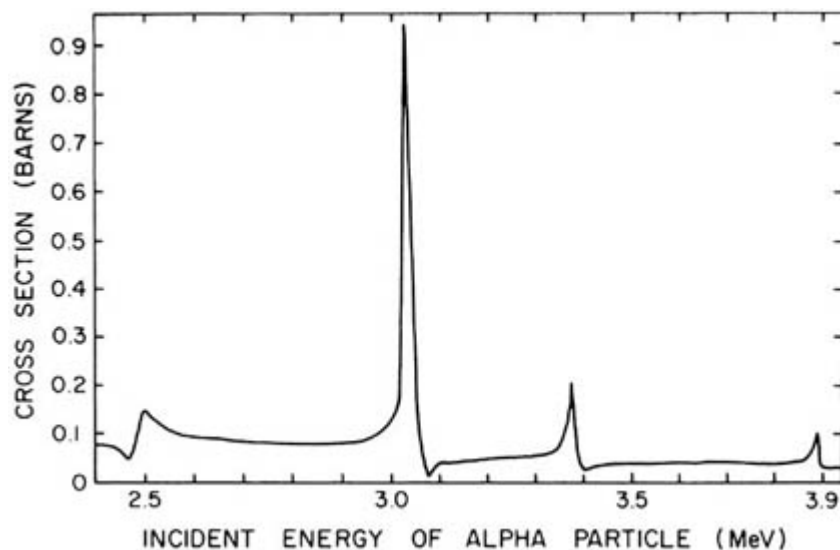

Figure B1.24.12. Elastic cross section of helium ions scattered from oxygen atoms. The pronounced peak in the spectrum around 3.04 MeV represents the resonance scattering cross section that is often used in detection

of oxygen.

-16-

Figure B1.24.13. A thin film of LaCaMnO_3 on an LaAlO_3 substrate is characterized for oxygen content with 3.05 MeV helium ions. The sharp peak in the backscattering signal at channel 160 is due to the resonance in the scattering cross section for oxygen. The solid line is a simulation that includes the resonance scattering cross section and was obtained with RUMP [3]. Data from E B Nyeanchi, National Accelerator Centre, Faure, South Africa.

B1.24.6 PARTICLE-INDUCED X-RAY EMISSION (PIXE)

The PIXE method [20] is based on the spectrometry of the radiation released during the filling of vacancies of inner atomic levels. These vacancies are produced by bombarding a sample with energetic (a few MeV) ions that are normally derived from a high-voltage accelerator. The binding energies of the electrons in the outer layers of the electron shell of an atom are of the order of eV and radiation produced from the rearrangement of electrons in these levels will be in the region of visible wavelength. On the other hand, the binding energies of the inner levels are of the order of keV and radiation produced from processes involving these levels will be in the x-ray region. More importantly, as the electron energy levels of each element are quantized and unique, the measurement of the x-ray energy offers the possibility of determining the presence of a specific element in the sample. Furthermore, the x-ray intensity of a specific energy is proportional to the concentration of the corresponding element in the sample.

The relative simplicity of the method and the penetrative nature of the x-rays, yield a technique that is sensitive to elements with $Z > 10$ down to a few parts per million (ppm) and can be performed quantitatively from first principles. The databases for PIXE analysis programs [21, 22 and 23] are typically so well developed as to include accurate fundamental parameters, allowing the absolute precision of the technique to be around 3% for major elements and 10–20% for trace elements. A major factor in applying the PIXE technique is that the bombarding energy of the

projectiles is a few orders of magnitude more than that of the binding energies of the electrons in the atom and, as the x-rays are produced from the innermost levels, no chemical information is obtained in the process. The advantage of this is that the technique is also not matrix dependent and offers quantitative information regardless of the chemical states of the atoms in the sample. The major application of the technique is the determination of trace element concentrations and, due to the accuracy and non-destructive nature of the technique [24], there are few other techniques that can compete.

The PIXE technique is described schematically in figure B1.24.14. A beam of energetic ions (normally protons of around 3 MeV) is used to eject inner-shell electrons from atoms in a sample. This unstable condition of the atom cannot be maintained and these vacancies are filled by outer-shell electrons. This means that the electrons make a transition in energy in moving from one level to another, and this energy can be released in the form of characteristic x-rays, the energies of which identify the atom. In a competing process, called Auger electron spectroscopy, this energy can also be transferred to another electron that is ejected from the atom and can be detected by an electron detector. Therefore, the step from ionization to x-ray production is not 100% efficient. The x-ray production efficiency is called the fluorescence yield and must be included in the database for quantitative measurements. The x-rays that are emitted from the sample are measured using an energy dispersive detector that has a typical energy resolution around 2.5% (150 eV at 6 keV).

Figure B1.24.14. A schematic diagram of x-ray generation by energetic particle excitation. (a) A beam of energetic ions is used to eject inner-shell electrons from atoms in a sample. (b) These vacancies are filled by outer-shell electrons and the electrons make a transition in energy in moving from one level to another; this energy is released in the form of characteristic x-rays, the energy of which identifies that particular atom. The x-rays that are emitted from the sample are measured with an energy dispersive detector.

By convention, the transitions filling vacancies in the innermost shell are called K x-rays, those filling the next shell are L x-rays, etc. The energies of L x-rays are normally much lower than those of K x-rays, and

similarly M x-rays have much lower energies than L x-rays. Due to the structure of the electron shells, there are naturally more possible transitions yielding L x-rays and even more possibilities of yielding M x-rays; therefore it becomes more complex to measure the higher-order x-rays. Typically, the analytical method is limited to K, L and M x-rays. The limitation of detecting elements with $Z > 10$ is due to the low energies of x-rays from the light elements that are absorbed before reaching the detector. The high yield of low-energy x-rays that originate from the major elements of a sample can be eliminated by a filter in front of the detector. Although the stopping of the bombarding ion is depth dependent, the measured x-ray energy gives no direct indication of the depth at which it was produced, and therefore the technique does not provide depth distribution information.

Typically, PIXE measurements are performed in a vacuum of around 10^{-4} Pa, although they can be performed in air with some limitations. Ion currents needed are typically a few nanoamperes and current is normally not a limiting factor in applying the technique with a particle accelerator. This beam current also normally leads to no significant damage to samples in the process of analysis, offering a non-destructive analytical method sensitive to trace element concentration levels.

An example of a PIXE spectrum is shown in [figure B1.24.15](#) this spectrum was obtained from the analysis of a piece of ivory to establish whether its source could be determined from trace element concentrations [25]. The spectrum shows the contribution from the different elements, also showing the high Ca yield originating from the Ca-rich matrix of the ivory. In this case an 80 μm Al filter was used to filter most of the x-rays from Ca, as they tend to dominate the spectrum. As most interest was focused on the higher-energy part of the spectrum (the higher-energy x-rays are typically not absorbed as much as those of low energy through the same filter) this enabled better sensitivities for the heavier elements to be obtained. To maximize the sensitivity and statistical accuracy, the yields from all the K- or L-shell x-rays from an element are used together to determine the concentration for each element [21]. As can be seen in the figure, the x-ray peaks are situated on a continuous background due to *bremsstrahlung* of the projectiles and secondary electrons and, typically, PIXE software programs perform non-linear iterative procedures to obtain accurate information on peaks and this background [26].

-19-

Figure B1.24.15. An example of a PIXE spectrum. This spectrum was obtained from the analysis of a piece of ivory to establish whether the origin of the ivory could be determined from trace element concentrations.

The spectrum shows the contribution from the different elements, also showing the Ca yield originating from the Ca-rich matrix of the ivory. In this case an 80 μm Al filter was used to filter most of the x-rays from Ca, as they tend to dominate the spectrum. As interest was focused on the higher-energy part of the spectrum (the higher-energy x-rays are typically not absorbed as much as those of low energy through the same filter), this enabled better sensitivities for the heavier elements to be obtained. The x-ray peaks are situated on a continuous background of *bremstrahlung* from the projectiles and secondary electrons and, typically, PIXE software programs perform non-linear iterative procedures to obtain accurate information on peaks and this background.

B1.24.7 NUCLEAR MICROPROBE (NMP)

A microprobe employs a focused beams of energetic ions, to provide information on the spatial distribution of elements at concentration levels that range from major elements to a few parts per million [27]. The range of techniques available that allowed depth information plus elemental composition to be obtained could all be used in exactly the same way; it simply became possible to obtain lateral information simultaneously.

-20-

The basis of the nuclear microprobe (NMP) is a source of energetic ions from a particle accelerator. These ions are then focused using either magnetic or electrostatic lenses to a minimum spot size less than $1 \mu\text{m}^2$. The technology of focusing ions is still at the stage where the resolution of the NMP does not compete with the electron microprobe. A set of deflection plates allows movement or scanning of the ion beam and, using computer control, the position of the bombarding beam is known. At each point of irradiation, analytical data are acquired. In this way, the analytical information obtained can be presented as an image. Naturally, the imaging capabilities of the NMP is limited by the sensitivity of each technique used since an entire spectrum must be collected at each 'pixel' in the image. For example, a 128×128 pixel image is equivalent to 16 384 single-point analyses. For this reason the analytical techniques used in imaging are mostly limited to PIXE in the case of trace elements, RBS and forward recoil spectrometry (FRS) for depth information and light elements and nuclear reaction analysis (NRA) to the detection of elements at high concentrations. Naturally the NMP can also be used in a point analysis mode, as for example in the case of geological applications [28]. Here the grain sizes that need to be analysed are often of the order of a few microns and a reasonably small bombarding beam is necessary to limit the analysis to a specific grain.

An example of the application of the PIXE technique using the NMP in the imaging mode [29] is shown in [figure B1.24.16](#). The figures show images of the cross section through a root of the *Phaseolus vulgaris L.* plant. In this case the material was sectioned, freeze-dried and mounted in vacuum for analysis. The scales on the right hand sides of the figures indicate the concentrations of the elements presented in ppm by weight. From the figures it is clear that the transports of the elements through the root are very different not only in the cases of the major elements Ca and K, but also in the case of the trace element Zn. These observations offer a wealth of information that is useful to a botanist studying dynamic processes in plant material.

The quantitative imaging capability of the NMP is one of the major strengths of the technique. The advanced state of the databases available for PIXE [21, 22 and 23] allows also for the analysis of layered samples as, for example, in studying non-destructively the elemental composition of fluid inclusions in geological samples.

The application of RBS is mostly limited to materials applications, where concentrations of elements are fairly high. RBS is specifically well suited to the study of thin film structures. The NMP is useful in studying lateral inhomogeneities in these layers [30] as, for example, in cases where the solid state reaction of elements in the surface layers occur at specific locations on the surfaces. Other aspects, such as lateral diffusion, can also be studied in three-dimensions.

Figure B1.24.16. An example of the application of the PIXE technique using the NMP in the imaging mode. The figures show images of the cross section through a root of the *Phaseolus vulgaris L.* plant. In this case the material was sectioned, freeze-dried and mounted in vacuum for analysis. The scales on the right of the figures indicate the concentrations of the elements in ppm by weight. It is clear that the transports of the elements through the root are very different, not only in the cases of the major elements Ca and K, but also in the case of the trace element Zn.

There are some special techniques that can be used with the NMP, specifically scanning transmission ion microscopy (STIM). In this case the bombarding ion beam is allowed to penetrate through a thin sample and the energies of the transmitted ions are measured. As the energy loss of the ions through the sample is directly proportional to the amount of material traversed, the sample 'thickness' can be imaged with very high

efficiency. The technique is so efficient because every ion is counted. Beam currents of only a few fA are needed, thus permitting an imaging resolution of about 100 nm. The technique is well suited for the study of biological material where cell structure is easily identifiable due to the thickness differences in different parts of cells. An example is shown of STIM measurements of human oral cancer cells in figure B1.24.17. The different images indicate areas of different thickness, starting from thin to thick areas. The technique offers a ‘thickness’ scan through the sample and, in this case, the cell walls of one specific cell can be seen in the areas dominated by thicker structures. There is relatively little material in the inner areas of the cell.

Figure B1.24.17. An example of scanning transmission ion microscopy (STIM) measurements of a human oral cancer cell. The different images indicate different windows in the energy of transmitted helium ions as indicated in the figure. White indicate areas of high counts. The technique offers a ‘thickness’ scan through the sample, and, in this case, the cell walls of one specific cell can be seen in the areas dominated by thicker structures (data from C A Pineda, National Accelerator Centre, Faure, South Africa).

Another special application of the NMP is the measurement of single event upset (SEU) in memory structures of computer chips [31]. In this technique, a single ion is directed onto a part of the memory structure, with a subsequent measurement of whether the memory bit was changed by the ion impact. In this way, the radiation hardness of different parts of the memory can be imaged. This information is valuable for production of components for space applications, where devices are subjected to high fluxes of ionizing radiation. A modern trend is also to study SEUs in living biological material to detect structures susceptible to radiation damage. A similar technique is the study of ion-beam-induced charge (IBIC) collection [32] from p–n junctions in semiconductor material. In this case, the ion beam is directed onto a p–n junction and the current flowing through the junction is measured. By rastering the beam an image can be obtained of the quality of these junctions.

B1.24.8 FORWARD RECOIL SPECTROMETRY (FRS)

Forward recoil spectrometry (FRS) [33], also known as elastic recoil detection analysis (ERDA), is fundamentally the same as RBS with the incident ion hitting the nucleus of one of the atoms in the sample in an elastic collision. In this case, however, the recoiling nucleus is detected, not the scattered incident ion. RBS and FRS are near-perfect complementary techniques, with RBS sensitive to high-Z elements, especially in the presence of low-Z elements. In contrast, FRS is sensitive to light elements and is used routinely in the detection of H at sensitivities not attainable with other techniques [34]. As the technique is also based on an incoming ion that is slowed down on its inward path and an outgoing nucleus that is slowed down in a similar fashion, depth information is obtained for the elements detected.

The analytically important parameters in FRS are exactly those of RBS. Naturally, the target nucleus can only recoil in the forward direction and, therefore, thick targets must be bombarded at an oblique angle to allow detection of the recoil. Thin targets allow the recoiling nucleus to be transmitted through the target. In the case of thick targets, the incident ion also has a high probability of scattering from the target into the detector. It is common that a filter is applied in front of the detector to remove scattered projectiles. This is possible because the projectile has a higher Z and lower energy and can be stopped while allowing the recoils through to the detector. Because of the kinematics as well as straggling, the depth resolution is somewhat worse than that obtainable with RBS. A simple schematic of the experimental setup for FRS is shown in figure B1.24.18.

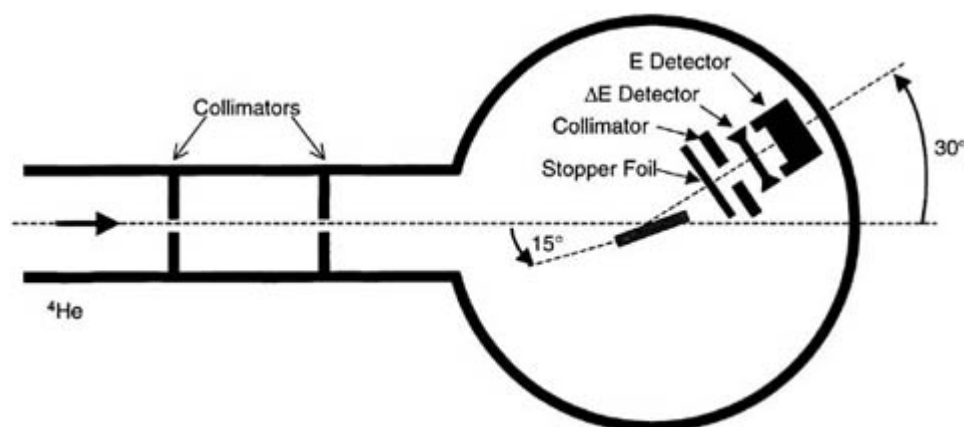

Figure B1.24.18. A simple schematic diagram of the experimental setup for FRS. The most common use of the technique is that of hydrogen detection using ^4He of a few MeV with the recoils being detected at 30° with respect to the beam direction and using a stopper foil to keep ^4He from hitting the detector. This set-up can be generalized to include an energy loss (ΔE) detector in front of the detector thus allowing, in one experiment, the separation of signals due to hydrogen, deuterium and tritium.

The most common use of FRS is the detection of H using ^4He of a few MeV, with the recoils being detected at 30° with respect to the beam direction and a stopper foil to keep ^4He from hitting the detector. This set-up can be generalized to include an energy loss (ΔE) detector in front of the detector, thus allowing the separation of signals from H, D and T in one experiment. The result of such an experiment [35] is shown in figure B1.24.19 where a sample was analysed for hydrogen, deuterium and tritium content using a 3.8 MeV ^4He beam, and detecting the recoils at 30° with a $13.6 \mu\text{m}$ ΔE detector. The three-dimensional graph shows a plot of the counts obtained versus ΔE on the one axis and the energy measured (with a surface barrier detector) after passing through the ΔE detector on the other axis. The traces due to the three isotopes of hydrogen can clearly be seen, with the edges at high E corresponding to the surface of the sample. The shape of the traces from the surface to lower energies are indicative of the depth distribution of isotopes in the sample.

Figure B1.24.19. The FRS result of an experiment where a sample was analysed for hydrogen, deuterium and tritium content using a 3.8 MeV ^4He beam, detecting the recoils at 30° with a $13.6\ \mu\text{m}$ ΔE detector. The three-dimensional graph shows a plot of the counts obtained versus ΔE on the one axis and the total energy ($E + \Delta E$) on the other axis. The traces due to the three isotopes of hydrogen can clearly be seen, with the edges at high E corresponding to the surface of the sample. The shape of the traces from the surface to lower energies are indicative of the depth distribution of these isotopes in the sample.

The most advanced applications of the FRS technique employ high-energy (some tens of MeV) heavy ions, such as Cl and I [36]. In this case a number of nuclei lighter than the projectile can be detected. A detector that can separate different nuclei is required. A two-stage detector is used in which either the time of flight or the energy loss ΔE is determined together with the energy, thus allowing the separation of nuclei with different mass (and Z in the case of ΔE).

An example of such a measurement is shown in [figure B1.24.20](#) where a $\Delta E-E$ detector telescope was used to discriminate between different elements. When using heavy ions as incident particles in the analysis of surface layers, care must be taken not to damage the surface.

Figure B1.24.20. An example of a heavy-ion (iodine) FRS measurement where a large $\Delta E-E$ detector

telescope was used to enable the discrimination of different elements. The plot shows counts (as intensity plot) versus ΔE and E . The sample analysed was graphite introduced in an experimental nuclear fusion device (tokamak). In this device, a plasma causes different elements to be deposited on the surface of the sample. These elements were determined using a 200 MeV I beam with the detector telescope at 37.5° with respect to the incident beam. It is clear that all the elements from Ni down to Be can be detected in one experiment. The starting points of the traces at high energies indicate concentration of the elements at or near the surface. The trend of the lines as a function of E indicates the concentrations of the elements as a function of depth.

B1.25 Surface chemical characterization

L Coulier and J W Niemantsverdriet

B1.25.1 INTRODUCTION

Chemical characterization of surfaces plays an important role in various fields of physics and chemistry, e.g. catalysis, polymers, metallurgy and organic chemistry. This section briefly describes the concepts and a few examples of the techniques that are most frequently used for chemical surface characterization, which are x-ray photoelectron spectroscopy (XPS), Auger electron spectroscopy (AES), ultraviolet photoelectron spectroscopy (UPS), secondary ion mass spectrometry (SIMS), temperature programmed desorption (TPD) and electron energy loss spectroscopy (EELS), respectively. We have tried to give examples in a broad range of fields. References to more extensive treatments of these techniques and others are given at the end of the section, see '[Further reading](#)'.

Although the techniques described undoubtedly provide valuable results on various materials, the most useful information almost always comes from a combination of several (chemical and physical) surface characterization techniques. Table B1.25.1 gives a short overview of the techniques described in this chapter.

B1.25.2 ELECTRON SPECTROSCOPY (XPS, AES, UPS)

B1.25.2.1 X-RAY PHOTOELECTRON SPECTROSCOPY (XPS)

X-ray photoelectron spectroscopy (XPS) is among the most frequently used surface chemical characterization techniques. Several excellent books on XPS are available [1, 2, 3, 4, 5, 6 and 7]. XPS is based on the photoelectric effect: an atom absorbs a photon of energy $h\nu$ from an x-ray source; next, a core or valence electron with binding energy E_b is ejected with kinetic energy (figure B1.25.1):

$$E_k = h\nu - E_b - \varphi \quad (\text{B1.25.1})$$

where E_k is the kinetic energy of the photoelectron, h is Planck's constant, ν is the frequency of the exciting radiation, E_b is the binding energy of the photoelectron with respect to the Fermi level of the sample and φ is the work function of the spectrometer. Routinely used x-ray sources are **Mg K α** ($h\nu = 1253.6$ eV) and **Al K α** ($h\nu = 1486.3$ eV). In XPS one measures the intensity of photoelectrons $N(E)$ as a function of their kinetic energy E_k . The XPS spectrum is a plot of $N(E)$ versus E_b ($= h\nu - E_k - \varphi$).

-2-

Table B1.25.1 Overview of the surface characterization techniques described in this chapter.

Acronym	Full name	Principle of measurement	Key information
XPS	X-ray photoelectron spectroscopy	Absorption of a photon by an atom, followed by the ejection of a core or valence electron with a characteristic binding energy.	Composition, oxidation state, dispersion
AES	Auger electron spectroscopy	After the ejection of an electron by absorption of a photon, an atom stays behind as an unstable ion, which relaxes by filling the hole with an electron from a higher shell. The energy released by this transition is taken up by another electron, the Auger electron, which leaves the sample with an element-specific kinetic energy.	Surface composition, depth profiles
UPS	UV photoelectron spectroscopy	Absorption of UV light by an atom, after which a valence electron is ejected.	Chemical bonding, work function
SIMS	Secondary ion mass spectroscopy	A beam of low-energy ions impinges on a surface, penetrates the sample and loses energy in a series of inelastic collisions with the target atoms leading to emission of secondary ions.	Surface composition, reaction mechanism, depth profiles
TPD	Temperature programmed desorption	After pre-adsorption of gases on a surface, the desorption and/or reaction products are measured while the temperature increases linearly with time.	Coverages, kinetic parameters, reaction mechanism
EELS	Electron energy loss spectroscopy	The loss of energy of low-energy electrons due to excitation of lattice vibrations.	Molecular vibrations, reaction mechanism

Photoelectron peaks are labelled according to the quantum numbers of the level from which the electron originates. An electron coming from an orbital with main quantum number n , orbital momentum l (0, 1, 2, 3, ... indicated as s, p, d, f, ...) and spin momentum s (+1/2 or -1/2) is indicated as nl_{l+s} . For every orbital momentum $l > 0$ there are two values of the total momentum: $j = l + 1/2$ and $j = l - 1/2$, each state filled with $2j + 1$ electrons. Hence, most XPS peaks come in doublets and the intensity ratio of the components is $(l + 1)/l$. When the doublet splitting is too small to be observed, the subscript $l + s$ is omitted.

Figure B1.25.2 shows the XPS spectra of two organoplatinum complexes which contain different amounts of chlorine. The spectrum shows the peaks of all elements expected from the compounds, the Pt 4f and 4d doublets (the 4f doublet is unresolved due to the low energy resolution employed for broad energy range scans), Cl 2p and Cl 2s, N 1s and C 1s. However, the C 1s cannot be taken as characteristic for the complex only. All surfaces that have not been cleaned by sputtering or oxidation in the XPS spectrometer contain carbon. The reason is that adsorbed hydrocarbons from the atmosphere give the optimum lowering of the surface free energy and hence, all surfaces are covered by hydrocarbon fragments [9].

-3-

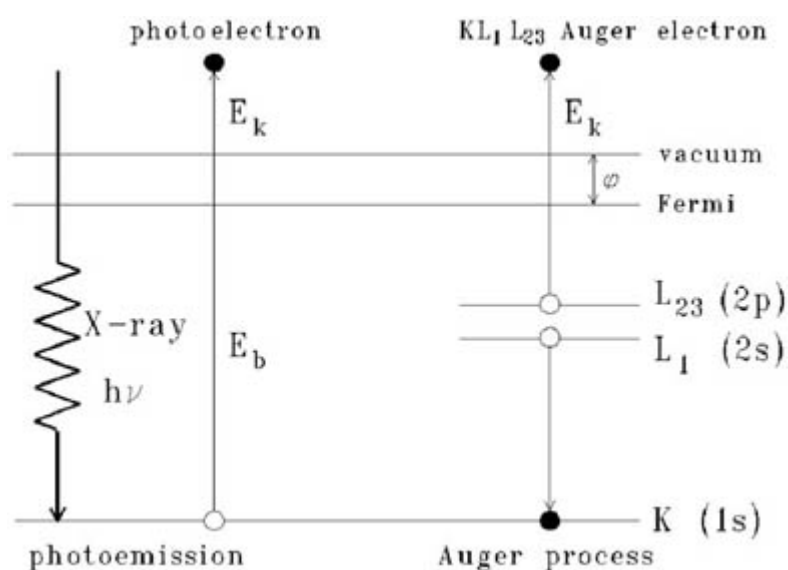

Figure B1.25.1. Photoemission and Auger decay: an atom absorbs an incident x-ray photon with energy $h\nu$ and emits a photoelectron with kinetic energy $E_k = h\nu - E_b$. The excited ion decays either by the indicated Auger process or by x-ray fluorescence.

Figure B1.25.2. XPS scans between 0 and 450 eV of two organoplatinum complexes showing peaks due to Pt, Cl, N and C. The C 1s signal represents not only carbon in the compound but also contaminant hydrocarbon fragments, as in any sample. The abbreviation ‘Me’ in the structures stands for CH₃ (courtesy of J C Muijsers, Eindhoven).

Because a set of binding energies is characteristic for an element, XPS can analyse chemical composition. Almost all photoelectrons used in laboratory XPS have kinetic energies in the range of 0.2 to 1.5 keV, and probe the outer layers of the sample. The mean free path of electrons in elemental solids depends on the kinetic energy. Optimum surface sensitivity is achieved with electrons at kinetic energies of 50–250 eV, where about 50% of the electrons come from the outermost layer.

Binding energies are not only element specific but contain chemical information as well: the energy levels of core electrons depend on the chemical state of the atom. Chemical shifts are typically in the range 0–3 eV. In general, the binding energy increases with increasing oxidation state and, for a fixed oxidation state, with the electronegativity of the ligands. Figure B1.25.3 illustrates the sensitivity of XPS binding energy to oxidation states for platinum in metal, and in the two organoplatinum complexes of [Figure B1.25.2](#). The Pt 4f_{7/2} peak of the metal comes at 71.0 eV, that of the complex where Pt has one Cl ligand at 72.0 eV, characteristic of Pt²⁺, while the binding energy of the Pt⁴⁺ in the complex with three Cl ligands on platinum is again 2 eV higher, 74.4 eV [9]. The binding energy goes up with the oxidation state of the platinum. The reason is that the 74 electrons in the Pt⁴⁺ ion (lower curve) feel a higher attractive force from the nucleus with a positive charge of 78⁺ than the 76 electrons in Pt²⁺ (middle curve) or the 78 in the neutral Pt atom (upper curve).

Figure B1.25.3. Pt 4f XPS spectra of platinum metal (top) and of the two organoplatinum compounds (a) and (b), middle and bottom respectively, shown in figure B1.25.2, illustrating that the Pt 4f binding energy reflects the oxidation state of platinum (from [9]).

-5-

Note that XPS measures binding energies. These are not necessarily equal to the energy of the orbitals from which the photoelectron is emitted. The difference is caused by reorganization of the remaining electrons when an electron is removed from an inner shell. Thus, the binding energy of the photoelectron contains both information on the state of the atom before photoionization (the initial state) and on the core-ionized atom left behind after the emission of an electron (the final state) [6]. Fortunately, it is often correct to interpret binding energy shifts in terms of initial state effects.

Determining compositions is possible if the distribution of elements over the outer layers of the sample and the surface morphology is known. Two limiting cases are considered, namely a homogeneous composition throughout the outer layers and an arrangement in which one element covers the other.

For homogeneous mixed samples it is relatively easy to determine the relative concentrations of the various constituents. For two elements one has approximately:

$$n_1/n_2 = (I_1/S_1)/(I_2/S_2) \quad (\text{B1.25.2})$$

where n_1/n_2 is the ratio of elements 1 and 2, I_1, I_2 are the intensities of the peaks of elements 1 and 2 (i.e. the area of the peaks) and S_1, S_2 are atomic sensitivity factors which are tabulated [8].

A more accurate calculation will account for differences in the energy dependent mean free paths of the elements and for the transmission characteristics of the electron analyser (see [7]).

An example in which XPS is used for studying surface compositions and oxidation states is illustrated in

[figure B1.25.2](#) and [figure B1.25.3](#) for two organoplatinum complexes. The samples were prepared for XPS by letting a solution of the complexes in dichloromethane dry on a stainless steel sample stub. The sample should thus be homogeneous and the use of [\(B1.25.2\)](#) permitted. [Figure B1.25.2](#) shows the wide scan up to a binding energy of 450 eV [9]. The figure shows immediately that the Cl peaks in the spectrum of the trichloride complex are about three times as intense as in the spectrum of the compound with one Cl. If we apply [\(B1.25.2\)](#) for the elements Pt, N and Cl, we obtain Pt:N:Cl = 1:1.9:4 for the trichloride complex, close to the true stoichiometry of 1:2:3.

In the case of metal particles distributed on a support material (e.g. supported catalysts), XPS yields information on the dispersion. A higher metal/support intensity ratio (at the same metal content) indicates a better dispersion [3].

Another good example of the application of XPS in a different field of chemistry is shown in [figure B1.25.4](#). This figure shows the C 1s spectrum of a polymer [11]. Four different carbon species can be distinguished. Reference tables indicate that the highest binding energy peak is due to carbon-fluorine species [7, 8]. The other three peaks are attributed (from high to low binding energy) to an ester species, an ether species and hydrocarbon/benzene fragments, respectively [8]. Hence, the carbon XPS spectrum nicely reflects the structure of the polymer. This example is also a nice illustration of the influence of the electronegativity of the ligands on the binding energy of carbon: the binding energy of carbon increases with the electronegativity of the ligands.

-6-

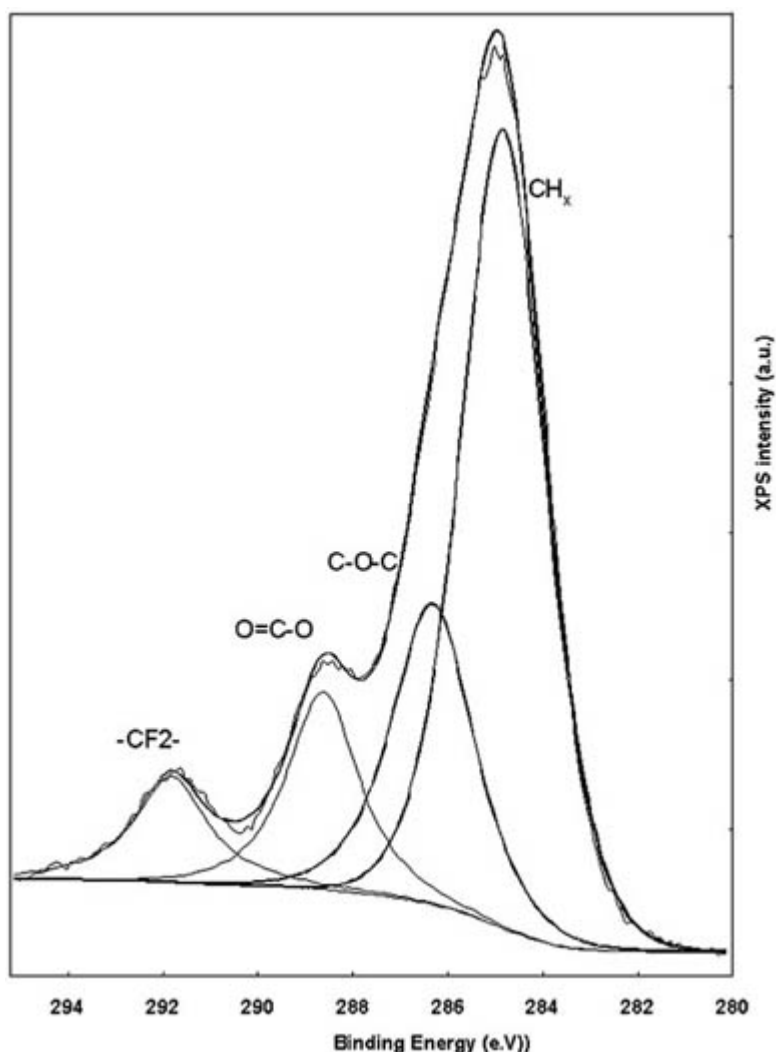

Figure B1.25.4. C 1s XPS spectrum of a polymer, illustrating that the C 1s binding energy is influenced by the chemical environment of the carbon. The spectrum clearly shows four different kinds of carbon, which corresponds well with the structure of the polymer (courtesy of M W G M Verhoeven, Eindhoven).

Owing to the limited escape depth of photoelectrons, the surface sensitivity of XPS can be enhanced by placing the analyser at an angle to the surface normal (the so-called take-off angle of the photoelectrons). This can be used to determine the thickness of homogeneous overlayers on a substrate.

This is demonstrated by the XPS spectra in [figure B1.25.5\(a\)](#) which show the Si 2p spectra of a silicon crystal with a thin (native) oxide layer, measured under take-off angles of 0° and 60° [12]. When the take-off angle is high, relatively more photoelectrons from the oxide surface region reach the analyser and the Si^{4+}/Si intensity ratio increases with increasing angle. [Figure B1.25.5\(b\)](#) shows the intensity ratio as a function of take-off angle, the line being a fit corresponding to a flat, homogeneous oxide layer with a uniform thickness of 2 nm.

-7-

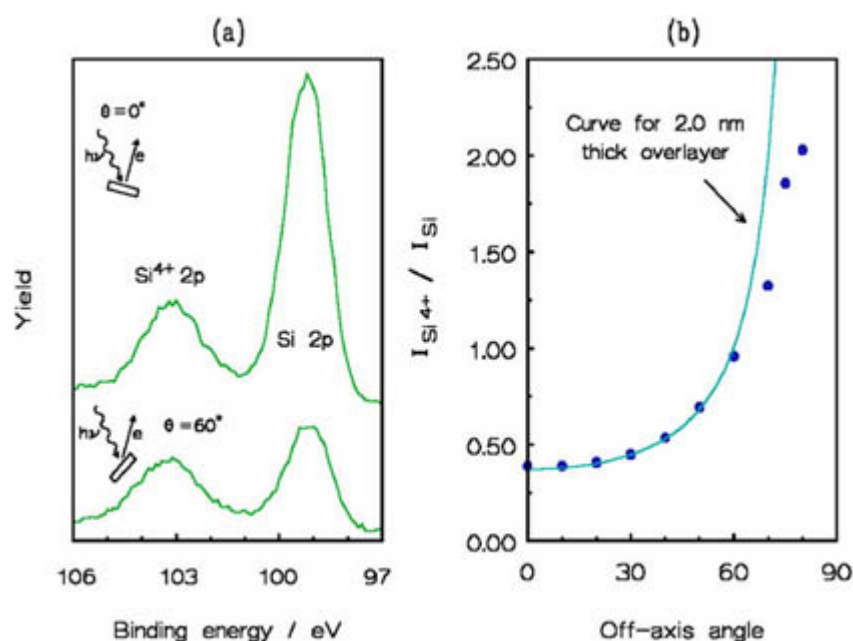

Figure B1.25.5. (a) XPS spectra at take-off angles of 0° and 60° as measured from the surface normal from a silicon crystal with a thin layer of SiO_2 on top. The relative intensity of the oxide signal increases significantly at higher take-off angles, illustrating that the surface sensitivity of XPS increases. (b) Plot of Si^{4+}/Si 2p peak areas as a function of take-off angle. The solid line is a fit which corresponds to an oxide thickness of 2.0 nm (from [12]).

An experimental problem in XPS is that electrically insulating samples may charge up during measurement, due to photoelectrons leaving the sample. Since the sample thereby acquires a positive charge, all XPS peaks in the spectrum shift by the same amount to higher binding energies. More serious than the shift itself is that different parts of the sample may acquire slightly different amounts of charge. This phenomenon, called differential charging, gives rise to broadening of the peaks and degrades the resolution. Correction for charging-induced shifts is made by using the binding energy of a known compound (in most cases one uses the C 1s binding energy of 284.6 eV). Alternatively, in certain circumstances, a low energy electron beam can be used to neutralize the charged surface and eliminate the shift.

Sensitive materials, such as metal salts or organometallic compounds, may decompose during XPS analysis, particularly when a standard x-ray source is used. Apart from the x-rays themselves, heat and electrons from the source may cause damage to the samples. In such cases, a monochromated x-ray source can offer a

solution [9]. Damage is in particular an issue in imaging XPS, where the x-ray intensity is focused in a narrow spot. In this mode, a small hole in front of the analyser entrance enables one to select electrons from an area of a few micrometres, such that an image of the surface composition can be made.

B1.25.2.2 AUGER ELECTRON SPECTROSCOPY (AES)

Auger electron spectroscopy is a powerful technique in the fields of materials and surface science [2, 3 and 4, 7]. In AES, core holes are created by exciting the sample with a beam of electrons. The excited ion relaxes by filling the core hole with an electron from a higher shell. The energy released by this transition is taken up by another electron, the Auger electron, which leaves the sample with an element-specific kinetic energy (figure B1.25.1). The Auger electrons appear as small peaks on a high background of secondary electrons, scattered by the sample from the incident beam. To enhance the visibility of the Auger peaks, spectra are usually presented in the derivative (dN/dE) mode, see figure B1.25.6.

Figure B1.25.6. Energy spectrum of electrons coming off a surface irradiated with a primary electron beam. Electrons have lost energy to vibrations and electronic transitions (loss electrons), to collective excitations of the electron sea (plasmons) and to all kinds of inelastic process (secondary electrons). The element-specific Auger electrons appear as small peaks on an intense background and are more visible in a derivative spectrum.

Auger peaks are labelled according to the x-ray level nomenclature. For example, KL_1L_2 stands for a transition in which the initial core hole in the K shell is filled from the L_1 shell, while the Auger electron is emitted from the L_2 shell. Valence levels are indicated by ‘V’ as in the KVV transitions of carbon or oxygen. The energy of an Auger electron formed in a KLM transition is to a good approximation given by

$$E_{KLM} = E_K - E_L - E_M - \delta E - \varphi \quad (B1.25.3)$$

where E_{KLM} is the kinetic energy of the Auger electron, E_i is the binding energy of an electron in the i shell ($i = K, L, M, \dots$), δE is the energy shift caused by relaxation effects and φ is the work function of the spectrometer. The δE term accounts for the relaxation effect involved in the decay process, which leads to a final state consisting of a heavily excited, doubly ionized atom.

Auger peaks also appear in XPS spectra. In this case, the x-ray ionized atom relaxes by emitting an electron with a specific kinetic energy E_k . One should bear in mind that in XPS the intensity is plotted against the binding energy, so one uses (B1.25.1) to convert to kinetic energy.

The strong point of AES is that it provides a quick measurement of elements in the surface region of conducting samples. For elements having Auger electrons with energies in the range of 100–300 eV where the mean free path of the electrons is close to its minimum, AES is considerably more surface sensitive than XPS.

Auger electron spectroscopy allows for three types of measurement. First, it provides the elemental surface composition of a sample. If the Auger decay process involves valence electrons, one often obtains information on the oxidation state as well, although XPS is certainly the better technique for this purpose. Second, owing to the short data collection times, AES can be combined with sputtering to measure concentrations as a function of depth, see figure B1.25.7. Third, as electron beams are easily collimated and deflected electrostatically, AES can be used to image the composition into a chemical map of the surface (scanning Auger spectroscopy). The best obtained resolution is now around 25 nm [7].

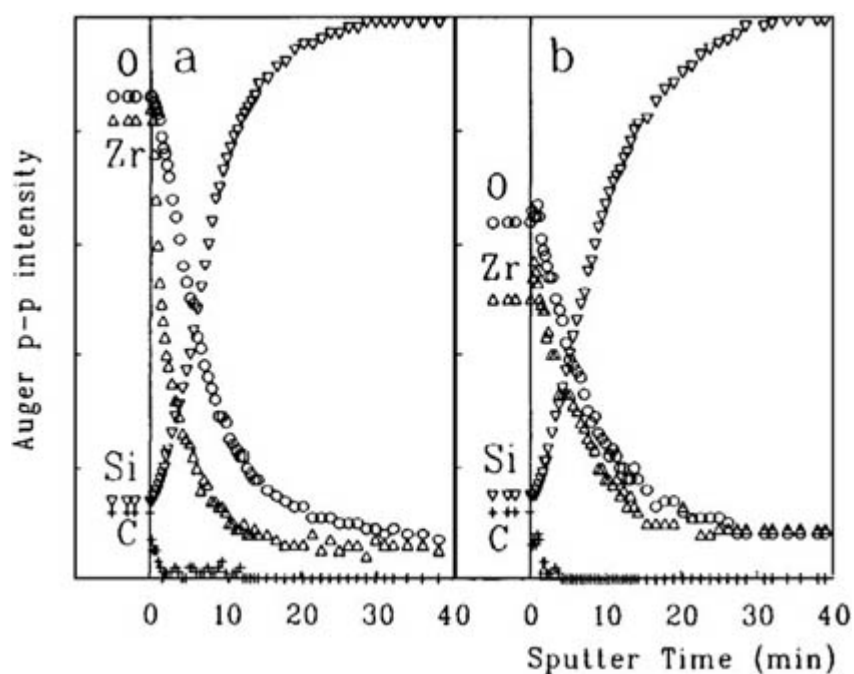

Figure B1.25.7. Auger sputter depth profile of a layered $ZrO_2/SiO_2/Si$ model catalyst. While the sample is continuously bombarded with argon ions that remove the outer layers of the sample, the Auger signals of Zr, O, Si and C are measured as a function of time. The depth profile is a plot of Auger peak intensities against sputter time. The profile indicates that the outer layer of the model catalyst contains carbon. Next Zr and O are sputtered away, but note that oxygen is also present in deeper layers where Zr is absent. The left-hand pattern is characteristic for a layered structure, and confirms that the zirconium is present in a well dispersed layer over the silicon oxide. The right-hand pattern is consistent with the presence of zirconium oxide in larger particles (from [27]).

A disadvantage of AES is that the intense electron beam easily causes damage to sensitive materials (polymers, insulators, adsorbate layers). Charging of insulating samples also causes serious problems.

B1.25.2.3 ULTRAVIOLET PHOTOELECTRON SPECTROSCOPY (UPS)

Ultraviolet photoelectron spectroscopy (UPS) [2, 3 and 4, 6] differs from XPS in that UV light (He I, 21.2 eV; He II, 40.8 eV) is used instead of x-rays. At these low exciting energies, photoemission is limited to valence electrons.

Hence, UPS spectra contain important chemical information. At low binding energies, UPS probes the density of states (DOS) of the valence band (but images it in a distorted way in a convolution with the unoccupied states). At slightly higher binding energies (5–15 eV), occupied molecular orbitals of adsorbed gases may become detectable. UPS also provides a quick measure of the macroscopic work function, ϕ , the energy separation between the Fermi and the vacuum level: $\phi = h\nu - W$, where W is the width of the spectrum. UPS is a surface science technique typically applied to single crystals, the main reason being that all elements contribute peaks to the valence band region. As a result, the UPS spectra of compounds which contain more than two elements are rather complicated.

B1.25.3 SECONDARY ION MASS SPECTROMETRY (SIMS)

Secondary ion mass spectrometry (SIMS) is by far the most sensitive surface technique, but also the most difficult one to quantify. SIMS is very popular in materials research for making concentration depth profiles and chemical maps of the surface. For a more extensive treatment of SIMS the reader is referred to [3] and [14, 15 and 16]. The principle of SIMS is conceptually simple: When a surface is exposed to a beam of ions (Ar^+ , Cs^+ , Ga^+ or other elements with energies between 0.5 and 10 keV), energy is deposited in the surface region of the sample by a collisional cascade. Some of the energy will return to the surface and stimulate the ejection of atoms, ions and multi-atomic clusters (figure B1.25.8). In SIMS, secondary ions (positive or negative) are detected directly with a mass spectrometer.

Figure B1.25.8. The principle of SIMS: Primary ions with an energy between 0.5 and 10 keV cause a collisional cascade below the surface of the sample. Some of the branches end at the surface and stimulate the emission of neutrals and ions. In SIMS, the secondary ions are detected directly with a mass spectrometer.

SIMS is, strictly speaking, a destructive technique, but not necessarily a damaging one. In the dynamic mode, used for making concentration depth profiles, several tens of monolayers are removed per minute. In static SIMS, however, the rate of removal corresponds to one monolayer per several hours, implying that the surface structure does not change during the measurement (between seconds and minutes). In this case one can be sure that the molecular ion fragments are truly indicative of the chemical structure on the surface.

The advantages of SIMS are its high sensitivity (ppm detection limit for certain elements), its ability to detect hydrogen and the emission of molecular fragments which often bear tractable relationships with the parent

structure on the surface. A disadvantage is that secondary ion formation is a poorly understood phenomenon and that quantitation is usually difficult. A major drawback is the matrix effect: Secondary ion yields of one element can vary tremendously with its chemical environment. This matrix effect and the elemental sensitivity variation of five orders of magnitude across the periodic table make quantitative interpretation of SIMS spectra of many compounds extremely difficult.

Figure B1.25.9(a) shows the positive SIMS spectrum of a silica-supported zirconium oxide catalyst precursor, freshly prepared by a condensation reaction between zirconium ethoxide and the hydroxyl groups of the support [17]. Note the simultaneous occurrence of single ions (H^+ , Si^{4+} , Zr^+) and molecular ions (SiO^+ , SiOH^+ , ZrO^+ , ZrOH^+ , ZrO_2^+). Also, the isotope pattern of zirconium is clearly visible. Isotopes are important in the identification of peaks, because all peak intensity ratios must agree with the natural abundance. In addition to the peaks expected from zirconia on silica mounted on an indium foil, the spectrum in figure B1.25.9(a) also contains peaks from the contaminants, Na^+ , K^+ and Ca^+ . This is typical for SIMS: sensitivities vary over several orders of magnitude and elements such as the alkalis are already detected when present in trace amounts.

Figure B1.25.9. Positive SIMS spectra of a $\text{ZrO}_2/\text{SiO}_2$ catalyst, (a) after preparation from $\text{Zr}(\text{OC}_2\text{H}_5)_4$, (b) after drying at 40°C and (c) after calcination in air at 400°C (from [17]).

-12-

The most useful information is in the relative intensities of the Zr^+ , ZrO^+ , ZrOH^+ and ZrO_2^+ ions. This is illustrated in figure B1.25.9(b) and figure B1.25.9(c) which show the isotope patterns of these ions of a freshly dried and a calcined catalyst, respectively [17]. Note that the SIMS spectrum of the fresh catalyst contains small but significant contributions from ZrOH^+ ions (107 amu, $^{90}\text{ZrOH}^+$, and 111 amu, $^{94}\text{ZrOH}^+$). ZrOH^+ is most probably a fragment ion from zirconium ethoxide. In the spectrum of the catalyst which was oxidized at 400°C , the isotope pattern in the ZrO range resembles that of Zr , indicating that ZrOH species are absent. Spectrum figure B1.25.9(b) of the zirconium ethoxide (O:Zr = 4:1) shows higher intensities of the ZrO_2^+ and ZrO^+ signals than the calcined ZrO_2 (O:Zr = 2:1) does. The way to interpret this information is to compare the spectra of the catalysts with reference spectra of ZrO_2 and zirconium ethoxide [17].

For single crystals, matrix effects are largely ruled out and excellent quantization has been achieved by

calibrating SIMS yields by means of other techniques such as EELS and TPD (see further) [18]. Here SIMS offers the challenging perspective to monitor reactants, intermediates and products of catalytic reactions in real time while the reaction is in progress.

A good example of monitoring adsorbed species on surfaces with SIMS is shown in figure B1.25.10. This figure shows positive SIMS spectra of the interaction of NO with the Rh(111) surface [19]. The lower curve shows the adsorption of molecular NO (peak at 236 amu) on Rh(111) at 120 K. The middle curve shows the situation after heating the sample to 400 K. The presence of the peaks at 220 amu (Rh_2N^+) and 222 amu (Rh_2O^+) and the absence of the Rh_2NO^+ (236 amu) indicate that NO has dissociated. Heating the sample at 400 K in H_2 causes the removal of atomic oxygen and, thus, the disappearance of the Rh_2O^+ at 222 amu, as can be seen in the upper curve.

Figure B1.25.10. SIMS spectra of the Rh(111) surface after adsorption of 0.12 ML NO at 120 K (bottom), after heating to 400 K (middle) and after reaction with H_2 at 400 K (top) (from [19]).

As in Auger spectroscopy, SIMS can be used to make concentration depth profiles and, by rastering the ion beam over the surface, to make chemical maps of certain elements. More recently, SIMS has become very popular in the characterization of polymer surfaces [14, 15 and 16].

B1.25.4 TEMPERATURE PROGRAMMED DESORPTION (TPD)

Thermal desorption spectroscopy (TDS) or temperature programmed desorption (TPD), as it is also called, is a simple and very popular technique in surface science. A sample covered with one or more adsorbate(s) is heated at a constant rate and the desorbing gases are detected with a mass spectrometer. If a reaction takes place during the temperature ramp, one speaks of temperature programmed reaction spectroscopy (TPRS).

TPD is frequently used to determine (relative) surface coverages. The area below a TPD spectrum of a certain species is proportional to the total amount that desorbs. In this way one can determine uptake curves that correlate gas exposure to surface coverage. If the pumping rate of the UHV system is sufficiently high, the mass spectrometer signal for a particular desorption product is linearly proportional to the desorption rate of the adsorbate [20, 21]:

$$r = -d\theta/dt = k_{\text{des}}\theta^n = \nu(\theta)\theta^n \exp(-E_{\text{des}}(\theta)/RT) \quad (\text{B1.25.4})$$

$$T = T_0 + \beta t$$

where r is the rate of desorption, E_{des} is the activation energy of desorption, θ is the coverage in monolayers, R is the gas constant, t is the time, T is the temperature, k_{des} is the reaction rate constant for desorption, T_0 is the temperature at the start, n is the order of desorption, β is the heating rate, equal to dT/dt and ν is the preexponential factor of desorption.

With the aid of (B1.25.4), it is possible to determine the activation energy of desorption (usually equal to the adsorption energy) and the preexponential factor of desorption [21, 24]. Attractive or repulsive interactions between the adsorbate molecules make the desorption parameters E_{des} and ν dependent on coverage [22]. In the case of TPRS one obtains information on surface reactions if the latter is rate determining for the desorption.

Figure B1.25.11 shows the temperature programmed reaction between 0.15 ML of CO and 0.24 ML of NO adsorbed at 150 K on a Rh(111) single crystal [23]. The spectra show the desorption of species with masses 28, 29, 30, 44 and 45, corresponding to N_2 , ^{13}CO , NO, N_2O and $^{13}\text{CO}_2$ respectively, as functions of the temperature. N_2 , ^{13}CO and $^{13}\text{CO}_2$ are the only desorption products, indicating that NO is totally dissociated and all N atoms are converted to N_2 . CO is not decomposed at all; part of it desorbs as CO and part of it reacts with atomic oxygen to CO_2 . At higher NO coverages (not shown) the TPD spectrum has also a mass 30 signal, which is due to desorption of NO [28]. In this case, the coverage of adsorbed CO is too low to convert all NO to N_2 and CO_2 .

Figure B1.25.11. Temperature programmed reactions of 0.15 ML of ^{13}CO coadsorbed with 0.24 ML of NO. Adsorption was done at 150 K and the heating rate was 5 K s^{-1} (from [23]).

The disadvantage of TPD is that, in order to derive the kinetic parameters, rather involved computations are necessary [21, 24]. As an alternative to the complete desorption analysis, many authors rely on simplified methods. The analysis of spectra using simplified analysis should be made with care, as simplified analysis methods may easily give erroneous results [21].

B1.25.5 ELECTRON ENERGY LOSS SPECTROSCOPY (EELS)

Molecules possess discrete levels of vibrational energy. Vibrations in molecules can be excited by interaction with waves and with particles. In electron-energy loss spectroscopy (EELS, sometimes HREELS for high resolution EELS), a beam of monochromatic, low energy electrons falls on the surface, where it excites lattice vibrations of the substrate, molecular vibrations of adsorbed species and even electronic transitions. An energy spectrum of the scattered electrons reveals how much energy the electrons have lost to vibrations, according to the formula

$$E = E_0 - h\nu \quad (\text{B1.25.5})$$

where E is the energy of the scattered electron, E_0 is the energy of the incident electrons, h is Planck's constant and ν is the frequency of the excited vibration. The use of electrons requires that experiments are done in high vacuum and preferably on the flat surfaces of single crystals or foils (making ultrahigh vacuum conditions desirable).

While infrared and Raman spectroscopy are limited to vibrations in which a dipole moment or the molecular polarizability changes, EELS detects all vibrations. Two excitation mechanisms play a role in EELS: dipole

and impact scattering [4].

In dipole scattering we are dealing with the wave character of the electron. Close to the surface, the electron sets up an electric field with its image charge in the metal. This oscillating field is perpendicular to the surface and excites only those vibrations in which a dipole moment changes in a direction normal to the surface, similarly as in reflection absorption infrared spectroscopy. The outgoing electron wave has lost an amount of energy equal to $h\nu$, see (B1.25.5), and travels mainly in the specular direction.

The second excitation mechanism, impact scattering, involves a short range interaction between the electron and the molecule (put simply, a collision) which scatters the electrons over a wide range of angles. The useful feature of impact scattering is that all vibrations may be excited and not only the dipole active ones. As in Raman spectroscopy, the electron may also take an amount of energy $h\nu$ away from excited molecules and leave the surface with an energy equal to $E_0 + h\nu$.

Figure B1.25.12 illustrates the two scattering modes for a hypothetical adsorption system consisting of an atom on a metal [3]. The stretch vibration of the atom perpendicular to the surface is accompanied by a change in dipole moment; the bending mode parallel to the surface is not. As explained above, the EELS spectrum of electrons scattered in the specular direction detects only the dipole-active vibration. The more isotropically scattered electrons, however, undergo impact scattering and excite both vibrational modes. Note that the comparison of EELS spectra recorded in specular and off-specular direction yields information about the orientation of an adsorbed molecule.

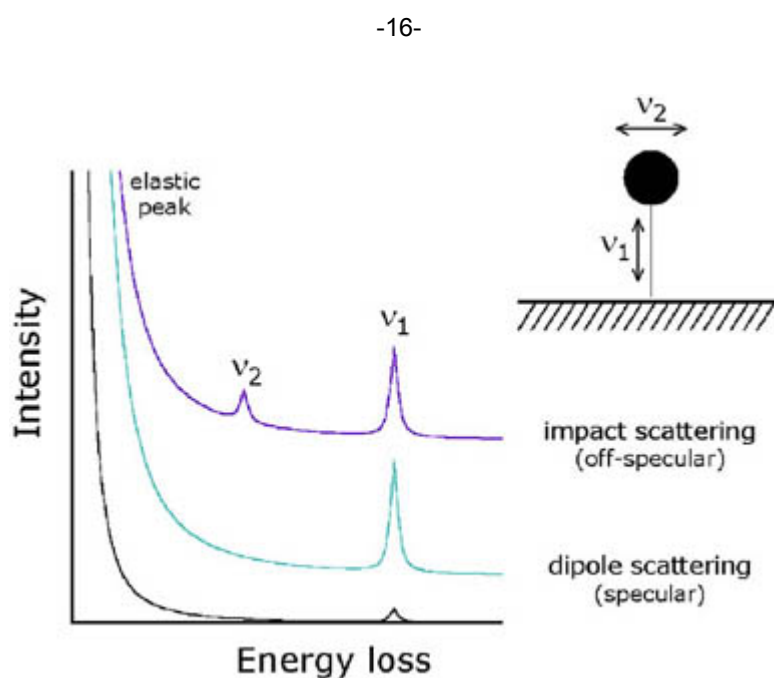

Figure B1.25.12. Excitation mechanisms in electron energy loss spectroscopy for a simple adsorbate system: Dipole scattering excites only the vibration perpendicular to the surface (ν_1) in which a dipole moment normal to the surface changes; the electron wave is reflected by the surface into the specular direction. Impact scattering excites also the bending mode ν_2 in which the atom moves parallel to the surface; electrons are scattered over a wide range of angles. The EELS spectra show the highly intense elastic peak and the relatively weak loss peaks. Off-specular loss peaks are in general one to two orders of magnitude weaker than specular loss peaks.

A strong point of EELS is that it detects losses in a very broad energy range, which comprises the entire infrared regime and extends even to electronic transitions at several electron volts. EELS spectrometers have to satisfy a number of stringent requirements. First, the primary electrons should be monochromatic. Second,

the energy of the scattered electrons should be measured with a high accuracy. Third, the low energy electrons must effectively be shielded from magnetic fields [25].

Figure B1.25.13 shows an HREELS spectrum of CO adsorption on a Rh(111) surface [26]. In the experiment 3 L of CO was adsorbed at a pressure of 1×10^{-8} mbar and $T = 200$ K. At zero energy loss one observes the highly intense elastic peak. The other peaks in the spectrum are loss peaks. At high energy, loss peaks due to dipole scattering are visible. In this case they are caused by CO vibration perpendicular to the surface. The peak at 2070 cm^{-1} is attributed to on-top adsorption of CO on Rh, while the peak at 1861 cm^{-1} corresponds to CO adsorption on a threefold Rh site. The loss peaks at low energy loss are due to metal-adsorbate vibrations. In this case it is the Rh-CO bond. The peak at 434 cm^{-1} is due to the Rh-CO vibration of the CO adsorbed on top, that at 390 cm^{-1} to the Rh-CO vibration in threefold CO. The CO molecules order in a $(2 \times 2) - 3\text{CO}$ structure, with one linear and two threefold CO molecules per (2×2) unit cell.

Figure B1.25.13. HREELS spectrum of CO adsorbed on Rh(111) at $T = 200$ K. Visible are the C-O vibration peaks at energy losses around $1800\text{--}2100 \text{ cm}^{-1}$ and the Rh-CO signals at energy losses $300\text{--}500 \text{ cm}^{-1}$ (courtesy of R Linke [26]).

B1.26 Surface physical characterization

W T Tysoe and Gefei Wu

B1.26.1 INTRODUCTION

The physical structure of a surface, its area, morphology and texture and the sizes of orifices and pores are often crucial determinants of its properties. For example, catalytic reactions take place at surfaces. Simple statistical mechanical estimates suggest that a surface-mediated reaction should proceed about 10^{12} times faster than the corresponding gas-phase reaction for identical activation energies [1]. The catalyst operates by lowering the activation energy of the reaction to accelerate the rate. The reaction rate, however, also increases in proportion to the exposed surface area of the active component of the catalyst so that maximizing its area also strongly affects its activity. Catalysts often have complicated morphologies, consisting of exposed regions, and small micro- and meso-pores. A traditional method for measuring these areas, which is still the workhorse for the catalytic chemists, is to titrate the surface with molecules of known 'areas' and to measure the amount that just covers it. This is done by pressurizing the sample using probe gases and gauging when a single layer of adsorbate forms. This relies on developing robust theoretical methods for determining the equilibrium between the gas phase and the surface. This was done in 1938 by Brunauer, Emmett and Teller. Brunauer and Emmett were catalytic chemists and Teller a theoretical physicist who was persuaded to undertake the theoretical task of developing an adsorption isotherm [2]. This he apparently did in one day and the Brunauer–Emmett–Teller isotherm was born. This, with minor modifications, is the isotherm still used today.

On planar systems, morphologies can be generally measured by directly imaging them using optical ([section B1.19](#) and [section B1.21](#)) or electron ([B1.18](#)) microscopies or using scanning probes (see [section B1.20](#)). Coarse morphologies can be measured using crude probes such as profilometers [3] and, more recently, at the atomic level, using atomic force microscopy ([section B1.20](#)). The measurement of the thickness and properties of thin films deposited onto planar surfaces is more of a challenge. Electron-based spectroscopic probes can measure the nature of the outer selvedge of planar films (see [section B1.6](#), [section B1.7](#), [section B1.21](#)). For example, x-ray photoelectron spectroscopy is useful for measuring films of few Ångströms thick using the electron escape depth. The film itself can be probed using optical spectroscopic techniques such as infrared ([B1.2](#)) and Raman ([B1.3](#)) spectroscopies. Ellipsometry, the change in polarization of linearly polarized light as it passes through the film, is used to measure film thickness non-destructively over a wide range. It is particularly useful for probing surface coatings such as anti-reflection and protective films and has been used very effectively to probe overlayers in ultrahigh vacuum and the formation kinetics of self-

assembled monolayers on gold.

The final technique addressed in this chapter is the measurement of the surface work function, the energy required to remove an electron from a solid. This is one of the oldest surface characterization methods, and certainly the oldest carried out *in vacuo* since it was first measured by Millikan using the photoelectric effect [4]. The observation of this effect led to the proposal of the Einstein equation:

$$E_k = h\nu - e\Phi \quad (\text{B1.26.1})$$

-2-

where ν is the light frequency, h is Planck's constant, E_k the kinetic energy of the emitted electron, e the charge on an electron and Φ the material work function. The resulting notion of wave-particle duality led directly to the development of quantum mechanics. This is not strictly a physical probe since the work function of a clean sample depends on its electronic structure. This is strongly affected by the presence of adsorbates, electronegative adsorbates leading to an increase in work function, and electropositive adsorbates to a decrease. The observations have technological implications, so that filaments used today as electron sources in cathode ray (television) and vacuum tubes (valves) are coated with electropositive alkaline earth compounds that lower the work function and enhance the thermionically emitted current. This allows the filaments to operate effectively at lower temperatures and thereby increases their lifetimes. The main experimental utility of this method is to measure, in a simple and direct way, the coverage of an adsorbate on a surface (see [section A1.7](#)).

B1.26.2 THE BRUNAUER-EMMETT-TELLER (BET) METHOD

B1.26.2.1 PRINCIPLES

(A) MEASUREMENTS OF SURFACE AREA BY GAS ADSORPTION

The central idea underlying measurements of the area of powders with high surface areas is relatively simple. Adsorb a close-packed monolayer on the surface and measure the number N of these molecules adsorbed per unit mass of the material (usually per gram). If the specific area occupied by each molecule is A_m , then the total surface area S_A of the sample is simply given by:

$$S_A = NA_m. \quad (\text{B1.26.2})$$

The saturation coverage during chemisorption on a clean transition-metal surface is controlled by the formation of a chemical bond at a specific site [5] and not necessarily by the area of the molecule. In addition, in this case, the heat of chemisorption of the first monolayer is substantially higher than for the second and subsequent layers where adsorption is *via* weaker van der Waals interactions. Chemisorption is often useful for measuring the area of a specific component of a multi-component surface, for example, the area of small metal particles adsorbed onto a high-surface-area support [6], but not for measuring the *total* area of the sample. Surface areas measured using this method are specific to the molecule that chemisorbs on the surface. Carbon monoxide titration is therefore often used to define the number of 'sites' available on a supported metal catalyst. In order to measure the total surface area, adsorbates must be selected that interact relatively weakly with the substrate so that the area occupied by each adsorbent is dominated by intermolecular interactions and the area occupied by each molecule is approximately defined by van der Waals radii. This

generally necessitates experiments being carried out at low temperatures such that $kT \ll \Delta H_{(\text{ads})}$, the heat of adsorption. Since now both the interaction of the first and subsequent adsorbate layers is dominated by van der Waals

-3-

forces, this leads not simply to the formation of a single monolayer, but also to the growth of second, third and subsequent layers. This distinction is shown in figure B1.26.1 which plots coverage versus pressure at constant temperature (an isotherm) for a molecule (hydrogen) which chemisorbs at the surface where the saturation of the monolayer is clearly evident from the appearance of a plateau [7]. In the case of physisorption, as demonstrated in figure B1.26.2, subsequent layers can grow so that the number of molecules adsorbed in the first monolayer is much more difficult to identify [8]. It is clear, in this case, that the first monolayer forms somewhere near the first 'knee' of the isotherm, labelled point 'B'. The importance of this point was first emphasized by Emmett [9]. In order to usefully measure the total surface area, the shape of the adsorption isotherm must be analysed to more clearly distinguish between monolayer (point B) and multilayer adsorption. In 1985, IUPAC introduced a classification of six different types of adsorption isotherm [11] (figure B1.26.3) exhibited by real surfaces. Types I–V were originally classified by Brunauer, Denning, Denning and Teller (BDDT) [10]. Type I represents the Langmuir isotherm [12] for monolayer coverage and is most often exhibited for chemisorption where the heat of adsorption in the first layer is much greater than that in subsequent layers, but also corresponds to physisorption by microporous adsorbents (pore width < 2 nm) within the solid. Type II are monolayer–multilayer isotherms and represent non-porous or macroporous adsorbents (pore width > 50 nm). Industrial adsorbents and catalysts which possess mesoporous (pore width 2–50 nm) structures often exhibit type IV behaviour. The shapes of types III and V isotherms are analogous to type II and IV respectively, but with weak gas–solid interactions. The stepwise type VI isotherms can be obtained with well defined, uniform solids. The origin of the shapes of some of these isotherms will be discussed in greater detail below.

Figure B1.26.1. Sorption isotherm for chemisorption of hydrogen on palladium film at 273 K (Stephens S J 1959 *J. Phys. Chem.* **63** 188–94).

-4-

(B) TYPICAL ISOTHERMS FOR THE PHYSICAL ADSORPTION OF GASES ON SURFACES

As noted above, an isotherm plots the number of molecules adsorbed on the surface at some temperature in equilibrium with the gas at some pressure. Adsorption gives rise to a change in the free energy which, of

course, depends on the number of molecules already adsorbed on the surface (defined as the coverage, θ , see [section A1.7](#)). If it is assumed for simplicity that the structure of the adsorbed phase is similar to that of a solid (so that, at equilibrium, the chemical potential of the bulk phase equals the chemical potential for the gas phase in equilibrium with it) then:

$$\mu_{\text{bulk}} = \mu^0 + RT \ln P_0 \quad (\text{B1.26.3})$$

where P_0 is the equilibrium vapour pressure. The chemical potential of the adsorbed phase in equilibrium with the gas at some temperature T can similarly be written as:

$$\mu_{\text{ads}} = \mu^0 + RT \ln P. \quad (\text{B1.26.4})$$

We assume for simplicity that the adsorbed phase has the same entropy as the solid so that only an energy change is associated with the transfer of material from the bulk to the adsorbed phase, then:

$$\Delta F = \mu_{\text{ads}} - \mu_{\text{bulk}} = N \Delta E \quad (\text{B1.26.5})$$

where ΔE is the change in energy per adsorbed atom or molecule in going from the solid to the adsorbed phase. Combining equation (B1.26.3), equation (B1.26.4) and equation (B1.26.5) yields:

$$\ln \frac{P}{P_0} = \frac{\Delta E}{kT}. \quad (\text{B1.26.6})$$

If we knew the variation in ΔE as a function of coverage θ , this would be the equation for the isotherm. Typically the energy for physical adsorption in the first layer, $-\Delta E_1$, when adsorption is predominantly through van der Waals interactions, is of the order of $10kT$ where T is the temperature and k the Boltzmann constant, so that, according to equation (B1.26.6), the first layer condenses at a pressure given by $P/P_0 \sim 10^{-3}$. This accounts for the rapid initial rise in the isotherm for low values of P/P_0 shown in [figure B1.26.2](#). In the case of chemisorption, where the interaction is even stronger, the first monolayer saturates at even lower values of P/P_0 . It is initially assumed that adsorption into the second layer is dominated by van der Waals interactions with the sample. The attractive van der Waals energy ϵ_a between two molecules in the gas-phase separated by a distance r is $\epsilon_a \sim -K_a/r^6$ where K_a is a constant. When combined with an r^{-12} repulsive potential, this yields the Lennard-Jones 6–12 equation. An adsorbed species interacts with atoms in the truncated bulk of the sample, and the number of these increases as $\sim r^3$ so that the net van der Waals interaction with the surface varies as r^{-3} . This indicates that the energy of adsorption in the second layer ΔE_2 , assuming this to be dominated by van der Waals interactions with the surface, is given by: $\Delta E_2 = \Delta E_1/2^3$.

From [equation \(B1.26.6\)](#), this yields $\ln(P/P_0) \sim -1.3$ so that the pressure at which this layer is complete should be $P/P_0 \sim 0.3$, a value significantly higher than that required to saturate the first layer. Similarly, the energy required to saturate the third layer will be reduced by a factor 3^3 , the fourth layer 4^3 and so on. Therefore, if a value of ΔE is assumed for the first layer, the pressures at which the second and subsequent layer saturate can be calculated from this value. Writing this in terms of the coverage θ yields a simple form for the variation of ΔE as a function of coverage as $\Delta E_1/\theta^3$. This yields an isotherm for physisorption dominated by van der Waals interactions with the surface as:

$$\ln \frac{P}{P_0} = \frac{\Delta E_1}{kT\theta^3}. \quad (\text{B1.26.7})$$

Such isotherms are shown in [figure B1.26.4](#) for the physical adsorption of krypton and argon on graphitized carbon black at 77 K [13] and are examples of type VI isotherms ([figure B1.26.3](#)). Equation (B1.26.7) further predicts that a plot of $\ln(P/P_0)$ versus $1/\theta^3$ should be linear: such a plot is displayed in [figure B1.26.5](#) [13] for the adsorption of argon on graphitized carbon black at 77 K and yields a good straight line.

Figure B1.26.2. Adsorption isotherm for nitrogen on anatase at 77 K showing ‘point B’ (Harkins W D 1952 *The Physical Chemistry of Surface Films* (New York: Reinhold)).

-6-

Figure B1.26.3. The IUPAC classification of adsorption isotherms for gas–solid equilibria (Sing K S W, Everett D H, Haul R A W, Mosoul L, Pierotti R A, Rouguerol J and Siemieniwska T 1985 *Pure. Appl. Chem.* 57 603–19).

Figure B1.26.4. The adsorption of argon and krypton on graphitized carbon black at 77 K (Eggers D F Jr, Gregory N W, Halsey G D Jr and Rabinovitch B S 1964 *Physical Chemistry* (New York: Wiley) ch 18).

-7-

Figure B1.26.5. Plot of $\ln(P/P_0)$ versus $1/\theta^3$ for argon on graphitized carbon black at 77 K (from the argon data in [figure B1.26.4](#)) (Eggers D F Jr, Gregory N W, Halsey G D Jr and Rabinovitch B S 1964 *Physical Chemistry* (New York: Wiley) ch 18).

It is clear, however, that not all isotherms display the stepwise behaviour shown in [figure B1.26.4](#). For

example, the isotherm for the adsorption of nitrogen on anatase [8] (figure B1.26.2) has a rapid increase in coverage at low pressures, corresponding to the saturation of the first monolayer, but varies much more smoothly with coverage at higher pressures. This effect is also seen in the data for argon on carbon black [13] (figure B1.26.4) where the steps become much less pronounced for multilayer adsorption. Part of the reason for this discrepancy is that, as the layer becomes thicker, intermolecular van der Waals interactions within the layer become more important. This has two effects. First, the difference in energy between layers becomes less pronounced, leading to a smoothing out of the curve. In addition, this decrease in energy difference for each layer means that subsequent layers start to grow even before previous monolayers have saturated. Finally, in the case of high-surface-area samples, the surface tends to become more heterogeneous, leading to a further smoothing out of the steps. The limiting case is an isotherm calculated on a different basis to that used for equation (B1.26.8). Here it is assumed that adsorption in the first layer is dominated by surface van der Waals interactions, but that adsorption into second and subsequent layers is dominated by intermolecular interactions between adsorbates. This clearly no longer results in a strong variation in ΔE with each layer and allows multilayer films to be formed in which another layer can start before the previous layer has been completed. This smooths out the isotherm resulting in a variation of coverage with P that more closely resembles that shown in figure B1.26.2. Such an isotherm has the advantage that it often more closely mimics the behaviour of nitrogen physisorbed on high-surface-area materials and, as such, is more useful in reproducibly identifying ‘point B’. This forms the basis of a reproducible method for measuring surface areas using the BET isotherm. The calculation of the BET isotherm assumes that:

-8-

1. There are B equivalent sites available for adsorption in the first layer.
2. Each molecule adsorbed in the first layer is considered to be a possible adsorption site for molecules adsorbing into a second layer, and each molecule adsorbed in the second layer is considered to be a ‘site’ for adsorption into the third layer, and so on.
3. All molecules in the second and subsequent layers are assumed to behave similarly to a liquid, in particular to have the same partition function. This is assumed to be different to the partition function (A2.2) of molecules adsorbed into the first layer.
4. Intermolecular interactions are ignored for all layers.

Detailed derivations of the isotherm can be found in many textbooks and exploit either statistical thermodynamic methods [1] or independently consider the kinetics of adsorption and desorption in each layer and set these equal to define the equilibrium coverage as a function of pressure [14]. The most common form of BET isotherm is written as a linear equation and given by:

$$\frac{P}{V(P - P_0)} = \frac{1}{V_m C} + \frac{P(C - 1)}{V_m C P_0}. \quad (\text{B1.26.8})$$

Here V_m is the volume of gas required to saturate the monolayer, V the total volume of gas adsorbed, P the sample pressure, P_0 the saturation vapour pressure and C a constant related to the enthalpy of adsorption. The resulting shape of the isotherm is shown plotted in figure B1.26.6 for $C = 500$. A plot of $P/V(P - P_0)$ against P/P_0 should give a straight line having a slope $(C - 1)/V_m C$ and an intercept $1/V_m C$. The BET surface area is then calculated using the following equation:

$$S_A = V_m N A_m \quad (\text{B1.26.9})$$

where S_A is the required surface area of the sample, V_m the volume of the adsorbed monolayer, N Avogadro's number and A_m the cross-sectional area of the adsorbed molecule. In the BET method, where nitrogen is generally used, the value of A_m is taken to be 16.2 \AA^2 per nitrogen molecule. Classically, this BET equation is used for only for systems that exhibit type II and IV isotherms.

-9-

Figure B1.26.6. BET isotherm plotted from [equation \(B1.26.8\)](#) using a value of $C = 500$.

(C) MEASUREMENT OF BET ISOTHERMS

Practically, using the BET method to measure surface area involves three steps: (1) obtaining a full adsorption isotherm, (2) evaluating the monolayer capacity and (3) the calculation of surface area using [equation \(B1.26.9\)](#). It should be emphasized that the BET surface area represents a 'standard' method for measuring the area of a high-surface-area material that allows samples from different laboratories to be compared. Note that, due to the simplifying assumptions of the derivation, the BET method does not work well for type III and V isotherms where the weak interaction between gas and solid makes it hard to discern the formation of the first layer. Attempts to modify the BET equation to take account of these situations have proven unreliable and impractical. Beyond the BET method, approaches such as the Gibbs adsorption isotherm [15], immersion calorimetry [16] or adsorption from solution [17] have been used but the BET method continues as a standard procedure for the determination of surface areas [18]. Generally the measured value of BET-area can be regarded as an effective area unless the material is ultramicroporous. In the case of porous materials, it is important to know the pore sizes and their distributions. This can be calculated for type IV adsorbents where the mesopore size distribution can be obtained using the Kelvin equation:

$$\ln \left(\frac{P}{P_0} \right) = -\frac{2\gamma V}{rRT} \quad (\text{B1.26.10})$$

This equation describes the additional amount of gas adsorbed into the pores due to capillary action. In this case, V is the molar volume of the gas, γ its surface tension, R the gas constant, T absolute temperature and r the Kelvin radius. The distribution in the sizes of micropores may be determined using the Horvath–Kawazoe method [19]. If the sample has both micropores and mesopores, then the T -plot calculation may be used [20]. The T -plot is obtained by plotting the volume adsorbed against the statistical thickness of adsorbate. This thickness is derived from the surface area of a non-porous sample, and the volume of the liquified gas.

B1.26.2.2 INSTRUMENTATION

Two parameters must be measured to apply the BET equation, the pressure at the sample and the amount adsorbed at this pressure. There are three common methods for measuring the amount of gas adsorbed, called the volumetric method, the gravimetric method and the dynamic method, of which the volumetric method is the commonest [21].

(A) VOLUMETRIC METHOD

This method essentially consists of admitting successive charges of gas (generally nitrogen) to the adsorbent using some form of volumetric measuring device such as a gas burette or pipette with the sample held at liquid nitrogen temperature (77 K). Nowadays, the amount of gas admitted to the sample can most conveniently be measured using a mass-flow controller. When equilibrium has been attained, the gas pressure in the dead space surrounding the sample is read using a manometer, and the quantity of gas remaining unadsorbed is then calculated with the aid of the gas law, assuming a perfect gas. The volume of the dead space of the apparatus must, of course, be accurately calibrated. A precision manometer should be employed. The quantity of gas adsorbed onto the surface can be calculated by subtracting the amount remaining unadsorbed from the total amount which has been admitted. This type of apparatus can be simply constructed from glass. Alternatively, commercial BET measuring apparatuses are also available using computers to collect the data and to calculate the resulting surface area [22]. Shown in figure B1.26.7 is a schematic diagram of a typical apparatus for measuring BET isotherms [23]. Helium, which does not adsorb at liquid nitrogen temperatures, is used to calibrate the volume of the dead space and the furnace is used to outgas the sample prior to gas adsorption. A mass-flow controller is often used instead of a burette or pipette to measure total amount of nitrogen that has been admitted.

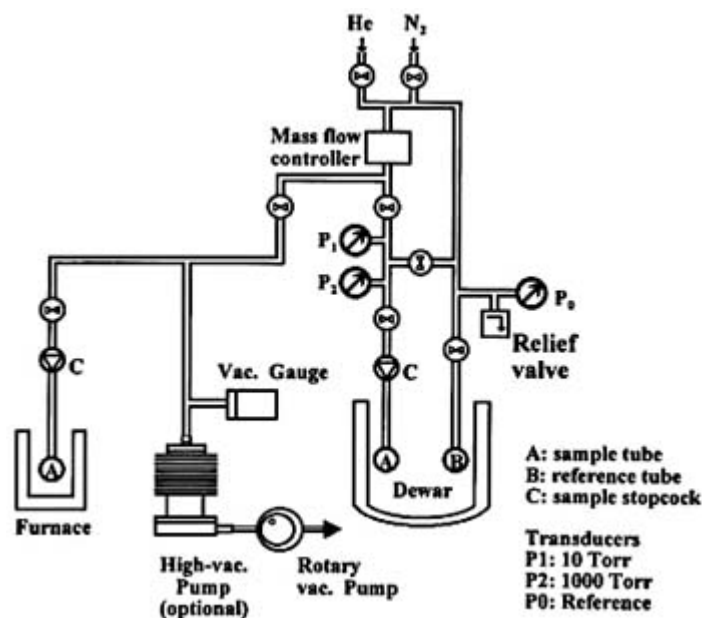

Figure B1.26.7. Diagram of a BET apparatus (representing an OMNISORB 100) (Beckman Coulter 1991 *OMNISORB Manual*).

(B) GRAVIMETRIC METHOD

This method is simple but experimentally more cumbersome than the volumetric method and involves the use of a vacuum microbalance or beam balance [22]. The solid is suspended from one arm of a balance and its increase in weight when adsorption occurs is measured directly. The ‘dead space’ calculation is thereby avoided entirely but a buoyancy correction is required to obtain accurate data. Nowadays this method is rarely used.

(C) DYNAMIC METHOD

This method has been developed using gas chromatographic techniques. The most popular way of implementing this method is by using a continuous nitrogen flow as first described by Nelsen and Eggertsen [24]. A known mixture of nitrogen and helium is passed through a bed of solid sample at ambient temperature (~ 300 K) where the exit gas is measured using a gas chromatographic detector. When the gas composition equilibrates as indicated by a constant base line on the GC recorder chart, the sample tube is immersed in a liquid nitrogen bath. The adsorption of nitrogen by the solid is then indicated by a negative excursion on the recorder chart corresponding to a loss of nitrogen from the system due to adsorption. After equilibrium is established at the particular partial pressure with the sample held at 77 K, the baseline attains its original level. The sample tube is then allowed to warm up to room temperature (300 K) by removal of the liquid nitrogen bath so that a positive excursion appears due to nitrogen desorption (see figure B1.26.8) [24]. The areas under these two curves should be equal and constitute a measure of the amount of nitrogen adsorbed. This method has drawn considerable interest due to its simplicity and speed and since it does not require a vacuum system. One of the main problems is that of deciding on the most appropriate conditions for ‘outgassing’ which can considerably affect the precision.

Figure B1.26.8. Adsorption/desorption peaks for nitrogen obtained with the continuous flow method (Nelsen F M and Eggertsen F T 1958 *Anal. Chem.* **30** 1387–90).

B1.26.2.3 EXPERIMENTAL NOTES

Nitrogen is the most widely used adsorbent (at 77 K) for the BET method and has been employed almost universally. Argon is more suited to the measurement of microporous zeolites. Krypton may be used for the measurement of very low-surface-area (less than $3 \text{ m}^2\text{g}^{-1}$) samples because it has a very low saturation vapour pressure (~ 2.45 Torr) at liquid nitrogen temperature so that the absolute pressure range is from 0 to approximately 0.75 Torr for a ratio of P/P_0 from 0 to 0.3. The absolute pressure range used for the measurement depends upon the type of data reduction required and the adsorbent's properties. The optimum

pressure range needed for BET surface area determinations may be taken to be for P/P_0 up to 0.3 [23].

B1.26.3 ELLIPSOMETRY

B1.26.3.1 PRINCIPLES

The term ellipsometry was first coined by Rothen in 1945 [25] to refer to the measurement of thin films of materials by monitoring the light reflected from them at some incident angle θ . The method is illustrated in [figure B1.26.9](#). The technique was used extensively before this [26]. In the simplest case, the film is transparent with refractive index n , such that light can be reflected or transmitted at the first interface. The transmitted beam propagates through the material and is reflected from the substrate. The reflected portion of the beam can either subsequently reflect from the film/air interface or reflect once again into the film and undergo further reflections. The multiple beams are eventually emitted together so that, in general they are attenuated and one of the parameters that can most simply be measured is the reflectivity of the film. In addition, because of the phase shifts that occur because of path length differences as the beam passes through the film, there is also a change of the phase of this beam which depends on the film thickness d and the wavelength of the light, λ . The way in which this phase change can be measured will be described below. Each of these values, that is, the reflectivity and the phase shift, depend on the polarization of the radiation (see below). When the light is polarized parallel to the surface it is said to be s polarized and when it is polarized perpendicularly to the surface, p polarized. The corresponding reflectivities are denoted R^s and R^p which, since there is a phase change on reflection, are generally complex numbers. The ratio of these values is defined as ρ which is given by:

$$\rho = \frac{R^p}{R^s}. \quad (\text{B1.26.11})$$

Since this is a complex number, it can be separated into an amplitude and a phase and written as:

$$\rho = \frac{|R^p|}{|R^s|} \exp(i\Delta) \quad (\text{B1.26.12})$$

where Δ is the difference between the phase shifts for p- and s-polarized light: $\Delta = \delta_s - \delta_p$. By convention, the ratio of the moduli of the reflectivities of the p- and s-polarized light $|R^p|/|R^s|$ is written in terms of another parameter Ψ where $\tan\Psi = |R^p|/|R^s|$. Thus, the parameters that are measured in ellipsometry are Ψ and Δ which can be related to the refractive index and thickness of the film.

Figure B1.26.9. Schematic diagram showing the reflection of light incident at an angle Θ from a medium with refractive index n_1 through a film of thickness d with refractive index n_2 .

(A) THE NATURE OF ELECTROMAGNETIC RADIATION

As shown by Maxwell, light consists of an oscillating electromagnetic field propagating in vacuum at the speed of light [27, 28, 29, 30, 31, 32 and 33]. Both the electric and magnetic fields are oriented perpendicularly to the direction of propagation of the light and perpendicularly to each other. By convention, the direction in which the electric field points defines the polarization direction so that plane-polarized light has an electric field component only in one direction. A common way to obtain plane-polarized light is to use a polarizer which only transmits light of one polarization and absorbs the other. Polarized spectacles have lenses made from such polarizing material. Maxwell was also able to demonstrate that the velocity v with which light propagates in a material is given by $v = 1/\sqrt{\mu\epsilon}$ where ϵ is the permittivity of the material, ϵ_0 that of vacuum, μ the permeability of the material and μ_0 the value in vacuum. When light propagates in vacuum, this reduces to $v = 1/\sqrt{\mu_0\epsilon_0}$ and yields the speed of light, c . This correspondence provided confirmation that light and electromagnetic radiation were one and the same. The refractive index of a material, n , is defined as $n = c/v$, and is therefore given by $n = \sqrt{\mu\epsilon}$. Since most materials under investigation are not magnetic, $\mu = 1$, and the equation for refractive index simplifies to $n = \sqrt{\epsilon}$.

As electromagnetic radiation propagates through space, the electric field converts into a magnetic field during the oscillation cycle. Thus, the energy present in the electric field converts to energy in a magnetic field. The magnetic field oscillates at the same frequency but 90° out of phase with the electric field so that, when the electric field is a maximum, the magnetic field is a minimum, and *vice versa*. This idea allows us to calculate the relative electric and magnetic field amplitudes in an electromagnetic wave. Let the electric field amplitude be E_0 and the corresponding magnetic field amplitude H_0 . The energy in a magnetic field is proportional to μH_0^2 and that in an electric field is proportional to ϵE_0^2 . Since the electric and magnetic fields interconvert in an electromagnetic wave, conservation of energy requires that these be equal, so that $H_0 = \sqrt{(\epsilon/\mu)}E_0$. Again, assuming that $\mu = 1$ for a non-magnetic material and using the equation for the refractive index above yields: $H_0 = nE_0$.

Non-polarized electromagnetic radiation, of course, comprises two perpendicular polarizations, which can change both in amplitude and in phase with respect to each other. If the two polarizations are in phase with each other, the resultant is just another linearly polarized beam, with the resultant polarization direction given by a simple vector addition of the

two electric field components. When the electric fields of the two polarizations are out of phase with each other, the resulting electric field precesses as it propagates through space. For example, if the two electric

fields are of equal magnitude but 90° out of phase with each other the electric field spirals as it moves through space. Depending on the relative phases, this rotation can be either clockwise or anti-clockwise. In this case, if we were able to look end on at the electric field vector, this would describe a circle and is therefore referred to as circularly polarized light. This particular combination of electric fields also carries with it angular momentum, and is responsible for the angular momentum selection rules in spectroscopy; this is really just the law of conservation of angular momentum. Different relative phases or amplitudes generally lead to elliptically polarized light, so that the phase shift Δ between the reflected and transmitted light measured in ellipsometry is manifested as elliptically polarized light. The different types of polarized light found as the phase shifts between 0 and 360° are shown in figure B1.26.10.

Figure B1.26.10. Various polarization configurations corresponding to different values of the phase shift, Φ

Light can also be absorbed by a material through which it passes. This leads to an attenuation in intensity of the light as it passes through the material, which decays exponentially as a function of distance through the material and is described mathematically by the Beer–Lambert law [34]:

$$I = I_0 \exp(-\epsilon cl) \quad (\text{B1.26.13})$$

where c is the concentration of the absorbant, l the path length and ϵ the extinction coefficient. This is represented in the mathematical description of the propagation of an electromagnetic wave by modifying the dielectric constant to add an imaginary part, k , which is generally written as: $n - ik$ where $i = \sqrt{-1}$.

(B) REFLECTION OF LIGHT FROM A DIELECTRIC SURFACE

Before discussing multiple reflections at a thin film, we will first examine the reflection of light from one material (with real refractive index n_1) into another (with refractive index n_2) [27, 32, 33]. It is assumed that the material does not absorb light and this situation is depicted in [figure B1.26.11](#). Since electromagnetic waves propagate in both materials, the behaviour at the interface is dictated by the boundary conditions for electric and magnetic fields. The components of \mathbf{E} and \mathbf{H} parallel to the surface (in the x direction in [figure B1.26.11](#)) and the components of \mathbf{D} and \mathbf{B}

perpendicular to the surface (in the z direction in [figure B1.26.11](#)) are continuous across the boundary. Thus the reflected and transmitted wave amplitudes can be calculated by simply applying these equations. We will consider the reflection of p-polarized radiation from the surface. The calculation of the equations for s-polarized radiation is essentially identical. The beam is incident at an angle θ_i , and a portion is reflected at an

angle θ_r . Of course, θ_i and θ_r are equal. The remaining light is transmitted at an angle θ_t which will be different to θ_i , due to refraction at the surface. The electric field amplitudes are taken to be E_i in the incident beam, E_r in the reflected beam and E_t in the transmitted beam. The corresponding values for magnetic field amplitudes are H_i , H_r and H_t respectively. Application of the above boundary conditions gives:

$$E_i^0 \cos \theta_i - E_r^0 \cos \theta_r = E_t^0 \cos \theta_t \quad (\text{B1.26.14})$$

$$H_i^0 + H_r^0 = H_t^0. \quad (\text{B1.26.15})$$

Using the above relationship between the electric and magnetic field amplitudes from equation (B1.26.15):

$$n_1 E_i^0 + n_1 E_r^0 = n_2 E_t^0. \quad (\text{B1.26.16})$$

In order to calculate the reflected amplitude, E_r^0 can be eliminated from equation (B1.26.15) and equation (B1.26.16) to yield:

$$\frac{(E_i^0 - E_r^0) \cos \theta_i}{\cos \theta_t} = \frac{n_1(E_i^0 - E_r^0)}{n_2} \quad (\text{B1.26.17})$$

where we have used $\theta_i = \theta_r$. Writing the reflection coefficient for p-polarized radiation as r^p (which equals E_r^0/E_i^0) yields:

$$r^p = \frac{n_2 \cos \theta_i - n_1 \cos \theta_t}{n_2 \cos \theta_i + n_1 \cos \theta_t} \quad (\text{B1.26.18})$$

which is the Fresnel equation for p-polarized radiation. A similar analysis can be carried out for s-polarized radiation using the boundary conditions in a similar way to yield:

$$r^s = \frac{n_1 \cos \theta_i - n_2 \cos \theta_t}{n_1 \cos \theta_i + n_2 \cos \theta_t}. \quad (\text{B1.26.19})$$

Corresponding equations can also be written for the transmitted portion of the beam. For a non-absorbing sample, the refractive index is real, so that $\exp(i\phi)$ is real where ϕ is the phase shift on reflection. This means that ϕ is either 0 or 180°. If, however, the sample absorbs light, the refractive index can become complex, resulting in a phase change of the light. This, for example, must be taken into account when reflecting light from a metallic (mirror) surface.

The reflection coefficients r^p and r^s give the electric field in the reflected beam for each polarization. Since the intensity of light is proportional to the square of the electric field, the reflectances for s- and p-polarized light can be written as $R^p = |r^p|^2$ and $R^s = |r^s|^2$, respectively. These are plotted in [figure B1.26.12](#) for a light beam incident from air ($n = 1$) onto a material with refractive index $n = 3$. It is evident that p-polarized radiation is reflected to a much lesser extent than s-polarized radiation, and exclusively s-polarized radiation is reflected at the polarizing angle. This effect is exploited in polarized sunglasses (as mentioned above) to minimize the reflective glare from surfaces by only allowing p-polarized light to be transmitted. At normal incidence, these equations reduce to:

$$R^s = R^p = \left(\frac{n_2 - 1}{n_2 + 1} \right)^2$$

which for glass with $n \sim 1.5$ gives about 4% reflectivity. The polarizing angle shown in [figure B1.26.12](#) is given by:

$$\tan \theta_i = \frac{n_2}{n_1}$$

and is known as the Brewster angle. p-polarized radiation is perfectly transmitted at this angle and Brewster windows (oriented at this angle) are used in lasers to minimize the loss of radiation in the laser cavity. This often results in laser light being polarized. This effect is exploited in polarimeters (see below). Note finally that the phase shift on reflection from a dielectric is 0° below the Brewster angle and 180° above.

Figure B1.26.11. Diagram showing light impinging from a material of refractive index n_1 at an angle θ_i onto a material with refractive index n_2 and reflected at an angle θ_r and transmitted at an angle θ_t .

-17-

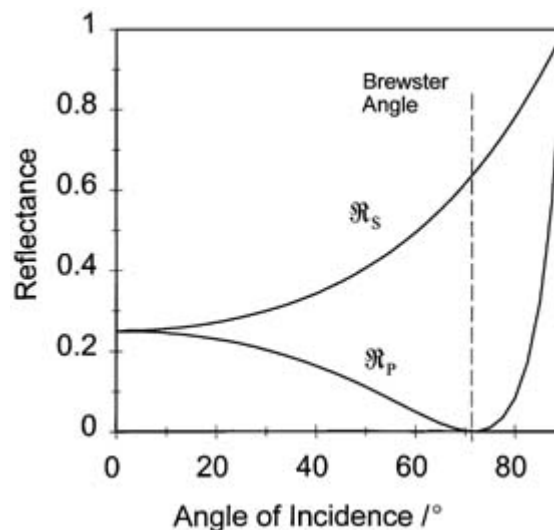

Figure B1.26.12. Plot of the reflectivity of s- and p-polarized light from a material with refractive index $n = 3$.

(C) REFLECTION AT MULTIPLE INTERFACES

We are now in a position to calculate the reflections from multiple interfaces using the simple example of a thin film of material of thickness d with refractive index n_2 sandwiched between a material of refractive index n_1 (where this is generally air with $n = 1$) deposited onto a substrate of refractive index n_3 [35, 36]. This is depicted in [figure B1.26.9](#). The resulting reflectivities for p- and s-polarized light respectively are given by:

$$R^p = \frac{r_{12}^p + r_{23}^p \exp(-i2\beta)}{1 + r_{12}^p r_{23}^p \exp(-i2\beta)} \quad (\text{B1.26.20})$$

and

$$R^s = \frac{r_{12}^s + r_{23}^s \exp(-i2\beta)}{1 + r_{12}^s r_{23}^s \exp(-i2\beta)} \quad (\text{B1.26.21})$$

where r_{ij}^s and r_{ij}^p are the reflection coefficients for s- and p-polarized radiation, respectively, at the interface between material i and j (equation (B1.26.18) and equation (B1.26.19)). The path length difference due to the film results in phase differences between different emerging beams giving rise to complex reflection coefficients and hence phase shifts. As noted above, this produces elliptically polarized light which can be analysed to yield the amplitude and phase shift and ultimately β . This parameter depends on the film thickness and the wavelength of light and is given by:

$$\beta = 2\pi \left(\frac{d}{\lambda} \right) n_2 \cos \theta_2. \quad (\text{B1.26.22})$$

-18-

These equations are generally too complex to be solved analytically even for relatively simpler systems and are therefore solved numerically. The way in which this is done will be described below. The measurement of Δ and Ψ clearly depends on the wavelength of light directly through this equation. However, both the real and imaginary parts of the refractive indices also depend on the wavelength of light. Now the reflectivity of the surface for s- and p-polarized light is $\mathfrak{R}^p = |r^p|^2$ and $\mathfrak{R}^s = |r^s|^2$ respectively. This dependence is also exploited in ellipsometry by measuring Δ and Ψ and a function of light wavelength in a technique known as spectroscopic ellipsometry [37].

B1.26.3.2 APPLICATIONS

(A) MEASUREMENT OF THE OPTICAL CONSTANTS OF MATERIALS USING ELLIPSOMETRY

In this case, the Fresnel (equation (B1.26.18) and equation (B1.26.19)) for reflection at a single interface are used. The phase shift is zero or 180° for a dielectric with a real refractive index, which can be measured directly from the reflectivities ([figure B1.26.12](#)). Intermediate phase shifts are found for absorbant materials with complex refractive indices which can also be measured from Δ and Ψ . This is generally done by numerically solving the Fresnel equation (B1.26.18) and equation (B1.26.19). Many ellipsometers include software to calculate these values directly and Fortran programs are also available to calculate these values. The variation in Ψ plotted as a function of the imaginary part of the refractive index is shown in [figure B1.26.13](#). This varies between 0 and 45° over the range of K values. The variation in Δ as a function of K with

$n = 2$ and an incidence angle of 70° is displayed in [figure B1.26.14](#). Again, the value of Δ varies as the imaginary part of the refractive index changes and can vary between 0 and 180° . It is important to emphasize that, unless a material is extremely pure, its optical constants can vary so that it is generally important to measure these parameters for a particular sample.

Figure B1.26.13. Plot of Ψ versus K , the imaginary part of the refractive index.

-19-

Figure B1.26.14. Plot of Δ versus K , the imaginary part of the refractive index.

(B) MEASUREMENT OF FILM THICKNESS AND OPTICAL PROPERTIES

The way in which ellipsometry can be used to measure film thickness will be illustrated for the simple case of a material with thickness d and complex refractive index n_2 deposited onto a substrate with complex refractive index n_3 with light incident from a material of refractive index n_1 . Since light is generally incident from air, n_1 is usually taken to be unity. This is done by measuring Δ and Ψ and using [equation \(B1.26.20\)](#) and [equation \(B1.26.21\)](#) to calculate the optical properties of the film and its thickness. Since, in addition to the film thickness, there are potentially six other variables in the system (the real and imaginary parts of each of the refractive indices) whereas only two parameters Δ and Ψ are measured, several of these must be determined independently. The substrate parameters can, for example, be measured prior to film deposition as described in the previous section and the refractive index of air is known. The variation in Δ and Ψ with the thickness d of a film of silicon dioxide (with refractive index 1.46) deposited onto a silicon substrate (with refractive index $3.872 - i0.037$) is shown plotted in [figure B1.26.15](#) [37]. This yields a trajectory of the allowed values of Δ and Ψ as the film thickness. Since the film thickness is measured from the interference between the light reflected from the boundary between air and the film and that reflected from the interface between the film and the substrate, the maximum film thickness d_{\max} that can be measured before the

trajectory shown in [figure B1.26.15](#) retraces itself is given by:

$$2d_{\max} \cos \theta_t = \frac{\lambda}{n_2} \quad (\text{B1.26.23})$$

where n_2 is included to take account of the change in wavelength as the light passes through the film with this refractive index. The angle of the transmitted light (θ_t) and the incidence angle (θ_i) are related through Snell's law so that:

$$\cos \theta_t = \sqrt{1 - \frac{\sin^2 \theta_i}{n_2^2}} \quad (\text{B1.26.24})$$

assuming that the light is incident from air ($n = 1$). Substitution into equation (B1.26.23) yields a value of d_{\max} as:

-20-

$$d_{\max} = \frac{\lambda}{2\sqrt{n_2^2 - \sin^2 \theta_2}} \quad (\text{B1.26.25})$$

This shows that the values of Δ and Ψ are identical for films of thickness nd_{\max} where n is an integer. Thus the trajectory shown in [figure B1.26.15](#) retraces itself for multiples of this maximum thickness. For the silicon dioxide film deposited onto silicon, this yields a value of $d_{\max} = 2832 \text{ \AA}$. Thus, in [figure B1.26.15](#) if values Δ and Ψ were measured to be 90 and 25° respectively, this would correspond to a film of $600 + n \times 2832 \text{ \AA}$ thick where $n = 0, 1, 2$ etc.

Figure B1.26.15. The Del/Psi trajectory for silicon dioxide on silicon with angle of incidence $\phi_1 = 70^\circ$ and wavelength $\lambda = 6328 \text{ \AA}$ (Tompkins H G 1993 *A Users Guide to Ellipsometry* (San Diego, CA: Academic)).

B1.26.3.3 INSTRUMENTATION

The following components make up an ellipsometer:

- (1) *Monochromatic light source.* This is generally a small laser, usually a helium–neon laser emitting red light at 6328 Å. The plasma tube of these lasers is usually terminated by a Brewster window (see [section B1.26.3.1](#)) to minimize losses in the laser cavity so that the light emitted by the laser is linearly polarized. If an unpolarized source is used, a polarizer is placed after the light source to produce linearly polarized light.
- (2) *An element that converts linearly polarized light into elliptically polarized light.* This component is made of a birefringent material where the refractive index of light that passes through the material depends on the light polarization with respect to its crystal lattice [33] where there are generally two perpendicular axes with different refractive indices for light polarized along each of these directions. Since, as shown above, the velocity of light through a medium depends on the refractive index, where the velocity of light v in the medium is given by $v = c/n$, this implies that light travels at different velocities depending on the polarization with respect to each of these directions. When the light is polarized along the direction of the smallest refractive index, the light travels the fastest and this is known as the ‘fast’ axis. Since light polarized along the other, higher-refractive-index axis travels more slowly, this is known as the ‘slow’ axis. The refractive indices of the fast and slow axis are

-21-

designated n_f and n_s , respectively, where it follows from the definitions that $n_s > n_f$. If we now imagine linearly polarized light incident on this material with the electric field vector oriented at 45° to each of these axes, the electric field of the incident light along both the slow and fast axes will be equal at $E_0 \cos 45^\circ$, where E_0 is the electric field amplitude of the polarized light. They will also be in phase. The frequency of the light, ν_0 , will be the same for both components within the material, but they will travel with different velocities. This means that after traversing a plate of this material of thickness d , the two components will no longer be in phase with each other so that, according to the discussion in [section B1.26.3.1](#), the light will, in general, be elliptically polarized. In order to calculate this, we first calculate the time required for light polarized along the fast and slow axes to traverse a disc of the birefringent material of thickness d . This is given by $t_s = d/v_s$ and $t_f = d/v_f$ for the slow and fast axes respectively. The difference in transit time for the two beams, $\Delta t = t_s - t_f$. If the period of oscillation of the light is τ ($= 1/\nu_0$), then if $\Delta t = \tau$, the slow beam is one period behind the fast beam and the phase difference is 2π radians. The phase difference for intermediate values of Δt designated $\Delta\phi$ is given by $(2\pi\Delta t/\tau)$. Combining these equations yields:

$$\Delta\phi = \frac{2\pi\nu_0 d}{c}(n_s - n_f). \quad (\text{B1.26.26})$$

If the wavelength of the incident radiation *in vacuo* is λ_0 , equation B1.26.26 becomes:

$$\Delta\phi = \frac{2\pi d}{\lambda_0}(n_s - n_f) \quad (\text{B1.26.27})$$

so the value of $\Delta\phi$ can be selected to be any desired value merely by varying the value of d for a material with particular values of n_s , n_f and λ . It is common to select $\Delta\phi = 90^\circ = (2\pi)/4$ radians, and this is known as a quarter-wave plate for a particular wavelength and produces circularly polarized light from linearly polarized light if the polarization direction of the incident beam is oriented at 45° to the fast and slow axes. Orientating the incident polarization to intermediate angles with respect to the fast and slow axes yields elliptically polarized light. This effect is exploited in the ellipsometer.

- (3) A polarizer which transmits only one polarization of radiation is required to define the state of polarization of the reflected beam.
- (4) The intensity of the reflected light must also be measured. Historically, this was done using the eye. Since, in general, a null (a measurement of the point at which the light decreases to zero) is required, this can be relatively sensitive. However, nowadays, the light intensity is generally measured using a photomultiplier tube.

- (5) These components must be mounted so that the incident and detection angles can be varied and kept equal and a place must be provided to mount the sample.

There are several possible configurations used to construct an ellipsometer [44]. We will describe one example of the one of the most common arrangements shown in [figure B1.26.16](#). The linearly polarized light emerging from the laser passes through the quarter-wave plate, which can be rotated to yield elliptically polarized light. When this reflects from the sample this also produces elliptically polarized light. The quarter-wave plate is rotated to find the condition such that, when the elliptically polarized light interacts with the sample, the phase change produced on reflection exactly compensates for the elliptical polarization of the incident light to produce linearly polarized light. The angle of the resulting linearly polarized light can be accurately determined using the polarizer placed before the detector (known as the analyser) by rotating it so that no light reaches the detector (the null condition). Being able to achieve this depends,

-22-

of course, on the quarter-wave plate being correctly oriented so as to exactly compensate for the effect of the sample and the analyser being oriented at exactly 90° to the direction of the resulting linearly polarized light. The experiment then consists of rotating both the quarter-wave plate and the analyser so that no light reaches the detector. This is often done automatically, and these resulting quarter-wave plate and analyser angles can be simply converted into the parameters Δ and Ψ [37, 44].

Figure B1.26.16. Schematic diagram of an ellipsometer.

B1.26.3.4 EXAMPLES

(A) BASIC STUDIES

Dielectric constants of metals, semiconductors and insulators can be determined from ellipsometry measurements [38, 39]. Since the dielectric constant can vary depending on the way in which a film is grown, the measurement of accurate film thicknesses relies on having accurate values of the dielectric constant. One common procedure for determining dielectric constants is by using a Kramers–Kronig analysis of spectroscopic reflectance data [39]. This method suffers from the series-termination error as well as the difficulty of making corrections for the presence of overlayer contaminants. The ellipsometry method is for the most part free of both these sources of error and thus yields the most accurate values to date [39].

(B) CHARACTERIZATION OF THIN FILMS AND MULTILAYER STRUCTURES

Ellipsometry measurements can provide information about the thickness, microroughness and dielectric function of thin films. It can also provide information on the depth profile of multilayer structures non-destructively, including the thickness, the composition and the degree of crystallinity of each layer [39]. The measurement of the various components of a complex multilayered film is illustrated in [figure B1.26.17](#) [40].

This also illustrates the use of different wavelengths of light to obtain much more information on the nature of the film. Here Δ and Ψ are plotted versus the wavelength of light (\bullet) and the line drawn through these data represents a fit calculated for the various films of yttrium oxide deposited on silica as shown at the bottom of the figure [40].

-23-

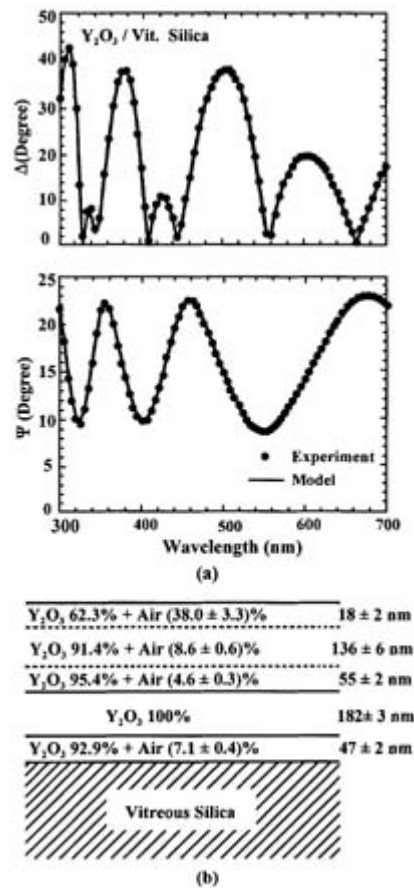

Figure B1.26.17. (a) Observed and calculated ellipsometric $[\Delta(\lambda), \Psi(\lambda)]$ spectra for the Y_2O_3 film on vitreous silica. Angle of incidence 75° . (b) Best-fit model of the Y_2O_3 film on vitreous silica (Chindaudom P and Vedam K 1994 *Physics of Thin Films* vol 19, ed K Vedam (New York: Academic) p 191).

(C) REAL-TIME STUDIES

With the development of multichannel spectroscopic ellipsometry, it is possible now to use real-time spectroscopic ellipsometers, for example, to establish the optimum substrate temperature in a film growth process [41, 42].

B1.26.4 WORK-FUNCTION MEASUREMENTS

B1.26.4.1 PRINCIPLES

The work function (Φ) is defined as the minimum work that has to be done to remove an electron from the bulk of the material to a sufficient distance outside the surface such that it no longer experiences an interaction with the surface electrostatic field [43, 44 and 45]. In other words, it is the minimum energy required to remove an electron from the

highest occupied level (the ‘Fermi level’) of a solid, through the surface, to the so-called vacuum reference level (figure B1.26.18). Thus it is influenced by two factors. The first is associated with the bulk electronic properties of the solid: work function increases with increasing binding energy. The second is associated with penetrating the surface dipole layer: work function changes with surface contamination and structure.

Figure B1.26.18. Schematic diagram of the energy levels in a solid.

In order to understand the tendency to form a dipole layer at the surface, imagine a solid that has been cleaved to expose a surface. If the truncated electron distribution originally present within the sample does not relax, this produces a steplike change in the electron density at the newly created surface (figure B1.26.19(A)).

Since the electron density $\rho(x) \propto |\psi(x)|^2$, where $\psi(x)$ is the electron wavefunction, this implies that the electron wavefunction varies in a similarly step-wise fashion at the interface. This indicates that $d^2\psi/dx^2|_s$, where s indicates that the derivative is evaluated at the surface, becomes infinite. Since the electron kinetic energy $E_K = (-\hbar^2/2m) (d^2\psi/dx^2)$, this creates an infinite-energy surface. This energy can be decreased by reducing $d^2\psi/dx^2$ and by allowing the wavefunction to become ‘smoother’ at the interface as shown in figure B1.26.19(B). This means that electron density previously within the sample extends outside the sample, producing a negative charge. Since the sample was originally electrically neutral, the excess charge outside the sample is balanced by a corresponding positive charge within it, resulting in an electric dipole moment at the surface. The work required to separate these charges increases the potential energy at the same time as the kinetic energy decreases. The equilibrium surface dipole moment corresponds to the minimum in this energy and this has been discussed in detail by Smoluchowski [46, 47]. In general, the greater the electron density of the sample, the larger will be the surface dipole. Thus, for the same metal, close-packed surfaces generally have the highest work functions; for example, in the case of copper, the work functions of the various surfaces are Cu(111): $\Phi = 4.94$ eV, Cu(100): $\Phi = 4.59$ eV, Cu(110): $\Phi = 4.48$ eV [45]. It is the presence of this surface dipole that renders the work function sensitive to changes in surface properties. For example, the surface dipole layer may change as a result of adsorption. Adsorbed species can be viewed as having a discrete dipole moment that tends to modify the total dipole layer at the surface by charge transfer and consequently change the work function. Thus, measurement of the work function change, $\Delta\Phi = \Phi_{\text{adsorbatecovered}} - \Phi_{\text{clean}}$ yields important information on the degree of charge reorganization upon adsorption and the surface coverage of the adsorbate. For example, adsorption of an electronegative species (for example, chlorine, hydrogen etc) will tend to increase the surface dipole moment causing an increase in work function ($\Delta\Phi$ positive).

Correspondingly, an electropositive adsorbate (for example, an alkali metal) decreases the surface dipole moment causing a decrease in the work function ($\Delta\Phi$ negative). These changes can be used to measure the adsorbate coverage as illustrated in figure B1.26.20. Here it is assumed that there are N adsorbates per unit area each having an effective charge q . This is balanced by an equal and opposite ‘image charge’ in the substrate a distance d away so that each adsorbate possesses a dipole moment $\mu = qd$. The separated layers of positive and negative charge can be thought of as forming a parallel-plate capacitor, where the potential difference between the capacitor plates corresponds to the change in work function of the sample. If the total charge per unit area on each of the plates is Q , then:

$$Q = C \Delta \Phi \tag{B1.26.28}$$

where C is the capacitance per unit area and is ϵ_0/d . Since $Q = Nq$, equation (B1.26.28) becomes:

$$Nq = \frac{\Delta \phi \epsilon_0}{d} \tag{B1.26.29}$$

which, remembering that $\mu = qd$, yields the Helmholtz equation:

$$\Delta \Phi = \frac{N\mu}{\epsilon_0} \tag{B1.26.30}$$

and shows that, for this simple case, the change in work function varies linearly with the adsorbate coverage N and the surface dipole moment of the adsorbate μ . A simplifying assumption in these equations is that either the coverage or the surface dipole moment or both are sufficiently small that the dipoles do not interact. If the distance between the dipoles decreases (as the coverage becomes larger) and/or if the dipole moment is large, the electric field created by one dipole can polarize adjacent dipoles to reduce their dipole moments. This effect is known as depolarization. This situation has been described by Topping [48] and Miller [49] and the resulting change in work function taking these effects into account is given by:

$$\Delta \Phi = \frac{N\mu(1 + 9\alpha N^{3/2})}{\epsilon_0} \tag{B1.26.31}$$

where α is the polarizability of the adsorbate. This reduces to equation (B1.26.30) for low coverages.

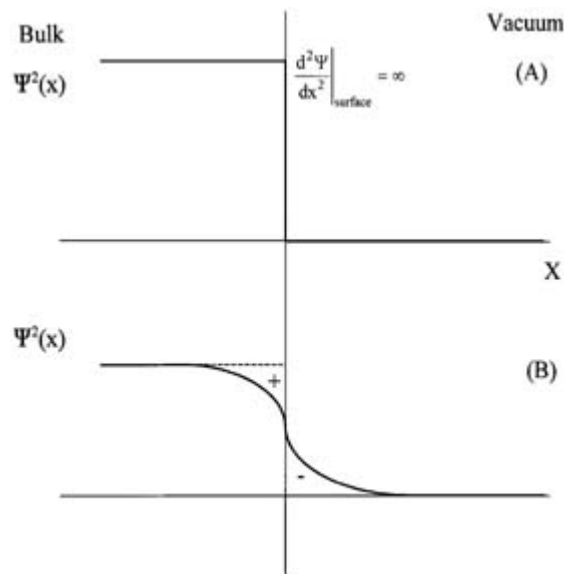

Figure B1.26.19. The variation of the electron density (A) from an unrelaxed surface and (B) showing the smoothing of the electron density to lower the kinetic density.

Figure B1.26.20. Diagram showing the dipole layer created on a surface by an electropositive adsorbate.

B1.26.4.2 INSTRUMENTATION

There are many ways to measure the work function or work function change which can be generally classified as electron emission methods (thermionic emission, field emission and photoelectron emission), low-energy electron beam (retarding-potential) methods and capacitance methods [50, 51 and 52]. Absolute work function values can be measured using emission methods while the other techniques measure only work-function changes.

-27-

The probes for measuring surface work functions are generally incorporated into an ultrahigh vacuum apparatus and supplement the existing vacuum-compatible, surface-sensitive probes (see for example [section B1.7](#), [section B1.9](#), [section B1.20](#), [section B1.21](#) and [section B1.25](#)). Rather than measuring the absolute value of the work function, it is often more interesting to measure the change in work function caused by some change to the surface. It can either be measured by modifying equipment already present in the vacuum system, for example using the electron gun of low-energy electron diffraction optics for the electron beam method or from the high-binding-energy cut-off in ultraviolet photoelectron spectroscopy. Specific probes for rapidly and conveniently measuring work-function changes can also be introduced separately into the chamber. The most common of these is the Kelvin probe or vibrating capacitor.

(A) THERMIONIC EMISSION METHOD

When a metal sample is heated, electrons are emitted from the surface when the thermal energy of the electrons, kT , becomes sufficient to overcome the work function Φ [53]. The probability of this electron emission depends on work function Φ and temperature T as expressed in the Richardson–Dushman equation:

$$J = A(1 - r)T^2 \exp(-e\Phi/kT) \quad (\text{B1.26.32})$$

where J is the thermionic emission current density, $A = 120 \text{ A cm}^{-2} \text{ deg}^{-2}$ and r is the reflection coefficient for electrons arriving at the work function barrier. Thus, plotting $\ln(J/T^2)$ against $1/kT$ yields a straight line with slope equal to $e\Phi$. The method is not generally suitable for monitoring adsorbates since the sample has to be heated to emit electrons.

(B) FIELD EMISSION METHOD

The barrier to electron removal from a surface can be reduced substantially by the presence of a strong

electric field. The physical situation involved in this process is shown in [figure B1.26.21](#) where, in the presence of an applied field, the work function is less than that at zero field. This increases the probability for electrons to ‘tunnel’ out of the sample [54]. This is a quantum mechanical phenomenon which can be formulated mathematically by considering a Fermi sea of electrons within the metal impinging on a potential barrier at the surface. The result is given by the Fowler–Nordheim equation as:

$$J = 6 \times 10^6 \left(\frac{\mu}{\Phi(\mu + \Phi)} \right) \left(\frac{E}{\alpha} \right)^2 \exp \left(\frac{-(6.8 \times 10^7 \alpha \Phi^{3/2})}{E} \right) \quad (\text{B1.26.33})$$

where J is the current arising from field emission, E is the electric field strength and α is a tabulated function equal to 0.95 ± 0.009 over the range of current densities normally encountered. A plot of $\ln(J/E^2)$ against $(1/E)$ can be used to determine Φ .

-28-

Figure B1.26.21. Potential energy curves for an electron near a metal surface. ‘Image potential’ curve: no applied field. ‘Total potential’ curve: applied external field = $-E_{\text{ex}}$.

This method needs a highly specialized sample configuration and the sample has to be a very sharp point (radius $\sim 10^{-5}$ cm) so that sufficiently high fields can be maintained for emission measurements. This requirement often precludes the use of other surface analysis techniques. However, for specialized applications, the field emission method may be the only one or the most convenient one available. It has been shown to be able to directly measure the work function change induced by the adsorption of a single atom on a tungsten plane [55]. Combined with field emission microscopy, the work function of different crystal planes can be detected. Much of the early understanding of adsorption was obtained with this device and a large number of data on single-crystal work functions have been produced by this technique [52].

(C) PHOTOELECTRON EMISSION METHOD

When photons of sufficiently high frequency ν are directed onto a metal surface, electrons are emitted in a process known as photoelectron emission [56]. The threshold frequency ν_0 is related to the work function by the expression

$$\Phi = h\nu_0/e. \quad (\text{B1.26.34})$$

The total electron current generated in this process is given by the Fowler equation:

$$J = BT^2 f \left[\frac{h(\nu - \nu_0)}{kT} \right] \quad (\text{B1.26.35})$$

where B is a parameter that depends on the material involved. The photoemitted current is measured as a function of photon energy; extrapolation allows the determination of ν_0 , and thus of Φ , to be made.

This technique requires a photon source (a light source with monochromator or filters) of calibrated spectral intensity and variable energy in the range around ν_0 , and an electron collector. Both the work function and the work-function change may be determined conveniently from the cut-off in inelastic electrons in a photoelectron spectrum [47]. As demonstrated by figure B1.26.18 electrons with the minimum kinetic energy barely surmount the work function, while electrons from the Fermi level (E_F , the highest occupied level) will have the maximum kinetic energy, $h\nu - \Phi$.

The work function can be calculated from the relationship

$$\Phi = h\nu - W \tag{B1.26.36}$$

where W is the energy width of the whole photoelectron spectrum. Adsorption changes the work function which in turn changes the width (W) of the UP spectrum. Φ and W are inversely related. The work-function change upon adsorption manifests itself in a shift in the low-kinetic-energy ‘secondary tail’, as shown in the inset in figure B1.26.22 [47].

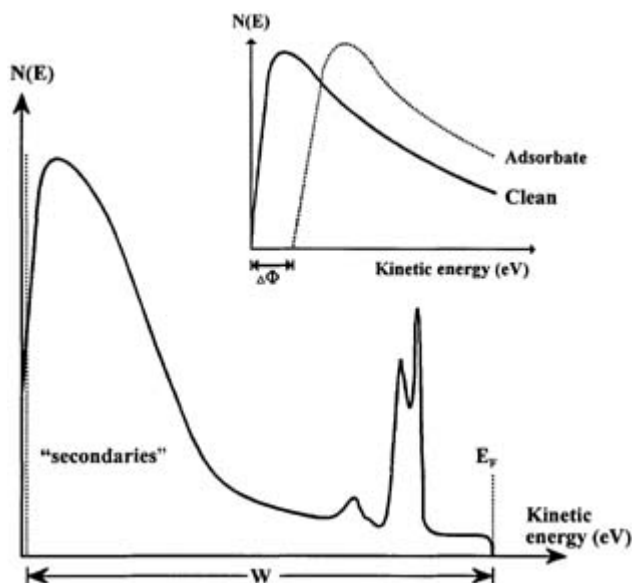

Figure B1.26.22. The energy width W of an ultraviolet photoelectron spectrum from a solid may be used to determine the work function. Changes in work function may be obtained from changes in the ‘cut-off’ of the secondary electron peak (inset) (Attard G and Barnes C 1988 *Surfaces* (Oxford: Oxford University Press)).

(D) LOW-ENERGY ELECTRON BEAM (RETARDING-POTENTIAL) METHODS

In this method, the sample is designed as an anode. Electrons emitted from the cathode by thermionic emission normally impinge on the anode sample on which a retarding potential is applied. Basically this can be arranged as a diode (known as the diode method) [57] or a triode (called the Shelton triode method) [58]. Different circuit arrangements give rise to different $I-V$ relationships and the difference in the work functions of the two electrode surfaces is measured. When a low-energy electron diffraction (LEED) apparatus is available (see section B1.9), this method can be implemented using the low-energy electrons from the LEED electron gun. In this case, electrons of known, low energy are incident on the sample. As the potential across

the sample is slowly made more negative, the current is measured and the relationship between sample and retarding voltage is shown in [figure B1.26.23](#) [50]. At low retarding voltage, most of the impinging electrons are collected. At some larger retarding voltage, the impinging electrons do not possess sufficient energy to reach the sample and so are reflected. This voltage is determined by the work functions of the sample and the electron gun filament, and by the accelerating voltage of the electron gun.

-30-

Changes in the work function of the sample, when the filament work function and the electron gun accelerating voltage are held constant, are manifested by a change in the cut-off retarding voltage (see [figure B1.26.23](#)).

Figure B1.26.23. Current–voltage curves observed in the retarding potential difference method of work-function measurement (Hudson J B 1992 *Surface Science* (Stoneham, MA: Butterworth–Heinemann)).

A low-energy electron beam can also be obtained using a field emission tip and used in the field emission retarding-potential method. This combination provides an absolute measure of the sample work function and the resolution is excellent [52].

(E) CAPACITANCE METHODS

When an electrical connection is made between two metal surfaces, a contact potential difference arises from the transfer of electrons from the metal of lower work function to the second metal until their Fermi levels line up. The difference in contact potential between the two metals is just equal to the difference in their respective work functions. In the absence of an applied emf, there is electric field between two parallel metal plates arranged as a capacitor. If a potential is applied, the field can be eliminated and at this point the potential equals the contact potential difference of the two metal plates. If one plate of known work function is used as a reference electrode, the work function of the second plate can be determined by measuring this applied potential between the plates [52]. One can determine the zero-electric-field condition between the two parallel plates by measuring directly the tendency for charge to flow through the external circuit. This is called the static capacitor method [59].

Historically, the first and most important capacitance method is the vibrating capacitor approach implemented by Lord Kelvin in 1897. In this technique (now called the Kelvin probe), the reference plate moves relative to the sample surface at some constant frequency and the capacitance changes as the interelectrode separation changes. An AC current thus flows in the external circuit. Upon reduction of the electric field to zero, the AC current is also reduced to zero. Originally, Kelvin detected the zero point manually using his quadrant electrometer. Nowadays, there are many elegant and sensitive versions of this technique. A piezoceramic foil can be used to vibrate the reference plate. To minimize noise and maximize sensitivity, a phase-locked

detection circuit is used and a feedback loop may automatically null the electric field. The whole process can be carried out electronically to provide automatic recording of the contact potential and any changes which occur.

-31-

This technique does not involve heating the sample to high temperature or exposing it to high electric fields. Nor is there a need for a hot filament which cannot be used at high pressures. When mounted on a linear motion manipulator, the reference plate assembly can be moved away from the sample leaving no interference with other techniques. One major shortcoming of this technique is that the work function of the reference plate, or electrode, must be precisely known for an absolute determination of the sample work function. Moreover, when relative changes are examined, the work function of the reference electrode must be stable, either unaffected by adsorption or cleanable before each experiment. This disadvantage may be compensated for by using an inert metal such as gold. In addition, the reference electrode must be well shielded to reduce the effects of external electric and magnetic fields on the experiment [52].

B1.26.4.3 APPLICATIONS

(A) SURFACE CHARACTERIZATION

Measurement of the work function of a surface is an important part of overall surface characterization. Surface electron charge density can be described in terms of the work function and the surface dipole moment can be calculated from it (equation (B1.26.30) and equation (B1.26.31)). Likewise, changes in the chemical or physical state of the surface, such as adsorption or geometric reconstruction, can be observed through a work-function modification. For studies related to cathodes, the work function may be the most important surface parameter to be determined [52].

(B) MEASUREMENT OF ADSORPTION ISOTHERMS

Almost all adsorbates cause work function changes ($\Delta\Phi$). Plotting $\Delta\Phi$ versus pressure at various temperatures produces an adsorption isotherm which can be used to determine heats of adsorption and the surface coverage [60]. Much early understanding of adsorption was gained by this method. In particular alkali and alkali earth adsorption has been rather extensively studied in this way. This is illustrated in figure B1.26.24 for the adsorption of alkali metals on W(100) [61]. The change in work function is depicted as solid lines which initially decrease with increasing coverage as expected for an electropositive adsorbate. The dots connected by the dashed line represent the work functions of each of the bulk alkali metals and each of the work-function curves tends asymptotically to these values for large coverages. These curves are not linear as a function of coverage because of depolarization effects (equation (B1.26.31)) and so reach a minimum before attaining their bulk values.

-32-

B1.27 Calorimetry

Kenneth N Marsh

B1.27.1 INTRODUCTION

Calorimetry is the basic experimental method employed in thermochemistry and thermal physics which enables the measurement of the difference in the energy U or enthalpy H of a system as a result of some process being done on the system. The instrument that is used to measure this energy or enthalpy difference (ΔU or ΔH) is called a calorimeter. In the first section the relationships between the thermodynamic functions and calorimetry are established. The second section gives a general classification of calorimeters in terms of the principle of operation. The third section describes selected calorimeters used to measure thermodynamic properties such as heat capacity, enthalpies of phase change, reaction, solution and adsorption.

B1.27.2 RELATIONSHIP BETWEEN THERMODYNAMIC FUNCTIONS AND CALORIMETRY

The first law of thermodynamics relates the energy change in a system at constant volume to the work done on the system w and the heat added to the system q ,

$$\Delta U = w + q. \quad (\text{B1.27.1})$$

Both heat and work are a flow of energy, heat being a flow resulting from a difference in temperature between the system and the surroundings and work being an energy flow caused by a difference in pressure or the application of other electromechanical forces such as electrical energy. For the case where the system is thermally isolated from its surrounding, termed *adiabatically enclosed*, there is no heat flow to or from the surrounds, i.e. $q = 0$ so that

$$\Delta U = w_{\text{adiabatic}}. \quad (\text{B1.27.2})$$

A calorimeter is a device used to measure the work w that would have to be done under adiabatic conditions to bring about a change from state 1 to state 2 for which we wish to measure $\Delta U = U_2 - U_1$. This work w is generally done by passing a known constant electric current \mathfrak{I} for a known time t through a known resistance R embedded in the calorimeter, and is denoted by w_{elec} where

$$w_{\text{elec}} = \mathfrak{I}^2 R t. \quad (\text{B1.27.3})$$

In general it is difficult to construct a calorimeter that is truly adiabatic so there will be unavoidable heat leaks q . It is also possible that non-deliberate work is done on the calorimeter such as that resulting from a change in volume against a non-zero external pressure $p_{\text{ext}}(-\int p_{\text{ext}} dV)$, often called pV work. Additional work w' may be done on the system by energy introduced from stirring or from energy dissipated due to self-heating of the device used to measure the temperature. The basic equation for the energy change in a calorimeter is

$$\Delta U = w_{\text{elec}} - \int p_{\text{ext}} dV + w' + q. \quad (\text{B1.27.4})$$

The pV work term is not normally measured. It can be eliminated by suspending the calorimeter in an evacuated space ($p = 0$) or by holding the volume of the calorimeter constant ($dV = 0$) to give

$$\Delta U = w_{\text{elec}} + w' + q. \quad (\text{B1.27.5})$$

This is the working equation for a constant volume calorimeter. Alternatively, a calorimeter can be maintained at constant pressure p equal to the external pressure p_{ext} in which case

$$- \int_{V_1}^{V_2} p_{\text{ext}} dV = p(V_2 - V_1) \quad (\text{B1.27.6})$$

and

$$\Delta U = U_2 - U_1 = w_{\text{elec}} - pV_1 - pV_2 + w' + q \quad (\text{B1.27.7})$$

hence

$$\Delta(U + pV) = (U + pV)_2 - (U + pV)_1 = w_{\text{elec}} + w' + q. \quad (\text{B1.27.8})$$

The quantity $U + pV$ is termed the enthalpy H , hence

$$\Delta H = H_2 - H_1 = w_{\text{elec}} + w' + q. \quad (\text{B1.27.9})$$

is the working equation for a constant pressure calorimeter.

The heat capacity at constant volume C_V is defined from the relations

-3-

$$\Delta U = \int_{T_1}^{T_2} C_V dT \quad (\text{B1.27.10})$$

and

$$C_V \stackrel{\text{def}}{=} (\partial U / \partial T)_V \stackrel{\text{def}}{=} \lim_{T_2 \rightarrow T_1} \{ [U(T_2, V_2) - U(T_1, V_1)] / (T_2 - T_1) \}. \quad (\text{B1.27.11})$$

Values of $C_V(T)$ can be derived from a constant volume calorimeter by measuring ΔU for small values of $(T_2 - T_1)$ and evaluating $\Delta U / (T_2 - T_1)$ as a function of temperature. The energy change ΔU can be derived from a knowledge of the amount of electrical energy required to change the temperature of the sample + container

from T_1 to T_2 , w_{elec} (sample + container), and the energy required to change the temperature of the container only from T_1 to T_2 , w_{elec} (container). If the volume of the sample is kept constant, and the calorimeter is adiabatic ($q = 0$) or the heat leak is independent of the amount of sample and no other work is done then:

$$\Delta U = U(T_2, V) - U(T_1, V) = w_{\text{elec}}(\text{sample + container}) - w_{\text{elec}}(\text{container}). \quad (\text{B1.27.12})$$

Except for gases, it is very difficult to determine C_V . For a solid or liquid the pressure developed in keeping the volume constant when the temperature is changed by a significant amount would require a vessel so massive that most of the total heat capacity would be that of the container. It is much easier to measure the difference

$$\Delta H = H(T_2, p) - H(T_1, p) = w_{\text{elec}}(\text{sample + container}) - w_{\text{elec}}(\text{container}) \quad (\text{B1.27.13})$$

between the enthalpies of the initial and final states when the pressure is kept constant and derive the heat capacity at constant pressure C_p defined by

$$C_p \stackrel{\text{def}}{=} (\partial H / \partial T)_p \stackrel{\text{def}}{=} \lim_{T_2 \rightarrow T_1} [(H(T_2, V_2) - H(T_1, V_1)) / (T_2 - T_1)]. \quad (\text{B1.27.14})$$

The enthalpy change ΔH for a temperature change from T_1 to T_2 can be obtained by integration of the constant pressure heat capacity

$$\Delta H = \int_{T_1}^{T_2} C_p \, dT. \quad (\text{B1.27.15})$$

The entropy change ΔS for a temperature change from T_1 to T_2 can be obtained from the following integration

$$\Delta S = \int_{T_1}^{T_2} (C_p / T) \, dT. \quad (\text{B1.27.16})$$

B1.27.3 OPERATING PRINCIPLE OF A CALORIMETER

All calorimeters consist of the calorimeter proper and its surround. This surround, which may be a jacket or a bath, is used to control the temperature of the calorimeter and the rate of heat leak to the environment. For temperatures not too far removed from room temperature, the jacket or bath usually contains a stirred liquid at a controlled temperature. For measurements at extreme temperatures, the jacket usually consists of a metal block containing a heater to control the temperature. With non-isothermal calorimeters (calorimeters where the temperature either increases or decreases as the reaction proceeds), if the jacket is kept at a constant temperature there will be some heat leak to the jacket when the temperature of the calorimeter changes. Hence, it is necessary to correct the temperature change observed to the value it would have been if there was no leak. This is achieved by measuring the temperature of the calorimeter for a time period both before and after the process and applying Newton's law of cooling. This correction can be reduced by using the technique of adiabatic calorimetry, where the temperature of the jacket is kept at the same temperature as the calorimeter as a temperature change occurs. This technique requires more elaborate temperature control and it is primarily used in accurate heat capacity measurements at low temperatures.

With most non-isothermal calorimeters, it is necessary to relate the temperature rise to the quantity of energy released in the process by determining the calorimeter constant, which is the amount of energy required to increase the temperature of the calorimeter by one degree. This value can be determined by electrical calibration using a resistance heater or by measurements on well-defined reference materials [1]. For example, in bomb calorimetry, the calorimeter constant is often determined from the temperature rise that occurs when a known mass of a highly pure standard sample of, for example, benzoic acid is burnt in oxygen.

B1.27.4 CLASSIFICATION OF CALORIMETERS

B1.27.4.1 CLASSIFICATION BY PRINCIPLE OF OPERATION

ISOTHERMAL CALORIMETERS (MORE PRECISELY, QUASI-ISOTHERMAL)

These include calorimeters referred to as calorimeters with phase transitions. The temperatures of the calorimeter (i.e. the vessel) $T(c)$ and the jacket $T(s)$ in such calorimeters remain constant throughout the experiment. For calorimeters with phase transition, the calorimetric medium is usually a pure solid (its stable modification) in equilibrium with the liquid phase of the same substance, for example, ice and water. The reaction chamber is placed inside a vessel inside the layer of this substance. The jacket also contains an equilibrium mixture of two phases of the same substance. For an exothermic process, part of the solid substance melts in the vessel, and the volume change of the liquid is precisely measured. Another calorimeter of this type is an isothermal titration calorimeter. One of the reactants is added at such a rate that, for an endothermic system, the enthalpy or energy change is balanced by the simultaneous addition of electrical energy so the calorimeter remains isothermal. The energy added is a direct measure of the energy or enthalpy change. For an exothermic system electrical energy that is added at a constant rate is counterbalanced by the removal of energy at a constant rate (by, for example, a thermoelectric cooling device) to maintain the calorimeter isothermal. The reactant is then added at such a rate that the calorimeter remains isothermal when the addition of electrical energy is discontinued.

-5-

ADIABATICALLY-JACKETED CALORIMETERS

The energy released when the process under study takes place makes the calorimeter temperature $T(c)$ change. In an adiabatically jacketed calorimeter, $T(s)$ is also changed so that the difference between $T(c)$ and $T(s)$ remains minimal during the course of the experiment; that is, in the best case, no energy exchange occurs between the calorimeter (unit) and the jacket. The thermal conductivity of the space between the calorimeter and jacket must be as small as possible, which can be achieved by evacuation or by the addition of a gas of low thermal conductivity, such as argon.

HEAT-FLOW CALORIMETERS

These calorimeters are enclosed in a thermostat ('heat sink') which has a much greater heat capacity than that of the calorimeter vessel proper. The energy released in the calorimeter is negligibly small compared with the heat capacity of the thermostat, and hence the thermostat temperature $T(s)$ does not change. The outer surface of the calorimeter (vessel) is in direct thermal contact with the inner surface of the thermostat, and the energy flow occurs through a series of thermopiles, which consist of a large number of thermocouples connected in series. The flow of energy through the thermocouples gives rise to a voltage. The thermopiles are designed so that the majority of energy that flows from the calorimeter to the thermostat flows through them as rapidly as possible and the area under the curve of the voltage produced against time is a measure of the overall quantity of the energy released (or taken up) in the process occurring in the calorimeter.

ISOPERIBOLE CALORIMETERS

This type of calorimeter is normally enclosed in a thermostatted-jacket having a constant temperature $T(s)$ and the calorimeter (vessel) temperature $T(c)$ changes through the energy released as the process under study proceeds. The thermal conductivity of the intermediate space must be as small as possible. Most combustion calorimeters fall into this group.

B1.27.4.2 CLASSIFICATION BY DESIGN

LIQUID CALORIMETERS

A liquid serves as the calorimetric medium in which the reaction vessel is placed and facilitates the transfer of energy from the reaction. The liquid is part of the calorimeter (vessel) proper. The vessel may be isolated from the jacket (isoperibole or adiabatic), or may be in good thermal contact (heat-flow type) depending upon the principle of operation used in the calorimeter design.

ANEROID (LIQUIDLESS) CALORIMETERS

The reaction vessel is situated inside a metal of high thermal conductivity having a cylindrical, spherical, or other shape which serves as the calorimetric medium. Silver is the most suitable material because of its high thermal conductivity, but copper is most frequently used.

-6-

COMBINED CALORIMETERS

These are a combination of the liquid and aneroid types.

B1.27.4.3 SELECTION OF METHOD OF MEASUREMENT

In designing a calorimeter, consideration must be given to the combination of the principle of its operation with the type of design and this depends on the ultimate goal. Thus, isoperibole calorimeters may be a liquid, aneroid, or a combined calorimeter type with a static or rotating vessel (dynamic). For adiabatically-jacketed calorimeters, one normally uses a combined or aneroid design that enables the creation of a vacuum between the unit and the jacket, which is essential for proper thermal isolation of the unit. Isothermal calorimeters require special consideration depending on their application. To characterize a calorimeter design, it is necessary to specify its type by all the classifications, for example, adiabatic aneroid static or isoperibole liquid dynamic calorimeter.

The selection of the operating principle and the design of the calorimeter depends upon the nature of the process to be studied and on the experimental procedures required. However, the type of calorimeter necessary to study a particular process is not unique and can depend upon subjective factors such as technical restrictions, resources, traditions of the laboratory and the inclinations of the researcher.

B1.27.5 CALORIMETERS FOR SPECIFIC APPLICATIONS

Various books and chapters in books are devoted to calorimeter design and specific applications of calorimetry. For several decades the Commission on Thermodynamics of the International Union of Pure and

Applied Chemistry (IUPAC) has been responsible for a series of volumes on experimental thermodynamics and thermochemistry. *Experimental Thermochemistry*, volume I, published in 1956, edited by F D Rossini [2], dealt primarily with combustion calorimetry. Volume II published in 1962, edited by H A Skinner [3], primarily documented advances in combustion calorimetry since the first volume. In 1979 an update of much of the material covered in *Experimental Thermodynamics*, volumes I and II, was published under the title *Combustion Calorimetry* with editors S Sunner and M Månsson [4]. The first volume in the series *Experimental Thermodynamics, Calorimetry of Non-Reacting Systems*, edited by J P McCullough and D W Scott [5] was published in 1968. This volume covered the general principle of calorimeter design for non-reacting systems. It included a detailed discussion of adiabatic and drop calorimeters for the measurements of heat capacity, calorimeters for measurement of enthalpies of fusion and vaporisation, and calorimeters for the measurement of heat capacities of liquids and solutions close to room temperature. The second volume, *Experimental Thermodynamics of Non-Reacting Systems*, edited by B LeNeindre and B Vodar [6], published in 1975, was concerned with the measurement of a broader class of thermodynamic and transport properties over a wide range of temperature and pressure. A number of the techniques covered, such as density of a fluid as a function of temperature and pressure and speed of sound, allow the calculation of energy differences by non-calorimetric methods. Volume III, *Measurement of Transport Properties of Fluids*, edited by W A Wakeham, A Nagashima and J V Sengers [7], published in 1991, was concerned primarily with the measurement of the transport properties of fluids. Volume IV, *Solution Calorimetry*, edited by K N Marsh and P A G O'Hare [8] was published in 1994. This book covered calorimetric techniques for the measurement of enthalpies of reaction of organic substances, heat capacity and excess enthalpy of mixtures of organic compounds in both the liquid and gas phase, calorimetry of electrolyte solutions at high

-7-

temperature and pressure, microcalorimetric application in biological systems, titration calorimetry, and the calorimetric determination of pressure effects. *IUPAC Chemical Data Series No 32, Enthalpies of Vaporization of Organic Compounds* by V Majer and V Svoboda [9], contains a detailed review of calorimeters used to measure enthalpy of vaporization. Other monographs dealing extensively with calorimetric techniques have been published. These include *Specialist Periodical Reports, Chemical Thermodynamics*, volume 1 [10], which covered combustion and reaction calorimetry, heat capacity of organic compounds, vapour-flow calorimetry and calorimetric methods at high temperature. *Physical Methods of Chemistry*, Volume VI, *Determination of Thermodynamic Properties* [11, 12] contains a chapter on calorimetry and a chapter devoted to differential thermal methods including differential thermal calorimetry.

B1.27.5.1 MEASUREMENT OF HEAT CAPACITY

The most important thermodynamic property of a substance is the standard Gibbs energy of formation as a function of temperature as this information allows equilibrium constants for chemical reactions to be calculated. The standard Gibbs energy of formation $\Delta_f G^\circ$ at 298.15 K can be derived from the enthalpy of formation $\Delta_f H^\circ$ at 298.15 K and the standard entropy ΔS° at 298.15 K from

$$\Delta_f G^\circ = \Delta_f H^\circ - T \Delta S^\circ. \quad (\text{B1.27.17})$$

The enthalpy of formation is obtained from enthalpies of combustion, usually made at 298.15 K while the standard entropy at 298.15 K is derived by integration of the heat capacity as a function of temperature from $T = 0$ K to 298.15 K according to [equation \(B1.27.16\)](#). The Gibbs–Helmholtz relation gives the variation of the Gibbs energy with temperature

$$\left\{ \partial(G/T) / \partial T \right\}_p = -H/T^2. \quad (\text{B1.27.18})$$

Hence it is necessary to measure the heat capacity of a substance from near 0 K to the temperature required for equilibrium calculations to derive the enthalpy as a function of temperature according to [equation \(B1.27.15\)](#).

-8-

LOW TEMPERATURE HEAT CAPACITY

For solids and non-volatile liquids accurate heat capacity measurements are generally made in an adiabatic calorimeter. A typical low temperature aneroid-type adiabatic calorimeter used to make measurements between 4 K and about 300 K is shown in [figure B1.27.1](#). The primary function of the complex assembly is to maintain the calorimeter proper at any desired temperature between 4 K and 300 K. The only energy gain should be from the addition of electrical energy during a measurement. The upper part of the calorimeter contains vessels for holding liquid nitrogen and helium that provide low temperature heat sinks. Construction materials are generally those having high thermal conductivity (e.g. copper) plated with reflectant material (e.g. chromium) to reduce radiant energy transfer. The calorimeter proper and its surrounding adiabatic shield are suspended by silk lines and can be raised to bring them into good thermal contact with the lower tank, thereby cooling the calorimeter. When the calorimeter proper has reached its desired temperature, thermal contact is broken by lowering the calorimeter and the adiabatic shield. Adiabatic conditions are maintained by keeping the temperature of the adiabatic shield at the temperature of the calorimeter and heat conduction is minimized by maintaining a high vacuum (10^{-3} Pa) inside the cryostat. The temperature is normally measured with high precision using a calibrated platinum resistance thermometer. A major source of heat leak is through the electrical leads. This can be minimized by tempering the leads as they pass through the nitrogen and helium tanks and then bringing them to the calorimeter temperature with an electrical heater on the floating ring. In operation, a known amount of electrical energy is added through the heater and the temperature rise (usually of the order of 5 K) is measured to within 10^{-3} K. The temperature of the adiabatic shield is automatically controlled to follow the temperature of the calorimeter.

HIGH TEMPERATURE HEAT CAPACITY

Adiabatic and drop calorimetry are the primary methods used to make measurements of heat capacity above room temperature. In drop calorimetry, a known mass of a sample at a known high temperature is dropped into a calorimeter vessel, usually close to room temperature and its temperature rise is measured. This method gives enthalpy differences, which are usually represented as a power series in the temperature. The equation can be differentiated to give the heat capacity. This method can be used to very high temperatures with moderate accuracy but it gives poor results when the sample undergoes phase transitions during the cooling process, since there may not be a complete transformation in the calorimeter. For systems with known phase

transitions adiabatic calorimetry is widely used. This technique is similar to that used in low temperature calorimetry except that no cooling is required. An example high temperature adiabatic calorimeter is shown in figure B1.27.2. An adiabatic shield that in the figure is the outer silver cup surrounds the calorimeter proper. Its temperature is controlled to be as close as possible to that of the calorimeter proper. The shield is surrounded by an inner and outer guard, which consist of multiple layers of thin aluminium. The inner guard is usually heated to a temperature close to the calorimeter temperature. Since the main heat loss mechanism at high temperature is radiation, the volume surrounding the calorimeter does not need to be evacuated.

Figure B1.27.2. Schematic vertical section of a high-temperature adiabatic calorimeter and associated thermostat (Reprinted with permission from 1968 *Experimental Thermodynamics* vol I (Butterworth).)

Two methods are generally used when operating an adiabatic calorimeter. In the continuous-heating method, the calorimeter and shield are heated at a constant rate such that the temperature difference between the calorimeter and shield are minimal. At predetermined temperatures the power and time are recorded allowing the average heat capacity to be determined. This method allows for rapid measurement and the control of the shield temperature is less demanding. In the intermittent-heating method a known amount of power is added for a known time and the temperature change measured. The control of the adiabatic shield is more difficult because of the sudden changes in the rate of change of the temperature of the calorimeter at the beginning and end of the heating period. However, it is essential to use the intermittent method when a transition such as a solid–solid, liquid–solid, or an annealing process takes place.

HEAT CAPACITY OF GASES

The heat capacity of a gas at constant pressure C_p is normally determined in a flow calorimeter. The temperature rise is determined for a known power supplied to a gas flowing at a known rate. For gases at pressures greater than about 5 MPa Magee *et al* [13] have recently described a twin-bomb adiabatic calorimeter to measure C_p .

B1.27.5.2 COMBUSTION CALORIMETRY

Combustion or bomb calorimetry is used primary to derive enthalpy of formation values and measurements are usually made at 298.15 K. Bomb calorimeters can be subdivided into three types: (1) static, where the bomb or entire calorimeter (together with the bomb) remains motionless during the experiment; (2) rotating-

bomb calorimeters, where provision is made to rotate the bomb in the calorimetric media and (3) entirely rotating calorimeters, called dynamic. It is not necessary to use a rotating-bomb calorimeter for burning conventional organic compounds (containing only C, H, O and N). A stainless steel bomb without a corrosion-proof metal lining is suitable.

For burning organic substances containing heteroatoms of non-metals and metals, dynamic calorimeters of the combined or aneroid types are used. Liquid rotating-bomb calorimeters can also be used. For burning compounds containing halogens and sulphur, a bomb made of corrosion-resistant metal or lined with such a metal is generally used. The most resistant metal for the protection of the inner surface of a bomb used in combustion of chlorine-, sulphur- or bromine-containing organic compounds is tantalum, since it is very little affected by the products of combustion of these substances. Platinum can also be used as a protective layer, even though it is prone to react with the reaction products (e.g. $\text{Cl}_2 + \text{HCl} + \text{H}_2\text{O}$); the correction required to account for the enthalpy of such a reaction can be made by the analysis of the quantity of platinum dissolved. To study comparatively slow bomb processes, an adiabatically jacketed calorimeter designed as a combined or aneroid type or an isothermal calorimeter can be used only if the reaction can be conducted under static conditions.

STATIC BOMB CALORIMETER

An example of a static bomb calorimeter used to measure energies of combustion in oxygen is shown in [figure B1.27.3](#). The bomb is typically a heavy walled vessel capable of withstanding pressures of 20 MPa. A precisely known mass of the material to be burnt is held in a small platinum cup and oxygen is added to a pressure of about 3 MPa. The bomb is either immersed in a known mass of water or suspended in an evacuated vessel (aneroid type). The material is ignited by passing a current through a thin platinum wire stretched between the two metal posts, which causes an attached cotton or polythene fuse to burn. A small amount of water is added to the calorimeter to ensure that any solution that is formed is sufficiently dilute to allow the small corrections associated with the various solution processes to be

calculated. The amount of material in the vessel is chosen to give a temperature rise of from 1 K to 3 K, for a typical bomb immersed in about 3 kg H_2O . For an organic compound this corresponds to a mass of from 0.5 g to 1.6 g. A static bomb calorimeter is used for substances containing only carbon, hydrogen, oxygen and nitrogen giving only carbon dioxide, water and N_2 and possibly small amounts of HNO_2 and HNO_3 . The temperature rise is typically measured to between 10^{-4} K and 10^{-5} K and is measured with either a platinum resistance or a quartz thermometer. In order to relate the temperature rise to the energy of combustion, the calorimeter constant (the amount of energy required to increase the temperature of the calorimeter by 1 K) must be known. This can be obtained either by direct electrical calibration or by burning a certified reference material whose energy of combustion has been determined in specifically designed calorimeters. Direct electrical calibration is not simple as it involves the installation of a high power electrical heater within the bomb. Measurements on reference materials are usually made at a National Standards Laboratory. Reference materials suitable for the calibration of various calorimeters have been recommended by the International Union of Pure and Applied Chemistry (IUPAC) [1]. Benzoic acid is the most used reference material and its energy of combustion is known to about 1 part in 15,000. Involatile liquids or solids can usually be burnt directly. Volatile materials must be encapsulated in either plastic bags or glass ampoules. Combustion of these samples requires the addition of a known mass of an auxiliary material, which is usually an involatile oil whose energy of combustion is known.

Figure B1.27.3. Typical static combustion bomb. (Reproduced with permission from A Gallencamp & Co. Ltd.)

ROTATING BOMB CALORIMETER

For substances containing elements additional to C, H, O and N a rotating bomb calorimeter is generally used. A typical rotating bomb calorimeter system is shown in [figure B1.27.4](#). With this calorimeter considerably more water is added to the combustion bomb and the continuous rotation of the bomb both about the cylindrical axis and end over

-13-

end ensures that the final solution is homogeneous and in equilibrium with the gaseous products. At the completion of the experiment this solution is withdrawn and analysed. Substances containing S, Si, P and the halogens can be studied in such calorimeters. To ensure that the products are in a known oxidation state it is generally necessary to add small quantities of reducing agents or other materials.

Figure B1.27.4. Rotating bomb isoperibole calorimeter. A, stainless steel bomb, platinum lined; B, heater; C, thermostat can; D, thermostat inner wall; E, thermostat water; G, sleeve for temperature sensor; H, motor for bomb rotation; J, motor for calorimeter stirrer; K, connection to cooling or heating unit for thermostat; L, circulation pump.

Precision combustion measurements are primarily made to determine enthalpies of formation. Since the combustion occurs at constant volume, the value determined is the energy change $\Delta_c U$. The enthalpy of combustion $\Delta_c H$ can be calculated from $\Delta_c U$, provided that the change in the pressure within the calorimeter is known. This change can be calculated from the change in the number of moles in the gas phase and assuming ideal gas behaviour. Enthalpies of formation of compounds that do not readily burn in oxygen can often be determined by combusting in fluorine and the enthalpy of formation of volatile substances can be determined using flame calorimetry. For compounds that only combust at an appreciable rate at high temperature, such as zirconium in chlorine, the technique of hot-zone calorimetry is used. In this method one heats the sample only very rapidly with a known amount of energy until it reaches a temperature where combustion will occur. Alternatively, a well characterized material such as benzoic acid can be used as an auxiliary material which, when it burns, raises the temperature sufficiently for the material to combust. These methods have been discussed in detail [2, 3 and 4].

B1.27.5.3 ENTHALPIES OF PHASE CHANGE

Accurate enthalpies of solid–solid transitions and solid–liquid transitions (fusion) are usually determined in an adiabatic heat capacity calorimeter. Measurements of lower precision can be made with a differential scanning calorimeter (see later). Enthalpies of vaporization are usually determined by the measurement of the amount of energy required to vaporize a known mass of sample. The various measurement methods have been critically reviewed by Majer and Svoboda [9]. The actual technique used depends on the vapour pressure of the material. Methods based on

-14-

vaporization into a vacuum are best suited for pressures from about 25 kPa down to 10^{-4} Pa. This method has been extensively developed by Sunner's group in Lund [14]. The most recent design allows measurement on samples down to 5 mg over a temperature range from 300 K to 423 K with an accuracy of about 1%. Methods based on vaporization into a steady stream of carrier gas, useful in the range 0.05 Pa to 25 kPa, have also been developed in Lund under Wadsö [15] and gas flow cells based on their designs are commercially available. The method is accurate to between 0.2 and 0.5%. Methods based on vaporization into a closed system, useful in the range 5 kPa to 3 MPa fall into two types; recycle and controlled withdrawal. Both types can give an accuracy approaching 0.1%. Methods based on recycle often contain a second calorimeter to determine the heat capacity of the flowing gas.

B1.27.5.4 SOLUTION CALORIMETRY

Solution calorimetry covers the measurement of the energy changes that occur when a compound or a mixture (solid, liquid or gas) is mixed, dissolved or adsorbed in a solvent or a solution. In addition it includes the measurement of the heat capacity of the resultant solution. Solution calorimeters are usually subdivided by the method in which the components are mixed, namely, batch, titration and flow.

BATCH CALORIMETERS

Batch calorimeters are instruments where there is no flow of matter in or out of the calorimeter during the time the energy change is being measured. Batch calorimeters differ in the way the reactants are mixed and in the method used to determine the enthalpy change. Enthalpy changes can be measured by the various methods

outlined above; isothermal, adiabatic, heat flow or isoperibole. It is necessary to have the reactants separated in the calorimeter. The most common method is to maintain one of the reactants in an ampoule that is broken to release its contents, which initiates the reaction. Initially, thin walled glass ampoules were used but these usually required the narrow neck to be flame-sealed after the contents were added. In recent years there have been significant improvements in ampoule design. An ampoule particularly suited for solids consists of a stainless steel cylinder with replaceable thin glass windows at each end. The cylinder can be taken apart with one half forming a cup into which the solid can be added and weighed. Wadsö and coworkers have developed a variety of ampoules that attach to the stirrer. The glass window is broken by depressing the stirrer so as to impinge against an ampoule-breaking pin. This technique ensures good mixing of the reactants. A typical solution calorimeter is shown in [figure B1.27.5](#)

Ampoules are satisfactory when the presence of a vapour space is not important. When volatile organic compounds are mixed in the presence of a vapour space there can be a considerable contribution to the measured heat effect from the vaporization. This results from the change in the vapour composition that occurs so as to maintain vapour-liquid equilibrium with the liquid mixture. For a small enthalpy of mixing, this correction can be greater than the enthalpy of mixing itself. A batch method suitable for the measurement of enthalpies of mixing in the absence of a vapour space is shown in [figure B1.27.6](#). Known masses of liquids A and B are separately confined over mercury and are mixed by rotation of the entire calorimeter. When liquids are mixed at constant pressure there is a volume change on mixing. The side arm C, which is partially filled with mercury, allows for the expansion or contraction of the mixture against the air space D. The calorimeter operates in the isoperibole mode.

-15-

TITRATION OR DILUTION CALORIMETERS

In a titration or dilution calorimetry one fluid is added from a burette, usually at a well-defined rate, into a calorimeter containing the second fluid. One titration is equivalent to many batch experiments. Calorimeters are typically operated in either the isoperibole or isothermal mode. The method has been extensively developed by Izatt, Christensen and co-workers at Brigham Young University for the measurement of formation constants and enthalpies of reaction for a variety of organic and inorganic compounds. This technique is described in detail by Oscarson *et al* [23]. A titration calorimeter typically has a vapour space, which for large enthalpies of reaction or solution in a solvent with a low vapour pressure does not give rise to significant errors. The vapour space can be eliminated by filling the cell completely and, as the titration proceeds, the excess liquid flows out of the calorimeter into a reservoir. The calculations of the enthalpy change for such a procedure is complex. To measure enthalpies of mixing of organic liquids, Stokes and Marsh [20] have used an alternative method that eliminates both the vapour space and the effect of volume changes on mixing. Their isothermal dilution calorimeter is shown in figure B1.27.7. The calorimeter proper, made from either stainless steel or glass, contains a stirrer, a sealed heater, a thermistor to measure the temperature, and a silver rod connected to a Peltier device. A known volume of mercury is added from a

pipette and one component is added to completely fill the calorimeter. The calorimeter is then brought to isothermal conditions within 10^{-3} K. For endothermic reactions the Peltier device removes energy at a rate sufficient to counterbalance the power introduced from the stirrer. The second component is then injected into the calorimeter from a burette, displacing the mercury. Electrical power is added to maintain the calorimeter approximately isothermal. Usually the rate of addition of the second component is adjusted so that the calorimeter remains isothermal to within 10^{-3} K during the addition. The injection is stopped at selected intervals and the calorimeter brought back to isothermal conditions by either the addition of additional electrical power or additional liquid from the burette. The volume of the mercury pipette is such that one run, which comprises about 20 individual measurement, covers over half the composition range. The components are then interchanged to determine the second half of the curve. The two runs should give results overlapping to within 1%. For exothermic systems the Peltier device is run at high power and the energy removed is counterbalanced by the addition of electrical energy to maintain the calorimeter isothermal. When the second component is added, the power is turned off for known periods of time. This calorimeter has been modified to measure enthalpies of solution of gases in liquids and Stokes [20] has described a version of this calorimeter that uses the overflow technique. Titration and dilution calorimeters have the disadvantage that they are difficult to operate at high pressures or at temperatures considerably removed from ambient. Flow calorimetry does not suffer these disadvantages.

FLOW CALORIMETERS

In a flow calorimeter one or more streams flow in and out of the calorimeter. Flow calorimeters are suited for measurements over a wide range of temperatures and pressures on both liquids and gases. A wide pressure range is possible because measurement are usually made in a small bore tube, and a wide temperature range is feasible because the in-flowing material can be readily brought to the calorimeter temperature by heat exchange with the out-flowing fluid. In a flow experiment there is generally no vapour space and changes in volume on mixing are inconsequential. Flow methods are not suitable for measurement involving solids, and usually large volumes of materials are required.

-19-

Various flow calorimeters are available commercially. Flow calorimeters have been used to measure heat capacities, enthalpies of mixing of liquids, enthalpy of solution of gases in liquids and reaction enthalpies. Detailed descriptions of a variety of flow calorimeters are given in *Solution Calorimetry* by Grolier [17], by Albert and Archer [18], by Ott and Wormald [21], by Simonson and Mesmer [24] and by Wadsö [25].

A flow calorimeter developed by Picker suitable for the measurement of heat capacity of a liquid is shown in figure B1.27.8. The method measures the difference in heat capacity between the fluid under study and some reference fluid. The apparatus contains two thermistors T_1 and T_2 used to measure the temperature change that occurs when the flowing fluid is heated by two identical heaters Z_1 and Z_2 . The standard procedure is to flow the reference material from A through both cells. With the same fluid, same power and same flow rate the temperature change ΔT should be the same. The temperature difference observed on flowing the sample material from B through cell C_1 while the reference is still flowing through C_2 is a measure of the heat capacity difference between the two liquids. The flow method has been extensively developed for measurement on biological systems and on liquid mixtures at high temperatures and pressures. The apparatus constructed by Christensen and Izatt, shown in figure B1.27.9 can be used to measure positive and negative enthalpy changes at pressures up to 40.5 MPa and temperatures up to 673 K. Two high pressure pumps were used for the fluid flow. Mixing occurs in the top half of the isothermal cylinder where the fluid from the two pumps meet. A control heater encircles the cylinder, which is attached by three heat-leak rods to a base plate maintained 1 K below the cylinder temperature. A pulsed electrical current is passed through the control heater to maintain the temperature of the cylinder the same as that of the walls of the oven. During mixing the frequency of the pulses are either increased or decreased depending on the size of the enthalpy of mixing. Commercial calorimeters are available based on both the Picker and Christensen *et al* designs.

B1.27.6 DIFFERENTIAL SCANNING CALORIMETRY

Boerio-Goats and Callanan [12] have recently reviewed different thermal methods, including differential scanning calorimetry. A differential scanning calorimeter (DSC) consists of two similar cells containing a sample and a reference material. In one type of DSC both cells are subjected to a controlled temperature change by applying power to separate heaters and the temperature difference between the sample and reference cells is observed. When an endothermic change occurs in the sample, for example, melting, the sample temperature lags behind that of the reference. In a power compensated DSC the power to that cell is increased to keep the heating rate of the sample and reference cells the same. A schematic diagram of a typical DSC is shown in [figure B1.27.10](#). Another type of calorimeter, developed initially by Tian and Calvet, is also considered a differential scanning calorimeter but is called a heat-flux or heat-conduction calorimeter. A schematic diagram of this type of calorimeter is shown in [figure B1.27.11](#). In this calorimeter two sets of thermopiles, consisting of multiple junction thermocouples, connect both cells to a large block enclosing the sample. The output of the two thermopiles, when connected in opposition gives a measure of the difference in energy flows between the sample and reference when both are heated at the same rate. Both types of DSC can be used to measure heat capacities, enthalpies of phase change, adsorption, dehydration, reaction and polymerization. The major advantage of DSC is the rapidity of the measurements, the small sample requirement, and

-21-

the ready availability of commercially available equipment capable of operating from liquid nitrogen temperatures to well above 1000 K by unskilled personnel. With the majority of DSC instruments it is possible to obtain heat capacities with an accuracy approaching 2–3%, provided one uses the optimum sample size and scan rate along with careful calibration of the temperature scale and the calorimetric response. Reference materials are used to calibrate a DSC and to check the correct operating conditions. Differential scanning calorimeters have been developed for specific applications. A very precise calorimeter, developed by Privilov and coworkers [17] and now available commercially, has been used to measure the heat capacity of very small amounts of biological materials in aqueous solutions.

Figure B1.27.10. Schematic diagram of a power-compensated DSC.

Figure B1.27.11. Schematic diagram of a Tian–Calvet heat-flux or heat-conduction calorimeter.

B1.27.7 ACCELERATING RATE CALORIMETRY

Special calorimeters have been developed to make thermal hazard evaluations. In an exothermic chemical reaction there is the possibility of a runaway reaction occurring where the energy released from the reaction increases the temperature with a consequent increase in the reaction rate, thus increasing the release of energy. If there are insufficient resources to remove the generated energy, hazardous temperature and pressure regimes can be encountered. An accelerating rate calorimeter or ARC, initially developed at Dow Chemical, is available commercially to study such thermal hazards. A schematic diagram is shown in figure B1.27.12. The reaction vessel consists of a spherical bomb that can withstand pressures greater than 20 MPa and temperatures to 770 K. The calorimeter operates in an adiabatic mode under computer control in a heat-wait-see mode. After the reaction comes to thermal equilibrium the rate of temperature rise due to the reaction is determined. If this is less than a preset value the calorimeter temperature is increased in steps and the process repeated until the reaction rate is sufficient to give the preset temperature rise. The chemical reaction then proceeds at its own rate and the temperature and pressure recorded. From these measurements the kinetic parameters are determined and used to establish the conditions that could lead to a runaway reaction. A problem with this calorimeter is that the massive vessel required to withstand the pressure has a heat capacity well in excess of the heat capacity of the reactants. This problem can be overcome by having a thin-walled vessel within the bomb and the pressure in the space between the reaction vessel and the bomb is automatically controlled to the pressure in the calorimeter.

Figure B1.27.12. Schematic diagram of an accelerating rate calorimeter (ARC).

B1.27.8 SPECIALIZED CALORIMETERS

Ultra sensitive Calvet type microcalorimeters are available commercially to measure the deterioration of materials over relatively long periods. For example, the lifetime of a battery can be estimated from the energy released when it is placed in such a calorimeter on open circuit [27]. Similarly the shelf life of drugs and other digestible products can be evaluated from the very small calorimetric response that results from decomposition reactions [28]. Calorimeters have also been developed to measure the heat effects associated with the uptake of oxygen and carbon dioxide in living plants. Such measurements have been used to identify species that exhibit high rates of metabolism [29]. Calorimeters are also used to measure the rate of enzyme reaction and as a clinical tool to identify micro-organisms and test the effect of drugs in inhibiting the growth of such micro-organisms.

B1.27.9 RECENT DEVELOPMENTS

Recent developments in calorimetry have focused primarily on the calorimetry of biochemical systems, with the study of complex systems such as micelles, proteins and lipids using microcalorimeters. Over the last 20 years microcalorimeters of various types including flow, titration, dilution, perfusion calorimeters and calorimeters used for the study of the dissolution of gases, liquids and solids have been developed. A more recent development is pressure-controlled scanning calorimetry [26] where the thermal effects resulting from varying the pressure on a system either step-wise or continuously is studied.

B1.28 Electrochemical methods

Alexia W E Hodgson

B1.28.1 INTRODUCTION

Electrochemical methods may be classified into two broad classes, namely potentiometric methods and voltammetric methods. The former involves the measurement of the potential of a working electrode immersed in a solution containing a redox species of interest with respect to a reference electrode. These are equilibrium experiments involving no current flow and provide thermodynamic information only. The potential of the working electrode responds in a Nernstian manner to the activity of the redox species, whilst that of the reference electrode remains constant. In contrast, in voltammetric methods the system is perturbed

and involves the control of the electrode potential or the current as the independent variable, and measurement of the resulting current or potential.

The latter may be further subdivided into *transient experiments*, in which the current and potential vary with time in a non-repetitive fashion; *steady-state experiments*, in which a unique interrelation between current and potential is generated, a relation that does not involve time or frequency and in which the steady-state current achieved is independent of the method adopted and *periodic experiments*, in which current and potential vary periodically with time at some imposed frequency.

In this chapter, transient techniques, steady-state techniques, electrochemical impedance, photoelectrochemistry and spectroelectrochemistry are discussed.

B1.28.2 INTRODUCTION TO ELECTRODE REACTIONS

Electrode processes are a class of heterogeneous chemical reaction that involves the transfer of charge across the interface between a solid and an adjacent solution phase, either in equilibrium or under partial or total kinetic control. A simple type of electrode reaction involves electron transfer between an inert metal electrode and an ion or molecule in solution. Oxidation of an electroactive species corresponds to the transfer of electrons from the solution phase to the electrode (anodic), whereas electron transfer in the opposite direction results in the reduction of the species (cathodic). Electron transfer is only possible when the electroactive material is within molecular distances of the electrode surface; thus for a simple electrode reaction involving solution species of the form

in which species O is reduced at the electrode surface to species R by the transfer of n electrons, the overall conversion

-2-

may be divided into three steps [1, 3]:

The scheme involves the transport of the electroactive species from the bulk solution to the electrode surface, where it can undergo electron transfer, thus forming the reduced species R at the electrode surface. Finally, the reduced species is transported from the electrode surface back to the bulk solution. The overall reaction rate will be limited by the slowest step, therefore a particular reaction might be controlled by either the kinetics of electron transfer or by the rate at which material is brought to or from the electrode surface. The rate of electron transfer can be experimentally controlled through the electrode potential imposed and can vary by several orders of magnitude in a small potential interval. For the steps involving the transport of species to and from the electrode surface there are three distinct modes of mass transport regime which can occur: diffusion, migration and convection.

The nature of electrode processes can, of course, be more complex and also involve phase formation, homogeneous chemical reactions, adsorption or multiple electron transfer [1, 2, 3 and 4].

B1.28.2.1 ELECTRON TRANSFER

For a simple electron transfer reaction containing low concentrations of a redox couple in an excess of electrolyte, the potential established at an inert electrode under equilibrium conditions will be governed by the Nernst equation and the electrode will take up the equilibrium potential E_e for the couple O/R . In terms of current density, the dynamic situation at the electrode surface is expressed by $j = \bar{j} + \bar{j} = 0$, the sum of the partial cathodic and partial anodic current densities, which have opposite signs and the magnitude of which at equilibrium potential is defined as $j_0 = -\bar{j} = \bar{j}$. The exchange current density, j_0 , is a measure of the amount of electron transfer activity at the equilibrium potential. On applying a potential to the electrode, the system will seek to move towards a new equilibrium where the concentrations of the electroactive species are those demanded by the Nernst equation for the applied potential, and an associated current of reduction or oxidation will flow. The rate of electron transfer can be described by classical kinetics, and hence expressed by the product of a rate constant with the concentration of the reactant at the electrode surface. The rate of the heterogeneous electron transfer will depend on the potential gradient at the interface driving the transfer of electrons between the electrode and the solution phases and in general will take the form of $\bar{k} = k_0 \exp(-\alpha_c n F / RT) E$ and $\bar{k} = k_0 \exp(-\alpha_a n F / RT) E$ for a reduction and oxidation process respectively. α_c and α_a are the cathodic and anodic transfer coefficients, F is the Faraday constant and k_0 the standard rate constant [1, 2, 3 and 4]. By substituting and defining the overpotential, $\eta = E - E_e$, as the deviation of the potential from the equilibrium

value, the Butler–Volmer equation for current density may be derived:

$$j = j_0 \left\{ \exp\left(\frac{\alpha_a n F}{RT} \eta\right) - \exp\left(\frac{-\alpha_c n F}{RT} \eta\right) \right\}$$

which represents the fundamental equation of electrode kinetics. The equation may be simplified for the limiting cases in which very high positive or very high negative overpotentials are applied, leading to the Tafel equations, which provide a simple method for determining exchange current density and transfer coefficient (figure B1.28.1). For very low overpotentials the equation simplifies to $j = j_0 (nF/RT)\eta$, indicating that very close to the equilibrium potential, the current density varies linearly with overpotential.

Figure B1.28.1. Schematic Tafel plot for the experimental determination of j_0 and α .

B1.28.2.2 MASS TRANSPORT

Diffusion, convection and migration are the forms of mass transport that contribute to the essential supply and removal of material to and from the electrode surface [1, 2, 3 and 4].

Diffusion may be defined as the movement of a species due to a concentration gradient, which seeks to maximize entropy by overcoming inhomogeneities within a system. The rate of diffusion of a species, the flux, at a given point in solution is dependent upon the concentration gradient at that particular point and was first described by Fick in 1855, who considered the simple case of linear diffusion to a planar surface:

-4-

$$\text{Flux} = -D \frac{dc_i(x)}{dx}$$

where dc_i/dx is the concentration gradient and D is the diffusion coefficient (figure B1.28.2). The flux of species to and from the electrode surface must also be accompanied by the conversion of reactant to product and by the flux of electrons. The flux of material crossing the electrode boundary can therefore be converted to current density by equating the two fluxes:

$$\frac{j}{nF} = -D \frac{dc_i(x)}{dx}$$

The second of Fick's laws expresses the change in concentration of a species at a point as a function of time due to diffusion (figure B1.28.2). Hence, the one-dimensional variation in concentration of material within a volume element bounded by two planes x and $x + dx$ during a time interval dt is expressed by $\partial c_i(x,t)/\partial t = D (\partial^2 c_i(x,t)/\partial x^2)$. Fick's second law of diffusion enables predictions of concentration changes of electroactive material close to the electrode surface and solutions, with initial and boundary conditions appropriate to a particular experiment, provide the basis of the theory of instrumental methods such as, for example, potential-step and cyclic voltammetry.

Figure B1.28.2. Fick's laws of diffusion. (a) Fick's first law, (b) Fick's second law.

Convection is the movement of a species due to external mechanical forces. This can be of two types: natural convection, which arises from thermal gradients or density differences within the solution, and forced convection, which can take the form of gas bubbling, pumping or stirring. The former is undesirable and can occur in any solution

at normal sized electrodes on the time scale of ten or more seconds. In contrast, the latter has the function of overcoming contributions from natural convection and of increasing the rate of mass transport and hence facilitates the study of the kinetics of electrode reactions. Forced convection usually possesses well defined hydrodynamic behaviour, thus enabling the quantitative description of the flow in the solution and the prediction of the pattern of mass transport to the electrode.

Migration is the movement of ions due to a potential gradient. In an electrochemical cell the external electric field at the electrode/solution interface due to the drop in electrical potential between the two phases exerts an electrostatic force on the charged species present in the interfacial region, thus inducing movement of ions to or from the electrode. The magnitude is proportional to the concentration of the ion, the electric field and the ionic mobility.

Most electrochemical experiments are designed so that one of the mass transport regimes dominates over the others, thus simplifying the theoretical treatment, and allowing experimental responses to be compared with theoretical predictions. Normally, specific conditions are selected where the mass-transport regime results only from diffusion or convection. Such regimes allow mass transport to be described by a set of mathematical equations, which have analytical solutions. A common experimental practice to render the migration of reactants and products negligible is to add an excess of inert supporting electrolyte, thus ensuring that any migration is dominated by the ions of the electrolyte. Electro-neutrality is also thus maintained, ensuring that electric fields do not build up in the solution. Furthermore, the addition of a high concentration of electrolyte increases the solution conductivity, compresses the double-layer region to dimensions of 10–20 Å, and ensures a constant ionic strength during the electrochemical experiment. As a consequence, the activities of the electroactive species and thus the applied potentials, as predicted by the Nernst equation and by the rate of electron transfer, remain constant throughout the experiment.

B1.28.3 TRANSIENT TECHNIQUES

Voltammetry relies on the registering of current–potential profiles, whether by controlling the potential of the working electrode and recording the resulting current or by measuring the potential response as a function of an applied current. The electrochemical cell, as well as a conducting medium, must also contain at least one other electrode. In a two-electrode configuration, the second electrode is a reference electrode that serves both as a standard against which the working potential is measured and as the necessary current-carrying electrode where the rate of charge transfer must be equal and opposite to that of the working electrode. Commonly, these two functions are separated in a three-electrode configuration, in which a secondary or counter electrode is employed as the current-carrying electrode and a separate reference electrode reports the potential of the working electrode. This prevents any undesirable polarization of the reference electrode, since only small currents flow in the reference electrode loop. Placement of the reference electrode close to the working electrode enables the exclusion of the majority of the solution IR_u drop, which is often achieved by the use of a Luggin capillary [1, 2].

The measurement of the current for a redox process as a function of an applied potential yields a voltammogram characteristic of the analyte of interest. The particular features, such as peak potentials, half-wave potentials, relative peak/wave height of a voltammogram give qualitative information about the analyte electrochemistry within the sample being studied, whilst quantitative data can also be determined. There is a wealth of voltammetric techniques, which are linked to the form of potential program and mode of current measurement adopted. Potential-step and potential-sweep

-6-

techniques are carried out under conditions where diffusion is the only mode of mass transport and the experiment is designed such that diffusion may be described by linear diffusion to a plane electrode and changes in concentration occur perpendicular to the surface [1, 2, 3, 4 and 5].

B1.28.3.1 LINEAR-SWEEP AND CYCLIC VOLTAMMETRY

Linear-sweep and cyclic voltammetry were first reported in 1938 and described theoretically in 1948 by Randles and Sevcik [1, 2, 3, 4, 5 and 6]. The techniques consist of scanning the potential between two chosen limits at a known sweep rate, v , and measuring the current response arising from any electron transfer process. In linear-sweep voltammetry the scan terminates at the chosen end potential, E_f , whereas in cyclic voltammetry, the potential is reversed back at E_f toward the starting potential E_i , or another chosen potential limit. The potential limits define the electrode reactions that take place so that the potential scan is normally chosen to start at a potential value where no electrode reaction occurs and swept towards positive or negative potentials to investigate oxidation or reduction processes, respectively. The current–potential curves for a simple reversible electrode reaction are characterized by unsymmetrical peaks with the current density increasing as the sweep rate is raised. On the forward sweep, the current begins to rise as the potential reaches the vicinity of the reversible formal potential E^0 , then passes through a maximum before decreasing again as the potential is sufficiently driven to produce a diffusion-limited current. The surface concentration of an electroactive species, R , decreases as the potential is made more positive and the rate of oxidation increases, until it becomes effectively zero, at which point the reaction is diffusion controlled. In terms of concentration profiles, the flux of species to the electrode surface increases with potential (hence time) and continues to increase until the surface concentration reaches zero, at which point the flux to the surface starts to decrease, since the surface concentration remains at zero, yielding the peak-shaped response (figure B1.28.3). On the reverse sweep, anodic current continues to flow until the potential is still sufficiently negative to cause the oxidation of R . When the potential, however, reaches the vicinity of E^0 , the oxidized species produced can diffuse back to the electrode surface to be reduced, the current becomes cathodic and a similar peak-shaped

response is obtained as the reaction becomes diffusion controlled.

The scan rate, $\nu = |dE/dt|$, plays a very important role in sweep voltammetry as it defines the time scale of the experiment and is typically in the range 5 mV s^{-1} to 100 V s^{-1} for normal macroelectrodes, although sweep rates of 10^6 V s^{-1} are possible with microelectrodes (see later). The short time scales in which the experiments are carried out are the cause for the prevalence of non-steady-state diffusion and the peak-shaped response. When the scan rate is slow enough to maintain steady-state diffusion, the concentration profiles with time are linear within the Nernst diffusion layer which is fixed by natural convection, and the current–potential response reaches a plateau steady-state current. On reducing the time scale, the diffusion layer cannot relax to its equilibrium state, the diffusion layer is thinner and hence the currents in the non-steady-state will be higher.

-7-

Figure B1.28.3. Concentration profiles of an electroactive species with distance from the electrode surface during a linear sweep voltammogram.

Cyclic voltammetry provides a simple method for investigating the reversibility of an electrode reaction ([table B1.28.1](#)). The reversibility of a reaction closely depends upon the rate of electron transfer being sufficiently high to maintain the surface concentrations close to those demanded by the electrode potential through the Nernst equation. Therefore, when the scan rate is increased, a reversible reaction may be transformed to an irreversible one if the rate of electron transfer is slow. For a reversible reaction at a planar electrode, the peak current density, j_p , is given by

$$j_p = 2.69 \times 10^5 n^{3/2} D^{1/2} c_i^\infty \nu^{1/2}$$

where n is the number of electrons, D is the diffusion coefficient, c_i^∞ the concentration of the electroactive species in the bulk and ν the sweep rate. Of particular importance is the proportionality of the peak current to the square root of the scan rate. In addition, for a reversible couple, the cathodic and anodic peak potentials are separated by $59/n$ mV, the reversible half-wave potential is situated midway between the peaks, the peak potential is independent of scan rate and the peak current ratio equals 1 ([figure B1.28.4](#)). As the response becomes less reversible, the separation between the peaks increases, as an overpotential is necessary to drive

reduction and oxidation reactions, and the shape of the peaks will become more drawn out. Beyond the peak, however, the electrode reaction remains diffusion controlled. For totally irreversible systems the reverse peak disappears completely and the peak current density is expressed by

$$j_p = 2.99 \times 10^5 n(\alpha n_\alpha)^{1/2} c_i^\infty D^{1/2} \nu^{1/2}$$

-8-

where α is the transfer coefficient and n_α the number of electrons transferred up to and including the rate-determining step. The majority of redox couples fall between the two extremes and exhibit quasi-reversible behaviour. When investigating an electrode reaction for reversibility it is essential to obtain results over a sweep-rate range of at least two orders of magnitude, in order not to reach erroneous conclusions. In addition, although subsequent cyclic voltammograms enable valuable mechanistic information to be deduced, the first sweep cycle only should be considered for accurate analysis of kinetic data.

If adsorbed electroactive species are present on the electrode surface, the shape of the cyclic voltammogram changes, since the species do not need to diffuse to the electrode surface. In this case the peaks are symmetrical with coincident peak potentials provided the kinetics are fast.

Table B1.28.1 Diagnostic tests for reversibility of electrode processes in cyclic voltammetry at 293 K.

Reversible process	Irreversible process	Quasi-reversible process
$\Delta E_p = E_p^A - E_p^C = 59/n$ (mV)	Absence of reverse peak	$\Delta E_p > 59/n$ (mV), increases with ν
$ E_p - E_{p/2} = 59/n$ (mV)	$ E_p - E_{p/2} = 48/\alpha_C n_\alpha$ (mV)	$ I_p^A/I_p^C = 1$, if $\alpha_C = \alpha_A = 0.5$
$ I_p^A/I_p^C = 1$	$I_p^C \propto \nu^{1/2}$	I_p increases with $\nu^{1/2}$; I_p not $\propto \nu^{1/2}$
$I_p \propto \nu^{1/2}$	E_p^C dependent of ν	E_p^C shifts with increasing ν
E_p independent of ν		
$E > E_p, I \propto t^{-1/2}$		

Figure B1.28.4. Cyclic voltammogram for a simple reversible electrode reaction in a solution containing only oxidized species.

On investigating a new system, cyclic voltammetry is often the technique of choice, since a number of qualitative experiments can be carried out in a short space of time to gain a feeling for the processes involved. It essentially permits an electrochemical spectrum, indicating potentials at which processes occur. In particular, it is a powerful method for the investigation of coupled chemical reactions in the initial identification of mechanisms and of intermediates formed. Theoretical treatment for the application of this technique extends to many types of coupled mechanisms.

B1.28.3.2 POTENTIAL-STEP TECHNIQUES

In a potential-step experiment, the potential of the working electrode is instantaneously stepped from a value where no reaction occurs to a value where the electrode reaction under investigation takes place and the current *versus* time (chronoamperometry) or the charge *versus* time (chronocoulometry) response is recorded. The transient obtained depends upon the potential applied and whether it is stepped into a diffusion control, in an electron transfer control or in a mixed control region. Under diffusion control the transient may be described by the Cottrell equation obtained by solving Fick's second law with the appropriate initial and boundary conditions [1, 2, 3, 4, 5 and 6]:

$$|j| = \frac{nFD^{1/2}c_i^\infty}{\pi^{1/2}t^{1/2}}.$$

Immediately after the imposition of a large negative overpotential in a solution containing oxidized species, O , a large current is detected, which decays steadily with time. The change in potential from E_c will initiate the very rapid reduction of all the oxidized species at the electrode surface and consequently of all the electroactive species diffusing to the surface. It is effectively an instruction to the electrode to instantaneously change the concentration of O at its surface from the bulk value to zero. The chemical change will lead to concentration gradients, which will decrease with time, ultimately to zero, as the diffusion-layer thickness increases. At time $t = 0$, on the other hand, $\partial c_i / \partial x)_{x=0}$ will tend to infinity. The linearity of a plot of j *versus* $t^{-1/2}$ confirms whether the reaction is under diffusion control and can be used to estimate values for the diffusion coefficient. It is a good technique for determining exact kinetic parameters when a mechanism is fully understood. Under mixed control, where the rates of diffusion and electron transfer are comparable, the current decays less steeply: at short times it will be controlled by electron transfer but, as the surface concentration is depleted, mass transport will become the rate-limiting step.

When analysing the data, it is important to consider a wide time range to ensure the reliability of the data, since at short times, <1 ms, it will be determined by the charging time of the double layer, and at longer times, >10 s, by the effects of natural convection.

Potential-step techniques can be used to study a variety of types of coupled chemical reactions. In these cases the experiment is performed under diffusion control, and each system is solved with the appropriate initial and boundary conditions.

Double potential steps are useful to investigate the kinetics of homogeneous chemical reactions following electron transfer. In this case, after the first step—raising to a potential where the reduction of O to R occurs under diffusion control—the potential is stepped back after a period τ , to a value where the reduction of O is mass-transport controlled. The two transients can then be compared and the kinetic information obtained by looking at the ratio of

the currents, which are a function of both τ and the homogeneous rate constant, k . This is a good method for obtaining exact information, provided that the mechanism is already understood.

B1.28.3.3 PULSE VOLTAMMETRY

Pulse techniques were originally devised to provide enhanced sensitivity in classical polarography for analytical applications [7, 8 and 9]. Sub-nanomolar detection limits can, in fact, be achieved with mercury electrodes where charging and background faradic currents are minimal. At solid electrodes (C, Pt, Au), charging currents and background currents arising from electrode surface reactions limit the level of analyte detection. However, pulse techniques remain particularly useful when looking at analyte concentrations of 10^{-5} M and lower, where voltammetric techniques such as linear-sweep voltammetry and cyclic voltammetry become limited by the difficulty of measuring faradic currents in the presence of background currents. Many step techniques have been devised, based on the succession of potential steps of varying height and in forward and reverse directions [2, 6, 7]. They find wide application in digitally based potentiostats, the electronics of which are suited to their exploitation. The current is normally sampled toward the end of the potential pulse, after the capacitative current has decayed, and the pulse widths are adjusted to fit between this limit and the onset of natural convection. Normal-pulse voltammetry (NPV), differential-pulse voltammetry (DPV) and square-wave voltammetry (SWV) are perhaps the most widely used of a variety of pulse techniques that have been developed.

In NPV [2, 7, 10, 11], short pulses of increasing height are superimposed on a constant base potential, E_b , where no reaction occurs (figure B1.28.5(a)). At the end of the pulse of width, t_p (typically 50–60 ms), the potential is returned to E_b , where it is held for another fixed period of a few seconds, before being pulsed again with a height increase determined by the scan rate. The current is sampled at the end of each pulse and the values are plotted against the potential to give a voltammetric profile similar to a steady-state voltammogram. The maximum current is given by the Cottrell equation, $j = nFDc_i^\infty / \pi^{1/2} t_s^{1/2}$, where t_s is the time at which the current is measured. NPV is therefore a good technique for determining diffusion coefficients.

In DPV [2, 7, 11] the pulse height is kept constant and the base potential is either swept constantly or is incremented in a staircase (figure B1.28.5(b)). The current is sampled just before the end of the pulse and just before pulse application, and the difference between the two measurements is plotted as a function of the potential. The resulting voltammogram is peak-shaped since it essentially is the differential of a steady-state shaped response, and for this feature the technique particularly lends itself to analytical purposes, enabling lower detection limits to be achieved. For a reversible system, the peak is symmetric with $E_p = E_{1/2} - \Delta E/2$, where ΔE is the pulse amplitude. In general, DPV is better at eliminating capacitative contributions and the peak-shaped response is useful for distinguishing two waves with close half-wave potentials.

Figure B1.28.5. Applied potential–time waveforms for (a) normal pulse voltammetry (NPV), (b) differential pulse voltammetry (DPV), and (c) square-wave voltammetry (SWV), along with typical voltammograms obtained for each method.

SWV is an alternative voltammetric technique, first reported in 1952 by Barker and Jenkins [12] and subsequently developed into the form known today by Osteryoung *et al* [13, 14, 15 and 16]. The potential–time waveform is composed of a sequence of symmetrical square-wave pulses superimposed on an underlying ramp (figure B1.28.5(c)). The critical parameters are the step height of the underlying potential scan, ΔE_s ; the height of the square-wave pulse, E_{sw} ; the pulse width, t_p and the time at which the current is sampled on the forward and reverse pulses, t_s . Current measurements are made near the end of the pulse in each square-wave cycle: once at the end of the forward pulse and once at the end of the reverse pulse. However, capacitive contributions can be discriminated against before they decay, since over a small potential range between forward and reverse pulses, the capacity is constant and is thus annulled by subtraction. Consequently, shorter pulses than in DPV and NPV can be applied, enabling higher frequencies to be employed and much faster analysis to be carried out. The difference between the two currents, the net current, is plotted *versus* the base staircase potential, yielding a peak-shaped response. Since the square-wave modulation amplitude is large, the reverse pulses cause the reverse reaction to occur and, thus, the net current is larger

than either the forward or the reverse components. This, coupled with the effective discrimination against charging currents, enables a more sensitive analysis. The resulting peak-shaped voltammograms are symmetrical with characteristic position, width and height: the peak potential, E_p , coincides with the half-wave potential of a redox couple, the peak width indicates the effective number of electrons transferred and the peak current is proportional to the analyte concentration. In addition, the peak shape and position have been found to be largely independent of the size and geometry of the electrode. The net current is generally

compared with theoretical predictions of a dimensionless current Ψ , which are related by the Cottrell equation for the characteristic time:

$$j = \left(n F c \left(\frac{D}{\pi t_p} \right)^{1/2} \right) \Psi$$

where t_p is the pulse width. As well as for analysis, SWV has been found to be well suited to kinetic investigations.

B1.28.3.4 STRIPPING VOLTAMMETRY

Stripping voltammetry involves the pre-concentration of the analyte species at the electrode surface prior to the voltammetric scan. The pre-concentration step is carried out under fixed potential control for a predetermined time, where the species of interest is accumulated at the surface of the working electrode at a rate dependent on the applied potential. The determination step leads to a current peak, the height and area of which is proportional to the concentration of the accumulated species and hence to the concentration in the bulk solution. The stripping step can involve a variety of potential waveforms, from linear-potential scan to differential pulse or square-wave scan. Different types of stripping voltammetries exist, all of which commonly use mercury electrodes (dropping mercury electrodes (DMEs) or mercury film electrodes) [7, 17].

Anodic-stripping voltammetry (ASV) is used for the analysis of cations in solution, particularly to determine trace heavy metals. It involves pre-concentrating the metals at the electrode surface by reducing the dissolved metal species in the sample to the zero oxidation state, where they tend to form amalgams with Hg. Subsequently, the potential is swept anodically resulting in the dissolution of the metal species back into solution at their respective formal potential values. The determination step often utilizes a square-wave scan (SWASV), since it increases the rapidity of the analysis, avoiding interference from oxygen in solution, and improves the sensitivity. This technique has been shown to enable the simultaneous determination of four to six trace metals at concentrations down to fractional parts per billion and has found widespread use in seawater analysis.

Cathodic stripping voltammetry follows a similar sequence of events, except that trace anionic species are reduced in the form of insoluble salts with metal constituents on the electrode surface, e.g. Ag and Hg, during application of a short, relatively positive deposition potential. The applied potential is then swept linearly or pulsed from the deposition potential in the cathodic direction resulting in the selective desorption of the anionic species according to the respective formal potential values. Cathodic stripping voltammetry can be used to determine organic and inorganic compounds that form an insoluble film at the electrode surface. Various inorganic analytes such as halide ions, sulphide ions and oxo-anions are capable of forming insoluble Hg salts which can be pre-concentrated on the Hg electrode surface and be measured.

Adsorptive stripping analysis involves pre-concentration of the analyte, or a derivative of it, by adsorption onto the working electrode, followed by voltammetric measurement of the surface species. Many species with surface-active properties are measurable at Hg electrodes down to nanomolar levels and below, with detection limits comparable to those for trace metal determination with ASV.

Improved sensitivities can be attained by the use of longer collection times, more efficient mass transport or pulsed waveforms to eliminate charging currents from the small faradic currents. Major problems with these methods are the toxicity of mercury, which makes the analysis less attractive from an environmental point of view, and surface fouling, which commonly occurs during the analysis of a complex solution matrix. Several methods have been reported for the improvement of the pre-concentration step [17, 18]. The latter is, in fact,

strongly influenced by the choice of solvent, electrode material, pH, electrode potential and temperature. A constant mass-transport rate leads to better reproducibility and hence stirring is often used with static mercury drop electrodes and stationary electrodes. Hydrodynamic electrodes are also employed in order to increase the sensitivity and decrease the detection limits.

Recent years have witnessed the exploitation of stripping voltammetry in chemical sensors. Complex, fixed-site ASV analysers are used to determine a wide range of metals, such as Cr, Ni, Cu, V, Sn, As and Cd, in the effluents from mining, mineral processing, metal-finishing and related industries. The portable instrumentation and low power demands of stripping analysis satisfy many of the requirements for on-site *in situ* measurements. The development of remotely deployed submersible stripping probes, easy-to-use microfabricated metal sensor strips and micromachined, hand-held total stripping analysers have been reported to move the measurement of trace metals to the field and to perform them more rapidly, reliably and inexpensively [17, 18, 19 and 20].

B1.28.4 STEADY-STATE TECHNIQUES

In the study of electrode reactions, the rates of electron transfer are very often high compared to mass transport, rendering the extrapolation of mechanistic and kinetic data unfeasible. It is therefore essential for the study of electrode reactions and the extrapolation of kinetic information to disrupt the equilibrium by increasing the rate of mass transport and forcing the process into a mixed-control region where the rate of electron transfer is comparable to that of mass transport. There are several methods available for increasing and varying the rate of mass transport in a controlled way, amongst which are hydrodynamic electrodes and microelectrodes [1, 2, 3 and 4]. In both cases, the regime may be described by solvable systems that may be used to predict the rate of mass transport and in the interpretation of experimental data. In hydrodynamic electrodes, the increased rate of mass transport of species is brought about by external mechanical forces, which can arise from the movement of the electrode, agitation of the solution or flowing of the solution past the electrode surface. The resulting forced convection leads to the thinning of the Nernst diffusion layer with a consequent increase in the linear concentration gradient that exists across it and hence to current densities as large as 100 times greater than the steady-state diffusion-limited value. By measuring the current–potential response as a function of mass transport it is thus possible to extrapolate kinetic information regarding an electrode reaction, provided it is under mixed control. There are a number of electrode designs that fall into the category of hydrodynamic electrodes, which include the rotating-disc electrode (RDE), the rotating ring–disc electrode (RRDE), the wall-jet electrode, the wall-pipe electrode, the tube electrode and the channel electrode [21, 22, 23, 24, 25, 26 and 27]. The RDE and RRDE are perhaps the most commonly employed in kinetic and mechanistic studies, and these will be further discussed together with the channel electrode. Microelectrodes, scanning electrochemical microscopy (SECM) and sonoelectrochemistry are also discussed.

B1.28.4.1 ROTATING-DISC ELECTRODES

A rotating-disc electrode (RDE) consists of a disc of electrode material embedded into a larger insulating sheath, and attached to the rotor spindle *via* a suitable electrical contact. The disc and sheath are rotated about a vertical axis. Upon rotation, a pump-action flow is initiated, which brings solution perpendicularly to the electrode surface and throws it out in a radial direction on meeting disc and sheath (figure B1.28.6). A more quantitative description of the flow patterns can be made by the use of cylindrical polar coordinates, by looking at the variation of the solution-flow velocity components V_x , V_r and V_θ as a function of x , the distance perpendicular to the surface of the electrode. The change in concentration of an electroactive species with time due to convection and diffusion may be written as [1, 2, 4, 5]

$$\frac{\partial c_i}{\partial t} = D \left[\frac{\partial^2 c_i}{\partial x^2} + \frac{\partial^2 c_i}{\partial r^2} + \frac{1}{r} \frac{\partial c_i}{\partial r} + \frac{1}{r^2} \frac{\partial^2 c_i}{\partial \theta^2} \right] - \left[V_x \frac{\partial c_i}{\partial x} + V_r \frac{\partial c_i}{\partial r} + \frac{V_\theta}{r} \frac{\partial c_i}{\partial \theta} \right].$$

diffusion convection

However, the equation can be simplified, since the system is symmetrical and the radius of the disc is normally small compared to the insulating sheath. The access of the solution to the electrode surface may be regarded as uniform and the flux may be described as a one-dimensional system, where the movement of species to the electrode surface occurs in one direction only, namely that perpendicular to the electrode surface:

$$\frac{\partial c_i}{\partial t} = D \frac{\partial^2 c_i}{\partial x^2} - V_x \frac{\partial c_i}{\partial x} \quad \text{where} \quad V_x = -0.51 \omega^{3/2} \nu^{-1/2} x^2.$$

The importance of convection in the system increases as the square of the distance from the electrode surface, and close to the surface it is not a dominant form of mass transport. Hence concentration changes will arise due to both diffusion and convection. In the Nernst diffusion model, this trend is exaggerated, and for the mass transport behaviour at an RDE, a plot of the concentration of electroactive species, c_i , versus the distance from the electrode surface, x , is divided into two distinct zones (figure B1.28.6). At the electrode surface, i.e. $x = 0$, the concentration of the electroactive species will be c_i^0 and up to a distance δ away from the electrode, there is a stagnant layer, in which diffusion is the only form of mass transport (the Nernst diffusion layer). Outside this layer, mass transport is dominated by strong convection and the concentration is maintained at the bulk value, c_i^∞ . The diffusion-layer thickness is determined by the rotation rate of the disc, the layer becoming thinner with increasing rotation rate. In this model, the values of c_i^0 and δ will depend on the applied potential and the electrode rotation rate, respectively. In a linear-sweep experiment at a given rotation rate, the concentration profiles, (dc_i/dx) , within the diffusion layer will vary linearly as the applied potential at the RDE is swept from a value where no electron transfer occurs towards values positive to E_c^0 . As the experiment is driven further, the surface concentration of the electroactive species eventually reaches zero, at which point the current response reaches its limiting plateau value. The limiting current density is expressed by [1, 2, 4, 5]

$$j_L = \frac{nFDc_i^\infty}{\delta} = nFk_m c_i^\infty$$

-15-

where k_m is the mass-transport coefficient and the diffusion-layer thickness is $\delta = 1.61 \nu^{1/6} c_i^\infty \omega^{-1/2}$, where ω is the rotational speed in rad s^{-1} , and ν is the kinematic viscosity of the solution. Substituting for δ leads to the Levich equation

$$j_L = 0.621 n F D^{2/3} \nu^{-1/6} c_i^\infty \omega^{1/2}.$$

The expression for the mass-transport-limiting current density may be employed together with the Nernst equation to deduce the complete current–potential response in a solution containing only oxidized or reduced species

$$E = E_c^0 + \frac{2.3RT}{nF} \log \frac{I_L - I}{I}$$

in which I are current values from the rising portion of the curve (under mixed control). This equation, of

course, only holds for fast electron-transfer reactions, where the surface concentrations are related through the Nernst equation. For a reversible electrode reaction, therefore, a plot of potential *versus* the logarithmic quotient should have a slope of $(59/n)$ mV (at 298 K) and the formal potential for the couple will coincide with the half-wave potential, $E_{1/2}$, of the curve (potential corresponding to $1/2 I_L$) (figure B1.28.7). On reversing the scan, the current–potential curve will exactly retrace the forward scan, as the electroactive species will continue to be reduced or oxidized at the same potentials as in the forward sweep. The product formed at the electrode surface during both scans quickly disappears into the bulk solution through convection and is not available for the reverse electron transfer during the back-sweep. In addition to analysing the shape of a current–potential curve at a single rotation rate, the relationship between limiting current densities and mass transport can also be investigated. A common treatment for RDE data is to plot the limiting current density *versus* the square root of rotation speed, with a linear plot confirming conditions of mass-transport control, and the slope being used to determine the other parameters.

Figure B1.28.6. (a) Convection within the electrolyte solution, due to rotation of the electrode; (b) Nernst diffusion model for steady state.

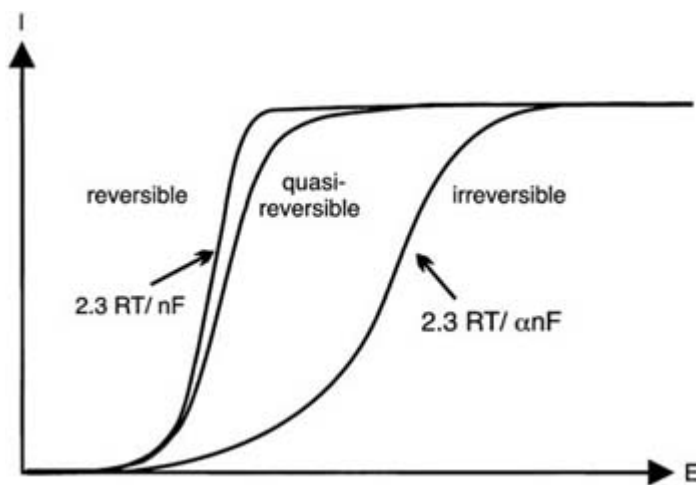

Figure B1.28.7. Schematic shape of steady-state voltammograms for reversible, quasi-reversible and irreversible electrode reactions.

In the case of an irreversible electrode reaction, the current-potential curve will display a similar shape, with

j_L still proportional to $\omega^{1/2}$, but the curve is drawn out along the potential axis. The current-potential curve may be described by [1, 2, 4, 5]

-17-

$$E = E_{1/2} + \frac{2.3RT}{\alpha nF} \log \frac{I_L - I}{I}$$

in which the log plot remains linear but with a slope of $2.3RT/\alpha nF$ (figure B1.28.7). The most obvious feature of the irreversible voltammogram is that the half-wave potential no longer falls near the reversible formal potential, reflecting the sluggish electron transfer kinetics. An activation overpotential is required to drive the reaction.

The rotating-disc is also well suited to the study of coupled chemical reactions [2, 4].

It is essential for the rotating-disc that the flow remain laminar and, hence, the upper rotational speed of the disc will depend on the Reynolds number and experimental design, which typically is 1000 s^{-1} or 10,000 rpm. On the lower limit, 10 s^{-1} or 100 rpm must be applied in order for the thickness of the boundary layer to be comparable to that of the radius of the disc.

The great advantage of the RDE over other techniques, such as cyclic voltammetry or potential-step, is the possibility of varying the rate of mass transport to the electrode surface over a large range and in a controlled way, without the need for rapid changes in electrode potential, which lead to double-layer charging current contributions.

B1.28.4.2 ROTATING RING-DISC ELECTRODES

The rotating ring-disc electrode (RRDE) consists of a central disc separated from a concentric ring electrode by a thin, non-conducting gap. It was first developed by Frumkin and Nekrasov to detect unstable intermediates in electrochemical reactions [1, 2, 22]. As with the RDE, on rotation of the disc, solution is pulled towards the centre of the disc and then thrown out radially across the surface of the structure. The ring is effectively situated downstream to the disc. This permits the intermediates formed on the disc, as the result of an oxidation or reduction process, to be detected at the ring following their mass transport across the insulating gap between the electrodes. Hence, information on intermediates can be obtained before they reach the bulk solution or react further with the electrolyte solution. The ring and the disc are independent from one another and can hence be potentiostatted independently.

In order to employ the RRDE for quantitative studies, it is necessary to describe the transport of species from disc to ring. In the absence of homogeneous chemical reactions, the electrogenerated species at the disc reaction is transported to the ring by diffusion across the stagnant layer at the electrode surface, by convection across the gap and diffusion across the stagnant layer at the ring electrode. The collection efficiency, N_0 , is defined as the ratio of the mass-transport-controlled current for the electrode reactions at ring and disc, $N_0 = -i_{\text{ring}}/i_{\text{disc}}$, where the minus sign arises because the reactions at the ring and at the disc occur in the opposite direction. The collection efficiency thus represents the fraction of material produced at the disc that is detected at the ring. Analytical solutions of the convective-diffusion transport at the ring-disc enables the collection efficiency for specific disc and ring dimensions to be calculated:

$$N_0 = 1 - F\left(\frac{\alpha}{\beta}\right) + \beta^{2/3} [1 - F(\alpha)] - (1 + \alpha + \beta)^{2/3} \left\{ 1 - F\left[\left(\frac{\alpha}{\beta}\right)(1 + \alpha + \beta)\right] \right\}$$

where α , β and F are defined as

$$\alpha = \left(\frac{r_2}{r_1}\right)^3 - 1$$

$$\beta = \left(\frac{r_3}{r_1}\right)^3 - \left(\frac{r_2}{r_1}\right)^3$$

$$F(\theta) = \frac{3^{1/2}}{4\pi} \ln \left\{ \frac{(1 + \theta^{1/3})^3}{1 + \theta} \right\} + \frac{3}{2\pi} \arctan \left(\frac{2\theta^{1/3} - 1}{3^{1/2}} \right) + \frac{1}{4}$$

and r_1 , r_2 and r_3 are the radius of the disc, the radius of the disc surrounded by the insulating sheath and the radius of the disc surrounded by sheath and ring, respectively. The collection efficiency is a function of r_1 , r_2 and r_3 and does not depend on the rotation speed or the nature of the redox species. Since access of material to the ring is not uniform, some of the material will be transported back into solution and collection efficiencies are typically around 0.2–0.3 and strongly depend on the geometry of the electrodes and the distance between them. The rotation rate will affect the time taken for the intermediates to be transported from the disc to the ring, short-lived intermediates requiring higher rotation rates and the construction of RRDEs with thin inter-electrode gaps. The rotation rate will not, however, affect the efficiency, since the currents at both the generator and collector electrodes will be enhanced.

A number of different types of experiment can be designed, in which disc and ring can either be swept to investigate the potential region at which the electron transfer reactions occur, or held at constant potential (under mass-transport control), depending on the information sought.

The RRDE is very useful for the detection of short-lived intermediates, in the investigation of reaction mechanisms, but also in the distinction of free and adsorbed intermediates, as the latter are not transported to the ring.

B1.28.4.3 CHANNEL-FLOW ELECTRODES

Forced convection can also arise from the movement of electrolyte solution over a stationary working electrode. In a channel electrode, the electrode is embedded smoothly in one wall of a thin, rectangular duct through which electrolyte is mechanically pumped [3, 6, 26, 27]. The design of the flow cell consists of two plates sealed together, with typical dimensions of 30–50 mm in length, <10 mm in width and a distance between the plates of less than 1 mm (the cell height). The electrode is embedded either at the centre of the base plate or attached to the centre of the cover plate by means of an adhesive.

The solution flow is normally maintained under laminar conditions and the velocity profile across the channel is therefore parabolic with a maximum velocity occurring at the channel centre. Thanks to the well defined hydrodynamic flow regime and to the accurately determinable dimensions of the cell, the system lends itself well to theoretical modelling. The convective–diffusion equation for mass transport within the rectangular duct may be described by

$$\frac{\partial c_i}{\partial t} = D \left(\frac{\partial^2 c_i}{\partial x^2} + \frac{\partial^2 c_i}{\partial y^2} + \frac{\partial^2 c_i}{\partial z^2} \right) c_i - \left(v_x \frac{\partial c_i}{\partial x} + v_y \frac{\partial c_i}{\partial y} + v_z \frac{\partial c_i}{\partial z} \right)$$

where v_x , v_y , v_z are the solution-velocity profiles in the directions x , y , z . By convention, the direction of flow is designated as the x -direction and the y -direction is that normal to the electrode. The equation may be considerably simplified by removal of the time dependence under steady-state conditions and by neglecting axial diffusion to the macroelectrode, since convection is considerably faster. The diffusion layer is situated very close to the electrode surface and is small compared to the cell depth, decreasing as the flow rate is increased. The Lévêque approximation further simplifies the system by approximating the parabolic flow to a linear flow near the electrode surface, provided that the electrode is less wide than the channel (for edge effects to be neglected) and the height, h , of the channel is much greater than the width, d . In an analogous fashion as for the RDE, solution for a simple mass-transport-limited electrode reaction leads to the Levich equation

$$I_{\text{lim}} = 0.925nF c_i^{\infty} D^{2/3} v_f^{1/3} (h^2 d)^{-1/3} w x_e^{2/3}$$

where v_f is the solution volume flow rate, x_e the length of the electrode, and d and w the height and width of the cell, respectively. Analytical solutions for the channel electrode also extend to more complicated electrode reactions involving coupled homogeneous reactions.

Amongst the greatest advantages of channel-flow electrodes is the possibility of controlling the rate of mass transport over a range of three orders of magnitude, from 10^{-4} to $10^{-1} \text{ cm}^3 \text{ s}^{-1}$, and of varying the mass-transport coefficient by altering the cell depth and the electrode length. These rates are, in fact, not attainable at other hydrodynamic electrodes, such as the RDE and the wall-jet electrode. In addition, there is no risk of a build-up of a stagnant zone since the spent solution flows to waste.

The channel-flow electrode has often been employed for analytical or detection purposes as it can easily be inserted in a flow cell, but it has also found use in the investigation of the kinetics of complex electrode reactions. In addition, channel-flow cells are immediately compatible with spectroelectrochemical methods, such as UV/VIS and ESR spectroscopy, permitting detection of intermediates and products of electrolytic reactions. UV–VIS and infrared measurements have, for example, been made possible by constructing the cell from optically transparent materials.

B1.28.4.4 MICROELECTRODES

A microelectrode is an electrode with at least one dimension small enough that its properties are a function of size, typically with at least one dimension smaller than $50 \mu\text{m}$ [28, 29, 30, 31, 32 and 33]. If compared with electrodes employed in industrial-scale electrosynthesis or in laboratory-scale synthesis, where the characteristic dimensions can be of the order of metres and centimetres, respectively, or electrodes for voltammetry with millimetre dimension, it is clear that the size of the electrodes can vary dramatically. This enormous difference in size gives microelectrodes their unique properties of increased rate of mass transport, faster response and decreased reliance on the presence of a conducting medium. Over the past 15 years, microelectrodes have made a tremendous impact in electrochemistry. They have, for example, been used to improve the sensitivity of ASV in environmental analysis, to investigate rapid

The *increased rate of mass transport* is one of the most attractive and advantageous properties of microelectrodes over conventional electrodes, as the increased transport of the reactant to the electrode surface allows it to reach steady-state regimes rapidly. The diffusion rates increase with decreasing electrode size beyond that obtained with other steady-state techniques. For example, with a 10 μm diameter disc, the steady-state, mass-transfer coefficient, k_m , is comparable to that of a rotating disc revolving at an experimentally impossible 250,000 rpm. The *discrimination against charging currents* is another very important property. In fact, the magnitude of the charging current depends on the area of the capacitor, and for a microelectrode it decreases with electrode area. Thus, a microelectrode has a very reduced interface capacitance, and the charging current decays much more quickly than with conventional electrodes and faster response times may be achieved. Another property of microelectrodes is the *decreased distortion from IR_u* , the potential drop between working and reference electrodes generated by the passage of current through a solution and expressed in terms of the product of the solution resistance and the current flowing in the circuit. With conventional electrodes, it is usual to add supporting electrolyte to minimize the solution resistance, but with microelectrodes, the current passing through the cell is low, often of the order of 10^{-9} A, and hence problems with IR_u drop are greatly reduced. This proves to be an advantage to experiments with either a large current, I , or a large resistance, R , as for example in experiments with solvents of very low dielectric constant, in media with very low ionic strength, or in studies of solutions with high concentrations of electroactive species. Electrochemical measurements can be therefore made in new and unique chemical environments, which are not amenable at larger electrodes, and experiments have been reported in frozen acetonitrile, low-temperature glasses, ionically conductive polymers, oil-based lubricants and milk. In addition, the use of electrolyte-free organic media can greatly extend the electrochemical potential window, thus allowing studies of species with high redox potentials. Furthermore, such dimensions offer obvious analytical advantages, including the exploration of microscopic domains, measurement of local concentration profiles, detection in micro-flow systems and analysis of very small sample volumes [28].

Microelectrodes with several geometries are reported in the literature, from spherical to disc to line electrodes; each geometry has its own critical characteristic dimension and diffusion field in the steady state. The diffusional flux to a spherical microelectrode surface may be regarded as planar at short times, therefore displaying a transient behaviour, but spherical at long times, displaying a steady-state behaviour [28, 34]. If a potential is applied so that the reaction $O + ne^- \rightarrow R$, becomes diffusion controlled, the current density at a microsphere electrode can be expressed by

$$j = \frac{nFD^{1/2}c_1}{\pi^{1/2}t^{1/2}} + \frac{nFDC_1}{r}$$

transient term steady-state term

This expression is the sum of a transient term and a steady-state term, where r is the radius of the sphere. At short times after the application of the potential step, the transient term dominates over the steady-state term, and the electrode is analogous to a plane, as the depletion layer is thin compared with the disc radius, and the current varies with time according to the Cottrell equation. At long times, the transient current will decrease to a negligible value, the depletion layer is comparable to the electrode radius, spherical diffusion controls the transport of reactant, and the current density reaches a steady-state value. At times intermediate to the limiting conditions of Cottrell behaviour or diffusion control, both transient and steady-state terms need to be considered and thus the full expression must be used. However, many experiments involving microelectrodes are designed such that one of the simpler current expressions is valid.

Of course, in order to vary the mass transport of the reactant to the electrode surface, the radius of the electrode must be varied, and this implies the need for microelectrodes of different sizes. Spherical electrodes are difficult to construct, and therefore other geometries are often employed. Microdiscs are commonly used in the laboratory, as they are easily constructed by sealing very fine wires into glass epoxy resins, cutting

perpendicular to the axis of the wire and polishing the front face of the disc that is created [30]. Because of its planar geometry, the diffusion field over the surface of a microdisc is non-uniform and the flux only approximates that of a hemisphere. The rate of diffusion to the edge of the disc will be higher than to the centre. Therefore, the rates of diffusion to the disc are estimated as space-averaged quantities and a factor of $4/\pi$ is required to adjust the equation for a spherical microelectrode to describe the diffusion of reactant to the surface of a microdisc electrode, which becomes $j = 4nFDc_1^\infty/\pi r$, where r is now the radius of the disc.

Similarly to the response at hydrodynamic electrodes, linear and cyclic potential sweeps for simple electrode reactions will yield steady-state voltammograms with forward and reverse scans retracing one another, provided the scan rate is slow enough to maintain the steady state [28, 35, 36, 37 and 38]. The limiting current will be determined by the slowest step in the overall process, but if the kinetics are fast, then the current will be under diffusion control and hence obey the above equation for a disc. The slope of the wave in the absence of IR_u drop will, once again, depend on the degree of reversibility of the electrode process.

All types of voltammetry may be applied to microelectrodes, including normal, reverse pulse and square-wave voltammetry. Pulse voltammetry and potential-step program at microelectrodes discriminate against charging currents and the boundary conditions are set much faster between pulses, since the electrode responds in a much more rapid fashion to a potential change [11, 15, 16]. Cyclic voltammetry measurements can be made on a much more rapid time scale than with electrodes of conventional size and be operated in the range of tens of nanoseconds, without important distortion by IR_u drop and concerns regarding charging currents. This renders the characterization of rates and mechanisms of very fast chemical reactions as well as determination of trace quantities of transient species possible. At high sweep rates, however, only linear diffusion needs to be considered [28].

The advantages of microelectrodes for low-volume detection and spatially and temporally resolved measurements have been largely exploited in biology and medicine [39, 40 and 41]. One of the most active and longer-standing fields is neuroscience, where the development of the electroanalysis of brain extracellular fluid has been remarkable, since it can be relatively non-invasive due to the small size and low currents flowing. An example is the monitoring of the release of neurotransmitters with carbon microelectrodes in either amperometric mode or using fast cyclic voltammetry [42, 43]. Carbon materials are the most common starting materials and have also been applied to other electroactive compounds such as histamine, anticancer drugs and ascorbic acid. Extension of the investigation of cellular systems to non-electroactive neurochemicals has led to the development of enzyme-modified microelectrodes for measurements of glutamate, glucose, and choline and acetylcholine. Voltammetric measurements have also been reported in single cells, although the living cells are separated from the parent organism. Microelectrodes have also found widespread use in sensor technology and environmental analysis. Due to the high rate of steady-state diffusion at a microelectrode, their response is independent of convection, thus enabling their use for the analysis of flowing systems. In order to enhance the current response at microelectrodes, a number of approaches have been described. Amongst these are random arrays of microdisc electrodes [44, 45 and 46] and interdigitated arrays of microband electrodes [47, 48]. Arrays of microelectrodes enable the enhancement of the current response, whilst retaining the properties of a single microelectrode, and have been used as highly sensitive detectors in flow-injection analysis and in liquid chromatography.

B1.28.4.5 SCANNING ELECTROCHEMICAL MICROSCOPY

SECM is a scanning-probe technique introduced by Bard *et al* in 1989 [49, 50 and 51] based on previous studies by the same group on *in situ* STM [52] and simultaneous work by Engstrom *et al* [53 and 54], who were the first to show that an amperometric microelectrode could be used as a local probe to map the concentration profile of a larger active electrode. SECM may be envisaged as a 'chemical' microscope based on faradic current changes as a microelectrode is moved across a surface of a sample. It has proved useful for

obtaining topographical and chemical information on a wide range of sample surfaces, including electrodes, minerals, polymers and biological materials.

The apparatus consists of a tip-position controller, an electrochemical cell with tip, substrate, counter and reference electrodes, a bipotentiostat and a data-acquisition system. The microelectrode tip is held on a piezoelectric pusher, which is mounted on an inchworm-translator-driven x - y - z three-axis stage. This assembly enables the positioning of the tip electrode above the substrate by movement of the inchworm translator or by application of a high voltage to the pusher *via* an amplifier. The substrate is attached to the bottom of the electrochemical cell, which is mounted on a vibration-free table [55, 56, 57 and 58]. A number of different size and shape tips have been reported. The most common are disc shaped with diameters of 0.6–25 μm formed by sealing a Pt, Au wire or carbon fibre of the required radius in a glass capillary and polishing the sealed end. The glass wall surrounding the disc is sharpened to a conical shape to decrease the possibility of contact between glass and substrate as the tip is moved close to the latter. For most studies, the ratio of the diameter of the entire tip end, including the insulator, to that of the electrode itself should typically be ≈ 10 . Metal electrodes down to the nanometre scale have also been fabricated by sealing an etched Pt or Pt–Ir wire in a suitable insulating material, leaving the etched end exposed. Commercial SECM instruments have only recently appeared on the market.

With SECM, almost any kind of electrochemical measurement may be carried out, whether voltammetric or potentiometric, and the addition of spatial resolution greatly increases the possibilities for the characterization of interfaces and kinetic measurements [55, 56, 57, 58 and 59]. It may be employed as an electrochemical tool for the investigation of heterogeneous and homogeneous reactions, as an imaging device, or for microfabrication, making use of different modes of operation. In amperometric *feedback mode* a three- or four-electrode configuration is employed, in which a microelectrode tip serves as the working electrode, the potential is controlled *versus* the reference electrode and the current flows between tip and counter-electrodes. The potential of the sample may also be controlled and it may thus serve as a second working electrode. The electrolyte solution contains a redox mediator, e.g. a reducible species O , such that when a suitably negative potential is applied to the tip, its reduction takes place at a rate governed by diffusion of the electroactive species to the electrode. If the tip is more than several tip diameters away from the surface, the steady-state current is given by $I_{T_{\infty}} = 4nFDc_i^{\infty}r$, for a disc-shaped tip, where r is the radius of the tip. However, when the tip is brought within a few tip radii to a conductive substrate, the reduced species formed at the tip diffuses to the substrate where it is re-oxidized. As a consequence, an additional flux of O to the tip is produced which leads to an increase in the tip current, known as positive feedback. The smaller the tip–substrate distance the larger is the effect. In contrast, if the substrate is an electrical insulator, the reducible species cannot be regenerated and, since the diffusion of O from the bulk is hindered at small distances to the substrate, the tip current will be smaller than $I_{T_{\infty}}$, i.e. negative feedback. Therefore, by scanning over the surface of a substrate, the variation in current can be related to changes in the distance and hence to the topography of the substrate. Besides feedback mode, several other modes exist, such as *generation/collection mode*, where species generated at one working electrode are detected at the second, *penetration mode*, in which a small tip is used to penetrate a microstructure and extract spatially resolved information about concentrations, kinetic and mass-transport parameters, and *ion-transfer feedback mode*, recently developed and useful for studies of ion-transfer reactions at liquid/liquid and liquid/membrane interfaces. The SECM

methodologies are based on quantitative theory, which has been developed for a variety of systems involving heterogeneous and homogeneous processes and different tip and substrate geometries. In many cases, analytical approximations allow the generation of theoretical dependences and an analysis of experimental data [60, 61, 62, 63 and 64].

The high rate of mass transfer in SECM enables the study of fast reactions under steady-state conditions and allows the mechanism and physical localization of the interfacial reaction to be probed. It combines the useful

features of microelectrodes and thin-layer cells in dimensions not easily attainable in larger electrochemical cells. The mass-transfer rate in SECM is a function of the tip–substrate distance. At large distances, d , $k_m \approx D/r$, whereas for small distances ($d < r$), $k_m \approx D/d$. The large effective k_m obtainable enables fast heterogeneous reaction rates to be measured under steady-state conditions. Zhou and Bard measured a rate constant of 6×10^7 Ms for the electro-hydrodimerization of acrylonitrile (AN) and observed the short-lived intermediate AN^- for this process [65].

Heterogeneous reactions at a substrate can also be probed without the need for an external voltage, if for example the mediator regeneration is chemical in nature rather than electrochemical. This has opened the possibility of studying dissolution of ionic single crystals and locating individual sites of reactivity in multiphase systems. It can be used to map the local surface reactivity in either feedback or collection mode. Feedback mode has been employed, for example, to probe the surface reactivity of a titanium substrate covered with TiO_2 and to individuate precursor sites for pitting corrosion, whereas collection mode has been used to image fluxes of species produced or consumed at the substrate, such as iontophoretic fluxes of electroactive species through porous membranes [56, 57, and 58].

Among the systems most studied by SECM are heterogeneous electron transfer reactions at the metal/ solution interface. Nonetheless, the diversity of interfaces and processes that can be studied with SECM has grown to include liquid/liquid and liquid/gas interfaces [66], and materials of biological significance [67]. It is a promising technique for the mapping of biochemical activity, for example transport in tissues and immobilized enzyme kinetics. Detection of single molecules has also recently been reported [68].

B1.28.4.6 SONOELECTROCHEMISTRY

The technique of applying ultrasound during electrochemical measurements and reactions is known as sonoelectrochemistry or sonovoltammetry and is a field that has grown rapidly in recent years [69, 70, 71 and 72]. The dominant ultrasonic effects are the enhanced mass transport of electroactive substrate to the electrode and the activation of the electrode surface through a cavitation cleaning action. The latter are violent collapses of oscillating bubbles, which can cause effects such as depassivation and erosion. The huge effects on the rate of mass transport to the electrode surface may be envisaged as an extremely thinned diffusion layer of uniform accessibility, partly induced by acoustic streaming, when ultrasonic horn transducers are employed, and by cavitation collapse of micro-bubbles at the solid–liquid interface.

Two major sources of ultrasound are employed, namely ultrasonic baths and ultrasonic immersion horn probes [70, 71]. The former consists of fixed-frequency transducers beneath the exterior of the bath unit filled with water in which the electrochemical cell is then fixed. Alternatively, the metal bath is coated and directly employed as electrochemical cell, but in both cases the results strongly depend on the position and design of the set-up. The ultrasonic horn transducer, on the other hand, is a transducer provided with an electrically conducting tip (often Ti6Al4V), which is immersed in a three-electrode thermostatted cell to a depth of 1–2 cm directly facing the electrode surface.

The ultrasound intensity and the distance between the horn and the electrode may be varied at a fixed frequency, typically of 20 kHz. This cell set-up enables reproducible results to be obtained due to the formation of a macroscopic jet of liquid, known as acoustic streaming, which is the main physical factor in determining the magnitude of the observed current.

The effects of ultrasound-enhanced mass transport have been investigated by several authors [73, 74, 75 and 76]. Empirically, it was found that, in the presence of ultrasound, the limiting current for a simple reversible electrode reaction exhibits quasi-steady-state characteristics with intensities considerably higher in magnitude compared to the peak current of the response obtained under silent conditions. The current density can be

described by $j_{\text{lim}} = nFDc_i^\infty/\delta$, where the diffusion layer δ depends on the distance between the horn and the electrode and on the ultrasound intensity. Superimposed on the faradic current a fluctuation or noise is also detected consistent with the turbulent nature of the macroscopic jet of liquid and the presence of oscillating and cavitating bubbles.

In an alternative design, the actual tip of the ultrasonic horn may be used as the working electrode after insertion of an isolated metal disc [77, 78 and 79]. With this electrode, known as the sonotrode, very high limiting currents are obtained at comparatively low ultrasound intensities, and diffusion layers of less than 1 μm have been reported. Furthermore, the magnitude of the limiting currents has been found to be proportional to $D^{2/3}$, enabling a parallel to be drawn with hydrodynamic electrodes.

The cleaning or depassivation effect is of great importance in sonoelectrochemistry, as it can be employed to wash off surface-adsorbed species and reduce blocking of the electrode by adsorption of reaction products. This effect has been reported, for example, for the depassivation of iron electrodes and for the removal of deposits and in the presence of polymer films on the electrode surface. However, damage of the electrode surface, especially for materials of low hardness such as lead or copper, can also occur under harsh experimental conditions and applied intensities [70, 71, 80].

Sonoelectrochemistry has been employed in a number of fields such as in electroplating for the achievement of deposits and films of higher density and superior quality, in the deposition of conducting polymers, in the generation of highly active metal particles and in electroanalysis. Furthermore, the sonolysis of water to produce hydroxyl radicals can be exploited to initiate radical reactions in aqueous solutions coupled to electrode reactions.

B1.28.5 ELECTROCHEMICAL IMPEDANCE SPECTROSCOPY

In contrast to transient techniques, which involve the perturbation of a system and studying its relaxation with time, when the perturbation is sinusoidal, the analysis is performed in the frequency domain, which is obtained by applying Laplace transforms to the time-domain information. Alternating-current impedance techniques employ the ratio of an imposed sinusoidal voltage and the resulting sinusoidal current to define the impedance, which is a function of the frequency of the signal. When a steady-state system is perturbed by an applied AC voltage, it relaxes to a new steady state and the time taken for this relaxation is known as τ . $\tau = RC$, where R is the resistance and C the capacitance of the system. Analysis of this relaxation process provides information about the system. In the frequency domain, fast processes, low τ , occur at high frequencies, while slow processes, with high τ , occur at low frequencies. Thus, dipolar properties may be studied at high frequencies, bulk properties at intermediate frequencies and surface properties at low frequencies.

Methods for measuring the impedance can be divided into controlled current and controlled potential [2, 4, 81]. Under controlled potential conditions, the potential of the electrode is sinusoidal at a given frequency with the amplitude being chosen to be sufficiently small to assure that the response of the system can be considered linear. The ratio of the response to the perturbation is the transfer function, or impedance, Z , when considering the response of an AC current to an AC voltage imposition and is defined as $E = IZ$, where E and I are the waveform amplitudes for the potential and the current respectively. Impedance may also be envisaged as the resistance to the flow of an alternating current.

Two different components contribute to impedance: the resistive or real component due to resistors and the reactive or imaginary component from AC circuitry elements, such as capacitors, inductors, etc. Unlike the resistive component, the reactive impedance affects not only the magnitude of the AC wave but also its time-

dependent characteristic, the phase. For example, when an alternating voltage wave is applied to a capacitor, the resulting current waveform will lead the applied voltage by 90°. Due to this reason the introduction of complex notation is convenient. Thus, when a system is perturbed by a sinusoidal potential, varying with time according to

$$E(t) = E_0 \exp(i\omega t)$$

the response can be expressed in terms of

$$I(t) = I_0 \exp(i\omega t - \varphi)$$

where i is the complex number, $E(t)$ and $I(t)$ are the instantaneous values, E_0 and I_0 the peak amplitude of the potential and the current respectively, φ the phase angle difference and ω the angular frequency in radians ($\omega = 2\pi f$).

Introducing the complex notation enables the impedance relationships to be presented as Argand diagrams in both Cartesian and polar co-ordinates (r, φ). The former leads to the Nyquist impedance spectrum, where the real impedance is plotted against the imaginary and the latter to the Bode spectrum, where both the modulus of impedance, r , and the phase angle are plotted as a function of the frequency. In AC impedance the cell is essentially replaced by a suitable model system in which the properties of the interface and the electrolyte are represented by appropriate electrical analogues and the impedance of the cell is then measured over a wide frequency range, usually between 10^4 and 10^{-3} Hz. By comparing the measured results with values calculated from the model system, the suitability of the model and the values of the parameters can be evaluated. In fact, one of the advantages of EIS is that impedance functions frequently display many of the features exhibited by passive electrical circuits. The most important elements employed in equivalent circuits are the resistor R , which represents the resistance that charge carriers encounter in a specific medium, the capacitor C , which represents the accumulation of charged species, and the inductance L , which represents the deposition of surface layers (figure B1.28.8). An analogy, however, is not always feasible, due to the active nature of electrochemical interfaces and the chemical nature of charge transfer processes, as well as the non-ideal electric behaviour of real electrochemical systems. Furthermore, problems can arise in selecting a correct equivalent circuit out of a large number of possibilities, because of the uncertainty connected with the impedance at low frequency and because of the large number of possible combinations of mechanistic reactions that can produce the same impedance shape within error limits. Various methods have been reported to discriminate for the correct equivalent circuit and to obtain values for the elements in the circuit [81, 82 and 83]. Spectra displaying one time constant are simple to interpret and may be easily resolved graphically directly from the spectra; however, more complex methods such as deconvolution and complex nonlinear least-square methods, or a combination of these are required for more complicated spectra. A number of software packages are based on these different types of methods.

Figure B1.28.8. Equivalent circuit for a three-electrode electrochemical cell. WE, CE and RE represent the working, counter and reference electrodes; R_s is the solution resistance, R_u the uncompensated resistance, R_t the charge-transfer resistance, R_r the resistance of the reference electrode, C_d the double-layer capacitance and C_r the parasitic loss to the ground.

AC impedance spectroscopy is widely employed for the investigation of both solid- and liquid-phase phenomena. In particular, it has developed into a powerful tool in corrosion technology and in the study of porous electrodes for batteries [84, 85, 86 and 87]. Its usage has grown to include applications ranging from fundamental studies of corrosion mechanisms and material properties to very applied studies of quality control and routine corrosion engineering. In corrosion, EIS enables one to obtain instantaneous corrosion-rate information, polarization resistance and information on the kinetics and mechanisms of charge transfer processes such as oxide growth and metal dissolution. The technique is frequently employed in the monitoring of polymer-coated metals to investigate the corrosion protection, the dielectric properties, the onset of defect formation and the processes of coating degradation [84].

B1.28.6 PHOTOELECTROCHEMISTRY

The combination of electrochemistry and photochemistry is a form of dual-activation process. Evidence for a photochemical effect in addition to an electrochemical one is normally seen in the form of photocurrent, which is extra current that flows in the presence of light [88, 89 and 90]. In photoelectrochemistry, light is absorbed into the electrode (typically a semiconductor) and this can induce changes in the electrode's conduction properties, thus altering its electrochemical activity. Alternatively, the light is absorbed in solution by electroactive molecules or their reduced/oxidized products inducing photochemical reactions or modifications of the electrode reaction. In the latter case electrochemical cells (RDE or channel-flow cells) are constructed to allow irradiation of the electrode area with UV/VIS light to excite species involved in electrochemical processes and thus promote further reactions.

Conduction in semiconductors requires that electrons in the valence band be excited into the conduction band either by thermal or photochemical excitation. Upon excitation, an unoccupied vacancy (a hole) is left in the valence band. The hole and the excited electrons can move in response to an applied electric field and so permit the passage of current. Semiconduction can be controlled via doping of small quantities of material, which can be either electron donating or electron accepting, leading to n-type and p-type semiconductors [91, 92, 93 and 94]. In a solution containing a redox couple, electron transfer will occur until the electrochemical potentials of the semiconductor and the solution are equal (figure B1.28.9). The semiconductor will have a net positive or negative charge, which is situated near the surface of the solid, known as the space-charge layer (2–500 nm thickness). The bands may be envisaged as bent: band-bending downwards indicates excess of negative charge at the surface, whereas band-bending upwards indicates an excess of positive holes. Potentiostatic control of a semiconductor can change the energy of the conduction and valence bands with consequent changes in the band bending, leading to the supply and removal of charge carriers within the space layer and enabling electrolysis to occur at the solid/liquid interface. For the n-type semiconductor TiO_2 , for example, the conduction and valence bands are bent upward at the surface, provided that a very negative potential is not applied to the electrode. An applied potential leading to no band-bending—i.e. to an absence of the space-charge layer—is called the flat-band potential of the semiconductor. Upon irradiation with light of an equal or greater energy than the band gap, the photochemically promoted electrons will be swept into the bulk of the material by the electric field present in the space-charge layer, whilst the holes in the valence band will migrate to the surface of the solid (figure B1.28.10). As a result, photo-oxidation processes will be promoted to occur at the solid–liquid interface.

-28-

Figure B1.28.9. Energetic situation for an n-type semiconductor (a) before and (b) after contact with an electrolyte solution. The electrochemical potentials of the two systems reach equilibrium by electron exchange at the interface. Transfer of electrons from the semiconductor to the electrolyte leads to a positive space charge layer, W . U_s is the potential drop in the space-charge layer.

Figure B1.28.10. Schematic representation of an illuminated (a) n-type and (b) p-type semiconductor in the presence of a depletion layer formed at the semiconductor–electrolyte interface.

-29-

In the last 30 or more years, research in the field of photoelectrochemistry and photocatalysis has greatly expanded, with advances being made in the fundamental understanding of the faradic processes that control charge transfer at semiconductor/liquid junctions, and with the development of stable efficient and inexpensive photoelectrochemical cells [95, 96 and 97]. Semiconductor photoelectrochemistry has had an impact in a number of fields. Photocorrosion has been exploited to prepare technologically useful structures such as lenses that are integrated with light-emitting diodes and mated optical fibres. It has also led to the formation of porous Si electrodes, which have received much attention due to their interesting optoelectronic properties. Photoelectrochemical surface preparation of semiconductor materials has been used to clean solids and to evaluate etch pit densities.

Photoelectrochemistry may be used as an *in situ* technique for the characterization of surface films formed on metal electrodes during corrosion. Analysis of the spectra allows the identification of semiconductor surface phases and the characterization of their thickness and electronic properties.

Furthermore, semiconductor powders can be employed for the catalytic generation of useful products such as H₂ and O₂ that can be used for the destruction of pollutants [98, 99 and 100].

B1.28.7 SPECTROELECTROCHEMISTRY

In addition to the mechanism of electrode reactions, readily deduced using voltammetric techniques, the electrochemist seeks knowledge of the chemical composition and properties of electro-generated intermediates and films formed on electrode surfaces. Spectroelectrochemistry allows the simultaneous acquisition of electrochemical and spectroscopic data, which offer additional information to the investigation of a wide range of complex surface and homogeneous processes occurring in electrochemical systems [101, 102, 103 and 104]. Advances made in instrumentation over the past three decades have enabled the adaptation of spectroscopic methods to *in situ* application in an electrochemical cell and the development of new techniques, which have found widespread use in structure characterization of electrode surfaces, in identification of homogeneous phase molecules, and in studies of species adsorbed at the electrode/electrolyte interface.

One of the first *in situ* combined electrochemical/spectroscopic techniques to be investigated employed UV/VIS detection, where solution-phase spectra of organic radicals generated at an electrode could be recorded. Typically, organic intermediates or products possess additional absorption bands not observed in the parent molecule, which can be used to fingerprint the electro-generated species. In addition to spectra, useful information may be obtained by monitoring the absorbance as a function of time during a potential-step experiment. When the potential is stepped from a value where no electrode transfer takes place to one where an electro-generated species is formed, the spectroscopic intensity–time response of the products may be analysed and, from the shape and size, estimates of the lifetime of the electrode intermediates can be extrapolated.

In UV–VIS spectroelectrochemistry, optically transparent electrodes (OTEs) are utilized. A beam of monochromatic UV–VIS light is directed perpendicularly through the OTE, then through the diffusion layer next to the electrode and the bulk solution, before passing out of the electrochemical cell through an exit window and being detected. The beam is attenuated by the presence of absorbing species in the solution, therefore enabling spectral and temporal information about the concentrations of such species in the diffusion layer at the electrode to be obtained. An alternative design is the optically transparent thin layer electrode, in which a minigrad electrode is employed [2, 103, 105].

-30-

Infrared spectroscopy has also been widely employed in electrochemistry [105, 106, and 107]. Spectra aid the identification of reactants, of products and of long-lived intermediates and allow changes in the interfacial solvent to be tracked. A variety of spectral sampling and data acquisition methods have been developed to approach *in situ* detection of species. In external reflection sampling methods, the infrared beam is directed through a polarizer onto the front surface of a highly polished disc-shaped working electrode with high reflectivity in the infrared spectral region, such as Pt, Au or Ag. A special, thin-layer electrochemical cell is used that permits the infrared beam to enter and strike the disc, where it is reflected out of the cell and detected. In contrast, in attenuated total internal reflection sampling methods, the working electrode is a thin film of metal deposited on one surface of an ATR crystal. The metal film must be sufficiently thin to allow penetration of the IR evanescent wave beyond the metal solution interface. The ATR crystal forms the bottom of a chamber that holds the electrolyte solution and the counter and reference electrodes and the crystal is positioned so that the metal film is inside the chamber. This method has not been widely used in electrochemistry partly due to the difficulty in the preparation of the thin metal film working electrodes. Nonetheless, the latter design overcomes molecular transport limitations imposed by external reflection methods, where a thin solution layer of the order 1–5 μm between the front face of the working electrode and the infrared transparent window is required to minimize absorption of infrared radiation by the solvent. In fact, diffusion of species into and out of the thin-layer region is restricted and can lead to reactant depletion or product accumulation.

Luminescence has been used in conjunction with flow cells to detect electro-generated intermediates downstream of the electrode. The technique lends itself especially to the investigation of photoelectrochemical processes, since it can yield information about excited states of reactive species and their lifetimes. It has become an attractive detection method for various organic and inorganic compounds, and highly sensitive assays for several clinically important analytes such as oxalate, NADH, amino acids and various aliphatic and cyclic amines have been developed. It has also found use in microelectrode fundamental studies in low-dielectric-constant organic solvents.

One of the most important advances in electrochemistry in the last decade was the application of STM and AFM to structural problems at the electrified solid/liquid interface [108, 109]. Sonnenfield and Hansma [110] were the first to use STM to study a surface immersed in a liquid, thus extending STM beyond the gas/solid interfaces without a significant loss in resolution. *In situ* local-probe investigations at solid/liquid interfaces can be performed under electrochemical conditions if both phases are electronic and ionic conducting and this

offers a great advantage since the Fermi levels of both substrate and tip can be precisely adjusted independently of each other. This opens the possibility of correlating structural to physical properties, since charge transfer central to electrochemical reactivity occurs within a few atomic diameters of the electrode surface, in the inner Helmholtz plane, and the detailed arrangement of atoms and molecules at this interface strongly controls the corresponding electrochemical reactivity. Since its introduction in electrochemistry, STM investigations have focused on studies of metal electrodes, i.e. Au, Pt, Pd and Rh, their surface charges in the double-layer potential region, and the surface changes caused by the formation of surface oxides. In addition, it has been employed in reconstruction and restructuring studies of metal surfaces, in studies of underpotential deposition of metals, in the investigation of adsorption/desorption processes, as well as in the understanding of processes controlling deposition and corrosion at semiconductor electrodes.

Amongst other spectroscopic techniques which have successfully been employed *in situ* in electrochemical investigations are ESR, which is used to investigate electrochemical processes involving paramagnetic molecules, Raman spectroscopy and ellipsometry.

B1.29 High-pressure studies

Malcolm F Nicol

B1.29.1 INTRODUCTION

This chapter introduces the physical chemistry of materials under high pressures. Space limitations permit only a broad-brush introductory survey. High-pressure studies range from designing equipment to generate, to confine and to measure high pressures to spectroscopic studies from 10^5 Hz to beyond 10^{19} Hz at temperatures from below 1 K to 10^5 K and beyond for all sorts of elements, compounds, solutions and mixtures. To say that these are extreme ranges of conditions is an understatement.

To gain a sense of the range of behaviours, consider what happens to one element familiar to every chemist and physicist: oxygen. At ambient temperature, oxygen, O_2 , exists as the canonical odourless, colourless gas of elementary school and as a purple, orange, red, blue or black solid depending on the pressure and the direction from which you look at the crystals. It becomes a metal and, at low temperatures, an antiferromagnet or a superconductor. In the solid phase stable above 10 GPa, O_2 has a strong infrared vibrational absorption band in the stretching region. Then, of course, there is the O_3 isomer which has not been studied at high pressures.

Similarly ‘strange’ things happen to other materials. Above 5 GPa, CO spontaneously polymerizes; the

structure of the product is $(O=C-C=O)_n$. Indeed, almost every carbon compound with unsaturated bonds becomes unstable with respect to reactions that produce saturated compounds at this or slightly higher pressures. Somewhat above 100 GPa, CsI and Xe also are metals. By 100 TPa and 10^5 K—yes, experiments have been done to these conditions—the density of Al exceeds 12 g cm^{-3} , or about five times greater than at ambient pressure. All but the 1s and possibly 2s electrons remain localized on an Al nucleus.

Books are available on many of these subjects. The objective here, therefore, is to introduce several fundamental issues and point to additional information by citing key references and suggesting further reading. We begin by briefly delimiting what we mean by *high pressure*. Then, we discuss how high pressures are achieved and measured before describing the behaviours of a few familiar materials at high pressures.

B1.29.2 WHAT IS PRESSURE?

Almost everyone has a concept of ‘pressure’ from weather reports of the pressure of the atmosphere around us. In this context, ‘high pressure’ is a sign of good weather while very low pressures occur at the ‘eyes’ of cyclones and hurricanes. In elementary discussions of mechanics, hydrostatics of fluids and the gas laws, most scientists learn to compute pressures in static systems as force per unit area, often treated as a scalar quantity. They also learn that unbalanced pressures cause fluids to flow. Winds are the flow of the atmosphere from regions of high to low

pressures. However, high and low pressures in the atmosphere rarely deviate by as much as 10% from the local mean pressure, about 0.1 megapascal at ‘sea level’. The pascal (Pa) is the SI unit of pressure, $1 \text{ Pa} = 1 \text{ N m}^{-2} = 10^{-5} \text{ bar}$. One standard atmosphere is about $1.013 \times 10^5 \text{ Pa}$. Local fluctuations in the pressure of the atmosphere are, however, much smaller than the difference between the average pressure at ‘sea level’ and at the peaks of high mountains. The average pressure near the top of Mount Everest is less than one-quarter of atmospheric pressure at ‘sea level’.

This example of high and low pressure also shows the ambiguities of these terms in science. All these pressures are essentially *constant* in terms of the range of pressures encountered in nature. From negative pressures in solids under tension (e.g., on the wall of flask confining a fluid), pressure in nature increases through the very low-pressure vacuum of interplanetary space (less than 10^{-13} Pa) to well in excess of 10^{20} Pa at the centres of neutron stars! In these terms, *high pressure* and *low pressure* are relative terms with different meanings in different areas of chemistry and physics. Test this by searching an electronic database for ‘high pressure’. A discussion of high-pressure studies, therefore, must decide what pressure is and what high means; just how high is high.

Relationships from thermodynamics provide other views of pressure as a macroscopic state variable. Pressure, temperature, volume and/or composition often are the controllable independent variables used to constrain equilibrium states of chemical or physical systems. For fluids that do not support shears, the pressure, P , at any point in the system is the same in all directions and, when gravity or other accelerations can be neglected, is constant throughout the system. That is, the equilibrium state of the system is subject to a hydrostatic pressure. The fundamental differential equations of thermodynamics:

$$dU = -PdV + TdS$$

$$dA = -PdV - SdT$$

identify P through the Maxwell relations:

$$P = -(\partial U/\partial V)_S = -(\partial A/\partial V)_T.$$

Two other Maxwell relations define the direction systems change to achieve equilibrium:

$$V = \rho^{-1} = (\partial H/\partial P)_S = (\partial G/\partial P)_T.$$

In both mechanical (constant S , minimize H) and thermal (constant T , minimize G) contexts, pressure drives a system to become smaller or denser.

The situation is more complex for rigid media (solids and glasses) and more complex fluids: that is, for most materials. These materials have finite yield strengths, support shears and may be anisotropic. As samples, they usually do not relax to hydrostatic equilibrium during an experiment, even when surrounded by a hydrostatic pressure medium. For these materials, P should be replaced by a stress tensor, σ_{ij} , and the appropriate thermodynamic equations are more complex.

The take-home lesson is that the vast majority of high-pressure studies are on solids or other rigid media and are not done under hydrostatic conditions. The stresses and stress-related properties may vary throughout the sample. Unless the probes are very local and focus on a small region of the sample, measurements are averages over a range of, often uncharacterized, conditions.

As well as macroscopic equations of state relating free energies, enthalpy, entropy, density, composition, temperatures and pressure, high-pressure science also concerns how changes of pressure and other macroscopic constraints affect the microscopic molecular and electronic structures of matter. At low pressures, the chemistry of most materials is described in terms of electrons tightly bound to specific atoms, molecules or ions and relatively weaker intermolecular van der Waals or ionic forces. The itinerant conduction electrons of metals are an exception; they are delocalized throughout the solid. The highly local nature of most electrons reflects the drive to minimize their potential energies.

To a rough approximation, the kinetic and potential energies of electrons in simple systems vary with density as $\rho^{2/3}$ and $-\rho^{1/3}$, respectively. This means that kinetic energy considerations should dominate at very high densities. Localized electrons should, therefore, eventually delocalize at very high pressures, converting ionic and molecular materials to more closely packed extended network structures and to metals at high pressures. Again, of course, the question occurs: how high is very high? Experiments provide the answer, or at least a lower limit. Where the answer is missing, experimenters are driven to try to attain even higher pressures.

Many experiments support the pressure-delocalization principle. Most unsaturated organic molecules including CO and C₂N₂ polymerize at pressures of the order of 10 GPa [1, 2 and 3]. Layered covalent solids like graphite and hexagonal boron nitride (h-BN) transform to dense, three-dimensional network materials, diamond and cubic boron nitride (c-BN) [4, 5 and 6]. Solid oxygen, solid and fluid iodine, fluid hydrogen and nitrogen, xenon, and cesium iodide are examples of materials developing metallic behaviour at pressures of the order of 100 GPa [7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21 and 22]. Later sections provide more details about some of these transformations. At intermediate pressures, the energies of atomic and molecular orbitals change with pressure. By measuring electronic spectra at high pressures, differences of these energy changes can be determined for various different orbitals. In some cases, spectral features change by as much as 0.1 eV GPa⁻¹. Drickamer named this phenomenon pressure-tuning spectroscopy and has written extensively about observations for many systems [23, 24 and 25].

B1.29.3 WHAT PRESSURES ARE HIGH?

What then are high pressures? The answer to this question involves the bias of personal experience. I often remark in an off-hand manner that 'In my laboratory, we consider 5 kbar a low pressure'. We have several reasons for setting the low-high boundary around 1 GPa. This and slightly higher pressures can conveniently be achieved by use of commercial autoclaves several litres in size, mechanical compressors and fluid or even compressed-gas pressure media. Many commercial processes run at these and lower pressures. These include the Haber synthesis of ammonia, a method for producing high-density polyethylene, and recently developed methods for producing vaccines by denaturing viruses or for sterilizing (pascalizing) strawberry jam and other foods at ambient temperature which preserve their flavours better than pasteurizing at higher temperatures.

The rates of several chemical reactions accelerate by factors of 10⁴ or more between 0.1 and 100 MPa at ambient temperature, so much interesting chemistry occurs at these lower pressures. At such 'low' pressures, Bridgman [26] even showed how to cook eggs at 'room' temperature.

At ambient temperature, however, few materials remain fluid at pressures much higher than 1 GPa. Fluids also are much more difficult to confine at higher pressures. Absolute pressures have been measured with dead-weight testers only to about 2.5 GPa, that is to the pressure of a solid-solid phase transition in elemental bismuth at 298 K [27]. The importance of non-hydrostatic stresses and changes to the technology of high-pressure studies above 1 GPa suggest the rough dividing line which I have adopted for this essay.

The energies of chemical changes provide a third criterion for defining high pressures. Many unsaturated

organic compounds dimerize or polymerize at high pressures because the products are denser by about $10^{-5} \text{ m}^3 \text{ mol}^{-1}$ ($10 \text{ cm}^3 \text{ mol}^{-1}$). At a pressure of 1 GPa, the corresponding decrease of the energy, enthalpy and free energy is 10 kJ mol^{-1} or relatively modest compared with chemical bond energies. At 10 GPa, for the same difference of molar volume, the energies decrease by 100 kJ mol^{-1} , an amount comparable to bond energies. That is, chemical change can be anticipated at pressures somewhat above 1 GPa.

B1.29.4 HOW ARE HIGH PRESSURES ACHIEVED?

Laboratory high-pressure studies follow many approaches. The pressure may remain constant (so-called static experiments) or be transient (so-called dynamic experiments where shock waves generated by an explosion, impact or laser ablation compress a sample for a few microseconds or shorter times). Many devices have been used for static experiments to about 20 GPa; Jayaraman described many of these in three articles [28, 29 and 30]. Many static high-pressure cells are variants of the piston–cylinder apparatus frequently used to illustrate compression in elementary discussions of the thermodynamics of gases. An external force on a piston free to move within a cylinder applies pressure to a sample that is confined as long as the seal between the piston and cylinder remains leaktight. Bridgman’s anvils [31] represent a different concept. The concept confines the sample between two pistons made of a hard material shaped as truncated cones and a crushable cylindrical gasket. The classical Bridgman design used cemented tungsten carbide anvils and a lava (pyrophyllite) gasket. External force applied to the anvils crush the cylinder, preventing the sample from ‘blowing out’, while applying pressure to the confined sample. Many dual-piston, tetrahedral and cubic cells elaborate on one or both of these concepts of compressing a sample within a confined, sealed volume.

All static studies at pressures beyond 25 GPa are done with diamond-anvil cells conceived independently by Jamieson [32] and by Weir *et al* [33]. In these variants of Bridgman’s design, the anvils are single-crystal gem-quality diamonds, the hardest known material, truncated with small flat faces (culets) usually less than 0.5 mm in diameter. Diamond anvils with 50 μm diameter or smaller culets can generate pressures to about 500 GPa, the highest static laboratory pressures equivalent to the pressure at the centre of the Earth.

Dynamic experiments with conventional (chemical) explosives or projectiles accelerated in gas guns have achieved 1 TPa in favourable cases. Laser-driven shocks have produced higher shock pressures [34], and measurements to 75 TPa have been reported for shock waves generated during underground tests of nuclear explosives (for a recent discussion see [35]). Sample volumes in static experiments range from litres at pressures up to 10 GPa to 0.1 nl at 500 GPa. Samples for commercial dynamic high-pressure production of diamond powder was done on the 100 kl scale. Most samples for shock wave studies are smaller; laser-driven shock wave experiments often use microlitre samples.

In static experiments, the temperatures of samples can be controlled from less than 1 to more than 5000 K and can be measured with reasonable accuracy. For low temperatures, entire pressure vessels are thermostatted by mounting them in cryostats or surrounding them with heaters or furnaces. With these techniques, the temperatures are uniform throughout the sample. The strengths of the materials used to construct the vessel, however, limit the temperatures and pressures that can be achieved by such external heating methods. For higher temperatures, internal heating is used: that is, the sample is heated while the confining pressure vessel is kept at a lower temperature to maintain its mechanical strength. This can be done by surrounding the sample with heating elements mounted inside the pressure vessel around the sample or by irradiating the sample with an intense infrared or visible laser. Internal-heating methods may involve very large temperature gradients, up to 10^8 K m^{-1} ($100 \text{ K } \mu\text{m}^{-1}$), and challenge thermometry. The irreversible nature of the work done when shock waves compress a sample necessarily increases the sample’s temperature; however, the temperature of the shocked state is often impossible to characterize. Indeed, measuring temperatures achieved during dynamic experiments is one of the biggest unsolved problems of high-pressure research.

B1.29.5 HOW ARE HIGH PRESSURES MEASURED?

Absolute pressure measurements by dead-weight piston–cylinder methods have been made only to 2.5 GPa, although Getting recently developed a cell which may extend absolute measurements to 5 GPa [27]. Pressures achieved during shock experiments are computed with the Rankine–Hugoniot equations which assume that the shocked, high-temperature state is one of thermodynamic equilibrium and mass, momentum, and energy are conserved [35]. Several procedures have been developed to relate densities and other properties of states achieved during shock experiments to values of the same properties on ambient or zero-Kelvin isotherms. Pressures in static experiments above 2.5 GPa are often determined by measuring the density of a convenient material like NaCl or Au confined with the sample being studied by x-ray diffraction or by a secondary probe that has been calibrated in terms of x-ray densities. Typical secondary probes include luminescence spectra of ruby (dilute Cr^{3+} in Al_2O_3) [36] or Sm:YAG [37] or Raman spectra of nitrogen [38] or diamond [39]. In each secondary probe, a spectral feature—a narrow emission line or vibrational band—whose energy can be measured precisely changes energy with pressure in an established, ideally simple manner.

B1.29.6 HIGH-PRESSURE FORMS OF FAMILIAR OR USEFUL MATERIALS: DIAMOND, FLUID METALLIC HYDROGEN, METALLIC OXYGEN, IONIC CARBON DIOXIDE, GALLIUM NITRIDE

The most important commercial products of high-pressure science are the extremely hard materials, synthetic diamond [40, 41 and 42] and (c-BN) [43]. At ambient pressure, diamond is less stable than the less dense allotrope, graphite. c-BN also may be less stable than the less dense h-BN isomer with its graphitic structure of rings of alternating B and N atoms. Diamond and c-BN with four equivalent sp^3 bonds per atom are denser than graphite and h-BN with three sp^2 bonds, each shorter than an sp^3 bond and one very long intermolecular van der Waals bond per atom. The volume change, ΔV , for the transformations from graphite to diamond is negative. Thus, the $\Delta(PV) = P\Delta V$ contribution to the change of enthalpy or Gibbs' free energy is negative and becomes even more negative at higher pressures, so the denser forms of each material become more stable at higher pressures. Rearranging the bonds around each atom involves high-energy barriers that separate the low and high density forms (for a historical review of these processes see [44]). Although Yagi and Utsumi [45] showed that the graphite converted to the hexagonal form of diamond at

ambient temperature above 10 GPa, complete conversion and recovery to ambient pressure was not possible unless the product was heated under pressure to more than 1100 K. That is, high temperatures and high pressures are used to overcome the thermodynamic and kinetic barriers to making the desirable dense hard materials that can be recovered metastably. The high barrier also impedes reversion of the recovered diamond and c-BN to the stable graphitic forms at low temperatures. Besides the high-pressure route, diamond can be synthesized at low pressures, even less than 0.1 MPa, by kinetically controlled gas–surface reactions.

Large quantities of both diamond and c-BN are produced by static or shock methods for industrial cutting applications. Most of the synthetic material is finely powdered and can be bound or compacted to make tools. Manufacturing costs for large crystals are too high for the commercial gem market; however, large diamonds of exceptionally high quality are made for special applications: e.g. x-ray monochromators for high-intensity synchrotrons. For cutting steels, c-BN is particularly valuable, because diamond tools tend to react with the steel, forming iron carbide.

Metallic hydrogen has been a holy grail of high-pressure research since Wigner and Huntington suggested that

it might be stable above about 10 GPa [46]. Many claims to the contrary notwithstanding, metallic solid hydrogen has not been found at ambient temperatures to 342 GPa [47]. Weir *et al*, however, found that fluid hydrogen becomes highly conductive under shock compression at lower pressures, 140 GPa, and higher temperatures [11]. The fact that homonuclear diatomic molecular fluids become conductive at lower pressures—and necessarily higher temperatures—than solid phases of the same systems is evident in nitrogen and iodine, and may be a general phenomenon. Further careful experiments must be done to confirm this conjecture. Detailed studies of the conductivities of supercritical Cs and Hg show that the transition from low to high electrical conductivity has neither the characteristics of a thermodynamic phase transition nor a general relationship to the vapour–liquid critical point [48, 49, 50 and 51].

Oxygen is the low-*Z* diatomic which is known to transform to a metal and, at about 1 K, a superconductor at high pressures. The transition pressure is slightly greater than 100 GPa [7]. The conductive phase consists of O₂ molecules; that is, it is not an atomic phase. Optical, infrared and visual spectral, and x-ray diffraction data show that the relevant ϵ phase of oxygen is very anisotropic, and it is reasonable to conjecture that the electrical conductivity also depends upon crystallographic orientation. The other group VI elements also have metallic, superconductive phases at high pressures and low temperatures.

Recent work on the carbon dioxide system shows another unusual high-pressure behaviour. Raman spectra of carbon dioxide show that CO₂ molecules remain the basis of the phases to more than 40 GPa at temperatures below a few hundred Kelvin [52]. These results, however, do not mean that the molecular crystals are the stable phases; indeed, recent studies of the combustion of carbon at high pressures by Yoo *et al* [53] reach another conclusion. They initiated combustion of a mixture of carbon and oxygen at pressures between 7 and 13 GPa by heating the carbon with a Nd:YAG laser, quenching the products to ambient temperature under pressure and recording their Raman spectra. As well as features of unreacted O₂ and CO₂ in some samples, they found vibron bands characteristic of the carbonate ion near 734 and 1079 cm⁻¹, a band assigned to CO⁺⁺ near 2243 cm⁻¹, and several lattice modes between 100 and 350 cm⁻¹. These features, including the shape of the lattice-mode spectrum, closely match the spectra of ϵ , the ionic dimer of NO₂, reported by Agnew *et al* [54], apart from minor shifts because of different pressures, force constants and reduced masses. At higher pressures, heating carbon to ignition was more difficult because diamond formed, which greatly reduced the absorption of the Nd:YAG radiation. The could not be quenched to ambient pressure at ambient temperature; it transformed to CO₂ below 2 GPa. When the was compressed above 15 GPa at ambient temperature, the sharp band near 1100 cm⁻¹ either disappeared or broadened

-7-

above. This change was reversible with pressure and was attributed to either amorphization of CO⁺⁺CO₃⁻ or transitions to larger multimers.

An ionic dimer of carbon dioxide has a critical implication for understanding detonation chemistry of energetic organic molecules. This dimerization provides a reasonable explanation for the kink in shock compression Hugoniot of CO₂ [55], which, if correct, implies that the dimer forms on the time scale of shock loading and detonation. Because water and some nitrogen oxides also become more ionic at these high pressures, interactions and chemical reactivities of these ionic H–C–N–O species will differ from those of the neutral species assumed, in most models, to be the major detonation products over a wide range of high pressures and temperatures [56]. Furthermore, because ionic species are implicated in planetary ‘ices’ like H₂O, CH₄ and NH₃ [57, 58, 59 and 60], the ionic dimer should have some bearing in understanding the internal structure and magnetism of the Jovian planets [61].

Interest in AlN, GaN, InN and their alloys for device applications as blue light-emitting diodes and blue lasers has recently opened up new areas of high-pressure synthesis. Near atmospheric pressure, GaN and InN are unstable with respect to decomposition to the elements far below the temperatures where they might melt. Thus, large boules of these materials typically used to make semiconductor devices cannot be grown from the

melt or annealed at temperatures approaching their melting points. Devices have been grown by heteroepitaxial methods, depositing GaN on Al₂O₃ or SiC substrates, although high defect concentrations because of mismatched lattice constants and thermal expansivities are a serious problem. Grzegory *et al* [62] showed how to overcome this limitation for GaN by growing large crystals from N₂ dissolved in liquid Ga at pressures up to 2 GPa. AlN but not InN also have been grown this way [63]. These relatively slow processes produce excellent materials.

Wallace *et al* explored another approach, metathesis reactions. By igniting a mixture of GaI₃ and Li₃N confined at pressures of the order of 4 GPa, they produced fine-crystalline GaN [63]. The thermodynamic driving force for the process is the very negative enthalpy of forming LiI. With appropriate mixtures and pressures, they produced CrN, Cr₂N, TaN and other nitrides by this metathesis route. The metathesis method, like the direct reactions between elements that Yoo *et al* used to make c-BN, β-Si₃N₄, B₂O₃ and other materials [64, 65], yields more crystalline products at higher confining pressure. Recently, Wallace [66] devised combinations of reagents, chemical diluents and confinement so that GaN and InN crystals of similar quality can be made at as low as ambient pressure.

B1.29.7 SPECTROSCOPY AT HIGH PRESSURES

Almost every modern spectroscopic approach can be used to study matter at high pressures. Early experiments include NMR [67], ESR [68]; vibrational infrared [33] and Raman [69]; electronic absorption, reflection and emission [23, 24 and 25, 70]; x-ray absorption [71] and scattering [72], Mössbauer [73] and gc-ms analysis of products recovered from high-pressure photochemical reactions [74]. The literature contains too many studies to do justice to these fields by describing particular examples in detail, and only some general rules, appropriate to many situations, are given.

The frequencies of vibrational modes usually increase with increasing pressure because the corresponding potential wells become narrower and the force constants increase. In wavenumber terms, these increases range up to the order of 10 cm⁻¹ GPa⁻¹. A notable exception is the stretching mode of an O-H...O hydrogen bond. Other instances of modes whose frequencies decrease with increasing pressure suggest molecular or lattice instabilities that lead to phase transitions at higher pressures. Usually, the transition occurs before the frequency of the mode reaches zero.

-8-

Most electronic valence transitions shift to longer wavelengths at higher pressures: that is, the gap between the highest occupied orbital and lowest unoccupied orbital tends to decrease upon compression. The rates of shift usually are larger (1) for pure materials than for solutes in a solvent and (2) for stronger (more allowed) transitions. However, these correlations are not quantitative, and many transitions shift in the opposite direction. The largest shifts are of the magnitude 0.1 eV GPa⁻¹. Many d-d bands of transition element compounds vary linearly with the fifth power of the metal-ligand distance.

New methods appear regularly. The principal challenges to the ingenuity of the spectroscopist are availability of appropriate radiation sources, absorption or distortion of the radiation by the windows and other components of the high-pressure cells, and small samples. Lasers and synchrotron radiation sources are especially valuable, and use of beryllium gaskets for diamond-anvil cells will open new applications. Impulse-stimulated Brillouin [75], coherent anti-Stokes Raman [76, 77], picosecond kinetics of shocked materials [78], visible circular and x-ray magnetic circular dichroism [79, 80] and x-ray emission [72] are but a few recent spectroscopic developments in static and dynamic high-pressure research.

An especially interesting recent example is Benedetti *et al*'s use of circular dichroism (CD) spectroscopy to detect a pressure-induced change of the configuration at the metal centre of the octahedral chiral Δ- and Λ-tris

[cyclo O,O' 1(R),2(R)-dimethylethylene dithosphato] chromium(III) [79]. The pressure medium was Nujol[®]. To measure the CD spectrum, they had to overcome the birefringence of the strained diamond windows of the high-pressure cell. They did this by recording and averaging spectra of the sample—and of a blank cell filled with Nujol[®]—for each of four 90° rotations of the cell around the axis normal to the windows. The measurements for the blank showed that the baseline obtained by this averaging procedure was close to ideal, although a small further correction was required.

FURTHER READING

This brief essay could neither deal with all fields of high-pressure science nor any one field in depth. The literature of articles, reviews, books, and conference proceedings for this field is extensive and only a few are cited in the references. Here, we suggest a few books and conference proceedings for the reader interested in exploring the field further. This somewhat arbitrary selection is the author's; it emphasizes recent books and a few classic works.

B 2.1 Ultrafast spectroscopy

Warren F Beck

B2.1.1 INTRODUCTION

The development of the millisecond and microsecond flash photolysis experiments by George Porter and co-workers [1, 2] in the 1950s marks the true birth of time-resolved spectroscopy. Porter's work, which provided for the first time a way to capture the absorption spectrum of a short-lived kinetic intermediate in a photochemical reaction, helped to start a new era in physical chemistry, one that was focused on the mechanism and dynamics of chemical reactions. Owing to the subsequent development of mode-locked laser sources, beginning with the picosecond ruby and neodymium–glass lasers in the 1960s, the sub-picosecond passively mode-locked dye laser in the late 1970s and, most recently, the femtosecond self-mode-locked Ti–sapphire laser in the early part of this decade, the time resolution for spectroscopic measurements has advanced three orders of magnitude, from the 10 ps to the 10 fs regime [3]. It is now possible to conduct a wide variety of spectroscopies with ultrashort laser pulses of photons selectable over the entire spectral range from the x-ray region [4, 5] to the terahertz or far-infrared (IR) region [6, 7, 8, 9 and 10]. A variety of robust methods have been developed to probe the time evolution of populations and coherences. The shortest time scale that is now routinely accessible is comparable to or shorter than the period of molecular vibrations, the fundamental time scale of chemistry.

This chapter focuses on the primary experimental methods of ultrafast spectroscopy, as discussed in terms of studies on intramolecular dynamics in the condensed phase or in proteins. Ultrafast spectroscopy generally denotes spectroscopy that exploits the time resolution obtainable with mode-locked laser sources. The ultrafast regime encompasses electronic and vibrational energy transfer, charge transfer and structural dynamics involving isomerization and the breaking of bonds. In many cases, these processes can be optically triggered so that the time course can be studied with a delayed probing or gating pulse. The initial and delayed pulses are derived from a pulse train emitted by a single mode-locked light source; the ultrashort timing of the experiment is usually derived from the distance of flight of the optical pulses using a technique that is reminiscent of interferometry. After a discussion of the current ideas in producing and characterizing tunable ultrashort optical pulses for spectroscopy, the chapter discusses methods for time-resolved fluorescence spectroscopy, pump–probe methods for time-resolved absorption spectroscopy and multipulse photon-echo techniques for the measurement of coherence. The chapter closes with a brief discussion of the use of phase-controlled, multiple-pulse sequences for advanced, highly selective spectroscopies and for the control of chemical dynamics.

B2.1.2 FEMTOSECOND LIGHT SOURCES

The development of ultrafast spectroscopy has paralleled progress in the technical aspects of pulse formation [11]. Because mode-locked laser sources are tunable only with difficulty, until recently the most heavily studied physical and chemical systems were those that had strong electronic absorption spectra in the neighbourhood of conveniently produced wavelengths.

As one important example, the introduction of the prism-controlled, colliding-pulse, mode-locked (CPM) dye laser [12, 13] led almost immediately to developments in measurement technique with pulses of less than 100

fs duration; Shank and co-workers used an amplified CPM laser [14] in their work with 6 fs pulses in 1987 [15]. Until recently, the pulses used in those experiments were the shortest optical pulses characterized. The transition-state spectroscopy of Zewail and Bernstein [16, 17, 18, 19, 20, 21 and 22] exploited an amplified CPM laser after frequency doubling and/or continuum generation. The chemical systems that were most easily studied, however, were those that could be stimulated either by the 620 nm output of the CPM directly or after frequency doubling to 310 nm. In addition, the CPM laser and its contemporary, more tunable alternative, the pulse-compressed, synchronously pumped dye laser [11], were tools that could be effectively used only by researchers with extensive backgrounds in lasers and optics.

These limitations have recently been eliminated using *solid-state* sources of femtosecond pulses. Most of the femtosecond dye laser technology that was in wide use in the late 1980s [11] has been rendered obsolete by three technical developments: the self-mode-locked Ti-sapphire oscillator [23, 24, 25, 26 and 27], the chirped-pulse, solid-state amplifier (CPA) [28, 29, 30 and 31], and the non-collinearly pumped optical parametric amplifier (OPA) [32, 33 and 34]. Moreover, although a number of investigators still construct home-built systems with narrowly chosen capabilities, it is now possible to obtain versatile, nearly state-of-the-art apparatus of the type described below from commercial sources. Just as home-built NMR spectrometers capable of multidimensional or solid-state spectroscopies were still being home built in the late 1970s and now are almost exclusively based on commercially prepared apparatus, it is reasonable to expect that ultrafast spectroscopy in the next decade will be conducted almost exclusively with apparatus from commercial sources based around entirely solid-state systems.

Figure B2.1.1 depicts an instrument that takes advantage of many of the most recent technical developments. The best strategy for generating wavelength-tunable ultrashort laser pulses for time-resolved spectroscopy involves use of an OPA as the only wavelength-tunable element. This approach is organized around the principle that extremely stable, fixed wavelength, high-energy pulse trains can now be generated using an amplified Ti-sapphire-based system. The chief advantage of instruments like the one shown in figure B2.1.1 is that experimental demands for specific operating wavelengths are met by adjustment of the *last* device in the pulse-forming chain, the OPA. One can expect such a design to be considerably more robust and user-friendly than systems based on wavelength tunable oscillators, which demand manipulation of *every* device in the instrument in response to tuning to a new wavelength.

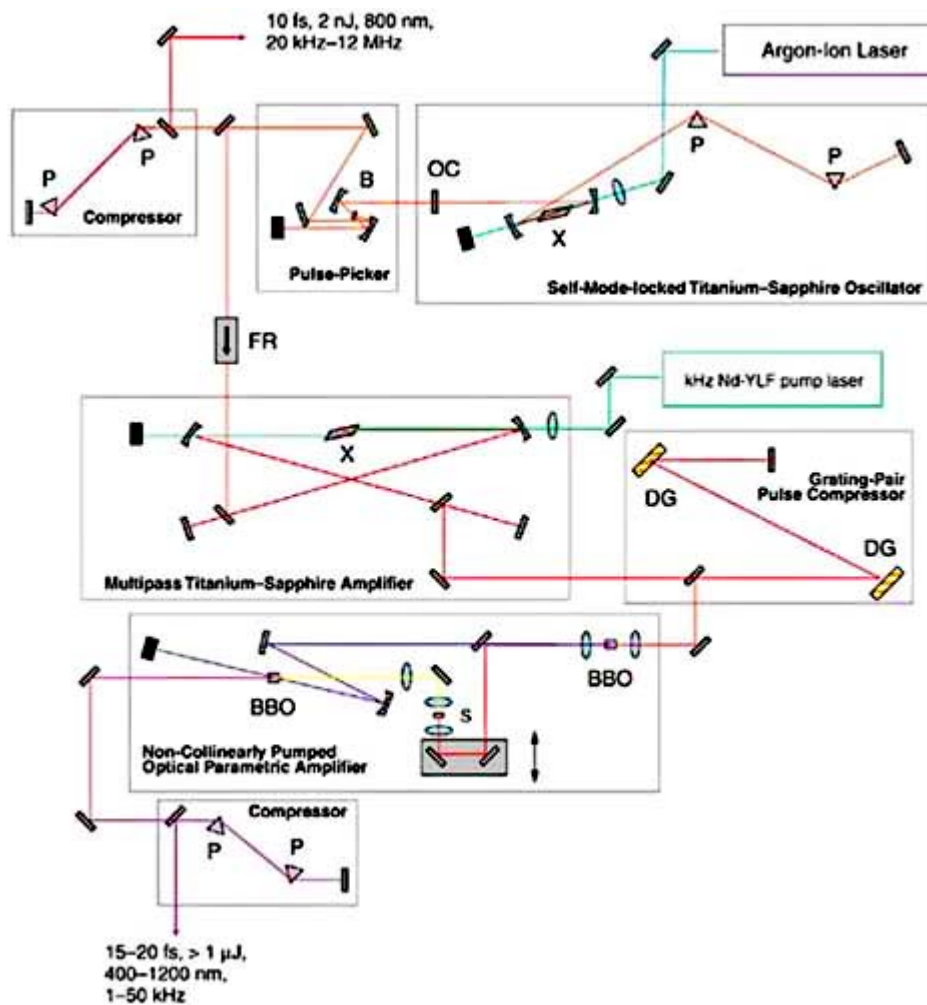

Figure B2.1.1 Femtosecond light source based on an amplified titanium–sapphire laser and an optical parametric amplifier. Symbols used: P, Brewster dispersing prism; X, titanium–sapphire crystal; OC, output coupler; B, acousto-optic pulse selector (Bragg cell); FR, Faraday rotator and polarizer assembly; DG, diffraction grating; BBO, β -barium borate nonlinear crystal.

B2.1.2.1 OSCILLATORS

The most commonly used femtosecond oscillator at this point is the self-mode-locked Ti–sapphire laser [23, 24, 25, 26 and 27], shown in figure B2.1.1 which can *routinely* produce pulses of light with durations adjustable over the 10–150 fs range. The wavelength of the Ti–sapphire oscillator can be tuned over the 700–1100 nm range using an intracavity slit or birefringent filter, providing pulse durations that are essentially limited by the bandwidth of the filtering element. (It should be emphasized, however, that tuning an oscillator of this type is not as routinely done as is tuning an OPA.) The pulse energy that can be directly obtained from the oscillator is typically limited to the 2 nJ/pulse regime, but the oscillator emits pulses at a high repetition rate, typically 75–100 MHz, depending on the cavity dimensions.

The Ti–sapphire oscillator is extremely useful as a stand-alone source of femtosecond pulses in the near-IR region of the spectrum. Some ultrafast experiments, especially of the pump–probe variety (see below), can be conducted with pulses obtained directly from the oscillator or after pulse selection at a lower repetition rate. Far-IR (terahertz) radiation is usually generated using a semiconductor (usually GaAs) substrate and focused Ti–sapphire oscillator pulses [7]. If somewhat higher-energy pulses are required for an experiment, the Ti–sapphire oscillator can be *cavity dumped* by an intracavity acousto-optical device known as a *Bragg cell*,

producing perhaps 50 nJ pulses but at a reduced repetition rate, typically between 200 kHz and 1 MHz [35]. The energy available from a cavity-dumped Ti-sapphire laser is intense enough to generate a continuum-like source in a single-mode optical fibre. Wiersma and co-workers [36] generated 5 fs pulses by compressing these continuum pulses with a sequence of gratings and prisms. Comparable oscillators have been described that exploit other types of solid-state gain media. Although Ti-sapphire crystals are widely used because the absorption spectrum overlaps favourably with the output spectra of argon-ion and frequency-doubled Nd:YVO₄ continuous-wave lasers, Cr-LISAF may be favoured in the future as a gain medium for femtosecond oscillators because it can be pumped by continuous-wave GaAs diode lasers [37, 38].

B2.1.2.2 AMPLIFICATION

Although many useful femtosecond spectroscopic experiments on condensed-phase targets can be easily performed with low-energy pulses, in the 100 pJ to 1 nJ regime, higher-energy pulses are required if wavelength tunability is desired. A femtosecond continuum [39] can be generated in water or sapphire if the pulse energy is higher than 200 nJ; OPA sources require even higher energies, in excess of 1 μJ/pulse. Amplification of Ti-sapphire oscillators is at this point routinely performed, with excellent commercial systems readily available of the regenerative amplifier type [28, 30, 31, 40, 41], and there are simple multipass amplifier designs [42, 43] that are easily constructed in the laboratory.

Pulses are selected for amplification from the oscillator's 75–100 MHz pulse train at a much lower repetition rate, ranging in published designs from 10 Hz to 250 kHz, either by a Pockels cell or a Bragg cell (as shown in [figure B2.1.1](#)). The selected pulse train is amplified in Ti-sapphire gain media using a method known as *chirped-pulse amplification* [28, 29, 30 and 31]. In this scheme, oscillator pulses are stretched temporally well into the picosecond regime prior to amplification so that the damage threshold for the gain crystal is not exceeded [44]. If the amplifier is designed to operate in the >10kHz regime, like the one depicted in [figure B2.1.1](#) a stretcher may not be required. A grating-pair pulse compressor [45] is used to compress the pulse back nearly to its original duration after it emerges from the amplifier. Regenerative amplifiers capable of producing 75–150 fs pulses are the most common systems in use [30, 40], but recently a multipass ring amplifier has been described that produces 20 fs pulses [43]. The multipass amplifier depicted in [figure B2.1.1](#) is a non-ring design that permits a more facile input and extraction of the amplified pulse.

The most common commercially prepared amplifier systems are pumped by frequency-doubled Nd:YAG or Nd:YLF lasers at a 1–5 kHz repetition rate; a continuously pumped amplifier that operates typically in the 250 kHz regime has been described and implemented commercially [40]. The average power of all of the commonly used types of Ti-sapphire amplifier systems approaches 1 W, so the energy per pulse required for an experiment effectively determines the repetition rate.

B2.1.2.3 OPTICAL PARAMETRIC AMPLIFICATION

Perhaps the ultimate femtosecond light source, the OPA exploits a nonlinear parametric process to amplify a portion of

a femtosecond continuum [32, 33 and 34, 46, 47 and 48]. In most designs, a portion of the output of a regenerative or multipass Ti-sapphire amplifier is frequency doubled in a nonlinear crystal to prepare an intense *pump* pulse. Less than 1 μJ/pulse of the amplifier's output is reserved to seed a single-filament continuum [47] in a thin sapphire crystal. A second nonlinear crystal is used as the gain medium for the parametric process, which splits an input pump photon at frequency ω_3 into two output photons, a signal photon at frequency ω_1 and an idler photon at frequency ω_2 , with energy conserved ($\omega_3 = \omega_1 + \omega_2$). The parametric process is greatly enhanced by the presence of *seed* light at either ω_1 or ω_2 , which is supplied by the continuum [46]. The apparatus can be adjusted to select a certain range of frequencies from the continuum

for amplification in the nonlinear crystal, allowing the production of wavelength-tunable output pulses derived either from the signal or idler with adjustable pulse durations. At this point, β -barium borate (BBO) is the material of choice for the nonlinear crystal.

The OPA should not be confused with an optical parametric oscillator (OPO), a resonant-cavity parametric device that is synchronously pumped by a femtosecond, mode-locked oscillator. 14 fs pulses, tunable over much of the visible regime, have been obtained by Hache and co-workers [49, 50] with a BBO OPO pumped by a self-mode-locked Ti-sapphire oscillator.

Shortly after the development of high-energy/pulse Ti-sapphire regenerative amplifier systems, a number of investigators reported progress in using OPAs in producing tunable sources of very short pulses. Wilson and co-workers [46] showed early on that an *experimentally* useful source for femtosecond spectroscopy with <50 fs pulses was obtained through the use of continuum seeding of a type I nonlinear OPA crystal, which was pumped by the *fundamental* output of an amplified Ti-sapphire laser. The main problem with the early systems was inherent to the physics of *collinearly pumped* parametric amplification: the signal, idler and pump frequencies have different group velocities (see below) in the nonlinear crystal, which limits the amount and frequency bandwidth of the parametric gain. In other language, the phase-matching condition for the collinearly pumped OPA works only over a small bandwidth, which tends to limit the pulse duration to fairly long (100 fs) pulses, and tuning of the OPA to different signal wavelengths requires reoptimization of the crystal's orientation. The design advanced by Wilson's group takes advantage of the smaller mismatch in group velocities in the near-IR part of the spectrum; other designs employing pumping with the second harmonic of the Ti-sapphire laser provide direct access to visible signal pulses but with significantly longer durations (150 fs) [48].

Very recently, Hache and co-workers [49] found that a *non-collinear* pumping of an OPO crystal produces a phase-matching condition that is *independent of signal wavelength* over a very broad bandwidth. This discovery makes it possible to obtain very high parametric gain in an OPA with a single pass through the crystal and adjustable signal bandwidths. The result is a source of light with wide tunability and adjustable pulse durations, the ultimate femtosecond light source. The design for the OPA depicted in [figure B2.1.1](#) is an adaptation of that recently described by Riedle and co-workers [32]. 400 nm light obtained by frequency doubling the output of a regenerative Ti-sapphire amplifier is overlapped at an angle of 3.7° with the femtosecond continuum light. This angle produces in BBO the wavelength-independent phase-matching condition noted by Hache and co-workers. Riedle and co-workers demonstrated that signal pulses of 15–20 fs duration could be obtained from this system, with tunability over most of the 400–800 nm visible range. Using a similar approach, but with some changes in the details of producing the continuum seed light that were intended to produce as broad a signal bandwidth as possible, De Silvestri and co-workers [34] subsequently showed that signal pulses as short as 7.2 fs in the visible regime could be produced. In contemporaneous work, Kobayashi and co-workers [33] obtained sub-10 fs pulses from the visible signal *and* near-IR idler from a comparable apparatus. These latter two results have nearly matched the legendary performance of the pulse-compressed CPM dye laser of Shank and co-workers [15].

A surprising aspect of the recent work on non-collinearly pumped OPA systems is that it appears that fairly long pump pulses, in the 150 fs regime, are to be preferred over shorter pulses if sub-10 fs signal pulses are desired. Mature commercial regenerative amplifier designs operating over the 1–250 kHz repetition-rate range are already capable of producing these pulses. Thus, the experimental motivation for developing amplifier systems capable of producing very short pulses *directly* has vanished for *spectroscopic* applications; however, there are a number of important applications for short, high-energy pulses, such as driving the formation of femtosecond pulses of x-rays [5]. High-energy physics applications for short, amplified pulses have been reviewed recently by Mourou and co-workers [51].

B2.1.2.4 PULSE COMPRESSION

Owing to its wide spectral bandwidth, a short optical pulse is distorted temporally by passing through the beamsplitters, lenses, filters, etc, that are required for an ultrafast spectroscopic experiment. The distortion arises from the dispersion of the speed of light in a medium as a function of wavelength, or group-velocity dispersion (GVD). The sweep of frequencies observed at a given spatial position is known as chirp (in analogy to the sound of a frequency-swept audio pulse) or group-delay dispersion (GDD). This phenomenon is usually described in terms of a Taylor series expansion of the phase ϕ of the optical pulse around the centre frequency, ω_0 [11, 52]. The first derivative term represents the group delay, $t(\omega) = d\phi/d\omega$. The quadratic term, corresponding to the *linear* sweep in the group delay with respect to wavelength, can be corrected by an optical delay line with *negative* GDD (alternatively speaking, *anomalous dispersion*) [53], constructed from a pair of diffraction gratings [45], a pair of dispersing prisms with Brewster angled surfaces [54] or, less often, by a Gires–Tournois interferometer (GTI) [55, 56]. The amount of negative GDD is determined by the distance of separation between the two prisms or gratings or between the two reflective films in the interferometer.

In most femtosecond experiments, a double-passed pair of prisms is inserted into the beam prior to its reaching the measurement apparatus. In [figure B2.1.1](#) a pair of prisms is depicted after the OPA and after the pulse-picker (for use in oscillator-only experiments). This practice allows one to *precompensate* for the GDD imparted to the beam by the optics in the measurement apparatus so that the pulses are as short as possible when they arrive at the sample's position. The prisms are typically manipulated by translating one or both of the prisms normal to the base so as to increase or decrease the amount of prism glass traversed; this permits a small amount of positive GDD to be added or subtracted. The pulse duration at the sample's position is usually determined with an intensity autocorrelation measurement, performed by replacing the sample with a nonlinear crystal, such as potassium dihydrogen phosphate (KDP) or BBO. An even more significant problem associated with GDD is that the formation of a short pulse in an oscillator requires many round-trips through the gain medium, so it is routine to place a pair of prisms or a GTI in the oscillator's cavity to repair the damage suffered by the pulse on each trip. The design of Murnane and co-workers [25] depicted for the oscillator in [figure B2.1.1](#) exemplifies this practice, which was first established in the final design for the CPM dye laser by Valdmanis and Fork [13]. In the future, oscillators may not require prism pairs; it is now possible to fabricate *chirped mirrors* that employ multiple layers of dielectric coatings to provide for a precise compensation of quadratic and cubic phase distortions that arise from the gain medium of a femtosecond oscillator [26]. In fact, a commercial design employing a chirped-mirror, Ti-sapphire oscillator and a solid-state continuous-wave Nd-YVO₄ pump laser in a single, compact, sealed (no user controls!) enclosure has just become available. Such a source would be expected to be unusually robust.

The shortest optical pulses actually used so far (1998) in ultrafast spectroscopic experiments were obtained by Shank and co-workers from an amplified CPM laser [57]. In these extraordinary experiments, a sequence of a pair of prisms

and a pair of gratings was employed. The reason for this additional complexity was that the cubic-term phase distortion imparted by the prism pair is of opposite sign of that imparted by the grating pair. As a result, it was possible to null simultaneously the quadratic and cubic dispersion terms at the position of the sample [15]. Most optical materials exhibit *normal* dispersion; the index of refraction increases monotonically with respect to frequency. Some materials, however, exhibit an anomalous dispersion regime in the near-IR part of the spectrum. Hochstrasser and co-workers exploited the finding that the mid-IR substrates CaF₂ and BaF₂, used, for instance, for beamsplitters and windows, imparts GDD to a transmitted beam that is of the opposite sign of that imparted by Ge, which was used as a long-pass filter [58]. Fused silica optical fibres exhibit anomalous dispersion at wavelengths above 1.3 μm [59, 60]. The implication of this phenomenon is that positively chirped IR pulses can be compressed by being propagated in a fibre. Further, short IR pulses can be propagated in a fibre for arbitrarily long distances without suffering a change in pulse duration [61, 62].

B2.1.3 FEMTOSECOND TIME-RESOLVED SPECTROSCOPY

In lieu of electronic timing mechanisms, a form of interferometry is usually employed in ultrafast spectroscopy to obtain time resolution on the picosecond or shorter time scales. The simplest ultrafast measurement apparatus is that shown in figure B2.1.2 an *autocorrelator*. This instrument is used in various forms to measure the duration of an ultrashort laser pulse [63]. A pulse of light is first split into equal portions by a beamsplitter; the two parts are then recombined after they travel in the two arms of an interferometer (here, derived from the Michelson design) so that they are focused onto a thin (100 μm or less in thickness) nonlinear crystal. When the two pulses overlap *temporally and spatially*, the second harmonic is emitted along the direction that conserves momentum, between the direction of the two emerging fundamental pulses [64]. By moving one of the retroreflectors in the interferometer along the beam path towards or away from the beamsplitter, one of the pulses is made to scan *temporally* through the other pulse in the nonlinear crystal. Thus, the ultrafast timing of the experiment is provided by a simple measurement of displacement and knowledge of the speed of light. Reproducible displacements of the order of 1 μm , corresponding to a time-of-flight displacement of 6.67 fs in the interferometer, are routinely performed with computer-controlled linear actuators.

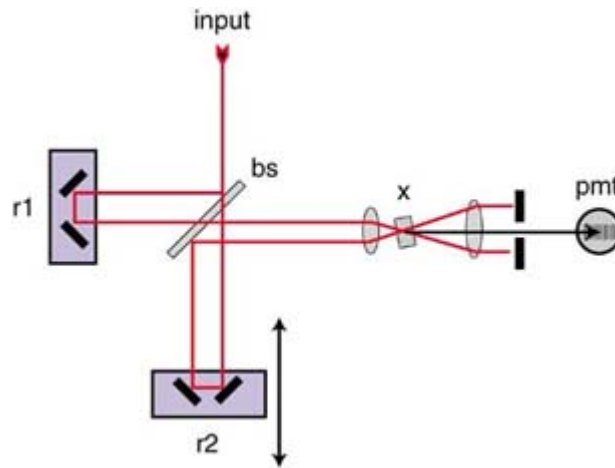

Figure B2.1.2 Modified Michelson interferometer for non-collinear intensity autocorrelation. Symbols used: r1, r2, retroreflecting mirror pair mounted on a translation stage; bs, beamsplitter; x, nonlinear crystal; pmt, photomultiplier tube.

The intensity of this *upconverted* light detected by a photodetector is described by the equation $I(\tau) = \int_{-\infty}^{+\infty} I(t - \tau)I(t) dt$, where $I(t)$ is the intensity of the pulse as a function of time t at a given point in the nonlinear crystal, and τ is the shift in time of the variably delayed or *gating* pulse, as controlled by one of the retroreflectors in the interferometer. The photodetector integrates the upconverted intensity for a given delay τ ; an example of the signal obtained by scanning τ is shown in figure B2.1.3(a) with the input pulse train provided by a self-mode-locked Ti-sapphire laser. The symmetrical shape of the autocorrelation trace arises from the convolution of the input $I(t)$ pulse shapes. The true shape of $I(t)$ and the dependence of the phase on wavelength can be obtained in a slightly more elaborate experiment called frequency-resolved optical gating (FROG) [65, 66, 67 and 68], a form of which can be performed by recording the autocorrelation traces as a function of wavelength by dispersing the upconverted light in a spectrometer placed before the photodetector [69].

Figure B2.1.3 Output of a self-mode-locked titanium–sapphire oscillator: (a) non-collinear intensity autocorrelation signal, obtained with a 100 μm β -barium borate nonlinear crystal; (b) intensity spectrum.

The spectrum of the femtosecond pulse provides some information on whether the input pulse is chirped, however, causing the temporal width of $I(t)$ to be broader than expected from the Heisenberg indeterminacy relationship.

-9-

The full width at half maximum of the autocorrelation signal, 21 fs, corresponds to a pulse width of 13.5 fs if a sech^2 shape for the $I(t)$ function is assumed. The corresponding output spectrum shown in [figure B2.1.3\(b\)](#) exhibits a width at half maximum of approximately 700 cm^{-1} . The time–bandwidth product $\Delta \tau \Delta \nu$ is close to 0.3. This result implies that the pulse was compressed nearly to the Heisenberg indeterminacy (or Fourier transform) limit [53] by the double-passed prism pair placed in the beam path prior to the autocorrelator.

The intensity autocorrelation measurement is comparable to all of the *spectroscopic* experiments discussed in the sections that follow because it exploits the use of a variably delayed, *gating* pulse in the measurement. In the autocorrelation experiment, the gating pulse is just a replica of the time-fixed pulse. In the spectroscopic experiments, the gating pulse is used to interrogate the populations and coherences established by the time-fixed pulse.

B2.1.3.1 FLUORESCENCE UPCONVERSION SPECTROSCOPY

Time-resolved fluorescence is perhaps the most direct experiment in the ultrafast spectroscopist’s palette. Because only one laser pulse interacts with the sample, the method is essentially free of the problems with field-matter time orderings that arise in all of the subsequently discussed multipulse methods. The signal

detected is usually directly proportional to the population in the resonantly prepared excited state alone. In systems that exhibit photochemistry, for instance, the time evolution of the fluorescence provides a direct view of the decay of the photochemically active state.

Fluorescence spectroscopy can be performed in the ultrafast regime with a nonlinear crystal and a short gating pulse in an experiment known as *fluorescence upconversion* [70, 71]. The interferometer shown in [figure B2.1.2](#) is modified so that an incident pulse is split into two pulses: a weaker pulse that is used to excite a sample and a stronger, gating pulse that is overlapped spatially in a nonlinear crystal with the fluorescence that is collected from the sample. Sum-frequency generation in the nonlinear crystal produces output photons with frequency ω_3 from the input gate photons of frequency ω_1 and fluorescence photons of frequency ω_2 ; since $\omega_3 = \omega_1 + \omega_2$, the output photons are *upconverted*, or transferred to a higher frequency by the gate pulse. The intensity of the beam of output photons is proportional to the product of the intensity of the gating and fluorescence photons; the gate photons slice out only those fluorescence photons that are temporally overlapped with the short gating pulse in the nonlinear crystal. This permits the time course of the fluorescence intensity at a particular frequency ω_2 to be mapped out by scanning the time delay for the gate pulse.

The frequency ω_2 that is detected in the fluorescence can be largely selected by adjusting the phase-matching condition for the nonlinear crystal. A double monochromator (or, alternatively, a prism and a single-stage monochromator) is used to discriminate between the upconverted fluorescence and the background interference from the second harmonic of the gating light. Even though the nonlinear crystal is angle-tuned to optimize the intensity of the upconverted fluorescence at the wavelength chosen by the monochromator, the strong gate pulse generates a significant second-harmonic signal that can often be as strong or stronger than the gated fluorescence. If the gate pulse is short, with a concomitantly large spectral bandwidth, the second-harmonic background may significantly overlap the fluorescence spectrum of the sample under study. In many respects this problem is comparable to that encountered in discriminating Rayleigh scattering from Raman scattering in the low Raman frequency regime. In Raman spectroscopy, however, the vibrational line shapes are usually much narrower than any fluorescence background; in fluorescence upconversion spectroscopy, the second-harmonic background from the gate pulse is often as broad as the fluorescence signal, making things comparably more difficult [71].

In [figure B2.1.4](#) a design for a fluorescence upconversion spectrometer is depicted that is based on one discussed by Jimenez and Fleming [71]. In the most versatile instrument, an OPA would be used to generate the wavelength-tunable excitation pulse, while a portion of the direct output of the amplified Ti-sapphire laser that pumps the OPA would be reserved for use as a strong gate pulse. This practice has several advantages: the gating and excitation pulses are implicitly time-synchronized and the excitation pulse can be well removed in wavelength from the region of the fluorescence photon, in order to minimize the second-harmonic gate background mentioned above. The experimental set-up depicted in [figure B2.1.4](#) employs two off-axis parabolic reflectors to collect and collimate the fluorescence emitted by the sample and then to focus it onto the nonlinear crystal. Other designs employ a single elliptical reflector to perform both tasks. The design shown here may permit low-temperature fluorescence studies to be executed, however, since the crystal and sample can be well separated on the optical table. Jimenez and Fleming [71] note that very few femtosecond fluorescence upconversion experiments have so far been attempted at low temperature.

Figure B2.1.4 Fluorescence upconversion spectrometer based on the use of off-axis elliptical reflectors for the collection and focusing of fluorescence. Symbols used: e1, e2, off-axis elliptical reflectors; s, sample; x, nonlinear crystal. (After Jimenez and Fleming [71].)

Over the last few years, the time resolution attainable in fluorescence upconversion has reached the sub-100 fs regime. The main problems associated with pushing the time resolution down further are sensitivity and GDD. The problem of collecting enough fluorescence photons and imaging them onto the nonlinear crystal, where detection occurs, is at odds with obtaining pulse-width-limited time resolution. Large elliptical or parabolic reflectors enhance the number of photons collected, but the time-of-flight dispersion increases with the surface area used on the reflector, so in many implementations the reflectors are masked. Lenses were used for collection and focusing in early experiments, as in the design discussed by Barbara and co-workers [70], but the time resolution obtainable is typically limited to the 250 fs regime owing to the GDD suffered by the fluorescence photons in being transmitted through the material used to make the lens. In principle, spherical confocal reflective optics might be used without time-of-flight dispersion. Even so, the nonlinear crystal itself imparts GDD and distorts the time response.

The instrument response function (IRF) for the fluorescence upconversion experiment, then, cannot be shorter than the intensity *cross-correlation* function, which can be obtained using an instrument like that shown in figure B2.1.4

-11-

in which the excitation and gate pulses used in the upconversion experiment are injected separately into the two arms of the interferometer. In the simplest case, the actual time response of the fluorescence resembles the *integral* of the IRF, $S(\tau) = \int_{-\infty}^{+\infty} I(t - \tau)F(t) dt$. The fluorescence signal $F(\tau)$ at the detection frequency ω_2 is, in the absence of other dynamics and rapid relaxation, a step function; the excitation pulse transfers a fraction of the ground-state population to the resonant excited state, which then emits fluorescence. As indicated in the above equation, the upconversion signal $S(\tau)$ responds as the gate pulse $I(t)$ is integrated by the step-response of $F(\tau)$. Of course, if ground-state recovery or energy-transfer processes deplete the resonant excited-state population, then $F(\tau)$ decays accordingly. The upconversion signal $S(\tau)$ then exhibits a shape that is effectively a *convolution* of the IRF and the excited-state population response $F(\tau)$. Since many experiments are intended to *determine* $F(\tau)$ via measurement of $S(\tau)$, one is often faced with *deconvolution* of the IRF from the measured signal in the course of data analysis. This problem has been extensively discussed in the literature [72]; the best solution, is, if possible, to make the IRF much shorter than the dynamics exhibited by $F(\tau)$ so that the measured signal is not significantly distorted.

An important extension to the simplest upconversion experiment at a single detection frequency ω_2 is the practice of measuring *time-resolved fluorescence spectra*, that is, the shape of the fluorescence spectrum

emitted by the sample at a given gate delay τ , $S(\omega_2, \tau)$. In most reported work, the $S(\omega_2, \tau)$ spectrum is built up by obtaining a family of single-wavelength transients, scanned at a given ω_2 as a function of τ . If the instrument provides for computer control of the angle tuning of the nonlinear crystal and the detection monochromator, it would be more efficient, with respect to experimental time, to directly scan ω_2 at a given time delay τ .

Perhaps the best example of a situation requiring knowledge of the time evolution of the fluorescence spectrum is that associated with *dynamic solvation*, the time-dependent reorganization of solvent dipoles in response to a light-induced change in the dipole moment of a dissolved chromophore [73, 74, 75, 76, 77 and 78]. As an example, figure B2.1.5 shows two upconversion traces obtained with the dye phenoxazone dissolved in methanol at room temperature. When the observation wavelength is tuned to the blue edge of the emission spectrum, at 570 nm, the fluorescence is observed to decay with a time constant of several picoseconds. If the observation wavelength is tuned to the red edge of the absorption spectrum at 650 nm, the fluorescence transient exhibits a rise with a similar time constant. These two upconversion transients evidence a blue-to-red shift of the time-resolved fluorescence spectrum owing to dynamic solvation on the picosecond time scale.

-12-

Figure B2.1.5 Fluorescence upconversion traces obtained at two observation wavelengths (full circles, 570 nm; open circles, 650 nm) at room temperature with an oxazine dye, phenoxazone, in methanol solvent. Figure courtesy of Professor S Rosenthal (Vanderbilt University).

The upconversion method can also be applied to the measurement of *anisotropy* [79], which returns information on the time dependence of the orientation of the excited-state transition-dipole moment with respect to time following excitation with a linearly polarized pulse of light. Anisotropy information can be used to study rotational diffusion [80, 81] in liquids, energy transfer between chromophores in proteins [79, 82] and excited-state isomerization [83, 84], to name just three common applications. The method takes advantage of photoselection of those molecules whose transition-dipole moments are aligned with the excitation pulse's plane of polarization to prepare an essentially polarized excited-state orientational distribution initially. The fluorescence that is emitted initially by this distribution is highly polarized; as time progresses, any mechanism that causes rotation of the excited-state transition-dipole moment, such as rotational diffusion, energy transfer and isomerization, will cause depolarization of the fluorescence.

The anisotropy function $r(t) = (I_{\parallel}(t) - I_{\perp}(t))/(I_{\parallel}(t) + 2I_{\perp}(t))$ is determined by two polarized fluorescence transients $I_{\parallel}(t)$ and $I_{\perp}(t)$ observed parallel and perpendicular, respectively, to the plane of polarization of the excitation pulse. In the upconversion experiment, the two measurements are most conveniently made by rotating the plane of polarization of the excitation pulse with respect to the fixed orientation of the input plane

of the nonlinear crystal. Because the photoselected angular distribution for a set of isolated transition dipoles exhibits a $\cos(\theta)$ dependence with respect to the angle θ between the plane of polarization of the excitation pulse and the observation plane, the anisotropy $r(t)$ decays from an initial value of 0.4 as the depolarization proceeds. The time course of the anisotropy is essentially a measure of the time-correlation function $\hat{\mu}_2(t)$ that describes the memory of the initial, photoselected dipole orientation $\hat{\mu}_1(0)$ as correlated with the probed dipole direction $\hat{\mu}_2(t)$ as a function of time [79, 84].

In certain situations involving coherently interacting pairs of transition dipoles, the initial fluorescence anisotropy value is expected to be larger than 0.4. As indicated by the theory described by Wynne and Hochstrasser [85, 86] and by Knox and Gülen [87, 88], the initial anisotropy expected for a pair of coupled dipoles oriented 90° apart, as an example,

-13-

is 0.7, and the decay of the anisotropy from 0.7 to 0.4 is a measure of the time scale for the decay of the electronic coherence between the two states. This theory has been applied to the interpretation of the decay of anisotropy in the analogous anisotropy measurement obtained using pump-probe (see below) stimulated-emission measurements in magnesium tetraphenylporphyrin [89] and in exciton-coupled chromophore pairs in cyanobacterial light-harvesting proteins [90, 91].

B2.1.3.2 PUMP-PROBE SPECTROSCOPY

An interferometric method was first used by Porter and Topp [1, 92] to perform a *time-resolved absorption* experiment with a Q -switched ruby laser in the 1960s. The nonlinear crystal in the autocorrelation apparatus shown in figure B2.1.2 is replaced by an absorbing sample, and then the transmission of the variably delayed pulse of light is measured as a function of the delay τ . This approach is known today as a *pump-probe* experiment; the first pulse to arrive at the sample transfers (*pumps*) molecules to an excited energy level and the delayed pulse *probes* the population (and, possibly, the coherence) so prepared as a function of time.

The pump-probe concept can be extended, of course, to other methods for detection. Zewail and co-workers [16, 18, 19 and 20, 93] have used the probe pulse to drive population from a reactive state to a state that emits fluorescence [94, 95, 96, 97 and 98] or photodissociates, the latter situation allowing the use of mass spectrometry as a sensitive and selective detection method [99, 100].

Pump-probe absorption experiments on the femtosecond time scale generally fall into two effective types, depending on the duration and spectral width of the pump pulse. If the pump spectrum is significantly narrower in width than the electronic absorption line shape, *transient hole-burning spectroscopy* [101, 102, 103, 104, 105, 106, 107, 108, 109, 110, 111, 112 and 113] can be performed. The second type of experiment, *dynamic absorption spectroscopy* [57, 114, 115, 116, 117, 118, 119, 120, 121 and 122], can be performed if the pump and probe pulses are short compared to the period of the vibrational modes that are coupled to the electronic transition.

Figure B2.1.6 depicts a standard type of apparatus used for the hole-burning type of time-resolved absorption experiment [112, 113, 123]. A pulse train from an amplified laser is split into two portions. The minor portion is used directly as a source of pump photons; the major portion is used to generate a broad-band probe source derived from a femtosecond continuum. In this application, the continuum is typically generated by focusing a $> 1 \mu\text{J}$ pulse of light into flowing water or ethylene glycol in a cuvette [39]; a continuum with particularly good optical properties can be generated in a thin sapphire crystal [47]. After the pump and probe pulses are overlapped in the sample, the transmitted probe light is dispersed in a monochromator and then detected either by a photodiode or by a multichannel detector, such as a charge-coupled device (CCD). The most common detection scheme involves using a mechanical chopper to modulate the intensity of the pump beam; the pump-induced changes in the transmission of the probe beam are then detected by using a lock-in amplifier.

Figure B2.1.6 Femtosecond spectrometer for transient hole-burning spectroscopy with a continuum probe. Symbols used: bs, 10% reflecting beamsplitter; p, polarizer. The continuum generator consists of a focusing lens, a cell containing flowing water or ethylene glycol or, alternatively, a sapphire crystal and a recollimating lens.

As an example, a series of transient hole-burning spectra obtained with a chirp-compensated continuum probe with a light-harvesting protein is shown in [figure B2.1.7](#) [112]. As the probe delay increases, the initially narrow transmission hole increases in width owing to vibrational redistribution and shifts about 500 cm^{-1} to the red owing to dynamic solvation. Analysis of this series of spectra was made in terms of overlapping spectral contributions from ground-state depletion, stimulated emission, and excited-state absorption. The time resolution of the experiment is limited by the width of the pump–probe cross-correlation function, which can be conveniently determined in this case using either FROG or a wavelength-resolved optical Kerr measurement [124].

The main cost of this enhanced time resolution compared to fluorescence upconversion, however, is the aforementioned problem of time ordering of the photons that arrive from the pump and probe pulses. When the probe pulse either precedes or trails the arrival of the pump pulse by a time interval that is significantly longer than the pulse duration, the action of the probe and pump pulses on the populations resident in the various resonant states is unambiguous. When the pump and probe pulses temporally overlap in the sample, however, all possible time orderings of field–molecule interactions contribute to the response and complicate the interpretation. Double-sided Feynman diagrams, which provide a pictorial view of the density matrix’s time evolution under the action of the laser pulses, can be used to determine the various contributions to the sample response [125].

The part of the response arising from a coherent interaction between the temporally overlapped probe and pump pulses is the so-called *coherence spike* [126, 127], which makes its appearance in the zero-delay region in [figure B2.1.7](#) essentially confined to the spectral region coinciding with the pump-pulse spectrum. Accordingly, the overall pump–probe signal’s temporal shape when viewed at a single-probe wavelength is not just the integral of the convolution of the pump and probe pulse temporal shapes. The intensity of the coherence spike is strongly dependent on the duration of the laser pulses employed in the experiment and the time scale of dephasing [127, 128].

Figure B2.1.7 Transient hole-burned spectra obtained at room temperature with a tetrapyrrole-containing light-harvesting protein subunit, the α subunit of *C*-phycoerythrin. Top: fluorescence and absorption spectra of the sample superimposed with the spectrum of the 80 fs pump pulses used in the experiment, which were obtained from an amplified CPM dye laser operating at 620 nm. Bottom: absorption-difference spectra obtained at a series of probe time delays.

The first *dynamic absorption* studies that afforded a view of a molecular response stimulated by *impulsive* excitation with femtosecond laser pulses were performed by Shank and co-workers in 1988 with 6 fs pulses from a fibre-grating pulse-compressed CPM laser [57]. This experiment might be called a degenerate pump–probe experiment since the 6 fs pulses were used both for pumping and probing; the broad spectral bandwidth had been used previously as a short, chirp-free, continuum-like probe in time-resolved hole-burning spectroscopy [101]. Under the conditions of impulsive excitation, where the pulse duration is short relative to the period of the coupled vibrations, vibrational wavepackets [129, 130] are created on structurally displaced excited-state potential energy surfaces. The wavepackets move back and forth under the forces of the excited-state potential and cause modulation of the stimulated-emission contribution to the pump–probe signal. A second pump–field–molecular interaction causes a stimulated transition of some of the moving excited-state wavepacket back down to the ground state at a position that is displaced from the equilibrium

molecular geometry, causing a ground-state wavepacket motion; that corresponds to the signal detected in conventional resonance Raman spectroscopy [130, 131]. Accordingly, the modulation of the ground-state depletion signal owing to the wavepacket motion on the ground-state surface is termed resonant-impulsive stimulated-Raman scattering (RISRS) [132]. Champion and co-workers [133, 134 and 135] have made extensive use of RISRS in their studies of heam motions in response to ligand photodissociation. Nelson and co-workers [132] have used RISRS to look at collective motions in molecular crystals.

[Figure B2.1.8](#) shows dynamic absorption results obtained with an IR dye in solution. The experiment was conducted with 13 fs pulses from a pulse-picked Ti–sapphire laser and a rapid-scanning pump–probe interferometer [136]. The single-wavelength transient was obtained by dispersing the transmitted probe light in a monochromator and monitoring at a single narrow range of wavelengths. The transient exhibits a modulation signal arising from excited-state vibrational wavepacket motions that is sustained for at least a picosecond. Modulations of this type can be frequency analysed using either Fourier transformation or a linear-prediction, singular-value decomposition (LPSVD) method, as was done in [figure B2.1.8\(b\)](#). The LPSVD method [137] fits the modulation pattern to a series of damped cosinusoids. The representation shown in [figure B2.1.8\(b\)](#) uses the frequencies and damping (dephasing) times to construct a spectral representation that resembles a conventional Raman spectrum. The modulation spectrum shown in [figure B2.1.8\(b\)](#) evidences contributions from several vibrational modes over the 100–1200 cm^{-1} range. The intensity of modulation for a given frequency is observed to depend strongly on the pulse duration; as the pulse duration is made shorter, the frequency window that provides impulsive excitation broadens. This windowing has been described by Lotshaw and McMorro in their discussion of non-resonant optical Kerr effect studies, where impulsive excitation of intramolecular and intermolecular vibrational modes in neat liquids can be studied through the use of orthogonally polarized pump and probe beams and optically heterodyned detection methods [138, 139, 140, 141 and 142].

Excited-state vibrational coherence of the type observed in [figure B2.1.8](#) is potentially a very important tool for the elucidation of excited-state reaction dynamics. The most well known example of this type of work is that of Mathies, Shank and co-workers on the dynamics of rhodopsin [118, 143]. Elsaesser and co-workers [144] used a two-colour dynamic absorption technique to study ultrafast intramolecular proton transfer in a benzotriazole dye in solution. Wynne and Hochstrasser [145] observed vibrational coherence associated with charge transfer in a contact ion-pair in solution. Diffey *et al* [122] used a comparison of excited-state and RISRS wavepacket modulation patterns to study ultrafast charge transfer in a bacteriochlorophyll dimer system isolated from a purple-bacterial light-harvesting chromophore. Vos and co-workers [146, 147 and 148] have observed excited-state vibrational coherence in purple-bacterial reaction centres; Stanley and Boxer observed analogous signals using fluorescence upconversion [149].

So far we have exclusively discussed time-resolved absorption spectroscopy with *visible* femtosecond pulses. It has become recently feasible to perform time-resolved spectroscopy with femtosecond IR pulses. Hochstrasser and co-workers [58, 150, 151, 152, 153, 154, 155, 156 and 157] have worked out methods to employ IR pulses to monitor chemical reactions following electronic excitation by visible pump pulses; these methods were applied in work on the light-initiated charge-transfer reactions that occur in the photosynthetic reaction centre [156, 157] and on the excited-state isomerization of the retinal pigment in bacteriorhodopsin [155]. Walker and co-workers [158] have recently used femtosecond IR spectroscopy to study vibrational dynamics associated with intramolecular charge transfer; these studies are complementary to those performed by Barbara and co-workers [159, 160], in which ground-state RISRS wavepackets were monitored using a dynamic-absorption technique with visible pulses.

Figure B2.1.8 Dynamic absorption trace obtained with the dye IR144 in methanol, showing oscillations arising from coherent wavepacket motion: (a) transient observed at 775 nm; (b) frequency analysis of the oscillations obtained using a linear prediction, singular-value-decomposition method.

In some extremely innovative recent experiments, Hochstrasser and co-workers [58] have described IR transient hole-burning experiments focused on characterizing inhomogeneous broadening in the amide I transition in several small polypeptides. 180 fs IR pulses centred at 1650 cm^{-1} were generated from a BBO OPA source through the use of difference-frequency mixing of the signal and idler pulses in a AgGaS_2 crystal. Narrower, 1 ps duration IR pulses were produced from the spectrally broad femtosecond IR pulses using a mechanically scannable Fabry–Perot etalon. The results were presented using a novel two-dimensional representation as shown in [figure B2.1.9](#) in which the time-resolved hole-burned spectra were plotted against the centre frequency of the pump spectrum that burned the hole. The results provide information on the extent of delocalization of the amide vibrational wavefunction along the peptide backbone.

Figure B2.1.9 Two-dimensional time-resolved IR holeburning spectra obtained with two small polypeptides, apamin and scyllatoxin, by Hochstrasser and co-workers [58]. Figure courtesy Professor R M Hochstrasser (University of Pennsylvania).

B2.1.3.3 PHOTON-ECHO AND TRANSIENT-GRATING SPECTROSCOPY

The methods discussed so far, fluorescence upconversion, the various pump–probe spectroscopies, and the polarized variations for the measurement of anisotropy, are essentially conventional spectroscopies adapted to the femtosecond regime. At the simplest level of interpretation, the information content of these conventional time-resolved methods pertains to *populations* in resonantly prepared or probed states. As applied to chemical kinetics, for most *slow* reactions (on the ten picosecond and longer time scales), populations adequately specify the position of the reaction coordinate; intermediates and products show up as time-delayed spectral entities, and assignment of the transient spectra to chemical structures follows, in most cases, the same principles used in spectroscopic experiments performed with continuous wave or nanosecond pulsed lasers.

The multiple-pulse methods discussed in this section, in contrast, can be used to obtain information on the time evolution of electronic or vibrational coherence, the correlation of *phase* between two states. In *fast*, sub-picosecond chemical reactions and in energy transfer, as examples, knowledge of the time evolution of coherence *and* population is essential if a correct physical model is to be established. For example, in the purple-bacterial photosynthetic reaction centre, the 3 ps time scale for the charge transfer from the bacteriochlorophyll dimer that serves as the primary electron donor to the pheophytin that serves as the electron acceptor is comparable to that of vibrational dephasing and just longer than the fast part of electronic dephasing [146, 149, 156, 161, 162, 163, 164, 165, 166 and 167]. It is certainly inadequate to describe this situation just in terms of populations and the states of the *individual* macrocycles that are involved in the charge-transfer reaction. A similar problem applies to the photophysics of retinal in the visual and proton-pumping proteins rhodopsin and bacteriorhodopsin. The light-initiated isomerization of retinal in these proteins occurs on the sub-picosecond time scale; it involves a time evolution from an excited electronic state to a isomerized ground state on a time scale that is shorter than that involved in vibrational dephasing [114, 117, 118, 120, 143].

Photon-echo and transient-grating spectroscopy exploit, in general, time-ordered interactions between three or more optical pulses [125, 168]. The principles involved are analogous to those that are well established for pulsed experiments in nuclear and electron magnetic resonance [169]. Although the methods discussed below were applied first for the study of electronic coherence, as picosecond and femtosecond IR sources were developed a set of corresponding methods were applied to the *direct* study of vibrational coherence. Simple multiple-pulse sequences, with control over relative delays between pulses, can be formed using interferometers with three (or more) arms. Importantly, the pulses can be aimed spatially so that the phase-matched (momentum-conserving) outgoing directions for the signal (echo or diffracted) pulses are spatially resolved from the transmitted excitation pulses, affording zero-background detection [170].

Transient-grating spectroscopy is performed using two pump pulses that are arranged to arrive at the sample at the same time but aimed to overlap at an angle [171]. A *transmission diffraction grating* is formed owing to the spatial interference between the two pump pulses. The grating consists of alternating regions of excited-state molecules, formed in the bright regions where the two incoming beams interfere constructively, and of ground-state molecules, left undisturbed in the dark regions where the two beams interfere destructively. A third, probing laser pulse is diffracted by the population grating into a direction that is resolved from the pump directions, allowing the intensity of the population grating to be measured as a function of time. Any physical process that causes the spatial pattern of ground- and excited-state molecules to fade away or become less distinct will be detected in terms of a decrease in the diffracted beam's intensity. Thus, in addition to being sensitive to population decay, the transient-grating experiment

-20-

can be used to detect spatial motion of molecules owing to transport or diffusion. For example, Miller and co-workers [172, 173 and 174] have employed transient-grating spectroscopy to study protein motions in hem proteins. Further, since the diffraction efficiency is sensitive to the orientation of the transition-dipole moments of the excited-state molecules, the transient-grating method can be used to characterize rotational diffusion. Fayer and co-workers have also exploited polarization gratings, formed by making the two coincident incoming beams be orthogonally polarized [171].

The simplest echo experiment, the two-pulse photon echo, reports information on the decay of coherence in terms of echo intensity. As in the corresponding spin-echo experiment in magnetic resonance, the first incident laser pulse rotates the Bloch vector [168, 175] from pure population in the ground state to an orientation corresponding to a coherent superposition state; the density matrix now exhibits off-diagonal elements as well as diagonal elements. During the waiting period t between the first and second pulses, the off-diagonal (coherence) elements in the density matrix decay according to the dephasing time, T_2 , while the on-diagonal (population) elements decay according to the lifetime of the resonantly prepared state, T_1 . The

second laser pulse rotates the Bloch vectors again so that the phase of rotation of the Bloch vectors is inverted, which leads to refocusing. The vectors are maximally refocused at an interval t after the second pulse, so that the *spontaneous* emission arising from the ensemble of molecules is radiated with spatial coherence, forming an *echo* pulse. Thus, the intensity of the echo as a function of the waiting time t can be described by an exponential decay with time constant T_2 [176]. If the two input pulses are directed along the directions \vec{k}_1 and \vec{k}_2 , echo signal beams are emitted along the $2\vec{k}_1 - \vec{k}_2$ and $2\vec{k}_2 - \vec{k}_1$ directions. In practice, the input and echo beams are recollimated by a single lens after they emerge from the sample; iris apertures are used to spatially isolate the direction of either of the echo beams so that the emerging input beams are blocked.

In liquids, the Bloch equations (single-dephasing time scale) picture [175] used above to describe the formation of echo signals is apparently inadequate. It is now known that electronic dephasing occurs over a distribution of time scales, so a single time constant T_2 is insufficient to describe all of the line-broadening dynamics [177]. The two-pulse echo method described above only is sensitive to the fastest of processes; in organic molecules in solution, the two-pulse echoes typically decay on the 20 fs or shorter time scale [176]. This is the time scale usually assigned to homogeneous line broadening. The slower electronic dephasing processes that contribute to inhomogeneous line broadening, involving solvent-induced fluctuations or radiationless decay between uncorrelated states, extend over the 10 fs to 100 ps (or longer) time scales in liquids and proteins [77, 78, 177].

A three-pulse or stimulated photon-echo experiment can be employed to characterize dephasing on a much longer time scale than is accessible to the two-pulse photon echo experiment. Figure B2.1.10 shows a three-pulse interferometer and beam-input geometry employed by Fleming and co-workers [170, 178, 179, 180 and 181]. The modified forward-box beam-input geometry allows three-pulse echoes (or grating signals) to be detected in the phase-matched $\vec{k}_1 - \vec{k}_2 + \vec{k}_3$ and $-\vec{k}_1 + \vec{k}_2 + \vec{k}_3$ directions. As in the Hahn stimulated spin-echo sequence [169], for a given waiting time t between the first two pulses, a plot of the echo intensity as a function of the time period T between the second and third pulses returns just the lifetime T_1 of the resonantly prepared state. At a given delay T , a plot of the intensity as a function t returns a decay related to the dephasing time T_2 , but there is a subtle change in the shape of the intensity envelope that is discernible as T is varied [170, 179, 182, 183, 184 and 185]. Figure B2.1.11 shows the results obtained from a three-pulse photon-echo experiment on a small protein subunit that binds an extended tetrapyrrole chromophore [186]. At early delays T , the shape is asymmetrical, with the maximum intensity shifted away from $t = 0$. As T is increased, so that the ensemble evolves for longer time periods prior to rephasing by the third pulse, the envelope becomes more symmetrical, and the maximum shifts back to near $t = 0$. The asymmetrical shape observed at early

delays T reports the presence of an echo, but the symmetrical signal observed at longer delays T arises from a free-induction decay only.

Figure B2.1.10 Stimulated photon-echo peak-shift (3PEPS) signals. Top: pulse sequence and interpulse delays t and T . Bottom: echo signals scanned as a function of delay t at three different population periods T , obtained with samples of a tetrapyrrole-containing light-harvesting protein subunit, the α subunit of *C*-phycoyanin.

Figure B2.1.11 3PEPS profile obtained at room temperature with samples of a tetrapyrrole-containing light-harvesting protein subunit, the α subunit of *C*-phycoyanin, as used in the previous figure.

This experiment is now known as a three-pulse stimulated photon-echo peak-shift (3PEPS) experiment. Weiner and Ippen [182] were the first to describe the echo-envelope-shifting phenomenon and its relationship to inhomogeneous line broadening; application of the 3PEPS method to problems of dynamic solvation has been popularized especially by the groups of Fleming [177, 178 and 179, 184, 185] and of Wiersma, who has advanced gated versions of the experiment that actually time-resolves the echo in order to obtain additional information [187, 188 and 189]. The 3PEPS method returns, in general, superior information on solvation dynamics as compared to that returned by dynamic Stokes shift measurements by fluorescence upconversion or transient hole-burning spectroscopy because no line shape assumptions have to be made; in fact, a full analysis of the time-correlation and line-broadening functions obtained from the 3PEPS experiment can be used to obtain all pertinent spectroscopic observables, including the absorption and fluorescence line shapes. Owing to the mapping of coherence into population by the second pulse in the sequence, dephasing can be studied using the 3PEPS method over an enormous time scale, generally as long as the lifetime of the resonant state [177]. Figure B2.1.12 shows the entire 3PEPS profile obtained from a series of experiments on the sample used for figure B2.1.11 conducted with a series of T delays. Several different time scales that contribute to electronic dephasing are notable, corresponding to a very fast decay on the <20 fs time scale, a roughly exponential decay on the 100 fs time scale, and a slower decay to a long-lived offset over the 200 fs to 1 ps time scale [186]. The magnitude of the peak shift for each component is proportional to the strength of coupling of solvent fluctuations on a given time scale to the electronic dipole of the resonant electronic state that is used as a probe [177].

Figure B2.1.12. 3PEPS profile obtained at room temperature with samples of a tetrapyrrole-containing light-harvesting protein subunit, the a subunit of C-phycoerythrin, as used in the previous figure.

As implied above, comparable two- and three-pulse echo experiments can be conducted with femtosecond IR pulses in order to study *vibrational* dephasing. Notable work in this area has been conducted by Fayer and co-workers with picosecond IR pulses obtained from a free-electron laser at Stanford University [190, 191, 192, 193, 194 and 195]. Vibrational states can also be prepared with visible femtosecond pulses through the use of stimulated Raman *coherences*. In this family of methods, two laser pulses with frequencies ω_1 and ω_2 act simultaneously to transfer population to a vibrational level of frequency $\omega_1 - \omega_2$. The chief advantage of using pairs of visible pulses is that a wider frequency range becomes accessible owing to the availability of very short visible pulses; experiments conducted with IR pulses are limited by time-bandwidth considerations to lower frequencies. At present, however, the stimulated Raman methods have only been used *non-resonantly*, so very intense femtosecond laser pulses are required, typically in the $\mu\text{J}/\text{pulse}$ regime. In contrast, photon-echo experiments conducted with resonant electronic states are generally conducted with pulse energies in the low nJ regime.

One important stimulated Raman method, known as the Raman echo experiment, is analogous to the three-pulse or stimulated photon-echo discussed above. Two pairs of visible pulses prepare and map vibrational coherences into population, respectively, and after a waiting period a fifth pulse is used to stimulate rephasing and echo formation. Berg and co-workers have used the Raman echo to probe the vibrational dephasing of rotating methyl groups in different solvent environments [196, 197]. Tokmakoff, Fleming, and their co-workers [198, 199, 200 and 201] have exploited the intrinsic two-dimensionality of the Raman echo experiment to explore anharmonic coupling between intermolecular modes in liquid CS_2 ; each axis of the experiment returns information that is analogous to that available from conventional stimulated coherent Raman spectroscopy, but in the two-dimensional representation cross-peaks appear that directly report coupling between two vibrational modes.

B2.1.3.4 COHERENT CONTROL AND FUTURE ULTRAFAST SPECTROSCOPIES

A number of investigators are now developing pulse-shaping and modulation techniques that are useful with ultrashort laser pulses. These methods will permit preparation of precisely timed *and phased* multipulse sequences of arbitrary complexity for use in nonlinear spectroscopy. In addition, rather than just exploiting pulse sequences to project coherences into echo intensities and time shifts for spectroscopic purposes, as in the methods discussed above, several investigators are devising pulse sequences to focus wavefunctions onto

potential surfaces in a non-statistical manner. This concept, known generally as *coherent control* [202, 203 and 204], refers to attempts to control chemical reactions with specially constructed sequences of ultrashort laser pulses of known phase evolution and duration.

Scherer *et al* [205, 206] showed how to prepare, using interferometric methods, pairs of laser pulses with known relative phasing. These pulses were employed in experiments on vapour phase I₂, in which wavepacket motion was detected in terms of fluorescence emission. A more general approach, which can be used in principle to generate pulse sequences of any type, is to transform a single input pulse into a *shaped* output profile, with the intensity and phase of the output under control throughout. The idea being exploited by a number of investigators, notably Warren and Nelson, is to use a programmable dispersive delay line constructed from a pair of diffraction gratings spaced by an *active* device that is used either to absorb or phase shift selectively the frequency-dispersed wavefront. The approach favoured by Warren and co-workers exploits a Bragg cell driven by a radio-frequency signal obtained from a frequency synthesizer and a computer-controlled arbitrary waveform generator [207]. Nelson and co-workers use a computer-controlled liquid-crystal pixel array as a mask [208]. In the future, it is likely that one or both of these approaches will allow execution of currently impossible nonlinear spectroscopies with highly selective information content. One can take inspiration from the complex pulse sequences used in modern multiple-dimension NMR spectroscopy to suppress unwanted interfering resonances and to enhance selectively the resonances from targeted nuclei.

A simple example of what is possible now, even with two-pulse sequences, is the work by Shank and co-workers on focused RISRS wavepackets. Bardeen *et al* [209] used pump pulses prepared on purpose with a linear, negative chirp to enhance the magnitude of wavepackets driven to the ground state by impulsive stimulated Raman scattering. In the simplest application, this kind of approach might be used to make it easier to detect weakly displaced normal modes in dynamic absorption spectroscopy. In a mode-selective chemistry example, focusing of wavepackets [204, 210] might be used to prepare a certain vibrational superposition state, which could be subsequently excited by another laser pulse to produce an enhanced product yield [211]. The goal of this kind of work is to drive chemical reactions in directions that are normally not possible along normal kinetically and energetically controlled routes [204].

B 2.2 Electron, ion and atom scattering

M R Flannery

B2.2.1 INTRODUCTION

This chapter deals with quantal and semiclassical theory of heavy-particle and electron–atom collisions. Basic and useful formulae for cross sections, rates and associated quantities are presented. A consistent description of the mathematics and vocabulary of scattering is provided. Topics covered include collisions, rate coefficients, quantal transition rates and cross sections, Born cross sections, quantal potential scattering, collisions between identical particles, quantal inelastic heavy-particle collisions, electron–atom inelastic collisions, semiclassical inelastic scattering and long-range interactions.

B2.2.2 COLLISIONS

B2.2.2.1 DIFFERENTIAL AND INTEGRAL CROSS SECTIONS

A uniform monoenergetic beam of *test* or *projectile* particles A with number density N_A and velocity v_A is incident on a single *field* or *target* particle B of velocity v_B . The direction of the relative velocity $\varpi = v_A - v_B$ is along the Z-axis of a Cartesian XYZ frame of reference. The incident current (or intensity) is then $j_i = N_A v_A$, which is the number of test particles crossing unit area normal to the beam in unit time. The differential cross section for scattering of the test particles into unit solid angle $d\Omega = d(\cos \psi) d\phi$ about the direction $\hat{v}'(\psi, \phi)$ of the final relative motion is

$$\frac{d\sigma(v; \psi, \phi)}{d\Omega} = \frac{\text{Number of test particles scattered by one field particle into unit solid angle per unit time}}{\text{Current } j_i \text{ of incident beam}}$$

The number of particles scattered per unit time by the field particle and detected per unit time is then

$$\frac{dN_d}{dt} = j_i \frac{d\sigma}{d\Omega} d\Omega = N_A v \frac{d\sigma}{d\Omega} d\Omega = N_A v \frac{d\sigma}{d\Omega} \frac{dA}{r^2}$$

where the detector, located along the scattered direction $\hat{v}(\psi, \phi)$, subtends an angle $d\Omega = dA/r^2$ at the scattering centre and projects an area $dA = r^2 d(\cos \theta) d\phi$ normal to the scattered beam. Thus $[d\sigma/d\Omega] d\Omega$ is the cross-sectional area of the beam that is intercepted by one target particle and scattered into the solid angle dA/r^2 of a cone with axis along $\hat{v}(\psi, \phi)$ and vertical angle $d\psi$. In classical terms (figure B2.2.1), the number of particles detected per second about direction (ψ, ϕ) is the number $N_A v(bdb d\phi)$ of incident particles crossing the initial areal element $bdb d\phi$ per second.

-2-

Hence

$$\frac{d\sigma}{d\Omega} = \frac{b db}{d(\cos \psi)}.$$

For an incident current flowing between two cylinders of radii b and $b + db$, then $j_i 2\pi [d\sigma/d\Omega] d(\cos \psi)$ is the number of particles scattered per second between the two cones of semivertical angles $\psi, \psi + d\psi$ (figure B2.2.1).

Figure B2.2.1. Scattering of a beam with current $j_i = N_A v$ particles per unit area incident between two cylinders of radii b and $b + db$ by one particle at rest in the laboratory.

The integral cross section for scattering over all directions is

$$\sigma(v) = \int_{-1}^{+1} d(\cos \psi) \int_0^{2\pi} \left[\frac{d\sigma}{d\Omega}(v; \psi, \phi) \right] d\phi.$$

The integral cross section is therefore the effective area presented by each field particle B for scattering of the test particles A into all directions. The *probability* that the test particles are scattered into a given direction $\hat{v}(\psi, \phi)$ is the ratio

$$\mathcal{P}(v; \psi, \phi) = \frac{d\sigma(v; \psi, \phi)}{d\Omega} / \sigma(v)$$

of the differential-to-integral cross sections.

B2.2.2.2 COLLISION RATES, COLLISION FREQUENCY AND PATH LENGTH

An electron or atomic beam of (projectile or test) particles A with density N_A of particles per cm^3 travels with speed v and energy E through an infinitesimal thickness dx of (target or field) gas particles B at rest with density N_B particles per cm^3 . The particles are scattered out of the beam by A–B collisions with integral cross section $\sigma(E)$ at a rate ($\text{cm}^{-3} \text{s}^{-1}$) given by the total number of collisions between A and B particles

$$\begin{aligned} \frac{dN_A(E)}{dt} &= -[N_A(E)v\sigma(E)]N_B \\ &= -k(E)N_A(E)N_B \\ &= -v_B(E)N_A(E) \end{aligned}$$

in unit time and unit volume. The *microscopic rate coefficient* ($\text{cm}^3 \text{s}^{-1}$) for the scattering of one test particle by one field particle is $k(E) = v\sigma(E)$. The frequency (s^{-1}) of collision between one test particle and N_B field particles (cm^{-3}) is $v_B = k(E)N_B$. Since $v = dx/dt$, the variation with x of intensity j_i of the attenuated beam is governed by

$$\frac{dj_i}{dx} = -[N_B\sigma(E)]j_i(x).$$

For constant density N_B and speed v , the solution is

$$\begin{aligned} j_i(E, x) &= j_i(E, 0) \exp[-N_B\sigma(E)x] \\ &= j_i(E, 0) \exp(-x/\lambda) \end{aligned}$$

where $\lambda \equiv 1/N_B\sigma(E) = v/v_B$ is the path length between collisions. Since $j_i = N_A v$, the density $N_A(E, x)$ obeys a similar equation. These equations describe the attenuation of a particle beam A travelling through a target gas B. For target gas particles with a distribution $f_B(v_B) dv_B$ in velocities v_A , the microscopic rate then becomes

$$k(E) = \int |v_A - v_B| \sigma(|v_A - v_B|) f_B(v_B) dv_B$$

where $E = \frac{1}{2}M_A v_A^2$ is the kinetic energy of the projectile beam. For an isothermal beam with an energy distribution $f_A(E) dE$ at temperature T , the macroscopic rate coefficient ($\text{cm}^3 \text{s}^{-1}$) or thermal rate constant is

$$k(T) = \int_0^\infty k(E) f_A(E) dE.$$

B2.2.2.3 ENERGY AND ANGULAR MOMENTUM: CENTRE OF MASS AND RELATIVE VELOCITY

The velocity of the centre of mass (CM) of the projectile and target particles of respective masses M_A and M_B is

$$\mathbf{V} = (M_A \mathbf{v}_A + M_B \mathbf{v}_B) / (M_A + M_B).$$

The relative velocity is

$$\mathbf{v} = \mathbf{v}_A - \mathbf{v}_B.$$

The velocities of A and B in terms of \mathbf{V} and \mathbf{v} are

$$\begin{aligned} \mathbf{v}_A &= \mathbf{V} + \frac{M_B}{M_A + M_B} \mathbf{v} \\ \mathbf{v}_B &= \mathbf{V} - \frac{M_A}{M_A + M_B} \mathbf{v}. \end{aligned}$$

The total kinetic energy then decomposes into the sum

$$\begin{aligned} E &= \frac{1}{2} M_A v_A^2 + \frac{1}{2} M_B v_B^2 = \frac{1}{2} M V^2 + \frac{1}{2} M_{AB} v^2 \\ &= E_{CM}(A + B) + E_{rel}(AB) \end{aligned}$$

of the energy $E_{CM} = \frac{1}{2} M V^2$ of the CM with mass $M = (M_A + M_B)$, and the energy $E_{rel} = \frac{1}{2} M_{AB} v^2$ of relative motion, where the reduced mass M_{AB} is $M_A M_B / (M_A + M_B)$. Let \mathbf{R} be the position of the CM relative to a fixed origin O and \mathbf{r} be the inter-particle separation. The total angular momentum about O similarly decomposes into the sum

$$\begin{aligned} \mathbf{L} &= \mathbf{R} \times M \mathbf{V} + \mathbf{r} \times M_{AB} \mathbf{v} \\ &= \mathbf{L}_{CM}(A + B) + \mathbf{L}_{rel}(AB) \end{aligned}$$

of angular momenta of the CM and of relative motion. For any collision in the absence of any external field, the energy E_{CM} and angular momentum \mathbf{L}_{CM} of the CM are always conserved for all types of collision. The two species, A and B, may be electrons, ions, atoms or molecules, with or without any internal structure and may therefore possess internal energy and angular momentum which must be taken into account. For structured particles E_{rel} and \mathbf{L}_{rel} can change in a collision.

B2.2.2.4 ELASTIC SCATTERING

Elastic scattering involves no permanent changes in the internal structures (states α and β) of A and B. Both the energy E_{rel} and angular momentum $\mathbf{L}_{rel}(AB)$ of relative motion are therefore all conserved.

B2.2.2.5 INELASTIC SCATTERING

Inelastic scattering produces a permanent change in the internal energy and angular momentum state of one or both structured collision partners A and B, which retain their original identity after the collision. For inelastic $i \equiv (\alpha, \beta) \rightarrow f \equiv (\alpha', \beta')$ collisional transitions, the energy $E_{i,f} = \frac{1}{2} M_{AB} v_{i,f}^2$ of relative motion, before (i) and after (f) the collision satisfies the energy conservation condition,

$$E_i + \epsilon_\alpha(\mathbf{A}) + \epsilon_\beta(\mathbf{B}) = E_f + \epsilon_{\alpha'}(\mathbf{A}) + \epsilon_{\beta'}(\mathbf{B})$$

where $\epsilon_{A,B}$ are the internal energies of A and B. The maximum amount of kinetic energy that can be transferred to internal energy is limited to the initial kinetic energy of relative motion, $E_{\text{rel}}(\mathbf{AB}) = \frac{1}{2} M_{AB} v_i^2$.

Excitation implies $\epsilon_i \equiv \epsilon_\alpha(\mathbf{A}) + \epsilon_\beta(\mathbf{B}) < \epsilon_{\alpha'}(\mathbf{A}) + \epsilon_{\beta'}(\mathbf{B}) \equiv \epsilon_f$ de-excitation (or superelastic) implies $\epsilon_f < \epsilon_i$ and energy resonance or excitation transfer implies $\epsilon_i = \epsilon_f$. Changes in angular momentum are limited by the conservation requirement that

$$L_{\text{rel}}(i) + L_\alpha(\mathbf{A}) + L_\beta(\mathbf{B}) = L_{\text{rel}}(f) + L_{\alpha'}(\mathbf{A}) + L_{\beta'}(\mathbf{B})$$

where $L_{\alpha,\beta}$ denotes the internal angular momentum of each isolated species. Collisions, in which only angular momentum is transferred without any energy change, are called *quasi-elastic* collisions.

B2.2.2.6 REACTIVE SCATTERING

Reactive scattering or a chemical reaction is characterized by a rearrangement of the component particles within the collision system, thereby resulting in a change of the physical and chemical identity of the original collision reactants A + B into different collision products C + D. Total mass is conserved. The reaction is exothermic when $E_{\text{rel}}(\mathbf{CD}) > E_{\text{rel}}(\mathbf{AB})$ and is endothermic when $E_{\text{rel}}(\mathbf{CD}) < E_{\text{rel}}(\mathbf{AB})$. A threshold energy is required for the endothermic reaction.

B2.2.2.7 CENTRE-OF-MASS TO LABORATORY CROSS SECTION CONVERSION

Theorists calculate cross sections in the CM frame while experimentalists usually measure cross sections in the laboratory frame of reference. The laboratory (Lab) system is the coordinate frame in which the target particle B is at rest before the collision i.e. $\mathbf{v}_B = 0$. The centre of mass (CM) system (or barycentric system) is the coordinate frame in which the CM is at rest, i.e. $\mathbf{v} = 0$. Since each scattering of projectile A into (ψ, ϕ) is accompanied by a recoil of target B into $(\pi - \psi, \phi + \pi)$ in the CM frame, the cross sections for scattering of A and B are related by

$$\left\{ \frac{d\sigma(\psi, \phi)}{d\Omega} \right\}_{\text{CM}} \equiv \left\{ \frac{d\sigma_A(\psi, \phi)}{d\Omega} \right\}_{\text{CM}} = \left\{ \frac{d\sigma_B(\pi - \psi, \phi + \pi)}{d\Omega} \right\}_{\text{CM}}$$

$$\left\{ \frac{d\sigma_B(\psi, \phi)}{d\Omega} \right\}_{\text{CM}} = \left\{ \frac{d\sigma(\pi - \psi, \phi - \pi)}{d\Omega} \right\}_{\text{CM}}$$

In the *Lab* frame, the projectile is scattered by θ_A and the target, originally at rest, recoils through angle θ_B . The number of particles scattered into each solid angle in each frame remains the same, the relative speed v is now v_A and $j_i = N_A v$ in each frame. Hence

$$\left\{ \frac{d\sigma_A(\theta_A, \phi)}{d\Omega_A} \right\}_{\text{Lab}} = \left\{ \frac{d\Omega}{d\Omega_A} \right\} \left[\frac{d\sigma(\psi, \phi)}{d\Omega} \right]_{\text{CM}}$$

$$\left\{ \frac{d\sigma_B(\theta_B, \phi)}{d\Omega_B} \right\}_{\text{Lab}} = \left\{ \frac{d\Omega}{d\Omega_B} \right\} \left[\frac{d\sigma(\psi, \phi)}{d\Omega} \right]_{\text{CM}}.$$

(A) TWO-BODY ELASTIC SCATTERING

The scattering and recoil angles θ_A and θ_B in the Lab frame are related to the CM scattering angle ψ by

$$\tan \theta_A = \frac{\sin \psi}{1 + \gamma \cos \psi} \quad \gamma = M_A/M_B$$

$$\theta_B = \frac{1}{2}(\pi - \psi) \quad 0 \leq \theta_B \leq \frac{1}{2}\pi.$$

The elastic cross sections for scattering and recoil in the Lab-frame are related to the cross section in the CM-frame by

$$\left\{ \frac{d\sigma_A(\theta_A, \phi)}{d\Omega_A} \right\}_{\text{Lab}} = \frac{(1 + \gamma^2 + 2\gamma \cos \psi)^{3/2}}{|1 + \gamma \cos \psi|} \left[\frac{d\sigma(\psi, \phi)}{d\Omega} \right]_{\text{CM}}$$

$$\left\{ \frac{d\sigma_B(\theta_B, \phi)}{d\Omega_B} \right\}_{\text{Lab}} = |4 \sin \frac{1}{2}\psi| \left[\frac{d\sigma(\psi, \phi)}{d\Omega} \right]_{\text{CM}}.$$

(B) TWO-BODY INELASTIC OR REACTIVE SCATTERING PROCESS $A + B \rightarrow C + D$

The energies E_i and E_f of relative motion of A and B and of C and D, respectively satisfy $E_f/E_i = 1 - \epsilon_{fi}/E_i$, where $\epsilon_{fi} = \epsilon_f - \epsilon_i$ is the increase in internal energy. The scattering and recoil angles are

$$\tan \theta_C = \frac{\sin \psi}{(\gamma_C + \cos \psi)} \quad \gamma_C = \left[\frac{M_A M_C}{M_B M_D} \right]^{1/2} \left(\frac{E_i}{E_f} \right)^{1/2}$$

$$\tan \theta_D = \frac{\sin \psi}{(|\gamma_D| - \cos \psi)} \quad \gamma_D = - \left[\frac{M_A M_D}{M_B M_C} \right]^{1/2} \left(\frac{E_i}{E_f} \right)^{1/2}.$$

-7-

The Lab and CM cross sections are then related by

$$\left\{ \frac{d\sigma_j(\theta_j, \phi)}{d\Omega_j} \right\}_{\text{Lab}} = \frac{[1 + 2\gamma_j \cos \psi + \gamma_j^2]^{3/2}}{|1 + \gamma_j \cos \psi|} \left[\frac{d\sigma(\psi, \phi)}{d\Omega} \right]_{\text{CM}}$$

where j denotes C or D. The scattering of a beam from a stationary target is governed by these equations. A crossed beam experiment in which two beams intersect at an angle is not in the Lab-frame. In this case the measured quantities can be similarly transformed [1] to CM for comparison with theoretical calculations.

B2.2.3 MACROSCOPIC RATE COEFFICIENTS

B2.2.3.1 SCATTERING RATE

$$\frac{dN_A}{dt} = -kN_A(t)N_B(t) = -\nu_B N_A(t).$$

A distribution $f_A(\mathbf{v}_A)$ of $N_A(t)$ test particles (cm^{-3}) of species A in a beam collisionally interacts with a distribution $f_B(\mathbf{v}_B)$ of $N_B(t)$ field particles of species B. Collisions with B will scatter A out of the beam at the loss rate ($\text{cm}^{-3} \text{s}^{-1}$)

$$k (\text{cm}^3 \text{s}^{-1}) = \int f_A(\mathbf{v}_A) d\mathbf{v}_A \int [v\sigma(v)] f_B(\mathbf{v}_B) d\mathbf{v}_B$$

The macroscopic rate coefficient $k (\text{cm}^3 \text{s}^{-1})$ for elastic collisions between the ensembles A and B is

$$k (\text{cm}^3 \text{s}^{-1}) = \tilde{\nu}_{AB} \int_0^\infty \sigma(\tilde{\epsilon}_{\text{rel}}) \tilde{\epsilon}_{\text{rel}} \exp(-\tilde{\epsilon}_{\text{rel}}) d\tilde{\epsilon}_{\text{rel}}$$

in terms of the integral cross section $\sigma(v)$ for A–B elastic scattering at relative speed $v = |\mathbf{v}_A - \mathbf{v}_B|$. The microscopic rate coefficient is $v\sigma(v)$. The frequency $\nu_B (\text{s}^{-1})$ of collision between one test particle A with N_B field particles is kN_B .

The rate coefficient for elastic scattering between two species with non-isothermal Maxwellian distributions is then

$$\tilde{\nu}_{AB} = \left[\frac{8k_B}{\pi} \left(\frac{T_A}{M_A} + \frac{T_B}{M_B} \right) \right]^{1/2}$$

-8-

where

$$\tilde{\epsilon}_{\text{rel}} = \frac{1}{2} \frac{M_A M_B v^2}{k_B (M_A T_B + M_B T_A)}.$$

and

$$k(T) = \langle \nu_{AB} \rangle \int_0^\infty \sigma(\epsilon) \epsilon \exp(-\epsilon) d\epsilon \quad (\text{cm}^3 \text{s}^{-1})$$

For isothermal distributions $T_A = T_B = T$, the rate is

$$k(T_c) = \langle \nu_c \rangle \int_0^\infty \sigma(\epsilon_c) \epsilon_c \exp(-\epsilon_c) d\epsilon_c \quad (\text{cm}^3 \text{s}^{-1})$$

where $\epsilon = \frac{1}{2}M_{AB}v^2/k_B T$ and $\langle v_{AB} \rangle = (8k_B T/\pi M_{AB})^{1/2}$. The rate of collisions of electrons A at temperature T_e with a gas of heavy-particles B at temperature T_B is

$$\frac{d}{dt}[N_A \langle \mathcal{E}_{AB} \rangle] = -k_E N_A(t) N_B(t) = -v_{EB} N_A(t)$$

where $\epsilon_e = \frac{1}{2}m_e v^2/k_B T_e$ and $\langle v_e \rangle = (8k_B T_e/\pi m_e)^{1/2}$.

B2.2.3.2 ENERGY TRANSFER RATE

Each of the species A transfers energy ϵ_{AB} to each species B. The amount of energy transferred per unit volume in unit time from ensemble A to ensemble B is

$$k_E = \int f_A(\mathbf{v}_A) d\mathbf{v}_A \int f_B(\mathbf{v}_B) d\mathbf{v}_B \int \mathcal{E}_{AB}(\mathbf{v}_A, \mathbf{v}_B; \psi, \phi) v \left(\frac{d\sigma}{d\Omega} \right) d\Omega.$$

where the macroscopic rate coefficient k_E (energy $\text{cm}^3 \text{s}^{-1}$) for the averaged energy loss $\langle \epsilon_{AB} \rangle$ is

The amount of energy lost in unit time, the energy-loss frequency, is $v_{EB} = k_E N_B(t)$. The energy-loss rate coefficient for two-temperature Maxwellian distributions is

$$k_E(T_A, T_B) = \frac{2M_A M_B}{(M_A + M_B)^2} k_B (T_A - T_B) \tilde{v}_{AB} \int_0^\infty \sigma_D(\tilde{\epsilon}_{\text{rel}}) (\tilde{\epsilon}_{\text{rel}})^2 \exp(-\tilde{\epsilon}_{\text{rel}}) d\tilde{\epsilon}_{\text{rel}}$$

-9-

where $\sigma_D(\tilde{\epsilon}_{\text{rel}})$ is the momentum transfer cross section at reduced energy $\tilde{\epsilon}_{\text{rel}}$. For isothermal distributions, $T_A = T_B$ and the energy rate coefficient k_E of course then vanishes.

B2.2.3.3 TRANSPORT CROSS SECTIONS AND COLLISION INTEGRALS

Transport cross sections are defined for integer $n = 1, 2, 3, \dots$, as

$$\sigma^{(n)}(E) = 2\pi \left[1 - \frac{1 + (-1)^n}{2(n+1)} \right]^{-1} \int_{-1}^{+1} [1 - \cos^n \theta] \frac{d\sigma}{d\Omega}(\cos \theta).$$

The diffusion and viscosity cross sections are given by the transport cross sections $\sigma^{(1)}$ and $\frac{2}{3}\sigma^{(2)}$, respectively.

Collision integrals are defined for integer $s = 0, 1, 2, \dots$, as

$$\begin{aligned} \Omega^{(n,s)}(T) &= [(s+1)!(k_B T)^{s+2}]^{-1} \int_0^\infty \sigma^{(n)}(E) E^{s+1} \exp(-E/k_B T) dE \\ &= [(s+1)!]^{-1} \int_0^\infty \sigma^{(n)}(\epsilon) \epsilon^{s+1} \exp(-\epsilon) d\epsilon \end{aligned}$$

where $\epsilon = \frac{1}{2}M_{AB}v^2/k_B T$. The external factors are chosen so that these expressions for $\sigma^{(n)}$ and $\Omega^{(n,s)}$ reduce to πd^2 for classical rigid spheres of diameter d . The rate coefficient k ($\text{cm}^3 \text{s}^{-1}$) for scattering can then be expressed, in terms of the collision integral, as equal to $\bar{v}_{AB}\Omega^{(0,0)}$. The amount of energy lost per cm^3 per second by collision can be expressed in terms of $\Omega^{(1,1)}$. Tables of transport cross sections and collision integrals for $(n, 6, 4)$ ion–neutral interactions are available [2, 3].

(C) CHAPMAN–ENSKOG MOBILITY FORMULA

When ions move under equilibrium conditions in a gas and an external electric field, the energy gained from the electric field \mathbf{E} between collisions is lost to the gas upon collision so that the ions move with a constant drift speed $\mathbf{v}_d = K \mathbf{E}$. The mobility K of ions of charge e in a gas of density N is given in terms of the collision integral by the Chapman–Enskog formula [2]

$$K = \frac{3e}{16N} \left(\frac{\pi}{2Mk_B T} \right)^{1/2} [\Omega^{(1,1)}(T)]^{-1}.$$

B2.2.4 QUANTAL TRANSITION RATES AND CROSS SECTIONS

B2.2.4.1 MICROSCOPIC RATE OF TRANSITIONS

In the general elastic/inelastic collision process

the external scattering or deflection of a beam of projectile particles A (electrons, ions, atoms) by target particles B (atoms, molecules) is accompanied by transitions (electronic, vibrational, rotational) within the internal structure of either or both collision partners. For a beam with incident momentum $\mathbf{p}_i = \hbar \mathbf{k}_i$ in the range $(\mathbf{p}_i, \mathbf{p}_i + d\mathbf{p}_i)$ or directed energy $E_i \equiv (E_i, \hat{\mathbf{p}}_i)$ in the range $(E_i, E_i + dE_i)$, the translational states representing the A–B relative or external motion undergo free–free transitions $(E_i, E_i + dE_i) \rightarrow (E_f, E_f + dE_f)$ within the translational continuum, while the structured particles undergo bound–bound (excitation, de-excitation, excitation transfer) or bound–free (ionization, dissociation) transitions $i \equiv (\alpha, \beta) \rightarrow f \equiv (\alpha', \beta')$ in their internal electronic, vibrational or rotational structure. The transition frequency (s^{-1}) for this collision is

$$\frac{dW_{if}}{d\hat{\mathbf{p}}_f} (\text{s}^{-1}) = \frac{2\pi}{\hbar} \frac{1}{g_i} \sum_{i,f} |V_{fi}|^2 \rho_f(E_f)$$

which is an average over the g_i initial degenerate internal states i and a sum over all g_f final degenerate internal states f of the isolated systems A and B. It is therefore the probability per unit time for scattering from a specified E_i —(external) continuum state into unit solid angle $d\hat{\mathbf{p}}_f$ accompanied by a transition from any one of the g_i initial states (α, β) to all final internal states (α', β') of degeneracy g_f and to all final translational states $\rho_f(E_f) dE_f$ of relative motion consistent with energy conservation. The double summation $\sum_{i,f}$ is over the g_i initial and g_f final internal states of A and B with total energy ϵ_i and ϵ_f respectively.

Check: The dimension of $[|V_{ij}|^2 \rho]$ is E , $[\hbar] = Et$ so that $dW_{ij}/d\hat{\mathbf{p}}_f$ indeed has the correct dimension of t^{-1} .

(A) INTERACTION MATRIX ELEMENT

The matrix element

$$V_{fi} = \langle N_f \Phi_f | V(\mathbf{r}_A, \mathbf{r}_B, \mathbf{R}) | N_i \Psi_i^+ \rangle_{\mathbf{r}, \mathbf{R}} = V_{if}^*$$

-11-

is an integration over the internal coordinates $\mathbf{r} \equiv \mathbf{r}_A, \mathbf{r}_B$ of the electrons of A and B and over the channel vector \mathbf{R} for A–B relative motion. The matrix element of the mutual electrostatic interaction $V(\mathbf{r}_A, \mathbf{r}_B, \mathbf{R})$ couples the eigenfunction $N_i \Psi_i^+(\mathbf{R}, \mathbf{r}_A, \mathbf{r}_B)$ of $[\hat{H}_{\text{rel}} + \hat{H}_{\text{int}} + V]$ of $[\hat{\mathbf{H}}_{\text{rel}} + \hat{\mathbf{H}}_{\text{int}} + V]$ for the complete collision system for all \mathbf{R} to the final $R \rightarrow \infty$ asymptotic state $N_f \Phi_f(\mathbf{R}, \mathbf{r}_A, \mathbf{r}_B)$, which is an eigenfunction only of the unperturbed Hamiltonian $[\hat{\mathbf{H}}_{\text{rel}} + \hat{\mathbf{H}}_{\text{int}}]$. The wavefunction

$$\begin{aligned} \Psi_i^+(\mathbf{R}, \mathbf{r}_A, \mathbf{r}_B) &= \sum_j \Phi_j^+(\mathbf{R}) \psi_\alpha(\mathbf{r}_A) \phi_\beta(\mathbf{r}_B) \\ &\equiv \sum_j \Phi_j^+(\mathbf{R}) \psi_j^{\text{int}}(\mathbf{r}) \end{aligned}$$

for the full collision system with Hamiltonian $\hat{\mathbf{H}}_{\text{rel}} + \hat{\mathbf{H}}_{\text{int}} + V$ tends at asymptotic R to

$$\Psi_i^+ \sim \sum_j \left[e^{i\mathbf{k}_j \cdot \mathbf{R}} \delta_{ij} + f_{ij}(\theta, \phi) \frac{e^{i\mathbf{k}_j \cdot \mathbf{R}}}{R} \right] \psi_j^{\text{int}}(\mathbf{r})$$

which represents an incoming plane wave of unit amplitude in the incident elastic channel i and an outgoing spherical waves of amplitude f_{ij} in all channels j , including i . The Kronecker symbol means $\delta_{ij} = 1, i = j$ and $\delta_{ij} = 0, i \neq j$. The final state at infinite separation R is

$$\Phi_f(\mathbf{R}, \mathbf{r}_A, \mathbf{r}_B) = e^{i\mathbf{k}_f \cdot \mathbf{R}} \psi_{\alpha'}(\mathbf{r}_A) \phi_{\beta'}(\mathbf{r}_B) \equiv e^{i\mathbf{k}_f \cdot \mathbf{R}} \psi_f^{\text{int}}(\mathbf{r})$$

which is an eigenfunction only of $\hat{\mathbf{H}}_{\text{rel}} + \hat{\mathbf{H}}_{\text{int}}$. The plane wave of unit amplitude describes the external relative motion with Hamiltonian $\hat{\mathbf{H}}_{\text{rel}}$ and $\phi_{\alpha\beta}(\mathbf{r}_A) \psi_{\beta\alpha}(\mathbf{r}_B)$ describes the internal, isolated, normalized atomic eigenstates of A and B with internal Hamiltonian $\hat{\mathbf{H}}_{\text{int}}$. The factors $N_{i,f}$ provide the possibility of having translational (scattering) states with arbitrary amplitudes which are not necessarily unity.

(B) TRANSITION OPERATOR

The interaction matrix element can also be written as

$$V_{fi} = \langle N_f \Phi_f | \hat{T} | N_i \Phi_i \rangle$$

where the transition operator, \hat{T} , is defined by $\hat{T}\Phi = V\Psi$. The transition operator \hat{T} therefore couples states which are eigenfunctions of the same unperturbed Hamiltonian $\hat{\mathbf{H}}_{\text{rel}} + \hat{\mathbf{H}}_{\text{int}}$, in contrast to V which couples

states Ψ_i^+ and Φ_f belonging to different Hamiltonians.

-12-

B2.2.4.2 DETAILED BALANCE BETWEEN RATES

The frequency (number per second) of $i \rightarrow f$ transitions from all g_i degenerate initial internal states and from the $\rho_i d\mathbf{E}_i$ initial external translational states is equal to the reverse frequency from the g_f degenerate final internal states and the $\rho_f d\mathbf{E}_f$ final external translational states. The *detailed balance relation* between the forward and reverse frequencies is therefore

$$[g_i \rho_i d\mathbf{E}_i d\hat{\mathbf{p}}_i] \left(\frac{dW_{if}}{d\hat{\mathbf{p}}_f} \right) d\hat{\mathbf{p}}_f = [g_f \rho_f d\mathbf{E}_f d\hat{\mathbf{p}}_f] \left(\frac{dW_{fi}}{d\hat{\mathbf{p}}_i} \right) d\hat{\mathbf{p}}_i$$

since $V_{if} = V_{fi}^*$. From energy conservation $\epsilon_i + E_i = \epsilon_f + E_f$ then $dE_i = dE_f$. The differential frequencies

$$\frac{dR_{if}}{d\hat{\mathbf{p}}_f} \equiv g_i \rho_i \frac{dW_{if}}{d\hat{\mathbf{p}}_f} = g_f \rho_f \frac{dW_{fi}}{d\hat{\mathbf{p}}_i} \equiv \frac{dR_{fi}}{d\hat{\mathbf{p}}_i}$$

for the forward and reverse transitions, $i \rightleftharpoons f$, are therefore equal.

B2.2.4.3 ENERGY DENSITY OF CONTINUUM STATES

The continuum wavefunctions $\phi_p(\mathbf{R})$ for the states of the $A-B$ relative motion satisfy the orthonormality condition

$$\int \rho(\mathbf{E}) d\mathbf{E} \int \phi_p(\mathbf{R}) \phi_{p'}^*(\mathbf{R}) d\mathbf{R} = 1.$$

The number of translational states per unit volume $d\mathbf{R}$ with directed energies $\mathbf{E} \equiv (E, \hat{\mathbf{p}})$ in the range $[\mathbf{E}, \mathbf{E} + d\mathbf{E}]$ is $\rho(\mathbf{E}) d\mathbf{E}$. This orthonormality condition for continuum states is analogous to the condition $\sum_j |\langle \phi_j | \phi_i \rangle|^2 = 1$ for bound states. For plane waves, $\phi_p(\mathbf{R}) = N \exp(i\mathbf{p} \cdot \mathbf{R}/\hbar)$, then

$$\begin{aligned} \langle \phi_{p'} | \phi_p \rangle &= |N|^2 (2\pi\hbar)^3 \delta(\mathbf{p} - \mathbf{p}') = |N|^2 (2\pi)^3 \delta(\mathbf{k} - \mathbf{k}') \\ &= |N|^2 \frac{(2\pi\hbar)^3}{mp} \delta(E - E') = \frac{1}{\rho(\mathbf{E})} \delta(E - E'). \end{aligned}$$

Note, irrespective of the method chosen to normalize the wavefunctions, that

$$|N|^2 \rho(\mathbf{E}) = \frac{mp}{(2\pi\hbar)^3}$$

always. The amplitude $|N|$ does, however, depend on the choice of normalization.

-13-

(1) For momentum normalized states, $\langle \phi_{\mathbf{p}} | \phi_{\mathbf{p}'} \rangle = \delta(\mathbf{p} - \mathbf{p}')$, $|N| = (2\pi\hbar)^{-3/2}$ and the density of states $\rho(\mathbf{E}) = mp$.

(2) For wavevector normalized states, $\langle \phi_{\mathbf{p}} | \phi_{\mathbf{p}'} \rangle = \delta(\mathbf{k} - \mathbf{k}')$, $|N| = (2\pi)^{-3/2}$ and the density of states $\rho(\mathbf{E}) = (mp/\hbar^3)$.

(3) For energy-normalized states, $\langle \phi_{\mathbf{p}} | \phi_{\mathbf{p}'} \rangle = \delta(E - E')$, $\rho(\mathbf{E}) = 1$ and $|N| = (mp/\hbar^3)^{1/2}$.

(4) For waves with unit amplitude, $|N| = 1$ and $\rho(\mathbf{E}) = (mp/\hbar^3)$.

Note that $\langle \phi_{\mathbf{p}} | \phi_{\mathbf{p}'} \rangle \rho(\mathbf{E}) d\mathbf{E}$ is dimensionless for all cases and yields unity for a single particle when integrated over all \mathbf{E} . The number of states in the phase-space element $d\mathbf{E} d\mathbf{R}$ is

$$dn = |N|^2 \rho(\mathbf{E}) d\mathbf{E} d\mathbf{R} = d\mathbf{p} d\mathbf{R} / (2\pi\hbar)^3$$

i.e. each translational state occupies a cell of phase volume $(2\pi\hbar)^3$. The density of states in the interval $[E, E + dE]$ is $\rho(E) = 4\pi\rho(\mathbf{E})$. The number of translational states per unit volume with energy in the scalar range $[E, E + dE]$ is

$$|N|^2 \rho(\mathbf{E}) d\mathbf{E} = \frac{2}{\sqrt{\pi}} \frac{(2\pi m)^{3/2}}{h^3} E^{1/2} dE.$$

Check. The number of free particles with all momenta \mathbf{p} in equilibrium with a gas bath of volume v at temperature T is the translational partition function Z_t . Since the fraction of particles with energy E is $\exp(-E/k_B T)/Z_t$, the *Maxwell distribution*

$$\begin{aligned} f_M(E) dE &= \frac{|N|^2 v \rho(\mathbf{E}) d\mathbf{E}}{Z_t} \exp(-E/k_B T) \\ &= \frac{2}{\sqrt{\pi}} (E/k_B T)^{1/2} \exp(-E/k_B T) d(E/k_B T) \end{aligned}$$

is then recovered.

CURRENT

Current is the number of particles crossing unit area in unit time. The current in a beam with directed energy E within the range $(E, E + dE)$ is

$$j dE = v |N|^2 \rho(\mathbf{E}) d\mathbf{E} = (p^2/h^3) dE.$$

-14-

The current per unit dE is the *current density* $j = (p^2/h^3)$. The *quantal expression for current*

$$\mathbf{J} \equiv \frac{\hbar}{2mi} [\phi_{\mathbf{p}}^* \nabla \phi_{\mathbf{p}} - \phi_{\mathbf{p}} \nabla \phi_{\mathbf{p}}^*]$$

when applied to the plane wave $\phi_{\mathbf{p}} = N \exp(i\mathbf{p} \cdot \mathbf{R}/\hbar)$, gives $\mathbf{j} = |N|^2 \mathbf{v}$. The current in a $(E, E + dE)$ -beam of

plane waves is then $j[\rho(\mathbf{E})d\mathbf{E}]$ so that the current density is $j(\mathbf{E}) = J\rho(\mathbf{E}) = |N|^2 v\rho(\mathbf{E})$, as before.

B2.2.4.4 INELASTIC CROSS SECTIONS

The differential cross section $d\sigma_{if}/d\hat{\mathbf{p}}_f$ for $i \rightarrow f$ transitions from any one of the g_i initial states is defined as $[dR_{if}/d\hat{\mathbf{p}}_f]/g_i j_i$, the transition frequency per unit incident current. Since current is the number of particles crossing unit area in unit time, the cross section is therefore the effective area presented by the target towards $i \rightarrow f$ internal transitions in the internal structures of the collision partners which are scattered into unit solid angle $d\hat{\mathbf{p}}_f$ about direction $\hat{\mathbf{p}}_f$ in the CM-frame.

(A) BASIC EXPRESSION FOR CROSS SECTION

The differential cross section for

collisions is therefore defined as

$$\frac{d\sigma_{if}}{d\hat{\mathbf{p}}_f} = \frac{1}{g_i j_i} \frac{dR_{if}}{d\hat{\mathbf{p}}_f} = \frac{2\pi}{\hbar} \left(\frac{\rho_i \rho_f}{j_i} \right) \frac{1}{g_i} \sum_{i,f} |\langle N_f \Phi_f | V(\mathbf{r}_A, \mathbf{r}_B, \mathbf{R}) | N_i \Psi_i^+ \rangle|^2$$

which is an average over the g_i initial internal degenerate states and a sum over the g_f final degenerate states. Since $j_i = |N_i|^2 v_i \rho_i = p_i^2/h^3$, an alternative form [4] for the cross section is

$$\frac{d\sigma_{if}}{d\hat{\mathbf{p}}_f} = \frac{2\pi}{\hbar v_i} \left(\frac{\rho_f}{g_i} \right) \sum_{i,f} |\langle N_f \Phi_f | V(\mathbf{r}_A, \mathbf{r}_B, \mathbf{R}) | \Psi_i^+ \rangle|^2.$$

B2.2.4.5 DETAILED BALANCE BETWEEN CROSS SECTIONS

When cast in terms of cross sections, the detailed balance relation in [section B2.2.4.2](#) is

$$g_i j_i(E_i) \frac{d\sigma_{if}}{d\hat{\mathbf{p}}_f} = g_f j_f(E_f) \frac{d\sigma_{fi}}{d\hat{\mathbf{p}}_i}.$$

-15-

The basic relationship satisfied by the differential cross sections for the forward and reverse $i \rightleftharpoons f$ transitions is

$$g_i p_i^2 \frac{d\sigma_{if}(E_i)}{d\hat{\mathbf{p}}_f} = g_f p_f^2 \frac{d\sigma_{fi}(E_f)}{d\hat{\mathbf{p}}_i}.$$

(A) COLLISION STRENGTHS

Collision strengths Ω_{if} exploit this detailed balance relation by being defined as

$$\Omega_{if} = g_i p_i^2 \sigma_{if}(E_i) = g_f p_f^2 \sigma_{fi}(E_f) = \Omega_{fi}.$$

They are therefore symmetrical in i and f .

(B) REACTIVE PROCESSES

For any reactive process

the detailed balance relations involving differential/integral cross sections are

$$g_A g_B p_{AB}^2 \left[\frac{d\sigma_{if}(E_{AB})}{d\hat{p}_{CD}} \right] = g_C g_D p_{CD}^2 \left[\frac{d\sigma_{fi}(E_{CD})}{d\hat{p}_{AB}} \right]$$

$$g_A g_B p_{AB}^2 \sigma_{if}(E_{AB}) = g_C g_D p_{CD}^2 \sigma_{fi}(E_{CD})$$

where $p_{JK}^2 = 2M_{JK}E_{JK}$, in terms of the reduced mass M_{JK} and relative energy E_{JK} of species J and K.

B2.2.4.6 EXAMPLES OF DETAILED BALANCE

(A) EXCITATION-DE-EXCITATION

$$e^-(E_i) + A_i \rightleftharpoons e^-(E_f) + A_f$$

$$\sigma_{if}(E_i) = \left(\frac{g_f}{g_i} \right) \left(\frac{E_f}{E_i} \right) \sigma_{fi}(E_f).$$

-16-

With energy conservation, $E_i = E_f + (\epsilon_f - \epsilon_i) \equiv E_f + \epsilon_{fi}$ the cross section for superelastic collisions ($E_f > E_i$) can be obtained from σ_{if} at energy E_i via the relation

$$\sigma_{fi}(E_i - \epsilon_{fi}) = \left(1 - \frac{\epsilon_{fi}}{E_i} \right)^{-1} \left(\frac{g_i}{g_f} \right) \sigma_{if}(E_i).$$

(B) DISSOCIATIVE RECOMBINATION/ASSOCIATIVE IONIZATION

Dissociative recombination and associative ionization are represented by the forward and backward directions of

The respective cross sections σ_{DR} and σ_{AI} are related by

$$\sigma_{DR}(E_e) = \left(\frac{g_A g_B}{g_e g_{AB^+}} \right) \left(\frac{k_{AB}^2}{k_e^2} \right) \sigma_{AI}(E_{AB})$$

where the statistical weight of each species j involved is denoted by g_j .

(C) RADIATIVE RECOMBINATION/PHOTOIONIZATION

Similarly, the cross sections for radiative recombination (RR) and for photoionization (PI), the forward and reverse directions of

are related by

$$\sigma_{\text{RR}}(E_c) = \left(\frac{g_A g_\nu}{g_e g_{A^+}} \right) \left(\frac{p_\nu^2}{p_e^2} \right) \sigma_{\text{PI}}(h\nu).$$

The photon statistical weight is $g_\nu = 2$, corresponding to the two directions of polarization of the photon. The photon energy E is related to its momentum p_ν and wavenumber k_ν and to the ionization energy $I_{n\ell}$ of the atom $A(n\ell)$ by

$$E = h\nu = p_\nu c = \hbar k_\nu c = I_{n\ell} + E_c$$

-17-

where c is the speed of light. This ratio is

$$\frac{p_\nu^2}{p_e^2} = \frac{(h\nu)^2}{(2E_c m_e c^2)} = \frac{\alpha^2 (h\nu)^2}{2E_c \epsilon_0}.$$

B2.2.4.7 FOUR USEFUL EXPRESSIONS FOR THE CROSS SECTION

The final expressions to be used for the calculation of cross sections depend on the particular choice of normalization of the continuum wavefunction for relative motion. Since it is often a vexing problem and is a continued source of confusion and error in the literature, these final expressions are worked out below. The external relative-motion part of the system wavefunction $N\Psi^+ \equiv \Psi_p(\mathbf{R}, \mathbf{r}_A, \mathbf{r}_B)$ is $N\phi_p(\mathbf{R})$. Since $|N|^2 \rho = mp/\hbar^3$, the density $\rho(\mathbf{E})$ of continuum states therefore depends on the choice of normalization factor N adopted for the continuum wave. For future reference, the amplitude N and the energy densities $\rho(\mathbf{E})$ associated with four common methods adopted for normalization of continuum waves are summarized in table B2.2.1. Also included is the amplitude N_ℓ of the corresponding radial partial wave

$$R_{\ell\ell}(r) \sim \frac{N_\ell}{r} \sin \left(kr - \frac{1}{2} \ell\pi + \eta_\ell \right)$$

of section B2.2.6.1. The external multiplicative factors $\gamma_{if} = (2\pi/\hbar)(\rho_i \rho_f / j_i)$ in the basic formula in section B2.2.4.4 for the cross section are also summarized in table B2.2.1 for the various normalization schemes. The reduced masses before and after the collision are $m_i = M_A M_B / (M_A + M_B)$ and $m_f = M_C M_D / (M_C + M_D)$, respectively.

(A) ENERGY-NORMALIZED INITIAL AND FINAL STATES

The wavefunctions

$$\chi_p = \rho^{1/2} N \Psi = (m p / 2\pi \hbar^3)^{1/2} \Psi_p(\mathbf{R}, \mathbf{r}_A, \mathbf{r}_B)$$

are energy-normalized according to

$$\langle \chi_p | \chi_{p'} \rangle = \delta(\mathbf{E} - \mathbf{E}').$$

The basic formula in [section B2.2.4.4](#) with $j_i = p_i^2 / (2\pi \hbar)^3$ yields

$$\frac{d\sigma_{if}}{d\hat{p}_f} = \frac{\pi}{k_i^2} \frac{1}{g_i} |T_{if}|^2 = \left(\frac{\hbar^2}{8\pi m_i E_i} \right) \frac{1}{g_i} |T_{if}|^2.$$

-18-

The transition probability is

$$P_{if} = |T_{if}|^2 = \sum_{i,f} \int |2\pi \langle \tilde{\chi}_f | V | \chi_i^+ \rangle|^2 d\hat{k}_i$$

the magnitude squared of the element T_{if} of the transition matrix T between χ_i^+ and $\tilde{\chi}_f$, the two energy-normalized eigenfunctions of $\hat{H}_{\text{rel}} + \hat{H}_{\text{int}} + V$ and $\hat{H}_{\text{rel}} + \hat{H}_{\text{int}}$, respectively. The detailed balance relation in this case is simply

$$|T_{if}|^2 = |T_{fi}|^2$$

thereby verifying that $|T_{if}|^2$ is indeed the $i \rightarrow f$ transition probability for transitions between all g_i initial and g_f final states. This type of normalization is convenient for *rearrangement collisions* such as *dissociative*, *radiative* and *dielectronic recombination*.

(B) UNIT AMPLITUDE INITIAL AND FINAL STATES

Here the initial and final wavefunctions with unit amplitude are Ψ_i^+ and Φ_f . They are each normalized according to

$$\langle \Psi_{p'} | \Psi_p \rangle = (2\pi)^3 \delta(\mathbf{p} - \mathbf{p}').$$

The basic expression in [section B2.2.4.4](#) with $j_i = |N_i|^2 v_i \rho_i$ and $|N_f|^2 \rho_f = m_f p_f / \hbar^3$ reduces to

$$\frac{d\sigma_{if}}{d\hat{p}_f} = \frac{v_f}{v_i} |f_{if}(\theta, \varphi)|^2$$

where the scattering amplitude is

$$f_{if} = -\frac{1}{4\pi}(2m_f/\hbar^2)\langle\Phi_f|V|\Psi_i^+\rangle$$

which couples scattering states Ψ_i^+ and Φ_f of unit amplitude. This expression is also applicable for rearrangement collisions $A + B \rightarrow C + D$ by including the reduced mass $m_f = M_C M_D / (M_C + M_D)$ of the reacted species after the collision. The integral cross section consistent with the above scattering amplitude is,

$$\sigma_{if}(E) = \frac{v_f}{v_i} \int_0^\pi d(\cos\theta) \int_0^{2\pi} |f_{if}(\theta, \varphi)|^2 d\varphi$$

-19-

at relative energy $E = k_i^2 \hbar^2 / 2M_{AB}$. The scattering amplitude consistent with the common use of

$$\sigma_{if}(E) = \frac{k_f}{k_i} \int_0^\pi d(\cos\theta) \int_0^{2\pi} |\tilde{f}_{if}(\theta, \varphi)|^2 d\varphi$$

for rearrangement collisions is

$$\tilde{f}_{if} = -\frac{1}{4\pi}(2\sqrt{m_i m_f}/\hbar^2)\langle\Phi_f|V|\Psi_i^+\rangle.$$

Both conventions are identical only for direct collisions $A(\alpha) + B(\beta) \rightarrow A(\alpha') + B(\beta')$. This normalization is customary [5] for *elastic* and *inelastic* scattering processes.

For symmetrical potentials $V(r)$ scattering is confined to a plane and f_{ij} depends only on scattering angle $\theta = \hat{\mathbf{k}}_i \cdot \hat{\mathbf{k}}_f$.

(C) MOMENTUM-NORMALIZED INITIAL AND FINAL STATES

Here the initial and final wavefunctions $\xi_{\mathbf{p}} = (2\pi\hbar)^{-3/2}\Psi_i^+$ and $\xi_{\mathbf{p}'} = (2\pi\hbar)^{-3/2}\Phi_f$ are normalized according to

$$\langle\xi_{\mathbf{p}'}|\xi_{\mathbf{p}}\rangle = \delta(\mathbf{p} - \mathbf{p}').$$

The cross section B2.2.4.4 is then

$$\frac{d\sigma_{if}}{d\hat{\mathbf{p}}_f} = \frac{v_f}{v_i} |f_{if}(\theta, \varphi)|^2$$

where the scattering amplitude [6, 7 and 8] is now

$$f_{if} = -(2\pi^2\hbar^3)(2m_f/\hbar^2)|\langle\xi_f|V|\xi_i^+\rangle|.$$

(D) ENERGY-NORMALIZED FINAL AND UNIT AMPLITUDE INITIAL STATES

Here the basic formula B2.2.4.4 yields

$$\frac{d\sigma_{if}}{d\hat{p}_f} = \frac{2\pi}{\hbar v_i} |\langle \tilde{\chi}_f | V | \Phi_i^+ \rangle|^2$$

-20-

which couples the initial scattering state Ψ_i^+ of unit amplitude with the energy-normalized final state $\tilde{\chi}_f = \rho_f^{1/2} N_f \Phi_f$. This normalization is customary for photoionization problems.

B2.2.5 BORN CROSS SECTIONS

Here an (undistorted) plane wave of unit amplitude is adopted for the channel wavefunction $\Psi_i^+ = \sum_j \Phi_j(\mathbf{R}) \psi_j^{\text{int}}(\mathbf{r})$ for the complete system. The differential cross section for elastic ($i = f$) or inelastic scattering ($i \neq f$) into $\hat{\mathbf{k}}_f(\theta, \phi)$ is then

$$\frac{d\sigma_{if}}{d\Omega} = \frac{v_f}{v_i} |f_{if}(\theta)|^2.$$

The Born scattering amplitude for A–B collisions is

$$f_{if}^{(B)}(\mathbf{K}) = -\frac{1}{4\pi} \frac{2M_{AB}}{\hbar^2} \int V_{fi}(\mathbf{R}) \exp(i\mathbf{K} \cdot \mathbf{R}) d\mathbf{R}$$

which is the Fourier transform of the interaction potential

$$V_{fi}(\mathbf{R}) = \langle \psi_f^{\text{int}}(\mathbf{r}) | V(\mathbf{r}, \mathbf{R}) | \psi_i^{\text{int}}(\mathbf{r}) \rangle$$

which couples the initial and final isolated states $\psi_j^{\text{int}}(\mathbf{r}) = \phi_j(\mathbf{r}_A) \psi_j(\mathbf{r}_B)$ of the atoms. The diagonal potential $V_{ii}(\mathbf{R})$ is the static interaction for elastic scattering. The Born scattering amplitude is a pure function only of the collisional momentum change

$$\mathbf{q} = \hbar \mathbf{K} = M_{AB}(\mathbf{v}_i - \mathbf{v}_f) = \hbar(\mathbf{k}_i - \mathbf{k}_f)$$

where \mathbf{v} is the A–B relative velocity. Since $K^2 = k_i^2 + k_f^2 - 2k_i k_f \cos\theta$, the *Born integral cross section* is

$$\begin{aligned} \sigma_{if}^B(k_i) &= \frac{2\pi}{M_{AB}^2 v_i^2} \int_{q_-}^{q_+} |f_{if}^{(B)}(q)|^2 q dq \\ &= \frac{2\pi}{(k_i a_0)^2} \int_{K_- a_0}^{K_+ a_0} |f_{if}^{(B)}(K)|^2 (K a_0) d(K a_0) \end{aligned}$$

where $q_{\pm} = \hbar K_{\pm} = \hbar|k_i \pm k_f|$ are the maximum and minimum momentum changes consistent with energy conservation. For symmetric interactions $V_{fi}(R)$, then

$$f_{if}^B(K) = -\frac{2M_{AB}}{\hbar^2} \int V_{fi}(R) \frac{\sin KR}{KR} R^2 dR.$$

B2.2.5.1 FERMİ GOLDEN RULES

Rule A. The transition rate (probability per unit time) for a transition from state Φ_i of a quantum system to a number $\rho(E) dE$ of continuum states Φ_E by an *external* perturbation V is

$$w_{if} = \frac{2\pi}{\hbar} |\langle \Phi_E | V | \Phi_i \rangle|^2 \rho_f(E) \equiv \frac{2\pi}{\hbar} |V_{i\epsilon}|^2 \rho_f(E)$$

to first order in V . Since $|V_{i\epsilon}|^2 \rho_f$ has the dimension of energy, w_{if} has the dimension t^{-1} .

Rule B. When the direct coupling $V_{i\epsilon}$ from only the initial state to the continuum vanishes, but the coupling $V_{n\epsilon} \neq 0$ for $n \neq i$, the transition can then occur via the intermediate states n at the rate

$$w_{if} = \frac{2\pi}{\hbar} \sum_n \left| \frac{V_{in} V_{n\epsilon}}{E - E_n} \right|^2 \rho_f(E).$$

These rules, A and B (which are not exact) are useful for both scattering and radiative processes and are often referenced as Fermi's Rules 2 and 1, respectively.

SCATTERING EXAMPLE

The cross section for inelastic scattering of beam of particles by potential $V(\mathbf{r}, \mathbf{R})$ is

$$\frac{d\sigma_{if}}{d\hat{\mathbf{p}}_f} = \frac{w_{if}}{J_i}.$$

A plane-wave monoenergetic beam, $\Phi_{i,f} = N_i, f \exp(i\mathbf{p}_{i,f} \cdot \mathbf{R}/\hbar) \phi_{i,f}(\mathbf{r})$ has current $j_i = |N_i|^2 v_i$ and density determined from $|N_f|^2 \rho_f(E) = M_{AB} p_f / (2\pi\hbar)^3$. Hence

$$\frac{d\sigma}{d\hat{\mathbf{p}}_f} = \frac{v_f}{v_i} \left| \frac{1}{4\pi} \frac{2M_{AB}}{\hbar^2} \int V_{fi}(\mathbf{r}) e^{i(\mathbf{p}_i - \mathbf{p}_f) \cdot \mathbf{r}/\hbar} d\mathbf{r} \right|^2.$$

Since this agrees with the first Born differential cross section for (in)elastic scattering, Fermi's Rule 2 is therefore valid to first order in the interaction V .

B2.2.5.2 ION (ELECTRON)–ATOM COLLISIONS

The electrostatic interaction between a structureless projectile ion P of charge $Z_P e$ and an atom A with nuclear charge $Z_A e$ is

$$V(\mathbf{r}, \mathbf{R}) = \frac{Z_A Z_P e^2}{R} - \sum_{j=1}^{N_A} \frac{Z_P e^2}{|\mathbf{R} - \mathbf{r}_j|}.$$

With the use of Bethe's integral

$$\int \frac{e^{i\mathbf{K} \cdot \mathbf{R}}}{|\mathbf{R} - \mathbf{r}_j|} d\mathbf{R} = \frac{4\pi}{K^2} e^{i\mathbf{K} \cdot \mathbf{r}_j}$$

the Born scattering amplitude (see B2.2.5) reduces to

$$|f_{if}^{(B)}(q)|^2 = \frac{4M_{PA}^2 Z_P^2 e^4}{q^4} |Z_A \delta_{if} - F_{if}^A(q)|^2$$

which is a function only of momentum transfer $q = \hbar K$. The dimensionless inelastic *form factor* for $i \rightarrow f$ inelastic transitions between states $\phi_{i,f}$ of atom A with Z_A electrons is defined as

$$F_{fi}^A(q) = \langle \phi_f(\mathbf{r}) | \sum_{j=1}^{Z_A} e^{i\mathbf{q} \cdot \mathbf{r}_j / \hbar} | \phi_i(\mathbf{r}) \rangle$$

where the integration is over all electron positions denoted collectively by $\mathbf{r} \equiv \mathbf{r}_j$. The integrated cross section is

$$\begin{aligned} \sigma_{if}(v_{PA}) &= \frac{8\pi Z_P^2 e^4}{v_{PA}^2} \int_{q_-}^{q_+} |Z_A \delta_{if} - F_{if}^A(q)|^2 \frac{dq}{q^3} \\ &= \frac{8\pi Z_P^2 a_0^2}{(v_{PA}/v_0)^2} \int_{K_- a_0}^{K_+ a_0} |Z_A \delta_{if} - F_{if}^A(K)|^2 \frac{d(Ka_0)}{(Ka_0)^3} \end{aligned}$$

-23-

where $v_0 = e^2/\hbar$ is the atomic unit (au) of velocity. The dimensionless momentum change $q/m_e v_0$ is Ka_0 . In the heavy-particle or high-energy limit, $q_+ \rightarrow \infty$ and

$$q_- \approx \frac{|\Delta E_{fi}|}{v_{PA}} \left[1 + \frac{\Delta E_{fi}}{2M_{PA} v_{PA}^2} \right]$$

where $\Delta E_{fi} = E_f - E_i$ is the energy lost by the projectile. Since

$$f_{if}^B(q) = f_C^{Z_P Z_A}(q) \delta_{if} + f_C^{Z_P}(q) F_{if}(q)$$

can be expressed in terms of the individual two-body amplitudes $f_{\mathbf{c}}^{z_1 z_2}$ for Coulomb elastic scattering between particles of charges z_1 and z_2 , the Born cross section for inelastic collisions can be written [9, 11, 28] in the useful form

$$\sigma_{if}^B(v_i) = \frac{2\pi}{M_{\text{eP}}^2 v_i^2} \int_{q_-}^{q_+} P_{fi}(q) \left(\frac{d\sigma}{d\Omega} \right)_{\text{el}} q \, dq$$

where $P_{fi}(q) = |F_{fi}^A(q)|^2$ is the transition probability for which the impulsive transfer of momentum q to atom A and where

$$\left(\frac{d\sigma}{d\Omega} \right)_{\text{el}} = \frac{4M_{\text{eP}}^2 Z_p^2 e^4}{q^4}$$

is the differential cross section for elastic (Coulomb) scattering with momentum q transferred from the projectile of charge $Z_p e$ to one electron of atom A.

B2.2.5.3 ATOM-ATOM COLLISIONS

The Born integral cross section for specific $(\alpha\beta) \rightarrow (\alpha'\beta')$ transitions in the collision

in terms of the atomic form factors is

$$\sigma_{\alpha\alpha'}^{\beta\beta'}(v_i) = \frac{8\pi a_0^2}{(v_i/v_0)^2} \int_{K-a_0}^{K+a_0} |Z_A \delta_{\alpha\alpha'} - F_{\alpha\alpha'}^A(K)|^2 |Z_B \delta_{\beta\beta'} - F_{\beta\beta'}^B(K)|^2 \frac{d(Ka_0)}{(Ka_0)^3}.$$

B2.2.5.4 QUANTAL AND CLASSICAL IMPULSE CROSS SECTIONS

In the impulse approximation [6, 9], the integral cross section for $(\alpha, \beta) \rightarrow (\alpha', \beta')$ transitions in A is

$$\sigma_{if}(v_i) = \frac{2\pi}{M_{\text{eB}}^2 v_i^2} \int_{q_-}^{q_+} |f_{\text{eB}}^{\beta\beta'}(q)|^2 |F_{\alpha\alpha'}^A(q)|^2 q \, dq$$

where $f_{\text{eB}}^{\beta\beta'}$ is the scattering amplitude for elastic $\beta = \beta'$ or inelastic $\beta \neq \beta'$ collisions between projectile B and an orbital electron of A. For structureless ions B, the Coulomb $f_{\text{eB}}^{\beta\beta'}(q)$ for elastic electron-ion collisions reproduces the Born approximation for B-A collisions. When Born amplitudes $f_{\text{eB}}^{\beta\beta'}(q)$ are used for fast atom B-e collisions, then the Born approximation for atom-atom collisions is also recovered for general scattering amplitudes $f_{\text{eB}}^{\beta\beta'}$. For slow atoms B, f_{eB} is dominated by s-wave elastic scattering so that $f_{\text{eB}} = -a$ and $\sigma_{\text{eB}} = 4\pi a^2$ where a is the scattering length. Then

$$\sigma_{if}(v_i) = \frac{2\pi a^2}{(v_i/v_0)^2} \int_{K-a_0}^{K+a_0} |F_{if}^A(K)|^2 (K a_0) d(K a_0)$$

which is a good approximation for collisional transitions $n'l \rightarrow n'l'$ in Rydberg atoms A. The full quantum impulse cross section [6, 9] for general $f_{\mathbf{eB}}^{\beta\beta'}$ has recently been presented in a valuable new form [28] which is the appropriate representation for direct classical correspondence. The classical impulse cross section was then defined [28] to yield the first general expression for the classical impulse cross section for $n\ell - n'\ell'$ and $n\ell - \ell'$ electronic transitions. The cross section satisfies the optical theorem and detailed balance. Direct connection with the classical binary encounter approximation (BEA) was established and the derived $n\ell - n'$ and $n\ell - \ell$ cross sections reproduce the standard BEA cross sections.

B2.2.5.5 ATOMIC FORM FACTOR AND GENERALIZED OSCILLATOR STRENGTH

In terms of the form factor $F_{if}(K)$, the generalized oscillator strength is defined as

$$f_{if}(K) = \left(\frac{2m_e E_{fi}}{q^2} \right) |F_{if}(q)|^2 = \frac{2E_{fi}^{\text{a.u.}}}{(K a_0)^2} |F_{if}(K)|^2$$

which tends to the dipole oscillator strength in the $K \rightarrow 0$ limit.

-25-

(A) SUM RULES

$$\begin{aligned} \sum_f f_{if}(K) &= \sum_f f_{if}(K) + \int_0^\infty \frac{df_{iE}}{dE} dE = N \\ \sum_f |F_{if}(K)|^2 &= \sum_f F_{if}(K) + \int_0^\infty \frac{dF_{iE}}{dE} dE \\ &= N + \sum_{j < k}^N |\langle \Psi_i | \exp(i\vec{K} \cdot (\vec{r}_j - \vec{r}_k)) | \Psi_i \rangle|^2 \end{aligned}$$

where N is the number of electrons. The summation \sum_f extends over all discrete and continuum states.

(B) ENERGY-CHANGE MOMENTS

The energy-change moments are defined as

$$\begin{aligned} S(\alpha, K) &= \sum_{f \neq i} (2\Delta E_{fi}^{\text{a.u.}})^\alpha f_{if}(K) \\ &= \sum_{f \neq i} (2\Delta E_{fi}^{\text{a.u.}})^{\alpha+1} |F_{if}(K)|^2 (K a_0)^{-2}. \end{aligned}$$

The exact energy-change moments for H(1s) are

$$\begin{aligned}
S(-1, K) &= \{1 - [1 + \frac{1}{4}(Ka_0)^2]^{-4}\}(Ka_0)^{-2} \\
S(0, K) &= 1 \\
S(1, K) &= (Ka_0)^2 + \frac{4}{3} \\
S(2, K) &= (Ka_0)^4 + 4(Ka_0)^2 + \frac{16}{3}.
\end{aligned}$$

B2.2.5.6 FORM FACTORS FOR ATOMIC HYDROGEN

The probability of a transition $i \rightarrow f$ resulting from any external perturbation which impulsively transfers momentum \mathbf{q} to the internal momenta of the electrons of the target system is

$$P_{if}(\mathbf{q}) = |F_{fi}(\mathbf{q})|^2.$$

-26-

The impulse can be due to sudden collision with particles or to exposure to electromagnetic radiation. The physical significance of the form factor is that P_{if} is the impulsive transition probability for any atom. For $nl \rightarrow n'l'$ transitions in atomic hydrogen,

$$P_{nl,n'l'}(\mathbf{q}) = \sum_{m,m'} |\langle \Psi_{nlm}(\mathbf{r}) | e^{i\mathbf{q}\cdot\mathbf{r}/\hbar} | \Psi_{n'l'm'}(\mathbf{r}) \rangle|^2,$$

with $\Psi(\mathbf{r}) = R_{nl}(r)Y_{lm}(\hat{\mathbf{r}})$, can be decomposed as

$$P_{nl,n'l'}(\mathbf{q}) = (2l+1)(2l'+1) \sum_{L=|l-l'|}^{l+l'} (2L+1) \begin{pmatrix} L & l & l' \\ 0 & 0 & 0 \end{pmatrix}^2 [f_{nl,n'l'}^{(L)}(q)]^2$$

where (\dots) is the Wigner's $3j$ -symbol and $f_{nl,n'l'}^{(L)}(q)$ is the radial integral

$$f_{nl,n'l'}^{(L)}(q) = \int_0^\infty R_{nl}(r)R_{n'l'}(r)j_L(qr)r^2 dr$$

where j_L is the modified Bessel function. For $nlm \rightarrow n'l'm'$ subshell transitions, the amplitude decomposes as

$$F_{nlm,n'l'm'}(\mathbf{q}) = 4\pi \sum_{L=|l-l'|}^{l+l'} i^L w_{lm'l'm'}^{(L)} f_{nl,n'l'}^{(L)}(q) Y_{L,M}(\hat{\mathbf{q}})$$

where $M = m - m'$ and where the coefficients

$$w_{lm'l'm'}^{(L)} = \left[\frac{(2l+1)(2l'+1)(2L+1)}{4\pi} \right]^{\frac{1}{2}} \begin{Bmatrix} L & l & l' \\ M & -m & m' \end{Bmatrix} \begin{Bmatrix} L & l & l' \\ 0 & 0 & 0 \end{Bmatrix}.$$

Exact algebraic expressions for the probability

$$P_{n,n'}(q) = \sum_{l'l'} \sum_{m,m'} |\langle n'l'm' | e^{iq \cdot r/\hbar} | nlm \rangle|^2$$

of $n \rightarrow n'$ transitions in atomic hydrogen, have been recently derived [11] as analytical functions of n and n' .

B2.2.5.7 ROTATIONAL EXCITATION

For ion-point dipole D interactions, only $\Delta J = \pm 1$ transitions are allowed. For ion-point quadrupole Q interactions only $\Delta J = 0, \pm 2$ transitions are allowed. The Born differential cross sections for $j \rightarrow J$ transitions are

-27-

$$\begin{aligned} \frac{d\sigma^{(d)}}{d\hat{k}_f}(J \rightarrow J+1) &= \frac{4}{3} \frac{k_f}{k_i} \left(\frac{J+1}{2J+1} \right) \frac{D^2}{K^2} \\ \frac{d\sigma^{(q)}}{d\hat{k}_f}(J \rightarrow J) &= \frac{4}{45} \frac{J(J+1)}{(2J-1)(2J+3)} Q^2 \\ \frac{d\sigma^{(q)}}{d\hat{k}_f}(J \rightarrow J+2) &= \frac{2}{15} \frac{k_f}{k_i} \frac{(J+1)(J+2)}{(2J+1)(2J+3)} Q^2 \end{aligned}$$

which are all spherical symmetrical. The sum

$$\sum \frac{d\sigma^{(q)}}{d\hat{k}_f}(J \rightarrow J, J \pm 2) = \frac{4}{45} Q^2$$

is independent of the initial value of J . The integral cross sections

$$\begin{aligned} \sigma^{(d)}(J \rightarrow J+1) &= \frac{8\pi}{3k_i^2} \left(\frac{J+1}{2J+1} \right) \ln \left(\frac{k_i+k_f}{k_i-k_f} \right) D^2 \\ \sigma^{(q)}(J \rightarrow J, J+2) &= \frac{8\pi}{15} \frac{k_f}{k_i} \frac{(J+1)(J+2)}{(2J+1)(2J+3)} Q^2 \end{aligned}$$

all satisfy the detailed balance relation

$$k_i^2(2J_i+1)\sigma(J_i \rightarrow J_f) = k_f^2(2J_f+1)\sigma(J_f \rightarrow J_i).$$

The summed diffusion cross sections are

$$\begin{aligned} \sigma^{(d)} &= \int \left[\sum_{J \pm 1} \frac{d\sigma}{d\hat{k}_f}(J \rightarrow J') \right] (1 - \cos \theta) d\hat{k}_f \\ &= \left(\frac{8\pi}{3k_i^2} \right) D^2 \\ \sigma^{(q)} &= (16\pi/45) Q^2. \end{aligned}$$

B2.2.5.8 LIST OF BORN CROSS SECTIONS FOR MODEL POTENTIALS

$$k^2 = (2M_{AB}/\hbar^2)E \quad K = 2k \sin \frac{1}{2}\theta$$

$$U = (2M_{AB}/\hbar^2)V \quad U/k^2 = V/E.$$

-28-

For a symmetric potential, the scattering amplitude is

$$f_B(K) = - \int U(R) \frac{\sin KR}{KR} R^2 dR.$$

The Born integral cross section is

$$\sigma_{if}^B(E) = \frac{2\pi}{k^2} \int_{K_-}^{K_+} |f_{if}^{(B)}(K)|^2 K dK$$

which is independent of the sign of the potential V .

(A) EXPONENTIAL

$$V(R) = V_0 \exp(-\alpha R)$$

$$f_B(K) = - \frac{2\alpha U_0}{(\alpha^2 + K^2)^2}$$

$$\sigma_B(E) = \frac{16}{3} \pi U_0^2 \left[\frac{3\alpha^4 + 12\alpha^2 k^2 + 16k^4}{\alpha^4(\alpha^2 + 4k^2)^3} \right] \xrightarrow{E \rightarrow \infty} \frac{4}{3} \pi \left(\frac{V_0}{E} \right) \left(\frac{U_0}{\alpha^4} \right).$$

(B) GAUSSIAN

$$V(R) = V_0 \exp(-\alpha^2 R^2)$$

$$f_B(K) = - \left(\frac{\pi^{1/2} U_0}{4\alpha^2} \right) \exp(-K^2/4\alpha^2)$$

$$\sigma_B(E) = \left(\frac{\pi^2 U_0}{8\alpha^4} \right) \left(\frac{V_0}{E} \right) [1 - \exp(-2k^2/\alpha^2)].$$

(C) SPHERICAL WELL/BARRIER

$$V(R) = V_0 \text{ for } R < a, \quad V(R) = 0 \text{ for } R > a, \quad U_0 = (2M_{AB}/\hbar^2)V_0$$

$$f_B(K) = - \frac{U_0}{K^3} [\sin Ka - Ka \cos Ka],$$

$$\sigma_B(E) = \frac{\pi}{2} \frac{V_0}{E} (U_0 a^4) [1 - (ka)^{-2} + (ka)^{-3} \sin 2ka - (ka)^{-4} \sin^2 2ka].$$

At low energies, $f_B \rightarrow (2M_{AB}/\hbar^2)V_0 a^3/3$ and the scattering is isotropic. At high energies, $\sigma_B(E) E^{-1}$.

-29-

(D) SCREENED COULOMB INTERACTION

$$V(R) = V_0 \exp(-\alpha R)/R.$$

$$f_B(K) = -\frac{U_0}{\alpha^2 + K^2}$$
$$\sigma_B(E) = \frac{4\pi U_0^2}{\alpha^2(\alpha^2 + 4k^2)}$$

where $U_0 = 2Z/a_0$. At low energies, $f_B = -U_0/\alpha^2$ is isotropic. At high energies, $\sigma_B \rightarrow \pi (V_0/E) (U_0\alpha^2)$.

(E) ELECTRON-ATOM MODEL STATIC INTERACTION

$$V(R) = -N(e^2/a_0)[Z + a_0/R] \exp(-2ZR/a_0).$$

$$f_B(\theta) = \frac{2N}{a_0} \left[\frac{2\alpha^2 + K^2}{(\alpha^2 + K^2)^2} \right] \quad \alpha = 2Z/a_0$$
$$\sigma_B(E) = \frac{\pi a_0^2 N^2 [12Z^4 + 18Z^2 k^2 a_0^2 + 7k^4 a_0^2]}{3Z^2 (Z^2 + k^2 a_0^2)^3}.$$

For atomic H (1s), $N = 1$ and $Z = 1$. For He ($1s^2$), the approximate parameters are $N = 2$ and $Z = 27/16$.

(F) POLARIZATION POTENTIAL

$$V(R) = V_0/(R^2 + R_0^2)^2$$

$$f_B(K) = -\frac{1}{4}\pi \left(\frac{U_0}{R_0} \right) \exp(-K R_0)$$
$$\sigma_B(E) = \left(\frac{\pi^3 U_0}{32 R_0^4} \right) \left(\frac{V_0}{E} \right) [1 - (1 + 4k R_0) \exp(-4k R_0)].$$

B2.2.6 QUANTAL POTENTIAL SCATTERING

The *Schrödinger* equation

$$\left(-\frac{\hbar^2}{2M_{AB}} \nabla_r^2 + V(\mathbf{r}) \right) \Psi_k^+(\mathbf{r}) = E \Psi_k^+(\mathbf{r})$$

-30-

solved subject to the asymptotic condition

$$\Psi_k^+(\mathbf{r}) \sim \exp(i\mathbf{k} \cdot \mathbf{r}) + \frac{1}{r} f(\theta, \phi) \exp(ikr)$$

for outgoing spherical waves is equivalent to the solution of the Lippman–Schwinger integral equation

$$\Psi_{\mathbf{k}}^+(\mathbf{r}) = \Phi_{\mathbf{k}}^+(\mathbf{r}) + \int G(\mathbf{r}, \mathbf{r}') U(\mathbf{r}') \Psi_{\mathbf{k}}^+(\mathbf{r}') d\mathbf{r}'$$

where the outgoing Green's function for a free particle is

$$G(\mathbf{r}, \mathbf{r}') = -\frac{1}{4\pi} \frac{\exp\{ik|\mathbf{r} - \mathbf{r}'|\}}{|\mathbf{r} - \mathbf{r}'|}.$$

Solution of the scattering amplitude may then be determined from the asymptotic form of $\Psi_{\mathbf{k}}^+(\mathbf{r})$ directly or from the integral representation

$$f(\theta, \phi) = -\frac{1}{4\pi} (2M_{AB}/\hbar^2) (\exp(i\mathbf{k}_f \cdot \mathbf{r}) |V(\mathbf{r})| \Psi_i^+).$$

The differential cross section for elastic scattering is

$$\frac{d\sigma}{d\Omega} = |f(\theta, \phi)|^2.$$

B2.2.6.1 PARTIAL WAVE EXPANSION

A plane wave of unit amplitude can be decomposed according to

$$\Phi_{\mathbf{k}}(\mathbf{r}) = \exp(i\mathbf{k} \cdot \mathbf{r}) = 4\pi \sum_{\ell, m} i^\ell j_\ell(kr) Y_{\ell m}^*(\hat{\mathbf{k}}) Y_{\ell m}(\hat{\mathbf{r}})$$

where j_ℓ is the spherical Bessel function which varies asymptotically as

$$j_\ell(kr) \sim \frac{1}{kr} \sin\left(kr - \frac{1}{2}\ell\pi\right).$$

-31-

The addition theorem for spherical harmonics is

$$4\pi \sum_m Y_{\ell m}^*(\hat{\mathbf{k}}) Y_{\ell m}(\hat{\mathbf{r}}) = (2\ell + 1) P_\ell(\hat{\mathbf{k}} \cdot \hat{\mathbf{r}}).$$

Another useful identity is,

$$\frac{\sin Kr}{Kr} = 4\pi \sum_{\ell, m} j_\ell(k_i r) j_\ell(k_f r) Y_{\ell m}(\hat{\mathbf{k}}_i) Y_{\ell m}^*(\hat{\mathbf{k}}_f)$$

where $K^2 = k_i^2 + k_f^2 - 2k_i k_f \cos \theta$. The system wavefunction $\Psi_{\mathbf{k}}^+(\mathbf{r}) \sim N \Phi_{\mathbf{k}}$ with amplitude N is expanded according to

$$\begin{aligned}\Psi_{\mathbf{k}}^+(\mathbf{r}) &= \sum_{\ell,m} i^\ell e^{i\eta_\ell} R_{\ell\ell}(r) Y_{\ell m}^*(\hat{\mathbf{k}}) Y_{\ell m}(\hat{\mathbf{r}}) \\ &= \frac{4\pi N}{kr} \sum_{\ell,m} i^\ell F_{\ell\ell}(r) Y_{\ell m}^*(\hat{\mathbf{k}}) Y_{\ell m}(\hat{\mathbf{r}}).\end{aligned}$$

The radial wave F_ℓ is the solution of the radial Schrödinger equation

$$\frac{d^2 F_\ell}{dr^2} + \left[k^2 - \left\{ U(r) + \frac{\ell(\ell+1)}{r^2} \right\} \right] F_\ell(r) = 0.$$

The reduced potential and energy are $U(r) = (2M_{AB}/\hbar^2)V(r)$ and $K^2 = (2M_{AB}/\hbar^2)E$, respectively. They both have dimensions of $[a_0^{-2}]$. Also $(ka_0)^2 = (2E/\varepsilon_0)(M_{AB}/m_e)$. Each ℓ -partial wave is separately scattered since the angular momentum of relative motion is conserved for central forces. The radial waves $R_{\ell\ell}(r)$ and $F_{\ell\ell}(r)$ vary asymptotically as

$$\begin{aligned}R_{\ell\ell}(r) &\sim \frac{N_\ell}{r} \sin(kr - \frac{1}{2}\ell\pi + \eta_\ell) \\ F_{\ell\ell}(r) &\sim e^{i\eta_\ell} \sin(kr - \frac{1}{2}\ell\pi + \eta_\ell).\end{aligned}$$

The amplitude of the partial radial wave $R_{\ell\ell}(r)$ is $N_\ell = 4\pi N/k$. In table B2.2.1 are displayed the amplitudes N and N_ℓ appropriate to various choices for normalization of the continuum wavefunctions $\Psi_{\mathbf{k}}(r)$.

Table B2.2.1 Continuum wavefunction normalization, density of states and cross section factors.

Type	$\langle \Phi_{\mathbf{k}'} \Phi_{\mathbf{k}} \rangle$	N	N_ℓ	$\rho(E)$	γ_{if}
Unit amplitude	$\left\{ \begin{array}{l} (2\pi)^3 \delta(\mathbf{k} - \mathbf{k}') \\ (2\pi\hbar)^3 \delta(\mathbf{p} - \mathbf{p}') \end{array} \right\}$	1	$\frac{4\pi}{k}$	mp/\hbar^3	$\frac{v_f}{v_i} \left(\frac{1}{4\pi} \right)^2 \left(\frac{2m_f}{\hbar^2} \right)^2$
Wavenumber	$\delta(\mathbf{k} - \mathbf{k}')$	$(2\pi)^{-3/2}$	$\left(\frac{2}{\pi} \right)^{1/2} \frac{1}{k}$	mp/\hbar^3	$\frac{v_f}{v_i} (2\pi^2)^2 \left(\frac{2m_f}{\hbar^2} \right)^2$
Momentum	$\delta(\mathbf{p} - \mathbf{p}')$	$(2\pi\hbar)^{-3/2}$	$\left(\frac{2}{\pi\hbar} \right)^{1/2} \frac{1}{k}$	mp	$\frac{v_f}{v_i} (2\pi^2\hbar^3)^2 \left(\frac{2m_f}{\hbar^2} \right)^2$
Directed energy	$\delta(E - E')$	$(mp/\hbar^3)^{1/2}$	$\left(\frac{2m}{\hbar^2} \frac{1}{\pi k} \right)^{1/2}$	1	$\frac{(2\pi)^4}{k_i^2}$

B2.2.6.2 SCATTERING AMPLITUDES

For symmetric interactions $V = V(r)$, the wavefunctions $\Psi_i^+ = \sum_j \Phi_j(\mathbf{R}) \psi_j^{\text{int}}(\mathbf{r})$ and $\exp(i\mathbf{k}_f \cdot \mathbf{r})$ are

decomposed into partial waves. From their asymptotic forms, the following partial wave expansions for the scattering amplitude

$$f(\theta) = \frac{1}{2ik} \sum_{\ell=0}^{\infty} (2\ell+1) [\exp(2i\eta_{\ell}) - 1] P_{\ell}(\cos \theta)$$

$$f(\theta) = \frac{1}{2ik} \sum_{\ell=0}^{\infty} (2\ell+1) [S_{\ell}(k) - 1] P_{\ell}(\cos \theta)$$

$$f(\theta) = \frac{1}{2ik} \sum_{\ell=0}^{\infty} (2\ell+1) T_{\ell}(k) P_{\ell}(\cos \theta)$$

can be deduced. The *scattering*, *transition* and *reactance* matrix elements are defined, in terms of the *phase shift* η_{ℓ} suffered by each partial wave, as

$$S_{\ell}(k) = \exp(2i\eta_{\ell})$$

$$T_{\ell}(k) = 2i \sin \eta_{\ell} \exp(i\eta_{\ell})$$

$$K_{\ell}(k) = \tan \eta_{\ell}.$$

The asymptotic ($kr \rightarrow \infty$) form of F_{ℓ} may then be written in terms of the following linear combinations:

-33-

$$R_{\ell}(r) \sim \frac{N_{\ell}}{r} \sin(kr - \frac{1}{2}\ell\pi + \eta_{\ell})$$

$$F_{\ell}(r) \sim e^{i\eta_{\ell}} \sin(kr - \frac{1}{2}\ell\pi + \eta_{\ell}).$$

$$F_{\ell}(kr) \sim \sin(kr - \ell\pi/2) + \left(\frac{T_{\ell}}{2i}\right) e^{i(kr - \ell\pi/2)}$$

$$= -\frac{1}{2i} [e^{-i(kr - \ell\pi/2)} - S_{\ell} e^{i(kr - \ell\pi/2)}]$$

$$= e^{i\eta_{\ell}} \cos \eta_{\ell} [\sin(kr - \ell\pi/2) + K_{\ell} \cos(kr - \ell\pi/2)]$$

expressed as a combinations of standing waves (trigonometric functions), of incoming (-) and outgoing (+) spherical waves (exponential functions) and of a standing wave and an outgoing spherical wave. The physical significance of the admixture coefficients S_{ℓ} , T_{ℓ} and K_{ℓ} is then transparent. The elements are connected by

$$S_{\ell} = 1 + T_{\ell} = (1 + iK_{\ell}) / (1 - iK_{\ell})$$

K_{ℓ} is real while both S_{ℓ} and T_{ℓ} are complex. In term of the full solutions F_{ℓ} of the radial *Schrödinger* equation, the *T*-matrix element for elastic scattering is

$$T_{\ell} = -\frac{2i}{k} \int_0^{\infty} F_{\ell}^{(0)}(r) U(r) F_{\ell}(r) dr$$

where $F_{\ell}^{(0)} = (kr) j_{\ell}(kr)$ is the radial component of the final plane wave. The Born approximation to T_{ℓ} is

obtained upon the substitution $F_\ell^{(0)} = F_\ell$.

B2.2.6.3 INTEGRAL CROSS SECTIONS

$$\begin{aligned}\sigma(E) &= \frac{4\pi}{k^2} \sum_{\ell=0}^{\infty} (2\ell + 1) \sin^2 \eta_\ell \\ &= \frac{\pi}{k^2} \sum_{\ell=0}^{\infty} (2\ell + 1) |T_\ell|^2 \\ &= \frac{2\pi}{k} \sum_{\ell=0}^{\infty} (2\ell + 1) [1 - \text{Re}S_\ell].\end{aligned}$$

-34-

The semiclassical version is obtained by the substitution $mvb = (\ell + \frac{1}{2})\hbar$ so that $K^2 b^2 = (\ell + \frac{1}{2})^2$ in terms of the impact parameter b . Regarding ℓ as a continuous variable,

$$\sigma(E) = \frac{\pi}{k^2} \int_0^\infty (2\ell + 1) |T_\ell|^2 d\ell = 2\pi \int_0^\infty |T(b)|^2 b db.$$

The transition matrix $|T(b)|^2$ is therefore the probability of scattering particles with impact parameter b .

B2.2.6.4 DIFFERENTIAL CROSS SECTIONS

The differential cross section for elastic scattering is

$$\frac{d\sigma}{d\Omega} = |f(\theta)|^2 = A(\theta)^2 + B(\theta)^2$$

where the real and imaginary parts of $f(\theta)$ are, respectively,

$$\begin{aligned}A(\theta) &= \frac{1}{2k} \sum_{\ell=0}^{\infty} (2\ell + 1) \sin 2\eta_\ell P_\ell(\cos \theta) \\ B(\theta) &= \frac{1}{2k} \sum_{\ell=0}^{\infty} (2\ell + 1) [1 - \cos 2\eta_\ell] P_\ell(\cos \theta).\end{aligned}$$

Their individual contributions to the integral cross sections are

$$\begin{aligned}\int A(\theta)^2 d\Omega &= \frac{4\pi}{k^2} \sum_{\ell=0}^{\infty} (2\ell + 1) \sin^2 \eta_\ell \cos^2 \eta_\ell \\ \int B(\theta)^2 d\Omega &= \frac{4\pi}{k^2} \sum_{\ell=0}^{\infty} (2\ell + 1) \sin^4 \eta_\ell.\end{aligned}$$

(A) EXPANSION IN LEGENDRE POLYNOMIALS

When expanded as a series of Legendre polynomials $P_L(\cos \theta)$, the differential cross section has the following form

$$\frac{d\sigma(E, \theta)}{d\Omega} = \frac{1}{k^2} \sum_{L=0}^{\infty} a_L(E) P_L(\cos \theta)$$

-35-

where the coefficients

$$a_L = \sum_{\ell=0}^{\infty} \sum_{\ell'=|\ell-L|}^{\ell+L} (2\ell+1)(2\ell'+1)(\ell\ell'00 | \ell\ell'L0)^2 \sin \eta_{\ell} \sin \eta_{\ell'} \cos(\eta_{\ell} - \eta_{\ell'})$$

are determined by the phase shifts η_{ℓ} and the Clebsch–Gordon coefficients $(\ell\ell'mm' | \ell\ell'LM)$.

(B) EXAMPLE: THREE-TERM EXPANSION IN COS θ

The differential cross section can be expanded as

$$\frac{d\sigma(E, \theta)}{d\Omega} = \frac{1}{k^2} [(a_0 - \frac{1}{2}a_2) + a_1 \cos \theta + \frac{3}{2}a_2 \cos^2 \theta].$$

The coefficients are

$$\begin{aligned} a_0 &= \sum_{\ell=0}^{\infty} (2\ell+1) \sin^2 \eta_{\ell} \\ a_1 &= 6 \sum_{\ell=0}^{\infty} (\ell+1) \sin \eta_{\ell} \sin \eta_{\ell+1} \cos(\eta_{\ell+1} - \eta_{\ell}) \\ a_2 &= 5 \sum_{\ell=0}^{\infty} [b_{\ell} \sin^2 \eta_{\ell} + c_{\ell} \sin \eta_{\ell} \sin \eta_{\ell+2} \cos(\eta_{\ell+2} - \eta_{\ell})] \end{aligned}$$

where

$$\begin{aligned} b_{\ell} &= \frac{\ell(\ell+1)(2\ell+1)}{(2\ell+1)(2\ell+3)} \\ c_{\ell} &= \frac{3(\ell+1)(\ell+2)}{2\ell+3}. \end{aligned}$$

(C) EXAMPLE: S- AND P-WAVE CONTRIBUTIONS

The combined S-, P-wave ($\ell = 0, 1$) contributions to the differential and integral cross sections are

$$\frac{d\sigma}{d\Omega} = \frac{1}{k^2} [\sin^2 \eta_0 + [6 \sin \eta_0 \sin \eta_1 \cos(\eta_1 - \eta_0)] \cos \theta + 9 \sin^2 \eta_1 \cos^2 \theta]$$

$$\sigma(E) = \frac{4\pi}{k^2} [\sin^2 \eta_0 + 3 \sin^2 \eta_1].$$

-36-

For pure S-wave scattering, the differential cross section (DCS) is isotropic. For pure P-wave scattering, the DCS is symmetric about $\theta = \pi/2$, where it vanishes; the DCS rises to equal maxima at $\theta = 0, \pi$. For combined S- and P-wave scattering, the DCS is asymmetric with forward-backward asymmetry.

B2.2.6.5 OPTICAL THEOREM

The optical theorem relates the integral cross section to the imaginary part of the forward scattering amplitude by

$$\sigma(E) = (4\pi/k) \text{Im} f(0).$$

This relation is a direct consequence of the conservation of flux. The target casts a shadow in the forward direction where the intensity of the incident beam becomes reduced by just that amount which appears in the scattered wave. This decrease in intensity or shadow results from interference between the incident wave and the scattered wave in the forward direction. Figure B2.2.2 for the density $|\Psi_k^*(\mathbf{r})|$ of section B2.2.6 illustrates how this interference tends to illuminate the shadow region at the right-hand side of the target. Flux conservation also implies that the phase shifts η_ℓ are always real. Thus

$$|S_\ell|^2 = 1 \quad |T_\ell|^2 = \text{Im} T_\ell.$$

B2.2.6.6 LEVINSON'S THEOREM

For a local potential $V(r)$ which supports η_ℓ bound states of angular momentum ℓ and energy $E_n < 0$, the phase shift $\lim_{k \rightarrow 0} \eta_\ell(k)$ tends in the limit of zero collision energy to $\eta_\ell \pi$. When the well becomes deep enough so as to introduce an additional bound level $E_{n+1} = 0$ at zero energy, then $\lim_{k \rightarrow 0} \eta_0(k) = (n_0 + \frac{1}{2})\pi$.

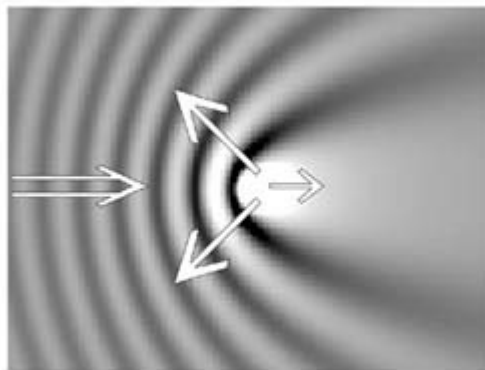

Figure B2.2.2. Scattering of an incident plane wave.

B2.2.6.7 PARTIAL WAVE EXPANSION FOR TRANSPORT CROSS SECTIONS

The transport cross sections

$$\sigma^{(n)}(E) = 2\pi \left[1 - \frac{1 + (-1)^n}{2(n+1)} \right]^{-1} \int_{-1}^{+1} [1 - \cos^n \theta] \frac{d\sigma}{d\Omega}(\cos \theta)$$

for $n = 1-4$ have the following phase shift expansions

$$\begin{aligned} \sigma^{(1)}(E) &= \frac{4\pi}{k^2} \sum_{\ell=0}^{\infty} (\ell+1) \sin^2(\eta_{\ell} - \eta_{\ell+1}) \\ \sigma^{(2)}(E) &= \frac{4\pi}{k^2} \left(\frac{3}{2}\right) \sum_{\ell=0}^{\infty} \frac{(\ell+1)(\ell+2)}{(2\ell+3)} \sin^2(\eta_{\ell} - \eta_{\ell+2}) \\ \sigma^{(3)}(E) &= \frac{4\pi}{k^2} \sum_{\ell=0}^{\infty} \frac{(\ell+1)}{(2\ell+5)} \left[\frac{(\ell+2)(\ell+3)}{(2\ell+3)} \sin^2(\eta_{\ell} - \eta_{\ell+3}) + \frac{3(\ell^2+2\ell-1)}{(2\ell-1)} \sin^2(\eta_{\ell} - \eta_{\ell+1}) \right] \\ \sigma^{(4)}(E) &= \frac{4\pi}{k^2} \left(\frac{5}{4}\right) \sum_{\ell=0}^{\infty} \frac{(\ell+1)(\ell+2)}{(2\ell+3)(2\ell+7)} \left[\frac{(\ell+3)(\ell+4)}{(2\ell+5)} \sin^2(\eta_{\ell} - \eta_{\ell+4}) + \frac{2(2\ell^2+6\ell-3)}{(2\ell-1)} \sin^2(\eta_{\ell} - \eta_{\ell-2}) \right]. \end{aligned}$$

The momentum-transfer or diffusion cross section is $\sigma^{(1)}$ and the viscosity cross section is $\frac{2}{3}\sigma^{(2)}$.

B2.2.6.8 BORN PHASE SHIFTS

For a symmetric interaction, the Born amplitude is

$$f_B(K) = - \int U(R) \frac{\sin KR}{KR} R^2 dR$$

where $U(r) = (2M_{AB}/\hbar^2)V(R)$. Comparison with the partial wave expansion for $f_B(K)$ and

$$\frac{\sin KR}{KR} = \sum_{\ell=0}^{\infty} (2\ell+1) [j_{\ell}(kR)]^2 P_{\ell}(\cos \theta)$$

provides the Born phase shift

$$\tan \eta_{\ell}^B(k) = -k \int_0^{\infty} U(R) [j_{\ell}(kR)]^2 R^2 dR.$$

(A) EXAMPLES OF THE BORN S-WAVE PHASE SHIFT

$$\tan \eta_0^B(k) = -\frac{1}{k} \int_0^\infty U(R) \sin^2(kR) dR.$$

For the potential $U = U_0 \frac{e^{-\alpha R}}{R}$

$$\tan \eta_0^B = -\frac{U_0}{4k} \ln[1 + 4k^2/\alpha^2].$$

For the potential $U = \frac{U_0}{(R^2 + R_0^2)^2}$

$$\tan \eta_0^B = -\frac{\pi U_0}{4k R_0^3} [1 - (1 + 2kR_0) e^{-2kR_0}].$$

(B) BORN PHASE SHIFTS (LARGE ℓ)

For $\ell \gg ka$,

$$\tan \eta_\ell^B = -\frac{k^{2\ell+1}}{[(2\ell+1)!!]^2} \int_0^\infty U(R) R^{2\ell+2} dR$$

valid only for finite-range interactions $U(R > a) = 0$. If $U = -U_0$, $R \leq a$ and $U = 0$, $R > a$, then

$$\tan \eta_\ell^B (\ell \gg ka) = U_0 a^2 \frac{(ka)^{2\ell+1}}{[(2\ell+1)!!]^2 (2\ell+3)}.$$

The ratio $\eta_{\ell+1}/\eta_\ell \sim (ka/2\ell)^2$.

B2.2.6.9 COULOMB SCATTERING

For elastic scattering by the interaction $V(r) = Z_A Z_B e^2/r$, the Coulomb wave can be decomposed as

$$\Psi_k^{(C)}(\mathbf{r}) = \frac{4\pi}{kr} \sum_{\ell, m} i^\ell e^{i\eta_\ell} F_{\ell\ell}(r) Y_{\ell m}^*(\hat{\mathbf{k}}) Y_{\ell m}(\hat{\mathbf{r}})$$

where the radial wave varies asymptotically as

$$F_\ell \sim \sin(kR - \frac{1}{2}\ell\pi + \eta_\ell^{(C)} - \beta \ln 2kR)$$

where the parameter β is $Z_A Z_B e^2/\hbar v$. The Coulomb phase shift is

$$\eta_\ell^{(C)} = \arg \Gamma(\ell + 1 + i\beta) = \text{Im} \ln \Gamma(\ell + 1 + i\beta)$$

to give the Coulomb S -matrix element

$$S_\ell^{(C)} = \exp[2i\eta_\ell^{(C)}] = \frac{\Gamma(\ell + 1 + i\beta)}{\Gamma(\ell + 1 - i\beta)}.$$

The Coulomb scattering amplitude is

$$f_C(\theta) = -\frac{\beta \exp[2i\eta_\ell^{(C)} - i\alpha \ln(\sin^2 \frac{1}{2}\theta)]}{2k \sin^2 \frac{1}{2}\theta}.$$

The Coulomb differential cross section $|f_C|^2$ is

$$\left(\frac{d\sigma}{d\Omega}\right)_{\text{Coul}} = \frac{Z_A^2 Z_B^2 e^4}{16E^2} \text{cosec}^4 \frac{1}{2}\theta.$$

This is the Rutherford scattering cross section. It is interesting to note that Born and classical theory also reproduce this cross section. Moreover,

$$\left(\frac{d\sigma}{d\Omega}\right)_{\text{Coul}}(q) = \frac{4M_{AB}^2 Z_A^2 Z_B^2}{q^4} = 4a_0^2 (M_{AB}/m_e)^2 \left[\frac{Z_A^2 Z_B^2}{(K a_0)^4} \right]$$

is a function only of the momentum transferred $q = \hbar K = 2\hbar k \sin \frac{1}{2}\theta$ in the collision. Note that $q^2 = 8M_{AB}E \sin^2 \frac{1}{2}\theta$.

B2.2.7 COLLISIONS BETWEEN IDENTICAL PARTICLES

The identical colliding particles, each with spin s , are in a resolved state with total spin S_t in the range $(0 \rightarrow 2s)$. The spatial wavefunction with respect to particle interchange satisfies $\Psi(\mathbf{R}) = (-1)^{S_t} \Psi(-\mathbf{R})$. Wavefunctions for identical particles with even or odd total spin S_t are therefore symmetric (S) or antisymmetric (A) with respect to particle

-40-

interchange. The appropriate combinations are $\Psi_{S,A}(\mathbf{R}) = \Psi(\mathbf{R}) \pm \Psi(-\mathbf{R})$, where the positive sign (symmetric wavefunction S) and the negative sign (antisymmetric wavefunction A) are associated with even and odd values of the total spin S_t , respectively. The scattering wavefunction for a pair of identical particles in spatially symmetric (+) or antisymmetric (-) states behaves asymptotically as

$$\Psi_{S,A}(\mathbf{R}) \rightarrow [\exp(i\mathbf{k} \cdot \mathbf{R}) \pm \exp(-i\mathbf{k} \cdot \mathbf{R})] + [f(\theta, \phi) \pm f(\pi - \theta, \phi + \pi)] \frac{\exp(i\mathbf{k} \cdot \mathbf{R})}{R}.$$

The differential cross section for scattering of *both* the projectile and target particles into direction θ is

$$\left(\frac{d\sigma}{d\Omega}\right)_{S,A} = |f(\theta, \phi) \pm f(\pi - \theta, \phi + \pi)|^2$$

in the CM-frame where scattering of the projectile into polar direction $(\pi - \theta, \phi + \pi)$ is accompanied by scattering of the identical target particle into direction (θ, ϕ) . This is related to the probability that both identical particles are scattered into θ . In the classical limit, where the particles are distinguishable, the classical cross section is

$$\left(\frac{d\sigma}{d\Omega}\right)_C = |f(\theta, \phi)|^2 + |f(\pi - \theta, \phi + \pi)|^2$$

the sum of the cross sections for observation of the projectile and target particles in the direction (θ, ϕ) . Since $P_\ell[\cos(\pi - \theta)] = (-1)^\ell P_\ell(\cos \theta)$, the differential cross section for ϕ -independent amplitudes f is then

$$\left(\frac{d\sigma}{d\Omega}\right)_{S,A} = \frac{1}{4k^2} \left| \sum_{\ell=0}^{\infty} \omega_\ell (2\ell + 1) [\exp 2i\eta_\ell - 1] P_\ell(\cos \theta) \right|^2.$$

For scattering in the symmetric (S) channel where S_t is even, $\omega_\ell = 2$ for ℓ even and $\omega_\ell = 0$ for ℓ odd. For scattering in the antisymmetric channel where S_t is odd, $\omega_\ell = 0$ for ℓ even and $\omega_\ell = 2$ for ℓ odd. The integral cross section is

$$\sigma_{S,A}(E) = \frac{8\pi}{k^2} \sum_{\ell=0}^{\infty} \omega_\ell (2\ell + 1) \sin^2 \eta_\ell.$$

Let g_A and g_S be the fractions of states with odd and even total spins $S_t = 0, 1, 2, \dots, 2s$. When the $2s + 1$ spin-states S_t are unresolved, the appropriate combination of symmetric and antisymmetric cross sections is the weighted mean

-41-

$$\begin{aligned} \frac{d\sigma}{d\Omega} &= g_S \left(\frac{d\sigma}{d\Omega}\right)_S + g_A \left(\frac{d\sigma}{d\Omega}\right)_A \\ \sigma(E) &= g_S \sigma_S(E) + g_A \sigma_A(E). \end{aligned}$$

B2.2.7.1 FERMION AND BOSON SCATTERING

(A) FERMIONS

For fermions with half-integral spin s , the statistical weights are $g_S = s/(2s + 1)$ and $g_A = (s + 1)/(2s + 1)$. The differential cross section for fermion-fermion scattering is then

$$\frac{d\sigma_F}{d\Omega} = |f(\theta)|^2 + |f(\pi - \theta)|^2 - \left(\frac{2}{2s + 1}\right) \text{Re}[f(\theta)f^*(\pi - \theta)].$$

The integral cross section fermion-fermion collisions is

$$\sigma_F = \frac{1}{2}[\sigma_S + \sigma_A] - \frac{1}{2}[\sigma_S - \sigma_A]/(2s + 1)$$

which reduces, for fermions with spin- $\frac{1}{2}$, to

$$\sigma_F(E) = \frac{2\pi}{k^2} \left[\sum_{\ell=\text{even}}^{\infty} (2\ell + 1) \sin^2 \eta_\ell + 3 \sum_{\ell=\text{odd}}^{\infty} (2\ell + 1) \sin^2 \eta_\ell \right].$$

(B) BOSONS

The statistical weights for bosons with integral spin s , are $g_S = (s + 1)/(2s + 1)$ and $g_A = s/(2s + 1)$. The differential cross section for boson–boson scattering is

$$\frac{d\sigma_B}{d\Omega} = |f(\theta)|^2 + |f(\pi - \theta)|^2 + \left(\frac{2}{2s + 1} \right) \text{Re}[f(\theta)f^*(\pi - \theta)].$$

The integral cross section boson–boson collisions is

$$\sigma_B = \frac{1}{2}[\sigma_S + \sigma_A] + \frac{1}{2}[\sigma_S - \sigma_A]/(2s + 1)$$

-42-

which reduces, for bosons with zero spin, to

$$\sigma_B(E) = \frac{8\pi}{k^2} \left[\sum_{\ell=\text{even}}^{\infty} (2\ell + 1) \sin^2 \eta_\ell \right].$$

Symmetry oscillations therefore appear in the differential cross sections for fermion–fermion and boson–boson scattering. They originate from the interference between unscattered incident particles in the forward ($\theta = 0$) direction and backward scattered particles ($\theta = \pi$, $\ell = 0$). A general differential cross section for scattering of spin- s particles is

$$\frac{d\sigma}{d\Omega} = |f(\theta)|^2 + |f(\pi - \theta)|^2 + \frac{(-1)^{2s}}{2s + 1} 2 \text{Re}[f(\theta)f^*(\pi - \theta)].$$

B2.2.7.2 COULOMB SCATTERING OF TWO IDENTICAL PARTICLES

(A) TWO SPIN-ZERO BOSONS

Two spin-zero bosons (e.g. ${}^4\text{He}$ – ${}^4\text{He}$)

$$\frac{d\sigma}{d\Omega} = \frac{\beta^2}{4k^2} [\text{cosec}^4 \frac{1}{2}\theta + \sec^4 \frac{1}{2}\theta + 2\text{cosec}^2 \frac{1}{2}\theta \sec^2 \frac{1}{2}\theta \cos \gamma].$$

(B) TWO SPIN- $\frac{1}{2}$ FERMIONS

Two spin- $\frac{1}{2}$ fermions (e.g. H^+-H^+ , $e^\pm-e^\pm$)

$$\frac{d\sigma}{d\Omega} = \frac{\beta^2}{4k^2} [\operatorname{cosec}^4 \frac{1}{2}\theta + \sec^4 \frac{1}{2}\theta - \operatorname{cosec}^2 \frac{1}{2}\theta \sec^2 \frac{1}{2}\theta \cos \gamma].$$

(C) TWO SPIN-1 BOSONS

Two spin-1 bosons (e.g. deuteron–deuteron)

$$\frac{d\sigma}{d\Omega} = \frac{\beta^2}{4k^2} [\operatorname{cosec}^4 \frac{1}{2}\theta + \sec^4 \frac{1}{2}\theta + \frac{2}{3} \operatorname{cosec}^2 \frac{1}{2}\theta \sec^2 \frac{1}{2}\theta \cos \gamma].$$

(a)–(c) are the Mott formulae, where $\beta = (Ze)^2/\hbar v$ and $\gamma = 2\beta \ln(\tan \frac{1}{2}\theta)$.

B2.2.7.3 SCATTERING OF IDENTICAL ATOMS

Two ground-state hydrogen atoms, for example, interact via the $X^1\Sigma_g^+$ and $b^3\Sigma_u^+$ electronic states of H_2 . The nuclei are interchanged by rotating the atom pair by π , then by reflecting the electrons first through the midpoint of R and then through a plane perpendicular to the original axis of rotation. The mid-point reflection changes the sign only of the ungerade state wavefunction and both Σ^+ states are symmetric with respect to the plane reflection.

The cross section for scattering by the gerade potential is then the combination

$$\left(\frac{d\sigma}{d\Omega}\right)_g = \frac{1}{4} \left(\frac{d\sigma}{d\Omega}\right)_S + \frac{3}{4} \left(\frac{d\sigma}{d\Omega}\right)_A$$

of S and A cross sections which involve the phase shifts η_l^S calculated under the singlet interaction. For scattering by the ungerade triplet interaction

$$\left(\frac{d\sigma}{d\Omega}\right)_u = \frac{1}{4} \left(\frac{d\sigma}{d\Omega}\right)_A + \frac{3}{4} \left(\frac{d\sigma}{d\Omega}\right)_S$$

where the S and A cross sections involve the phase shifts η_l^T calculated under the triplet interaction. Since the electrons have statistical weights $\frac{1}{4}$ and $\frac{3}{4}$ for the Σ_g^+ and Σ_u^+ states, the differential cross section for $H(1s) - H(1s)$ scattering by both potentials is

$$\frac{d\sigma}{d\Omega} = \frac{1}{4} \left(\frac{d\sigma}{d\Omega}\right)_g + \frac{3}{4} \left(\frac{d\sigma}{d\Omega}\right)_u.$$

These combinations also hold for the integral cross sections.

(C) SCATTERING OF INCIDENT BEAM ALONE

Since the current of incident particles $j_i = 2v$, the cross sections presented by the target (i.e. the number of incident particles removed from the beam in unit time per unit incident current) are 1/2 of all those above. For example,

$$\left(\frac{d\sigma}{d\Omega}\right)_{S,A}^I = \frac{1}{2}|f(\theta) \pm f(\pi - \theta)|^2 = \frac{1}{2}\left(\frac{d\sigma}{d\Omega}\right)_{S,A}$$

and

$$\sigma_{S,A}^I(E) = \frac{1}{2}\sigma_{S,A}(E).$$

B2.2.8 QUANTAL INELASTIC HEAVY-PARTICLE COLLISIONS

The wavefunction for the complete A–B collision system satisfies the Schrödinger equation

$$\begin{aligned} \mathcal{H}(\mathbf{r}, \mathbf{R})\Psi(\mathbf{r}, \mathbf{R}) &= \left[\hat{H}_{\text{int}}(\mathbf{r}) - \frac{\hbar^2}{2M_{AB}}\nabla_{\mathbf{R}}^2 + V(\mathbf{r}, \mathbf{R}) \right] \Psi(\mathbf{r}, \mathbf{R}) \\ &= E\Psi(\mathbf{r}, \mathbf{R}) \end{aligned}$$

where the internal Hamiltonian is the sum $\hat{H}_{\text{int}}(\mathbf{r}) = H_A(\mathbf{r}_A) + H_B(\mathbf{r}_B)$ of individual Hamiltonians $H_{A,B}$ for each isolated atomic or molecular species. The total energy (internal plus relative)

$$E = \frac{\hbar^2 k_i^2}{2M_{AB}} + \epsilon_i = \frac{\hbar^2 k_f^2}{2M_{AB}} + \epsilon_f$$

remains constant for all channels f throughout the collision. The combined internal energy ϵ_i of A and B at infinite separation R is $\epsilon_i(A) + \epsilon_i(B)$ which are the eigenvalues of the internal Hamiltonian \hat{H}_{int} corresponding to the combined eigenstates $\Phi_A(\mathbf{r}_A)\Phi_B(\mathbf{r}_B)$. There are two limiting formulations (*diabatic* and *adiabatic*) for describing the relative motion. These depend on whether the mutual electrostatic interaction $V(\mathbf{r}, \mathbf{R})$ between A and B at nuclear separation R , or the variation in the kinetic energy of relative motion, is considered to be a perturbation to the system, i.e. on whether the incident speed v_i is fast or slow in comparison with the internal motions, e.g. with the electronic speed of the electrons bound to A and B.

B2.2.8.1 ADIABATIC FORMULATION (KINETIC COUPLING SCHEME)

When relaxation of the internal motion during the collision is fast compared with the slow collision speed v_i , or when the relaxation time is short compared with the collision time, the kinetic energy operator $(2M_{AB}/\hbar^2)\nabla_{\mathbf{R}}^2$ is then considered as a small perturbation to the quasi-molecular A–B system at fixed \mathbf{R} . The system wavefunction $\Psi(\mathbf{r}, \mathbf{R}) = \sum_n F_n(\mathbf{R})\Phi_n(\mathbf{r}, \mathbf{R})$ can therefore be expanded in terms of the known ‘adiabatic’ molecular wavefunctions $\Phi_n(\mathbf{r}, \mathbf{R})$ for the quasi-molecule AB at fixed nuclear separation \mathbf{R} . This set of orthonormal eigenfunctions satisfies

$$[\hat{H}_{\text{int}}(\mathbf{r}) + V(\mathbf{r}, \mathbf{R})]\Phi_n(\mathbf{r}, \mathbf{R}) = E_n(\mathbf{R})\Phi_n(\mathbf{r}, \mathbf{R}).$$

As $R \rightarrow \infty$, both $\Phi_n(\mathbf{r}, \mathbf{R})$ and the eigenenergies $E_n(\mathbf{R})$ tend, in the limit of infinite nuclear separation \mathbf{R} , to the (diabatic) eigenfunctions $\Phi_n(\mathbf{R}_A, \mathbf{R}_B) = \psi_i(\mathbf{R}_A)\phi_j(\mathbf{R}_B)$, of \hat{H}_{int} with eigenenergies ϵ_n , respectively. The substitution $\Psi(\mathbf{r}, \mathbf{R}) = \sum_n F_n(\mathbf{R})\Phi_n(\mathbf{r}, \mathbf{R})$ into the Schrödinger equation results in the following set

$$[\nabla_{\mathbf{R}}^2 + \kappa_n^2(\mathbf{R})]F_n(\mathbf{R}) = \sum_j [X_{nj} \cdot \nabla_{\mathbf{R}} + T_{nj}(\mathbf{r})]F_j(\mathbf{R})$$

-45-

of coupled equations for the relative motion functions F_n . The local momentum K_n is determined from $\kappa_n^2 = 2M_{AB}[E - E_n(\mathbf{R})]/\hbar^2$ and the coupling matrix elements are

$$X_{nj}(\mathbf{R}) = -2\langle \Phi_n(\mathbf{r}, \mathbf{R}) | \nabla_{\mathbf{R}} | \Phi_j(\mathbf{r}, \mathbf{R}) \rangle_{\mathbf{r}}$$

and

$$T_{nj}(\mathbf{R}) = -\langle \Phi_n(\mathbf{r}, \mathbf{R}) | \nabla_{\mathbf{R}}^2 | \Phi_j(\mathbf{r}, \mathbf{R}) \rangle_{\mathbf{r}}.$$

Solution of this set for $F_n(\mathbf{R})$ represents the *adiabatic close-coupling method*. The adiabatic states are normally determined (via standard computational techniques of quantum chemistry) relative to a set of axes (X', Y', Z') with the Z'-axis directed along the nuclear separation \mathbf{R} . On transforming to this set which rotates during the collision, then $\psi(\mathbf{r}', \mathbf{R}')$, for the diatomic A–B case, satisfies

$$\left[\hat{H}_0(\mathbf{r}') + V(\mathbf{r}', \mathbf{R}') - \frac{\hbar^2}{2M_{AB}R'^2} \hat{K} \right] \Psi(\mathbf{r}', \mathbf{R}') = E\Psi(\mathbf{r}', \mathbf{R}')$$

where the perturbation operator to the molecular wavefunctions in the rotating frame is

$$\hat{K} = \frac{\partial}{\partial R'} \left(R'^2 \frac{\partial}{\partial R'} \right) - (\hat{L}_{X'} - \hat{J}_{X'})^2 - (\hat{L}_{Y'} - \hat{J}_{Y'})^2$$

in terms of the operators \hat{L} and \hat{J} for the total and internal angular momentum \mathbf{L} and \mathbf{j} respectively of the collision system. Note $L_{Z'} = J_{Z'}$, for diatoms. An advantage of using this rotating system in the adiabatic treatment is that radial perturbations, which cause vibrational $v \rightarrow v'$ and electronic $nl \rightarrow n'l$ transitions, originate from the first term (radial) of \hat{K} while angular perturbations (torques) which causes rotational $j \rightarrow J'$ and electronic $nl \rightarrow n'l$ transitions originate from the angular momentum operator products $[\hat{L}_{X'}\hat{J}_{X'} + \hat{L}_{Y'}\hat{J}_{Y'}]$. The use of a rotating frame causes some complication, however, to the direct use of the asymptotic boundary condition for $\Psi(\mathbf{r}', \mathbf{R}')$.

B2.2.8.2 DIABATIC FORMULATION (POTENTIAL COUPLING SCHEME)

When relaxation of the internal motion is slow compared with the fast relative speed v_j , then Ψ is expanded in terms of the known unperturbed (diabatic) orthonormal eigenstates $\Phi_j(\mathbf{r}_A, \mathbf{r}_B) = \psi_i(\mathbf{r}_A)\phi_k(\mathbf{r}_B)$ of \hat{H}_{int} according to

$$\Psi(\mathbf{r}, \mathbf{R}) = \sum_j F_j(\mathbf{R}) \Phi_j(\mathbf{r}).$$

-46-

Substituting into the Schrödinger equation, multiplying by $\Phi_n^*(\mathbf{r})$ and integrating over \mathbf{r} , shows that the unknown functions $F_n(\mathbf{R})$ for the relative motion in channel n satisfy the infinite set of coupled equations

$$[\nabla_{\mathbf{R}}^2 + \mathcal{K}_n^2(\mathbf{R})]F_n(\mathbf{R}) = \sum_{j \neq n} U_{nj}(\mathbf{R})F_j(\mathbf{R}).$$

The reduced potential matrix elements which couple the internal states n and j are

$$U_{nj}(\mathbf{R}) = \frac{2M_{AB}}{\hbar^2} V_{nj}(\mathbf{R}) = U_{jn}^*(\mathbf{R})$$

where the electrostatic interaction averaged over states n and j is

$$V_{nj}(\mathbf{R}) = \int \Phi_n^*(\mathbf{r}) V(\mathbf{r}, \mathbf{R}) \Phi_j(\mathbf{r}) d\mathbf{r}.$$

The local wavenumber K_n of relative motion under the static interaction V_{nn} is given by

$$\mathcal{K}_n^2(\mathbf{R}) = k_n^2 - U_{nn}(\mathbf{R}).$$

The diagonal elements U_{nn} are the *distortion* matrix elements which distort the relative motion from plane waves in elastic scattering, while the off-diagonal matrix elements, U_{ij} and U_{ji} , U_{jf} which couple states i and f either directly or via intermediate channels j cause inelastic scattering and polarization contributions to elastic scattering. In contrast to the *adiabatic formulation*, radial and angular transitions originate in the *diabatic formulation* from the radial and angular components to the potential coupling elements $V_{nj}(\mathbf{R})$. The set of coupled are solved subject to the usual asymptotic ($R \rightarrow \infty$) requirement that

$$F_j(\mathbf{R}) \sim \exp(ik_i Z) \delta_{ij} + f_{ij} \exp(ik_j R)/R$$

for the elastic $i = j$ and inelastic $i \neq j$ scattered waves. In terms of the amplitude f_{ij} for scattering into direction (θ, ϕ) , the differential and integral cross sections for $i \rightarrow j$ transitions are

$$\frac{d\sigma_{ij}}{d\Omega} = \frac{v_j}{v_i} |f_{ij}(\theta, \phi)|^2$$

and

$$\sigma_{ij} = \frac{v_j}{v_i} \int_0^\pi d(\cos \theta) \int_0^{2\pi} |f_{ij}(\theta, \phi)|^2 d\phi.$$

As well as obtaining the scattering amplitude from the above asymptotic boundary conditions, f_{if} can also be obtained from the *integral representation* for the scattering amplitude is

$$f_{if}(\theta) = \langle \Phi_f(\mathbf{r}) \exp(i\mathbf{k}_f \cdot \mathbf{R}) | V(\mathbf{r}, \mathbf{R}) | \Psi(\mathbf{r}, \mathbf{R}) \rangle_{\mathbf{r}, \mathbf{R}}$$

B2.2.8.3 INELASTIC SCATTERING BY A CENTRAL FIELD

When the atom–atom or atom–molecule interaction is spherically symmetric in the channel vector \mathbf{R} , i.e. $V(\mathbf{r}, \mathbf{R}) = V(r, R)$, then the orbital l and rotational j angular momenta are each conserved throughout the collision so that an ℓ -partial wave decomposition of the translational wavefunctions for each value of j is possible. The translational wave is decomposed according to

$$F_j(\mathbf{R}) = \frac{4\pi N}{k_i R} \sum_{\ell, m} i^\ell F_{j\ell}(R) Y_{\ell m}^*(\hat{\mathbf{k}}) Y_{\ell m}(\hat{\mathbf{R}})$$

and inserted into the *adiabatic* set of coupled equations (of [section B2.2.8.2](#)). The radial wavefunction $F_{j\ell}$ is then the solution of

$$\frac{d^2 F_{j\ell}}{dR^2} + \left[k_i^2 - \left\{ U_{ii}(R) + \frac{\ell(\ell+1)}{R^2} \right\} \right] F_{j\ell}(R) = \sum_{j \neq i} U_{ij}(R) F_{j\ell}(R)$$

which is the direct generalization of the quantal radial equation for potential scattering to directly include other channels $j \neq i$. The coupled equations are now solved subject to the requirements that

$$F_{i\ell}(k_i R) \sim \sin(k_i R - \ell\pi/2) + \left\{ \frac{T_{ii}^\ell}{2i} \right\} e^{i(k_i R - \ell\pi/2)}$$

for the elastic scattered wave and

$$F_{j\ell}(k_j R) \sim \left(\frac{k_i}{k_j} \right)^{\frac{1}{2}} \left\{ \frac{T_{ij}^\ell}{2i} \right\} e^{i(k_j R - \ell\pi/2)}$$

for the inelastic wave. The transition-matrix elements for elastic and inelastic scattering are

$$T_{ij}^\ell = -\frac{2i}{(k_i k_j)^{\frac{1}{2}}} \int_0^\infty F_{j\ell}^{(0)}(r) U_{ji}(r) F_{i\ell}(r) dr$$

where $F_{j\ell}^{(0)} = (k_f r) j_\ell(k_f r)$ and $F_{i\ell}(r)$ are the solutions of these coupled radial equations. The differential cross section for inelastic scattering is

$$\frac{d\sigma_{ij}}{d\Omega} = (1/4k_i^2) \left| \sum_{\ell=0}^{\infty} (2\ell + 1) T_{ij}^{\ell} P_{\ell}(\cos \theta) \right|^2.$$

The integral inelastic cross section is

$$\sigma_{ij}(E) = \frac{\pi}{k_i^2} \sum_{\ell=0}^{\infty} (2\ell + 1) |T_{ij}^{\ell}|^2.$$

The transition matrix $\mathbf{T}^{\ell} = \{T_{ij}^{\ell}\}$ is symmetrical, $T_{ij}^{\ell} = T_{ji}^{\ell}$, and the cross sections satisfy detailed balance. Each transition matrix element $|T_{ij}^{\ell}|^2$ is the probability of an $i \rightarrow j$ transition in the target for each value ℓ of the (orbital) angular momentum of relative motion.

B2.2.8.4 TWO-STATE TREATMENT

Here all couplings are ignored except the direct couplings between the initial and final states as in a two-level atom. The coupled equations to be solved are

$$\begin{aligned} [\nabla^2 + k_i^2 - U_{ii}(\mathbf{R})]\psi_i(\mathbf{R}) &= U_{if}(\mathbf{R})\psi_f(\mathbf{R}) \\ [\nabla^2 + k_f^2 - U_{ff}(\mathbf{R})]\psi_f(\mathbf{R}) &= U_{fi}(\mathbf{R})\psi_i(\mathbf{R}). \end{aligned}$$

(A) DISTORTED-WAVE APPROXIMATION

Here all matrix elements in the two-level equations (section B2.2.8.4) are included, except the back coupling $V_{if}\Psi_f$ term which provides the influence of the inelastic channel on the elastic channel and is required to conserve probability. Distortion of the elastic and outgoing inelastic waves by the averaged (static) interactions V_{ii} and V_{ff} respectively is therefore included. The two-state equations can then be decoupled and effectively reduced to one-channel problems. An analogous static-exchange distortion approximation, where exchange between the incident and one of the target particles also follows from the two-level treatment.

(B) BORN APPROXIMATION

Here the distortion (diagonal) and back coupling matrix elements in the two-level equations (section B2.2.8.4) are ignored so that $\psi_i(\mathbf{R}) = \exp(i\mathbf{k}_i \cdot \mathbf{R})$ remains an undistorted plane wave. The asymptotic solution for ψ_f when compared with the asymptotic boundary condition then provides the Born elastic ($i = f$) or inelastic scattering amplitudes

$$f_{ij}^B(\theta, \phi) = -\frac{1}{4\pi} \frac{2M_{AB}}{\hbar^2} \int V_{fi}(\mathbf{R}) e^{i\mathbf{k} \cdot \mathbf{R}} d\mathbf{R}.$$

The momentum change resulting from the collision is $\mathbf{Q} = \hbar\mathbf{K}$ where $\mathbf{k} = \mathbf{k}_i - \mathbf{k}_f$. The Born amplitude also follows by inserting $\psi(\mathbf{r}, \mathbf{R}) = \Phi_1(\mathbf{r}) \exp i(\mathbf{k}_1 \cdot \mathbf{R})$ in the integral representation. Comparison with potential scattering shows that the elastic scattering of structured particles occurs in the Born approximation via the averaged electrostatic interaction $V_{ii}(\mathbf{R})$.

For electron-ion or ion-ion collisions, the plane waves $\exp(i\mathbf{k}_i \cdot \mathbf{R})$ are simply replaced by Coulomb waves to

provide the Coulomb–Born approximation.

B2.2.8.5 EXACT RESONANCE

The two-state equations of section B2.2.8.4 cannot, in general, be solved analytically except for the specific case of *exact resonance* when $k_i = k_f = k$ and $U_{ii} = U_{ff} = U$, $U_{if} = U_{fi}$. Then the equations can be decoupled by introducing the linear combinations $\psi^\pm(\mathbf{R}) = \frac{1}{\sqrt{2}}[\psi_i(\mathbf{R}) \pm \psi_f(\mathbf{R})]$, so the two-state set can be converted to two one-channel decoupled equations

$$[\nabla^2 + k^2 - (U \pm U_{if})]\psi^\pm(\mathbf{R}) = 0.$$

The problem has therefore been reduced to potential scattering by the interactions $U_\pm = (U \pm U_{if})$ associated with elastic scattering amplitudes f^\pm . Hence the elastic ($i = f$) and ‘inelastic’ ($i \neq f$) amplitudes are

$$f_{ii} = (f^+ + f^-)/2 \quad f_{if} = (f^+ - f^-)/2.$$

In terms of the phase shifts η_l^\pm associated with potential scattering by U_\pm , the amplitudes for elastic and inelastic scattering are then

$$f_{in}(\theta) = \frac{1}{2ik} \sum_{l=0}^{\infty} (2l+1) [(e^{2i\eta_l^+} + e^{2i\eta_l^-})/2 - 1] P_l(\cos \theta)$$

and

$$f_{if}(\theta) = \frac{1}{2ik} \sum_{l=0}^{\infty} (2l+1) [(e^{2i\eta_l^+} - e^{2i\eta_l^-})/2 - 1] P_l(\cos \theta).$$

The corresponding differential cross sections $|f_{if}|^2$ will therefore exhibit interference oscillations. The integral cross sections are

$$\sigma_{ii} = \frac{4\pi}{k^2} \sum_{l=0}^{\infty} (2l+1) \left[\left(\frac{1}{2} \sin^2 \eta_l^+ + \sin^2 \eta_l^- \right) / - \frac{1}{4} \sin^2(\eta_l^+ - \eta_l^-) / 4 \right]$$

and

$$\sigma_{if} = \frac{\pi}{k^2} \sum_{l=0}^{\infty} (2l+1) \sin^2(\eta_l^+ - \eta_l^-)$$

respectively.

(A) EXAMPLES: ATOMIC COLLISIONS WITH IDENTICAL NUCLEI

Important cases of *exact resonance* are the *symmetrical resonance charge transfer* collision

which converts a fast ion beam f to a fast neutral beam and the excitation transfer collision

which transfers the internal excitation in the projectile beam fully to the target atom. The electronic molecular wavefunctions divide into even (gerade) or odd (ungerade) classes upon reflection about the mid-point of the internuclear line ($\mathbf{R} \rightarrow -\mathbf{R}$). In the separated atom limit, $\psi_{g,u} \sim \phi(r_A) \pm \phi(r_B)$. The potentials U_{\pm} in the former case are the gerade and ungerade interactions $V_{g,u}$. The phase shifts for elastic scattering by the resulting gerade (g) and ungerade (u) molecular potentials of A_2^+ are, respectively, η_{ℓ}^g and η_{ℓ}^u . The charge transfer (X) and transport cross sections are then

$$\begin{aligned}\sigma_X(E) &= \frac{\pi}{k^2} \sum_{\ell=0}^{\infty} (2\ell + 1) \sin^2(\eta_{\ell}^g - \eta_{\ell}^u) \\ \sigma_{u,g}^{(1)}(E) &= \frac{4\pi}{k^2} \sum_{\ell=0}^{\infty} (\ell + 1) \sin^2(\beta_{\ell} - \beta_{\ell+1}) \\ \sigma_{u,g}^{(2)}(E) &= \frac{4\pi}{k^2} \left(\frac{3}{2}\right) \sum_{\ell=0}^{\infty} \frac{(\ell + 1)(\ell + 2)}{(2\ell + 3)} \sin^2(\beta_{\ell} - \beta_{\ell+2}).\end{aligned}$$

-51-

For ungerade potentials, $\beta_{\ell} = \eta_{\ell}^g$ for ℓ even and η_{ℓ}^u for ℓ odd. For gerade potentials, $\beta_{\ell} = \eta_{\ell}^u$ for ℓ even and η_{ℓ}^g for ℓ odd. The diffusion cross section $\sigma_{u,g}^{(1)}$ contains (g/u) interference. The viscosity cross section $\sigma_{u,g}^{(2)}$ does not. For charge transfer between the heavier rare gas ions Rg^+ with their parent atoms Rg , the degenerate states at large internuclear separations are not s states but p states. The states are then $\Sigma_{g,u}$ which arise from the p state with $m = 0$ and $\Pi_{g,u}$ which arises from $m = \pm 1$ with space quantization along the molecular axis. Since there is no coupling between molecular states of different electronic angular momentum, the scattering by the $^2\Sigma_{g,u}$ pair and the $^2\Pi_{g,u}$ pair of Ne_2^+ potentials (for example) is independent. The cross section is therefore the combination

$$\sigma_{el,X}(E) = \frac{1}{3}\sigma_{\Sigma}(E) + \frac{2}{3}\sigma_{\Pi}(E)$$

of cross sections σ_{Σ} and σ_{Π} for the individual contributions arising from the isolated $^2\Sigma_{g,u}$ and $^2\Pi_{g,u}$ states to elastic el or charge-transfer X scattering. See [12, 13] for further details on excitation-transfer and charge-transfer collisions.

(B) SINGLET-TRIPLET SPIN-FLIP CROSS SECTION

This cross section is

$$\sigma_{\text{ST}}(E) = \frac{\pi}{k^2} \sum_{\ell=0}^{\infty} (2\ell + 1) \sin^2(\ell^s - \ell^t)$$

where $\eta_{\ell}^{s,t}$ are the phase shifts for individual potential scattering by the singlet and triplet potentials, respectively.

B2.2.8.6 PARTIAL WAVE ANALYSIS

In order to reduce the three-dimensional *diabatic* or *adiabatic* set of coupled equations for atom–atom and atom–molecule scattering to a corresponding working set of coupled radial equations, analogous to those in [section B2.2.8.3](#), the orbital angular momentum l of relative motion must be distinguished from the combined internal angular momentum j associated with the internal (rotational and electronic) degrees of freedom of the partners A and B at rest at infinite separation R . Both the orbital angular momentum l of relative motion and the internal angular momentum j of the atomic electrons or of molecular rotation are in general coupled. The total angular momentum $J = l + j$ and its component J_z along some fixed direction (of incidence) are each conserved. Angular momentum may therefore be exchanged between the internal (rotational) and translational (orbital) degrees of freedom via the couplings $V_{\text{nm}}(\mathbf{R})$ or $\hat{\mathbf{k}}$. Partial wave analysis is an exercise in angular momentum coupling and is well-established (e.g. [14]) for both the diabatic and adiabatic treatments of heavy-particle collisions.

-52-

B2.2.9 ELECTRON–ATOM INELASTIC COLLISIONS

B2.2.9.1 CLOSE-COUPPLING EQUATIONS FOR ELECTRON–ATOM (ION) COLLISIONS

A partial wave decomposition provides the full close-coupling quantal method for treating A–B collisions, electron–atom, electron–ion or atom–molecule collisions. The method [15] is summarized here for the inelastic processes

at collision speeds less or comparable with those target electrons actively involved in the transition. It is based upon an expansion of the total wavefunction Ψ for the $(e^- - A)$ - multi-electron system in terms of a sum of products of the known atomic target state wavefunctions $|\Phi_i\rangle$ and the unknown functions $F_i(r)$ for the relative motion. Here

$$\Psi^\Gamma(\mathbf{r}_1, \dots, \mathbf{r}_N; \mathbf{r}) = \mathcal{A} \sum_i \Phi_i^\Gamma(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_N; \hat{\mathbf{r}}) \frac{1}{r} F_i^\Gamma(r)$$

involves a sum over all discrete and an integral over the continuum states of the target. The operator \mathcal{A} antisymmetrizes the summation with respect to exchange of all pairs of electrons in accordance with the Pauli exclusion principle. The angular and spin momenta (denoted collectively by $\hat{\mathbf{r}}$) of the projectile electron have been coupled with the orbital and spin angular momenta of the target states $|\Phi_i\rangle$ to produce the ‘channel functions’ $\Phi_i^{LS\pi}(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_i; \hat{\mathbf{r}})$ which are eigenstates of the total orbital L , total spin S angular momentum, their Z -components M_L, M_S and parity π . The set $\Gamma \equiv LSM_L M_S \pi$ of quantum numbers are therefore conserved throughout the collision. By substituting the expansion for Ψ^Γ into the Schrödinger equation.

$$H_{N+1}\Psi^\Gamma = \left[\sum_{i=1}^{N+1} \left(-\frac{1}{2}\nabla_i^2 - \frac{Z}{r_i} \right) + \sum_{i>j=1}^{N+1} \frac{1}{r_{ij}} \right] \Psi^\Gamma$$

expressed in *atomic units*, the radial functions for the motion of the scattered electron satisfy the infinite set of coupled *integro-differential* equations

$$\left[\frac{d^2}{dr^2} + k_i^2 - \frac{\ell_i(\ell_i + 1)}{r^2} + \frac{2(Z - N)}{r} \right] F_i^\Gamma(r) = 2 \sum_j [V_{ij}^\Gamma(r) + W_{ij}^\Gamma(r)] F_j^\Gamma(r).$$

The direct potential couplings are represented by

$$V_{ij}^\Gamma(r) = Z_P \left[\frac{Z_i}{r} \delta_{ij} + \sum_{k=1}^N \left\langle \Phi_i^\Gamma \left| \frac{1}{|\mathbf{r}_k - \mathbf{r}|} \right| \Phi_j^\Gamma \right\rangle \right].$$

-53-

The non-local exchange couplings are represented by

$$W_{ij} F_j^\Gamma(r) = \sum_{k=1}^N \left\langle \Phi_i^\Gamma \left| \frac{1}{|\mathbf{r}_k - \mathbf{r}|} \right| (\mathcal{A} - 1) \Phi_j^\Gamma F_j^\Gamma \right\rangle.$$

The direct potential gives rise to the long-range polarization attraction which is very important for low-energy scattering. The exchange potentials are short range and are extremely complicated. Additional non-local potentials that arise from various correlations (which cannot be included directly but which can be constructed from pseudostates) can also be added to the right-hand side of the equations.

Numerical solution of this set of *close-coupled equations* is feasible only for a limited number of close target states. For each N , several sets of independent solutions F_{ij} of the resulting close-coupled equations are determined subject to $F_{ij} = 0$ at $r = 0$ and to the reactance \mathbf{K} -matrix asymptotic boundary conditions,

$$F_{ij}^\Gamma \sim \sin \theta_i \delta_{ij} + K_{ij}^\Gamma \cos \theta_i$$

for n open channels characterized by $k_i^2 = 2(E - E_i) > 0$. The argument is

$$\theta_i = k_i r - \frac{1}{2} \ell_i \pi + \frac{Z - N}{k_i} \ln(2k_i r) + \sigma_i$$

where ℓ_i is the orbital angular momentum of the scattered electron and where $\sigma_i = \arg \Gamma[\ell_i + 1 - i(Z - N)k_i]$ is the Coulomb phase. For closed channels, $k_i^2 < 0$ $F_{ij} \sim C_{ij} \exp(-|k_i|r)$ as $r \rightarrow \infty$. The scattering amplitude can then be expressed in terms of the elements T_{ij} of the $(n \times n)$ \mathbf{T} -matrix which is related to the \mathbf{K} and \mathbf{S} matrices by,

$$\mathbf{T}^\Gamma = \frac{2i\mathbf{k}^\Gamma}{\mathbf{I} - i\mathbf{K}^\Gamma} = \mathbf{S}^\Gamma - \mathbf{I}.$$

The integral cross section for the transition $i \equiv \alpha_a L_i S_i \rightarrow f \equiv \alpha_f L_f S_f$ in the target atom, where α denotes the additional quantum numbers required to completely specify the state, is then

$$\sigma_{if}(k_i^2) = \frac{\pi}{k_i^2} \sum_{L, S, \pi, \ell_i, \ell_f} \frac{(2L+1)(2S+1)}{2(2L_i+1)(2S_i+1)} |T_{ij}^\Gamma|^2.$$

According to detailed balance, the collision strength

$$\Omega_{if} = k_i^2 (2L_i + 1)(2S_i + 1) \sigma_{if}(k_i^2)$$

-54-

is therefore dimensionless and is symmetric with respect to $i \rightarrow f$ interchange. Further extensions, simplifications and calculational schemes of the basic close-coupling and related methods are found in [15, 16 and 17].

With modern high-speed computers, it is feasible to solve the coupled set of radial equations only for a restricted basis set of unperturbed states $\Phi_n(\mathbf{r})$ regarded as being closely and strongly coupled. For electron-atom (molecule) collisions at low energies E , the full quantal close-coupling method is extremely successful in predicting the cross sections and shapes and widths of resonances which appear at energies E just below the various thresholds for excitation of the various excited levels. As E increases past the threshold for ionization, it becomes less successful, and is plagued by problems with convergence both in the number of the basis states and in the number of partial waves used in the expansion for ψ^Γ . Other methods for intermediate and high energies are therefore preferable. For heavy-particle collisions and for electron collisions at high energies, semiclassical versions (in section B2.2.10) of the close-coupling equations can be derived.

B2.2.9.2 CLOSE COUPLING WITH PSEUDOSTATES AND CORRELATION

(A) PSEUDOSTATES

A partial acknowledgment of the influence of higher discrete and continuum states, not included within the wavefunction expansion, is to add, to the truncated set of basis states, functions of the form $\Psi_p(\mathbf{r})\Phi_p(\mathbf{r})$ where Φ_p is not an eigenfunction of the internal Hamiltonian \hat{H}_{int} but is chosen so as to represent some appropriate average of bound and continuum states. These pseudostates can provide full polarization distortion to the target by incident electrons and allows flux to be transferred from the the open channels included in the truncated set.

(B) CORRELATION

When the initial and final internal states of the system are not well-separated in energy from other states then the closed-coupling calculation converges very slowly. An effective strategy is to add a series of correlation terms involving powers of the distance r_{ij} between internal particles of projectile and target to the truncated close-coupling expansion which already includes the important states.

B2.2.9.3 THE R-MATRIX METHOD

This method, introduced originally in an analysis of nuclear resonance reactions, has been extensively developed [15, 16 and 17] over the past 20 years as a powerful *ab initio* calculational tool. It partitions configuration space into two regions by a sphere of radius $r = a$, where r is the scattered electron coordinate. In the internal region $r > a$, the electron-atom complex behaves almost as a bound state so that a configuration

interaction expansion of the total wavefunction ψ , as in atomic structure calculations, is appropriate. In the external region the scattered electron moves in the long-range multipole potential contained in the direct electrostatic interaction, and can be accurately represented by a perturbation approach. See [15, 16 and 17] for further details, for other modern quantal approximations and for various computational methods useful for electron–atom collisions over a wide energy range.

-55-

B2.2.9.4 ELECTRON–MOLECULE COLLISIONS

The close-coupling equations are also applicable to electron–molecule collision but severe computational difficulties arise due to the large number of rotational and vibrational channels that must be retained in the expansion for the system wavefunction. In the fixed nuclei approximation, the Born–Oppenheimer separation of electronic and nuclear motion permits electronic motion and scattering amplitudes $f_{nn'}(\mathbf{R})$ to be determined at fixed internuclear separations R . Then in the adiabatic nuclear approximation the scattering amplitude for $i \equiv n, v, J \rightarrow n', v', J' \equiv f$ transitions is

$$f_{if}(\mathbf{0}) = \langle \chi_{n'v'}(\mathbf{R}) Y_{J'M'}(\hat{\mathbf{R}}) | f_{nn'}(\mathbf{r}) | \chi_{nv}(\mathbf{R}) Y_{JM}(\hat{\mathbf{R}}) \rangle$$

and cross sections can be obtained. See [15] for further details.

B2.2.10 SEMICLASSICAL INELASTIC SCATTERING

The term *semiclassical* is used in scattering theory to denote many different situations.

- (a) The use of some time-dependent classical path $\mathbf{R}(t)$ within a time-dependent quantal treatment of the response of the internal degrees of freedom of A and B to the time-varying field $V(\mathbf{R}(t))$ created by the approach of A towards B along the classical trajectory $\mathbf{R}(t)$. This procedure generalizes classical theory for potential scattering to structured collision partners and inelastic transitions.
- (b) The use of the three-dimensional *eikonal-phase* $S(\mathbf{R})$, which is the solution of the *Hamilton–Jacobi equation*, for the channel wavefunction $\psi^+(\mathbf{R})$, within the full quantal expression for the cross section.
- (c) The use of JWKB approximate solutions of the radial *Schrödinger equation* for the radial wavefunction $R_{\epsilon, \ell}$ for A–B relative motion within the full quantum treatment of the A–B collision.

B2.2.10.1 CLASSICAL PATH THEORY

The basic assumption here is the existence over the inelastic scattering region of a common classical trajectory $\mathbf{R}(t)$ for the relative motion under an appropriately averaged *central* potential $\bar{v}[R(t)]$. The interaction $V[\mathbf{r}, \mathbf{R}(t)]$ between A and B may then be considered as time-dependent. The system wavefunction therefore satisfies

$$i\hbar \frac{\partial \Psi(\mathbf{r}, t)}{\partial t} = [\hat{H}_{\text{int}}(\mathbf{r}) + V(\mathbf{r}, \mathbf{R}(t))] \Psi(\mathbf{r}, t)$$

-56-

and can be expanded in terms of the eigenfunctions Φ_n of \hat{H}_{int} as

$$\Psi(\mathbf{r}, t) = \sum_n A_n(t) \Phi_n(\mathbf{r}) \exp(-iE_n t).$$

The transition amplitudes A_n then satisfy the set

$$i\hbar \frac{\partial A_n(b, t)}{\partial t} = \sum_n A_j(b, t) V_{nj}(\mathbf{R}(t)) \exp(i\omega_{nj} t)$$

of first-order equations coupled by the matrix elements $V_{nj}(\mathbf{R})$ between states n and j with energy separation $\hbar\omega_{nj} = E_n - E_j$. Once the classical trajectory $\mathbf{R} \equiv (R(t), \theta(t), \phi = \text{constant})$ is determined from the classical equations

$$\begin{aligned} \frac{dR}{dt} &= \pm v[1 - b^2/R^2 - \bar{V}(R)/E]^{1/2} \\ \frac{db}{dt} &= \frac{vb}{R^2} \end{aligned}$$

of motion for impact parameter b and kinetic energy $E = \frac{1}{2}M_{\text{AB}}v^2$, the coupled equations are solved subject to the requirement $A_n(b, t \rightarrow -\infty) = \delta_{ni}$. Since the probability for an $i \rightarrow f$ transition is $P_{if} = |A_f(b, t \rightarrow \infty)|^2$, the differential cross section for inelastic scattering is

$$\frac{d\sigma_{if}}{d\Omega} = \sum_n P_{if}(b_n, \phi) \left\{ \frac{d\sigma_{\text{el}}}{d\Omega} \right\}$$

where $d\sigma_{\text{el}}/d\Omega$ is the differential cross section $|bdb/d(\cos\theta)|$ for elastic scattering by $\bar{V}(R)$ and where the summation is over all trajectories b_n which pass through (θ, ϕ) . The integral cross section is

$$\sigma_{if} = 2\pi \int_0^\infty |A_f(b, \infty)|^2 b db.$$

IMPACT PARAMETER METHOD

This normally refers to the use of the straight-line trajectory $R(t) = (b^2 + v^2 t^2)^{1/2}$, $\theta(t) = \arctan(b/vt)$ within the classical path treatment. See Bates [18, 19] for examples and further discussion.

B2.2.10.2 LANDAU-ZENER CROSS SECTION

The Landau-Zener transition probability is derived from an approximation to the full two-state impact-parameter treatment of the collision. The single passage probability for a transition between the diabatic surfaces $H_{11}(\mathbf{R})$ and $H_{22}(\mathbf{R})$ which cross at R_X is the Landau-Zener transition probability

$$P_{12}(R_X; b) = 1 - \exp(-2\pi |H_{12}(R_X)|^2 / \hbar v_X |H'_{11} - H'_{22}|)$$

where H_{12} is the interaction coupling states 1 and 2. The diabatic curves are assumed to have linear shapes in the vicinity of the crossing at R_X , i.e. ($H'_{11} - H'_{22} = \Delta F$) and H_{12} is assumed constant. The adiabatic surfaces

$$W^\pm = \frac{1}{2}(H_{11} + H_{22}) \pm \frac{1}{2}[(H_{11} - H_{22})^2 + 4H_{12}]$$

do not cross (avoided crossing). They are separated at R_X by $w^+ - w^- = 2H_{12}(R_X)$. The probability for remaining on the adiabatic surface is $p_{12}(R_X)$. The probability for remaining on the diabatic surface or for pseudocrossing between the adiabatic curves is $1 - P_{12}(R_X)$. The overall transition probability for both the incoming and outgoing legs of the trajectory $\mathbf{R}(t)$ is then

$$\mathcal{P}_{12} = 2P_{12}(1 - P_{12}).$$

The Landau–Zener cross section is

$$\sigma_{12} = 4\pi \int_0^{R_X} P_{12}(1 - P_{12})b \, db$$

where the variation of P_{12} on impact parameter b arises from the speed $v_X \approx v_0(1 - b^2/R_X^2)^{1/2}$ at the crossing point R_X . For rectilinear trajectories $\mathbf{R} = \mathbf{b} + v_0 \mathbf{t}$,

$$\sigma_{12}(v_0) = 4\pi R_X^2 [E_3(\alpha) - E_3(2\alpha)]$$

where $E_n(\alpha) = \int_1^\infty y^{-n} \exp(-\alpha y) dy$ is the exponential integral with argument $\alpha = 2\pi |H_{12}|^2 / \hbar V_0 \Delta f$. See Nikitin [20, 21] for more elaborate models which include interference effects arising from the phases or eikonals associated with the incoming and outgoing legs of the trajectory.

B2.2.10.3 EIKONAL THEORIES

Here the relative motion wavefunction $F_n(\mathbf{R})$ is decomposed as [22]

$$F_n(\mathbf{R}) = A_n(\mathbf{R}) \exp iS_n(\mathbf{R}) \exp(-\chi_n(\mathbf{R})).$$

-58-

The classical action, or solution of the Hamilton–Jacobi equation $\nabla S_n(\mathbf{R}) = \kappa_n(\mathbf{R})$, for relative motion under the channel interaction $V_{nn}(\mathbf{R})$, is

$$S_n(\mathbf{R}) = \mathbf{k}_n \cdot \mathbf{R} + \int_{R_0}^R (\kappa_n - \mathbf{k}_n) \cdot d\mathbf{R}_n$$

where R_0 is the initial point on the associated trajectory $\mathbf{R}_n(t)$ where $\kappa_n = \mathbf{k}_n$. The current \mathbf{j}_n in channel n , assumed elastic, satisfies the conservation condition $\nabla \cdot \mathbf{j}_n = 0$, so that χ_n is the solution of

$$\nabla_{\mathbf{R}}^2 S_n - 2(\nabla_{\mathbf{R}} S_n) \cdot (\nabla_{\mathbf{R}} \chi_n) = 0.$$

Flux in channel n is therefore lost only via transition to another state f with a probability controlled solely by A_f . When many wavelengths of relative motion can be accommodated within the range of V_{nn} , as at the higher energies favoured by the diabatic scheme, the fast \mathbf{R} -variation of F_n is mainly controlled by S_n , and the original diabatic set of coupled equations then reduce to the simpler set

$$i\hbar \frac{\partial A_f(t)}{\partial t} = \sum_{n \neq f} A_n(t) V_{fn}(\mathbf{R}_f(t)) \exp i(S_n - S_f) \exp -(\chi_n - \chi_f)$$

of first-order coupled equations. When a common trajectory $\mathbf{R}_n(t) = \mathbf{R}(t)$ under some averaged interaction $\bar{V}(\mathbf{R})$ can be assumed for all channels n then

$$S_n(\mathbf{R}) - S_f(\mathbf{R}) = \omega_{fn} t + \hbar^{-1} \int_{t_0}^t [V_{ff}(\mathbf{R}(t)) - V_{nn}(\mathbf{R}(t))] dt$$

and the classical path equations are recovered [22].

(A) AVERAGED POTENTIAL

The orbit common to all channels is found by choosing the potential governing the relative motion as the average [22]

$$\mathcal{V}(\mathbf{R}) = \langle \Psi(\mathbf{r}, \mathbf{R}) | \hat{H}_{\text{int}}(\mathbf{r}) + V(\mathbf{r}, \mathbf{R}) | \Psi(\mathbf{r}, \mathbf{R}) \rangle_{\mathbf{r}}.$$

Hamilton's equations of motion for this interaction

$$\mathcal{V}(\mathbf{R}) = \sum_n \left[|A_n|^2 + \sum_f A_f^* A_n V_{fn} \exp i(S_n - S_f) \right]$$

-59-

are therefore coupled to the set of first-order equations for the transition amplitudes $A_f(\mathbf{R})$. An essential feature is that total energy is always conserved, being continually redistributed between the relative motion and internal degrees of freedom, as motion along the trajectory proceeds. In terms of the solutions $A_f(b_j, t)$ and the differential cross section $d\sigma_{\text{el}}^{(j)}$ for elastic scattering of particles with impact parameter $b_j(\theta)$ through θ by $\bar{V}(\mathbf{R})$, the semiclassical scattering amplitude is

$$f_{if}^j(\theta) = A_f[b_j(\theta), \infty] \exp iS'_f(b_j(\theta), \infty) \{d\sigma_{\text{el}}^{(j)}/d\Omega\}^{1/2}.$$

The accumulated classical action for orbit $b_j(\theta)$ is

$$S'_f(b_j, t) = \int_{\mathbf{R}_0}^{\mathbf{R}(t)} [\kappa_f(\mathbf{R}) - k_n(\mathbf{R})] \cdot d\mathbf{R}.$$

When the same scattering angle originates from more than one impact parameter b_j , then interference effects originate from the different actions associated with the different orbits $b_j(\theta)$. The contributions arising from N -

orbits which are well-separated combine according to

$$f_{if}(\theta) = -i \sum_{j=1}^N \alpha_j \beta_j f_{if}^j(\theta).$$

The coefficients $\alpha_j = \exp\pm\pi/4$ depends on whether the scattered particle emerges on the same side (+) of the axis as it entered, as in a collision overall repulsive, or on the opposite side (-), as in an overall attractive collision. The coefficients β_j is $\exp\pm\pi/4$ according to whether the sign of $db/d\theta$ is (+) or (-). The differential cross section will therefore exhibit characteristic oscillations, directly attributable to interference between the action phases $S_r^j(b_j)$ associated with each contributing classical path $b_j(\theta)$. The analysis can be extended, as in the uniform Airy function approximation to cover orbits which are not widely separated, as for the case of rainbow scattering or of caustics, in general, where the density of paths become infinite. This theory provides the basis of the multistate orbital treatment [22] which is successful for rotational and vibrational excitation in atom-molecule and ion-molecule collisions at higher energies $E_{AB} \geq 11$ eV. Other semiclassical treatments based on the JWKB approximation to the corresponding set of coupled equations for the radial wavefunction for relative motion can be found in [23, 24 and 25].

In figure B2.2.3 cross sections for the quenching process

for collision energies E ranging from the ultracold to 1 keV are displayed. The full quantal results [26] are shown together with those calculated [27] from the semiclassical multistate orbital method [22]. It is seen that results from both methods complement and connect with each other very well, in that the quantal treatment is computationally feasible up to $E \sim 1$ eV while semiclassical procedures are feasible at the higher collision energies.

-60-

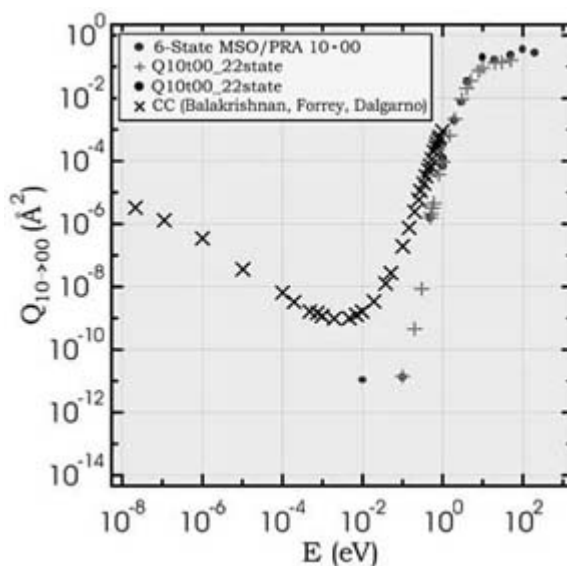

Figure B2.2.3. Vibrational relaxation cross sections (quantal and semiclassical) as a function of collision energy E .

(B) MULTICHANNEL EIKONAL METHOD

For electronic transitions in electron–atom and heavy-particle collisions at high impact energies, the major contribution to inelastic cross sections arises from scattering in the forward direction. The trajectories implicit in the action phases and set of coupled equations can be taken as rectilinear. The integral representation

$$f_{if}(\theta) = \langle \phi_f(\mathbf{r}) \exp(i\mathbf{k}_f \cdot \mathbf{R}) | V(\mathbf{r}, \mathbf{R}) | \Psi(\mathbf{r}, \mathbf{R}) \rangle_{\mathbf{r}, \mathbf{R}}$$

for the scattering amplitude, where

$$\Psi(\mathbf{r}, \mathbf{R}) = \sum_n A_n(\mathbf{R}) \phi_n(\mathbf{r}) \exp iS_n(\mathbf{R})$$

then provides the basis of the multichannel eikonal treatment [28] valuable, in particular, for heavy-particle collisions and for electron (ion)–excited atom collisions where, due to the large effect of atomic polarization (charge-induced dipole), the collision is dominated by scattering in the forward direction.

B2.2.11 LONG-RANGE INTERACTIONS

B2.2.11.1 POLARIZATION, ELECTROSTATIC AND DISPERSION INTERACTIONS

The long-range interaction $V(\mathbf{R})$ between two atomic/molecular species can be decomposed into

-61-

$$V_{\text{polarization}}(\mathbf{R}) + V_{\text{electrostatic}}(\mathbf{R}) + V_{\text{dispersion}}(\mathbf{R}).$$

The polarization interaction arises from the interaction between the ion of charge Ze and the multipole moments it induces in the atom or molecule AB. The dominant polarization interaction is the ion-induced dipole interaction

$$V_{\text{pol}}(Ze; \text{ind}D) = -\frac{\alpha_d Ze^2}{2R^4} [1 + (\alpha'_d/\alpha_d) P_2(\hat{\mathbf{s}} \cdot \hat{\mathbf{R}})]$$

where the averaged dipole polarizability is $\alpha_d = (\alpha_{\parallel} + 2\alpha_{\perp})/3$ and α_{\parallel} and α_{\perp} are the polarizabilities of AB in the directions parallel and perpendicular to the molecular axis $\hat{\mathbf{s}}$ of AB. The anisotropic polarizability is $\alpha'_d = 2(\alpha_{\parallel} - \alpha_{\perp})/3$. The next polarization interaction is the charge-induced quadrupole interaction, averaged over all molecular orientations

$$V_{\text{pol}}(Ze; \text{ind}Q) = -\bar{\alpha}_q Ze^2 / 2R^6$$

where $\bar{\alpha}_q$ is the averaged quadrupole polarizability. Additional polarization terms arise from permanent multipole moments of one partner and the dipole (or multipole) it induces in the other, averaged over all directions. The leading term is

$$V_{\text{pol}}(D; \text{ind}D) = -\frac{1}{R^6} (D_n^2 \bar{\alpha}_{di} + D_i^2 \bar{\alpha}_{dn})$$

where the subscripts i and n label the permanent dipole moments D and the dipole-polarizabilities $\alpha_{,i}$ of the

ion and neutral, respectively. The variation R_{-6} is similar to that for the charge-induced quadrupole interaction.

The electrostatic interaction results from the interaction of the ion with the permanent multipole moments of the neutral. For cylindrically symmetric neutrals or linear molecules, the ion–neutral multipole interaction is

$$V_{el}(Ze; \mathbf{D}, \mathbf{Q}) = -\frac{(Ze)D_n}{R^2} P_1(\hat{\mathbf{s}} \cdot \hat{\mathbf{R}}) + \frac{(Ze)Q_n}{R^3} P_2(\hat{\mathbf{s}} \cdot \hat{\mathbf{R}})$$

where $D_n = \int \mathbf{r} \rho(\mathbf{r}) d\mathbf{r}$ and $Q_n = \int (3z^2 - r^2) \rho(\mathbf{r}) d\mathbf{r}$ are the permanent dipole and quadrupole moments of the neutral. The ion dipole–neutral dipole interaction is

$$V_{el}(\mathbf{D}_i; \mathbf{D}_n) = -\frac{D_i D_n}{R^3} [2 \cos \theta_i \cos \theta_n - \sin \theta_i \sin \theta_n \cos(\phi_i - \phi_n)]$$

where θ_i and θ_n are the angles made by the ionic and molecular dipoles \mathbf{D}_i and \mathbf{D}_n and the line \mathbf{R} of centres and ϕ_i and ϕ_n are the azimuthal angles of rotation about the line of centres. The dipole–molecular quadrupole interaction is

$$V_{el}(\mathbf{D}_i, \mathbf{Q}_n) = \frac{3D_i Q_n}{2R^4} [(3 \cos^2 \theta_n - 1) \cos \theta_i - 2 \sin \theta_i \sin \theta_n \cos \theta_n \cos(\phi_i - \phi_n)].$$

-62-

The dispersion interaction arises between the fluctuating multipoles and the moments they induce and can occur even between spherically symmetric ions and neutrals. Thus,

$$V_{\text{dispersion}} \sim -\frac{C_6}{R^6} - \frac{C_8}{R^8} - \frac{C_{10}}{R^{10}} \dots$$

represents the interaction of the fluctuating dipole interacting with the induced dipole C_6 term and quadrupole C_8 term, respectively. The leading R^{-6} term represents the van der Waal's attraction.

B2.3 Reactive scattering

Paul J Dagdigan

B2.3.1 INTRODUCTION

Reactive scattering is one of a number of gas-phase phenomena included in the field of molecular collision dynamics, which is the study of the molecular mechanism of elementary physical and chemical rate processes. Other such dynamical processes include photodissociation, vibrational and rotational energy transfer, electronic quenching, unimolecular decay, reactions within weakly bound complexes and gas–surface interactions. The object of studying the dynamics of these processes is to gain an understanding of the behaviour of a system at the molecular level. We would like to unravel the forces exerted on the nuclei, as described by the potential energy surface (PES) of interaction, during the collisional encounter. We also wish to learn whether the system has jumped to another PES through an electronically non-adiabatic transition. In this section, techniques appropriate to the study of the dynamics of chemical reactions are emphasized. However, these techniques are generally applicable to the study of a variety of gas-phase collisional processes.

The implementation of molecular beam techniques and introduction of laser-based detection methods has allowed chemical reaction dynamics to be elucidated in far greater detail than is possible from inferences based on the temperature dependence of reaction rate constants. In an ideal crossed-beam reactive scattering experiment, which is illustrated schematically in [figure B2.3.1](#) two collimated beams of the reagents, of well defined velocities, are crossed in a collision centre, and the flux of reaction products in specified internal vibration–rotation quantum states scattered into particular solid angles is determined. In this way, the differential cross section for scattering of the reaction product in a given internal quantum state into a given solid angle element can be measured. There have been relatively few studies of reaction dynamics which have closely approximated this ideal, nor is the ideal experiment usually required in order to infer what one would like to understand about the dynamics of a particular reaction. While this section describes experimental techniques as applied to the study of chemically reactive collisions, these methods have also been applied to

the study of a wide range of collisional phenomena, including non-reactive energy transfer collisions, photodissociation, and gas–surface scattering.

Two radically different approaches have been taken for the study of reactive scattering. In the first, which approximates the ideal reactive scattering experiment, collimated beams are crossed in a high-vacuum chamber, and the products are detected with a rotatable detector. In most scattering experiments, a mass spectrometer, with electron bombardment ionization and mass-resolved detection of the ions transmitted through a radio-frequency (RF) electric quadrupole [1], is employed as the detector, and the products are identified from the mass-to-charge ratio of the detected ion, either the parent or a fragment ion. This detection method is ‘universal’ in that every atom or molecule can, in principle, be detected mass spectrometrically. An excellent description of such a molecular beam apparatus is given by Lee *et al* [2].

-2-

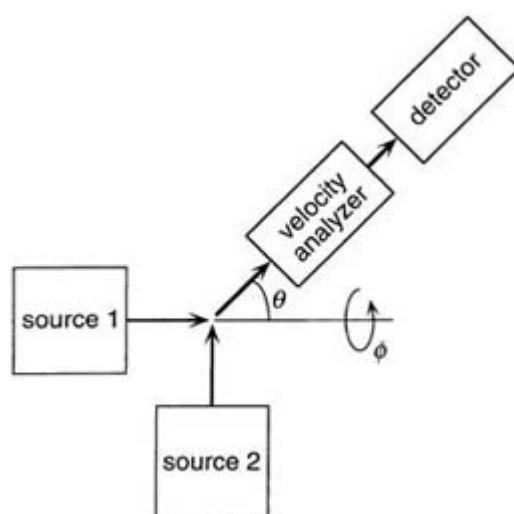

Figure B2.3.1. Schematic diagram of an idealized molecular beam scattering experiment.

In order to determine the partitioning of the energy available to the products into internal (vibrational and rotational) excitation and relative translational recoil energy of the products, the velocity of the detected products is determined, usually by a time-of-flight method [3]. In this way, the translational energy of the products can be determined. The mass spectrometer is essentially insensitive to the degree of internal excitation of the product, however, and the internal excitation of the products can be only determined indirectly, through energy conservation with the knowledge of the total energy available to the products (reaction exoergicity + translational and internal energy of the reagents).

The second approach to the study of reactive scattering involves the use of some spectroscopic method for the detection of the products in specified internal quantum states. Molecular spectroscopy is well suited to the determination of the relative populations in individual states since the quantum numbers of the upper and lower states of a molecular line in an assigned transition are known. Moreover, the intensities may be directly related to concentrations of specific internal states. The original implementation of this approach for the study of reactive scattering involved observation of spontaneous infrared emission from the radiative decay of vibrationally excited products [4, 5]. This approach is still being employed, however now usually with detection of the emission with Fourier transform [6], rather than grating-tuned spectrometers. In some cases, emission from electronically excited products can be observed for highly exothermic reactions.

For many reaction products and for the detection of molecules in their ground vibrational level, some laser-based spectroscopic method must be employed, rather than observation of spontaneous emission. The simplest spectroscopic method for determining concentrations of specified product internal states would involve the

application of the Beer–Lambert law on resolved molecular lines in direct absorption. However, the optical density of the product will be very small and limited by the requirement that the nascent reaction products do not undergo any secondary, relaxing collisions before being detected. In the gas phase, the collision frequency can be conveniently reduced by changing the density. The average time between collisions is increased by reducing the total pressure, and hence the concentration of the products. Very recently [7], an ultrasensitive absorption method has been developed and applied for the detection of reaction products.

-3-

A more sensitive method of detecting absorption, through observation of a so-called ‘action’ or ‘excitation’ spectrum, has been mainly employed for the detection of the reaction products. In most such experiments, a wavelength-tunable laser, usually a dye laser, is scanned over an electronic band system of the reaction product in question, and a signal indicative of molecular absorption is recorded. The relative intensities of spectral lines or bands are then converted into relative populations of the reaction product in specified internal quantum states. In this way the disposal of the available reaction energy into the internal degrees of freedom of this product is directly determined. If the accompanying product is an atom or a molecule with little internal excitation, the relative translational energy of the products can be obtained from energy conservation and knowledge of the total available energy. In this second approach, the angular distribution of the products is usually not determined. However, recent experiments employing Doppler resolution of isolated spectral lines have allowed determination of a low-resolution angular distribution of the product.

Most often, fluorescence excitation to an excited electronic state with the fundamental or frequency-doubled output of a wavelength-tunable dye laser has been employed for laser-based detection of the reaction products. In this method, the total, spectrally unresolved, photon emission from the detection zone is monitored as the laser wavelength is scanned over a molecular transition. Such an excitation spectrum provides the same information as would be available from an absorption spectrum, but with much higher detection sensitivity. This increased sensitivity arises from two factors. Fluorescence detection is a ‘zero-background’ technique and is limited only by background due to scattered light and quantum counting statistics, while absorption requires the measurement of ratios of signals. In addition, the sensitivity of fluorescence detection is greatly enhanced by the high spectral intensity of laser radiation, as opposed to incoherent radiation from lamps. Product internal state distributions have been determined with laser fluorescence detection in both beam- and bulb-type experiments.

The first half of this section discusses the use of the crossed beams method for the study of reactive scattering, while the second half describes the application of laser-based spectroscopic methods, including laser-induced fluorescence and several other laser-based optical detection techniques. Further discussion of both non-optical and optical methods for the study of chemical reaction dynamics can be found in articles by Lee [8] and Dagdigian [9].

B2.3.2 CROSSED-BEAMS METHOD

B2.3.2.1 THE BASIC SCATTERING EXPERIMENT AND SIGNAL INTENSITY

An ideal scattering experiment requires that the velocity spread of the reagent beams be narrow, so that the relative translational energy of the reagents is well defined. Effusive beams have a very broad velocity distribution, and their use in a scattering experiment usually required the insertion of a slotted-disk velocity selector [10] to reduce the velocity spread to a reasonable width. The flux in an effusive beam is not large, and the insertion of a velocity selector reduces the reagent beam flux significantly. The introduction of supersonic beam sources, with a dramatic narrowing of the velocity spread [11], radically increased the flux from beam sources and made the modern era of crossed-beam reactions possible. The term ‘supersonic’ refers to the fact that the molecular velocities in such a source are greater than the local speed of sound. In such a source and in

contrast to an effusive source, the backing pressure is high enough that the mean free path within the source is much smaller than the orifice diameter so that the gas behaves as a hydrodynamic fluid. Under ideal conditions the enthalpy is converted to net motion during the expansion of the gas into vacuum, and the local temperature becomes very low, leading to a very small spread of velocities about the mean.

-4-

In addition to obviating the need of velocity selection, the increased backing pressure over that attainable with an effusive source leads to significantly higher downstream beam densities.

A molecular beam scattering experiment usually involves the detection of low signal levels. Thus, one of the most important considerations is whether a sufficient flux of product molecules can be generated to allow a precise measurement of the angular and velocity distributions. The rate of formation of product molecules, dN/dt , can be expressed as

$$dN/dt = n_1 n_2 v_{rel} \sigma V_{coll} \quad (B2.3.1)$$

where the number densities of the reagent beams in the collision volume are given by n_1 and n_2 ; and v_{rel} , σ , V_{coll} are the relative velocity between the reagents, the integral reaction cross section, and the scattering volume, respectively. (Equation B2.3.1 is just a re-expression of the law of mass action since the product $v_{rel} \sigma$ is the microcanonical rate constant.) In an experiment with one supersonic beam and a velocity-selected effusive beam, typical values for the reagent beam densities are 10^{12} and 10^{10} molecules cm^{-3} , respectively, in a collision volume of 10^{-2} cm^3 . The relative velocity will be approximately 10^5 cm s^{-1} , and reaction cross section 10^{-15} cm^2 . This leads to an estimate of 10^{10} molecules s^{-1} for the total rate of production formation dN/dt .

The product molecules will scatter into a range of laboratory angles, depending upon the exoergicity of the reaction, the reaction dynamics, and kinematics, which is a function of the masses of the reagents and products. If we assume that the scattering is confined to 1 sr of solid angle (out of the total 4π), then the detector will receive $\sim 3 \times 10^6$ molecules s^{-1} if it subtends 1° in both directions (i.e. an angular acceptance of $1/3000$ sr). If, instead, the molecules were isotropically scattered, the detector would see a considerably smaller flux of $\sim 2 \times 10^5$ molecules s^{-1} . Of course, we desire not only the angular distribution of the products, but also the velocity distribution at each scattering angle, for a fuller understanding of the reaction dynamics.

If the molecules could be detected with 100% efficiency, the fluxes quoted above would lead to impressive detected signal levels. The first generation of reactive scattering experiments concentrated on reactions of alkali atoms, since surface ionization on a hot-wire detector is extremely efficient. Such detectors have been superseded by the 'universal' mass spectrometer detector. For electron-bombardment ionization, the rate of formation of the molecular ions can be written as

$$d[M^+]/dt = I_e \sigma [M] \quad (B2.3.2)$$

where I_e is the intensity of the electron beam (typically 10 mA cm^{-2} , or 6×10^{16} electrons $\text{cm}^2 \text{s}^{-1}$) and σ is the ionization cross section (typically 10^{-16} cm^2 for electrons of 150 eV energy). This leads to an estimated ionization rate of $k_i = I_e \sigma = 6$ s^{-1} . The molecules are, of course, not stationary in the ionization region but are travelling with a typical velocity of $\sim 5 \times 10^4$ cm s^{-1} . With an ionization region of length ~ 1 cm, the probability of ionization is thus estimated to be $\sim 10^{-4}$, which is a low detection efficiency. For example, the above quoted product flux of 3×10^6 molecules s^{-1} leads to only 360 detection ions s^{-1} . This ion count rate, or rates as low as even 1 ion s^{-1} , can be measured with good statistics in minutes if the background signal is not much larger than this. Hence, such beam-scattering experiments have been successful mainly through

careful reduction of the background ion count rate. This discussion of expected

-5-

product signal levels follows a discussion of intensities in crossed-beam reactive scattering experiments by Lee [8].

The background ion signal arises from two sources of molecules, namely the inherent background of molecules in a vacuum chamber and molecules effusing from the collision chamber into the detector chamber while the beams are on. The former arises from outgassing from the materials employed in the construction of the apparatus and the limitations in the pumps. The latter requires the careful design of differential pumping of the sources and the detector [2, 12].

B2.3.2.2 LABORATORY TO CENTRE-OF-MASS TRANSFORMATION

In a crossed-beam experiment the angular and velocity distributions are measured in the laboratory coordinate system, while scattering events are most conveniently described in a reference frame moving with the velocity of the centre-of-mass of the system. It is thus necessary to transform the measured velocity flux contour maps into the center-of-mass coordinate (CM) system [13]. Figure B2.3.2 illustrates the reagent and product velocities in the laboratory and CM coordinate systems. The CM coordinate system is travelling at the velocity c of the centre of mass

$$c = [m_1 v_1 + m_2 v_2] / (m_1 + m_2) \quad (\text{B2.3.3})$$

where the velocities of the reagents are v_1 and v_2 , with masses m_1 and m_2 , respectively. Thus, the velocities in the two coordinate systems are related by

$$v_i = c + u_i \quad \text{for } i = 1, 2. \quad (\text{B2.3.4})$$

Figure B2.3.2. Velocity vector diagram for a crossed-beam experiment, with a beam intersection angle of 90° . The laboratory velocities of the two reagent beams are v_1 and v_2 , while the corresponding velocities in the centre-of-mass coordinate system are u_1 and u_2 , respectively. The laboratory and CM velocities for one of the products (assumed here to be in the plane of the reagent velocities) are denoted v'_3 and u'_3 , respectively. The dashed circle denotes the possible laboratory velocities v'_3 for the full range of CM scattering angles θ' .

-6-

The CM velocities are given by

$$\mathbf{u}_1 = m_2 \mathbf{v}_{\text{rel}} / (m_1 + m_2) \quad (\text{B2.3.5a})$$

$$\mathbf{u}_2 = -m_1 \mathbf{v}_{\text{rel}} / (m_1 + m_2) \quad (\text{B2.3.5b})$$

where $v_{\text{rel}} = v_1 - v_2$ is the relative velocity.

The relative translational energy of the reagents is given by

$$E_{\text{trans}} = \frac{1}{2} \mu v_{\text{rel}}^2. \quad (\text{B2.3.6})$$

The energy available to the product equals

$$E'_{\text{tot}} = E_{\text{trans}} + E_{\text{int}} + \Delta E \quad (\text{B2.3.7})$$

where E_{int} is the internal excitation energy of the reagents and ΔE is the reaction exoergicity. The energy E'_{tot} can be partitioned between translational and internal excitation of the products. The CM speed of one of the products can be expressed as

$$u'_3 = \frac{m_4}{m_3 + m_4} \left(\frac{2}{\mu'} (E'_{\text{tot}} - E'_{\text{int}}) \right)^{1/2}. \quad (\text{B2.3.8})$$

where m_3 is the mass of this product, m_4 is the mass of the other product, $\mu' = m_3 m_4 / (m_3 + m_4)$ is the reduced mass of the products, and E'_{int} is the internal excitation energy of the products.

It can be seen from [figure B2.3.2](#) that scattering angles (relative to the direction of one of the reagent beams) are different in the laboratory and CM coordinate systems. If the detected product is very heavy compared with its partner, or if its translational energy is very small, then its speed will be small compared with the speed of the centre of mass of the system. In this case, the product is scattered into a small range of scattering angles about c , and determination of the CM angular distribution will be difficult. Moreover, the scattered intensity at one laboratory scattering angle can come from two CM scattering angles, as can be seen in [figure B2.3.2](#). From the intensity estimates presented in [section B2.3.2.1](#), this concentration of the scattered product into a small laboratory angular range will facilitate detection of the product molecules. By contrast, if the product CM speed is large, then the product can be scattered into all laboratory angles.

In addition to transforming the velocities and scattering angles between the laboratory and CM frames, we must also consider the transformation of the cross sections

$$\left(\frac{d^2 \sigma}{dv' d\Omega} \right)_{\text{lab}} = \left(\frac{d^2 \sigma}{du' d\omega} \right)_{\text{CM}} \frac{du' d\omega}{dv' d\Omega} \quad (\text{B2.3.9})$$

where the last term on the right-hand side is the Jacobian of the transformation. Because the internal energies of the products are quantized, the velocity of a product scattered into a specific direction can have only discrete values. Equation (B2.3.9) is written with the velocities as continuous variables since the experimental resolution in reactive scattering experiments is not sufficient to resolve the discrete product velocities, due to the spread in the reagent beam velocities and angles. A detailed derivation of the Jacobian has been presented [13], and we obtain

$$\frac{du' d\omega}{dv' d\Omega} = \frac{v'^2}{u^2} \quad (\text{B2.3.10})$$

Equation (B2.3.10) shows that the scattered intensity observed in the laboratory is distorted from that in the CM coordinate system. Those products which have a larger laboratory velocity or a smaller CM velocity will be observed in the laboratory with a greater intensity.

The detection technique can also have an effect upon the angle- and velocity-dependent intensities. Cross sections refer to fluxes of molecules into a given range of velocities and angles. The commonly employed technique of mass spectrometric detection provides a measure of the density in the ionization region. Since density and flux are related by the velocity, we must include a factor of $1/v'$ in making the transformation indicated in equation (B2.3.10) from the CM cross sections to the measured laboratory intensities.

If the reagent velocity and angular spreads are sufficiently small, one can infer the CM angle-velocity distributions, i.e. the CM differential cross section on the right-hand side of equation (B2.3.10), directly from the measured laboratory intensities, by simply transforming the velocities to the CM frame and removing the transformation of the Jacobian, with inclusion of the velocity-dependent detection efficiency. On the other hand, as the scattering experiments are often carried out with limited resolution, it is usually necessary to deconvolute the results over the experimental spread [14]. More commonly, a forward convolution technique is employed, in which the CM angle-velocity distribution is adjusted until the laboratory distribution calculated by transformation of the coordinate system and convoluted over the experimental spreads agrees with the measured laboratory distribution.

B2.3.2.3 BEAM SOURCES

Many reactive scattering experiments involve the reaction of an atomic species, such as hydrogen, oxygen, a halogen, or a metal atom, with a stable molecular reagent. A variety of techniques have been employed for the generation of the reagent atomic beam. Beams of halogen atoms have been prepared by thermal dissociation. At room temperature, these elements exist as diatomic molecules, while the equilibrium is shifted toward the monatomic species at sufficiently high temperatures. A detailed description of such a source for the production of Cl, Br, and I beams is given by Valentini *et al* [15]. The atomic beam is prepared by heating the halogen molecule, diluted in a rare gas, to 2000 °C in a graphite tube. At this temperature, dissociation to atoms is essentially complete. In order to reduce the spread in velocities, the gas mixture is expanded supersonically into vacuum. Problems with materials corrosion have, until recently, limited the intensities of atomic fluorine beams. Use of a nickel tube limits the temperature to 700 °C, for

-8-

which dissociation yields of <15% are obtained. Recently a F atom source employing a tube made of single-crystal MgF₂ has been constructed, and dissociation fractions of ~80% have been achieved at tube temperatures near 1000 °C [16, 17].

Thermal dissociation is not suitable for the generation of beams of oxygen atoms, and RF [18] and microwave [19] discharges have been employed in this case. The first excited electronic state, O(¹D), has a different spin multiplicity than the ground O(³P) state and is electronically metastable. The collision dynamics of this very reactive state have also been studied in crossed-beam reactions with a RF discharge source which has been optimized for production of O(¹D) [20].

Beams of metal atoms have been prepared by many researchers through thermal vaporization from a heated crucible. An example of such a source, employed for the generation of beams of alkaline earth atoms, is described by Irvin and Dagdigian [21]. By striking an electrical discharge within this source, beams

containing electronically excited metastable atoms could be prepared. For Ca, the conversion efficiency to the $3s3p\ ^3P$ and $3s4d\ ^1D$ metastable excited states was of the order of 80%. Laser ablation from a solid has been widely used to generate atomic atoms of refractory elements [22]. A detailed description of such a source for the production of a beam of atomic carbon has been given [23]. This source has been employed in crossed-beam studies of reactions of carbon atoms.

Laser photolysis of a precursor may also be used to generate a reagent. In a crossed-beam study of the $D + H_2$ reaction [24], a hyperthermal beam of deuterium atoms (0.5 to 1 eV translational energy) was prepared by 248 nm photolysis of DI. This preparation method has been widely used for the preparation of molecular free radicals, both in beams and in experiments in a cell, with laser detection of the products. Laser photolysis as a method to prepare reagents in experiments in which the products are optically detected is further discussed below.

In most reactive scattering experiments, the reagent beam sources, which are housed in differentially pumped enclosures, are fixed and cross at a 90° intersection angle, while the detector is rotated about the scattering centre. The stable molecular co-reagent is usually produced in an effusive or supersonic source of the pure reagent. Care must be taken to ensure that no clusters are formed in the beam source, for example by heating the source or by limiting the total pressure behind the source orifice.

B2.3.2.4 AN EXAMPLE REACTION: $F + H_2 \rightarrow HF + H$

This reaction has been intensively studied because of its accessibility to both experimental and theoretical treatments. This reaction is also important because it is the pumping mechanism for the hydrogen fluoride infrared chemical laser. We present some data from the extensive study in 1985 by Lee and co-workers (Neumark *et al* [25, 26]) and recent, higher resolution experiments by Faubel *et al* [27, 28]. Figure B2.3.3 presents a schematic diagram of the apparatus in which Lee and co-workers carried out their experiments [29]. An effusive beam of fluorine atoms was prepared by thermal dissociation of F_2 in a nickel tube at $650\ ^\circ C$. The velocity spread was reduced to 11% by passage through a slotted-disk chopper. The fluorine atom beam was crossed with a supersonic molecular hydrogen beam, and the incident relative translational energy was varied by changing the temperature of the molecular beam source. The products were detected in a triply differentially pumped mass spectrometer employing electron-impact ionization. Cryogenically cooled surfaces also provided additional pumping to reduce the background signal, primarily from diffuse scattering from surfaces. The laboratory velocity distributions of the product at various laboratory scattering angles were measured by a time-of-flight method with a mechanical chopper. Crossed-beam scattering of a normal

hydrogen beam, a *para*-hydrogen beam (all molecules in the $j = 0$ rotational level) [25], and beams of D_2 and HD [26] was studied.

Figure B2.3.3. Crossed-molecular beam apparatus employed for the study of the $F + D_2 \rightarrow DF + D$ reaction. Indicated in the figure are: (1) the effusive F atom source; (2) slotted-disk velocity selector; (3) liquid-nitrogen-cooled trap; (4) D_2 beam source; (7) skimmer; (8) chopper; (9) cross-correlation chopper for product velocity analysis; and (11) rotatable, ultrahigh-vacuum, triply differentially pumped, mass spectrometer detector chamber. Reprinted with permission from Lee [29]. Copyright 1987 American Association for the Advancement of Science.

We present results on the $F + D_2$ reaction. Study of the reaction of the D_2 isotopic reagent was easier because the background in the mass spectrometer was smaller at mass 21 (DF) than for mass 20 (HF). Moreover, the masses of the DF and D are less dissimilar, so that the DF product is less kinematically constrained in the range of accessible laboratory scattering angles. [Figure B2.3.4](#) presents the laboratory angular distribution and a velocity vector diagram for the reaction, showing the accessible angular ranges for the product vibrational levels. From this plot, it already appears that the bulk of the DF products is made in the $v = 3$ and 4 vibrational levels that are scattered backward in the CM frame with respect to the incident F atom beam.

Figure B2.3.4. Laboratory angular distribution of DF products from the $F + D_2$ reaction at an incident relative translational energy of $1.82 \text{ kcal mol}^{-1}$ [26]. The full curve shows the fit with the derived CM angle-velocity contour. The angular distributions for the $v = 1, 2, 3,$ and 4 vibrational levels are indicated by (— —), (— —), (.....), and (— · —), respectively. (By permission from AIP.)

The above conjectures need to be verified by measurement of the doubly differential cross sections in angle and velocity. Typical time-of-flight distributions at several laboratory scattering angles from the more recent, higher resolution experiments of Faubel *et al* [27, 28] are presented in [figure B2.3.5](#). We see that products formed in the different vibrational levels appear at distinct time intervals, corresponding to different laboratory velocities. From data such as those presented in [figure B2.3.5](#) and after transformation from the laboratory to the CM frame, the CM velocity flux contour map is obtained. [Figure B2.3.6](#) displays such a contour plot derived by Lee and co-workers (Neumark *et al* [26]) for the $F + D_2$ reaction at one collision energy. It can be seen that all DF vibrational levels are predominantly scattered into the backward hemisphere. The CM angular spread is seen to be larger for the highest energetically accessible level, $v = 4$.

Figure B2.3.5. Typical time-of-flight spectra of DF products from the $F + D_2$ reaction [28]. The collision energies and in-plane (Θ_{lab}) and out-of-plane (Φ_{lab}) laboratory scattered angles are given in each panel. The DF product vibrational quantum number ν_f associated with each peak is indicated. Reprinted with permission from Faubel *et al* [28]. Copyright 1997 American Chemical Society.

Figure B2.3.6. CM angle–velocity contour plot for the $F + D_2$ reaction at an incident relative translational energy of 1.82 kcal mol [26]. Contours are given at equally spaced intensity intervals. This CM differential cross section was used to generate the calculated laboratory angular distributions given in figure B2.3.4. (By permission from AIP.)

Keil and co-workers (Dharmasena *et al* [16]) have combined the crossed-beam technique with a state-selective detection technique to measure the angular distribution of HF products, in specific vibration–rotation states, from the $F + H_2$ reaction. Individual states are detected by vibrational excitation with an infrared laser and detection of the deposited energy with a bolometer [30].

B2.3.2.5 PROBLEMS WITH PRODUCT IDENTIFICATION

It is well known that the electron-impact ionization mass spectrum contains both the parent and fragment ions. The observed fragmentation pattern can be useful in identifying the parent molecule. This ion fragmentation also occurs with mass spectrometric detection of reaction products and can cause problems with identification of the products. This problem can be exacerbated in the mass spectrometric detection of reaction products because these internally excited molecules can have very different fragmentation patterns than thermal molecules. The parent molecules associated with the various fragment ions can usually be sorted out by comparison of the angular distributions of the detected ions [8].

Many of the problems associated with electron impact ionization, such as the formation of fragment ions, can be alleviated by the use of photoionization detection. When the photon wavelength is tuned below the dissociative ionization threshold, it is possible to ionize the molecule ‘softly’, with the formation of parent ions only. This advantage for photoionization arises because the cross sections generally rise rapidly from the energetic threshold, namely the ionization potential. Recently, a molecular beam scattering apparatus using photoionization mass spectrometric detection of the products has been constructed [12]. This apparatus, shown schematically in figure B2.3.7 takes advantage of the intense vacuum ultraviolet (VUV) radiation available from a third-generation synchrotron radiation source at a national facility, the advanced light source, at the Lawrence Berkeley National Laboratory. In most scattering experiments, the detector is rotated about the crossing point of the fixed reagent beams. In this newly constructed apparatus, the detector includes an electron storage ring and cannot be rotated; in this case, it is the

sources that are rotated about the scattering centre. This apparatus makes liberal use of turbomolecular pumps, which can be positioned in any orientation and are convenient for vacuum pumps on rotating assemblies.

Figure B2.3.7. Schematic apparatus of crossed molecular beam apparatus with synchrotron photoionization mass spectrometric detection of the products [12]. To vary the scattering angle, the beam source assembly is rotated in the plane of the detector. (By permission from AIP.)

B2.3.3 OPTICAL DETECTION OF THE REACTION PRODUCTS

Optical methods, in both bulb and beam experiments, have been employed to determine the relative populations of individual internal quantum states of products of chemical reactions. Most commonly, such methods employ a transition to an excited electronic, rather than vibrational, level of the molecule. Molecular electronic transitions occur in the visible and ultraviolet, and detection of emission in these spectral regions can be accomplished much more sensitively than in the infrared, where vibrational transitions occur. In addition to their use in the study of collisional reaction dynamics, laser spectroscopic methods have been widely applied for the measurement of temperature and species concentrations in many different kinds of reaction media, including combustion media [31] and atmospheric chemistry [32].

B2.3.3.1 LASER-INDUCED FLUORESCENCE DETECTION

The most widely employed optical method for the study of chemical reaction dynamics has been laser-induced fluorescence. This detection scheme is schematically illustrated in the left-hand side of figure B2.3.8. A tunable laser is scanned through an electronic band system of the molecule, while the fluorescence emission is detected. This maps out an ‘action spectrum’ that can be used to determine the relative concentrations of the various vibration–rotation levels of the molecule.

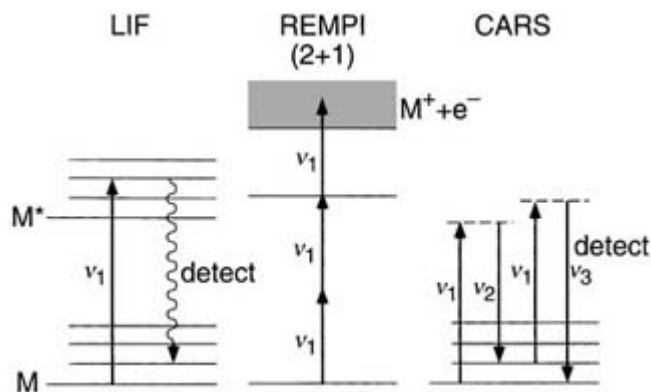

Figure B2.3.8. Energy-level schemes describing various optical methods for state-selectively detecting chemical reaction products: left-hand side, laser-induced fluorescence (LIF); centre, resonance-enhanced multiphoton ionization (REMPI); and right-hand side, coherent anti-Stokes Raman spectroscopy (CARS). The ionization continuum is denoted by a shaded area. The dashed lines indicate virtual electronic states. Straight arrows indicate coherent radiation, while a wavy arrow denotes spontaneous emission.

There are several requirements for this to be a suitable detection method for a given molecule. Obviously, the molecule must have a transition to a bound, excited electronic state whose wavelength can be reached with tunable laser radiation, and the band system must have been previously spectroscopically assigned. If the molecules are formed with considerable vibrational excitation, the available spectroscopic data may not extend up to these vibrational levels. Transitions in the visible can be accessed directly by the output of a tunable dye laser, while transitions in the ultraviolet can be reached by frequency-doubled radiation. The excited state must also have a reasonably short radiative lifetime (say $<10^{-5}$ s) with a near 100% fluorescence quantum yield (preferably independent of internal state). Finally, assignments of the individual rotational lines and the vibrational bands within the electronic transition must be available. These restrictions place considerable limits on the molecules which can be detected in this way—mainly diatomics and some triatomics. For incisive interpretation of the experimental observations, it is precisely those reactions involving small molecules whose collision dynamics can be treated theoretically with modern quantum mechanical methods.

Figure B2.3.9 presents a schematic diagram of a typical laser fluorescence experiment. In this apparatus, one of the reagents is prepared by photolysis of a suitable precursor [33] using radiation from an excimer laser (usually 248 nm from a KrF laser or 193 nm from a ArF laser). The tunable laser employed for fluorescence excitation counter-propagates along the beam of the excimer laser. Fluorescence of the product molecules is collected with a telescope and is imaged onto a photomultiplier. Because of their greater coverage of wavelengths, pulsed, rather than continuous (cw), lasers are almost universally employed. Thus, the photomultiplier output signal will typically appear at the 10–50

Hz repetition rate of the lasers and is usually sampled with a gated integrator, whose output is recorded with a laboratory computer. Analogue, rather than digital, electronics is usually employed because of pile-up of the detected photon counts in an experiment with reasonable product intensities.

Figure B2.3.9. Schematic diagram of an apparatus for laser fluorescence detection of reaction products. The dye laser is synchronized to fire a short delay after the excimer laser pulse, which is used to generate one of the reagents photolytically.

The principal source of background in laser fluorescence detection is laser light scattered diffusely from optical elements such as windows, and from surfaces such as the walls of the apparatus. The windows for entry and exit of the laser beam, which are significant sources of scattered light, are usually mounted on long (0.4–0.8 m) sidearms. Baffles are installed in the sidearms to prevent light from scattering off the inside of the sidearms. Further reduction of scattered light can be achieved through the use of imaging optics (as illustrated in figure B2.3.9 to relay fluorescence from the excitation zone to the photomultiplier detector, so that emission from only a well defined volume is detected. If the fluorescence is mainly at wavelengths greatly different from the excitation wavelength, as would be the case, for example, for a molecule with significantly different equilibrium internuclear separations in the ground and excited electronic state, and hence a very non-diagonal Franck–Cordon array, then spectral filtering can provide further reduction in the background signal.

B2.3.3.2 DETERMINATION OF PRODUCT INTERNAL STATE DISTRIBUTIONS

Considerable spectroscopic data are required for the determination of the relative populations in the various internal quantum levels of the product from the relative intensities of various lines, or bands, in a spectrum. As discussed above, the spectrum must be assigned, i.e. the quantum numbers of the upper and lower levels of the spectral lines must be available. In addition to the line positions, intensity information is also required.

To compare the relative populations of vibrational levels, the intensities of vibrational transitions out of these levels are compared. Figure B2.3.10 displays typical potential energy curves of the ground and an excited electronic state of a diatomic molecule. The intensity of a (v', v'') vibrational transition can be written as

$$I(v', v'') = C N_{v''} p_{v', v''} \quad (\text{B2.3.11})$$

where $N_{v''}$ is the desired density of product molecules in the vibrational level v'' , $p_{v', v''}$ is the vibrational band strength [34, 35], and C is a proportionality constant. If the electronic transition moment [36] is constant as a function of the internuclear separation, then $p_{v', v''}$ is proportional to the Franck–Cordon factor $q_{v', v''}$, i.e. the square of the overlap integral of the upper and lower vibrational wavefunctions (see figure B2.3.10). The band strengths are usually determined experimentally from measurement of the decay lifetime of the excited vibrational level and the branching of emission into the various ground state vibrational levels v'' , as illustrated for the A–X transition of the hydroxyl radical [37]. Alternatively, if the potential energy curves of the two electronic states can be calculated from spectroscopic data, e.g. by the RKR method [38], then Franck–Cordon factors can be computed [35] and used to estimate the relative band strengths.

Figure B2.3.10. Potential energy curves [42] of the ground $X^2\Pi$ and excited $A^2\Sigma^+$ electronic states of the hydroxyl radical. Several vibrational levels are explicitly drawn in each electronic state. One vibrational transition is explicitly indicated, and the upper and lower vibrational wavefunctions are plotted. The upper and lower state vibrational quantum numbers are denoted v' and v'' , respectively. Also shown is one of the three repulsive potential energy curves which correlate with the ground $O(^3P) + H$ dissociation asymptote. These cause predissociation of the higher rotational and vibrational levels of the $A^2\Sigma^+$ state.

The $H + NO_2 \rightarrow OH + NO$ reaction provides an excellent example of the use of laser fluorescence detection for the elucidation of the dynamics of a chemical reaction. This reaction is a prototype example of a radical-radical reaction in that the reagents and products are all open-shell free radical species. Both the hydroxyl and nitric oxide products can be conveniently detected by electronic excitation in the UV at wavelengths near 226 and 308 nm, respectively. Atlases of rotational line positions for the lowest electronic band systems of these molecules ($A^2\Sigma^+ - X^2\Pi$ for both) are available [39, 40], and accurate band strengths for transition between various vibrational levels in the ground and excited electronic states have been reported [37, 41]. Because it is crossed by repulsive electronic states correlating with the ground state atoms $O(^3P) + H$ (see figure B2.3.10), the $OH(A^2\Sigma^+)$ state has low fluorescence quantum yields for rotational levels $N' > 25, 17,$ and 4 for vibrational levels $v' = 0, 1,$ and 2 , respectively [42]. This causes some problems for the detection of higher vibrational levels of the OH product since the intensities of the vibrational bands are strongest for the so-called diagonal bands, i.e. those for which $\Delta v = v' - v'' = 0$ [37]. Because of the excited-state predissociation, the higher levels must be detected through the weaker off-diagonal bands ($\Delta v < 0$).

The dynamics of the $H + NO_2$ reaction have been studied by several different techniques including laser fluorescence excitation of the products, infrared chemiluminescence, crossed-beam scattering, and electron paramagnetic resonance. We highlight the laser fluorescence studies by Sauder and Dagdigian [43] and by Irvine *et al* [44]. In the former experiment, the NO products, in vibrational levels $v \leq 2$, were detected at the intersection of an atomic hydrogen beam, generated by a microwave discharge source, with a pulsed beam of NO_2 diluted in Ar. Figure B2.3.11 illustrates an excitation spectrum for the detection of NO products in the ground ($v = 0$) vibrational level. The structure in the spectrum results from the energy differences between the rotational/fine-structure levels in the upper and lower electronic states and the degree of internal excitation of the products. Figure B2.3.12 illustrates the rotational transitions allowed in a $2\Sigma^+ - 2\Pi$ electronic transition. With such a diagram it is possible to determine the rotational/fine-structure level being detected through the excitation of a specific rotational line in the spectrum.

Figure B2.3.11. (a) Experimental laser fluorescence excitation spectrum of the $A\ ^2\Sigma^+ - X\ ^2\Pi\ (0,0)$ band for the NO product from the $H + NO_2$ reaction [43]. Individual lines in the various rotational branches are denoted by the total angular momentum J of the lower state. (b) Simulated spectrum with the NO rotational state populations adjusted to reproduce the spectrum in (a). (By permission from AIP.)

Both OH and NO are open-shell free radicals, with doublet electron spin multiplicity. Consequently, the coupling of the angular momentum of the unpaired electron with the angular momentum N of nuclear rotation leads to a more complicated rotational energy level pattern than for a closed-shell molecule ($^1\Sigma^+$ electronic state) [45]. For the upper, $^2\Sigma^+$ electronic state, the electron spin $S = \frac{1}{2}$ can couple with the rotational angular momentum to yield two fine-structure levels, with total angular momenta $J = N + \frac{1}{2}$ and $N - \frac{1}{2}$. These are conventionally [34] denoted F_1 and F_2 , respectively, in order of increasing energy for a given value of J . The rotational energy is given approximately by $BN(N + 1)$, where B is the rotational constant, and the splitting of the fine-structure levels is usually much smaller and grows with increasing N . This pattern of rotational/fine-structure levels is illustrated in the upper portion of figure B2.3.12.

Figure B2.3.12. Rotational transitions between a specific pair of vibrational levels in a ${}^2\Sigma^+ - {}^2\Pi$ electronic transition. The total angular momentum J and the parity of the lowest rotational levels in each state are given. Hund's case (a) coupling is assumed for the ${}^2\Pi$ state. Conventional spectroscopic designations [34] are given for the allowed rotational transitions.

For the ${}^2\Pi$ state, the projection $\Lambda = 1$ of the electron orbital angular momentum along the internuclear axis can couple with the projection $\Sigma = \pm \frac{1}{2}$ to yield two spin-orbit levels, ${}^2\Pi_{\Omega}$, with $\Omega = \frac{1}{2}$ and $\frac{3}{2}$. The NO($X^2\Pi$) state follows so-called Hund's case (a) coupling [34], for which the spin-orbit splitting is much larger than the rotational energy. In this case, the rotational energy within each spin-orbit level is given approximately by $B[J(J+1) - \Omega^2]$, with half-integral $J \geq \Omega$. It should be noted that a Π state is orbitally degenerate, i.e. it has two components of the same energy. In Cartesian notation, these are often indicated as Π_x and Π_y . As a result, the rotational/fine-structure levels appear as nearly

degenerate pairs, with opposite parity, or symmetry with respect to reflection of all the coordinates through the space-fixed origin. These pairs of levels are called Λ -doublets.

For high rotational levels, or for a molecule like OH, for which the spin-orbit splitting is small, even for low J , the pattern of rotational/fine-structure levels approaches the Hund's case (b) limit. In this situation, it is not meaningful to speak of the projection quantum number Ω . Rather, we first consider the rotational angular momentum N exclusive of the electron spin. This is then coupled with the spin to yield levels with total angular momentum $J = N + \frac{1}{2}$ and $N - \frac{1}{2}$. As before, there are two nearly degenerate pairs of levels associated with each value of J .

The rotational/fine-structure levels of the lower, ${}^2\Pi$ electronic state in [figure B2.3.12](#) are drawn for a molecule near the case (a) limit since NO falls into this coupling scheme. Also indicated in the figure are the electric-dipole allowed rotational lines, indicated with conventional spectroscopic notation [34]. In the

spectrum displayed in [figure B2.3.11](#) the individual rotational lines appear to pile up into so-called ‘heads’ [34] at four distinct wavenumbers. The splitting between the two pairs of heads can be roughly identified with the NO(X ²Π) spin-orbit splitting.

In a conventional spectroscopic experiment, the intensity of a rotational transition within a given vibrational band can be written as

$$I(J', J'') = C' [N_{J''} (2J'' + 1)^{-1}] S_{J', J''} \quad (\text{B2.3.12})$$

where $N_{J''}$ is the density of the rotational/fine-structure level, J'' is its total angular momentum, $S_{J', J''}$ is the rotational line strength factor [34, 45], and C' is a proportionality constant. The relative intensities of the rotational lines can be used with equation (B2.3.12) to derive the rotational/fine-structure state distribution associated with a given vibrational level. Zare [45] presents a detailed discussion of the calculation of rotational line strength factors for diatomic electronic transitions.

Strictly speaking, equation (B2.3.12) does not apply to a measurement of the concentration through laser-induced fluorescence detection, as would be observed in the apparatus schematically illustrated in [figure B2.3.9](#). The rotational line strength factors $S_{J', J''}$ apply to the situation of isotropic irradiation and detection, which is clearly not the case for irradiation with a unidirectional polarized laser and detection of fluorescence emitted into a specific solid angle. Greene and Zare [46] have considered in detail the correct relationship between the molecular density and the intensity for arbitrary fluorescence excitation and detection geometries. In practice, because of the large angular momentum J often found for reaction products, the factors $S_{J', J''}$ follow fairly closely the J -dependence of the correct line strength factors, as long as lines in the same rotational branch are employed.

An additional inadequacy of equation (B2.3.12) is the assumption of an isotropic M_J distribution of product molecules in the detected rotational level. The product could be aligned because of the dynamics of the reaction. An extreme case is that of alignment imposed by kinematics for the mass combination $H + HL \rightarrow HH + L$, where H and L represent heavy and light atoms, respectively. From angular momentum conservation, we have $\mathbf{J}_{\text{tot}} = \mathbf{L}_i + \mathbf{J}_i = \mathbf{L}_f + \mathbf{J}_f$ where \mathbf{J}_{tot} is the total angular momentum of the system. Here, the vectors \mathbf{L} and \mathbf{J} are the orbital and rotational angular momenta, respectively, and the subscripts i and f denote the reagents and products, respectively. Because of the small moment of inertia of the HL reagent, \mathbf{J}_i will be small. Moreover, \mathbf{L}_f will also be small because of the small reduced mass of the $HH-L$ combination of the products. Thus, we have $\mathbf{L}_i = \mathbf{J}_f$. This then implies that the product rotational angular

-20-

momentum \mathbf{J}_f must be strongly polarized, with an anisotropic M_J distribution, since \mathbf{L}_i is perpendicular to the initial relative velocity.

The anisotropy of the product rotational state distribution, or the polarization of the rotational angular momentum, is most conveniently parametrized through multipole moments of the M_J distribution [45]. Odd multipoles, such as the dipole, describe the orientation of the angular momentum \mathbf{J} , i.e. which way the tips of the \mathbf{J} vectors preferentially point. Even multipoles, such as the quadrupole, describe the alignment of \mathbf{J} , i.e. the spatial distribution of the \mathbf{J} vectors, regarded as a collection of double-headed arrows. Orr-Ewing and Zare [47] have discussed in detail the measurement of orientation and alignment in products of chemical reactions and what can be learned about the reaction dynamics from these measurements.

At low laser powers, the fluorescence signal is linearly proportional to the power. However, the power available from most tunable laser systems is sufficient to cause partial saturation of the transition, with the result that the fluorescence intensity is no longer linearly proportional to the probe laser power. While more

elaborate treatments have been given [48, 49], saturation can be simply described by a rate-equation model of radiative transitions with the help of the 2-level diagram in figure B2.3.13. If the laser pulse can be approximated as a rectangular pulse of length T , then the fraction f of molecules originally in the lower state which are excited is

$$f = [W_{12}/(W_{12} + W_{21} + A_{21})][1 - \exp(-\{W_{12} + W_{21} + A_{21}\}T)]. \quad (\text{B2.3.13})$$

The fluorescence signal is linearly proportional to the fraction f of molecules excited. The absorption rate W_{12} and the stimulated emission rate W_{21} are proportional to the laser power. In the limit of low laser power, f is proportional to the laser power, while this is no longer true at high powers ($W_{12}, W_{21} \gg A_{21}$). Care must thus be taken in a laser fluorescence experiment to be sure that one is operating in the linear regime, or that proper account of saturation effects is taken, since transitions with different strengths reach saturation at different laser powers.

Figure B2.3.13. Model 2-level system describing molecular optical excitation, with first-order excitation rate constant W_{12} proportional to the laser power, and spontaneous (first-order rate constant A_{21}) and stimulated (first-order rate constant W_{21} proportional to the laser power) emission pathways.

Following the procedures outlined above, internal state distributions for the products of the $\text{H} + \text{NO}_2$ reaction have been determined [43, 44, 50]. Comparison of the intensities of various bands of the $\text{NO } A^2\Sigma^+ - X^2\Pi$ electronic transitions, through equation (B2.3.11), allows determination of the ratio of the populations of the vibrational levels of the NO product. From spectra such as that in figure B2.3.11 the rotational/fine-structure state distribution of the NO product in a particular vibrational level can be deduced. Figure B2.3.14 presents the vibration-rotation state distribution

derived for the NO product [43]. The vibrational state populations monotonically decrease with increasing v , up to $v = 3$, the highest detected level [50].

Figure B2.3.14. Experimentally derived vibration–rotation populations for the NO product from the $\text{H} + \text{NO}_2$ reaction [43]. The fine-structure labels F_1 and F_2 refer to the two ways that the projections Σ and Λ of the electron spin and orbital angular momenta along the internuclear axis of this open-shell can be coupled ($\Omega = \Lambda + \Sigma$). (By permission from AIP.)

In the work of Irvine *et al* [44], the OH product was detected, as illustrated by the fluorescence excitation spectrum in [figure B2.3.15](#). Since the rotational constant of OH is much larger than that of NO, the spectrum is much less congested. Since $\text{OH}(X^2\Pi)$ follows Hund’s case (b) coupling, the spin–orbit splitting is not directly reflected in any separations between rotational lines. The distribution in the product OH rotational/fine-structure levels was determined by the same methods as employed for the analysis of the NO spectrum. The degree of product OH vibrational excitation was found to be significantly greater than for the NO product. The $\text{H} + \text{NO}_2$ reaction proceeds on the ground state HONO PES, which has a fairly deep well corresponding to the stable nitrous acid molecule. Because of this well, the collision complex has a transient existence. However, its lifetime is not sufficiently long that the available energy is randomized through all the degrees of freedom. The ‘new’ OH bond is found to have more vibrational energy than the ‘old’ NO bond.

Figure B2.3.15. Laser fluorescence excitation spectrum of the $A\ ^2\Sigma^+-X\ ^2\Pi(1,3)$ band for the OH product, in the $v = 3$ vibrational level, from the $H + NO_2$ reaction [44]. (By permission from AIP.)

B2.3.3.3 PREPARATION OF REAGENTS

In most reactive scattering experiments in which the products are detected optically, a thermodynamically labile species is allowed to react with a stable molecular reagent. In many experiments, this involves allowing a beam of the unstable species, prepared in a separately pumped vacuum chamber, to impinge upon the scattering partner in a so-called beam-gas scattering arrangement. The beam is usually prepared by one of the methods described in [section B2.3.2.3](#), e.g. a high-temperature source of a beam of metal atoms or a microwave discharge source for a beam of hydrogen atoms. In some cases, two beams are crossed, and the products are detected in the collision zone [43, 51, 52]. In a few cases, the product of a reaction of two labile reagents have been studied, e.g. the OD product from the $O(^3P) + ND_2$ reaction [53]. In this study, the oxygen atoms were prepared in a microwave discharge source while the ND_2 reagent was prepared by laser photolysis of ND_3 .

Many optical studies have employed a quasi-static cell, through which the photolytic precursor of one of the reagents and the stable molecular reagent are slowly flowed. The reaction is then initiated by laser photolysis of the precursor, and the products are detected a short time after the photolysis event. To avoid collisional relaxation of the internal degrees of freedom of the product, the products must be detected in a shorter time when compared to the time between gas-kinetic collisions, that depends inversely upon the total pressure in the cell. In some cases, for example in case of the stable NO product from the $H + NO_2$ reaction discussed in [section B2.3.3.2](#), the products are not removed by collisions with the walls and may have long residence times in the apparatus. Study of such reactions are better carried out with pulsed introduction of the reagents into the cell or under crossed-beam conditions.

B2.3.3.4 EXTRACTION OF ANGULAR INFORMATION (CORRELATIONS)

With spectroscopic detection of the products, the angular distribution of the products is usually not measured. In principle, spectroscopic detection of the products can be incorporated into a crossed-beam scattering experiment of the type described in [section B2.3.2](#). There have been relatively few examples of such studies because of the great demands on detection sensitivity. The recent work of Keil and co-workers (Dharmasena *et al* [16]) on the $F + H_2$ reaction, mentioned in [section B2.3.3](#), is an excellent example of the implementation

of state-selective optical detection in the measurement of the angular distribution of a reaction product.

The use of photolytically generated reagents in a cell, combined with sub-Doppler detection, has allowed the extraction of information on the angular distribution and also the alignment of the products in experiments carried out in a cell [54]. The theoretical treatment of Shafer *et al* [55] shows how, in principle, the reaction product angular distribution can be extracted from measurement of its laboratory velocity distribution when one of the reagents is prepared by photolysis. It is well known that the angular distribution of photolytically formed fragments can be expressed as [45]

$$P(\theta_{\text{phot}}) = [1 + \beta P_2(\cos \theta_{\text{phot}})]/(4\pi) \quad (\text{B2.3.14})$$

where θ_{phot} is the angle between the \mathbf{E} vector of the photolysis laser and the fragment recoil direction, $P_2(x)$ is the second-order Legendre polynomial, and β is the recoil anisotropy parameter. The parameter β can vary from -1 (perpendicular-type transition) to 2 (parallel-type transition), where the type of transition refers to the direction of fragment recoil relative to the electronic transition moment of the dissociation transition [45].

In the bimolecular collision of the photolytically generated reagent, assumed to have a mass m_1 and laboratory speed v_1 , the centre-of-mass speed will be

$$c = m_1 v_1 / (m_1 + m_2) \quad (\text{B2.3.15})$$

if the velocity of the co-reagent (mass m_2) can be neglected. In this case, the relative velocity vector v_{rel} and c are parallel to the laboratory velocity v_1 of the photolytically generated reagent. The CM speed u'_3 of the detected product can be computed with equation (B2.3.8). Figure B2.3.16 illustrates how the laboratory velocity v'_3 of this product is related to the CM scattering angle, θ' . Shafer *et al* [55] show that the laboratory velocity distribution $f(v'_3)$ of the product is related to the CM differential cross section by

$$f(v'_3) = (2 v'_3 c u'_3)^{-1} \left(\frac{d\sigma}{d\omega} \right)_{\text{CM}} [1 + \beta P_2(\cos \alpha) P_2(\cos \theta'_{\text{phot}})] \quad \text{for } |c - u'_3| < v'_3 < (c + u'_3) \quad (\text{B2.3.16})$$

$$f(v'_3) = 0 \quad \text{for } v'_3 < |c - u'_3| \text{ or } v'_3 > (c + u'_3)$$

where

$$\cos \alpha = [v_3'^2 + c^2 - u_3'^2] / (2 v_3' c) \quad (\text{B2.3.17})$$

and θ'_{phot} is the angle between v'_3 and the \mathbf{E} vector of the photolysis laser.

Figure B2.3.16. Velocity diagram for the reaction of a photolytically generated reagent with an assumed stationary co-reagent. In this case, the relative velocity v_{rel} of the reagents is parallel to the velocity c of the centre of mass.

There are several practical limitations to the use of [Equation \(B2.3.16\)](#) for the determination of CM angular distributions. The optimum kinematics for the use of this equation is the case where the speed c of the centre of mass is approximately equal to the product CM speed u'_3 . In the limiting case where the latter is small, the product laboratory distribution is dominated by the angular distribution of the velocity c of the centre of mass and nothing can be learned about the product CM angular distribution. In the opposite limiting case where u'_3 is much larger than c , the angular distribution of v'_3 is limited by the angular distribution of the photolytically-prepared reagent. [Equation \(B2.3.16\)](#) assumes that the velocity of the co-reagent can be neglected. This applies to the situation where the reagents are pre-cooled in a supersonic beam expansion [56]. The effects of thermal averaging have been considered to describe photo-initiated reactors in room-temperature cells [54]. Information on the anisotropy of the rotational angular momentum can also be determined through the study of photo-initiated reactions by variation of the direction of the E vector of the probe laser [54, 57].

B2.3.3.5 OTHER SPECTROSCOPIC TECHNIQUES

In addition to laser fluorescence excitation, several other laser spectroscopic methods have been found to be useful for the state-selective and sensitive detection of products of reactive collisions: resonance-enhanced multiphoton ionization [58], coherent anti-Stokes Raman scattering [59], bolometric detection with laser excitation [30], and direct infrared absorption [7]. Several additional laser techniques have been developed for use in spectroscopic studies or for diagnostics in reacting systems. Of these, four-wave mixing [60] is applicable to studies of reaction dynamics although it does have a somewhat lower sensitivity than the techniques mentioned above.

The most widely used of these techniques is resonance-enhanced multiphoton ionization (REMPI) [58]. A schematic energy-level diagram of the most commonly employed variant (2 + 1) of this detection scheme is illustrated in the

centre of [figure B2.3.8](#). The molecules are irradiated with the focused output of a tunable laser. As the wavelength of the laser is tuned through a 2-photon transition in the molecule, there will be some electronic excitation. If the photon energy is sufficiently large that the ionization continuum can be reached by absorption of an additional photon by the molecule, then molecular ions can be efficiently produced. While non-resonant laser ionization is possible, the efficiency of ionization will be strongly enhanced at a 2-photon resonance in the molecule. This particular resonant ionization scheme is called 2 + 1 REMPI. Other ionization schemes are possible, with different numbers of photons required for electronic excitation and ionization of the molecule.

A REMPI spectrum is usually recorded by monitoring the molecular ion signal as the laser wavelength is scanned, although it is also possible to record the spectrum by monitoring the photoelectron signal. In most applications of REMPI, the laser-produced ions are mass analysed in a time-of-flight mass spectrometer (TOFMS) [61] in order to detect the desired molecular ion in the presence of background ions, for example from non-resonant ionization of other species in the reaction chamber. This mass discrimination is particularly important in probing chemical reaction products since the product ion signal could be obscured by a small degree of non-resonant ionization of reagent molecules present at much higher concentrations than the product.

This technique can be used both to permit the spectroscopic detection of molecules, such as H_2 and HCl , whose first electronic transition lies in the vacuum ultraviolet spectral region, for which laser excitation is possible but inconvenient [62], or molecules such as CH_3 that do not fluoresce. With 2-photon excitation, the required wavelengths are in the ultraviolet, conveniently generated by frequency-doubled dye lasers, rather than 1-photon excitation in the vacuum ultraviolet. [Figure B2.3.17](#) displays 2 + 1 REMPI spectra of the HCl and DCl products, both in their $\nu = 0$ vibrational levels, from the $\text{Cl} + (\text{CH}_3)_3\text{CD}$ reaction [63]. For some electronic states of HCl/DCl , both parent and fragment ions are produced, and the spectrum in [figure B2.3.17](#) for the DCl product was recorded by monitoring mass 2 (D^+) ions. In this case, both isotopomers (D^{35}Cl and D^{37}Cl) are detected.

In the ideal case for REMPI, the efficiency of ion production is proportional to the line strength factors for 2-photon excitation [64], since the ionization step can be taken to have a wavelength- and state-independent efficiency. In actual practice, fragment ions can be produced upon absorption of a fourth photon, or the ionization efficiency can be reduced through predissociation of the electronically excited state. It is advisable to employ experimentally measured ionization efficiency line strength factors to calibrate the detection sensitivity. With sufficient knowledge of the excited molecular electronic states, it is possible to understand the state dependence of these intensity factors [65].

Product angular and velocity distributions can be measured with REMPI detection, similar to Doppler probing in a laser-induced fluorescence experiment discussed in [section B2.3.3.5](#). With appropriate time- and space-resolved ion detection, it is possible, in principle, to determine the three-dimensional velocity distribution of a product (see [equation \(B2.3.16\)](#)). The time-of-arrival of a particular mass in the TOFMS will be broadened by the velocity of the neutral molecule being detected. In some modes of operation of a TOFMS, e.g. space-focusing conditions [61], the shift of the arrival time from the centre of a mass peak is proportional to the projection of the molecular velocity along the TOFMS axis. In addition, Doppler tuning of the probe laser allows one component of the velocity perpendicular to the TOFMS axis to be determined. A more general approach for the two-dimensional velocity distribution in the plane perpendicular to the TOFMS direction involves the use of imaging detectors [66].

Figure B2.3.17. REMPI spectra of the HCl and DCl products from the reaction of Cl atoms with (CH₃)₃CD [63]. The mass 36 and 2 ion signals are plotted as a function of the 2-photon wavenumber. Assignments of the *Q*-branch lines ($\Delta J = 0$) of the E $1\Sigma^+ - X 1\Sigma^+ (0,0)$ bands of H³⁵Cl and D³⁵Cl are given. In (b), both the D³⁵Cl and D³⁷Cl isotopomers are observed since D⁺ ions are monitored.

Welge and co-workers (Schnieder *et al* [67]) have developed a resonant ionization technique for hydrogen atoms which allows the determination of the velocity to $\sim 0.3\%$ by a time-of-flight method. The hydrogen atoms are sequentially irradiated in the detection zone with a 121.6 nm laser, which is resonant with the $n = 2 \leftarrow n = 1$ transition, and ~ 365 nm light to produce high- n Rydberg atoms:

The Rydberg atoms are allowed to drift through a ~ 1 m flight path, after which they are field ionized with a strong electric field, and the resulting ions collected with a particle detector. The key to the high-velocity resolution of this technique is to ionize the atoms far from the laser interaction region. By contrast, when the ions are produced in this region, space-charge effects can lead to a significant velocity spread. This detection technique has been applied to the study of the H + D₂ reaction through measurement of the velocity distribution of the D atom products [68]. The laboratory velocities of D atoms formed in coincidence with specific HD vibration-rotation states were resolved, and angularly resolved differential cross sections for the formation of HD products in specific states were determined. This H atom detection technique has also been extensively employed for the study of the dynamics of the photodissociation of hydride molecules [69].

Coherent anti-Stokes Raman spectroscopy (CARS) [59] has also found utility in the determination of the internal state distributions of products of chemical reactions. This is one of several coherent Raman spectroscopies based on the

existence of vibrational resonances in four-wave mixing. As illustrated in the schematic energy level diagram in the right-hand side of figure B2.3.8 electric fields at three frequencies are mixed to produce a fourth field. In most CARS experiments, ν_1 is held fixed, usually at 532 nm, the second harmonic of a Nd:YAG laser output, while ν_2 is scanned. The intensity of the output field at ν_3 is enhanced whenever the difference $\nu_1 - \nu_2$ equals the energy difference between two molecular levels connected by a Raman transition. Unlike the

normal, spontaneous Raman process, this mixing is coherent, and the output light is a coherent beam propagating in a particular direction. The high intensity and directionality provides a great increase in detection sensitivity. In reactive scattering experiments, the CARS technique has been employed for the determination of the vibration–rotation state distributions of H₂ and HD products in reactions yielding hydrogen molecular products, e.g. the H + D₂ [70] and H + HX (X = halogen) [71] reactions.

Recently, the state-selective detection of reaction products through infrared absorption on vibrational transitions has been achieved and applied to the study of HF products from the F + H₂ reaction by Nesbitt and co-workers (Chapman *et al* [7]). The relatively low sensitivity for direct absorption has been circumvented by the use of a multi-pass absorption arrangement with a narrow-band tunable infrared laser and dual beam differential detection of the incident and transmission beams on matched detectors. A particular advantage of probing the products through absorption is that the absolute concentration of the product molecules in a given vibration–rotation state can be determined.

B2.3.4 CONCLUSION

The molecular beam and laser techniques described in this section, especially in combination with theoretical treatments using accurate PESs and a quantum mechanical description of the collisional event, have revealed considerable detail about the dynamics of chemical reactions. Several aspects of reactive scattering are currently drawing special attention. The measurement of vector correlations, for example as described in [section B2.3.3.5](#), continue to be of particular interest, especially the interplay between the product angular distribution and rotational polarization.

In most theoretical treatments of the collision dynamics, the reaction is assumed to proceed on a single PES. However, reactions involving open-shell reagents or products will involve several PESs. For example, in the F + H₂ reaction, discussed in [section B2.3.2.4](#), three PESs emanate from the separated reagents, of which only one leads to the H + HF products. The F atom ground ²P_{3/2} spin–orbit state is connected to the products by this reactive PES, while the excited ²P_{1/2} state is not. Nevertheless, the ²P_{1/2} state does react with F₂ to a small extent because of non-adiabatic transitions between the PESs. There is considerable current interest in elucidating the role of such non-adiabatic transitions in collision dynamics.

The reaction of an atom with a diatomic molecule is the prototype of a chemical reaction. As the dynamics of a number of atom–diatom reactions are being understood in detail, attention is now being turned to the study of the dynamics of reactions involving larger molecules. The reaction of Cl atoms with small aliphatic hydrocarbons is an example of the type of polyatomic reactions which are now being studied [56, 63, 72, 73]. The idea of controlling the outcome of a chemical reaction by exciting a particular bond in a reagent has long held considerable appeal. Such bond-selected chemistry has been achieved with simple triatomic reagents such as partially deuterated water, HOD, by preparation of the reagent in a suitable vibrational level [74]. Current interest is focused on the extension to larger reagents. This is more difficult than in triatomics because of intramolecular redistribution of the initial excitation [75], which becomes more rapid in larger molecules.

FURTHER READING

Scoles G, Bassi D, Buck U and Lainé D (eds) 1988 *Atomic and Molecular Beam Methods* vol 1 (New York: Oxford University Press)

This book presents an extensive and detailed description of basic techniques for the generation and detection of atomic and molecular beams, as well as beam techniques for the study of molecular scattering processes.

-32-

Zare R N 1988 *Angular Momentum* (New York: Wiley)

This book presents a detailed exposition of angular momentum theory in quantum mechanics, with numerous applications and problems in chemical physics. Of particular relevance to the present section is an elegant and clear discussion of molecular wavefunctions and the determination of populations and moments of the rotational state distributions from polarized laser fluorescence excitation experiments.

Herzberg G 1989 *Molecular Spectra and Molecular Structure. I. Spectra of Diatomic Molecules* reprint (Malabar, FL: Krieger)

This book, originally published in 1950, is the first of a classic three-volume set on molecular spectroscopy. A rather complete discussion of diatomic electronic spectroscopy is presented. Volumes II (1945) and III (1967) discuss infrared and Raman spectroscopy and polyatomic electronic spectroscopy, respectively.

B2.4 NMR methods for studying exchanging systems

Alex D Bain

B2.4.1 INTRODUCTION

No molecule is completely rigid and fixed. Molecules vibrate, parts of a molecule may rotate internally, weak bonds break and re-form. Nuclear magnetic resonance spectroscopy (NMR) is particularly well suited to observe an important class of these motions and rearrangements. An example is the restricted rotation about bonds, which can cause dramatic effects in the NMR spectrum (figure B2.4.1).

Figure B2.4.1. Proton NMR spectra of the *N,N'*-dimethyl groups in 3-dimethylamino-7-methyl-1,2,4-benzotriazine, as a function of temperature. Because of partial double-bond character, there is restricted rotation about the bond between the dimethylamino group and the ring. As the temperature is raised, the rate of rotation around the bond increases and the NMR signals of the two methyl groups broaden and coalesce.

-2-

These exchanges often occur while the system is in macroscopic equilibrium—the sample itself remains the same and the dynamics may be invisible to other techniques. It is merely the environment of a given nucleus that changes. Since NMR follows an individual nucleus, it can easily follow these dynamic processes. This is just one of several reasons that the study of chemical exchange by NMR is important.

First is the observation of the phenomenon itself—the exchange of axial and equatorial ligands in trigonal bipyramidal species, the scrambling of carbonyl ligands in metal complexes and dynamic behaviour of rings was mainly revealed and studied in detail by NMR methods. Not only does NMR give a detailed picture of the mechanism of the exchange, but it also provides excellent ways of measuring the reaction rate.

Secondly, NMR is a good example of spectroscopy in general. The spectroscopic transition probability can be shown to have a simple physical interpretation in NMR: the total magnetization is divided amongst individual observable transitions and the intensity of a transition is related to its share of the total. This can be further generalized to exchanging systems, in which the transition probability now becomes a complex number. The exchange lineshapes can be decomposed into a sum of transitions, whose phase, intensity, position and linewidths are governed by the real and imaginary parts of the transition probability.

Finally, exchange is a kinetic process and governed by absolute rate theory. Therefore, study of the rate as a function of temperature can provide thermodynamic data on the transition state, according to equation (B2.4.1)). This equation, in which k is Boltzmann's constant and h is Planck's constant, relates the observed rate to the Gibbs free energy of activation, ΔG^\ddagger .

$$\text{Rate} = \frac{kT}{h} e^{-\Delta G^\ddagger/RT} = \frac{kT}{h} e^{-\Delta H^\ddagger/RT} e^{\Delta S^\ddagger/R}. \quad (\text{B2.4.1})$$

In order to separate the enthalpy and the entropy of activation, the rate is measured as a function of temperature. These data should give a straight line on an Eyring plot of $\log(\text{rate}/T)$ against $(1/T)$ (figure B2.4.2). The slope of the line gives ΔH^\ddagger , and the intercept at $1/T = 0$ is related to ΔS^\ddagger . A unimolecular reaction, such as many cases of exchange, might be expected to have a very small entropy change on going to the transition state. However, several systems have shown significant entropy contributions—entropy can make up more than 10% of the barrier. It is therefore important to measure the rates over as wide a range of temperatures as possible to obtain reliable thermodynamic data on the transition state.

There are several ways of measuring exchange rates with NMR, each with its own optimum range. Figure B2.4.2 illustrates this. A combination of spin–spin relaxation time (T_2) measurements at high temperature, bandshape analysis in the intermediate regime and selective inversions at low temperature, gives rates over a range of about five orders of magnitude. This provides a very well defined Eyring plot. The first fully analysed example of chemical exchange in NMR was the proton spectrum of dimethylamides [1], observed at about the same time (and in the same laboratory) as the phenomenon of scalar coupling between nuclei. Figure B2.4.1 illustrates this type of behaviour. If there is no rotation about the bond joining the N, N'-dimethyl group to the ring, the proton NMR signals of the two methyl groups will have different chemical shifts. If the rotation were very fast, then the two methyl environments would be exchanged very quickly and only a single, average, methyl peak would appear in the proton NMR spectrum. Between these two extremes, spectra like those in figure B2.4.1 are observed. At low temperature, when the rate is slow, two

Figure B2.4.2. Eyring plot of $\log(\text{rate}/T)$ versus $(1/T)$, where T is absolute temperature, for the *cis–trans* isomerism of the aldehyde group in furfural. Rates were obtained from three different experiments: T_2 measurements (squares), bandshapes (triangles) and selective inversions (circles). The line is a linear regression to the data. The slope of the line is $\Delta H^\ddagger/R$, and the intercept at $1/T = 0$ is $\Delta S^\ddagger/R$, where R is the gas constant. ΔH^\ddagger and ΔS^\ddagger are the enthalpy and entropy of activation, according to equation (B2.4.1)

sharp lines are seen. As the temperature is increased, the exchange becomes faster, the lines broaden, coalesce into a single line and finally become a single sharp line at the average chemical shift. This is perhaps the most familiar manifestation of chemical exchange in NMR.

The different types of chemical exchange in NMR are classified according to the rate relative to some NMR timescale. The example in [figure B2.4.1](#) is called intermediate exchange, in which the exchange rate is comparable to the chemical shift differences and coupling constants. Intermediate exchange gives an array of unusual and characteristic lineshapes in the spectrum, which can be explained quite neatly in terms of a generalized transition probability. Fast exchange is the regime well after coalescence, when only a single line is observed. There is still observable broadening due to exchange, and rates are measured from the linewidth, or equivalently, the spin–spin relaxation time, T_2 . In slow exchange, no dramatic line broadening is observed, but the exchange rate is comparable to the reciprocal of the spin–lattice relaxation time, T_1 . In this regime, modifications of the inversion-recovery experiment, or techniques related to the nuclear Overhauser effect (NOE), are used to measure rates.

The timescale is just one sub-classification of chemical exchange. It can be further divided into coupled *versus* uncoupled systems, mutual or non-mutual exchange, inter- or intra-molecular processes and solids *versus* liquids. However, all of these can be treated in a consistent and clear fashion.

-4-

The NMR experimental methods for studying chemical exchange are all fairly routine experiments, used in many other NMR contexts. To interpret these results, a numerical model of the exchange, as a function of rate, is fitted to the experimental data. It is therefore necessary to look at the theory behind the effects of chemical exchange. Much of the theory is developed for intermediate exchange, and this is the most complex case. However, with this theory, all of the rest of chemical exchange can be understood.

B2.4.2 INTERMEDIATE EXCHANGE

B2.4.2.1 INTRODUCTION

[Figure B2.4.1](#) shows the lineshape for intermediate chemical exchange between two equally populated sites without scalar coupling. For more complicated spin systems, the lineshapes are more complicated as well, since a spin may retain its coupling information even though its chemical shift changes in the exchange.

[Figure B2.4.3](#) shows an example of this in the aldehyde proton spectrum of ^{15}N -labelled formamide. Some lines in the spectrum remain sharp, while others broaden and coalesce. There is no fundamental difference between the lineshapes in [figures B2.4.1](#) and [figures B2.4.3](#)—only a difference in the size of the matrices involved. First, the uncoupled case will be discussed, then the extension to coupled spin systems.

-5-

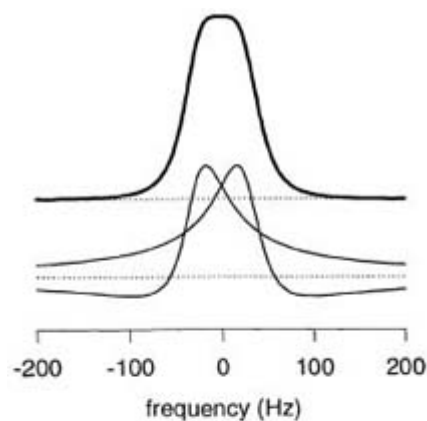

Figure B2.4.3. Proton NMR spectrum of the aldehyde proton in ^{15}N -labelled formamide. This proton has couplings of 1.76 Hz and 13.55 Hz to the two amino protons, and a coupling of 15.0 Hz to the ^{15}N nucleus. The outer lines in the spectrum remain sharp, since they represent the sum of the couplings, which is unaffected by the exchange. The inner lines of the multiplet broaden and coalesce, as in [figure B2.4.1](#). The other peaks in the 303 K spectrum are due to the NH_2 protons, whose chemical shifts are even more temperature dependent than that of the aldehyde proton.

The original analysis of the spectra in [figure B2.4.1](#) was done by the groups of Gutowsky [1] and McConnell [2], both of whom treated the spectrum as a whole in the frequency domain. Reeves showed [3] somewhat later that the two-site exchange lineshape ([figure B2.4.4\(a\)](#) and [figure B2.4.4\(b\)](#)) can be deconstructed into two transitions. More recently, it was demonstrated [4] that these transitions are defined by a generalized transition probability. This transition probability (now a complex number) which is just the product of how much coherence a transition receives at the start of an experiment, times how much the transition contributes to the total signal. This leads naturally into a discussion of the xy magnetizations in the time domain. As with most NMR, the choice of the time domain or the frequency domain depends on the problem.

(a)

(b)

Figure B2.4.4. The two-site equally populated exchange lineshape (figure B2.4.1) decomposed into two individual transitions. The bottom spectrum (a) is the situation before coalescence: two symmetrically out-of-phase lines. In slow exchange, these become the signals of the two sites. The top spectrum (b) is after coalescence: the lineshape is made up of two central lines, one positive and one negative. In fast exchange, the negative line broadens and loses intensity, to leave a single positive line at the average chemical shift.

B2.4.2.2 THE BLOCH EQUATIONS APPROACH

The Bloch equations for the motion of the x and y magnetizations (usually called the u - and v -mode signals), in the presence of a weak radiofrequency (RF) field, B_1 , are given in equation (B2.4.2)).

$$\frac{du}{dt} + \frac{u}{T_2} - (\omega_0 - \omega)v = 0$$

$$\frac{dv}{dt} + \frac{v}{T_2} + (\omega_0 - \omega)u = \gamma B_1 M_z.$$
(B2.4.2)

In this equation, ω is the frequency of the RF irradiation, ω_0 is the Larmor frequency of the spin, T_2 is the spin–spin relaxation time and M_z is the z magnetization of the spin system. The notation can be simplified somewhat by defining a complex magnetization, M , as in equation (B2.4.3).

$$M = u + iv. \quad (\text{B2.4.3})$$

With this definition, the Bloch equations can be written as in equation (B2.4.4).

$$\frac{dM}{dt} + i(\omega_0 - \omega)M + \frac{1}{T_2}M = i\gamma B_1 M_z. \quad (\text{B2.4.4})$$

In chemical exchange, the two exchanging sites, A and B, will have different Larmor frequencies, ω_A and ω_B . Assuming equal populations in the two sites, and the rate of exchange to be k , the two coupled Bloch equations for the two sites are given by equation (B2.4.5).

$$\begin{aligned} \frac{dM_A}{dt} + i(\omega_A - \omega)M_A + \frac{1}{T_2}M_A - kM_B + kM_A &= i\gamma B_1 M_{zA} \\ \frac{dM_B}{dt} + i(\omega_B - \omega)M_B + \frac{1}{T_2}M_B - kM_A + kM_B &= i\gamma B_1 M_{zB}. \end{aligned} \quad (\text{B2.4.5})$$

The observable NMR signal is the imaginary part of the sum of the two steady-state magnetizations, M_A and M_B . The steady state implies that the time derivatives are zero and a little further calculation (and neglect of T_2 terms) gives the NMR spectrum of an exchanging system as equation (B2.4.6).

$$v = \frac{1}{2}\gamma B_1 M_z \frac{k(\omega_A - \omega_B)^2}{(\omega_A - \omega)^2(\omega_B - \omega)^2 + 4k^2(\omega - (\omega_A + \omega_B)/2)^2}. \quad (\text{B2.4.6})$$

B2.4.2.3 MATRIX FORMULATION OF CHEMICAL EXCHANGE

Equation (B2.4.5) can be re-written in a matrix form [5] as equation (B2.4.7).

$$\frac{d}{dt} \begin{pmatrix} M_A \\ M_B \end{pmatrix} + i\mathbf{L} \begin{pmatrix} M_A \\ M_B \end{pmatrix} + \mathbf{R} \begin{pmatrix} M_A \\ M_B \end{pmatrix} + \mathbf{K} \begin{pmatrix} M_A \\ M_B \end{pmatrix} = i\gamma B_1 \begin{pmatrix} M_{zA} \\ M_{zB} \end{pmatrix}. \quad (\text{B2.4.7})$$

In this equation, the matrices \mathbf{L} , \mathbf{R} and \mathbf{K} are given by equation (B2.4.8), equation (B2.4.9) and equation (B2.4.10).

$$\mathbf{L} = \begin{pmatrix} \omega_A - \omega & 0 \\ 0 & \omega_B - \omega \end{pmatrix} \quad (\text{B2.4.8})$$

$$\mathbf{R} = \begin{pmatrix} \frac{1}{T_2} & 0 \\ 0 & \frac{1}{T_2} \end{pmatrix} \quad (\text{B2.4.9})$$

$$\mathbf{K} = \begin{pmatrix} k & -k \\ -k & k \end{pmatrix}. \quad (\text{B2.4.10})$$

The steady-state solution without saturation to this equation is obtained by setting the time derivatives to zero and taking the terms linear in B_1 , as in equation (B2.4.11).

$$\begin{pmatrix} M_A \\ M_B \end{pmatrix} = (i\mathbf{L} + \mathbf{R} + \mathbf{K})^{-1} \begin{pmatrix} M_{zA} \\ M_{zB} \end{pmatrix}. \quad (\text{B2.4.11})$$

Recall that \mathbf{L} contains the frequency ω (equation (B2.4.8)). To trace out a spectrum, equation (B2.4.11) is solved for each frequency. In order to obtain the observed signal v , the sum of the two individual magnetizations can be written as the dot product of two vectors, equation (B2.4.12).

$$v = (1 \ 1) \begin{pmatrix} M_A \\ M_B \end{pmatrix}. \quad (\text{B2.4.12})$$

This apparently artificial way of re-writing the Bloch equations is important, since this form applies to all exchanging systems—coupled or uncoupled—in the frequency domain. The description starts with the equilibrium z magnetizations. These are affected by all the NMR interactions: chemical shifts, relaxation and exchange. Finally, the observed signal is detected. This is the standard preparation–evolution–detection paradigm used in multi-dimensional NMR. There may be algebraic and numerical complications in setting up and solving the equations for different systems, but the form remains the same for all frequency-domain calculations.

B2.4.2.4 CHEMICAL EXCHANGE IN THE TIME DOMAIN

If the magnetizations, M_A and M_B , are created (by a pulse) at time zero, and then the B_1 magnetic field is turned off, equation (B2.4.7) can be simplified to equation (B2.4.13). Note that ω in the matrix \mathbf{L} (equation (B2.4.8)) is also zero.

-9-

$$\frac{d}{dt} \begin{pmatrix} M_A \\ M_B \end{pmatrix} = -(i\mathbf{L} + \mathbf{R} + \mathbf{K}) \begin{pmatrix} M_A \\ M_B \end{pmatrix}. \quad (\text{B2.4.13})$$

Equation (B2.4.13) is a pair of first-order differential equations, so its formal solution is given by equation (B2.4.14), in which $\exp()$ means the exponential of a matrix.

$$\begin{pmatrix} M_A(t) \\ M_B(t) \end{pmatrix} = \exp(-[i\mathbf{L} + \mathbf{R} + \mathbf{K}]t) \begin{pmatrix} M_A(0) \\ M_B(0) \end{pmatrix}. \quad (\text{B2.4.14})$$

This is the description of NMR chemical exchange in the time domain. Note that this equation and equation (B2.4.11) are Fourier transforms of each other. The time-domain and frequency-domain pictures are always related in this way.

In practice, the matrix $(i\mathbf{L} + \mathbf{R} + \mathbf{K})$ is diagonalized first, with a matrix of eigenvectors, \mathbf{U} , as in equation (B2.4.15), to give a diagonal matrix, $\mathbf{\Lambda}$, with the eigenvalues, λ^i , of \mathbf{L} down the diagonal.

$$\mathbf{\Lambda} = \mathbf{U}^{-1} (i\mathbf{L} + \mathbf{R} + \mathbf{K}) \mathbf{U}. \quad (\text{B2.4.15})$$

equation (B2.4.14) becomes equation (B2.4.16).

$$\begin{pmatrix} M_A(t) \\ M_B(t) \end{pmatrix} = \mathbf{U} \exp(-\mathbf{\Lambda}t) \mathbf{U}^{-1} \begin{pmatrix} M_A(0) \\ M_B(0) \end{pmatrix}. \quad (\text{B2.4.16})$$

The exponential of a diagonal matrix is again a diagonal matrix with exponentials of the diagonal elements, equation (B2.4.17)).

$$\begin{pmatrix} M_A(t) \\ M_B(t) \end{pmatrix} = \mathbf{U} \begin{pmatrix} e^{-\lambda_1 t} & 0 \\ 0 & e^{-\lambda_2 t} \end{pmatrix} \mathbf{U}^{-1} \begin{pmatrix} M_A(0) \\ M_B(0) \end{pmatrix}. \quad (\text{B2.4.17})$$

As was mentioned above, the observed signal is the imaginary part of the sum of M_A and M_B , so equation (B2.4.17)) predicts that the observed signal will be the sum of two exponentials, evolving at the complex frequencies λ_1 and λ_2 . This is the free induction decay (FID). In the limit of no exchange, the two frequencies are simply $i\omega_A$ and $i\omega_B$, as expected. When k is non-zero, the situation is more complex.

Without relaxation and exchange, \mathbf{L} is a Hermitian matrix with real eigenvalues and eigenvectors. However, when the exchange contributes significantly, the Hermitian character is lost and the eigenvalues and eigenvectors have both real and imaginary parts. The eigenvalues are given by the roots of the characteristic equation, (B2.4.18), in which δ is $(\omega_A - \omega_B)/2$.

-10-

$$\begin{vmatrix} i\delta + \frac{1}{T_2} + k - \lambda & -k \\ -k & -i\delta + \frac{1}{T_2} + k - \lambda \end{vmatrix} = 0. \quad (\text{B2.4.18})$$

The eigenvalues of equation (B2.4.16)) are given in equation (B2.4.19)).

$$\lambda = \left(\frac{1}{T_2} + k \right) \pm \sqrt{k^2 - \delta^2}. \quad (\text{B2.4.19})$$

These eigenvalues are the (complex) frequencies of the lines in the spectrum: the imaginary part gives the oscillation frequency and the real part gives the rate of decay. If $k < \delta$ (slow exchange) then there are two different imaginary frequencies, which become $\pm\delta$ in the limit of small k . Figure B2.4.4 a) shows this decomposition. In fast exchange, when k exceeds the shift difference, δ , the quantity in the square root in equation (B2.4.19) becomes positive, so the roots are pure real. This means that the spectrum is still two lines, but they are both at the average chemical shift (offset of zero) and have different widths (figure B2.4.4(b)).

It is convenient, for simple systems, to have explicit expressions for equation (B2.4.17). Since the original matrix is non-Hermitian, the matrix formed by the eigenvectors will not be unitary, and will have four independent complex elements. Let them be a , b , c and d , so that \mathbf{U} is given by equation (B2.4.20).

$$\mathbf{U} = \begin{pmatrix} a & b \\ c & d \end{pmatrix}. \quad (\text{B2.4.20})$$

Regardless of whether \mathbf{U} is unitary, its inverse is given by equation (B2.4.21), where Δ is the determinant of the matrix.

$$\mathbf{U}^{-1} = \frac{1}{\Delta} \begin{pmatrix} d & -b \\ -c & a \end{pmatrix}. \quad (\text{B2.4.21})$$

Equation (B2.4.16) then says that the signal is given by equation (B2.4.22), regardless of slow or fast exchange.

$$\text{Signal} = \frac{(a+c)(d-b)}{\Delta} e^{\lambda_1 t} + \frac{(b+d)(-c+a)}{\Delta} e^{\lambda_2 t}. \quad (\text{B2.4.22})$$

For slow exchange, a convenient matrix of eigenvectors is given by equation (B2.4.23).

$$\begin{pmatrix} k & i(\sqrt{\delta^2 - k^2} + \delta) \\ -i(\sqrt{\delta^2 - k^2} + \delta) & k \end{pmatrix}. \quad (\text{B2.4.23})$$

-11-

After coalescence, a possible set of eigenvectors is given in equation (B2.4.24). If these are substituted into (B2.4.22), the results are pure real, reflecting the fact that $k^2 - \delta^2$ is now positive.

$$\begin{pmatrix} \sqrt{k^2 - \delta^2} - i\delta & -\sqrt{k^2 - \delta^2} - i\delta \\ k & k \end{pmatrix}. \quad (\text{B2.4.24})$$

Because of the role of the eigenvectors in [equation \(B2.4.16\)](#), the factor (amplitude) multiplying the complex exponential is itself complex. The magnitude of the complex amplitude gives the intensity of the line and its phase gives the phase of the line (the mixture of absorption and dispersion). In slow exchange, the two lines have the same real part, but the imaginary parts have opposite signs, so the phase distortion is opposite, as in [\(figure B2.4.4\(a\)\)](#). The sum of these distorted lineshapes gives the familiar coalescence spectrum. In fast exchange, the two lines are both in phase, but one line is negative [\(figure B2.4.4\(b\)\)](#). This negative line is very broad, and decreases in absolute intensity as the rate increases, leaving only the single, positive, in-phase line for fast exchange.

B2.4.2.5 CHEMICAL EXCHANGE IN COUPLED SPIN SYSTEMS

The development given in the previous section is simply a special case of the general density matrix treatment of chemical exchange. In an uncoupled system, the whole of the coherence from one site is transferred to the other, since the signal is directly associated with a given nucleus. This simplifies the calculation. In a coupled spin system, particularly a strongly coupled system, this is no longer true. The relation between the lines in the spectrum and individual nuclei can be much more complicated. Furthermore, the amount of ‘mixing’ of nuclei in a given spectrum depends on the chemical shifts and couplings. Therefore, when a nucleus exchanges in a coupled system, coherence that was associated with a single line in one site may be distributed amongst several lines in the other site. In dealing with chemical exchange in coupled systems, it is necessary to keep track of the details of each of the lines in the spectrum, but the fundamental approach is the same.

There is an important special case, called mutual exchange. In all exchange phenomena, a specific nucleus experiences a different magnetic environment when it moves from one site to the other. However, in many cases, the new arrangement is simply a permutation of the old, as in the case of formamide in [\(figure B2.4.3\)](#). The two amide protons have switched places, but the chemical shifts and couplings are the same. All that has changed is the nuclei associated with each of them. This can be treated in the same way as all other exchanges, as two different sites. However, the permutation symmetry of the problem means that this is equivalent to copies of a single, mutual, exchange. The matrices are then reduced in size. It is possible to have quite complex permutations, so the analysis must be done carefully and systematically. It is therefore

important to identify mutual exchange and treat it appropriately.

Binsch [6] provided the standard way of calculating these lineshapes in the frequency domain, and implemented it in the program DNMR3 [7]. Formally, it is the same as the matrix description given in [section \(B2.4.2.3\)](#). The calculation of the matrices **L**, **R** and **K** is more complex for a coupled spin system, but that should not interfere with the understanding of how the method works. This work will be discussed later, but first the time-domain approach will be developed.

The basic equation [8] is the equation of motion for the density matrix, ρ , given in [equation \(B2.4.25\)](#), in which H is the Hamiltonian.

-12-

$$i \frac{\hbar}{2\pi} \frac{\partial}{\partial t} \rho = [H, \rho]. \quad (\text{B2.4.25})$$

It is more convenient to re-express this equation in Liouville space [8, 9 and 10], in which the density matrix becomes a vector, and the commutator with the Hamiltonian becomes the Liouville superoperator. In this formulation, the lines in the spectrum are some of the elements of the density ‘matrix’ vector, and what happens to them is described by the superoperator matrix. [equation \(B2.4.25\)](#) becomes [\(B2.4.26\)](#).

$$i \frac{\hbar}{2\pi} \frac{\partial}{\partial t} \rho = \mathbf{L} \rho. \quad (\text{B2.4.26})$$

This Liouville-space equation of motion is exactly the time-domain Bloch equations approach used in [equation \(B2.4.13\)](#). The magnetizations are arrayed in a vector, and anything that happens to them is represented by a matrix. In frequency units ($\hbar/2\pi = 1$), the formal solution to [equation \(B2.4.26\)](#) is given by [equation \(B2.4.27\)](#) (compare [equation \(B2.4.14\)](#)).

$$\rho(t) = \exp(-i\mathbf{L}t) \rho(0). \quad (\text{B2.4.27})$$

For a coupled spin system, the matrix of the Liouvillian must be calculated in the basis set for the spin system. Usually this is a simple product basis, often called product operators, since the vectors in Liouville space are spin operators. The matrix elements can be calculated in various ways. The Liouvillian is the commutator with the Hamiltonian, so matrix elements can be calculated from the commutation rules of spin operators. Alternatively, the angular momentum properties of Liouville space can be used. In either case, the chemical shift terms are easily calculated, but the coupling terms (since they are products of operators) are more complex. In [section B2.4.2.7](#), the Liouville matrix for the single-quantum transitions for an AB spin system is presented.

Relaxation or chemical exchange can be easily added in Liouville space, by including a Redfield matrix, **R**, for relaxation, or a kinetic matrix, **K**, to describe exchange. The equation of motion for a general spin system becomes [equation \(B2.4.28\)](#).

$$\rho(t) = \exp(-i\mathbf{L} - \mathbf{R} - \mathbf{K})t \rho(0). \quad (\text{B2.4.28})$$

In NMR, the magnetization in the xy plane is detected, so it is the expectation value of the I_x operator that is measured. This is just the unweighted sum of all the I_{x_i} operators for the individual spins i . It may be a function of several time variables (multi-dimensional experiments), including the time during the acquisition,

but it is always given by equation (B2.4.29).

$$\langle I_x(t) \rangle = \text{trace}(I_x \rho(t)). \quad (\text{B2.4.29})$$

In Liouville space, both the density matrix and the I_x operator are vectors. The dot product of these Liouville space

-13-

vectors is the trace of their product as operators. Therefore, the NMR signal, S , as a function of a single time variable, t , is given by equation (B2.4.30), in which the parentheses denote a Liouville space scalar product (compare equation (B2.4.12)).

$$S(t) = (I_x | \rho(t)). \quad (\text{B2.4.30})$$

The experiment starts at equilibrium. In the high-temperature approximation, the equilibrium density operator is proportional to the sum of the I_z operators, which will be called F_z . If there are multiple exchanging sites with unequal populations, p_i , the sum is a weighted one, as in equation (B2.4.31).

$$F_x = \sum_{i=1}^n p_i I_{xi}. \quad (\text{B2.4.31})$$

A simple, non-selective pulse starts the experiment. This rotates the equilibrium z magnetization onto the x axis. Note that neither the equilibrium state nor the effect of the pulse depend on the dynamics or the details of the spin Hamiltonian (chemical shifts and coupling constants). The equilibrium density matrix is proportional to F_z . After the pulse the density matrix is therefore given by F_x and it will evolve as in equation (B2.4.27). If (B2.4.28) is substituted into (B2.4.30), the NMR signal as a function of time t , is given by (B2.4.32). In this equation there is a distinction between the sum of the operators weighted by the equilibrium populations, F_x , from the unweighted sum, I_x . The detector sees each spin (but not each coherence!) equally well.

$$S(t) = (I_x | \exp([-i\mathbf{L} - \mathbf{R} - \mathbf{K}]t) F_x). \quad (\text{B2.4.32})$$

As with the uncoupled case, one solution involves diagonalizing the Liouville matrix, $i\mathbf{L} + \mathbf{R} + \mathbf{K}$. If \mathbf{U} is the matrix with the eigenvectors as columns, and Λ is the diagonal matrix with the eigenvalues down the diagonal, then (B2.4.32) can be written as (B2.4.33). This is similar to other eigenvalue problems in quantum mechanics, such as the transformation to normal co-ordinates in vibrational spectroscopy.

$$S(t) = (I_x | \mathbf{U} \exp(-i\Lambda t) \mathbf{U}^{-1} | F_x). \quad (\text{B2.4.33})$$

Note that the Liouville matrix, $i\mathbf{L} + \mathbf{R} + \mathbf{K}$ may not be Hermitian, but it can still be diagonalized. Its eigenvalues and eigenvectors are not necessarily real, however, and the inverse of \mathbf{U} may not be its complex-conjugate transpose. If complex numbers are allowed in it, equation (B2.4.33) is a general result. Since Λ is a diagonal matrix it can be expanded in terms of the individual eigenvalues, λ_j . The inverse matrix \mathbf{U}^{-1} can be applied ('backwards') to I_x , and we obtain equation (B2.4.34).

$$S(t) = \sum_j (\mathbf{U}^{-1} I_x)_j^* (\mathbf{U} F_x)_j e^{i\lambda_j t}. \quad (\text{B2.4.34})$$

In this equation, the index j runs over all the transitions and the exponents have both real and imaginary parts, which

-14-

give the linewidth and position of the lines. The terms before the exponential are also complex, giving the intensity and phase.

For a general system, these sets of equations are huge, as written. For n spins $-1/2$, the density matrix has 2^{2n} elements, so the Liouville matrix has 2^{4n} elements. However, the density matrix elements can be sorted according to coherence level—the number of quanta associated with the transition. In this case, the matrices block, and the largest single block is the one corresponding to the single-quantum transitions. Its size is the binomial coefficient $(2n)!/(n+1)!(n-1)!$. This can be further divided into blocks based on the factoring from spectral analysis. A transition can change the z quantum number of the spin wavefunction by only ± 1 . For three spins $-1/2$, the eight wave functions are divided as follows: one with z quantum number $+3/2$, three with $+1/2$, three with $-1/2$ and one with $-3/2$. Therefore, the 15 possible transitions are divided into two groups of three ($+3/2 \rightarrow +1/2$, and $-1/2 \rightarrow -3/2$), and a group of nine ($+1/2 \rightarrow -1/2$). Further reductions can be achieved using weak coupling approximations and magnetic equivalence. In practice, system of five or six spins can be treated with modern computers.

B2.4.2.6 GENERALIZED TRANSITION PROBABILITIES

The quantities $(\mathbf{U}^{-1}I_x)_j$ and $(\mathbf{U}F_x)_j$ in B2.4.34 are projections of the eigenvector j along I_x . From the above equations, this can be interpreted as follows. The term $(\mathbf{U}F_x)_j$ is the amount that the transition j received from the total x magnetization created from the equilibrium state and $(\mathbf{U}^{-1}I_x)_j$ is how much that transition contributes to the observed signal. These two terms may not be equal, as will be seen in exchanging systems. An informal way of thinking about these terms is to consider the transition moment, $\langle \phi_f | I_x | \phi_i \rangle$. If the ket–bra operator $|\phi_f\rangle \langle \phi_i|$ represents the transition, then the transition moment is the projection of the transition operator along the I_x operator.

In the usual preparation–evolution–detection paradigm, neither the preparation nor the detection depend on the details of the Hamiltonian, except in special cases. Starting from equilibrium, a hard pulse gives a density matrix that is just proportional to F_z . The detector picks up only the unweighted sum of the spin operators, I_x . It is only during an evolution (perhaps between sampling points in an FID) that these totals need be divided amongst the various lines in the spectrum. Therefore, one of the factors in the transition probability represents the conversion from preparation to evolution; the other factor represents the conversion back from evolution to detection.

Equation (B2.4.33) and equation (B2.4.34) are the basic equations for a time-domain description. For instance, they say that any time-domain NMR signal is the sum of decaying oscillations. This is obvious from the fact that it is described by a first-order differential equation, but (B2.4.34) gives a way of calculating the values of these exponentials for any system, static or dynamic. The distinctions amongst different types of spectrum lie in the eigenvalues and eigenvectors of the Liouville matrix $i\mathbf{L}+\mathbf{R}+\mathbf{K}$. equation (B2.4.34) describes static spectra, spin relaxation and spectra showing the effects of chemical exchange or T_2 relaxation, in a single, unified picture.

B2.4.2.7 EXAMPLE OF THE AB SPIN SYSTEM

For example, the observed transitions of an AB spin system have a Liouville matrix given in equation (B2.4.35). The coupling constant is J , and it is assumed that $\omega_B = -\omega_A = -\delta/2$, so that δ is the frequency difference between the two sites. The angle, θ , is defined for the AB system by the equation $\tan(\theta)=J/2\delta$. The Liouville space basis used here is the superspin equivalent of the four product operators $(I_x^A, I_x^A I_z^B, I_x^B, I_x^B I_z^A)$,

and a set of rules for calculating these elements is given elsewhere [12].

-15-

$$\begin{pmatrix} i\omega_A & iJ/2 & 0 & -iJ/2 \\ iJ/2 & i\omega_A & -iJ/2 & 0 \\ 0 & -iJ/2 & i\omega_B & iJ/2 \\ -iJ/2 & 0 & iJ/2 & i\omega_B \end{pmatrix}. \quad (\text{B2.4.35})$$

The four eigenvalues, which give the positions of the lines, are $\pm J/2 \pm ((J/2)^2 + (\delta/2)^2)^{1/2}$, as expected for an AB system. The matrix of eigenvectors as columns is given in equation (B2.4.36), in which $c = \cos(\theta)$, $s = \sin(\theta)$ and δ is defined above.

$$\text{Eigenvectors} = \begin{pmatrix} c & s & c & s \\ c & s & -c & -s \\ -s & c & s & -c \\ -s & c & -s & c \end{pmatrix}. \quad (\text{B2.4.36})$$

In the basis used in (B2.4.35), the total x magnetization is proportional to the vector (1, 0, 1, 0). Taking the dot product with the eigenvectors shows that the outer lines receive $(\cos\theta - \sin\theta)$ from the total, whereas the inner lines receive $(\cos\theta + \sin\theta)$. The squares of these terms give the familiar AB system intensities: $(1 - \sin 2\theta)$ and $(1 + \sin 2\theta)$.

Once the AB spin system is defined, the effects of chemical exchange can be calculated. This can be either non-mutual or mutual exchange. In the case of non-mutual exchange, there are two blocks, one for each site, and the exchange connecting them, as in equation (B2.4.37). For a simple product basis, the exchange always has this form: the off-diagonal blocks are themselves diagonal and the sum of the exchange contributions in any column must be zero, to preserve the number of spins. In this equation, zeros have been replaced by dots to emphasize the form of the matrix.

$$\begin{pmatrix} i\omega_A - k' & iJ/2 & \cdot & -iJ/2 & k & \cdot & \cdot & \cdot \\ iJ/2 & i\omega_A - k' & -iJ/2 & \cdot & \cdot & k & \cdot & \cdot \\ \cdot & -iJ/2 & i\omega_B - k' & iJ/2 & \cdot & \cdot & k & \cdot \\ -iJ/2 & \cdot & iJ/2 & i\omega_B - k' & \cdot & \cdot & \cdot & k \\ k' & \cdot & \cdot & \cdot & i\omega'_A - k & iJ'/2 & \cdot & -iJ'/2 \\ \cdot & k' & \cdot & \cdot & iJ'/2 & i\omega'_A - k & -iJ'/2 & \cdot \\ \cdot & \cdot & k' & \cdot & \cdot & -iJ'/2 & i\omega'_B - k & iJ'/2 \\ \cdot & \cdot & \cdot & k' & -iJ'/2 & \cdot & iJ/2 & i\omega'_B - k \end{pmatrix}. \quad (\text{B2.4.37})$$

In this equation, the primes on the imaginary parts indicate that the Larmor frequencies and coupling constants will be different. Also, if the equilibrium constant for the exchange is not 1, then the forward and reverse rates will not be equal. Note that the 1,2 block, in the top right, represents the rate from site 2 into site 1.

B2.4.2.8 MUTUAL EXCHANGE IN THE AB SYSTEM

In the case of mutual AB exchange this matrix can be simplified. The equilibrium constant must be 1, so $k = k'$. Also, ω^A is equal to ω_B and vice versa, and the coupling constant is the same. For instance, if \mathbf{L} is the Liouville matrix for one site, then the Liouville matrix for the other site is $\mathbf{P}^{-1}\mathbf{L}\mathbf{P}$, where \mathbf{P} is the matrix describing the permutation.

The exchange matrix, \mathbf{K} , is just the rate, k , times the unit matrix. In block form, the full matrix for two sites is given in the eigenvalue equation, (B2.4.38).

$$\begin{pmatrix} i\mathbf{L} - \mathbf{K} & \mathbf{K} \\ \mathbf{K} & i\mathbf{P}^{-1}\mathbf{L}\mathbf{P} - \mathbf{K} \end{pmatrix} \begin{pmatrix} a \\ \mathbf{P}^{-1}a \end{pmatrix} = \lambda \begin{pmatrix} a \\ \mathbf{P}^{-1}a \end{pmatrix}. \quad (\text{B2.4.38})$$

This equation is equivalent to the pair of equations in (B2.4.39).

$$\begin{aligned} i\mathbf{L}a - \mathbf{K}(1 - \mathbf{P}^{-1})a &= \lambda a \\ i\mathbf{P}^{-1}\mathbf{L}a - \mathbf{K}(\mathbf{P}^{-1} - 1)a &= \lambda \mathbf{P}^{-1}a. \end{aligned} \quad (\text{B2.4.39})$$

Since \mathbf{K} is a multiple of the unit matrix and the permutation is its own inverse, the two equations (B2.4.39) are the same. The Liouvillian for a single site is set up and the exchange is described by $\mathbf{K}(1 - \mathbf{P}^{-1})$.

Application of this approach to [equation \(B2.4.37\)](#) gives equation (B2.4.40). If $\omega_B = -\omega_A = -\delta/2$, the symmetry of the matrix and one additional transformation means that it can be broken into two 2×2 complex matrices, which can be diagonalized analytically. The resulting lineshapes match the published solutions [13].

$$\begin{pmatrix} i\omega_A - k & iJ/2 & k & -iJ/2 \\ iJ/2 & i\omega_A - k & -iJ/2 & k \\ k & -iJ/2 & i\omega_B - k & iJ/2 \\ -iJ/2 & k & iJ/2 & i\omega_B - k \end{pmatrix}. \quad (\text{B2.4.40})$$

B2.4.2.9 INTERMOLECULAR EXCHANGE

The phenomenon of intermolecular exchange is very common. The loss of couplings to hydroxyl protons in all but the very purest ethanol samples was observed at a very early stage. Proton transfer reactions are still probably the most carefully studied [14] class of intermolecular exchange.

In classical kinetics, intermolecular exchange processes are quite different from the unimolecular, first-order kinetics associated with intramolecular exchange. However, the NMR of chemical exchange can still be treated as pseudo-first-order kinetics, and all the previous results apply. One way of rationalizing this is as follows. NMR follows a particular nucleus, but typically only 1 in 10^5 nuclei is ‘visible’ (due to the small Boltzmann population difference). When a visible nucleus exchanges with another nucleus on another molecule, the probability is that the other nucleus is invisible. The exchange partners vastly overwhelm the visible nuclei.

However, all the nuclei have spin. An example of this occurs in the intermolecular exchange of an AB spin system, as in equation (B2.4.41).

In this case, a spin A that was coupled to the α orientation of the B spin may end up, after the exchange, coupled to either α or β . Because of the Boltzmann distribution, the amounts of α and β orientation are each

half of the sample. The first exchange is degenerate, but the second is a change of the B spin. This can be treated as exchange with a site in which the shifts are the same, but the coupling constant is of the opposite sign. If these spin parameters are used in [equation \(B2.4.37\)](#), then the lineshapes in [figure B2.4.5](#) are obtained.

Figure B2.4.5. Simulated lineshapes for an intermolecular exchange reaction in which the bond joining two strongly coupled nuclei breaks and re-forms at a series of rates, given beside the lineshape. In slow exchange, the typical spectrum of an AB spin system is shown. In the limit of fast exchange, the spectrum consists of two lines at the two chemical shifts and all the coupling has disappeared.

B2.4.2.10 CALCULATION OF THE SPECTRUM

Once the basic work has been done, the observed spectrum can be calculated in several different ways. If the problem is solved in the time domain, then the solution provides a list of transitions. Each transition is defined by four quantities: the integrated intensity, the frequency at which it appears, the linewidth (or decay rate in the time domain) and the phase. From this list of parameters, either a spectrum or a time-domain FID can be calculated easily. The spectrum has the advantage that it can be directly compared to the experimental result. An FID can be subjected to some sort of apodization before Fourier transformation to the spectrum; this allows additional line broadening to be added to the spectrum independent of the simulation.

The Bloch equation approach ([equation \(B2.4.6\)](#)) calculates the spectrum directly, as the portion of the spectrum that is linear in a B_1 observing field. Binsch generalized this for a fully coupled system, using an exact density-matrix approach in Liouville space. His expression for the spectrum is given by [equation \(B2.4.42\)](#). Note that this is formally the Fourier transform of [equation \(B2.4.32\)](#), so the time domain and frequency domain are connected as usual.

$$S(\omega) = \text{Re}[F_-(i\mathbf{L} - \mathbf{R} - \mathbf{K})^{-1}M_0]. \quad (\text{B2.4.42})$$

In practice, the spectrum is usually calculated by diagonalizing the matrix first [15], as was done in the time domain. This means that the large matrix does not have to be inverted for each point in the spectrum. However, for very large matrices, it may be numerically more efficient not to diagonalize, but rather to invert at each data point. For a six-spin system, the full matrix is 792×792 , and each additional spin multiplies each dimension by roughly a factor of 4. Since the time for a diagonalization scales roughly as the cube of the dimension of the matrix, larger spin systems become impractical. However, modern sparse-matrix methods for matrix inversion do not suffer from the same dramatic scaling, and so will become more efficient for larger spin systems.

The method for studying intermediate exchange in NMR is to obtain an excellent equilibrium spectrum of the system as a function of temperature. Then the theoretical apparatus developed above can be used to simulate and to fit the experimental data, in order to obtain the rate data.

B2.4.3 FAST EXCHANGE

B2.4.3.1 INTRODUCTION

In the limit of fast exchange, the lineshape of chemical exchange quickly becomes a single Lorentzian line. In [figure B2.4.4\(b\)](#) the negative line broadens directly as the rate, and loses absolute intensity as well. This combination of the increasing width and decreasing integral means that the negative line quickly becomes irrelevant to the experimental lineshape. This becomes a pure Lorentzian, whose width is proportional to $(\Delta\omega)^2/k$, where $\Delta\omega$ is the difference in Larmor frequency of the two sites and k is the exchange rate. Measuring the rate is then equivalent to measuring the spin–spin relaxation time, T_2 . The problem is that unless there is an estimate of $\Delta\omega$ (from a spectrum that is ‘frozen out’) an absolute value of the rate cannot be measured. However, T_2 measurements themselves have an associated timescale. If that can match the exchange rate, then an absolute rate can be measured.

B2.4.3.2 T_2 MEASUREMENTS

In principle, T_2 can be measured directly from the linewidth of the spectrum. However, since experimental linewidths are also governed by inhomogeneous broadening (magnetic field inhomogeneities etc), careful T_2 determinations require methods that cancel out inhomogeneous effects [16]. Three techniques are commonly available: the Carr–Purcell–Meiboom–Gill (CPMG) spin echo experiment, the $T_{1\rho}$ experiment and the offset-saturation method [17]. All three can be implemented easily on modern spectrometers.

The Hahn spin echo, with a single refocusing pulse, eliminates effects due to magnetic field inhomogeneities, so a study of the echo intensity as a function of the echo time should yield T_2 . However, if there is a field gradient present, diffusion in the sample can also attenuate the echo. Even with modern well shimmed magnets, the gradients are still large enough to affect a T_2 measurement in water. In the CPMG experiment, a series of closely spaced refocusing pulses suppresses diffusion effects. In this case, the echo intensity is measured as a function of echo number, and reliable values of T_2 can be obtained.

The parameter $T_{1\rho}$ is the longitudinal relaxation time of a magnetization which is spin locked along a radiofrequency magnetic field. The magnetization is flipped onto the x axis (for instance) by an RF pulse along y . The RF phase is changed by 90° , and the magnetization is then spin locked by the RF field, now along x . When the RF is shut off, the remaining xy magnetization can be detected directly. An analysis of the signal as a function of the spin-locking time yields T_2 . The offset-saturation experiment [18] consists of

irradiating the spin system with a known RF field at some offset from resonance until a steady state is achieved. The z magnetization is then measured by a non-selective observe pulse. A plot (figure B2.4.6) of the partially saturated z magnetization against offset from resonance will show a dip at resonance. The width of this dip is given by equation (B2.4.43).

Figure B2.4.6. Results of an offset-saturation experiment for measuring the spin–spin relaxation time, T_2 . In this experiment, the signal is irradiated at some offset from resonance until a steady state is achieved. The partially saturated z magnetization is then measured with a $\pi/2$ pulse. This figure shows a plot of the z magnetization as a function of the offset of the saturating field from resonance. Circles represent measured data; the line is a non-linear least-squares fit. The signal is normal when the saturation is far away, and dips to a minimum on resonance. The width of this dip gives T_2 , independent of magnetic field inhomogeneity.

$$\text{Dip width} = (\gamma B_2) \sqrt{T_1/T_2}. \quad (\text{B2.4.43})$$

-20-

If the strength of the saturating RF, ΔB_2 , and the spin–lattice relaxation time, T_1 , are known, then T_2 can be measured, again free of magnetic field inhomogeneities.

These T_2 measurements can allow reaction rates of 10^5 s^{-1} or more to be measured. In combination with slow- and intermediate-exchange methods, this means that rates can be measured over a range of more than five orders of magnitude. This means that excellent thermodynamic parameters can be obtained. [Figure B2.4.2](#) shows some results on furfural, a system which has unequally populated sites. For this case, the range of rates over which lineshape methods are useful is quite small. In the case of two-site, unequally populated exchange, the minor peak broadens faster than the major peak (the relative rate of broadening is the ratio of the major population to the minor). The minor peak disappears into the baseline quickly, but T_2 measurements can still provide good data.

These experiments yield T_2 which, in the case of fast exchange, gives the ratio $(\Delta\omega)^2/k$. However, since the experiments themselves have an implicit timescale, absolute rates can be obtained in favourable circumstances. For the CPMG experiment, the timescale is the repetition time of the refocusing pulse; for the $T_1\rho$ experiment, it is the rate of precession around the effective RF field. If this timescale is fast with respect to the exchange rate, then the experiment effectively measures T_2 in the absence of exchange. If the timescale is slow, the apparent T_2 contains the effects of exchange. Therefore, the apparent T_2 shows a dispersion as the

timescale of the measurement method is changed [19]. Practical spectrometer considerations of RF heating and duty cycle usually limit these timescales to tens of kilohertz. However, if the conditions are appropriate, this dispersion curve yields an absolute rate.

B2.4.4 SLOW EXCHANGE

B2.4.4.1 INTRODUCTION

The term ‘slow’ in this case means that the exchange rate is much smaller than the frequency differences in the spectrum, so the lines in the spectrum are not significantly broadened. However, the exchange rate is still comparable with the spin–lattice relaxation times in the system. Exchange, which has many mathematical similarities to dipolar relaxation, can be observed in a NOESY-type experiment (sometimes called EXSY). The rates are measured from a series of EXSY spectra, or by performing modified spin–lattice relaxation experiments, such as those pioneered by Hoffman and Forsen [20].

In the absence of exchange (and ignoring dipolar relaxation), each z magnetization will relax back to equilibrium at a rate governed by its own T_1 , as in (B2.4.44).

$$\frac{d}{dt}[M(t) - M(\infty)] = -\frac{1}{T_1}[M(t) - M(\infty)]. \quad (\text{B2.4.44})$$

If there are two sites, A and B, then an analogous equation can be written, as in (B2.4.45).

$$\frac{d}{dt} \begin{bmatrix} M_A(t) - M_A(\infty) \\ M_B(t) - M_B(\infty) \end{bmatrix} = \begin{pmatrix} \frac{1}{T_1^A} & 0 \\ 0 & \frac{1}{T_1^B} \end{pmatrix} \begin{bmatrix} M_A(t) - M_A(\infty) \\ M_B(t) - M_B(\infty) \end{bmatrix}. \quad (\text{B2.4.45})$$

-21-

If the two sites exchange with rate k during the relaxation, then a spin can relax either through normal spin–lattice relaxation processes, or by exchanging with the other site. [equation \(B2.4.45\)](#) becomes (B2.4.46).

$$\frac{d}{dt} \begin{bmatrix} M_A(t) - M_A(\infty) \\ M_B(t) - M_B(\infty) \end{bmatrix} = \begin{pmatrix} -\frac{1}{T_1^A} - k & k \\ k & -\frac{1}{T_1^B} - k \end{pmatrix} \begin{bmatrix} M_A(t) - M_A(\infty) \\ M_B(t) - M_B(\infty) \end{bmatrix}. \quad (\text{B2.4.46})$$

This equation is very similar to (B2.4.13). The basic situation is just as in intermediate exchange, except that it describes z magnetizations rather than xy . The frequencies are zero, and the matrix now has pure real eigenvalues, but the approach is the same. The time domain is a natural one for slow exchange, since a relaxation experiment follows the z magnetizations as a function of time. As before, the time dependence is obtained by diagonalizing the relaxation/exchange matrix and calculating the magnetizations for each time at which they are sampled. In this case, the solution is given by [equation \(B2.4.47\)](#), the same as [equation \(B2.4.14\)](#), except there are no imaginary terms.

$$\begin{bmatrix} M_A(t) - M_A(\infty) \\ M_B(t) - M_B(\infty) \end{bmatrix} = \exp(-[R + K]t) \begin{pmatrix} M_A(0) - M_A(\infty) \\ M_B(0) - M_B(\infty) \end{pmatrix}. \quad (\text{B2.4.47})$$

B2.4.4.2 TWO-DIMENSIONAL METHODS

There are two main applications of slow chemical exchange: one is to determine the qualitative mechanism, and the other is to measure the rates of the processes as accurately as possible. For the first case, in which we have a spectrum in slow exchange, we need to establish the mechanism: which site is exchanging with which. For this purpose, the homonuclear two-dimensional experiment EXSY (the same pulse sequence as NOESY, but involving exchange) is by far the best technique to use. Exchange between sites leads to a pair of symmetrical cross-peaks joining the diagonal peaks of the same site, so the mechanism is very obvious.

The EXSY pulse sequence starts with two $\pi/2$ pulses separated by the incrementable delay, t_1 . This modulates the z magnetizations, so that the relaxation that occurs during the mixing time which follows, t_m , is frequency labelled. Finally, the z magnetizations are sampled with a third $\pi/2$ pulse. Magnetization from a different site that enters via exchange will have a different frequency label. A two-dimensional Fourier transform then produces the spectrum. The initial rate of increase of the cross-peak gives the rate of exchange. A series of EXSY experiments as a function of mixing times will define the mechanism and give an estimate of the rates.

However, care must be taken in choosing the mixing time if there are multiple exchange processes. If the mixing time is too long, there is a substantial probability that a spin may have exchanged twice in that time, leading to spurious cross-peaks. Orrell and his group [21] have solved this problem by treating the effect of exchange on the z magnetizations correctly, and have written a program which simulates the two-dimensional spectrum as a function of the mixing time.

Since exchange and coupled relaxation have the same mathematical form, both may contribute to a NOESY/EXSY spectrum, as in [figure B2.4.7](#). For small molecules, since the NOE is positive and exchange creates saturation transfer (like a negative NOE), the NOESY and EXSY cross peaks have opposite signs. For macromolecules in the spin-diffusion limit, the peaks have the same sign, but exchange cross-peaks can usually be distinguished by their much stronger temperature dependence.

-22-

Figure B2.4.7. Contour plot of a phase-sensitive NOESY/EXSY spectrum of the derivative of TEMPO. The peaks are positive, with the exception of the circled peaks, which are negative. The spectrum shows the exchange of the four methyl groups in this molecule. A combination of a ring-flip and inversion at nitrogen means that the axial methyl on one side of the ring exchanges with the equatorial methyl on the other side. The positive cross-peaks show the exchange of the two sets of methyls. However, there are also NOE cross-peaks between methyl groups on the same side of the ring. Since this is a small molecule, the NOE peaks are of opposite sign to the exchange peaks. There are two NOE cross-peaks for each methyl, since the exchange process is relatively fast, and distributes the NOE between the two exchange partners.

B2.4.4.3 ONE-DIMENSIONAL SELECTIVE-INVERSION METHODS

For careful rate measurements, once the mechanism is established, it is our opinion that one-dimensional methods are superior to quantitative 2D ones. Apart from the fact that 1D spectra can be integrated more easily, there is also more control over the experiment. Modern spectrometers can create almost any type of selective excitation, so that there is control of the conditions at the start of the relaxation. For two sites, a non-selective inversion that inverts both sites equally will mask most of the exchange effects and the relaxation will be dominated by T_1 . However, if one site is inverted selectively, then that site can regain equilibrium by either T_1 processes or by exchanging with the other site that was left at equilibrium [20]. The inverted signal will relax at roughly the sum of the exchange and spin-lattice relaxation rate, while the signal that was unperturbed at the start of the experiment shows a characteristic transient, as in [figure B2.4.8](#). These one-dimensional selective-inversion experiments have been widely used in systems without scalar coupling, such as methyl groups or ^{13}C spectra.

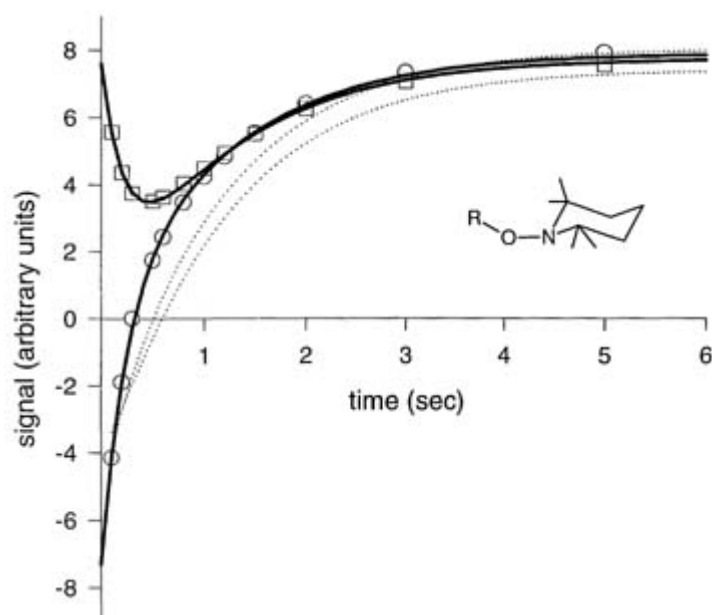

Figure B2.4.8. Relaxation of two of the exchanging methyl groups in the TEMPO derivative in [figure B2.4.7](#). The dotted lines show the relaxation of the two methyl signals after a non-selective inversion pulse (a typical T_1 experiment). The heavy solid line shows the recovery after the selective inversion of one of the methyl signals. The inverted signal (circles) recovers more quickly, under the combined influence of relaxation and exchange with the non-inverted peak. The signal that was not inverted (squares) shows a characteristic transient. The lines represent a non-linear least-squares fit to the data.

For multiple sites, a wide range of initial conditions is available. For instance, in a three-site exchange amongst A, B and C, the signal due to A can be inverted selectively. This will provide rate information on the A–B exchange and the A–C exchange, but relatively little about B–C. This is one example of using the initial conditions to suppress or enhance the observation of particular processes. The definition of how selective a selective inversion may be gives an added degree of control over the experiment.

The selective-inversion experiment gives excellent rate data. The description of the time evolution of the z magnetizations in [equation \(B2.4.47\)](#) is exact. There are no assumptions about short mixing times or initial rates. Standard non-linear least-squares methods allow fitting these curves to the measured data and deriving values for the rates involved. Believing in the error estimates of these multi-parameter fitting procedures can be dangerous, however. A more reliable error estimate can be obtained by ‘profiling’. In this procedure, a global fit to all parameters is done first. Then the rate (or any other parameter of interest) is fixed at a different value, and the data are re-fitted using all the other parameters. As the rate is moved from the optimum value, the fit will become worse, as measured by the sum of the squares of the deviations between real data and the model. When the ‘badness of fit’ exceeds a critical level of the F statistic, the value of the rate is at the end of a confidence interval. This confidence interval can be several times larger than the one calculated from the usual standard deviation in a nonlinear least-squares fit. Even with this error estimate, it is possible to measure rates with errors of less than 10%. [Figure B2.4.8](#) shows the quality of result that is possible.

In a selective-inversion experiment, it is the relaxation of the z magnetizations that is being studied. For a system without scalar coupling, this is straightforward: a simple pulse will convert the z magnetizations directly into observable signals. For a coupled spin system, this relation between the z magnetizations and the observable transitions is much more complex [22].

In a coupled spin system, the number of observed lines in a spectrum does not match the number of independent z magnetizations and, furthermore, the spectra depend on the flip angle of the pulse used to observe them. Because of the complicated spectroscopy of homonuclear coupled spins, it is only recently that selective inversions in simple coupled spin systems [23] have been studied. This means that slow chemical exchange can be studied using proton spectra without the requirement of single characteristic peaks, such as methyl groups.

The z magnetizations of the spin system are key to the problem, since the exchange is measured in competition with their relaxation processes. However, for a coupled spin system, the lines in the spectrum do not directly reflect the z magnetizations. Even for two weakly coupled spins, there are four lines in the spectrum (two doublets), but there are only three independent z magnetizations. There are indeed four energy levels, but the sum of their populations must be constant. There are three independent quantities: the total magnetization of A , the total X magnetization, and a shared $I_z J_z$ magnetization. For coupled systems, especially those with strong coupling, the relation of the z magnetizations to the observed spectrum can be quite complex.

There are several complications. One is the flip angle dependence of the spectra [22, 24]. For a non-equilibrium state of a coupled spin system, the observed intensities of the lines depend on the flip angle used to observe them. In particular, spectra are only 'true' reflections of the z magnetizations in the limit of small flip angles. A further complication arises because the z magnetizations are part of a larger manifold of coherences that also includes the zero-quantum transitions. Both the z magnetizations and the zero-quantum transitions have coherence level zero and they cannot be separated by pulses or phase cycling [11]. This is the problem with the zero-quantum coherences in NOESY, for instance. For instance, for three spins there are eight z magnetizations, one of which is fixed as the total number of spins. However, there are 20 coherence level zero density matrix elements, leaving six pairs of zero quantum transitions. The 15 observable xy magnetizations for a three-spin system cannot correspond directly to the eight z magnetizations. Provided that these complications are recognized, they can be treated easily with standard spin-dynamics techniques.

The xy magnetizations can also be complicated. For n weakly coupled spins, there can be $n^* 2^{n-1}$ lines in the spectrum and a strongly coupled spin system can have up to $(2n)!/((n-1)!(n+1)!)$ transitions. Because of small couplings, and because some lines are weak combination lines, it is rare to be able to observe all possible lines. It is important to maintain the distinction between mathematical and practical relationships for the density matrix elements.

These complications require some careful analysis of the spin systems, but fundamentally the coupled spin systems are treated in the same way as uncoupled ones. Measuring the z magnetizations from the spectra is more complicated, but the analysis of how they relax is essentially the same.

B2.4.5 EXCHANGE IN SOLIDS

Exchange in the solid state follows the same basic principles as in liquids. The classic Cope re-arrangement of bullvalene occurs in both the liquid and solid state [25], and the lineshapes in the spectra are similar. However, because of chemical shielding anisotropy (CSA) and quadrupolar and dipolar effects, the Larmor

frequency of a given spin depends on the orientation of the individual molecule. In a liquid, where there is isotropic tumbling, these effects average out and exchange is only evident if there is a change in isotropic chemical shift. In a solid, almost any type of molecular motion can cause lineshape and other effects. Furthermore, many NMR spectra of solids are run under the conditions of magic-angle spinning. This introduces a further timescale into the spectroscopy: the spinning rate, which can now go up to 25 kHz or more. The basic principles are the same, but the systems studied and the observed phenomena can be quite different.

Intermediate exchange is the regime in which lineshape changes are the most obvious manifestation. In ^{13}C magic-angle spinning (MAS) spectra, there can be all the liquid-like coalescence phenomena [26]. These can be analysed just as before. Another type occurs when a molecule re-orientates in the crystal lattice. Since the magnetic environment of the nucleus is anisotropic, the Larmor frequency of the spin changes. One of the most familiar examples is the effect of dynamics on powder patterns in deuterium spectra [27]. In a typical carbon–deuterium bond, the quadrupole coupling of the deuterium nucleus is about 160 kHz. This defines a timescale that is very useful for polymers and biological membranes, and deuterium spectra are widely used. Quite detailed information is available: lineshapes are significantly different for twofold jumps, threefold jumps or continuous diffusion. For instance, in a *tert*-butyl group, overall rotation can be distinguished from rotations of individual methyl groups.

Magic-angle spinning of solid samples provides an experimental parameter not available in liquids. A full analysis of the combined effects of dynamics and MAS for all relative timescales is a very complex problem, but for slow exchange there are techniques that are intuitive. The first is EXSY, which works well in MAS spectra, although the interpretation is confused by the phenomenon of spin diffusion. Cross-peaks can be due to the exchange of spin polarization (rather than the nuclei themselves) via the dipolar interaction. One-dimensional methods that use MAS are also available. The TOSS pulse sequence will eliminate spinning sidebands, provided there is no internal dynamics in the sample. If there is exchange on the timescale of a rotor period, the careful cancellation will no longer work, and sidebands will reappear [28]. Another use of spinning is the ODESSA [29] pulse sequence, which selectively inverts some of the sidebands, which then relax back due to chemical exchange.

B2.4.6 CONCLUSIONS

In order to study chemical exchange in NMR, it is necessary to have a scale against which to measure it. In fast and intermediate exchange, the timescale is the difference in Larmor frequency between the two sites. As the exchange rate approaches this timescale, the lines in the one-dimensional spectrum broaden, coalesce and sharpen into single lines. For intermediate exchange, the lineshape provides the best information. In fast exchange, the rate is starting to dominate the timescale, but useful information can still be extracted from T_2 measurements. In slow exchange, the spin–lattice relaxation provides a timescale. In this regime, modifications of methods for measuring T_1 and the NOE

are used. In MAS spectra of solids, the spinning rate provides another timescale. When the timescales match, dramatic effects can often be observed.

Once the exchange has been established, it is necessary to measure its rate. This is usually done by simulating the NMR experiment with a mathematical model and adjusting the rate in the model until it matches experiment. This means simulating the lineshape in intermediate exchange, or simulating the coupled relaxation of the z magnetizations in slow exchange. In both these cases, the model is similar. There is a matrix which describes each site in the exchange. These matrices form the diagonal of a larger block-diagonal matrix. The blocks are then connected by the exchange process, to form one large matrix. The exchange is

described by the eigenvalues and eigenvectors of the single large matrix.

The exact form of the matrices depend on the situation. In slow exchange, the matrices are real and they model the multi-exponential relaxation of the z magnetizations. In intermediate exchange, the matrix has both real and imaginary parts, as do the eigenvalues and eigenvectors. The model in this case produces a series of transitions, whose intensity, phase, position and width are given by a complex-valued transition probability. The intermediate-exchange spectrum is just the sum of these transitions.

The NMR methods for studying chemical exchange are fundamentally no different from standard NMR methods. Chemical exchange effects appear in the spectrum and in measurements of the relaxation times, so careful measurement of these will provide good exchange data. Perhaps this is the single conclusion: apart from some algebraic and numerical details, chemical exchange is identical to 'normal' NMR.

B2.5 Gas-phase kinetics studies

David Luckhaus and Martin Quack

B2.5.1 INTRODUCTION

The key to experimental gas-phase kinetics arises from the measurement of time, concentration, and temperature. Chemical kinetics is closely linked to time-dependent observation of concentration or amount of substance. Temperature is the most important single statistical parameter influencing the rates of chemical reactions (see [chapter A3.4](#) for definitions and fundamentals).

The rich history of experimental chemical kinetics can be broadly classified according to various conceptual phases. The starting point of quantitative chemical kinetics was the formulation, in 1850 by Wilhelmy [1], of the time dependence of concentrations by a differential equation corresponding to a pseudo-first-order rate law for the hydrolysis ('inversion') of cane sugar. The observation of the concentration of cane sugar was carried out spectroscopically in the early experiments by following the time-dependent rotation of the plane of polarized light by the reaction mixture after mixing the reactant and the catalyst (the acid). During the following half-century, until about 1900, the nature of such phenomenological rate laws was clarified, as was the role of the rate constant and its temperature dependence. This epoch is characterized by the concepts introduced by van't Hoff 2 and Arrhenius 3. It became clear that a distinction must be made between *phenomenological rate laws* for reactions following from a compound mechanism, such as the inversion of cane sugar, and rate laws and rate constants for *elementary reactions*, which can be combined into a compound mechanism. These new concepts characterize the second phase of chemical kinetics studies. For about half a century from 1900 to 1950, experimental investigations concentrated on elementary reactions and the mechanisms in which they are combined. The fathers of gas-phase kinetics, such as Bodenstein, Lindemann, and Hinshelwood, may be named as the representatives of this period.

During the course of these studies the necessity arose to study ever-faster reactions in order to ascertain their elementary nature. It became clear that the mixing of reactants was a major limitation in the study of fast elementary reactions. Fast mixing had reached its high point with the development of the accelerated and stopped-flow techniques [4, 5], reaching effective time resolutions in the millisecond range. Faster reactions were then frequently called 'immeasurably fast reactions' [1].

The new concept overcoming this limitation in the third phase of experimental kinetics started around 1950,

and consisted of initiating a chemical reaction by a very fast physical perturbation and measuring the subsequent relaxation kinetics without a mixing step in the experiment. Various schools developed techniques along these lines, such as Norrish and Porter with flash photolysis [7, 8], and Eigen's school with *T*-jump and other relaxation techniques [6]. Weller's kinetics of fluorescence change can be classified as an indirect technique along these lines [9, 10 and 11], and the Davidson and Jost schools developed shock-wave methods [12]. While the ideas for such techniques can be traced to earlier theoretical papers by Nernst and Einstein, the actual experimental developments started around 1950, initiating what has been called 'a race against time' [7, 8]. In particular, in relation to the laser-flash photolysis and pump-probe techniques developed after 1960, the essence of this race is to generate ever shorter laser pulses for 'pumping' a sample and well-controlled pulse delays for probing the sample's time evolution, where the lengths of the pulses define

-2-

the limits of the time resolution of the techniques. Nanosecond resolution was available by about 1966, picosecond resolution around 1970, and by about 1985 the domain around 10 fs had been reached. Since that time progress by these techniques towards shorter times has slowed down somewhat, a typical value being about 5 fs today (see [chapter B2.1](#)). One might mention, however, a paper on the '0 fs' pulse [13] (dated 1 April 1990).

In parallel with this race against time, new experimental concepts were introduced, which escape the race by switching to a conceptually new approach. Among these are the molecular-beam-scattering techniques developed by Datz, Taylor, Martin, Herschbach, Lee, and others [14, 15], measuring reaction cross sections without time resolution instead of time evolution and reaction rates. NMR line-shape methods proposed by Gutowsky and Holm [16, 17] are further examples for alternative techniques, where time-dependent rates are calculated from time independent information. Neither of these techniques, however, is very well suited to study very fast intramolecular primary processes, which mark the starting point of all chemical reactions and may be considered to characterize the present fourth phase of experimental chemical kinetics. The new concept making these processes accessible to experimental investigation starts from high-resolution molecular spectra in the frequency domain (stationary or at least without short-time resolution) to derive ultimately the full molecular quantum-chemical kinetics in the time ranges from nanoseconds to attoseconds [18]. This experimental approach was, in fact, historically the first one to provide non-trivial three-dimensional molecular quantum wave packet dynamics [18, 19, and 20], some time even before the first one-dimensional molecular quantum wave packet kinetics became available by short-pulse techniques (see [7, 21, 22 and 23] and references cited therein). The scope of the present chapter is to cover the most important experimental techniques in current use, including some of the well-established but also some of the most recent ones, together with current developments and to illustrate them with a few typical examples of results. The presentation by necessity is exemplary and not exhaustive.

On a modest level of detail, kinetic studies aim at determining overall phenomenological rate laws. These may serve to discriminate between different mechanistic models. However, to *it prove* a compound reaction mechanism, it is necessary to determine the rate constant of each elementary step individually. Many kinetic experiments are devoted to the investigations of the temperature dependence of reaction rates. In addition to the obvious practical aspects, the temperature dependence of rate constants is also of great theoretical importance. Many statistical theories of chemical reactions are based on thermal equilibrium assumptions. Non-equilibrium effects are not only important for theories going beyond the classical transition-state picture. Eventually they might even be exploited to control chemical reactions [24]. This has led to the increased importance of energy or even quantum-state-resolved kinetic studies, which can be directly compared with detailed quantum-mechanical models of chemical reaction dynamics [25, 26].

Many experimental methods may be distinguished by whether and how they achieve time resolution—directly or indirectly. Indirect methods avoid the requirement for fast detection methods, either by determining relative rates from product yields or by transforming from the time axis to another coordinate, for example the distance or flow rate in flow tubes. Direct methods include (laser-) flash photolysis [27], pulse radiolysis [28]

(see also [chapter A3.5](#) on ion reactions), and the important relaxation techniques, which study the relaxation of a reacting system back into equilibrium after a perturbation [29]. Here one distinguishes two types of perturbation methods: (i) small perturbations from equilibrium leading to relaxation kinetics in the narrower sense with generalized first-order kinetics [6] and (ii) large perturbations from equilibrium leading to generally nonlinear rate laws. Typical examples for large perturbations are temperature jumps achieved through laser heating or in shock-tube experiments [30].

The time resolution of these methods is determined by the time it takes to initiate the reaction, for example the mixing time in flow tubes or the laser pulse width in flash photolysis, and by the time resolution of the detection. Relatively

-3-

slow reactions can be monitored by taking samples and quickly quenching the reaction by cooling to low temperature or by dilution. The samples can then be analysed using conventional analytical techniques [31]. For time-dependent monitoring, any physical–chemical property changing during the course of a reaction can be used. Perhaps most important are spectroscopic detection techniques, particularly IR (infrared) and UV–VIS (ultraviolet–visible) absorption and fluorescence techniques. Directly recording spectroscopic signals as a function of time can achieve a time resolution of about 0.1 ns in favourable cases. Even higher time resolution of a few femtoseconds can be realised in pump–probe, laser flash-photolysis experiments [22, 32] (see also [chapter B2.1](#) on ultrafast spectroscopy).

A completely different approach, in particular for fast unimolecular processes, extracts state-resolved kinetic information from molecular spectra without using any form of time-dependent observation. This includes conventional line-shape methods, as well as the quantum-dynamical analysis of rovibrational overtone spectra [18, 33, 34 and 35].

At this point, we only mention the very important molecular-beam techniques [15, 27, 36, 37 and 38] that allow the study of isolated molecules, largely without thermal congestion. They are ideally suited to the investigation of unimolecular processes, in particular dissociation reactions and energy redistribution processes (see [chapter A3.13](#) on energy redistribution in reacting systems). The determination of state-resolved cross sections for bimolecular reactions in crossed molecular beams has paved the way for mechanistic investigations of elementary processes in the greatest possible detail (see [chapter B2.3](#) *Reactive scattering*).

B2.5.2 FLOW TUBES

[Figure B2.5.1](#) schematically illustrates a typical flow-tube set-up. In gas-phase studies, it serves mainly two purposes. On the one hand it allows highly reactive shortlived reactant species, such as radicals or atoms, to be prepared at well-defined concentrations in an inert buffer gas. On the other hand, the flow replaces the time dependence, t , of a reaction by the dependence on the distance x from the point where the reactants are mixed by the simple transformation with the flow velocity v_f :

$$t - t_0 = \frac{x - x_0}{v_f}. \quad (\text{B2.5.1})$$

Instead of shifting the detector position, as indicated in [figure B2.5.1](#) one often varies the location of the reactant mixing region using moveable injectors. This allows complex, possibly slow, but powerful, analytical techniques to be used for monitoring gas-phase reactions. In combination with mass-spectrometric detection,

both reactants and products can be monitored quantitatively [39, 40 and 41]. A further possibility consists of keeping the position $(x-x_0)$ in equation B2.5.1 constant and varying the flow velocity v_f thereby varying $(t-t_0)$. This technique is called ‘accelerated flow’.

-4-

Figure B2.5.1. Schematic representation of a typical flow tube set-up with moveable detection. Adapted from [110].

The time-to-distance transformation requires fast mixing and a known flow profile, ideally a turbulent flow with a well-defined homogeneous composition perpendicular to the direction of flow (‘plug-flow’), as indicated by the shaded area in figure B2.5.1. More complicated profiles may require numerical transformations.

One of the major limiting factors for the time resolution of flow-tube experiments is the time required for mixing reactants and—to a lesser extent—the resolution of distance. With typical fast flow rates of more than 25 ms^{-1} [42, 43] the time resolution lies between milliseconds and microseconds.

Modern applications of the technique include kinetic studies of post-combustion processes and their complex reaction systems. The influence of traces of NO_x on the reaction kinetics of the H_2/O_2 and $\text{CO}/\text{H}_2\text{O}/\text{O}_2$ systems has recently been investigated in a high-pressure, turbulent-flow reactor at pressures up to 14 atm between 750 K and 1100 K [31, 44]. The reaction was monitored by taking samples at a fixed position and varying the location where the fuel ($\text{CO}/\text{H}_2\text{O}/\text{NO}_x$ or H_2/NO_x) is injected into a hot stream of O_2 . The samples were instantly quenched in the hot-water-cooled sampling probe and analysed with a variety of analytical techniques including Fourier-transform infrared spectroscopy. The results were interpreted in terms of a reaction mechanism including 52 elementary reactions, assuming instant mixing and homogeneous composition perpendicular to the flow direction.

NO generally catalyses ‘fuel consumption’ by transforming hydroperoxyl radicals into highly-reactive hydroxyl radicals:

-5-

As a stable radical, however, NO can also catalyze the recombination of radicals (X,Y) at higher concentrations, eventually inhibiting overall oxidation [45]:

The balance of these two effects was found to depend delicately on the stoichiometry, pressure, and temperature. The results were used to develop a more comprehensive CO/H₂O/O₂/NO_x reaction mechanism, incorporating the explicit fall-off behaviour of recombination reactions [46, 47].

B2.5.3 RELAXATION METHODS

Two types of relaxation techniques are distinguished, depending on whether the perturbation applied is small or large.

B2.5.3.1 RELAXATION AFTER A SMALL PERTURBATION FROM EQUILIBRIUM

Perturbation or relaxation techniques are applied to chemical reaction systems with a well-defined equilibrium. An ‘instantaneous’ change of one or several state functions causes the system to relax into its new equilibrium [29]. In gas-phase kinetics, the perturbations typically exploit the temperature (*T*-jump) and pressure (*P*-jump) dependence of chemical equilibria [6]. The relaxation kinetics are monitored by spectroscopic methods.

T-jump techniques can achieve fast heating of the reaction system by pulsed radiation, for example with a microwave source or an IR laser. In the latter case one often adds an efficient inert absorber, such as SF₆. The heating of the reaction system then results from fast collisional relaxation of the initially-excited absorber molecules [48, 49].

When the perturbation is small, the reaction system is always close to equilibrium. Therefore, the relaxation follows generalized first-order kinetics, even if bi- or trimolecular steps are involved (see [chapter A3.4](#)). Take, for example, the reversible bimolecular step

With equilibrium concentrations c^{eq} , the (small) deviation from equilibrium is given by

$$\Delta_c = c_A - c_A^{\text{eq}} = c_B - c_B^{\text{eq}} = c_C^{\text{eq}} - c_C = c_D^{\text{eq}} - c_D. \quad (\text{B2.5.91})$$

$$k_2 c_A^{\text{eq}} c_B^{\text{eq}} = k_{-2} c_C^{\text{eq}} c_D^{\text{eq}} \quad (\text{B2.5.10})$$

-6-

and neglecting terms quadratics in Δ_c leads to the approximate first-order rate law for this elementary step:

$$-\frac{dc_A}{dt} = -\frac{d\Delta_c}{dt} = k_{\text{eff}} \Delta_c \quad (\text{B2.5.11})$$

For this reaction alone, one would thus obtain a simple exponential relaxation with relaxation time

$$k_{\text{eff}} = \{k_2(c_A^{\text{eq}} + c_B^{\text{eq}}) + k_{-2}(c_C^{\text{eq}} + c_D^{\text{eq}})\}. \quad (\text{B2.5.12})$$

More generally, the relaxation follows generalized first-order kinetics with several relaxation times τ_i , as depicted schematically in figure B2.5.2 for the case of three well-separated time scales. The various relaxation times determine the turning points of the product concentration on a logarithmic time scale. These relaxation times are obtained from the eigenvalues of the appropriate rate coefficient matrix ([chapter A3.4](#)). The time resolution of T -jump relaxation techniques is often limited by the rate at which the system can be heated. With typical T -jumps of several Kelvin, the time resolution lies in the microsecond range.

Figure B2.5.2. Schematic relaxation kinetics in a T -jump experiment. c measures the progress of the reaction, for example the concentration of a reaction product as a function of time t (abscissa with a logarithmic time scale). The reaction starts at t_0 . (a) Simple relaxation kinetics with a single relaxation time. (b) Complex reaction mechanism with several relaxation times τ_i . The different relaxation times τ_i are given by the turning points of c as a function of $\ln(t)$. Adapted from [110].

-7-

T -jump experiments are particularly well-suited to the study of the dissociation kinetics of weakly-bound

molecules or molecular complexes. Markwalder *et al* [49] used the laser-induced T -jump method to investigate the temperature and pressure dependence of NO_2 recombination kinetics:

With $\text{M} = \text{He}$, experiments were carried out between 255 K and 273 K with a few millibar NO_2 at total pressures between 300 mbar and 200 bar. Temperature jumps on the order of 1 K were effected by pulsed irradiation ($\ll 1 \mu\text{s}$) with a CO_2 laser at 9.2– 9.6 μm and with SiF_4 or perfluorocyclobutane as primary IR absorbers ($\ll 1$ mbar). Under these conditions, the dissociation of N_2O_4 occurs within the irradiated volume on a time scale of a few hundred microseconds. NO_2 and N_2O_4 were monitored simultaneously by recording the time-dependent UV absorption signal at 420 nm and 253 nm, respectively. The recombination rate constant k_{rec} can be obtained from the effective first-order relaxation time, τ_{R} . A derivation analogous to (equation (B2.5.9), equation (B2.5.10), equation (B2.5.11) and equation (B2.5.12)) yield

$$k_{\text{rec}} = \frac{\tau_{\text{R}}^{-1}}{K_{\text{c}} + 4[\text{NO}_2]} \quad (\text{B2.5.15})$$

where K_{c} is the equilibrium constant of equation (B2.5.14). k_{rec} , K_{c} , and $[\text{NO}_2]$ all refer to the final temperature. At 255 K, the authors obtained the typical fall-off curve depicted in figure B2.5.3. Even at 200 bar, the effective rate constant is still less than half the extrapolated high-pressure limit. The final results of the high- ($k_{\text{rec},\infty}$) and low-pressure ($k_{\text{rec},0}$) limiting rate constants (see chapter A3.4) were [49]

$$k_{\text{rec},\infty} = (2.2 \pm 0.2) \times 10^6 (T/\text{K})^{(2.3 \pm 0.2)} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1} \quad (\text{B2.5.16})$$

$$k_{\text{rec},0} = (7.5 \pm 0.8) \times 10^{35} (T/\text{K})^{(-9.0 \pm 0.9)} \times [\text{He}] \text{ cm}^6 \text{ mol}^{-2} \text{ s}^{-1} \quad (\text{B2.5.17})$$

where the temperature is given in Kelvin.

-8-

Figure B2.5.3. The fall-off curve of reaction (B2.5.14) with $\text{M} = \text{He}$ between 0.3 bar and 200 bar. The dashed lines represent the extrapolated low- and high-pressure limits. $k_{\text{rec},0} = (2.1 \pm 0.2) \times 10^{14} \times [\text{He}] \text{ cm}^6 \text{ mol}^{-2} \text{ s}^{-1}$ and $k_{\text{rec},\infty} = (7.0 \pm 0.7) \times 10^{11} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ yield the best fit (full curve) to the experimental data (full circles). Adapted from [49].

B2.5.3.2 PERIODIC SMALL PERTURBATION FROM EQUILIBRIUM AND ULTRASOUND ABSORPTION

The previous subsection described single-experiment perturbations by T -jumps or P -jumps. By contrast, sound and ultrasound may be used to induce small periodic perturbations of an equilibrium system that are equivalent to periodic pressure and temperature changes. A temperature amplitude $\delta T \approx 0.002$ K and a pressure amplitude $\delta P \approx 30$ mbar are typical in experiments with high-frequency ultrasound. Figure B2.5.4 illustrates the situation for different rates of chemical relaxation with the angular frequency of the sound wave ω and the relaxation time τ_R :

$\omega\tau_R \ll 1$. The sample relaxes fast with the displacement from equilibrium synchronous with the sound wave.

$\omega\tau_R \approx 1$. Compared with the sound wave, the system relaxes slowly. It lags behind, the phase is shifted, and amplitudes are reduced by damping.

$\omega\tau_R \gg 1$. Very slow relaxation.

As an example for the mathematical treatment, we take the bimolecular reaction

Figure B2.5.4. Periodic displacement from equilibrium through a sound wave. The full curve represents the temporal behaviour of pressure, temperature, and concentrations in the case of a very fast relaxation. The other lines illustrate various situations, with $\omega\tau_R$ according to table B2.5.1. ω is the angular frequency of the sound wave and τ_R is the chemical relaxation time. Adapted from [110].

Table B2.5.1 Form of the ‘chemical wave’ $y_\omega(t)$ (equation B2.5.24) for the various cases depicted in figure B2.5.4.

Case		Amplitude	Phase shift	$y_\omega(t)$
1	$\omega\tau_R \ll 1$	$\approx a$	≈ 0	$a \sin(\omega t)$
2	$\omega\tau_R = 10 \gg 1$		$\approx \pi/2$	

		$\approx a / (\omega\tau_R)$		$-[a/(\omega\tau_R)] \cos(\omega t)$
3	$\omega\tau_R = 1$	$a/\sqrt{2}$	$\pi/4$	$(a/\sqrt{2}) \sin(\omega t - \pi/4)$
4	$\omega\tau_R = \sqrt{3}$	$a/2$	$\pi/3$	$(a/2) \sin(\omega t - \pi/3)$

The turnover variable

$$x = c_A(t=0) - c_A = c_B(t=0) - c_B \quad (\text{B2.5.19})$$

-10-

obeys a first-order rate law near the equilibrium value, x_{eq} , which, in turn, depends on the temperature change ΔT induced by the sound wave:

$$\frac{dx}{dt} = k_{\text{eff}}(x_{\text{eq}}(T + \Delta T) - x). \quad (\text{B2.5.20})$$

For small ΔT , the temperature dependence of the effective first-order rate constant, k_{eff} , can be neglected. With $y = x_{\text{eq}}(T) - x$ and with the shift of the equilibrium, $\Delta x_{\text{eq}} = x_{\text{eq}}(T) - x_{\text{eq}}(T + \Delta T)$, one obtains

$$-\frac{d\Delta y}{dt} = (y - \Delta x_{\text{eq}})\{k_b + k_a(c_A^{\text{eq}} + c_B^{\text{eq}})\} = \frac{y - \Delta x_{\text{eq}}}{\tau_R}. \quad (\text{B2.5.21})$$

As long as ΔT , Δx_{e} , and Δx remain small, they will be proportional to the sinusoidal pressure wave. In particular

$$\Delta x_{\text{eq}} = a \sin(\omega t). \quad (\text{B2.5.22})$$

This leads to

$$y(t) + \tau_R \frac{dy(t)}{dt} = a \sin(\omega t) \quad (\text{B2.5.23})$$

with the general solution

$$y(t) = \left[y(0) + \frac{a\omega\tau_R}{1 + \omega^2\tau_R^2} \right] \exp\left(\frac{-t}{\tau_R}\right) + \frac{a}{1 + \omega^2\tau_R^2} \sin(\omega t) - \frac{a\omega\tau_R}{1 + \omega^2\tau_R^2} \cos(\omega t). \quad (\text{B2.5.24})$$

For sufficiently long times (index w), the exponential can be neglected, leaving an oscillation of the turnover variable phase shifted with respect to the sound wave and with its amplitude reduced by the finite relaxation time τ_R :

$$y_w(t) = \frac{a}{\sqrt{1 + \omega^2 \tau_R^2}} \sin(\omega t - \arctan(\omega \tau_R)). \quad (\text{B2.5.25})$$

The easily accessible frequency range of sound and ultrasound waves confines the range of applicability of this technique to relaxation times, τ_R , between 10^{-4} s and 10^{-9} s. The derivation given here is, of course, independent of the underlying chemical process, as long as it is characterized by a single relaxation time. In general a complex relaxation spectrum is possible, so that the method reaches its limit for complex reactions as the interpretation of the results may become ambiguous. Extensive descriptions of relaxation experiments with small perturbations—both single and periodic—can be found in [29, 50]. Here one can also find numerous relaxation-time expressions for various equilibrium systems (uni-, bi-, trimolecular and reverse).

-11-

B2.5.3.3 RELAXATION AFTER LARGE PERTURBATION: SHOCK-WAVE EXPERIMENTS

A general limitation of the relaxation techniques with small perturbations from equilibrium discussed in the previous section arises from the restriction to systems starting at or near equilibrium under the conditions used. This limitation is overcome by techniques with large perturbations. The most important representative of this class of relaxation techniques in gas-phase kinetics is the shock-tube method, which achieves T -jumps of some 1000 K (accompanied by corresponding P -jumps) [30, 51, 52 and 53]. Shock tubes are particularly useful for measuring the temperature dependence of reaction rates up to high temperatures. Figure B2.5.5 shows a schematic representation of the experimental set-up. The shock tube consists of a high- and a low-pressure part (R), separated by a diaphragm (d). The latter is filled with the reaction mixture and is operated either as a static cell or as a low-pressure flow tube. The high-pressure part is filled with a light, inert gas, such as H_2 or He, whose pressure is increased until the diaphragm breaks. This creates a shock wave travelling through the reaction mixture with supersonic speed. Behind the shock front the temperature can jump by more than 1000 K within $1\ \mu\text{s}$ or less. After passing the detection zone, where the relaxation is followed spectroscopically, the wave front is reflected back at the end of the tube. The resulting change of the temperature as a function of time is depicted in figure B2.5.6. The temperature T_2 after the wave front is determined indirectly from the speed, u , at which the wave front travels through the tube. For a highly-dilute reaction mixture in a monoatomic gas with atomic mass M one obtains

$$T_2 = T_1 \left(\frac{Mu^2}{5RT_1} - \frac{1}{3} \right) \left(\frac{Mu^2 + 1}{5RT_1} \right) \left(\frac{16Mu^2}{5RT_1} \right)^{-1} \quad (\text{B2.5.26})$$

where T_1 is the temperature before the wave front has passed.

Figure B2.5.5. Schematic representation of a shock-tube apparatus. The diaphragm d separates the high-

pressure part from the low-pressure reaction chamber R. The speed of the shock wave is determined by the time Δt it takes to pass two observation points. The reaction itself is monitored spectroscopically using the light source L and a detector D close to the reflection wall W. Adapted from [110].

-12-

Figure B2.5.6. Temperature as a function of time in a shock-tube experiment. The first T -jump results from the incoming shock wave. The second is caused by the reflection of the shock wave at the wall of the tube. The rise time δt typically is less than $1 \mu\text{s}$, whereas the time delay between the incoming and reflected shock wave is on the order of several hundred microseconds. Adapted from [110].

A classic shock-tube study concerned the high-temperature recombination rate and equilibrium for methyl radical recombination [54, 55]. Methyl radicals were first produced in a fast decomposition of diazomethane at high temperatures ($T > 1000 \text{ K}$)

Subsequently, the recombination of methyl radicals was studied by the high-temperature UV absorption of the methyl radicals near 216 nm [54, 55].

-13-

Figure B2.5.7 shows the absorption traces of the methyl radical absorption as a function of time. At the time resolution considered, the appearance of CH_3 is practically instantaneous. Subsequently, CH_3 disappears by recombination (equation B2.5.28). At temperatures below 1500 K, the equilibrium concentration of CH_3 is negligible compared with C_2H_6 (left-hand trace): the recombination is complete. At temperatures above 1500 K (right-hand trace) the equilibrium concentration of CH_3 is appreciable, and thus the technique allows the determination of both the equilibrium constant and the recombination rate [54, 55]. This experiment resolved a famous controversy on the temperature dependence of the recombination rate of methyl radicals. While standard RRKM theories [57, 58] predicted an increase of the high-pressure recombination rate coefficient $k_{\text{rec}^\infty}(T)$ by a factor of 10–30 between 300 K and 1400 K, the statistical-adiabatic-channel model predicts a

slight decrease of $k_{\text{rec},\infty}(T)$ with increasing temperature [59, 60], in agreement with experiment [54, 55]. This temperature dependence of the high-pressure recombination rate coefficient for radical–radical association is now a generally accepted feature, frequently reconfirmed for other examples in this class of reaction. The secondary isotope effect for the recombination of CD_3 has also been studied for this reaction [54, 55].

Figure B2.5.7. Oscilloscope trace of the UV absorption of methyl radical at 216 nm produced by decomposition of azomethane after a shock wave (after [54]): at (a) 1280 K and (b) 1575 K.

In a more recent example, a shock-tube experiment was used to study the thermal decomposition of methylamine between 1500 K and 2000 K [61, 62]:

$$k(T) = 8.17 \times 10^{16} \exp(-30710 \text{ K}/T) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1} (\pm 20\%). \quad (\text{B2.5.30})$$

The pyrolysis of CH_3NH_2 (<1 mbar) was performed at 1.3 atm in Ar, spectroscopically monitoring the concentration of NH_2 radicals behind the reflected shock wave as a function of time. The interesting aspect of this experiment was the combination of a shock-tube experiment with the particularly sensitive detection of the NH_2 radicals by frequency-modulated, laser-absorption spectroscopy [61]. Compared with ‘conventional’ narrow-bandwidth laser-absorption detection the signal-to-noise ratio could be increased by a factor of 20, with correspondingly more accurate values for the rate constant $k(T)$.

B2.5.4 FLASH PHOTOLYSIS WITH FLASH LAMPS AND LASERS

One of the most important techniques for the study of gas-phase reactions is flash photolysis [8, 63]. A reaction is initiated by absorption of an intense light pulse, originally generated from flash lamps (duration $\approx 1 \mu\text{s}$). Nowadays these have frequently been replaced by pulsed laser sources, with the shortest pulses of the order of a few femtoseconds [22, 64].

B2.5.4.1 FLASH PHOTOLYSIS WITH FLASH LAMPS

The absorption of a light pulse ‘instantaneously’ generates reactive species in high concentrations, either through the formation of excited species or through photodissociation of suitable precursors. The reaction can

then be followed spectroscopically by monitoring reactant and product concentrations. Among the classic studies using this technique, one may mention methyl radical spectroscopy used to study recombination at room temperature [56, 65, 66, 67, and 68].

A recent example of laser flash-lamp photolysis is given by Hippler *et al* [69], who investigated the temperature and pressure dependence of the thermal recombination rate constant k_{rec} for the reaction

The experiments were performed in a static reaction cell in a large excess of N_2 (2–200 bar). An UV laser pulse (193 nm, 20 ns) started the reaction by the photodissociation of N_2O to form O atoms in the presence of NO. The reaction was monitored via the NO_2 absorption at 405 nm using a Hg–Xe high-pressure arc lamp, together with direct time-dependent detection. With a 20–200-fold excess of NO, the formation of NO_2 followed a pseudo-first-order rate law:

$$[\text{NO}_2] = [\text{NO}_2]_{t=\infty} (1 - \exp\{-k_{\text{rec}}[\text{NO}]t\}). \quad (\text{B2.5.32})$$

Direct time-dependent detection is limited by the response time of detectors, which depends on the frequency range, and the electronics used for data acquisition. In the most favourable cases, modern detector/oscilloscope combinations achieve a time resolution of up to 100 ps, but 1 ns is more typical. Again, this reaction has been of fundamental theoretical interest for a long time [59, 60].

B2.5.4.2 LASER FLASH PHOTOLYSIS AND PUMP-PROBE TECHNIQUES

The so-called pump-probe technique uses a first photolysis pump pulse to generate reactive species and a second ‘probe’ pulse to detect reactant and product species. Figure B2.5.8 illustrates the experimental set-up. The time resolution is achieved through varying the delay between the pump pulse, which initiates the reaction, and the probe pulse, which monitors the reaction. Variable, short time delays in the picosecond range are conveniently realized through geometrical variation of the optical path length that the probe pulse travels. The probe pulse monitors reactant or product species either through direct absorption or by fluorescence excitation (laser-induced fluorescence, LIF), which generally is much more sensitive [70].

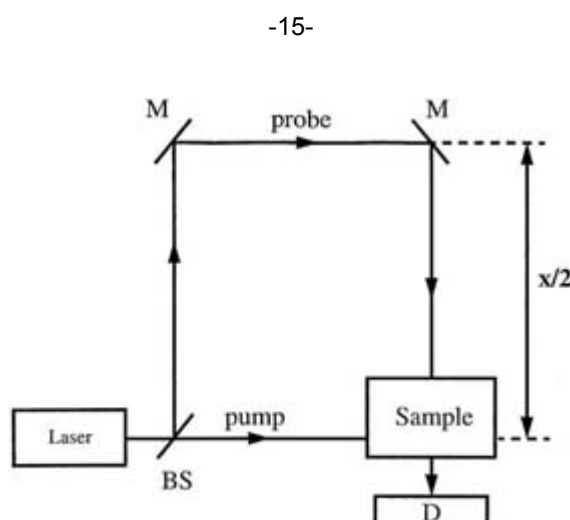

Figure B2.5.8. Schematic representation of laser-flash photolysis using the pump-probe technique. The beam splitter BS splits the pulse coming from the laser into a pump and a probe pulse. The pump pulse initiates a reaction in the sample, while the probe beam is diverted by several mirrors M through a variable delay line.

The detector D monitors the absorption of the probe beam as a function of the delay between the pulses given by $x/2c$, where c is the speed of light and x is the difference between the optical path travelled by the probe and by the pump pulse. Adapted from [110].

With the short pulses available from modern lasers, femtosecond time resolution has become possible [7, 71, 72 and 73]. Producing accurate time delays between pump and probe pulses on this time scale represents a major challenge for the experimentalist, since light only travels $0.3 \mu\text{m fs}^{-1}$. Table B2.5.2 summarizes typical laser pulses and characteristic times that are now available.

Table B2.5.2. Examples for pulsed lasers with different pulse durations and corresponding path lengths. For comparison the last column also gives the distance travelled by atoms with a velocity of 1000 ms^{-1} (in parentheses) [81].

Pulse duration	Laser	Availability	Optical path
100–200 ns	Atmospheric CO ₂ laser	Commercial	30–60 m (0.1–0.2 mm)
1–2 ns	Atmospheric CO ₂ laser, mode coupled with saturable absorber	Available	30–60 cm (1–2 μm)
100 fs–1 ps	Solid-state laser (e.g. Ti:sapphire), dye laser	Commercial	0.03–0.3 mm (100 pm–1 nm)
8 fs	Laser with subsequent pulse compression	World record [108]	2.4 μm (8.4 pm)
6.5 fs	Ti:sapphire, mode coupling, with saturable absorber (semiconductor)	World record [64]	2 μm (6.5 pm)

One of the early examples for kinetic studies on the femtosecond time scale is the photochemical predissociation of NaI [74]:

(B2.5.33)

The experiment is illustrated in figure B2.5.9. The initial pump pulse generates a localized wavepacket in the first excited S_1 state of NaI, which evolves with time. The potential well in the S_1 state is the result of an avoided crossing with the ground state. Every time the wavepacket passes this region, part of it crosses to the lower surface before the remainder is reflected at the outer wall of the S_1 potential. The crossing leads to ground-state dissociation products Na ($^2S_{1/2}$) + ($^2P_{3/2}$). The crossing is monitored with the time-delayed probe pulse, which excites ground-state Na ($^2P^0 \leftarrow ^2S_{1/2}$). A photomultiplier detects the fluorescence back to the ground state. Figure B2.5.10 shows the resulting LIF signal as a function of the probe delay. One clearly recognizes the signature of the oscillatory wavepacket motion with a relatively long oscillation period of 1 ps, resulting from the flat potential and the heavy masses.

Figure B2.5.9. Schematic representation of the potential curves for the photodissociation of NaI as a function of the interatomic distance R . L1 and L2 are the pump and probe laser pulses, respectively. The dissociation limits are (I) $\text{Na}(^2\text{S}_{1/2}) + \text{I}(^2\text{P}_{3/2})$, (II) $\text{Na}(^2\text{S}_{1/2}) + \text{I}(^2\text{P}_{1/2})$, (III) $\text{Na}^+(^1\text{S}_0) + \text{I}^-(^1\text{S}_0)$, and (IV) $\text{Na}(^2\text{P}) + \text{I}(^2\text{P}_{3/2})$.

E is the excitation energy relative to the lowest dissociation limit (I). Adapted from Rosker *et al* [74].

-17-

Figure B2.5.10. LIF signal of free Na atoms produced in the photodissociation of NaI. $t - t_0$ is the delay between the photolysis pulse (at t_0) and the probe pulse. Adapted from [111].

B2.5.4.3 THE PRINCIPLE OF CONTINUOUS DETECTION WITH UNCERTAINTY-LIMITED TIME AND FREQUENCY RESOLUTION

In this approach one uses narrow-band continuous wave (cw) lasers for continuous spectroscopic detection of reactant and product species with high time and frequency resolution. Figure B2.5.11 shows an experimental scheme using detection lasers with a 1 MHz bandwidth. Thus, one can measure the energy spectrum of reaction products with very high energy resolution. In practice, today one can achieve an uncertainty-limited resolution given by

$$\Delta\nu\Delta t \geq \frac{1}{4\pi}. \quad (\text{B2.5.34})$$

This technique with very high frequency resolution was used to study the population of different hyperfine structure levels of the iodine atom produced by the IR-laser-flash photolysis of organic iodides through multiphoton excitation:

-18-

Figure B2.5.11. Schematic set-up of laser-flash photolysis for detecting reaction products with uncertainty-limited energy and time resolution. The excitation CO_2 laser pulse LP (broken line) enters the cell from the left, the tunable cw laser beam CW-L (full line) from the right. A filter cell FZ protects the detector D, which determines the time-dependent absorbance, from scattered CO_2 laser light. The pyroelectric detector PY measures the energy of the CO_2 laser pulse and the photon drag detector PD its temporal profile. A complete description can be found in [109].

Figure B2.5.12 shows the energy-level scheme of the fine structure and hyperfine structure levels of iodine. The corresponding absorption spectrum shows six sharp hyperfine structure transitions. The experimental resolution is sufficient to determine the Doppler line shape associated with the velocity distribution of the I atoms produced in the reaction. In this way, one can determine either the temperature in an oven—as shown in Figure B2.5.12—or the primary translational energy distribution of I atoms produced in photolysis, equation B2.5.35.

Figure B2.5.12. Hyperfine structure energy level scheme and spectrum for the $I(^2P_{3/2}) \leftrightarrow I(^2P_{1/2})$ fine structure transition [109].

B2.5.5 MULTIPHOTON EXCITATION

B2.5.5.1 MECHANISMS OF MULTIPHOTON EXCITATION

The common flash-lamp photolysis and often also laser-flash photolysis are based on photochemical processes that are initiated by the absorption of a photon, $h\nu$. The intensity of laser pulses can reach GW cm^{-2} or even TW cm^{-2} , where multiphoton processes become important. Figure B2.5.13 summarizes the different mechanisms of multiphoton excitation [75, 76, 112]. The direct multiphoton absorption of mechanism (i) requires an odd number of photons to reach an excited atomic or molecular level in the case of strict electric dipole and parity selection rules [117].

The Goeppert–Mayer two- (or multi-) photon absorption, mechanism (ii), may look similar, but it involves intermediate levels far from resonance with one-photon absorption. A third, quasi-resonant stepwise mechanism (iii), proceeds via single-photon excitation steps involving near-resonant intermediate levels. Finally, in mechanism (iv), there is the stepwise multiphoton absorption of incoherent radiation from thermal light sources or broad-band statistical multimode lasers. In principle, all of these processes and their combinations play a role in the multiphoton excitation of atoms and molecules, but one can broadly

distinguish two situations.

- (A) During the multiphoton excitation of molecular vibrations with IR lasers, many (typically 10–50) photons are absorbed in a quasi-resonant stepwise process until the absorbed energy is sufficient to initiate a unimolecular reaction, dissociation, or isomerization, usually in the electronic ground state. The record in the number of absorbed photons (about 500 photons of a CO₂ laser) was reached with the C₆₀ molecule [77]. This case proved an exception in that the primary reaction was ionization. The IR multiphoton excitation is the starting point for a new gas-phase photochemistry, IR laser chemistry, which encompasses numerous chemical processes.
- (B) The multiphoton excitation of electronic levels of atoms and molecules with visible or UV radiation generally leads to ionization. The mechanism is generally a combination of direct, Goeppert–Mayer, and quasi-resonant stepwise processes. Since ionization often requires only two or three photons, this type of multiphoton excitation is used for spectroscopic purposes in combination with mass-spectrometric detection of ions.

B2.5.5.2 IR MULTIPHOTON EXCITATION AND IR LASER CHEMISTRY

The most commonly used laser-light source in IR laser chemistry is the atmospheric CO₂ laser, with IR emission lines between 900 cm⁻¹ and 1100 cm⁻¹, in the fingerprint range of the IR spectrum, where characteristic molecular vibrations can be excited. With a photon energy of about 12 kJ mol⁻¹, on the order of 10–40 photons are needed to initiate a chemical reaction in the energy range of 100–500 kJ mol⁻¹. The laser pulses are 100 ns– μs long, but a series of 1–2 ns pulses can be generated by mode coupling. Typical intensities are 100 MW cm⁻². [Figure B2.5.14](#) schematically illustrates the photodissociation of CF₃I (equation [B2.5.35](#)) after multiphoton excitation via the CF stretching vibration at 1070 cm⁻¹. More than 17 photons are needed to break the C–I bond, a typical value in IR laser chemistry. Contributions from direct absorption (i) are insignificant, so that the process almost exclusively follows the quasi-resonant mechanism (iii), which can be treated by generalized first-order kinetics. As an example, [figure B2.5.15](#) illustrates the formation of I atoms (upper trace) during excitation with the pulse sequence of a mode-coupled CO₂ laser (lower trace). In addition to the intensity, *I*, the fluence, *F*, of radiation is a very important parameter in IR laser chemistry (and more generally in multiphoton excitation):

$$F(t) = \int_0^t I(t') dt'. \quad (\text{B2.5.36})$$

Figure B2.5.13. Schematic representation of the four different mechanisms of multiphoton excitation: (i) direct, (ii) Goeppert–Mayer (iii) quasi-resonant stepwise and (iv) incoherent stepwise. Full lines (right) represent the coupling path between the energy levels and broken arrows the photon energies with angular frequency ω ($\Delta\omega$ is the frequency width of the excitation light in the case of incoherent excitation), see also [112].

Consequently, the reaction yield F_p in [figure B2.5.15](#) is shown as a function of the fluence, F . At the end of a laser-pulse sequence with a typical fluence $F \simeq 3 \text{ J cm}^{-2}$, practically 100% of the CF_3I is photolysed. As described in [section B2.5.4.3](#), the product-level distribution of the iodine atoms formed in this type of reaction can be determined

spectroscopically. Table B2.5.3 shows the results of such an analysis of the population of hyperfine structure levels and of the translational energy distribution for the IR multiphoton dissociation of different organic iodides. The average product translational energy (in the centre-of-mass system) does not change much from the small CF_3I to the much larger $\text{C}_6\text{F}_5\text{I}$ molecule. Its relative share of the total energy, however, decreases: much more energy appears as the internal energy of the C_6F_5 fragment. This can be readily understood assuming a roughly statistical distribution over the large number of internal degrees of freedom. Such results are crucial for a more accurate dynamical understanding of the processes taking place during a chemical reaction.

Table B2.5.3. Product energy distribution for some IR laser chemical reactions. $\langle E_t \rangle$ is the average relative translational energy of fragments, $\langle E_{\text{int}} \rangle$ is the average vibrational and rotational energy of polyatomic fragments, and f_t is the fraction of the total product energy appearing as translational energy [109].

Reaction	$\langle E_t \rangle / (\text{kJ mol}^{-1})$	$\langle E_{\text{int}} \rangle / (\text{kJ mol}^{-1})$	f_t
$\text{CF}_3\text{I} \rightarrow \text{CF}_3 + \text{I}$	9.9	19.8	0.33
$\text{CF}_3\text{CHF}\text{I} \rightarrow \text{CF}_3\text{CHF} + \text{I}$	10.9	100.9	0.097
$\text{C}_6\text{F}_5\text{I} \rightarrow \text{C}_6\text{F}_5 + \text{I}$	13.5	233.0	0.055

Figure B2.5.14. The IR laser chemistry of CF_3I excited up to the dissociation energy D_0 with about 17 quanta of a CO_2 laser, $h\nu_{\text{CO}_2}$. The dissociation is detected by uncertainty limited cw absorption ($h\nu_{\text{cw}}$), see figures B2.5.11 and B2.5.12. The energy levels of the C–I stretching vibration are not drawn to scale. In reality their separation is much smaller. Adapted from [109].

Figure B2.5.15. Iodine atom formation in the IR laser chemistry of CF_3I (excitation at 1074.65 cm^{-1} , probe on the $F = 4 \rightarrow F = 3$ hyperfine structure transition, see figure B2.5.12.) (a) The absorbance as a function of time (effective absorption cross section σ_{eff} full curve, left ordinate) shows clear steps at each maximum of the mode locked CO_2 laser pulse sequence (intensity, broken curve, right ordinate). (b) The fraction F_p of dissociating molecules as a function of fluence F .

In exceptional cases, the IR laser excitation can lead to ionization. An interesting example is the CO_2 -laser-induced ionization of C_{60} , where $n \geq 500$ photons are absorbed and vibrations are excited far beyond the ionization threshold of the molecule

The C_{60}^+ is excited further and decomposes stepwise into C_{58}^+ , C_{56}^+ , etc with the formation of C_2 units [77].

In contrast to the ionization of C_{60} after vibrational excitation, typical multiphoton ionization proceeds via the excitation of higher electronic levels. In principle, multiphoton ionization can either be used to generate ions and to study their reactions, or as a sensitive detection technique for atoms, molecules, and radicals in reaction kinetics. The second application is more common. In most cases of excitation with visible or UV laser radiation, a few photons are enough to reach or exceed the ionization limit. A particularly important technique is resonantly enhanced multiphoton ionization (REMPI), which exploits the resonance of monochromatic laser radiation with one or several intermediate levels (in one-photon or in multiphoton processes). The mechanisms are distinguished according to the number of photons leading to the resonant intermediate levels and to the final level, as illustrated in figure B2.5.16. Several lasers of different frequencies may be combined.

Figure B2.5.16. Different multiphoton ionization schemes. Each scheme is classified according to the number of photons that lead to resonant intermediate levels and to the ionization continuum (hatched area). Adapted from [110].

As an example, we mention the detection of iodine atoms in their $^2P_{3/2}$ ground state with a 3 + 2 multiphoton ionization process at a laser wavelength of 474.3 nm. Excited iodine atoms ($^2P_{1/2}$) can also be detected selectively as the resonance condition is reached at a different laser wavelength of 477.7 nm. As an example, [figure B2.5.17](#) shows REMPI iodine atom detection after IR laser photolysis of CF_3I . This ‘pump–probe’ experiment involves two, delayed, laser pulses, with a 200 ns IR photolysis pulse and a 10 ns probe pulse, which detects iodine atoms at different times during and after the photolysis pulse. This experiment illustrates a fundamental problem of product detection by multiphoton ionization: with its high intensity, the short-wavelength probe laser radiation alone can photolyse the

reactant CF_3I molecules. One cannot distinguish between iodine atoms produced by the photolysis pulse and those produced by the probe pulse. In the present example the problem is solved by the well-founded assumption that the photolysis of CF_3I by a visible probe pulse produces excited iodine atoms ($^2P_{1/2}$), whereas the IR photolysis pulse leads to ground-state iodine atoms ($^2P_{3/2}$). In general, however, significant perturbations of the reaction system are to be expected from the REMPI spectroscopic detection of products.

Figure B2.5.17. (a) Time-dependent intensity I and reduced fluence F/F_0 for a single-mode CO_2 laser pulse used in the IR laser photolysis of CF_3I . F_0 is the total fluence of the laser pulse. (b) VIS-REMPI iodine atom signals obtained with CO_2 laser pulses of different fluence (after [113]).

B2.5.5.4 LASER ISOTOPE SEPARATION AND MODE-SELECTIVE REACTIONS

Apart from the obvious property of defining pulses within short time intervals, the pulsed laser radiation used in reaction kinetics studies can have additional particular properties: (i) high intensity, (ii) high monochromaticity, and (iii) coherence. Depending on the type of laser, these properties may be more or less pronounced. For instance, the pulsed CO_2 lasers used in IR laser chemistry easily reach intensities between MW cm^{-2} and GW cm^{-2} . Special lasers used in nuclear fusion experiments may even reach $10^{21} \text{ W cm}^{-2}$ [78, 79]. Ideally the monochromaticity, $\Delta\nu$, is related to the pulse length, Δt , through

$$\Delta\nu\Delta t \simeq 1. \quad (\text{B2.5.39})$$

Although this limit is not always reached. The same is true for the coherence of the radiation. Each of these properties can be exploited for particular chemical applications. The monochromaticity can be used to initiate a chemical reaction of particular molecules in a mixture. The laser isotope separation of ^{12}C and ^{13}C in natural abundance exploits the isotope shift of molecular vibrational frequencies. At $10\text{--}50 \text{ cm}^{-1}$, the corresponding shift of IR absorption wavenumbers is large compared to the spectral width of the CO_2 laser pulse ($\leq 0.1 \text{ cm}^{-1}$), which makes the ^{13}C isotope separation relatively easy. Table B2.5.4 summarizes this and other similar applications [75, 80, 81]. The intermolecular selectivity of IR-multiphoton excitation can be greatly increased by two-frequency-two-step schemes such as in the new spectroscopic technique of IRLAPS (InfraRed Laser Assisted Photofragment Spectroscopy [115]).

Table B2.5.4 Laser isotope separation (see also [75]).

Isotope Source Comments

^2H	CHF_2Cl	High selectivity at room temperature
^{10}B	BCl_3	Early laser isotope separation after IR multiphoton excitation high selectivity at room temperature
^{13}C	CHF_2Cl	Two-step separation scheme ($220 \text{ mg } ^{13}\text{C h}^{-1}$)
$^{14}\text{N}, ^{15}\text{N}$	CH_3NO_2	Selectivity through two absorption bands
$^{16}\text{O}, ^{17}\text{O}$	OCS	IR–UV double resonance; also selective for S and C
$^{29}\text{Si}, ^{30}\text{Si}$	Si_2F_6	Reaction of both isotopes with high selectivity (high fluence)
^{34}S	SF_6	Early report of laser isotope separation
$^{35}\text{Cl}, ^{37}\text{Cl}$	CF_2Cl_2	Also selective with respect to C
Mo	MoF_6	Applied to several isotopes; low selectivity and yield
^{235}U	UF_6	Dissociation with two lasers at different wavelengths (two-colour dissociation)

[Figure B2.5.18](#) compares this *inter* molecular selectivity with *intra* molecular or mode selectivity. In an IR plus UV, two-photon process, it is possible to break either of the two bonds selectively in the same HOD molecule. Depending on whether the OH or the OD stretching vibration is excited, the products are either H + OD or HO + D [24]. In large molecules, *intramolecular* selectivity competes with fast *intramolecular* (i.e. unimolecular) vibrational energy redistribution (IVR) processes, which destroy the selectivity. In laser experiments with D-difluorobutane [82], it was estimated that, in spite of frequency selective excitation of the CHDF end group, no selective reaction would occur on time scales above 10^{-11} s, [figure B2.5.18](#). In contrast to IVR processes, which can be very fast, the *intermolecular* energy transfer processes, which may reduce intermolecular selectivity, are generally much slower, since they proceed via bimolecular energy exchange, which is limited by the collision frequency (see [chapter A3.13](#)).

Figure B2.5.18. General scheme for *inter*- and *intramolecular* selectivity in laser chemistry. Intermolecular selectivity: a laser with frequency ν_A selectively excites molecules A, which subsequently react, in a mixture of A and B molecules. *Intramolecular* selectivity: a laser with frequency ν_1 (ν_2) selectively excites the chromophore Chr_1 (Chr_2) of a molecule which preferentially follows reaction 1 (2) at this position (after [75]).

Strategies for achieving intra- and intermolecular selectivity are the subject of a very active field of current research with many open questions. Under the label ‘coherent control’ it includes approaches that exploit the coherence properties of laser radiation to control chemical reactions. Figure B2.5.18 summarizes the different schemes of intra- and intermolecular selectivity.

B2.5.6 CHEMICAL ACTIVATION

The formation of reactive species by photodissociation of a precursor through flash photolysis can be regarded as a special case of chemical activation. More generally, this technique exploits the enthalpy of a chemical reaction to generate species with a non-equilibrium energy distribution (relative to the ambient temperature). Using different reactions to produce the same reactive species allows one to study the energy dependence of the ensuing reaction kinetics (or collisional deactivation). Historically, the method has played a central role in the experimental study of collisional energy-transfer processes and non-equilibrium effects on chemical reaction rates [83, 84, 85, 86 and 87].

Although modern laser techniques can in principle achieve much narrower energy distributions, optical excitation is frequently not a viable method for the preparation of excited reactive species. Therefore chemical activation—often combined with (laser-) flash photolysis—still plays an important role in gas-phase kinetics, in particular of unstable species such as radicals [88]. Chemical activation also plays an important role in energy-transfer studies (see [chapter A3.13](#)).

A recent study of the vibrational-to-vibrational (V–V) energy transfer between highly-excited oxygen molecules and ozone combines laser-flash photolysis and chemical activation with detection by time-resolved LIF [89]. Partial laser-flash photolysis at 532 nm of pure ozone in the Chappuis band produces translationally-hot oxygen atoms $O(^3P)$. In the chemical-activation step they react with ozone to form an electronic ground-state $O_2(\tilde{X}^3\Sigma_g^-, v'')$ with up to $v'' = 27$ quanta of vibrational excitation in an excess of thermally populated ozone:

$$k = 3.9 \times 10^{-11} \text{ cm}^3 \text{ s}^{-1}. \quad (\text{B2.5.41})$$

The chemical-activation step is between one and two orders of magnitude faster than the subsequent collisional deactivation of vibrationally excited O_2 . Finally, the population of individual vibrational levels v'' of O_2 is probed through LIF in the Schumann–Runge band ($B^3\Sigma_u^- \leftarrow X^3\Sigma_g^-$): after exciting the oxygen molecules to the vibrational ground state of their first electronically excited state ($v' = 0$), the ensuing fluorescence back to the electronic ground state is detected by a photomultiplier tube and recorded as a function of time. The resulting collisional relaxation rate constants as a function of the vibrational excitation of O_2

$$\frac{d[O_2(v'')]}{dt} = k_{v''}(O_3)[O_2(v'')][O_3] \quad (\text{B2.5.42})$$

show a pronounced maximum near $v'' = 23$, as illustrated in [figure B2.5.19](#). At this value, the $v'' \rightarrow v'' - 1$ transition happens to be in almost perfect resonance with the symmetric stretch fundamental of O_3 . The resonance enhancement by one to two orders of magnitude is typical for collisional V–V energy transfer of highly-excited molecules.

-29-

Figure B2.5.19. The collisional deactivation rate constant $k_{v''}(O_3)$ (equation B2.5.42) as a function of the vibrational level v'' . Adapted from [89]. Experimental data are represented by full circles with error bars. The broken curve is to serve as a guide to the eye.

B2.5.7 LINE-SHAPE METHODS

Energy (or frequency) spectra are fundamentally related to the underlying time-dependent processes through

the Fourier transformation. In practice, however, the relation between spectroscopically-observed line shapes and kinetic (reaction) processes is neither simple nor unambiguous [18]. There are many contributions to observed line shapes [33]. Apart from finite instrumental resolution, spectra may be inhomogeneously broadened through thermal congestion. A simple example is the Doppler broadening as a result of the Maxwell–Boltzmann velocity distribution leading to a Gaussian line shape.

Even if the homogeneous line shape can be extracted, many other processes can contribute. Every decay process contributes to the finite lifetime of an excited species, A^* , with an individual decay constant k_j^*

$$-\frac{d[A^*]}{dt} = \sum_j k_j^* [A^*] \quad (\text{B2.5.44})$$

$$k_{\text{eff}} = \sum_j k_j^*. \quad (\text{B2.5.45})$$

-30-

The exponential decay of the A^* population corresponds to a Lorentzian line shape for the absorption (or emission) cross section, σ , as a function of energy E . The lineshape is centred around its maximum at E_0 . The full-width at half-maximum (Γ) is proportional to k_{eff} :

$$\sigma(E) = \sigma(E_0) \frac{(\Gamma/2)^2}{(E - E_0)^2 + (\Gamma/2)^2} \quad (\text{B2.5.46})$$

$$\Gamma = k_{\text{eff}} h / (2\pi). \quad (\text{B2.5.47})$$

Apart from the *natural lifetime* due to spontaneous emission, both uni- and bimolecular processes can contribute to the observed value of Γ . One important contribution k_{col} comes from *collisional broadening*, which can be distinguished by its pressure dependence (or dependence upon concentration $[M]$ of the collision partner):

$$k_{\text{col}} = \left(\frac{8k_B T}{\pi \mu} \right)^{1/2} \langle \sigma_{\text{col}} \rangle [M]. \quad (\text{B2.5.48})$$

Equation B2.5.48 introduces the effective average collision cross section $\langle \sigma_{\text{col}} \rangle$. Here, the lifetime broadening results from the (collisional) perturbation of A^* by collisions with M .

Lifetimes of 1 ps translate into linewidths of about 5 cm^{-1} . Thus, line-shape methods are ideally suited to measure very fast decay processes, in particular predissociation of excited species. An example is the predissociation of O_2 molecules excited above $50\,000 \text{ cm}^{-1}$, which gives rise to the broadening of the Schumann–Runge bands

This is the source of ozone, through the reaction $O_2 + O \xrightarrow{[M]} O_3$. One obtains a pronounced dependence of the

decay rate on the vibrational level of O_2^* and to a lesser extent on its rotational state [90, 91]. Typical decay rate constants for this reaction range from $1.5 \times 10^{11} \text{ s}^{-1}$ to $7.5 \times 10^{11} \text{ s}^{-1}$. Another important example is the predissociation of methyl radicals [54]

The results are summarized in [table B2.5.5](#). The rate constants k_j of individual decay channels may be obtained from the relative yields of all primary reaction products, which can be determined in stationary experiments.

-31-

Table B2.5.5. The photochemical decomposition of methyl radicals (UV excitation at 216 nm). $\bar{\Gamma}$ is the wavenumber linewidth of the methyl radical absorption and k is the effective first-order decay constant [54].

Decay process	$\bar{\Gamma}(\text{cm}^{-1})$	$\Delta\nu = hc\bar{\Gamma} (\text{s}^{-1})$	$k = 2\pi\Delta\nu (\text{s}^{-1})$	$\tau = 1/k(\text{fs})$
$\text{CH}_3^* \rightarrow \text{CH}_2 + \text{H}$	60	1.8×10^{12}	1.13×10^{13}	88
$\text{CD}_3^* \rightarrow \text{CD}_2 + \text{D}$	8	2.4×10^{11}	1.51×10^{12}	663

Similar considerations have been exploited for the systematic analysis of room-temperature and molecular-beam IR spectra in terms of intramolecular vibrational relaxation rates [33, 34, 92, 94] (see also [chapter A3.13](#)).

B2.5.8 INTRAMOLECULAR KINETICS FROM HIGH-RESOLUTION SPECTROSCOPY

Molecular spectroscopy offers a fundamental approach to intramolecular processes [18, 94]. The spectral analysis in terms of detailed quantum mechanical models in principle provides the complete information about the wave-packet dynamics on a level of detail not easily accessible by time-resolved techniques.

The approach is ideally suited to the study of IVR on fast timescales, which is the most important primary process in unimolecular reactions. The application of high-resolution rovibrational overtone spectroscopy to this problem has been extensively demonstrated. Effective Hamiltonian analyses alone are insufficient, as has been demonstrated by explicit quantum dynamical models based on *ab initio* theory [95]. The fast IVR characteristic of the CH chromophore in various molecular environments is probably the most comprehensively studied example of the kind [96] (see [chapter A3.13](#)). The importance of this question to chemical kinetics can perhaps best be illustrated with the following examples. The atom recombination reaction

is well known to occur as a very slow trimolecular process. By contrast, the polyatomic recombination

happens quickly as a sequence of bimolecular recombination and collisional energy-transfer steps, with a relatively long-lived intermediate, $\text{CHR}_1\text{R}_2\text{R}_3^*$. The reason is the possibility of transferring energy intramolecularly from the

-32-

initially excited C–H bond to other parts of the polyatomic molecule, according to the scheme

This illustrates the steps of energy transfer from the initially highly-excited C–H bond to other parts of the molecule, subsequent concentration of energy in one part of the molecule (CR_3^{**}), and finally rupture of the corresponding bond. A typical example of this kind is the chemical activation reaction (abbreviated)

It is the first IVR step of B2.5.59 that is investigated by high-resolution spectroscopy. The analysis, outlined in some detail in [18], follows the scheme in figure B2.5.20. This kind of analysis has been applied to the evolution of entropy in the single, isolated molecule CHD_2F , as shown in figure B2.5.21. In this case, entropy is investigated as a relevant time-dependent observable of kinetics (see chapter A3.4). In the example, the question of time-reversal symmetry on the femtosecond timescale has been studied [18, 114, 116], but many other applications can be thought of.

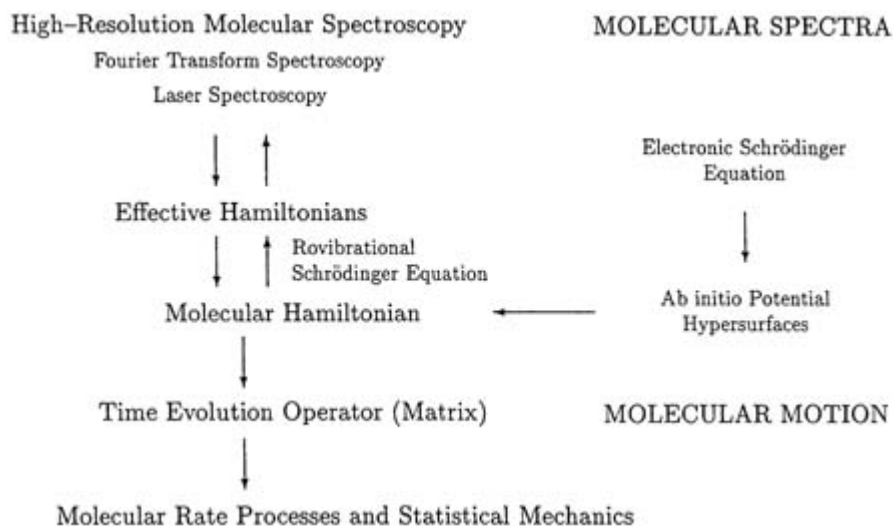

Figure B2.5.20. The combined experimental and theoretical approach ‘Molecular spectra and motion’ (after [18]).

-33-

Figure B2.5.21. Time-dependent entropy $S(t)/S_{\max}$ of CHD_2F starting from a pure CH stretching excitation with six quanta ($\nu_s = 6$) at $t = 0$ fs. Time evolution with time reversal at $t = 1$ ps (after [114]).

This kind of ‘dynamical spectroscopic analysis’ is not restricted to fast primary IVR processes. It would apply just as well to the study of completely unimolecular reactions, viz isomerizations such as H-atom transfer reactions, for example $\text{CH}_2\text{O} \rightleftharpoons \text{HCHO}$ [97] $\text{HCN} \rightleftharpoons \text{HNC}$ [98], and references cited therein), and $\text{HCCH} \rightleftharpoons \text{H}_2\text{CC}$ [99] and references cited therein) (although the spectroscopic aspects have not been fully exploited in these cases), as well as the carefully studied $\text{NH}_2 \rightleftharpoons \text{NH}_3\text{O}$ [100, 101]. Recent studies on the tunnelling dynamics of hydrogen peroxide and aniline have actually carried through the method to a model for one of chemistry’s most fundamental processes: the stereomutation of chiral molecular structures [102, 103, 104, 105 and 106], see also [107]. Figure B2.5.22 illustrates the minimum energy path for the interconversion of the left- and right-handed forms of hydrogen peroxide, roughly corresponding to the torsion about the O–O bond. The quantum dynamics are governed by tunnelling through the low barrier in the *trans* configuration, even at

very high energies, a phenomenon readily understood in terms of an adiabatic picture of the stereomutation kinetics. The detailed model extracted from experimental spectra with the support of quantum-chemical calculations allows one to describe the observed mode specificity of the stereomutation in terms of the full six-dimensional quantum wavepacket dynamics. The time-dependent probability density in the reaction coordinate (figure B2.5.23) illustrates the acceleration of the stereomutation by IR excitation of the antisymmetric bend vibration (ν_6). An approximately Gaussian wavepacket initially localized on one side of the *trans* barrier (figure B2.5.22) moves periodically between the two potential wells. In the vibrational ground state ($\nu = 0$), this corresponds to the stereomutation of a chiral equilibrium structure through tunnelling to its enantiomer within 1.5 ps. Exciting the antisymmetric bend vibration ($\nu_6 = 1$) roughly halves the time required for stereomutation, an effect that could be

-34-

considered as catalysis by IR (vibrational) excitation. Figure B2.5.23 also illustrates the high degree of adiabaticity of this process: the initial form of the wavepacket in the reaction coordinate is found to be approximately conserved, even after about 10^2 tunnelling periods, although the spectroscopic result (as analysed by theory) is exact in full six-dimensional dynamics. While ν_6 can thus be considered to be a promoting mode for stereomutation, other vibrations of H_2O_2 (except torsion) have been shown to be inhibiting modes, slowing down the stereomutation process. Thus, one has cases of inhibition of a reaction by vibrational excitation. A certain degree of thermal averaging allows one to evaluate a relaxation time corresponding to rate constants more characteristic for ordinary racemization kinetics [103, 107] in contrast to the strictly periodic process shown in figure B2.5.23.

Figure B2.5.22. Potential V along the minimum energy path for the stereomutation of hydrogen peroxide. Adapted from [103].

Related results of promotion (catalysis) and inhibition of stereomutation by vibrational excitation have also been obtained for the much larger molecule, aniline-NHD ($\text{C}_6\text{H}_5\text{NHD}$), which shows short-time chirality and stereomutation [104, 105]. This kind of study opens the way to a new look at kinetics, which shows ‘coherent’ and mode-selective dynamics, even in the absence of coherent external fields. The possibility of enforcing coherent dynamics by fields (‘coherent control’) is discussed in chapter A3.13.

-35-

Figure B2.5.23. Mode-specific stereomutation tunnelling in hydrogen peroxide: time-dependent probability density $|\Psi|^2$ in the reaction coordinate τ (see figure B2.5.22). The probability density was integrated over the remaining coordinates (OH stretches, OH bends, OO stretch). The initial wavepacket at $t = 0$ was strictly localized on one side of the torsional barrier. $\nu_6 = 0$ refers to the vibrational ground state and $\nu_6 = 1$ to an initial state with one quantum of antisymmetric OOH bend excitation.

B2.5.9 SUMMARIZING OVERVIEW ON GAS-PHASE KINETICS STUDIES

Gas-phase kinetics studies are ideally concerned with the most fundamental events of chemical reactions related to ‘isolated, single molecules’ either as elementary unimolecular reactions, isolated bimolecular collisions, or trimolecular reactions. The experimental study of such fast elementary processes has progressed to a point where it is possible to ‘prove a reaction mechanism’ by identifying each elementary reaction contributing to the total reactive flux and by demonstrating that any conceivable additional contribution to the total reactive flux must be negligible. In fact gas-phase kinetics studies have even gone beyond this fundamental goal of reaction kinetics. By using the techniques of femtosecond spectroscopy and quantum-chemical kinetics from high-resolution spectroscopy it is possible to look into the very details of the primary processes that initiate chemical reactions. These fields are still in active development and most of the fruits from these fields still remain to be harvested.
