B3.1 Quantum structural methods for atoms and molecules

Jack Simons

B3.1.1 WHAT DOES QUANTUM CHEMISTRY TRY TO DO?

Electronic structure theory describes the motions of the electrons and produces energy surfaces and wavefunctions. The shapes and geometries of molecules, their electronic, vibrational and rotational energy levels, as well as the interactions of these states with electromagnetic fields lie within the realm of quantum structure theory.

B3.1.1.1 THE UNDERLYING THEORETICAL BASIS—THE BORN–OPPENHEIMER MODEL

In the Born–Oppenheimer [1] model, it is assumed that the electrons move so quickly that they can adjust their motions essentially instantaneously with respect to any movements of the heavier and slower atomic nuclei. In typical molecules, the valence electrons orbit about the nuclei about once every 10^{-15} s (the inner-shell electrons move even faster), while the bonds vibrate every 10^{-14} s, and the molecule rotates approximately every 10^{-12} s. So, for typical molecules, the fundamental assumption of the Born–Oppenheimer model is valid, but for loosely held (e.g. Rydberg) electrons and in cases where nuclear motion is strongly coupled to electronic motions (e.g. when Jahn–Teller effects are present) it is expected to break down.

This separation-of-time-scales assumption allows the electrons to be described by electronic wavefunctions that smoothly ‘ride’ the molecule’s atomic framework. These electronic functions are found by solving a Schrödinger equation whose Hamiltonian \hat{H}_e contains the kinetic energy T_e of the electrons, the Coulomb repulsions among all the molecule’s electrons V_{ee} , the Coulomb attractions V_{en} among the electrons and all of the molecule’s nuclei, treated with these nuclei held clamped, and the Coulomb repulsions V_{nn} among all of these nuclei, but it does not contain the kinetic energy T_N of all the nuclei. That is, this Hamiltonian keeps the nuclei held fixed in space. The electronic wavefunctions ψ_k and energies E_k that result

$$\hat{H}_e \psi_k = E_k \psi_k$$

thus depend on the locations $\{Q_i\}$ at which the nuclei are sitting. That is, the E_k and ψ_k are parametric functions of the coordinates of the nuclei, and, of course, the wavefunctions ψ_k depend on the coordinates of all of the electrons.

These electronic energies’ dependence on the positions of the atomic centres cause them to be referred to as electronic energy surfaces such as that depicted below in [figure B3.1.1](#) for a diatomic molecule. For nonlinear polyatomic molecules having N atoms, the energy surfaces depend on $3N - 6$ internal coordinates and thus can be very difficult to visualize. In [figure B3.1.2](#), a ‘slice’ through such a surface is shown as a function of two of the $3N - 6$ internal coordinates.

Figure B3.1.1. Energy as a function of internuclear distance for a typical bound diatomic molecule or ion.

The Born–Oppenheimer theory is soundly based in that it can be derived from a Schrödinger equation describing the kinetic energies of all electrons and of all N nuclei plus the Coulomb potential energies of interaction among all electrons and nuclei. By expanding the wavefunction Ψ that is an eigenfunction of this full Schrödinger equation in the complete set of functions $\{\psi_k\}$ and then neglecting all terms that involve derivatives of any ψ_k with respect to the nuclear positions $\{Q_i\}$, one can separate variables such that:

- (1) the electronic wavefunctions and energies obey

$$\hat{H}_e \psi_k = E_k \psi_k$$

- (2) the nuclear motion (i.e. vibration/rotation) wavefunctions obey

$$(\hat{T}_N + E_k) \chi_{k,L} = E_{k,L} \chi_{k,L}$$

where T_N is the kinetic energy operator for movement of all nuclei.

Each and every electronic energy state, labelled k , has a set, labelled L , of vibration/rotation energy levels $E_{k,L}$ and wavefunctions $\chi_{k,L}$.

B3.1.1.2 NON-BORN–OPPENHEIMER CORRECTIONS—RADIATIONLESS TRANSITIONS

Because the Born–Oppenheimer model is obtained from the full Schrödinger equation by making approximations, it is not exact. Thus, in certain circumstances it becomes necessary to correct the predictions of the Born–Oppenheimer theory (i.e. by including the effects of the neglected coupling terms using perturbation theory). For example, when developing a theoretical model to interpret the rate at which electrons are ejected from rotationally/vibrationally hot NH^- ions, we had to consider [3] coupling between:

- (1) $^2\Pi$ NH^- in its $\nu = 1$ vibrational level and in a high rotational level (e.g. $J > 30$) prepared by laser excitation of vibrationally ‘cold’ NH^- in $\nu = 0$ having high J (due to natural Boltzmann populations), see [figure B3.1.3](#) and
- (2) $^3\Sigma^-$ NH neutral plus an ejected electron in which the NH is in its $\nu = 0$ vibrational level (no higher level

is energetically accessible) and in various rotational levels (labelled N).

Because NH has an electron affinity of 0.4 eV, the total energies of the above two states can be equal only if the kinetic energy KE carried away by the ejected electron obeys

$$KE = E_{\text{vib/rot}}(\text{NH}^- (v = 1, J)) - E_{\text{vib/rot}}(\text{NH} (v = 0, N)) - 0.4 \text{ eV}.$$

In the absence of any coupling terms, no electron detachment would occur. It is only by the anion converting some of its vibration/rotation energy and angular momentum into electronic energy that the electron that occupies a bound N_{2p} orbital in NH^- can gain enough energy to be ejected.

My own research efforts [4] have, for many years, involved taking into account such non-Born–Oppenheimer couplings, especially in cases where vibration/rotation energy transferred to electronic motions causes electron detachment, as in the NH^- case detailed above. Professor Yngve Öhrn has been active [5] in attempting to avoid using the Born–Oppenheimer approximation and, instead, treating the dynamical motions of the nuclei and electrons simultaneously. Professor David Yarkony has contributed much [6] to the recent treatment of non-Born–Oppenheimer effects and to the inclusion of spin–orbit coupling in such studies.

B3.1.1.3 WHAT IS LEARNED FROM AN ELECTRONIC STRUCTURE CALCULATION?

The knowledge gained via structure theory is great. The electronic energies $E_k(Q)$ allow one to determine [7] the geometries and relative energies of various isomers that a molecule can assume by finding those geometries $\{Q_i\}$ at which the energy surface E_k has minima $\partial E_k / \partial Q_i = 0$, with all directions having positive curvature (this is monitored by considering the so-called Hessian matrix $H_{i,j} = \partial^2 E_k / \partial Q_i \partial Q_j$: if none of its eigenvalues are negative, all directions have positive curvature). Such geometries describe stable isomers, and the energy at each such isomer geometry gives the relative energy of that isomer. Professor Berny Schlegel [8] has been one of the leading figures in using gradient and Hessian information to locate stable structures and transition states. Professor Peter Pulay [9] has done as much as anyone to develop the theory that allows us to compute gradients and Hessians for most commonly used electronic structure methods.

There may be other geometries on the E_k energy surface at which all ‘slopes’ vanish $\partial E_k / \partial Q_i = 0$, but at which not all directions possess positive curvature. If the Hessian matrix has only one negative eigenvalue, there is only one direction leading downhill away from the point $\{Q_i\}$ of zero force; all the remaining directions lead uphill from this point. Such a geometry describes that of a *transition state*, and its energy plays a central role in determining the rates of reactions which pass through this transition state. The energy surface shown in [figure B3.1.2](#) displays such transition states, and it also shows a second-order saddle point (i.e. a point where the gradient vanishes and the Hessian has two directions of negative curvature).

Figure B3.1.2. Two-dimensional slice through a $(3N - 6)$ -dimensional energy surface of a polyatomic molecule or ion. After [2].

Figure B3.1.3. Energies of NH^- and of NH pertinent to the autodetachment of $v = 1, J$ levels of NH^- formed by laser excitation of $v = 0, J''$ NH^- .

At any geometry $\{Q_i\}$, the gradient vector having components $\partial E_k / \partial Q_i$ provides the forces ($F_i = -\partial E_k / \partial Q_i$) along each of the coordinates Q_i . These forces are used in molecular dynamics simulations which solve the Newton $\mathbf{F} = m\mathbf{a}$ equations and in molecular mechanics studies which are aimed at locating those geometries where the \mathbf{F} vector vanishes (i.e. the stable isomers and transition states discussed above).

Also produced in electronic structure simulations are the electronic wavefunctions $\{\psi_k\}$ and energies $\{E_k\}$ of each of the electronic states. The separation in energies can be used to make predictions on the spectroscopy of the system. The wavefunctions can be used to evaluate the properties of the system that depend on the spatial distribution of the electrons. For example, the z component of the dipole moment [10] of a molecule μ_z can be computed by integrating

the probability density for finding an electron at position \mathbf{r} multiplied by the z coordinate of the electron and the electron's charge e : $\mu_z = \int e \psi_k^* \psi_k z \, d\mathbf{r}$. The average kinetic energy of an electron can also be computed by carrying out such an average-value integral: $\int \psi_k^* (-\hbar^2 / 2m_e \nabla^2) \psi_k \, d\mathbf{r}$. The rules for computing the average value of any physical observable are developed and illustrated in popular undergraduate text books on

physical chemistry [11] and in graduate-level texts [12].

Not only can electronic wavefunctions tell us about the average values of all the physical properties for any particular state (i.e. ψ_k above), but they also allow us to tell us how a specific ‘perturbation’ (e.g. an electric field in the Stark effect, a magnetic field in the Zeeman effect and light’s electromagnetic fields in spectroscopy) can alter the specific state of interest. For example, the perturbation arising from the electric field of a photon interacting with the electrons in a molecule is given within the so-called electric dipole approximation [12] by:

$$\hat{H}_{\text{pert}} = \sum_j e^2 \mathbf{r}_j \cdot \mathbf{E}(t)$$

where \mathbf{E} is the electric field vector of the light, which depends on time t in an oscillatory manner, and \mathbf{r}_j gives the spatial coordinates of the j th electron. This perturbation, \hat{H}_{pert} can induce transitions to other states ψ_k , with probabilities that are proportional to the square of the integral:

$$\int \psi_k^* \hat{H}_{\text{pert}} \psi_k \, d\mathbf{r}.$$

So, if this integral were to vanish, transitions between ψ_k and ψ_k would not occur, and would be referred to as ‘forbidden’. Whether such integrals vanish or not often is determined by symmetry. For example, if ψ_k were of odd symmetry under a plane of symmetry σ_v of the molecule, while ψ_k were even under σ_v , then the integral would vanish unless one or more of the three Cartesian components of the dot product $\mathbf{r}_j \cdot \mathbf{E}$ were odd under σ_v . The general idea is that for the integral not to vanish, the direct product of the symmetries of ψ_k and of ψ_k must match the symmetry of at least one of the symmetry components present in \hat{H}_{pert} . Professor Poul Jørgensen [13] has been involved in developing such so-called response theories for perturbations that may be time dependent (e.g. as in the interaction of light’s electromagnetic radiation).

B3.1.1.4 SUMMARY

In summary, computational *ab initio* quantum chemistry attempts to solve the electronic Schrödinger equation for the $E_k(\mathbf{R})$ energy surfaces and wavefunctions $\psi_k(\mathbf{r};\mathbf{R})$ on a ‘grid’ of values for the ‘clamped’ nuclear positions. Because the Schrödinger equation produces wavefunctions, it has a great deal of predictive power. Wavefunctions contain all the information needed to compute dipole moments, polarizability, etc and transition properties such as the electric dipole transition strengths among states. They also permit the evaluation of system responses with respect to external perturbations such as geometrical distortions [9], which provides information on vibrational frequencies and reaction paths.

B3.1.2 WHY IS IT SO DIFFICULT TO CALCULATE ELECTRONIC ENERGIES AND WAVEFUNCTIONS WITH REASONABLE ACCURACY?

As a scientific tool, *ab initio* quantum chemistry is not yet as accurate as modern laser spectroscopic measurements, for example. Moreover, it is difficult to estimate the accuracies with which various methods predict bond energies and lengths, excitation energies and the like. In the opinion of the author, chemists who

rely on the results of quantum chemistry calculations must better understand what underlies the concepts and methods of this field. Only by so doing will they be able to judge for themselves the value of given quantum chemistry data to their own research. There exist a variety of sources of further information on the ‘jargon’, underlying theory, methodologies, and current strengths and weaknesses of *ab initio* quantum chemistry. In 1996, Head-Gordon [14] produced a nice overview entitled ‘Quantum chemistry and molecular processes’, Schaefer *et al* [15] offered a very good discussion in 1995; Simons [16] offered a somewhat earlier perspective in 1991. The present chapter includes many of the ideas contained in these and other earlier descriptions of this field’s impacts, but also attempts to extend the perspective to include more recent developments.

Returning now to the issue of the accuracy of various electronic structure predictions, it is natural to ask why it is so difficult to achieve reasonable accuracy (i.e. ca. 1 kcal mol⁻¹ in computed bond energies or activation energies) even with the most sophisticated and computer-resource-intensive quantum chemistry calculations. The reasons include the following.

- (A) *Many-body problems with R^{-1} potentials* are notoriously difficult. It is well known that the Coulomb potential falls off so slowly with distance that mathematical difficulties can arise. The $4\pi R^2$ dependence of the integration volume element, combined with the R^{-1} dependence of the potential, produce ill-defined interaction integrals unless attractive and repulsive interactions are properly combined. The classical or quantum treatment of ionic melts [17], many-body gravitational dynamics [18] and Madelung sums [19] for ionic crystals are all plagued by such difficulties.
- (B) *The electrons require quantal treatment and they are indistinguishable.* The electron’s small mass produces local de Broglie wavelengths that are long compared to atomic ‘sizes’, thus necessitating quantum treatment. Their indistinguishability requires that permutational symmetry be imposed on solutions of the Schrödinger equation.
- (C) *All mean-field models of electronic structure require large corrections.* Essentially all *ab initio* quantum chemistry approaches introduce a ‘mean field’ potential V_{mf} that embodies the average interactions among the N electrons. The difference between the mean-field potential and the true Coulombic potential is termed [20] the ‘*fluctuation potential*’. The solutions $\{\Psi_k, E_k\}$ to the true electronic Schrödinger equation are then approximated in terms of solutions $\{\Psi_k^0, E_k^0\}$ to the model Schrödinger equation in which V_{mf} is used. Improvements to the solutions of the model problem are made using perturbation theory or the variational method. Such approaches are expected to work when the difference between the starting model and the final goal is small in some sense.

The most elementary mean-field models of electronic structure introduce a potential that an electron at r_1 would experience if it were interacting with a *spatially averaged* electrostatic charge density arising from the $N - 1$ remaining electrons:

-7-

$$V_{\text{mf}}(\mathbf{r}_1) = \int \rho_{N-1}(\mathbf{r}') \frac{e^2}{|\mathbf{r}_1 - \mathbf{r}'|} d\mathbf{r}'.$$

Here $\rho_{N-1}(\mathbf{r}')$ represents the probability density for finding the $N - 1$ electrons at \mathbf{r}' , and $e^2 / |\mathbf{r}_1 - \mathbf{r}'|$ is the mutual Coulomb repulsion between electron density at r_1 and \mathbf{r}' .

The magnitude and ‘shape’ of such a mean-field potential is shown below [21] in figure B3.1.4 for the two 1s electrons of a beryllium atom. The Be nucleus is at the origin, and one electron is held fixed 0.13 Å from the nucleus, the maximum of the 1s orbital’s radial probability density. The Coulomb potential experienced by the second electron is then a function of the second electron’s position along the x -axis (connecting the Be nucleus and the first electron) and its distance perpendicular to the x -axis. For simplicity, this second electron

is arbitrarily constrained to lie on the x -axis. Along this direction, the Coulomb potential is singular, and hence the overall interactions are very large.

Figure B3.1.4. Fluctuation and mean-field SCF potentials for a 2s electron in Be.

On the ordinate, two quantities are plotted: (i) the mean-field potential between the second electron and the other 1s electron computed, via the self-consistent field (SCF) process (described later), as the interaction of the second electron with a spherical $|1s|^2$ charge density centred on the Be nucleus; and (ii) the fluctuation potential (F) of this average (mean-field) interaction.

As a function of the inter-electron distance, the fluctuation potential decays to zero more rapidly than does the mean-field potential. However, the magnitude of F is quite large and remains so over an appreciable range of inter-electron distances. The corrections to the mean-field picture are therefore quite large when measured in kcal mol^{-1} . For example, the differences (called pair correlation energies) ΔE between the true (state-of-the-art quantum chemical calculation as discussed later) energies of the interaction among the four electrons in the Be atom and the mean-field estimates of these interactions are given in [table B3.1.1](#) in electronvolts ($1 \text{ eV} = 23.06 \text{ kcal mol}^{-1}$).

Table 3.1.1 Pair correlation energies for the four electrons in Be.

Orbital pair	$1s_\alpha 1s_\beta$	$1s_\alpha 2s_\alpha$	$1s_\alpha 2s_\beta$	$1s_\beta 2s_\alpha$	$1s_\beta 2s_\beta$	$2s_\alpha 2s_\beta$
ΔE (eV)	1.126	0.022	0.058	0.058	0.022	1.234

Another example of the difficulty is offered in figure B3.1.5. Here we display on the ordinate, for helium's 1S ($1s^2$) state, the probability of finding an electron whose distance from the He nucleus is 0.13 \AA (the peak of the 1s orbital's density) and whose angular coordinate relative to that of the other electron is plotted on the abscissa. The He nucleus is at the origin and the second electron also has a radial coordinate of 0.13 \AA . As the relative angular coordinate varies away from 0° , the electrons move apart; near 0° , the electrons approach one another. Since both electrons have opposite spin in this state, their mutual Coulomb repulsion alone acts to keep them apart.

Figure B3.1.5. Probability (as a function of angle) for finding the second electron in He when both electrons are located at the maximum in the 1s orbital's probability density. The bottom line is that obtained using a Hylleraas-type function, and the other related to a highly-correlated multiconfigurational wavefunction. After [22].

What figure B3.1.5 shows is that, for a highly accurate wavefunction (one constructed using so-called Hylleraas functions [23] that depend explicitly on the coordinates of the two electrons as well as on their interparticle distance coordinate), one finds a 'cusp' in the probability density for finding one electron in the neighbourhood of another electron with the same spin. The probability plot for the Hylleraas function is the lower bold curve in figure B3.1.5. The line above the Hylleraas plot was extracted from a configuration interaction wavefunction for He obtained using a rather large atomic orbital (AO) basis set [22]. Even for such a sophisticated wavefunction (of the type used in many state-of-the-art *ab initio* calculations), the cusp in the relative probability distribution is, clearly, not well represented. Finally, the Hartree–Fock (HF) probability, which is not even displayed above, would, if plotted, be flat as a function of the angle shown above and thus clearly very much in error.

B3.1.2.1 SUMMARY

The above evidence shows why an *ab initio* solution of the Schrödinger equation is a very demanding task if high accuracy is desired. The HF potential takes care of 'most' of the interactions among the N electrons (which interact via long-range Coulomb forces and whose dynamics requires the application of quantum physics and permutational

-9-

symmetry). However, the residual fluctuation potential is large enough to cause significant corrections to the HF picture. The reality is that electrons in atoms and molecules undergo dynamical motions in which their Coulomb repulsions cause them to 'avoid' one another at every instant of time, not only in the average-repulsion manner that the mean-field models embody. The inclusion of instantaneous spatial correlations (usually called *dynamical correlations*) among electrons is necessary to achieve a more accurate description of the atomic and molecular electronic structure.

B3.1.3 WHAT ARE THE ESSENTIAL CONCEPTS OF *AB INITIO* QUANTUM CHEMISTRY?

The mean-field potential and the need to improve it to achieve reasonably accurate solutions to the true electronic Schrödinger equation introduce three constructs that characterize essentially all *ab initio* quantum chemical methods: *orbitals*, *configurations* and *electron correlation*.

B3.1.3.1 ORBITALS AND CONFIGURATIONS—WHAT ARE THEY (REALLY)?

(A) HOW THE MEAN-FIELD MODEL LEADS TO ORBITALS AND CONFIGURATIONS

The mean-field potentials that have proven most useful are all one-electron additive: $V_{\text{mf}}(\mathbf{r}) = \sum_j V_{\text{mf}}(\mathbf{r}_j)$. Since the electronic kinetic energy $\hat{T} = \sum_j \hat{T}_j$ operator is also one-electron additive, so is the mean-field

Hamiltonian $\hat{H}^0 = \hat{T} + \hat{V}_{\text{mf}}$. The additivity of \hat{H}^0 implies that the mean-field energies E_k^0 are additive and the wavefunctions $\{\Psi_k^0\}$ can be formed in terms of products of functions $\{\phi_k\}$ of the coordinates of the individual electrons.

Thus, it is the *ansatz* that V_{mf} is separable that leads to the concept of *orbitals*, which are the one-electron functions $\{\phi_j\}$ found by solving the one-electron Schrödinger equations: $(\hat{T}_1 + \hat{V}_{\text{mf}}(\mathbf{r}_1)) \phi_j(\mathbf{r}_1) = \epsilon_j \phi_j(\mathbf{r}_1)$; the eigenvalues $\{\epsilon_j\}$ are called *orbital energies*.

Given the complete set of solutions to this one-electron equation, a complete set of N -electron mean-field wavefunctions can be written. Each $\{\Psi_k^0\}$ is constructed by forming a product of N orbitals chosen from the set of $\{\phi_j\}$, allowing each orbital in the list to be a function of the coordinates of one of the N electrons (e.g. $\Psi_k^0 = |\phi_{k1}(\mathbf{r}_1)\phi_{k2}(\mathbf{r}_2)\phi_{k3}(\mathbf{r}_3) \dots \phi_{kN-1}(\mathbf{r}_{N-1})\phi_{kN}(\mathbf{r}_N)|$, as above). The corresponding mean-field energy is evaluated as the sum over those orbitals that appear in Ψ_k^0 : $E_k^0 = \sum_{j=1, N} \epsilon_{kj}$.

Because of the indistinguishability of the N electrons, the antisymmetric component of any such orbital product must be formed to obtain the proper mean-field wavefunction. To do so, one applies the so-called antisymmetrizer operator [24] $\hat{A} = \sum_P (-1)^P \hat{P}$, where the permutation operator \hat{P} runs over all $N!$ permutations of the N electrons. Application of \hat{A} to a product function does not alter the occupancy of the functions $\{\phi_{kj}\}$ in $\{\Psi_k^0\}$, it simply scrambles the order which the electrons occupy the $\{\phi_{kj}\}$ and it causes the resultant function (which is often denoted $|\phi_{k1}(\mathbf{r}_1)\phi_{k2}(\mathbf{r}_2)\phi_{k3}(\mathbf{r}_3) \dots \phi_{kN-1}(\mathbf{r}_{N-1})\phi_{kN}(\mathbf{r}_N)|$ and called a Slater determinant) to obey the Pauli exclusion principle.

Because the electrons also possess intrinsic spin, the one-electron functions $\{\phi_j\}$ used in this construction are taken to

-10-

be eigenfunctions of $(\hat{T}_1 + \hat{V}_{\text{mf}}(\mathbf{r}_1))$ multiplied by either an α or β spin function. This set of functions is called the set of mean-field *spin orbitals*.

By choosing to place N electrons into N specific spin orbitals, one specifies a *configuration*. By making other choices of which $N\phi_j$ to occupy, one describes other configurations. Just as the one-electron mean-field Schrödinger equation has a complete set of spin-orbital solutions $\{\phi_j$ and $\epsilon_j\}$, the N -electron mean-field Schrödinger equation has a complete set of antisymmetric N -electron Slater determinants. When these determinants are combined to generate functions that are eigenfunctions of the total S^2 and S_z and eigenfunctions of the molecule's point group symmetry (or 2 and z for atoms), one has what are called *configuration state functions* (CSFs) whose mean-field energies are also given by .

(B) THE SELF-CONSISTENT MEAN-FIELD (SCF) POTENTIAL

The one-electron additivity of the mean-field Hamiltonian \hat{H}^0 gives rise to the concept of spin orbitals for *any* additive $V_{\text{mf}}(\mathbf{r})$. In fact, there is no *single* mean-field potential; different scientists have put forth different suggestions for V_{mf} over the years. Each gives rise to spin orbitals and configurations that are specific to the particular V_{mf} . However, if the difference between any particular mean-field model and the full electronic

Hamiltonian is fully treated, corrections to all mean-field results should converge to the same set of exact states. In practice, one is never able to treat *all* corrections to any mean-field model. Thus, it is important to seek particular mean-field potentials for which the corrections are as small and straightforward to treat as possible.

In the most commonly employed mean-field models [25] of electronic structure theory, the configuration specified for study plays a central role in defining the mean-field potential. For example, the mean-field Coulomb potential felt by a $2p_x$ orbital's electron at a point \mathbf{r} in the $1s^2 2s^2 2p_x 2p_y$ configuration description of the carbon atom is:

The above mean-field potential is used to find the $2p_x$ orbital of the carbon atom, which is then used to define the mean-field potential experienced by, for example, an electron in the $2s$ orbital:

Notice that the orbitals occupied in the configuration under study appear in the mean-field potential. However, it is \hat{V}_{mf} that, through the one-electron Schrödinger equation, determines the orbitals. For these reasons, the solution of these

-11-

equations must be carried out in a so-called SCF manner. One begins with an approximate description of the orbitals in $\{\Psi_k^0\}$. These orbitals then define \hat{V}_{mf} and the equations $(\hat{T}_1 + \hat{V}_{\text{mf}}(\mathbf{r}_1))\phi_j(\mathbf{r}_1) = \epsilon_j \phi_j(\mathbf{r}_1)$ are solved for 'new' spin orbitals. These orbitals are then be used to define an improved \hat{V}_{mf} which gives another set of solutions to $(\hat{T}_1 + \hat{V}_{\text{mf}}(\mathbf{r}_1))\phi_j(\mathbf{r}_1) = \epsilon_j \phi_j(\mathbf{r}_1)$. This iterative process is continued until the orbitals used to define \hat{V}_{mf} are identical to those that result as solutions of $(\hat{T}_1 + \hat{V}_{\text{mf}}(\mathbf{r}_1))\phi_j(\mathbf{r}_1) = \epsilon_j \phi_j(\mathbf{r}_1)$. When this condition is reached, one has achieved 'self-consistency'.

B3.1.3.2 WHAT IS ELECTRON CORRELATION?

By expressing the mean-field interaction of an electron at \mathbf{r} with the $N - 1$ other electrons in terms of a probability density $\rho_{N-1}(\mathbf{r}')$ that is independent of the fact that another electron resides at \mathbf{r} , the mean-field models ignore spatial *correlations* among the electrons. In reality, as shown in [figure B3.1.5](#) the conditional probability density for finding one of $N - 1$ electrons at \mathbf{r}' , given that one electron is at \mathbf{r} depends on \mathbf{r} . The absence of a spatial correlation is a direct consequence of the spin-orbital *product nature* of the mean-field wavefunctions $\{\Psi_k^0\}$.

To improve upon the mean-field picture of electronic structure, one must move beyond the single-configuration approximation. It is essential to do so to achieve higher accuracy, but it is also important to do so to achieve a *conceptually* correct view of the chemical electronic structure. Although the picture of configurations in which N electrons occupy N spin orbitals may be familiar and useful for systematizing the electronic states of atoms and molecules, these constructs are approximations to the true states of the system. They were introduced when the mean-field approximation was made, and neither orbitals nor configurations can be claimed to describe the proper eigenstates $\{\Psi_k, E_k\}$. It is thus inconsistent to insist that the carbon atom be thought of as $1s^2 2s^2 2p^2$ while insisting on a description of this atom accurate to ± 1 kcal mol⁻¹.

B3.1.3.3 SUMMARY

The SCF mean-field potential takes care of 'most' of the interactions among the N electrons. However, for all

mean-field potentials proposed to date, the residual or fluctuation potential is large enough to require significant corrections to the mean-field picture. This, in turn, necessitates the use of more sophisticated and computationally taxing techniques (e.g., high-order perturbation theory or large variational expansion spaces) to reach the desired chemical accuracy.

For electronic structures of atoms and molecules, the SCF model requires quite substantial corrections to bring its predictions in line with experimental fact. Electrons in atoms and molecules undergo dynamical motions in which their Coulomb repulsions cause them to ‘avoid’ one another at every instant of time, not only in the average-repulsion manner of mean-field models. The inclusion of *dynamical correlations* among electrons is necessary to achieve a more accurate description of atomic and molecular electronic structure. No single spin-orbital product wavefunction is capable of treating electron correlation to *any* extent; its product nature renders it incapable of doing so.

-12-

B3.1.4 HOW TO INTRODUCE ELECTRON CORRELATION VIA CONFIGURATION MIXING

B3.1.4.1 THE MULTI-CONFIGURATION WAVEFUNCTION

In most of the commonly used *ab initio* quantum chemical methods [26], one forms a set of configurations by placing N electrons into spin orbitals in a manner that produces the spatial, spin and angular momentum symmetry of the electronic state of interest. The correct wavefunction Ψ is then written as a linear combination of the mean-field configuration functions $\{\Psi_k\}$: $\Psi = \sum_k C_k \Psi_k^0$. For example, to describe the

ground 1S state of the Be atom, the $1s^2 2s^2$ configuration is augmented by including other configurations such as $1s^2 3s^2$, $1s^2 2p^2$, $1s^2 3p^2$, $1s^2 2s 3s$, $3s^2 2s^2$, $2p^2 2s^2$, etc, all of which have overall 1S spin and angular momentum symmetry. The various methods of electronic structure theory differ primarily in how they determine the $\{C_k\}$ expansion coefficients and how they extract the energy E corresponding to this Ψ .

B3.1.4.2 THE PHYSICAL MEANING OF MIXING IN ‘EXCITED’ CONFIGURATIONS

When considering the ground 1S state of the Be atom, the following four antisymmetrized spin-orbital products are found to have the largest C_k amplitudes:

$$\Psi \cong C_1 |1s^2 2s^2| - C_2 [|1s^2 2p_x^2| + |1s^2 2p_y^2| + |1s^2 2p_z^2|].$$

The fact that the latter three terms possess the same amplitude C_2 is a result of the requirement that a state of 1S symmetry is desired. It can be shown [27] that this function is equivalent to

$$\begin{aligned} \Psi \cong \frac{1}{6} C_1 |1s\alpha 1s\beta| & \{ [(2s - a2p_x)\alpha(2s + a2p_x)\beta - (2s - a2p_x)\beta(2s + a2p_x)\alpha] \\ & + [(2s - a2p_y)\alpha(2s + a2p_y)\beta - (2s - a2p_y)\beta(2s + a2p_y)\alpha] \\ & + [(2s - a2p_z)\alpha(2s + a2p_z)\beta - (2s - a2p_z)\beta(2s + a2p_z)\alpha] \} \end{aligned}$$

where $a = \sqrt{3C_2/C_1}$.

Here two electrons occupy the $1s$ orbital (with opposite, α and β spins) while the other electron pair resides in $2s$ - $2p$ polarized orbitals in a manner that instantaneously correlates their motions. These *polarized orbital*

pairs ($2s \pm a2p_{x,y \text{ or } z}$) are formed by combining the 2s orbital with the $2p_{x,y \text{ or } z}$ orbital in a ratio determined by C_2/C_1 . This way of viewing an electron pair correlation forms the basis of the generalized valence bond (GVB) method that Professor Bill Goddard [28] pioneered.

This ratio C_2/C_1 can be shown to be proportional to the magnitude of the coupling $\langle 1s^2 2s^2 | \hat{H} | 1s^2 2p^2 \rangle$ between the two

-13-

configurations involved and inversely proportional to the energy difference ($\langle 1s^2 2s^2 | \hat{H} | 1s^2 2s^2 \rangle - \langle 1s^2 2p^2 | \hat{H} | 1s^2 2p^2 \rangle$) between these configurations. In general, configurations that have similar Hamiltonian expectation values and that are coupled strongly give rise to strongly mixed (i.e. with large $|C_2/C_1|$ ratios) polarized orbital pairs.

A set of polarized orbital pairs is described pictorially in figure B3.1.6. In each of the three equivalent terms in the above wavefunction, one of the valence electrons moves in a $2s+a2p$ orbital polarized in one direction while the other valence electron moves in the $2s-a2p$ orbital polarized in the opposite direction. For example, the first term $(2s-a2p_x)\alpha(2s+a2p_x)\beta - (2s-a2p_x)\beta(2s+a2p_x)\alpha$ describes one electron occupying a $2s-a2p_x$ polarized orbital while the other electron occupies the $2s+a2p_x$ orbital. The electrons thus reduce their Coulomb repulsion by occupying *different* regions of space; in the SCF picture $1s^2 2s^2$, both electrons reside in the same 2s region of space. In this particular example, the electrons undergo *angular correlation* to ‘avoid’ one another.

Figure B3.1.6. Polarized orbital pairs involving 2s and $2p_z$ orbitals.

Let us consider another example. In describing the π^2 electron pair of an olefin, it is important to mix in ‘doubly excited’ configurations of the form $(\pi^*)^2$. The physical importance of such configurations can again be made clear by using the identity

$$\begin{aligned}
 & C_1 | \dots \phi \alpha \phi \beta \dots | - C_2 | \dots \phi' \alpha \phi' \beta \dots | \\
 &= C_1 / 2 \{ | \dots (\phi - x \phi') \alpha (\phi + x \phi') \beta \dots | - | \dots (\phi - x \phi') \beta (\phi + x \phi') \alpha \dots | \}
 \end{aligned}$$

where $x = (C_2/C_1)^{1/2}$.

In this example, the two non-orthogonal ‘polarized orbital pairs’ involve mixing the π and π^* orbitals to produce two left–right polarized orbitals as depicted in figure B3.1.7. Here one says that the π^2 electron pair undergoes left–right correlation when the $(\pi^*)^2$ configuration is introduced.

Figure B3.1.7. Left- and right-polarized orbital pairs involving π and π^* orbitals.

B3.1.4.3 ARE POLARIZED ORBITAL PAIRS HYBRID ORBITALS?

It should be stressed that these polarized orbital pairs are *not* the same as hybrid orbitals. The latter are used to describe directed bonding, but polarized orbital *pairs* are each a ‘mixture’ of two mean-field orbitals with amplitude $x = (C_2/C_1)^{1/2}$ and with a *single electron* in each, thereby allowing the electrons to be spatially correlated and to ‘avoid’ one another. In addition, polarized orbital pairs are *not generally orthogonal* to one another; hybrid orbital sets are.

B3.1.4.4 RELATIONSHIP TO THE GENERALIZED VALENCE BOND PICTURE

In these examples, the analysis allows one to *interpret* the combination of pairs of configurations that differ from one another by a ‘double excitation’ from one orbital (ϕ) to another (ϕ') as equivalent to a singlet coupling of two polarized orbitals ($\phi - a\phi'$) and ($\phi + a\phi'$). As mentioned earlier, this picture is closely related to the GVB model that Goddard [28] and Goddard and Harding [29] developed. In the simplest embodiment of the GVB model, each electron pair in the atom or molecule is correlated by mixing in a configuration in which that pair is ‘doubly excited’ to a correlating orbital. The direct product of all such pair correlations generates the simplest GVB-type wavefunction.

In most *ab initio* quantum chemical methods, the correlation calculation is actually carried out by forming a linear combination of the mean-field configuration state functions and determining the $\{C_k\}$ amplitudes by some procedure. The identities discussed in some detail above are then introduced merely to permit one to interpret the presence of configurations that are ‘doubly excited’ relative to the dominant mean-field configuration in terms of polarized orbital pairs.

B3.1.4.5 SUMMARY

The dynamical interactions among electrons give rise to instantaneous spatial correlations that must be handled to arrive at an accurate picture of the atomic and molecular structure. The single-configuration picture provided by the mean-field model is a useful starting point, but it is *incapable* of describing electron correlations. Therefore, improvements are needed. The use of doubly-excited configurations is a mechanism by which Ψ can place electron *pairs*, which in the mean-field picture occupy the same orbital, into different regions of space thereby lowering their mutual Coulombic repulsions. Such electron correlation effects are referred to as *dynamical electron correlation*; they are extremely important to include if one expects to achieve chemically meaningful accuracy.

B3.1.5 THE SINGLE-CONFIGURATION PICTURE AND THE HF APPROXIMATION

Given a set of N -electron space- and spin-symmetry-adapted configuration state functions $\{\Phi_j\}$ in terms of which Ψ is to be expanded as $\Psi = \sum_j C_j \Phi_j$, two primary questions arise: (1) how to determine the $\{C_j\}$ coefficients and the energy E and (2) how to find the ‘best’ spin orbitals $\{\phi_j\}$? Let us first consider the case where a single configuration is used so only the question of determining the spin orbitals exists.

B3.1.5.1 THE SINGLE-DETERMINANT WAVEFUNCTION

(A) THE CANONICAL SCF EQUATIONS

The simplest trial function employed in *ab initio* quantum chemistry is the single Slater determinant function in which N spin orbitals are occupied by N electrons:

$$\Psi = |\phi_1 \phi_2 \phi_3 \dots \phi_N|.$$

For such a function, variational optimization of the spin orbitals to make the expectation value $\langle \Psi | \hat{H} | \Psi \rangle$ stationary produces [30] the canonical HF equations

$$\hat{F} \phi_i = \varepsilon_i \phi_i$$

where the so-called Fock operator \hat{F} is given by

$$\hat{F} \phi_i = \hat{h} \phi_i + \sum_{j(\text{occupied})} [\hat{J}_j - \hat{K}_j] \phi_i.$$

The Coulomb (\hat{J}_j) and exchange (\hat{K}_j) operators are defined by the relations

$$\hat{J}_j \phi_i = \int \phi_j^*(r') \phi_j(r') / |r - r'| d\tau' \phi_i(r)$$

and

$$\hat{K}_j \phi_i = \int \phi_j^*(r') \phi_i(r') / |r - r'| d\tau' \phi_j(r)$$

the symbol \hat{h} denotes the sum of the electronic kinetic energy, and electron–nuclear Coulomb attraction operators. The $d\tau$ implies integration over the spin variables associated with the ϕ_i (and, for the exchange

operator, ϕ_i), as a result of which the exchange integral vanishes unless the spin function of ϕ_j is the same as that of ϕ_i ; the Coulomb integral is non-vanishing no matter what the spin functions of ϕ_j and ϕ_i .

(B) THE EQUATIONS HAVE ORBITAL SOLUTIONS FOR OCCUPIED AND UNOCCUPIED ORBITALS

The HF [31] equations $\hat{F}\phi_i = \varepsilon_i\phi_i$ possess solutions for the spin orbitals in Ψ (the *occupied* spin orbitals) as well as for orbitals not occupied in Ψ (the *virtual* spin orbitals) because the \hat{F} operator is Hermitian. Only the ϕ_i occupied in Ψ appear in the Coulomb and exchange potentials of the Fock operator.

(C) THE SPIN-IMPURITY PROBLEM

As formulated above, the HF equations yield orbitals that do not guarantee that Ψ has proper spin symmetry. To illustrate, consider an open-shell system such as the lithium atom. If $1s\alpha$, $1s\beta$, and $2s\alpha$ spin orbitals are chosen to appear in Ψ , the Fock operator will be

$$\hat{F} = \hat{h} + \hat{J}_{1s\alpha} + \hat{J}_{1s\beta} + \hat{J}_{2s\alpha} - [\hat{K}_{1s\alpha} + \hat{K}_{1s\beta} + \hat{K}_{2s\alpha}].$$

Acting on an α spin orbital $\phi_{k\alpha}$ with F and carrying out the spin integrations, one obtains

$$\hat{F}\phi_{k\alpha} = \hat{h}\phi_{k\alpha} + (2\hat{J}_{1s} + \hat{J}_{2s})\phi_{k\alpha} - (\hat{K}_{1s} + \hat{K}_{2s})\phi_{k\alpha}.$$

In contrast, when acting on a β spin orbital, one obtains

$$\hat{F}\phi_{k\beta} = \hat{h}\phi_{k\beta} + (2\hat{J}_{1s} + \hat{J}_{2s})\phi_{k\beta} - (\hat{K}_{1s})\phi_{k\beta}.$$

Spin orbitals of α and β type do *not* experience the same exchange potential in this model because Ψ contains two α spin orbitals and only one β spin orbital. A consequence is that the optimal $1s\alpha$ and $1s\beta$ spin orbitals, which are themselves solutions of $\hat{F}\phi_i = \varepsilon_i\phi_i$, do not have identical orbital energies (i.e. $\varepsilon_{1s\alpha} \neq \varepsilon_{1s\beta}$) and are not spatially identical. This resultant spin polarization of the orbitals gives rise to *spin impurities* in Ψ . The determinant $|1s\alpha 1s'\beta 2s\alpha|$ is not a

-17-

pure doublet spin eigenfunction, although it is an S_z eigenfunction with $M_s = 1/2$; it contains both $S = 1/2$ and $S = 3/2$ components. If the $1s\alpha$ and $1s'\beta$ spin orbitals were spatially identical, then $|1s\alpha 1s'\beta 2s\alpha|$ would be a pure spin eigenfunction with $S = 1/2$.

The above single-determinant wavefunction is referred to as being of the unrestricted Hartree–Fock (UHF) type because no restrictions are placed on the spatial nature of the orbitals in Ψ . In general, UHF wavefunctions are not of pure spin symmetry for any open-shell system or for closed-shell systems far from their equilibrium geometries (e.g. for H_2 or N_2 at long bond lengths) These are significant drawbacks of methods based on a UHF starting point. Such a UHF treatment forms the basis of the widely used and highly successful Gaussian 70 through Gaussian-9X series of electronic structure computer codes [32] which derive from Pople [32] and co-workers.

To overcome some of the problems inherent in the UHF method, it is possible to derive SCF equations based on minimizing the energy of a wavefunction formed by spin projecting a single Slater determinant starting

function (e.g. using $\{ |1s\alpha\ 2s\beta\rangle - |1s\beta\ 2s\alpha\rangle \} / 2^{1/2}$ for the singlet excited state of He rather than $|1s\alpha\ 2s\beta\rangle$). It is also possible for a trial wavefunction of the form $|1s\alpha\ 1s\beta\ 2s\alpha\rangle$ to constrain the $1s\alpha$ and $1s\beta$ orbitals to have exactly the same spatial form. In both cases, one then is able to carry out what are called restricted Hartree–Fock (RHF) calculations.

B3.1.5.2 THE LINEAR COMBINATIONS OF ATOMIC ORBITALS TO FORM MOLECULAR ORBITALS EXPANSION OF THE SPIN ORBITALS

The HF equations must be solved iteratively because the J_i and K_i operators in F depend on the orbitals ϕ_i for which solutions are sought. Typical iterative schemes begin with a ‘guess’ for those ϕ_i that appear in Ψ , which then allows \hat{F} to be formed. Solutions to $\hat{F}\phi_i = \varepsilon_i\phi_i$ are then found, and those ϕ_i which possess the space and spin symmetry of the occupied orbitals of Ψ and which have the proper energies and nodal character are used to generate a new \hat{F} operator (i.e. new \hat{J}_i and \hat{K}_i operators). This iterative HF SCF process is continued until the ϕ_i and ε_i do not vary significantly from one iteration to the next, at which time one says that the process has converged.

In practice, solution of $\hat{F}\phi_i = \varepsilon_i\phi_i$ as an integro-differential equation can be carried out only for atoms [34] and linear molecules [35] for which the angular parts of the ϕ_i can be exactly separated from the radial because of axial- or full-rotation group symmetry (e.g. $\phi_i = Y_{l,m}(\theta, \phi)R_{n,l}(r)$ for an atom and $\phi_i = \exp(im\phi)R_{n,l,m}(\rho, z)$ for a linear molecule).

In the procedures most commonly applied to nonlinear molecules, the ϕ_i are expanded in a *basis* χ_μ according to the linear combinations of AOs to form molecular orbitals (LCAO–MO) [36] procedure:

$$\phi_i = \sum_{\mu} C_{\mu,i} \chi_{\mu}$$

-18-

This reduces $\hat{F}\phi_i = \varepsilon_i\phi_i$ to a matrix eigenvalue-type equation:

$$\sum_{\nu} F_{\mu,\nu} C_{\nu,i} = \varepsilon_i \sum_{\nu} S_{\mu,\nu} C_{\nu,i}$$

where $S_{\mu,\nu} = \langle \chi_{\mu} | \chi_{\nu} \rangle$ is the overlap matrix among the AOs and

$$F_{\mu,\nu} = \langle \chi_{\mu} | \hat{h} | \chi_{\nu} \rangle + \sum_{\delta,\kappa} [\gamma_{\delta,\kappa} \langle \chi_{\mu} \chi_{\delta} | \hat{g} | \chi_{\nu} \chi_{\kappa} \rangle - \gamma_{\delta,\kappa}^{\text{ex}} \langle \chi_{\mu} \chi_{\delta} | \hat{g} | \chi_{\kappa} \chi_{\nu} \rangle]$$

is the matrix representation of the Fock operator in the AO basis. Here and elsewhere, the symbol \hat{g} is used to represent the electron–electron Coulomb potential $e^2/|\mathbf{r} - \mathbf{r}'|$.

The charge- and exchange-density matrix elements in the AO basis are:

$$\gamma_{\delta,\kappa} = \sum_{i(\text{occupied})} C_{\delta,i} C_{\kappa,i}$$

and

$$\gamma_{\delta,\kappa}^{\text{ex}} = \sum_{i(\text{occupied and same spin})} C_{\delta,i} C_{\kappa,i}$$

where the sum in $\gamma_{\delta,\kappa}^{\text{ex}}$ runs over those occupied spin orbitals whose m_s value is equal to that for which the Fock matrix is being formed (for a closed-shell species, $\gamma_{\delta,\kappa}^{\text{ex}} = 1/2\gamma_{\delta,\kappa}$).

It should be noted that by moving to a matrix problem, one does not remove the need for an iterative solution; the $F_{\mu,\nu}$ matrix elements depend on the $C_{\nu,i}$ LCAO–MO coefficients which are, in turn, solutions of the so-called Roothaan [30] matrix HF equations: $\sum_{\nu} F_{\mu,\nu} C_{\nu,i} = \epsilon_i \sum_{\nu} S_{\mu,\nu} C_{\nu,i}$. One should also note that, just as $\hat{F}\phi_i = \epsilon_i \phi_i$ possesses a complete set of eigenfunctions, the matrix $F_{\mu,\nu}$, whose dimension M is equal to the number of atomic basis orbitals, has M eigenvalues ϵ_j and M eigenvectors whose elements are the $C_{\nu,i}$. Thus, there are *occupied and virtual* MOs each of which is described in the LCAO–MO form with the $C_{\nu,i}$ coefficients obtained via solution of $\sum_{\nu} F_{\mu,\nu} C_{\nu,i} = \epsilon_i \sum_{\nu} S_{\mu,\nu} C_{\nu,i}$.

B3.1.5.3 AO BASIS SETS

(A) SLATER-TYPE ORBITALS AND GAUSSIAN-TYPE ORBITALS

The basis orbitals commonly used in the LCAO–MO process fall into two primary classes:

- (1) Slater-type orbitals (STOs) $\chi_{n,l,m}(r, \theta, \phi) = N_{n,l,m,\zeta} Y_{l,m}(\theta, \phi) r^{n-1} \exp(-\zeta r)$, are characterized by the quantum numbers n , l and m and the exponent (which characterizes the ‘size’) ζ . The symbol $N_{n,l,m,\zeta}$ denotes the normalization constant.
- (2) Cartesian Gaussian-type orbitals (GTOs) $\chi_{a,b,c}(r, \theta, \phi) = N'_{a,b,c,\alpha} x^a y^b z^c \exp(-\alpha r^2)$, are characterized by the quantum numbers a , b and c , which detail the angular shape and direction of the orbital, and the exponent α which governs the radial ‘size’.

For both types of orbitals, the coordinates r , θ and ϕ refer to the position of the electron relative to a set of axes attached to the centre on which the basis orbital is located. Although STOs have the proper ‘cusp’ behaviour near the nuclei, they are used primarily for atomic- and linear-molecule calculations because the multi-centre integrals which arise in polyatomic-molecule calculations cannot efficiently be performed when STOs are employed. In contrast, such integrals can routinely be done when GTOs are used. This fundamental advantage of GTOs has led to the dominance of these functions in molecular quantum chemistry.

To overcome the primary weakness of GTO functions (i.e. their radial derivatives vanish at the nucleus whereas the derivatives of STOs are non-zero), it is common to combine two, three, or more GTOs, with combination coefficients which are fixed and *not* treated as LCAO–MO parameters, into new functions called *contracted* GTOs or CGTOs. Typically, a series of tight, medium, and loose GTOs are multiplied by *contraction coefficients* and summed to produce a CGTO, which approximates the proper ‘cusp’ at the nuclear centre.

Although most calculations on molecules are now performed using Gaussian orbitals (STOs are still commonly employed in atomic calculations), it should be noted that other basis sets can be used as long as they span enough of the region of space (radial and angular) where significant electron density resides. In fact,

it is possible to use plane wave orbitals [37] of the form $\chi(r, \theta, \phi) = N \exp[i(k_x r \sin\theta \cos\phi + k_y r \sin\theta \sin\phi + k_z r \cos\theta)]$, where N is a normalization constant and k_x , k_y , and k_z are the quantum numbers detailing the momenta of the orbital along the x , y and z Cartesian directions. The advantage to using such ‘simple’ orbitals is that the integrals one must perform are much easier to handle with such functions; the disadvantage is that one must use many such functions to accurately describe sharply peaked charge distributions of, for example, inner-shell core orbitals.

(B) BASIS SET LIBRARIES

Much effort has been devoted to developing sets of STO or GTO basis orbitals for main-group elements and the lighter transition metals. This ongoing effort is aimed at providing standard basis set libraries which:

- (1) yield predictable chemical accuracy in the resultant energies;
- (2) are cost effective to use in practical calculations;

-20-

- (3) are relatively transferable so that a given atom’s basis is flexible enough to be used for that atom in various bonding environments.

The fundamental core and valence basis. In constructing an AO basis, one can choose from among several classes of functions. First, the size and nature of the primary core and valence basis must be specified. Within this category, the following choices are common.

- (1) A *minimal basis* in which the number of STO or CGTO orbitals is equal to the number of core and valence AOs in the atom.
- (2) A *double-zeta (DZ)* basis in which twice as many STOs or CGTOs are used as there are core and valence AOs. The use of more basis functions is motivated by a desire to provide additional variational flexibility so the LCAO–MO process can generate MOs of variable diffuseness as the local electronegativity of the atom varies.
- (3) A *triple-zeta (TZ)* basis in which three times as many STOs or CGTOs are used as the number of core and valence AOs (and, yes, there now are quadruple-zeta (QZ) and higher-zeta basis sets appearing in the literature).
- (4) Dunning and Dunning and Hay [38] developed CGTO bases which range from approximately DZ to substantially beyond QZ quality. These bases involve contractions of primitive uncontracted GTO bases which Huzinaga [39] had earlier optimized. These Dunning bases are commonly denoted as follows for first-row atoms: (10s,6p/5s,4p), which means that 10 s-type primitive GTOs have been contracted to produce five separate s-type CGTOs and that six primitive p-type GTOs were contracted into four separate p-type CGTOs in each of the x , y and z directions.
- (5) Even-tempered basis sets [40] consist of GTOs in which the orbital exponents α_k belonging to series of orbitals consist of geometrical progressions: $\alpha_k = a\beta^k$, where a and β characterize the particular set of GTOs.
- (6) STO-3G bases [41] were employed some years ago, but have recently become less popular. These bases are constructed by least-squares fitting GTOs to STOs which have been optimized for various electronic states of the atom. When three GTOs are employed to fit each STO, a STO-3G basis is formed.
- (7) 4-31G, 5-31G and 6-31G bases [42] employ a single CGTO of contraction length 4, 5, or 6 to describe the core orbital. The valence space is described at the DZ level with the first CGTO constructed from three primitive GTOs and the second CGTO built from a single primitive GTO.
- (8) More recently, the Dunning group has focused on developing basis sets that are optimal not for use in SCF-level calculations on atoms and molecules, but that have been optimized for use in correlated calculations. These so-called correlation-consistent bases [43] are now widely used because more and more *ab initio* calculations are being performed at a correlated level.
- (9) Atomic natural orbital (ANO) basis sets [44] are formed by contracting Gaussian functions so as to reproduce the natural orbitals obtained from correlated (usually using a configuration interaction with

single and double excitation (CISD) level wavefunction) calculations on atoms.

Optimization of the *orbital exponents* (ζ s or α s) and the GTO-to-CGTO *contraction coefficients* for the kind of bases described above have undergone explosive growth in recent years. As a result, it is not possible to provide a single or even a few literature references from which one can obtain the most up-to-date bases. However, the theory group at the Pacific Northwest National Laboratories (PNNL) offer a webpage [45] from which one can find (and even download in a form prepared for input to any of several commonly used electronic structure codes) a wide variety of Gaussian atomic basis sets.

Polarization functions. One usually enhances any core and valence functions with a set of so-called polarization

-21-

functions. They are functions of one higher angular momentum than appears in the atom's valence orbital space (e.g. d-functions for C, N and O and p-functions for H), and they have exponents (ζ or α) which cause their radial sizes to be similar to the sizes of the valence orbitals (i.e. the polarization p orbitals of the H atom are similar in size to the 1s orbital). Thus, they are *not* orbitals which describe the atom's valence orbital with one higher l value; such higher- l valence orbitals would be radially more diffuse.

The primary purpose of the polarization functions is to give additional angular flexibility to the LCAO–MO process in forming the valence MOs. This is illustrated below in figure B3.1.8 where polarization d_{π} orbitals are seen to contribute to formation of the bonding π orbital of a carbonyl group by allowing polarization of the carbon atom's p_{π} orbital toward the right and of the oxygen atom's p_{π} orbital toward the left.

Figure B3.1.8. The role of d-polarization functions in the π bond between C and O.

The polarization functions are essential in strained ring compounds because they provide the angular flexibility needed to direct the electron density into the regions between the bonded atoms.

Functions with higher l values and with 'sizes' like those of lower- l valence orbitals are also used to introduce additional angular correlation by permitting angularly polarized orbital pairs to be formed. Optimal polarization functions for first- and second-row atoms have been tabulated and are included in the PNNL Gaussian orbital web site data base [45].

Diffuse functions. When dealing with anions or Rydberg states, one must further *augment* the basis set by adding so-called diffuse basis orbitals. The valence and polarization functions described above do not provide enough radial flexibility to adequately describe either of these cases. Once again, the PNNL web site data base [45] offers a good source for obtaining diffuse functions appropriate to a variety of atoms.

Once one has specified an AO basis for each atom in the molecule, the LCAO–MO procedure can be used to

determine the $C_{v,i}$ coefficients that describe the occupied and virtual orbitals. It is important to keep in mind that the basis orbitals are *not* themselves the SCF orbitals of the isolated atoms; even the proper AOs are combinations (with atomic values for the $C_{v,i}$ coefficients) of the basis functions. The LCAO–MO–SCF process itself determines the magnitudes and signs of the $C_{v,i}$; alternations in the signs of these coefficients allow radial nodes to form.

-22-

B3.1.5.4 THE PHYSICAL MEANING OF ORBITAL ENERGIES

The HF–SCF equations $\hat{F}\phi_i = \varepsilon_i\phi_i$ imply that ε_i can be written as

$$\begin{aligned}\varepsilon_i &= \langle \phi_i | \hat{F} | \phi_i \rangle = \langle \phi_i | \hat{h} | \phi_i \rangle + \sum_{j(\text{occupied})} \langle \phi_i | \hat{J}_j - \hat{K}_j | \phi_i \rangle \\ &= \langle \phi_i | \hat{h} | \phi_i \rangle + \sum_{j(\text{occupied})} [J_{i,j} - K_{i,j}].\end{aligned}$$

Thus ε_i is the average value of the kinetic energy plus the Coulombic attraction to the nuclei for an electron in ϕ_i plus the sum over all of the spin orbitals occupied in Ψ of the Coulomb minus exchange interactions. If ϕ_i is an occupied spin orbital, the term $[J_{i,i} - K_{i,i}]$ disappears and the latter sum represents the Coulomb minus exchange interaction of ϕ_i with all of the $N - 1$ *other* occupied spin orbitals. If ϕ_i is a virtual spin orbital, this cancellation does not occur, and one obtains the Coulomb minus exchange interaction of ϕ_i with all N of the occupied spin orbitals.

Hence the orbital energies of *occupied* orbitals pertain to interactions appropriate to a total of N electrons, while the orbital energies of *virtual* orbitals pertain to a system with $N + 1$ electrons. This usually makes SCF virtual orbitals not very good for use in subsequent correlation calculations or for use in interpreting electronic excitation processes. To correlate a pair of electrons that occupy a valence orbital requires double excitations into a virtual orbital of similar size; the SCF virtual orbitals are too diffuse. For this reason, significant effort has been devoted to developing methods that produce so-called ‘improved virtual orbitals’ (IVOs) [46] that are of more utility in performing correlated calculations.

(A) KOOPMANS’ THEOREM

Let us consider a model of the vertical (i.e. at fixed molecular geometry) detachment or attachment of an electron to an N -electron molecule.

- (1) In this model, *both* the parent molecule and the species generated by adding or removing an electron are treated at the single-determinant level.
- (2) The HF orbitals of the parent molecule are used to describe both species. It is said that such a model neglects ‘*orbital relaxation*’ (i.e. the reoptimization of the spin orbitals to allow them to become appropriate to the daughter species).

Within this model, the energy difference between the daughter and the parent can be written as follows (ϕ_k represents the particular spin orbital that is added or removed):

- (1) For electron detachment

$$E^{N-1} - E^N = -\varepsilon_k.$$

(2) For electron attachment

$$E^N - E^{N+1} = -\varepsilon_k.$$

-23-

So, within the limitations of the single-determinant, frozen-orbital model, the ionization potentials (IPs) and electron affinities (EAs) are given as the negative of the occupied and virtual spin-orbital energies, respectively. This statement is referred to as *Koopmans' theorem* [47]; it is used extensively in quantum chemical calculations as a means for estimating IPs and EAs and often yields results that are qualitatively correct (i.e., ± 0.5 eV).

(B) ORBITAL ENERGIES AND THE TOTAL ENERGY

The total SCF electronic energy can be written as

$$E = \sum_{i(\text{occupied})} \langle \phi_i | \hat{h} | \phi_i \rangle + \sum_{i>j(\text{occupied})} [J_{i,j} - K_{i,j}]$$

and the sum of the orbital energies of the occupied spin orbitals is given by

$$\sum_{i(\text{occupied})} \varepsilon_i = \sum_{i(\text{occupied})} \langle \phi_i | \hat{h} | \phi_i \rangle + \sum_{i,j(\text{occupied})} [J_{i,j} - K_{i,j}].$$

These two expressions differ in a very important way; the sum of occupied orbital energies double counts the Coulomb minus exchange interaction energies. Thus, within the HF approximation, the sum of the occupied orbital energies is *not* equal to the total energy.

B3.1.5.5 SOLVING THE Roothaan SCF Equations

Before moving on to discuss methods that go beyond the single-configuration mean-field model, it is important to examine some of the computational effort that goes into carrying out an SCF calculation.

Once atomic basis sets have been chosen for each atom, the *one- and two-electron integrals* appearing in $F_{\mu,\nu}$ must be evaluated. There are numerous, highly-efficient computer codes [48] which allow such integrals to be computed for s, p, d, f and even g, h and i basis functions. After executing one of these 'integral packages' for a basis with a total of P functions, one has available (usually on the computer's hard disk) of the order of $P^2/2$ one-electron ($\langle \chi_{\mu} | \hat{h} | \chi_{\nu} \rangle$ and $\langle \chi_{\mu} | \chi_{\nu} \rangle$) and $P^4/8$ two-electron ($\langle \chi_{\mu} \chi_{\delta} | \hat{g} | \chi_{\nu} \chi_{\kappa} \rangle$) integrals. When treating extremely large AO basis sets (e.g. 1000 or more basis functions), modern computer programs [49] calculate the requisite integrals, but never store them on the disk. Instead, their contributions to $F_{\mu,\nu}$ are accumulated 'on the fly' after which the integrals are discarded. Recently, much progress has been made towards achieving an evaluation of the non-vanishing (i.e. numerically significant) integrals [48] as well as solving the subsequent SCF equations in a manner whose effort *scales linearly* [50] with the number of basis functions for large P .

After the requisite integrals are available or are being computed on the fly, to begin the SCF process one must input into the computer routine which computes $F_{\mu,\nu}$ the *initial 'guesses'* for the $C_{\nu,i}$ values corresponding to the occupied

orbitals. These initial guesses are typically made as follows.

- (1) If one has available the $C_{v,i}$ values for the system from a calculation performed at a nearby geometry, one can use these $C_{v,i}$ values.
- (2) If one has $C_{v,i}$ values appropriate to fragments of the system (e.g. for C and O atoms if the CO molecule is under study or for CH₂ and O if H₂CO is being studied), one can use these.
- (3) If one has no other information available, one can carry out one iteration of the SCF process in which the two-electron contributions to $F_{\mu,\nu}$ are ignored (i.e. take $F_{\mu,\nu} = \langle \chi_\mu | h | \chi_\nu \rangle$) and use the resultant solutions to $\sum_\nu F_{\mu,\nu} C_{v,i} = \varepsilon_i \sum_\nu S_{\mu,\nu} C_{v,i}$ as initial guesses.

Once the initial guesses have been made for the $C_{v,i}$ of the occupied orbitals, the full $F_{\mu,\nu}$ matrix is formed and new ε_i and $C_{v,i}$ values are obtained by solving $\sum_\nu F_{\mu,\nu} C_{v,i} = \varepsilon_i \sum_\nu S_{\mu,\nu} C_{v,i}$. These new orbitals are then used to form a new $F_{\mu,\nu}$ matrix from which new ε_i and $C_{v,i}$ are obtained. This iterative process is carried on until the ε_i and $C_{v,i}$ do not vary (within specified tolerances) from iteration to iteration, at which time the SCF process has reached self-consistency.

B3.1.6 METHODS FOR TREATING ELECTRON CORRELATION

B3.1.6.1 AN OVERVIEW OF VARIOUS APPROACHES

There are numerous procedures currently in use for determining the ‘best’ wavefunction of the form

$$\Psi = \sum_I C_I \Phi_I$$

where Φ_I is a spin- and space-symmetry-adapted CSF consisting of determinants $|\phi_{I1}\phi_{I2}\phi_{I3}\dots\phi_{IN}|$ (see [14, 16, 26]). In all such wavefunctions there are two kinds of parameters that need to be determined—the C_I and the LCAO–MO coefficients describing the ϕ_{Ik} . The most commonly employed methods used to determine these parameters include the following.

(A) THE MULTICONFIGURATIONAL SELF-CONSISTENT FIELD METHOD

In this approach [51], the expectation value $\langle \Psi | \hat{H} | \Psi \rangle / \langle \Psi | \Psi \rangle$ is treated variationally and made stationary with respect to variations in the C_I and $C_{v,i}$ coefficients. The energy functional is a quadratic function of the C_I coefficients, and so one can express the stationary conditions for these variables in the secular form

$$\sum_J H_{I,J} C_J = E C_I.$$

However, E is a quartic function of the $C_{v,i}$ s because $H_{I,J}$ involves two-electron integrals $\langle \phi_i \phi_j | \hat{g} | \phi_k \phi_l \rangle$ that depend quartically on these coefficients.

It is well known that minimization of the function (E) of several nonlinear parameters (the $C_{v,i}$) is a difficult task that can suffer from poor convergence and may locate local rather than global minima. In a multiconfigurational self-consistent field (MCSCF) wavefunction containing many CSFs, the energy is only weakly dependent on the orbitals that appear in CSFs with small C_I values; in contrast, E is strongly dependent on those orbitals that appear in the CSFs with larger C_I values. One is therefore faced with minimizing a function of many variables that depends strongly on several of the variables and weakly on many others.

For these reasons, in the MCSCF method the number of CSFs is usually kept to a small to moderate number (e.g. a few to several thousand) chosen to describe *essential correlations* (i.e. configuration crossings, near degeneracies, proper dissociation, etc, all of which are often termed *non-dynamical correlations*) and important dynamical correlations (those electron-pair correlations of angular, radial, left–right, etc nature that are important when low-lying ‘virtual’ orbitals are present).

(B) THE CONFIGURATION INTERACTION METHOD

In this approach [52], the LCAO–MO coefficients are determined first via a single-configuration SCF calculation or an MCSCF calculation using a small number of CSFs. The C_I coefficients are subsequently determined by making the expectation value $\langle \Psi | \hat{H} | \Psi \rangle / \langle \Psi | \Psi \rangle$ stationary.

The CI wavefunction is most commonly constructed from CSFs of Φ_j that include:

- (1) all of the CSFs in the SCF or MCSCF wavefunction used to generate the molecular orbitals ϕ_i . These are referred to as the ‘reference’ CSFs;
- (2) CSFs generated by carrying out single-, double-, triple-, etc, level ‘excitations’ (i.e. orbital replacements) relative to reference CSFs. CI wavefunctions limited to include contributions through various levels of excitation are denoted S (singly), D (doubly), SD (singly and doubly), SDT (singly, doubly, and triply) excited.

The orbitals from which electrons are removed can be restricted to focus attention on the correlations among certain orbitals. For example, if the excitations from the core electrons are excluded, one computes the total energy that contains no core correlation energy. The number of CSFs included in the CI calculation can be far in excess of the number considered in typical MCSCF calculations. CI wavefunctions including 5000 to 50 000 CSFs are routine, and functions with one to several billion CSFs are within the realm of practicality [53].

The need for such large CSF expansions should not be surprising considering (i) that each electron pair requires *at least* two CSFs to form polarized orbital pairs, (ii) there are of the order of $N(N-1)/2 = X$ electron pairs for N electrons, hence (iii) the number of terms in the CI wavefunction scales as 2^X . For a molecule containing ten electrons, there could be $2^{45} = 3.5 \times 10^{13}$ terms in the CI expansion. This may be an overestimate of the number of CSFs needed, but it demonstrates how rapidly the number of CSFs can grow with the number of electrons.

The $H_{I,J}$ matrices are, in practice, evaluated in terms of one- and two-electron integrals over the MOs using the Slater–Condon rules [54] or their equivalent. Prior to forming the $H_{I,J}$ matrix elements, the one- and two-electron integrals,

which can be computed only for the atomic (e.g. STO or GTO) basis, must be transformed [55] to the MO

basis. This transformation step requires computer resources proportional to the fifth power of the number of basis functions, and thus is one of the more troublesome steps in most configuration interaction calculations.

For large CI calculations, the full $H_{I,J}$ matrix is *not* formed and stored in the computer's memory or on disk; rather, 'direct CI' methods [56] identify and compute non-zero $H_{I,J}$ and immediately add up contributions to the sum $\sum_j H_{I,J} C_j$. Iterative methods [57], in which approximate values for the C_j coefficients are refined through sequential application of $\sum_j H_{I,J}$ to the preceding estimate of the C_j vector, are employed to solve these large eigenvalue problems.

(C) THE MØLLER-PLESSET PERTURBATION METHOD

This method [58] uses the single-configuration SCF process to determine a set of orbitals $\{\phi_i\}$. Then, using an unperturbed Hamiltonian equal to the sum of the N electrons' Fock operators $\hat{H}^0 = \sum_{i=1,N} \hat{F}(i)$, perturbation theory is used to determine the C_1 amplitudes for the CSFs. The MPPT procedure [59] is a special case of many-body perturbation theory (MBPT) in which the UHF Fock operator is used to define \hat{H}^0 . The amplitude for the *reference* CSF is taken as unity and the other CSFs' amplitudes are determined by the Rayleigh–Schrödinger perturbation using $\hat{H} - \hat{H}^0$ as the perturbation.

In the MPPT/MBPT method, once the reference CSF is chosen and the SCF orbitals belonging to this CSF are determined, the wavefunction Ψ and energy E are determined in an order-by-order manner. The perturbation equations *determine* what CSFs to include and their particular order. This is one of the primary strengths of this technique; it does not require one to make further choices, in contrast to the MCSCF and CI treatments where one needs to choose which CSFs to include.

For example, the first-order wavefunction correction Ψ^1 is

$$\Psi^1 = - \sum_{i < j, m < n} [\langle i, j | \hat{g} | m, n \rangle - \langle i, j | \hat{g} | n, m \rangle] [\varepsilon_m - \varepsilon_i + \varepsilon_n - \varepsilon_j]^{-1} | \Phi_{i,j}^{m,n} \rangle$$

where the SCF orbital energies are denoted ε_k and $\Phi_{i,j}^{m,n}$ represents a CSF that is *doubly excited* (ϕ_i and ϕ_j are replaced by ϕ_m and ϕ_n) relative to Φ . Only doubly-excited CSFs contribute to the *first-order wavefunction*; the fact that the contributions from singly-excited configurations vanish in Ψ^1 is known as the *Brillouin theorem* [60].

The energy E is given through second order as

$$E = E_{\text{SCF}} - \sum_{i < j, m < n} | \langle i, j | \hat{g} | m, n \rangle - \langle i, j | \hat{g} | n, m \rangle |^2 / [\varepsilon_m - \varepsilon_i + \varepsilon_n - \varepsilon_j].$$

Both Ψ and E are expressed in terms of two-electron integrals $\langle i, j | \hat{g} | m, n \rangle$ coupling the virtual spin orbitals ϕ_m and ϕ_n to the spin orbitals from which the electrons were excited ϕ_i and ϕ_j as well as the orbital energy differences $[\varepsilon_m - \varepsilon_i + \varepsilon_n - \varepsilon_j]$ accompanying such excitations. Clearly, the major contributions to the correlation energy are made by double excitations into virtual orbitals $\phi_m \phi_n$ with large $\langle i, j | \hat{g} | m, n \rangle$ integrals and small orbital energy gaps $[\varepsilon_m - \varepsilon_i + \varepsilon_n - \varepsilon_j]$. In higher-order corrections, contributions from CSFs that are singly, triply, etc excited relative to Φ appear, and additional contributions from the doubly-excited CSFs also

enter.

(D) THE COUPLED-CLUSTER METHOD

In the coupled-cluster (CC) method [61], one expresses the wavefunction in a somewhat different manner:

$$\Psi = \exp(T)\Phi$$

where Φ is a single CSF (usually the UHF determinant) used in the SCF process to generate a set of spin orbitals. The operator \hat{T} is expressed in terms of operators that achieve spin-orbital excitations as follows:

$$T = \sum_{i,m} t_i^m \hat{m}^+ \hat{i} + \sum_{i,j}^{m,n} t_{i,j}^{m,n} \hat{m}^+ \hat{n}^+ \hat{j} \hat{i} + \dots$$

where the combination of operators $\hat{m}^+ \hat{i}$ denotes the *creation* of an electron in the virtual spin orbital ϕ_m and the *removal* of an electron from the occupied spin orbital ϕ_i to generate a single excitation. The operation $\hat{m}^+ \hat{n}^+ \hat{j} \hat{i}$ therefore represents a double excitation from $\phi_i \phi_j$ to $\phi_m \phi_n$.

The amplitudes t_i^m , $t_{i,j}^{m,n}$, etc, which play the role of the C_1 coefficients in CC theory, are determined through the set of equations generated by projecting the Schrödinger equation in the form

$$\exp(-T)\hat{H}\exp(T)\Phi = E\Phi$$

against CSFs which are single, double, etc, excitations relative to Φ :

$$\begin{aligned} \langle \Phi_i^m | \hat{H} + [\hat{H}, T] + \frac{1}{2}[[\hat{H}, T], T] + \frac{1}{6}[[[\hat{H}, T], T], T] + \frac{1}{24}[[[[\hat{H}, T], T], T], T] | \Phi \rangle &= 0 \\ \langle \Phi_{i,j}^{m,n} | \hat{H} + [\hat{H}, T] + \frac{1}{2}[[\hat{H}, T], T] + \frac{1}{6}[[[\hat{H}, T], T], T] + \frac{1}{24}[[[[\hat{H}, T], T], T], T] | \Phi \rangle &= 0 \\ \langle \Phi_{i,j,k}^{m,n,p} | \hat{H} + [\hat{H}, T] + \frac{1}{2}[[\hat{H}, T], T] + \frac{1}{6}[[[\hat{H}, T], T], T] + \frac{1}{24}[[[[\hat{H}, T], T], T], T] | \Phi \rangle &= 0 \end{aligned}$$

and so on for higher-order excited CSFs.

It can be shown [62] that the expansion of the exponential operators truncates exactly at the fourth power in T . As a result, the exact CC equations are *quartic equations* for the t_i^m , $t_{i,j}^{m,n}$, etc amplitudes. The matrix elements appearing in

the CC equations can be expressed in terms of one- and two-electron integrals over the spin orbitals including those occupied in Φ and the virtual orbitals not in Φ .

These quartic equations are solved in an iterative manner and, as such, are susceptible to convergence difficulties. In any such iterative process, it is important to start with an approximation reasonably close to the final result. In CC theory, this is often achieved by neglecting all of the terms that are nonlinear in the t amplitudes (because the t s are assumed to be less than unity in magnitude) and ignoring factors that couple different doubly-excited CSFs (i.e. the sum over i', j', m' and n'). This gives t amplitudes that are equal to the

amplitudes of the first-order MPPT/MBPT wavefunction:

$$t_{i,j}^{m,n} = -\langle i, j | \hat{g} | m, n \rangle' / [\varepsilon_m - \varepsilon_i + \varepsilon_n - \varepsilon_j].$$

As Bartlett [63] and Pople have both demonstrated [64], there is a close relationship between the MPPT/MBPT and CC methods when the CC equations are solved iteratively starting with such an MPPT/MBPT-like initial ‘guess’ for these double-excitation amplitudes.

(E) DENSITY FUNCTIONAL THEORIES

These approaches provide alternatives to the conventional tools of quantum chemistry. The CI, MCSCF, MPPT/MBPT, and CC methods move beyond the single-configuration picture by adding to the wavefunction more configurations whose amplitudes they each determine in their own way. This can lead to a very large number of CSFs in the correlated wavefunction and, as a result, a need for extraordinary computer resources.

The density functional approaches are different [65]. Here one solves a set of orbital-level equations

$$\left[-\hbar^2/2m_e \nabla^2 - \sum_A Z_A e^2 / |\mathbf{r} - \mathbf{R}_A| + \int \rho(\mathbf{r}') e^2 / |\mathbf{r} - \mathbf{r}'| d\mathbf{r}' + U(\mathbf{r}) \right] \phi_i = \varepsilon_i \phi_i$$

in which the orbitals $\{\phi_i\}$ ‘feel’ potentials due to the nuclear centres (having charges Z_A), Coulombic interaction with the *total* electron density $\rho(\mathbf{r}')$ and a so-called *exchange-correlation* potential denoted $U(\mathbf{r}')$. The particular electronic state for which the calculation is being performed is specified by forming a corresponding density $\rho(\mathbf{r}')$. Before going further in describing how density functional theory (DFT) calculations are carried out, let us examine the origins underlying this theory.

The so-called Hohenberg–Kohn [66] theorem states that the *ground-state* electron density $\rho(\mathbf{r})$ describing an N -electron system uniquely determines the potential $V(\mathbf{r})$ in the Hamiltonian

$$\hat{H} = \sum_j \left\{ -\hbar^2/2m_e \nabla_j^2 + V(r_j) + \frac{1}{2} \sum_{k \neq j} e^2 / r_{j,k} \right\}$$

and, because \hat{H} determines the ground-state energy and wavefunction of the system, the ground-state density $\rho(\mathbf{r})$

determines the ground-state properties of the system. The proof of this theorem proceeds as follows.

- (a) $\rho(\mathbf{r})$ determines N because $\int \rho(\mathbf{r}) d^3r = N$.
- (b) Assume that there are two distinct potentials (aside from an additive constant that simply shifts the zero of total energy) $V(\mathbf{r})$ and $V'(\mathbf{r})$ which, when used in \hat{H} and \hat{H}' , respectively, to solve for a ground state produce $E_0, \Psi(\mathbf{r})$ and $E'_0, \Psi'(\mathbf{r})$, $\Psi'(\mathbf{r})$ that have the same one-electron density: $\int |\Psi|^2, dr_2, dr_3 \dots dr_N = \rho(\mathbf{r}) = \int |\Psi'|^2, dr_2, dr_3 \dots dr_N$.
- (c) If we think of Ψ' as trial variational wavefunction for the Hamiltonian \hat{H} , we know that

$$\begin{aligned}
E_0 < \langle \Psi' | \hat{H} | \Psi' \rangle &= \langle \Psi' | \hat{H}' | \Psi' \rangle + \int \rho(\mathbf{r}) [V(\mathbf{r}) - V'(\mathbf{r})] d^3r \\
&= E'_0 + \int \rho(\mathbf{r}) [V(\mathbf{r}) - V'(\mathbf{r})] d^3r.
\end{aligned}$$

(d) Similarly, taking Ψ as a trial function for the H' Hamiltonian, one finds that

$$E'_0 < E_0 + \int \rho(\mathbf{r}) [V'(\mathbf{r}) - V(\mathbf{r})] d^3r.$$

(e) Adding the equations in (c) and (d) gives

$$E_0 + E'_0 < E_0 + E'_0.$$

A clear contradiction.

Hence, there cannot be two distinct potentials V and V' that give the same ground-state $\rho(\mathbf{r})$. So, the ground-state density $\rho(\mathbf{r})$ uniquely determines N and V , and thus \hat{H} , and therefore Ψ and E_0 . Furthermore, because Ψ determines all the properties of the ground state, then $\rho(\mathbf{r})$, in principle, determines all such properties. This means that even the kinetic energy and the electron–electron interaction energy of the ground state are determined by $\rho(\mathbf{r})$. It is easy to see that $\int \rho(\mathbf{r}) V(\mathbf{r}) d^3r = V[\rho]$ gives the average value of the electron–nuclear (plus any additional one-electron additive potential) interaction in terms of the ground-state density $\rho(\mathbf{r})$, but how are the kinetic energy $T[\rho]$ and the electron–electron interaction $V_{ee}[\rho]$ energy expressed in terms of ρ ?

The main difficulty with DFTs is that the Hohenberg–Kohn theorem shows that the *ground-state* values of T , V_{ee} , V , etc are all unique functionals of the *ground-state* ρ (i.e. that they can, in principle, be determined once ρ is given), but it does not tell us what these functional relations are.

To see how it might make sense that a property such as the kinetic energy, whose operator $(-\hbar^2/2m_e)\nabla^2$ involves derivatives, can be related to the electron density, consider a simple system of N non-interacting electrons moving in a three-dimensional cubic ‘box’ potential. The energy states of such electrons are known to be

-30-

$$E = (\hbar^2/8m_e L^2)(n_x^2 + n_y^2 + n_z^2)$$

where L is the length of the box along the three axes and n_x , n_y , and n_z are the quantum numbers describing the state. We can view $n_x^2 + n_y^2 + n_z^2 = R^2$ as defining the squared radius of a sphere in three dimensions, and we realize that the density of quantum states in this space is one state per unit volume in the n_x , n_y , and n_z space. Because n_x , n_y , and $n_z E = (\hbar^2/2m_e L^2)R^2$ is one-eighth the volume of the sphere of radius R :

$$\Phi(E) = \frac{1}{8}(4\pi/3)R^3 = (\pi/6)(8m_e L^2 E / \hbar^2)^{3/2}.$$

Since there is one state per unit of such volume, $\Phi(E)$ is also the number of states with energy less than or equal to E , and is called the *integrated density of states*. The number of states $g(E)dE$ with energy between E and $E + dE$, the *density of states*, is the derivative of Φ :

$$g(E) = d\Phi/dE = (\pi/4)(8m_e L^2 / \hbar^2)^{3/2} E^{1/2}.$$

If we calculate the total energy for N electrons, with the states having energies up to the so-called *Fermi energy* (E_F) (i.e. the energy of the highest occupied molecular orbital HOMO) doubly occupied, we obtain the ground-state energy:

$$E_0 = 2 \int_0^{E_F} g(E)E \, dE = (8\pi/5)(2m_e/h^2)^{3/2} L^3 E_F^{5/2}.$$

The total number of electrons N can be expressed as

$$N = 2 \int_0^{E_F} g(E) \, dE = (8\pi/3)(2m_e/h^2)^{3/2} L^3 E_F^{3/2}$$

which can be solved for E_F in terms of N to then express E_0 in terms of N instead of E_F :

$$E_0 = (3h^2/10m_e)(3/8\pi)^{2/3} L^3 (N/L^3)^{5/3}.$$

This gives the total energy, which is also the kinetic energy in this case because the potential energy is zero within the ‘box’, in terms of the electron density $\rho(x,y,z) = (N/L^3)$. It therefore may be plausible to express kinetic energies in terms of electron densities $\rho(\mathbf{r})$, but it is by no means clear how to do so for ‘real’ atoms and molecules with electron–nuclear and electron–electron interactions operative.

In one of the earliest DFT models, the *Thomas–Fermi* theory, the kinetic energy of an atom or a molecule is approximated using the above type of treatment on a ‘local’ level. That is, for each volume element in \mathbf{r} space, one

assumes the expression given above to be valid, and then one integrates over all \mathbf{r} to compute the total kinetic energy:

$$T_{\text{TF}}[\rho] = \int (3h^2/10m_e)(3/8\pi)^{2/3} [\rho(\mathbf{r})]^{5/3} \, d^3r = C_F \int [\rho(\mathbf{r})]^{5/3} \, d^3r$$

where the last equality simply defines the C_F constant (which is 2.8712 in atomic units). Ignoring the correlation and exchange contributions to the total energy, this T is combined with the electron–nuclear V and Coulombic electron–electron potential energies to give the Thomas–Fermi total energy:

$$E_{0,\text{TF}}[\rho] = C_F \int [\rho(\mathbf{r})]^{5/3} \, d^3r + \int V(\mathbf{r})\rho(\mathbf{r}) \, d^3r + e^2/2 \int \rho(\mathbf{r})\rho(\mathbf{r}')/|\mathbf{r} - \mathbf{r}'| \, d^3r \, d^3r'.$$

This expression is an example of how E_0 is given as a *local density functional approximation* (LDA). The term local means that the energy is given as a functional (i.e. a function of ρ) which depends only on $\rho(\mathbf{r})$ at the points in space, but not on $\rho(\mathbf{r})$ at more than one point in space.

Unfortunately, the Thomas–Fermi energy functional does not produce results that are of sufficiently high accuracy to be of great use in chemistry. What is missing in this theory are the exchange energy and the correlation energy; moreover, the kinetic energy is treated only in the approximate manner described.

In the book by Parr and Yang [67], it is shown how Dirac was able to address the exchange energy for the ‘uniform electron gas’ (N Coulomb *interacting* electrons moving in a uniform positive background charge whose magnitude balances the charge of the N electrons). If the exact expression for the exchange energy of the uniform electron gas is applied on a local level, one obtains the commonly used Dirac *local density approximation to the exchange energy*:

$$E_{\text{ex,Dirac}}[\rho] = -C_x \int [\rho(\mathbf{r})]^{4/3} d^3r$$

with $C_x = (3/4) (3/\pi)^{1/3} = 0.7386$ in atomic units. Adding this exchange energy to the Thomas–Fermi total energy $E_{0,\text{TF}}[\rho]$ gives the so-called Thomas–Fermi–Dirac (TFD) energy functional.

Because electron densities vary rather strongly spatially near the nuclei, corrections to the above approximations to $T[\rho]$ and $E_{\text{ex,Dirac}}$ are needed. One of the more commonly used so-called *gradient-corrected* approximations is that invented by Becke [68], and referred to as the Becke88 exchange functional:

$$E_{\text{ex}}(\text{Becke88}) = E_{\text{ex,Dirac}}[\rho] - \gamma \int x^2 \rho^{4/3} (1 + 6\gamma x \sinh^{-1}(x))^{-1} d\mathbf{r}$$

where $x = \rho^{-4/3} |\nabla\rho|$, and γ is a parameter chosen so that the above exchange energy can best reproduce the known exchange energies of specific electronic states of the inert gas atoms (Becke finds γ to equal 0.0042). A common

gradient correction to the earlier $T[\rho]$ is called the Weizsacker correction and is given by

$$\delta T_{\text{Weizsacker}} = (1/72)(\hbar/m_e) \int |\nabla\rho(\mathbf{r})|^2 / \rho(\mathbf{r}) d\mathbf{r}.$$

Although the above discussion suggests how one might compute the ground-state energy once the ground-state density $\rho(\mathbf{r})$ is given, one still needs to know how to obtain ρ . Kohn and Sham [69] (KS) introduced a set of so-called KS orbitals obeying the following equation:

$$\left\{ -(\hbar^2/2m_e)\nabla^2 + V(\mathbf{r}) + e^2/2 \int \rho(\mathbf{r}')/|\mathbf{r} - \mathbf{r}'| d\mathbf{r}' + U_{\text{xc}}(\mathbf{r}) \right\} \phi_j = \varepsilon_j \phi_j$$

where the so-called exchange-correlation potential $U_{\text{xc}}(\mathbf{r}) = \delta E_{\text{xc}}[\rho]/\delta\rho(\mathbf{r})$ could be obtained by functional differentiation if the exchange-correlation energy functional $E_{\text{xc}}[\rho]$ were known. KS also showed that the KS orbitals $\{\phi_j\}$ could be used to compute the density ρ by simply adding up the orbital densities multiplied by orbital occupancies n_j :

$$\rho(\mathbf{r}) = \sum_j n_j |\phi_j(\mathbf{r})|^2.$$

Here $n_j = 0, 1$ or 2 is the occupation number of the orbital ϕ_j in the state being studied. The kinetic energy

should be calculated as

$$T = \sum_j n_j \langle \phi_j(\mathbf{r}) | -(\hbar^2/2m_e)\nabla^2 | \phi_j(\mathbf{r}) \rangle.$$

The same investigations of the idealized ‘uniform electron gas’ that identified the Dirac exchange functional, found that the correlation energy (per electron) could also be written exactly as a *function* of the electron density ρ of the system, but only in two limiting cases—the high-density limit (large ρ) and the low-density limit. There still exists no exact expression for the correlation energy even for the uniform electron gas that is valid at arbitrary values of ρ . Therefore, much work has been devoted to creating efficient and accurate interpolation formulae connecting the low- and high-density uniform electron gas expressions (see appendix E in [67] for further details). One such expression is

$$E_C[\rho] = \int \rho(\mathbf{r}) \varepsilon_c(\rho) d\mathbf{r}$$

-33-

where

$$\varepsilon_c(\rho) = A/2 \{ \ln(x/X) + 2b/Q \tan^{-1}(Q/(2x+b)) - bx_0/X_0 [\ln((x-x_0)^2/X) + 2(b+2x_0)/Q \tan^{-1}(Q/(2x+b))] \}$$

is the correlation energy per electron. Here $x = r_s^{1/2}$, $X = x^2 + bx + c$, $X_0 = x_0^2 + bx_0 + c$ and $Q = (4c - b^2)^{1/2}$, $A = 0.0621814$, $x_0 = -0.409286$, $b = 13.0720$, and $c = 42.7198$. The parameter r_s is how the density ρ enters since $\frac{4}{3}\pi r_s^3$ is equal to $1/\rho$; that is, r_s is the radius of a sphere whose volume is the effective volume occupied by one electron. A reasonable approximation to the full $E_{xc}[\rho]$ would contain the Dirac (and perhaps gradient corrected) exchange functional plus the above $E_C[\rho]$, but there are many alternative approximations to the exchange-correlation energy functional [68]. Currently, many workers are doing their best to ‘cook up’ functionals for the correlation and exchange energies, but no one has yet invented functionals that are so reliable that most workers agree to use them.

To summarize, in implementing any DFT, one usually proceeds as follows.

- (1) An AO basis is chosen in terms of which the KS orbitals are to be expanded.
- (2) Some initial guess is made for the LCAO–KS expansion coefficients $C_{j,a} : \phi_j = \sum_a C_{j,a} \chi_a$.
- (3) The density is computed as $\rho(\mathbf{r}) = \sum_j n_j |\phi_j(\mathbf{r})|^2$. Often, $\rho(\mathbf{r})$ is expanded in an AO basis, which need not be the same as the basis used for the ϕ_j , and the expansion coefficients of ρ are computed in terms of those of the ϕ_j . It is also common to use an AO basis to expand $\rho^{1/3}(\mathbf{r})$ which, together with ρ , is needed to evaluate the exchange-correlation functional’s contribution to E_0 .
- (4) The current iteration’s density is used in the KS equations to determine the Hamiltonian $\{-1/2\nabla^2 + V(\mathbf{r}) + e^2/2 \int \rho(\mathbf{r}')/|\mathbf{r} - \mathbf{r}'| d\mathbf{r}' + U_{xc}(\mathbf{r})\}$ whose ‘new’ eigenfunctions $\{\phi_j\}$ and eigenvalues $\{\varepsilon_j\}$ are found by solving the KS equations.
- (5) These new ϕ_j are used to compute a new density, which, in turn, is used to solve a new set of KS equations. This process is continued until convergence is reached (i.e. until the ϕ_j used to determine the

current iteration's ρ are the same ϕ_j that arise as solutions on the next iteration).

(6) Once the converged $\rho(\mathbf{r})$ is determined, the energy can be computed using the earlier expression

$$E[\rho] = \sum_i n_i \langle \phi_j(\mathbf{r}) | -(\hbar^2/2m_e)\nabla^2 | \phi_j(\mathbf{r}) \rangle + \int V(\mathbf{r})\rho(\mathbf{r}) d\mathbf{r} + e^2/2 \int \rho(\mathbf{r})\rho(\mathbf{r}')/|\mathbf{r}-\mathbf{r}'| d\mathbf{r} d\mathbf{r}' + E_{xc}[\rho].$$

In closing this section, it should once again be emphasized that this area is currently undergoing explosive growth and much scrutiny [70]. As a result, it is nearly certain that many of the specific functionals discussed above will be replaced in the near future by improved and more rigorously justified versions. It is also likely that extensions of DFTs to excited states (many workers are actively pursuing this) will be placed on more solid ground and made applicable to molecular systems. Because the computational effort involved in these approaches scales much less strongly [71] with the basis set size than for conventional (MCSCF, CI, etc) methods, density functional methods offer great promise and are likely to contribute much to quantum chemistry in the next decade.

(F) EFFICIENT AND WIDELY DISTRIBUTED COMPUTER PROGRAMS EXIST FOR CARRYING OUT ELECTRONIC STRUCTURE CALCULATIONS

The development of electronic structure theory has been ongoing since the 1940s. At first, only a few scientists had access to computers, and they began to develop numerical methods for solving the requisite equations (e.g. the HF equations for orbitals and orbital energies, the configuration interaction equations for electronic state energies and wavefunctions). By the late 1960s, several research groups had developed reasonably efficient computer codes (written primarily in Fortran with selected subroutines that needed to be written especially efficiently in machine language), and the explosive expansion of this discipline was underway. By the 1980s and through the 1990s, these electronic structure programs began to be used by practicing 'bench chemists' both because they became easier to use and because their efficiency and the computers' speed grew to the point where modest to large molecules could be studied.

Web page links [72] to many of the more widely used programs offer convenient access. At present, more electronic structure calculations are performed by non-theorists than by practicing theoretical chemists, largely because of the proliferation of such programs. This does not mean that all that needs to be done in electronic structure theory is done. The rates at which improvements are being made in the numerical algorithms used to solve the problems as well as at which new models are being created remain as high as ever. For example, Professor Rich Friesner [73] has developed and Professor Emily Carter [74] has implemented, for correlated methods, a highly efficient way to replace the list of two-electron integrals $(\phi_i\phi_j|1/r_{12}|\phi_k\phi_l)$, which number N^4 , where N is the number of AO basis functions, by a much smaller list $(\phi_i\phi_j|g)$ from which the original integrals can be rewritten as

$$(\phi_i\phi_j|1/r_{12}|\phi_k\phi_l) = \sum_g (\phi_i(g)\phi_j(g)) \int d\mathbf{r} \phi_k(\mathbf{r})\phi_l(\mathbf{r})/|\mathbf{r}-\mathbf{g}|.$$

This tool, which they call *pseudospectral methods*, promises to reduce the CPU, memory and disk storage requirements for many electronic structure calculations, thus permitting their application to much larger molecular systems. In addition to ongoing developments in the underlying theory and computer

implementation, the range of phenomena and the kinds of physical properties that one needs electronic structure theory to address is growing rapidly. There is every reason to believe that this sub-discipline of theoretical chemistry is continuing to blossom.

B3.1.6.2 COMPUTATIONAL REQUIREMENTS, STRENGTHS AND WEAKNESSES OF VARIOUS METHODS

(A) COMPUTATIONAL STEPS

Essentially all of the techniques discussed above require the evaluation of one- and two-electron integrals over the N AO basis functions: $\langle \chi_a | \hat{f} | \chi_b \rangle$ and $\langle \chi_a \chi_b | \hat{g} | \chi_c \chi_d \rangle$. As mentioned earlier, there are of the order of $N^4/8$ such two-electron integrals that must be computed (and perhaps stored on disk); their computation and storage is a major consideration in performing conventional *ab initio* calculations. Much current research is being devoted to reducing the number of such integrals that must be evaluated using either the pseudo-spectral methods discussed earlier or methods that approximate

-35-

integrals between product distributions (one such distribution is $\chi_a \chi_c$ and another is $\chi_b \chi_d$ when the integral $\langle \chi_a \chi_b | \hat{g} | \chi_c \chi_d \rangle$ is treated) whenever the distributions involve orbitals on sites that are distant from one another.

Another step that is common to most, if not all, approaches that compute orbitals of one form or another is the solution of matrix eigenvalue problems of the form

$$\sum_{\nu} F_{\mu,\nu} C_{\nu,i} = \epsilon_i \sum_{\nu} S_{\mu,\nu} C_{\nu,i}.$$

The solution of any such eigenvalue problem requires a number of computer operations that scales as the dimension of the $F_{\mu,n}$ matrix to the third power. Since the indices on the $F_{\mu,n}$ matrix label AOs, this means that the task of finding all eigenvalues and eigenvectors scales as the cube of the number of AOs (N^3).

The DFT approaches involve basis expansions of orbitals $\phi_i = \sum_{\nu} C_{i,\nu} \chi_{\nu}$ and of the density ρ (or various fractional powers of ρ), which is a quadratic function of the orbitals ($\rho = \sum_i n_i |\phi_i|^2$). These steps require computational effort scaling only as N^2 , which is one of the most important advantages of these schemes. No cumbersome large CSF expansion and associated large secular eigenvalue problem arise, which is another advantage.

The more conventional quantum chemistry methods provide their working equations and energy expressions in terms of one- and two-electron integrals over the final MOs: $\langle \phi_i | \hat{f} | \phi_j \rangle$ and $\langle \phi_i \phi_j | \hat{g} | \phi_k \phi_l \rangle$. The MO-based integrals can only be evaluated by *transforming* the AO-based integrals [55]. Clearly, the N^5 scaling of the integral transformation process makes it an even more time-consuming step than the (N^4) atomic integral evaluation and a severe *bottleneck* to applying *ab initio* methods to larger systems. Much effort has been devoted to expressing the working equations of various correlated methods in a manner that does not involve the fully-transformed MO-based integrals.

Once the requisite one- and two-electron integrals are available in the MO basis, the multiconfigurational wavefunction and energy calculation can begin. Each of these methods has its own approach to describing the configurations $\{\Phi_i\}$ included in the calculation and how the $\{C_i\}$ amplitudes and the total energy E are to be

determined.

The *number of configurations* (N_C) varies greatly among the methods and is an important factor to keep in mind. Under certain circumstances (e.g. when studying reactions where an avoided crossing of two configurations produces an activation barrier), it may be *essential* to use more than one electronic configuration. Sometimes, one configuration (e.g. the SCF model) is adequate to capture the qualitative essence of the electronic structure. In all cases, many configurations will be needed if a highly accurate treatment of electron–electron correlations are desired.

The value of N_C determines how much computer time and memory is needed to solve the N_C -dimensional $\sum_J H_{I,J} C_J = E C_I$ secular problem in the CI and MCSCF methods. Solution of these matrix eigenvalue equations requires computer time that scales as N_C^2 (if few eigenvalues are computed) to N_C^3 (if most eigenvalues are obtained).

So-called *complete active space* (CAS) methods form *all* CSFs that

-36-

can be created by distributing N valence electrons among P valence orbitals. For example, the eight non-core electrons of H_2O might be distributed, in a manner that gives $M_S = 0$, among six valence orbitals (e.g. two lone-pair orbitals, two OH σ -bonding orbitals and two OH σ^* -antibonding orbitals). The number of configurations thereby created is 225. If the same eight electrons were distributed among ten valence orbitals 44 100 configurations result; for 20 and 30 valence orbitals, 23 474 025 and 751 034 025 configurations arise, respectively. Clearly, practical considerations dictate that CAS-based approaches be limited to situations in which a few electrons are to be correlated using a few valence orbitals.

(B) VARIATIONAL METHODS PROVIDE UPPER BOUNDS TO ENERGIES

Methods that are based on making the functional $\langle \Psi | \hat{H} | \Psi \rangle / \langle \Psi | \Psi \rangle$ stationary yield *upper bounds* to the lowest energy state having the symmetry of the CSFs in Ψ . The CI and MCSCF methods are of this type. They also provide approximate excited-state energies and wavefunctions in the form of other solutions of the secular equation [75] $\sum_J H_{I,J} C_J = E C_I$. Excited-state energies obtained in this manner obey the so-called *bracketing theorem*; that is, between any two approximate energies obtained in the variational calculation, there exists at least one true eigenvalue. These are strong attributes of the variational methods, as is the long and rich history of developments of analytical and computational tools for efficiently implementing such methods.

(C) VARIATIONAL METHODS ARE NOT SIZE-EXTENSIVE

Variational techniques suffer from a serious drawback, however: they are not necessarily *size extensive* [76]. The energy computed using these tools cannot be trusted to scale with the size of the system. For example, a calculation performed on two CH_3 species at large separation may not yield an energy equal to twice the energy obtained by performing the *same* kind of calculation on a single CH_3 species. Lack of size extensivity precludes these methods from use in extended systems (e.g. polymers and solids) where errors due to improper size scaling of the energy produce nonsensical results.

By carefully adjusting the variational wavefunction used, it is *possible* to circumvent size-extensivity problems for selected species. For example, the CI calculation on Be_2 using all $^1\Sigma_g$ CSFs formed by placing the four valence electrons into the $2\sigma_g$, $2\sigma_u$, $3\sigma_g$, $3\sigma_u$, $1\pi_u$, and $1\pi_g$ orbitals can yield an energy equal to twice that of the Be atom described by CSFs in which the two valence electrons of the Be atom are placed into the

2s and 2p orbitals in all ways consistent with a 1S symmetry. Such CAS-space MCSCF or CI calculations [77] are size extensive, but it is impractical to extend such an approach to larger systems.

(D) MOST PERTURBATION AND CC METHODS ARE SIZE-EXTENSIVE, BUT DO NOT PROVIDE UPPER BOUNDS AND THEY ASSUME THAT ONE CSF DOMINATES

In contrast to variational methods, perturbation theory and CC methods achieve their energies by projecting the Schrödinger equation against a reference function $\langle \Phi |$ to obtain [78] a *transition formula* $\langle \Phi | \hat{H} | \Psi \rangle$, rather than from an expectation value $\langle \Psi | \hat{H} | \Psi \rangle$. It can be shown that this difference allows non-variational techniques to yield size-extensive energies.

-37-

This can be seen by considering the second-order MPPT energy of two non-interacting Be atoms. The reference CSF is $\Phi = |1s_a^2 2s_a^2 1s_b^2 2s_b^2|$; as discussed earlier, only doubly-excited CSFs contribute to the correlation energy through second order. These ‘excitations’ can involve atom a, atom b, or both atoms. However, CSFs that involve excitations on both atoms (e.g. $|1s_a^2 2s_a 2p_a 1s_b^2 2s_b 2p_b|$) give rise to one- and two-electron integrals over orbitals on both atoms (e.g. $\langle 2s_a 2p_a | \hat{g} | 2s_b 2p_b \rangle$) that vanish if the atoms are far apart, so contributions due to such CSFs vanish. Hence, only CSFs that are excited on one or the other atom contribute to the energy. This, in turn, results in a second-order energy that is additive as required by any size-extensive method. In general, a method will be size extensive *if* its energy formula is additive *and* the equations that determine the C_J amplitudes are themselves separable. The MPPT/MBPT and CC methods possess these characteristics.

However, size-extensive methods have two serious weaknesses. Their energies do *not* provide upper bounds to the true energies of the system (because their energy functional is not of the expectation-value form for which the upper bound property has been proven). Moreover, they express the correct wavefunction in terms of corrections to a (presumed dominant) reference function which is usually taken to be a single CSF (although efforts have been made to extend the MPPT/MBPT and CC methods to allow for multiconfigurational reference functions, this is not yet standard practice). For situations in which two CSFs ‘cross’ along a reaction path, the single-dominant-CSF assumption breaks down, and these methods can have difficulty.

B3.1.7 THERE ARE METHODS THAT CALCULATE ENERGY DIFFERENCES RATHER THAN ENERGIES

In addition to the myriad of methods discussed above for treating the energies and wavefunctions as solutions to the electronic Schrödinger equation, there exists a family of tools that allow one to compute energy differences ‘directly’ rather than by first finding the energies of pairs of states and subsequently subtracting them. Various energy differences can be so computed: differences between two electronic states of the same molecule (i.e. electronic excitation energies ΔE), differences between energy states of a molecule and the cation or anion formed by removing or adding an electron (i.e. IPs and EAs).

Because of space limitations, we will not be able to elaborate much further on these methods. However, it is important to stress that:

- (1) these so-called *Greens function* or *propagator* methods [71] utilize essentially the same input

information (e.g. AO basis sets) and perform many of the same computational steps (e.g. evaluation of one- and two-electron integrals, formation of a set of mean-field MOs, transformation of integrals to the MO basis, etc) as do the other techniques discussed earlier;

- (2) these methods are now rather routinely used when ΔE , IP, or EA information is sought. In fact, the 1998 version of the Gaussian program includes an electron propagator option.

The basic ideas underlying most, if not all, of the energy-difference methods follow

-38-

- (1) One forms a *reference wavefunction* Ψ (this can be of the SCF, MPn, CC, etc variety); the energy differences are computed relative to the energy of this function.
- (2) One expresses the *final-state wavefunction* Ψ' (i.e. describing the excited, cation, or anion state) in terms of an operator Ω acting on the reference Ψ : $\Psi' = \Omega\Psi$. Clearly, the Ω operator must be one that removes or adds an electron when one is attempting to compute IPs or EAs, respectively.
- (3) One writes equations which Ψ and Ψ' are expected to obey. For example, in the early development of these methods [80], the Schrödinger equation itself was assumed to be obeyed, so $\hat{H}\Psi = E\Psi$ and $\hat{H}'\Psi' = E'\Psi'$ are the two equations (note that, in the IP and EA cases, the latter equation, and the associated Hamiltonian \hat{H}' , refer to one fewer and one more electrons than does the reference equation $\hat{H}\Psi = E\Psi$).
- (4) One combines $\Omega\Psi = \Psi'$ with the equations that Ψ and Ψ' obey to obtain an equation that Ω must obey. In the above example, one: (a) uses $\Omega\Psi = \Psi'$ in the Schrödinger equation for Ψ' , (b) allows Ω to act from the left on the Schrödinger equation for Ψ and (c) subtracts the resulting two equations to achieve $(\hat{H}'\hat{\Omega} - \hat{\Omega}\hat{H})\Psi = (E' - E)\Omega\Psi$ or, in commutator form $[\hat{H}', \hat{\Omega}]\Psi = \Delta E\hat{\Omega}\Psi$. By expressing the Hamiltonian in the second-quantization form, only one \hat{H} appears in this final so-called *equation of motion* (EOM) $[\hat{H}, \hat{\Omega}]\Psi = \Delta E\hat{\Omega}\Psi$ (i.e. in the second-quantized form, \hat{H}' and \hat{H} are one and the same).
- (5) One can, for example, express Ψ in terms of a superposition of configurations $\Psi = \sum_j C_j \Phi_j$ whose amplitudes C_j have been determined from an MCSCF, CI or MPn calculation and express Ω in terms of second-quantization operators $\{O_K\}$ that cause single-, double-, etc, level excitations (for the IP (EA) cases, Ω is given in terms of operators that remove (add), remove and singly excite (add and singly excite) electrons): $\Omega = \sum_K D_K \hat{O}_K$.
- (6) Substituting the expansions for Ψ and for $\hat{\Omega}$ into the EOM $[\hat{H}, \hat{\Omega}]\Psi = \Delta E\hat{\Omega}\Psi$, and then projecting the resulting equation on the left against a set of functions (e.g. $\{\hat{O}_{K'}|\Psi\rangle\}$ or $\{\hat{O}_{K'}|\Phi_0\rangle$, where Φ_0 is the dominant component of Ψ), gives a matrix eigenvalue–eigenvector equation:

$$\sum_K \langle \hat{O}_{K'}|\Psi|[\hat{H}, \hat{O}_K]\Psi\rangle D_K = \Delta E \sum_K \langle \hat{O}_{K'}|\Psi|\hat{O}_K\Psi\rangle \hat{D}_K$$

to be solved for the \hat{D}_K operator coefficients and the excitation energies ΔE . Such are the working equations of the EOM (or Greens function or propagator) methods.

In recent years, these methods have been greatly expanded and have reached a degree of reliability where they now offer some of the most accurate tools for studying excited and ionized states. In particular, the use of time-dependent variational principles have allowed the much more rigorous development of equations for energy differences and nonlinear response properties [81]. In addition, the extension of the EOM theory to include coupled-cluster reference functions [82] now allows one to compute excitation and ionization energies using some of the most accurate *ab initio* tools.

B3.1.8 SUMMARY OF AB INITIO METHODS

At this time, it may not be possible to say which method is preferred for applications where all are practical. Nor is it possible to assess, in a way that is applicable to most chemical species, the accuracies with which various methods

-39-

predict bond lengths and energies or other properties. However, there are reasons to recommend some methods over others in specific cases. For example, certain applications require a size-extensive energy (e.g. extended systems that consist of a large or macroscopic number of units or studies of weak intermolecular interactions), so MBPT/MPPT-, CC- or CAS-based MCSCF are preferred. Moreover, many chemical reactions and bond-breaking events require two or more ‘essential’ electronic configurations. For them, single-configuration-based methods such as conventional CC and MBTP/MPPT should be used only with caution; MCSCF or CI calculations are preferred. Very large molecules, in which thousands of AO basis functions are required, may be impossible to treat by methods whose effort scales as N^4 or higher; density functional methods would be the only choice then.

For all calculations, the choice of AO basis set must be made carefully, keeping in mind the N^4 scaling of the two-electron integral evaluation step and the N^5 scaling of the two-electron integral transformation step. Of course, basis functions that describe the essence of the states to be studied are essential (e.g. Rydberg or anion states require diffuse functions and strained rings require polarization functions).

As larger atomic basis sets are employed, the size of the CSF list used to treat a dynamic correlation increases rapidly. For example, many of the above methods use singly- and doubly-excited CSFs for this purpose. For large basis sets, the number of such CSFs (N_C) scales as the number of electrons squared n_e^2 times the number of basis functions squared N^2 . Since the effort needed to solve the CI secular problem varies as N_C^2 or N_C^3 (the latter being to find all eigenvalues and vectors), a dependence as strong as $n_e^6 N^6$ can result. To handle such large CSF spaces, all of the multiconfigurational techniques mentioned in this paper have been developed to the extent that calculations involving of the order of 100–5000 CSFs are routinely performed and calculations using even several billion CSFs are possible [53].

Some of the most significant advances that have been made recently in expanding the applicability of the *ab initio* methods to larger systems are based on recognizing that many of the two-electron integrals and one- and two-electron density matrix elements arising in the pertinent working equations vanish if expressed in terms of localized (atomic or molecular) orbitals. For example, in a polymer consisting of P monomer units (or a crystal composed of P unit cells), the integrals and density matrix elements indexed by monomer units far distant from one another are negligible. Thus, if a method whose effort scales as the k th power of the number of AOs (N) per monomer (or unit cell) is applied to a system having P units, the effort should *not* scale as $(PN)^k$ but, hopefully, as PN^k . Indeed, for the DFT ($k = 3$), SCF ($k = 4$) and MP2 ($k = 5$) methods, specialized techniques [50] have allowed for the implementation of codes scaling linearly (or nearly so for MP2) with the system ‘size’ P (i.e. the number of units).

Other methods, most of which can be viewed as derivatives of the techniques introduced above, have been and are still being developed; stimulated by the explosive growth in computer power and changes in computer architecture realized in recent years. All indications are that this growth pattern will continue; so *ab initio* quantum chemistry is likely to have an even larger impact on future chemistry research and education (through new insights and concepts). For many of the most commonly employed *ab initio* quantum chemistry tools, the computational efforts, as characterized by how they scale with the system size P (i.e. the number of units), with basis set size N and with the number of electronic configurations N_C , as well their variational nature and size extensivity are summarized in [table B3.1.2](#).

Table 3.1.2 Properties of commonly used methods.

Method	Variational/size extensive	Computational scaling
HF	Yes/Yes	N^4 integrals; N^3 eigenvalues; P^1
GVB	Yes/Yes	N^4 integrals N^4 (per electron pair) GVB equations
DFT	No/Yes	N^3 eigenvalues; N^2 integrals; P^1 N^3 orbital orthogonalization; P^1
MP2	No/Yes	N^5 ; P^2
CI	Yes/No	N^5 transformed integrals; N_C^2 to solve for <i>one</i> CI energy and eigenvector
CISD	Yes/No	N^5 transformed integrals; $n^2 N^4$ to solve for one CI energy and eigenvector
CAS-MCSCF	Yes/Yes	N^5 transformed integrals; N_C^2 to solve for CI energy; many iterations also needed
CCS	No/Yes	N^4
CCSD	No/Yes	N^6
CCSDT	No/Yes	N^8
CCSD(T)	No/Yes	N^7

Figure B3.1.9 [83] displays the errors (in picometres compared to experimental findings) in the equilibrium bond lengths for a series of 28 molecules obtained at the HF, MP2-4, CCSD, CCSD(T), and CISD levels of theory using three polarized correlation-consistent basis sets (valence DZ through to QZ).

Figure B3.1.9. Distribution in errors (picometres) in calculated bond lengths for 28 test molecules.

Clearly, the HF method, independent of basis, systematically underestimates the bond lengths over a broad percentage range. The CISD method is neither systematic nor narrowly distributed in its errors, but the MP2 and MP4 (but not MP3) methods are reasonably accurate and have narrow error distributions if valence TZ or QZ bases are used. The CCSD(T), but not the CCSD, method can be quite reliable if valence TZ or QZ bases are used.

In closing this section and this chapter, I wish to remind the reader that my discussion has been limited to *ab initio* techniques; that is, to methods that begin with the electronic Schrödinger equation attempt to solve it without explicitly introducing any experimental data or any numerical results from another calculation. There exists a whole family of alternative approaches called *semi-empirical methods* [84] in which (a) overlaps between pairs of orbitals distant from one another are neglected, (b) many of the two-electron integrals appearing in *ab initio* methods are neglected (because they are ‘small’ in some sense) and (c) certain combinations of one- and two-electron integrals that can be (approximately) related to orbital energies of a constituent atom are not computed explicitly but are replaced by experimental data (or data from an *ab initio* calculation) on that atom. Interested readers in these approaches to electronic structure are referred to the articles given in [84].

- [54] The so-called Slater-Condon rules express the matrix elements of any one-electron (F) plus two-electron (G) additive operator between pairs of antisymmetrized spin-orbital products that have been arranged (by permuting spin-orbital ordering) to be in so-called maximal coincidence. Once in this order, the matrix elements between two such Slater determinants (labelled $|i\rangle$ and $|j\rangle$) are summarized as follows:
(i) if $|i\rangle$ and $|j\rangle$ are identical, then

$$\langle F + G \rangle = \sum_i \langle \phi_i | f | \phi_i \rangle + \sum_{i>j} [\langle \phi_i \phi_j | g | \phi_i \phi_j \rangle - \langle \phi_i \phi_j | g | \phi_j \phi_i \rangle]$$

where the sums over i and j run over all spin orbitals in $|\rangle$;

(ii) if $|\rangle$ and $|\prime\rangle$ differ by a single spin-orbital mismatch ($\phi_p \neq \phi'_p$),

$$\langle F + G \rangle = \langle \phi_p | f | \phi'_p \rangle + \sum_j [\langle \phi_p \phi_j | g | \phi'_p \phi_j \rangle - \langle \phi_p \phi_j | g | \phi_j \phi'_p \rangle]$$

where the sum over j runs over all spin orbitals in $|\rangle$ except ϕ_p ;

(iii) if $|\rangle$ and $|\prime\rangle$ differ by two spin orbitals ($\phi_p \neq \phi'_p$ and $\phi_q \neq \phi'_q$),

$$\langle F + G \rangle = \langle \phi_p | f | \phi'_p \rangle + \sum_j [\langle \phi_p \phi_j | g | \phi'_p \phi_j \rangle - \langle \phi_p \phi_j | g | \phi_j \phi'_p \rangle]$$

(note that the F contribution vanishes in this case);

(iv) if $|\rangle$ and $|\prime\rangle$ differ by three or more spin orbitals, then

$$\langle F + G \rangle = 0$$

- [55] Nesbet R K 1963 Computer programs for electronic wave-function calculations *Rev. Mod. Phys.* **35** 552–7
It would seem that the process of evaluating all N^4 of the $\langle \phi_i \phi_j | g | \phi_k \phi_l \rangle$, each of which requires N^4 additions and multiplications, would require computer time proportional to N^8 . However, it is possible to perform the full transformation of the two-electron integral list in a time that scales as N^5 by first performing a transformation of the $\langle \chi_a \chi_b | g | \chi_c \chi_d \rangle$ to an intermediate array $\langle \chi_a \chi_b | g | \chi_c \phi \rangle = \sum_d C_{d,i} \langle \chi_a \chi_b | g | \chi_c \chi_d \rangle$ which requires N^5 multiplications and additions. The list $\langle \chi_a \chi_b | g | \chi_c \phi \rangle$ is then transformed to a second-level transformed array $\langle \chi_a \chi_b | g | \phi_k \phi_l \rangle = \sum_c C_{c,k} \langle \chi_a \chi_b | g | \chi_c \phi \rangle$, which requires another N^5 operations. This sequential transformation is repeated four times until the final $\langle \phi_i \phi_j | g | \phi_k \phi_l \rangle$ array is in hand

- [71] This is because no four-indexed two-electron integral like expressions enter into the integrals needed to compute the energy. All such integrals involve $\rho(\mathbf{r})$ or the product $\rho(\mathbf{r})\rho(\mathbf{r})$; because ρ is itself expanded in a basis (say of M functions), even the term $\rho(\mathbf{r})\rho(\mathbf{r})$ scales no worse than M^2 . The solution of the KS equations for the KS orbitals ϕ_i involves solving a matrix eigenvalue problem; this is expected to scale as M^3 . However, as discussed in [section \(B3.1.8\)](#), the scalings of the DFT, SCF, and MP2 methods have been reduced even further

B3.2 Quantum structural methods for the solid state and surfaces

Frank Starrost and Emily A Carter

B3.2.1 INTRODUCTION

We are entering an era when condensed matter chemistry and physics can be predicted from theory with increasing realism and accuracy. This is particularly important in cases where experiments lead to ambiguous conclusions, for regimes in which there still exists no experimental probe and for predictions of the properties of modern materials in order to select the most promising ones for synthesis and experimental testing. For example, continuing miniaturization in microelectronics heightens the importance of understanding of quantum effects, which computational materials theory is poised to provide, based to some degree on the methods presented here.

Our intention is to give a brief survey of advanced theoretical methods used to determine the electronic and geometric structure of solids and surfaces. The electronic structure encompasses the energies and wavefunctions (and other properties derived from them) of the electronic states in solids, while the geometric structure refers to the equilibrium atomic positions. Quantities that can be derived from the electronic structure calculations include the electronic (electron energies, charge densities), vibrational (phonon spectra), structural (lattice constants, equilibrium structures), mechanical (bulk moduli, elastic constants) and optical (absorption, transmission) properties of crystals. We will also report on techniques used to study solid surfaces, with particular examples drawn from chemisorption on transition metal surfaces.

In his chapter on the fundamentals of quantum mechanics of condensed phases ([A1.3](#)), James R Chelikowsky introduces the plane wave pseudopotential method. Here, we will complement his chapter by introducing in some detail tight-binding methods as the simplest pedagogical illustration of how one can construct crystal wavefunctions from atomic-like orbitals. These techniques are very fast but generally not very accurate. After reviewing some of the efforts made to improve upon the local density approximation (LDA, explained in [A1.3](#)), we will discuss general features of the technically more complex all-electron band structure methods, focusing on the highly accurate but not very fast linear augmented plane wave (LAPW) technique as an example. We will introduce the idea of orbital-free electronic structure methods based directly on density functional theory (DFT), the computational effort of which scales linearly with size, allowing very large

systems to be studied. The periodic Hartree–Fock (HF) method and the promising quantum Monte Carlo (QMC) techniques will be briefly sketched, representing many-particle approaches to the condensed phase electronic structure problem.

In the final section, we will survey the different theoretical approaches for the treatment of adsorbed molecules on surfaces, taking the chemisorption on transition metal surfaces, a particularly difficult to treat yet extremely relevant surface problem [1], as an example. While solid state approaches such as DFT are often used, hybrid methods are also advantageous. Of particular importance in this area is the idea of embedding, where a small cluster of surface atoms around the adsorbate is treated with more care than the surrounding region. The advantages and disadvantages of the approaches are discussed.

-2-

B3.2.2 TIGHT-BINDING METHODS

B3.2.2.1 TIGHT BINDING: FROM EMPIRICAL TO SELF-CONSISTENT

The wavefunction in a solid can be thought to originate from two different limiting cases. One extreme is the nearly free electron (NFE) approach. The idea here is that the valence electrons are hardly affected by the periodic potential of the atomic cores. Their wavefunctions can then be assumed to be easily described as linear combinations of the solutions for free electrons: the plane waves, $\exp(i\mathbf{k} \cdot \mathbf{r})$. The NFE approximation is particularly useful for so-called NFE metals, such as the alkali metals. At the other extreme, the solid can be viewed as constructed from individual atoms. The valence wavefunctions of the solid are then approximated as linear combinations of the wavefunctions of the valence electrons of the atoms (see also [section A1.3.5.6](#)). In this case, the electrons are considered to be ‘tightly bound’ to the atoms. This is a physically reasonable view of covalently bound solids and molecules, where localized chemical bonds are the norm (bulk silicon, organic or biomolecules etc). Methods which employ this view of the electrons in the solid are called tight-binding (TB) methods. The wavefunctions are generally expanded in atomic orbitals (in a linear combination of atomic orbitals (LCAO) formalism) or similarly localized functions.

An advantage of TB is that generally the number of basis functions linearly combined to give the wavefunctions is rather small. The solution of the Schrödinger equation in these bases is then fast because the matrices representing the operators are small. Also, the construction of the Hamiltonian matrix elements is fast, since generally a number of, sometimes drastic, approximations are made. At the same time, however, the small basis set generally limits the quality of the TB results, since the variational freedom for the solution of the Schrödinger equation is not as high as in other methods. The approximations of Hamiltonian matrix elements often further reduce the quality of the results.

Today, the term TB method is generally understood to refer to a technique using TB basis functions in which the Hamiltonian matrix elements are adjusted to reproduce results from experiments and/or from more sophisticated electronic structure methods [2]. Depending on the degree of dependence on external parameters, the methods are called empirical or semi-empirical TB. A number of approaches are used for the fitting of the TB parameters, generally a tough minimization task with many minima (using genetic algorithms has proved quite efficient [3, 4]). It has been noted that ‘great care is needed to test the resulting model for reasonable behavior outside the range of the fit’ [5, 6]. A disadvantage of the empirical methods is that it is difficult to distinguish to what extent the parametrization or the method itself is responsible for errors in the results.

Frequent approximations made in TB techniques in the name of achieving a fast method are the use of a minimal basis set, the lack of a self-consistent charge density, the fitting of matrix elements of the potential,

the assumption of an orthogonal overlap matrix, a cut-off radius used in the integration to determine matrix elements, and the neglect of matrix elements that require three-centre integrals and crystal-field terms. We will now provide more details on these approximations.

Generally, the following *ansatz* for the wavefunction is made:

$$\psi_i(\mathbf{r}) = \sum_{\alpha l} c_{\alpha l}^i \varphi_{\alpha l}(\mathbf{r}),$$

-3-

where $\varphi_{\alpha\lambda}(\mathbf{r}) = \langle \mathbf{r} | \varphi_{\alpha\lambda} \rangle$ represents an atomic orbital of symmetry α (such as s, p_x, p_y, p_z) at atom l .

This yields the generalized eigenvalue problem

$$\underline{H}\underline{c}^i = \epsilon_i \underline{S}\underline{c}^i, \quad (\text{B3.2.1})$$

with the elements of the Hamiltonian matrix $H_{\alpha\lambda\beta\mu} \equiv \langle \varphi_{\alpha\lambda} | \mathbf{H} | \varphi_{\beta\mu} \rangle$ and the overlap matrix $S_{\alpha\lambda\beta\mu} \equiv \langle \varphi_{\alpha\lambda} | \varphi_{\beta\mu} \rangle$. In the TB approximation, the basis functions are thought to be sufficiently localized such that contributions to the Hamiltonian matrix usually are accounted for only up to at most the third or fourth neighbour. Frequently a minimal basis set is used, i.e. a single orbital $\varphi_{\alpha\lambda}$ is used per atom and per orbital symmetry to expand the wavefunction.

In orthogonal TB methods, the overlap matrix is assumed to be diagonal, even though the basis functions of adjacent sites ordinarily are not orthogonal [6]. Harrison has shown that this approximation can be compensated for by adjustments to the Hamiltonian matrix elements (these adjustments are arrived at automatically in methods depending on fitting, for example, a DFT band structure) [7]. However, this approach reduces the transferability of the TB parameters to other structures [8]. Including the overlap matrix brings with it the additional cost of its calculation and solving the generalized eigenvalue problem, see equation (B3.2.1), rather than an ordinary eigenvalue problem.

One can construct an effective potential, written here in the DFT language (see, for example, [equation A1.3.38](#) of A1.3) as

$$v_{\text{eff}}(\mathbf{r}) = v_{\text{ext}}(\mathbf{r}) + v_{\text{H}}[\rho(\mathbf{r})] + v_{\text{xc}}[\rho(\mathbf{r})]. \quad (\text{B 3.2.2})$$

To rationalize the ‘two-centre approximation’, the effective potential is written as

$$v_{\text{eff}}(\mathbf{r}) = \sum_l v_{\text{eff},l}(|\mathbf{r} - \mathbf{R}_l|),$$

where $v_{\text{eff},l}$ is centred on the atom l and vanishes away from the atom, which need not involve any approximation.

In the calculation of the elements

$$H_{\alpha l \beta m} = \left\langle \varphi_{\alpha l} \left| T + \sum_n v_{\text{eff},n} \right| \varphi_{\beta m} \right\rangle$$

with $T = -\frac{1}{2}\nabla^2$ the kinetic energy operator, several types of potential matrix elements can be distinguished [6]:

- (1) Three-centre terms, i.e. $l \neq m \neq n$. These are frequently neglected, in what is called the two-centre approximation, based on the assumed strong localization of the orbitals $\varphi_{\alpha\lambda}(\mathbf{r})$.
-

-4-

- (2) Inter-atomic two-centre matrix elements $\langle \varphi_{\alpha\lambda} | v_{\text{eff},l} + v_{\text{eff},m} | \varphi_{\beta\mu} \rangle$. These matrix elements represent the hopping of electrons from one site to another. They can be described [7] as linear combinations of so-called Slater–Koster elements [9]. The coefficients depend only on the orientation of the atoms l and m in the crystal. For elementary metals described with s, p, and d basis functions there are ten independent Slater–Koster elements. In the traditional formulation, the orientation is neglected and the two-centre elements depend only on the distance between the atoms [6]. (In several models [6, 10], they have been made dependent on the environment of the atoms l and m .) These elements are generally fitted to reproduce DFT results such as the band structure or the values of DFT matrix elements in diatomics.
- (3) Intra-atomic matrix elements, or on-site terms, with $l = m$. Traditionally, the potential contributions from other atomic sites, $v_{\text{eff},n \neq \lambda = \mu}$, so-called crystal-field terms, are neglected [10]. In this case, then the only non-zero on-site terms have $\alpha = \beta$, since basis functions on the same site are orthogonal atomic orbitals. There are methods which include these crystal-field terms [11, 12]. Physically, these diagonal elements represent the energy required to place an electron in a specific orbital. In some implementations, they are set to the orbital energy values of the neutral free atom [13], guaranteeing the correct limit for isolated atoms. However, this approach ignores the potential contributions to the diagonal elements due to different environments in a molecule or crystal; these are taken into account in other variants of the method [6, 10, 11].

Most TB approaches are not charge self-consistent. This means that they do not ensure that the charge derived from the wavefunctions yields the effective potential v_{eff} assumed in their calculation. Some methods have been developed which yield charge densities consistent with the electronic potential [14, 15 and 16].

The localized nature of the atomic basis set makes it possible to implement a linear-scaling TB algorithm, i.e. a TB method that scales linearly with the number of electrons simulated [17]. (For more information on linear scaling methods, see [section B3.2.3.3](#).)

The accuracy of most TB schemes is rather low, although some implementations may reach the accuracy of more advanced self-consistent LCAO methods (for examples of the latter see [18, 19 and 20]). However, the advantages of TB are that it is fast, provides at least approximate electronic properties and can be used for quite large systems (e.g., thousands of atoms), unlike some of the more accurate condensed matter methods. TB results can also be used as input to determine other properties (e.g., photoemission spectra) for which high accuracy is not essential.

B3.2.2.2 APPLICATIONS OF TIGHT-BINDING METHODS

TB methods have been widely used to study properties of simple semiconductors such as Si [11] and GaN [16]. In the latter study, the effect of dislocations on the electronic structure of GaN was investigated with a view toward understanding how dislocations affect the material's optical properties. The large supercell of 224 atoms led to TB as the method of choice. This particular variant of TB fits TB matrix elements to DFT-LDA results and solves self-consistently for atomic charges. It has also been used to predict reaction energetics of organic molecules, the structure of large biomolecules and the surface geometry and band

structure of III–V semiconductors [15]. The TB method is expected to provide qualitatively reasonable results for systems where localized atomic charges make sense and hence is not expected to perform as well for metallic systems. Despite potential problems of TB for metals, the TB approach has also been used to study the phonon spectrum of the transition metal molybdenum [6], the elastic constants,

-5-

vacancies and surfaces of monatomic transition and noble metals and the Hall coefficient of complex perovskite crystals [10]. As an example of data available from a TB calculation, a TB variant of extended Hückel theory [21, 22] was used to describe the initial states in photoemission from GaN [23]. The parameters were fitted to the bulk band structure $E_n(\mathbf{k})$ (for a definition, see section A1.3.6). As displayed in figure (B3.2.1) good agreement is found for the occupied states (negative energies), while larger differences for the conduction bands (positive energies) reveal a typical problem of the TB methods: they are far less capable of describing the delocalized conduction band states (the same is true for delocalized valence states in a metal, as mentioned above). In figure (B3.2.2) we show a series of calculated photoemission spectra compared to experimental results [23]. The dispersion of the main peaks as a function of emission angle and photon energy agrees reasonably well in theory and experiment.

Figure B3.2.1. The band structure of hexagonal GaN, calculated using EHT-TB parameters determined by a genetic algorithm [23]. The target energies are indicated by crosses. The target band structure has been calculated with an *ab initio* pseudopotential method using a quasiparticle approach to include many-particle corrections [194].

-6-

Figure B3.2.2. A series of photoemission spectra. The angles give the polar angle of electron emission at the stated photon energy scanning the surface Brillouin zone from $\bar{\Gamma}$ to \bar{M} . Left: A calculation using the tight-binding parametrization (given the band structure in figure (B3.2.1)) for the initial states [23]. Right: Experimental spectra by Dhesi *et al* [195]. The difference in binding energies is due to the experimental difficulty in determining the Fermi energy [23]. (Experimental figure by Professor K E Smith.)

B3.2.3 FIRST-PRINCIPLES ELECTRONIC STRUCTURE METHODS

In this section, we briefly review the basic elements of DFT and the LDA. We then focus on improvements suggested to remedy some of the shortcomings of the LDA (see section B3.2.3.1). A wide variety of techniques based on DFT have been developed to calculate the electron density. Many approaches do not calculate the density directly but rather solve for either a set of single-electron orbitals, or the Green's function, from which the density is derived.

In section B3.2.3.2, we introduce a number of techniques commonly referred to as *ab initio* all-electron electronic structure methods. *Ab initio* methods, in particular, aim at calculating the energies of electrons and their wavefunctions as accurately as possible, introducing as few adjustable parameters as possible. (Empirical or semi-empirical methods include the empirical pseudopotential approach (see section A1.3.5.5) and many TB techniques (see section B3.2.2).) Within the *ab initio* band structure approach, two communities exist that differ in their treatment of the singular nature of realistic, Coulomb-like crystal potentials. In the pseudopotential approach discussed by Chelikowsky in chapter A1.3, the Coulomb singularity ($-Z/r$) of the crystal potential is replaced by a smoother function, whereas in the so-called 'all-electron' approach, the Coulomb singularity is retained. The pseudopotential transformation limits the range of electron energies which can be accessed. However, since the pseudo-wavefunction is much smoother than the all-electron wavefunction (which has large oscillations near the nucleus), the pseudopotential allows the use of a plane

wave basis set, which is comparatively easy to handle. In principle, the all-electron methods have no limitation on the energy range of calculations. This is achieved by a sophisticated representation of the wavefunction.

The so-called orbital-free DFT technique, which aims to directly calculate the electron density for which the

total energy is minimal, is presented as an example of methods whose computational effort scales linearly with system size (see [section B3.2.3.3](#)). In [section B3.2.3.4](#), we discuss the periodic HF method, an alternative approach to DFT that offers a well defined starting point for many-particle corrections. Finally, the two most frequently used QMC techniques are described in [section B3.2.3.5](#).

B3.2.3.1 THE LOCAL DENSITY APPROXIMATION AND BEYOND

In DFT, the electronic density rather than the wavefunction is the basic variable. Hohenberg and Kohn showed [24] that all the observable ground-state properties of a system of interacting electrons moving in an external potential $v_{\text{ext}}(\mathbf{r})$ are uniquely dependent on the charge density $\rho(\mathbf{r})$ that minimizes the system's total energy. However, there is no known formula to calculate from the density the total energy of many electrons moving in a general potential. Hohenberg and Kohn proved that there exists a universal functional of the density, called $G[\rho]$, such that the expression

$$E[\rho] = \int v_{\text{ext}}(\mathbf{r})\rho(\mathbf{r}) d^3r + \frac{1}{2} \int \frac{\rho(\mathbf{r})\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d^3r d^3r' + G[\rho] \quad (\text{B 3.2.3})$$

has as its minimum value the correct ground-state energy associated with $v_{\text{ext}}(\mathbf{r})$. Here, the first term on the right-hand side represents the energy due to an external potential, including the electron–nuclear potential, while the second term is the classical Coulomb energy of the electronic system. The functional $G[\rho]$ is valid for any number of electrons and any external potential, but it is unknown and further steps are necessary to approximate it.

Kohn and Sham [25] decompose $G[\rho]$ into the kinetic energy of an analogous set of non-interacting electrons with the same density $\rho(\mathbf{r})$ as the interacting system,

$$T_s[\rho] = \sum_i \left\langle \psi_i \left| -\frac{1}{2} \nabla^2 \right| \psi_i \right\rangle$$

(where $\psi_i(\mathbf{r}) = \langle \mathbf{r} | \psi_i \rangle$ is the wavefunction of electron i), and the exchange and correlation energy of an interacting system with density $\rho(\mathbf{r})$, $E_{\text{xc}}[\rho]$. The functional $E_{\text{xc}}[\rho]$ is not known exactly. Physically, it represents all the energy corrections beyond the Hartree term to the independent-particle model, i.e. the non-classical many-body effects of exchange and correlation (xc) and the difference between the kinetic energy of the interacting electron system $T[\rho]$ and the analogous non-interacting system $T_s[\rho]$.

In the LDA, the exchange and correlation energy is approximated using the exchange and correlation energy of the homogeneous electron gas at the same density (see [section A1.3.3.3](#)). The crystal density is obtained by solving the single-particle Kohn–Sham equation

-8-

$$\left(-\frac{1}{2} \nabla^2 + v_{\text{eff}}(\mathbf{r}) \right) \psi_i(\mathbf{r}) = E_i \psi_i(\mathbf{r}), \quad (\text{B 3.2.4})$$

for a self-consistent potential v_{eff} i.e. a potential which is produced by the density ρ . In bulk crystal calculations, the index i runs over both the Bloch vector \mathbf{k} (see [section A1.3.4](#)) and the band index n (in a simple crystal, this band could be derived, for example, entirely from s states). The solutions to equation (B3.2.4) are often called Kohn–Sham orbitals. The crystal density is then

$$\rho(\mathbf{r}) = \sum_i \psi_i^*(\mathbf{r})\psi_i(\mathbf{r}).$$

The eigenenergy E_i can be defined as the derivative of the total energy of the many-electron system with respect to the occupation number of a specific orbital [26]. In HF theory (where equation (B3.2.4) applies and the v_{eff} contains a non-local exchange operator, see section A1.3.1.2 and [chapter B3.1](#)), Koopmans' theorem states that the single-particle eigenvalue is the negative of the ionization energy (neglecting the relaxation of the electronic system). In contrast, the identification of the highest occupied Kohn–Sham eigenvalue with the negative of the ionization energy is a controversial subject [27]. While there is no rigorous connection between eigenvalue differences and excitation energies in either HF or DF theory, comparisons of these values are common practice (see below for more appropriate methods). Relative differences among occupied single-particle energies often agree well with the experiment. Even though DFT only provides a solution for the ground state of the electronic system, the energy differences in the lower conduction bands, i.e. low-energy excited states, often are represented surprisingly well, too. However, in LDA calculations of semiconductors and insulators, almost always the size of the gap between the valence band maximum and the conduction band minimum is underestimated, since many-particle effects are incorrectly represented by the parametrized exchange–correlation energy (see, for example, [28]). One *ad hoc* remedy, which works well for many systems and which is employed in the examples presented here, is to use what is amusingly referred to as a *scissor operator*, i.e. a rigid shift, to correct the gap size [29, 30]. Typically the shift is determined by knowing, for example, the DFT error in predicting the measured optical band gap. The entire conduction band is shifted rigidly upward by the amount to match the experimental band gap.

More advanced techniques take into account quasiparticle corrections to the DFT-LDA eigenvalues. Quasiparticles are a way of conceptualizing the elementary excitations in electronic systems. They can be determined in band structure calculations that properly include the effects of exchange and correlation. In the LDA, these effects are modelled by the exchange–correlation potential $v_{\text{xc}}^{\text{LDA}}$. In order to more accurately account for the interaction between a particle and the rest of the system, the notion of a local potential has to be generalized and a non-local, complex and energy-dependent exchange–correlation potential has to be introduced, referred to as the self-energy operator $\Sigma(\mathbf{r}, \mathbf{r}'; E)$. The self-energy can be expanded in terms of the screened Coulomb potential W , where $W = \epsilon^{-1}v$ is the Coulomb interaction v screened by the inverse dielectric function ϵ^{-1} . In a lowest order expansion in W , the self-energy can be approximated as $\Sigma = GW$, giving the *GW* approximation [31]. Here G is the one-electron Green's function describing the propagation of an additional electron injected into a system of other electrons (it can also describe the extraction of an electron).

-9-

To be a bit more explicit (following [32, 33]), the quasiparticle energies and wavefunctions are given by

$$(T + v_{\text{ext}} + v_{\text{H}})\psi_{nk}(\mathbf{r}) + \int d\mathbf{r}' \Sigma(\mathbf{r}, \mathbf{r}'; E_{nk})\psi_{nk}(\mathbf{r}') = E_{nk}\psi_{nk}(\mathbf{r}),$$

where T is the kinetic energy operator, v_{ext} is the external potential due to the ions, and v_{H} is the Hartree Coulomb interaction. Since the self-energy operator in general is non-Hermitian, the quasiparticle energies E_{nk} are complex in general, and the imaginary part gives the lifetime of the quasiparticle. To first order in W , the self-energy is then given by

$$\Sigma(\mathbf{r}, \mathbf{r}'; E) = \frac{i}{2\pi} \int d\omega e^{-i\delta\omega} G(\mathbf{r}, \mathbf{r}'; E - \omega)W(\mathbf{r}, \mathbf{r}'; \omega)$$

where δ is a positive infinitesimal and ω corresponds to an excitation frequency. The inputs are the full interacting Green's function,

$$G(\mathbf{r}, \mathbf{r}'; E) = \sum_{nk} \frac{\psi_{nk}(\mathbf{r})\psi_{nk}^*(\mathbf{r}')}{E - E_{nk} - i\delta_{nk}},$$

where δ_{nk} is an infinitesimal and the dynamically screened Coulomb interaction,

$$W(\mathbf{r}, \mathbf{r}'; \omega) = \Omega^{-1} \int d\mathbf{r}'' \epsilon^{-1}(\mathbf{r}, \mathbf{r}''; \omega) v(\mathbf{r}'' - \mathbf{r}'),$$

where ϵ^{-1} is the inverse dielectric matrix, $v(\mathbf{r}) = 1/|\mathbf{r}|$ and Ω is the volume of the system. Usually the calculations start with the construction of the Green's function and the screened Coulomb potential from self-consistent LDA results. The self-energy Σ then has to be obtained together with G in a self-consistent procedure. However, due to the severe computational cost of this procedure, it is usually not carried out (see, for example, [34]). Instead, it is common practice to construct the self-energy operator non-self-consistently using the self-consistent LDA results to determine quasiparticle corrections to the LDA energies, resulting in the quasiparticle band structure. The GW approximation has been applied to a wide range of metals, semiconductors and insulators, where it has been found to lead to striking improvements in the agreement of optical excitation spectra with the experiment (see, for example [32, 35, 36 and 37]). Recent studies also found that the GW charge density is close to the experiment for diamond structure semiconductors [38], and lifetimes of low-energy electrons in metals have been calculated [39].

Another disadvantage of the LDA is that the Hartree Coulomb potential includes interactions of each electron with itself, and the spurious term is not cancelled exactly by the LDA self-exchange energy, in contrast to the HF method (see A1.3), where the self-interaction is cancelled exactly. Perdew and Zunger proposed methods to evaluate the self-interaction correction (SIC) for any energy density functional [40]. However, full SIC calculations for solids are extremely complicated (see, for example [41, 42 and 43]). As an alternative to the very expensive GW calculations, Pollmann *et al* have developed a pseudopotential built with self-interaction and relaxation corrections (SIRC) [44].

-10-

The pseudopotential is derived from an all-electron SIC-LDA atomic potential. The relaxation correction takes into account the relaxation of the electronic system upon the excitation of an electron [44]. The authors speculate that ‘...the ability of the SIRC potential to produce considerably better band structures than DFT-LDA may reflect an extra nonlocality in the SIRC pseudopotential, related to the nonlocality or orbital dependence in the SIC all-electron potential. In addition, it may mimic some of the energy and the non-local space dependence of the self-energy operator occurring in the GW approximation of the electronic many body problem’ [45].

The LDA also fails for strongly correlated electronic systems. Examples of such systems are the late 3d transition-metal mono-oxides MnO, FeO, CoO, and NiO. Within the local spin density approximation (LSDA), the energy gaps calculated for MnO and NiO are too small [46] and, even worse, FeO and CoO are predicted to be metallic, whereas experimentally they have been found to be large-gap insulators. While the GW approximation yields an energy gap of NiO in reasonable agreement with experiment [47], the computational cost of this procedure is very high. The SIC-LDA method reproduces quite well the strong localization of the d electrons in transition metal compounds, but the orbital energies obtained by SIC are usually in strong disagreement with experimental results (for transition metal oxides, for example, occupied d bands are approximately $\frac{1}{2}$ Hartree below the oxygen valence band—a separation not seen in spectroscopic data: see, for example, the experimental results in [48]) [49]. An alternative solution to this problem is offered by the LDA+ U method [49, 50], where LDA encompasses the LSDA. In the LDA+ U technique, the electrons are divided into two subsystems which are treated separately: the strongly localized (d or f) electrons and the delocalized s and p electrons. The latter are treated by standard LDA. The on-site interactions among the

strongly localized electrons on each atom, however, are taken into account by a term $\frac{1}{2}U \sum_{i \neq j} n_i n_j$, where n_i are the occupation numbers of the strongly localized orbitals and U is the Coulomb interaction parameter (for details on the first-principles calculation of U , see [51]). At least for localized d or f states, the LDA+ U technique may be viewed as an approximation to the GW approximation [49]. Band gaps, valence band widths and magnetic moments have been calculated with LDA+ U that agree with experiment for a variety of transition metal compounds [49, 52], among other applications.

B3.2.3.2 ALL-ELECTRON DFT METHODS

(A) INTRODUCTION

When the highest accuracy is sought for the electronic and geometric properties of crystals, all the electrons of the atoms in the crystal and the full Coulomb singularity of the nuclear potential must be accounted for. All-electron approaches, which do just that, generally cannot compete with pseudopotential techniques in speed and simplicity of algorithm. However, the latter suffer from severe drawbacks when it comes to the construction of the very pseudopotentials these methods depend upon: even for so-called *ab initio* potentials, the pseudopotentials are far from uniquely determined. Additionally, problems with transferability and the construction of potentials for such elements as the transition metals remain. All-electron techniques can deal with any element and there are no worries about transferability of the potential. However, the accuracy comes at a price: due to the Coulomb singularity of the potential at the nuclear positions, the wavefunctions are highly oscillatory close to the nucleus. For those all-electron methods that use wavefunctions to represent the electrons (a Green's function method, for example, does not), this means that a simple plane wave basis set cannot be used for the expansion of the wavefunctions. To reach convergence of a plane wave $\exp(i\mathbf{k} \cdot \mathbf{r})$ expansion would require a prohibitive number of basis functions. Thus, specialized basis sets have been invented for all-electron calculations.

We now discuss the most important theoretical methods developed thus far: the augmented plane wave (APW) and the Korringa–Kohn–Rostoker (KKR) methods, as well as the linear methods (linear APW (LAPW), the linear muffin-tin orbital [LMTO] and the projector-augmented wave [PAW]) methods.

In the early all-electron techniques, the crystal was separated into spheres around the atoms, so-called ‘muffin-tin’ spheres, and the interstitial region in between. Inside the spheres, the potential was approximated as spherically symmetric, while in the interstitial region it was assumed to be constant. This shape approximation of the potential is reasonable for close-packed crystals such as hexagonally close-packed metals, where the spheres cover a large fraction of the crystal volume. However, in less densely arranged crystals, such as diamond structure semiconductors (see figure (A1.3.4) the muffin-tin approximation leads to large errors. In the diamond and the related zincblende structures, only 34% of the volume is covered by touching muffin-tin spheres (figure (B3.2.3)). For all of the all-electron methods, versions have been developed that are not restricted to shape approximations of the potential. These techniques are referred to as general, or full, potential methods.

Figure B3.2.3. The muffin-tin spheres in the (110) plane of a zincblende crystal. The nuclei are surrounded by spheres of equal size, covering about 34% of the crystal volume. Unoccupied tetrahedral positions are indicated by crosses. The conventional unit cell is shown at the bottom; the crystal directions are noted.

(B) THE AUGMENTED PLANE WAVE METHOD

The APW technique was proposed by Slater in 1937 [53, 54]. It remains the most accurate of the band structure methods for the muffin-tin approximation of the potential. The wavefunction is expanded in basis functions $\varphi_i(\mathbf{k} + \mathbf{G}_i, E, \mathbf{r})$, the APWs, each of which is identical to the plane wave $\exp(i(\mathbf{k} + \mathbf{G}_i) \cdot \mathbf{r})$ in the interstitial region, where \mathbf{G}_i are the reciprocal lattice vectors (see section A1.3.4). The plane waves are augmented, i.e. they are joined continuously at the surface of the spheres by solutions of the radial Schrödinger equation. This means that in the spherical harmonic expansion of a plane wave around the centre of a muffin-tin sphere, the respective Bessel function inside the sphere is replaced by a solution $\phi_{li}(r, E)$ of the radial Schrödinger equation for a given energy. The radial function matches the Bessel function, $j_l(|\mathbf{k} + \mathbf{G}_i|r)$, value at the sphere boundary and must be regular (non-singular) at the origin.

-12-

With the basis functions $\varphi_i(\mathbf{k} + \mathbf{G}_i, E, \mathbf{r})$, a variational solution is sought to the Kohn–Sham equation, equation (B3.2.4). Since the Hamiltonian matrix elements now depend nonlinearly upon the energy due to the energy-dependent basis functions, the resulting secular equation is solved by finding the roots of the determinant of the $\underline{H}(E) - E\underline{S}(E)$ matrix. (The problem cannot be treated by the eigenvalue routines of linear algebra.)

Numerically, the determination of the roots can be difficult because the determinant's value may change by several orders of magnitude when the energy E is changed by only a few meV. Another difficulty can result at degenerate roots where the value of the determinant does not change sign. Additionally, the secular equation becomes singular when a node of the radial solution falls at the muffin-tin sphere boundary (the so-called 'asymptote problem').

Physically, the APW basis functions are problematic as they are not smooth at the sphere boundary, i.e., they have discontinuous slope. While in a fully converged solution of the secular equation, this discontinuity should disappear, alternative methods have been sought instead. Following a suggestion by Marcus [55] in 1967, the LAPW provided a way to avoid the above-mentioned drawbacks of the APW technique, as we now discuss.

(C) THE LINEAR AUGMENTED PLANE WAVE METHOD

The main disadvantage of the APW technique is that it leads to a nonlinear secular problem because the basis functions depend on the energy. A number of attempts have been made to construct linear versions of the APW approach by introducing energy-independent basis functions in different ways. In 1970, Koelling invented the *alternative* APW [56] and Bross the *modified* APW [57]. In 1975, Andersen constructed the LAPW [58] formalism, which today is the most popular APW-like band structure method. Further extensions of the linear methods appeared in the early 1990s: Singh developed the LAPW *plus localized orbitals* (LAPW+LO [59]) in 1991 and Krasovskii the *extended* LAPW (ELAPW [60]) in 1994. Recently the APW+LO technique has been implemented by Sjöstedt and Nordström [61] according to an idea by Singh. While the LAPW technique is generally used in combination with DFT approaches, it has also been applied based on the LDA+ U [62] and HF theories [63].

The LAPW method, as suggested in 1975 [58, 64], avoids the problem of the energy dependence of the Hamiltonian matrix by introducing energy-independent APW basis functions. Here, too, the APWs are derived from plane waves by augmentation: Bessel functions $j_l(|\mathbf{k} + \mathbf{G}_l|r)$ in the Rayleigh decomposition inside the muffin-tin sphere are replaced by functions $u_l(r)$ derived from the spherical potential, which are *independent* of the energy of the state that is sought and that match the Bessel functions at the sphere radius in value and in slope (see figure (B3.2.4)). The plane wave part of the basis remains the same but the energy-independent APWs allow the energies and the wavefunctions to be determined by solving a standard generalized eigenvalue problem.

-13-

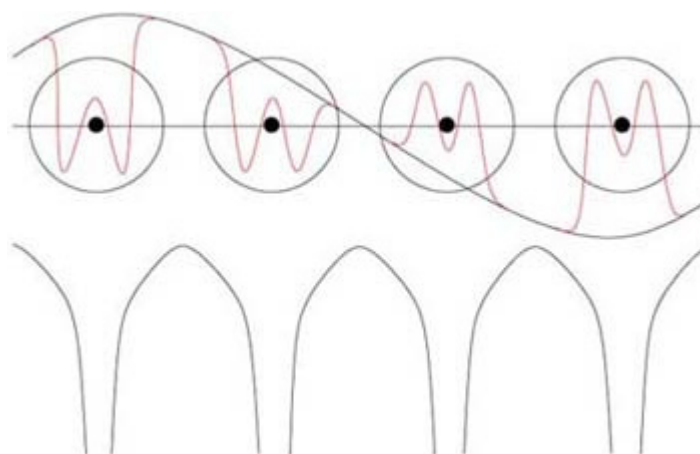

Figure B3.2.4. A schematic illustration of an energy-independent augmented plane wave basis function used in the LAPW method. The black sine function represents the plane wave, the localized oscillations represent the augmentation of the function inside the atomic spheres used for the solution of the Schrödinger equation. The nuclei are represented by filled black circles. In the lower part of the picture, the crystal potential is sketched.

In linearizing the APW problem as it is done in the LAPW method, the variational freedom of the APW basis set is reduced. The reason is that the wavefunction inside the spheres is rigidly coupled to its plane wave expansion in the interstitial region [65]. This means that the method cannot yield an accurate wavefunction even if the eigenvalue is within a few eV of the chosen energy parameters [66]. Flexibility is defined in this context as the possibility to change the wavefunction inside the spheres independently from the wavefunction in the interstitial region. Flexibility can be achieved in the linear band structure methods by adding basis functions localized inside the spheres whose value and slope vanish at the sphere boundary [54, 67, 68]. A ‘flexible’ basis set extending the LAPW with localized functions is preferable to the one used in the pure LAPW technique. Flexible linear methods are the MAPW, the LAPW+LO and the ELAPW, the latter of which provides a necessary degree of flexibility with a minimal number of basis functions [65].

The additional functions increase the matrix dimension slightly and thus the computational effort. However, the increased flexibility of the basis set makes possible a number of extensions of the LAPW method. One is a $\mathbf{k} \cdot \mathbf{p}$ formulation of the ELAPW method [68], which would lead to large errors in the regular LAPW due to its lesser flexibility. The augmented Fourier components (AFC) technique [69] for treating a general potential is based on this. The AFC method is an alternative to the full-potential LAPW (FLAPW) method [70, 71]. (Recently progress has been made in increasing the computational efficiency of the FLAPW method [72].) The AFC method does not have the same demanding convergence criteria as the FLAPW method but yields physically equivalent results [69].

The general potential LAPW techniques are generally acknowledged to represent the state of the art with respect to accuracy in condensed matter electronic-structure calculations (see, for example, [62, 73]). These methods can provide the best possible answer within DFT with regard to energies and wavefunctions.

-14-

(D) THE KORRINGA-KOHN-ROSTOKER TECHNIQUE

The KKR method uses multiple-scattering theory to solve the Kohn-Sham equations [74, 75]. Rather than calculate the wavefunction, modern incarnations calculate the Green's function G . The Green's function is the solution to the equation schematically given by $(H - E)G(E) = -\delta$, where H is the Hamiltonian, E the single-electron energy and δ the delta function $\delta(\mathbf{r} - \mathbf{r}')$. The properties of the system, such as the electron density, the density of states and the total energy can be derived from the Green's function [73]. The crystal is represented as a sum of non-overlapping potentials; in the modern version, there are no shape approximations, i.e. the potentials are space-filling [76]. Within the multiple-scattering formalism, the wavefunction is built up by taking into account the scattering and rescattering of a free-electron wavefunction by scatterers. The scatterers are (generally) the atoms of the crystal and the single-scattering properties (the properties of the isolated scatterer) are derived from the effective, singular potentials of the atoms (given in equation (B3.2.2)). The Green's matrix is then constructed from the knowledge of the scattering properties of the single scatterers and the analytically known Green's function of the free electron. The full-potential KKR method has been shown to have the same level of accuracy as the full-potential LAPW method [73]. The Green's function formulation offers the advantage of easy inclusion of defects in the bulk or clean surfaces. Such calculations start with the Green's function of the periodic crystal and include the perturbation through a Dyson equation [77]. Yussouff states that the difference in speeds between the linear methods and his 'fast' KKR technique is at most a factor of ten, in favour of the former [78]. While the KKR technique has an accuracy comparable to the APW method, it has the disadvantage of not being a linear approach, limiting speed and simplicity.

(E) THE LINEAR MUFFIN-TIN ORBITAL METHOD

The LMTO method [58, 79] can be considered to be the linear version of the KKR technique. According to official LMTO historians, the method has now reached its 'third generation' [79]: the first starting with Andersen in 1975 [58], the second commonly known as TB-LMTO. In the LMTO approach, the wavefunction is expanded in a basis of so-called muffin-tin orbitals. These orbitals are adapted to the potential by constructing them from solutions of the radial Schrödinger equation so as to form a minimal basis set. Interstitial properties are represented by Hankel functions, which means that, in contrast to the LAPW technique, the orbitals are localized in real space. The small basis set makes the method fast computationally, yet at the same time it restricts the accuracy. The localization of the basis functions diminishes the quality of the description of the wavefunction in the interstitial region.

In the commonly used atomic sphere approximation (ASA) [79], the density and the potential of the crystal are approximated as spherically symmetric within overlapping muffin-tin spheres. Additionally, all integrals, such as for the Coulomb potential, are performed only over the spheres. The limits on the accuracy of the method imposed by the ASA can be overcome with the full-potential version of the LMTO (FP-LMTO)

which gives highly accurate total energies [79, 80]. It was found that the FP-LMTO is ‘at least as accurate as, and much faster than,’ pseudopotential plane wave calculations in the determination of structural and dynamic properties of silicon [80]. The FP-LMTO is considerably slower than LMTO-ASA, however, and it has been found that ASA calculations can yield accurate results if the full expansion, rather than only the spherical part, of the charge is used in what is called a full-charge (rather than a full-potential) method and the integrals are performed exactly [73, 79].

The LMTO method is the fastest among the all-electron methods mentioned here due to the small basis size. The accuracy of the general potential technique can be high, but LAPW results remain the ‘gold standard’.

(F) THE PROJECTOR AUGMENTED WAVE TECHNIQUE

The projector augmented-wave (PAW) DFT method was invented by Blöchl to generalize both the pseudopotential and the LAPW DFT techniques [81]. PAW, however, provides all-electron one-particle wavefunctions not accessible with the pseudopotential approach. The central idea of the PAW is to express the all-electron quantities in terms of a pseudo-wavefunction (easily expanded in plane waves) term that describes interstitial contributions well, and one-centre corrections expanded in terms of atom-centred functions, that allow for the recovery of the all-electron quantities. The LAPW method is a special case of the PAW method and the pseudopotential formalism is obtained by an approximation. Comparisons of the PAW method to other all-electron methods show an accuracy similar to the FLAPW results and an efficiency comparable to plane wave pseudopotential calculations [82, 83]. PAW is also formulated to carry out DFT dynamics, where the forces on nuclei and wavefunctions are calculated from the PAW wavefunctions. (Another all-electron DFT molecular dynamics technique using a mixed-basis approach is applied in [84].)

PAW is a recent addition to the all-electron electronic structure methods whose accuracy appears to be similar to that of the general potential LAPW approach. The implementation of the molecular dynamics formalism enables easy structure optimization in this method.

(G) ILLUSTRATIVE EXAMPLES OF THE ELECTRONIC AND OPTICAL PROPERTIES OF MODERN MATERIALS

As an indication of the types of information gleaned from all-electron methods, we focus on one recent approach, the ELAPW method. It has been used to determine the band structure and optical properties over a wide energy range for a variety of crystal structures and chemical compositions ranging from elementary metals [60] to complex oxides [85], layered dichalcogenides [86, 87] and nanoporous semiconductors [88]. The $\mathbf{k} \cdot \mathbf{p}$ formulation has also enabled calculation of the complex band structure of the Al (100) surface [89].

As an illustration of the accuracy of the AFC ELAPW- $\mathbf{k} \cdot \mathbf{p}$ method, we present the dielectric function of GaAs. The dielectric function is a good gauge of the quality of a method, since not only do the energies enter the calculation, but also the wavefunctions *via* the matrix elements of the momentum operator $-i\nabla$. For the calculation of the dielectric function (equation (A1.3.87)) of GaAs, the conduction bands were rigidly shifted so that the highest peak agreed in both experiment and theory, a shift of 0.75 eV. The imaginary part of the dielectric function is shown in [figure B3.2.5](#). Comparing the energy differences between the three peaks, we find that they agree to within 2 meV. For a wider comparison, we plot the results of two more experiments (which only have measured the two peaks at lower photon energy) and several all-electron calculations of the dielectric function of GaAs in [figure B3.2.6](#). The FLAPW results agree almost exactly with the AFC ELAPW values. The discrepancies compared to the experimental results found for the other methods are considerably larger than for the general potential LAPW results, particularly for E_1 .

Figure B3.2.5. The imaginary part of the dielectric function of GaAs, according to the AFC ELAPW- $k\cdot p$ method (solid curve) [195] and the experiment (dashed curve) [196]. To correct for the band gap underestimated by the local density approximation, the conduction bands have been shifted so that the E_2 peaks agree in theory and experiment.

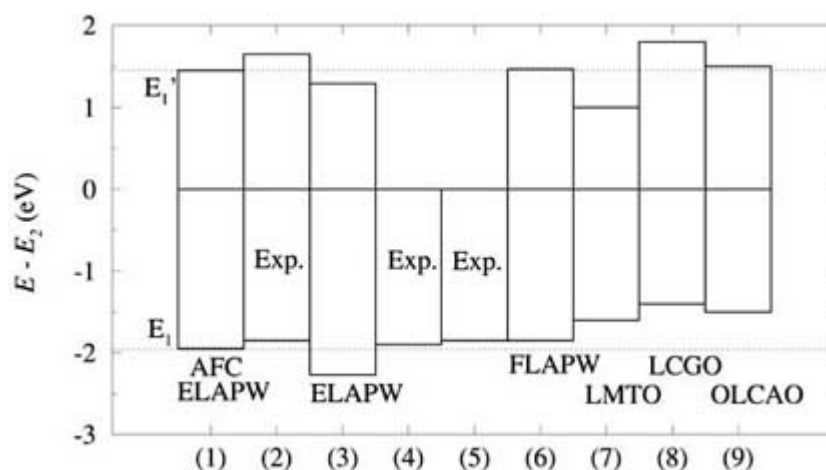

Figure B3.2.6. The energies of the E_1 and E'_1 peaks relative to the E_2 peak of the imaginary part of the dielectric function of GaAs, calculated by self-consistent DFT all-electron methods. These energies do not depend on the gap size. The theoretical methods are noted, as are experimental results obtained by ellipsometry (see [chapter B1.2.6](#)). The lower (upper) histogram gives the energy of peak E_1 (E'_1) relative to E_2 . LCGO designates a linear-combination-of-Gaussian-orbitals method, OLCAO an orthogonalized linear-combination-of-atomic-orbitals approach. Sources: (1) [195], (2) [196], (3) [197], (4) [198], (5) [199], (6) [200], (7) [199], (8) [201], (9) [202].

A recent study of a class of nanoporous materials, the cetineites [88], offers further illustration of the possibilities offered by the modern band structure methods. The crystal is constructed of tubes of 0.7 nm diameter arranged in a two-dimensional hexagonal structure with ‘flattened’ SbSe_3 pyramids arranged between the tubes (see figure B3.2.7). Cetineites are of potential technological interest because, singularly among nanoporous materials, they are semiconductors rather than insulators. In [figure B3.2.8](#), we show the

comparison of the predicted density of states to the ultraviolet photoemission spectrum (PES, see [chapter B1.1](#)). The DOS can explain the two main structures in the PES at about -3 and -12 eV. Their relative intensities agree with those suggested by the DOS curve. Three structures in the DOS at -1 , -6 and -9 eV are not resolved in the PES. This may be due to the selection rules of the photoemission process, not accounted for in the theory, or perhaps due to incomplete angle integration experimentally. The experimental results confirm, in particular, that the number of states is very high close to the valence band maximum. An orbital analysis shows that these states are derived mainly from the p states of the O and Se constituents of the crystal, with the chalcogen dominating near the top of the valence band. Electrons in the Se p states are thus most easily excited into the conduction band. This, together with their high DOS, makes the Se p states located on the pyramids the prime candidates for the initial states of the photoconductivity observed in the cetineites.

Figure B3.2.7. A perspective view of the cetineite (Na;Se). The height of the figure is three lattice constants c . The shaded tube is included only as a guide to the eye. (From [88].)

Figure B3.2.8. Comparison of the photoemission spectrum for the cetinite (Na;Se) and the density of states calculated by the AFC ELAPW- k - p method [88].

As another example of properties extracted from all-electron methods, figure B3.2.9 shows the results of a PAW simulation of benzene molecules on a graphite surface. The study aimed to show the extent to which the electronic structure of the molecule is modified by interaction with the surface, and why the images do not reflect the molecular structure. The PAW method was used to determine the structure of the molecule at the surface, the strength of the interaction between the surface and the molecules, and to predict and explain scanning tunnelling microscope (STM) images of the molecule on the surface [90] (the STM is described in section B1.19).

Figure B3.2.9. A benzene molecule on a graphite surface [90]. The geometry and the charge density (indicated by the surfaces of constant density) have been obtained using the PAW method. (Figure by Professor P E Blöchl.)

B3.2.3.3 LINEAR-SCALING ELECTRONIC STRUCTURE METHODS

DFT calculations such as the ones mentioned in chapter A1.3 and section B3.2.3.2 become computationally very expensive when the unit cell of the interesting system becomes large and complex, with certain parts of the computational algorithm typically scaling cubically with system size. A recent objective for treating large systems is to have the computational burden scale no more than linearly with system size. Methods achieving this are called linear-scaling or $O(N)$ (order N) methods, most of which are based on the Kohn–Sham equation (see equation (B3.2.4)), aiming to calculate single-electron wavefunctions, the Kohn–Sham orbitals. These

methods tend to be faster than the conventional Kohn–Sham approach above a few hundred atoms [20, 91, 92 and 93]. Another class of methods is based directly on the DFT of Hohenberg and Kohn [24]. With these techniques one seeks to determine directly the density that minimizes the total energy; they are often referred to as orbital-free methods [94, 95, 96 and 97]. Such orbital-free calculations do not have the bottlenecks present in orbital-based $O(N)$ DFT calculations, such as the need to localize orbitals to achieve linear scaling, orbital orthonormalization, or Brillouin zone sampling. Without such bottlenecks, the calculations become very inexpensive.

Equation (B3.2.3) lists the terms comprising the calculation of the total energy. The term due to the external potential and the Hartree term describing the Coulomb repulsion energy among the electrons already explicitly depend on the density instead of on orbitals. More difficult to evaluate is $G[\rho] = T_s[\rho] + E_{xc}[\rho]$, a functional which is not known exactly. However, over the years a number of high-quality exchange–correlation functionals have been developed for all kinds of systems. Only quite recently have more accurate kinetic energy density functionals (KEDFs) become available [97, 98 and 99] that afford linear-scaling computations.

One current limitation of orbital-free DFT is that since only the total density is calculated, there is no way to identify contributions from electronic states of a certain angular momentum character l . This identification is exploited in non-local pseudopotentials so that electrons of different l character ‘see’ different potentials, considerably improving the quality of these pseudopotentials. The orbital-free methods thus are limited to local pseudopotentials, connecting the quality of their results to the quality of the available local potentials. Good local pseudopotentials are available for the alkali metals, the alkaline earth metals and aluminium [100, 101] and methods exist for obtaining them for other atoms (see section VI.2 of [97]).

The orbital-free method has been used for molecular-dynamics studies of the formation of the self-interstitial defect in Al [102], pressure-induced glass-to-crystal transitions in sodium [103] and ion–electron correlations in liquid metals [101]. Calculations of densities for various Al surfaces have shown excellent agreement between the charge densities as calculated by Kohn–Sham DFT and an orbital-free method using a KEDF with a density-dependent response kernel [99]. The method was used recently to examine the metal–insulator transition in a two-dimensional array of metal quantum dots [104], where the theory showed that minute overlap of the nanoparticle’s wavefunctions is enough to transform the array from an insulator to a metal. As an example of the ease with which large simulations can be performed, figure B3.2.10 shows a plot of the charge density from an orbital-free calculation of a vacancy among 255 Al atoms [98], carried out on a workstation.

Figure B3.2.10. Contour plot of the electron density obtained by an orbital-free Hohenberg–Kohn technique [98]. The figure shows a vacancy in bulk aluminium in a 256-site cell containing 255 Al atoms and one empty site, the vacancy. Dark areas represent low electron density and light areas represent high electron density. A Kohn–Sham calculation for a cell of this size would be prohibitively expensive. Calculations on smaller cell sizes using both techniques yielded densities that were practically identical.

B3.2.3.4 THE HARTREE–FOCK METHOD IN CRYSTALS

The HF method (discussed in section A1.3.1.2) is an alternative to DFT approaches. It does not include electron correlation effects, i.e. non-classical electron–electron interactions beyond the Coulomb and exchange interactions. The neglect of these terms means that the Coulomb interaction is unscreened, and hence the electron repulsion energy is too large, overestimating ionic character, which leads to band gaps that are too large by a factor of two or more and valence band widths that are too wide by 30–40% [63]. However, the HF results can be used as a well defined starting point for the inclusion of many-particle corrections such as the GW approximation [31, 32] or, with considerably less computational effort, the results can be improved considerably by accounting for the Coulomb hole and screening the exchange interaction using the dielectric function [63, 105].

Ab initio HF programs for crystals have been developed [106, 107] and have been applied to a wide variety of bulk and surface systems [108, 109]. As an example, a periodic HF calculation using pseudopotentials and an LCAO basis predicted binding energies, lattice parameters, bulk moduli and central-zone phonon frequencies of 17 III–V and IV–IV semiconductors. The authors find that ‘...[o]n the whole, the HF LCAO data appear no worse than other *ab initio* results obtained with DF-based Hamiltonians’ [110]. They suggest that the largest part of the errors with respect to experiment is due to correlation effects and to a lesser extent due to the imperfections of the pseudopotentials [110]. More recently, the electronic and magnetic properties of transition metal oxides and halides such as perovskites, which had been a problem earlier, have been investigated with spin-unrestricted HF [111]. In general, the periodic HF method is best suited for the study of highly ionic, large band gap crystals because such systems are the least sensitive to the lack of electron correlation.

B3.2.3.5 QUANTUM MONTE CARLO

QMC techniques provide highly accurate calculations of many-electron systems. In variational QMC (VMC) [112, 113 and 114], the total energy of the many-electron system is calculated as the expectation value of the Hamiltonian. Parameters in a trial wavefunction are optimized so as to find the lowest-energy state (modern methods instead minimize the variance of the local energy $\frac{H\Psi}{\Psi}$ [115]). A Monte Carlo (MC) method is used to perform the multi-dimensional integrations necessary to determine the expectation value,

$$E = \frac{\int |\Psi|^2 \frac{H\Psi}{\Psi} d\tau}{\int |\Psi|^2 d\tau}$$

where ψ is the trial wavefunction and $|\Psi|^2 / \int |\Psi|^2 d\tau$ is a normalized probability distribution. The integration is performed by summing up the local energy at points, corresponding to electron configurations, given by the probability distribution. A random walk algorithm, such as the Metropolis algorithm [116], is used to sample those regions of configuration space more heavily where the probability density is high. The standard Slater–Jastrow trial wavefunction is the product of a Slater determinant of single-electron orbitals and a Jastrow factor, a function which includes the description of two-electron correlation. As an example, the trial wavefunction used for a silicon crystal contained 32 variational parameters whose optimization required the calculation of the local energy for 10 000–20 000 statistically independent electron configurations [117]. In contrast to the DMC technique described below, the accuracy of a VMC calculation depends on the quality of the many-particle wavefunction used [114]. In figure B3.2.11 we show the determination of the lattice constant of GaAs by VMC by minimization of the total energy [118]. This figure illustrates the roughness of the potential energy surface due to statistical errors, which poses a challenge then for the calculation of forces with QMC.

Figure B3.2.11. Total energy *versus* lattice constant of gallium arsenide from a VMC calculation including 256 valence electrons [118]; the curve is a quadratic fit. The error bars reflect the uncertainties of individual values. The experimental lattice constant is 10.68 au, the QMC result is 10.69 (± 0.1) au (Figure by Professor W Schattke).

In the diffusion QMC (DMC) method [114, 119], the evolution of a trial wavefunction (typically wavefunctions of the Slater–Jastrow type, for example, obtained by VMC) proceeds in imaginary time, $\tau = it$, according to the time-dependent Schrödinger equation, which then becomes a diffusion equation. All

components of the wavefunction except for the ground-state wavefunction are damped by the time evolution operator $\exp(-iHt) = \exp(-H\tau)$. The DMC was developed as a simplification of the Green's function MC technique [113]. A particularly well known use of the Green's function MC technique was the determination by Ceperley and Alder of the energy of the uniform electron gas as a function of its density [120]. This $E(\rho)$ was subsequently parametrized by Perdew and Zunger for the commonly used LDA exchange–correlation potential [40]. Usually two approximations are made to make DMC calculations tractable: the fixed-node approximation, in which the nodes, the places where the trial function changes sign, are kept fixed for the solution to enforce the fermion symmetry of the wavefunction and the so-called short-time approximation, whose effect can be made very small [114]. Excited states have been calculated by replacing an orbital in the Slater determinant of the trial wavefunction by a conduction-band orbital [121].

Recently, a method has been proposed to overcome the problems associated with calculating forces in both VMC and DMC [122]. It has been suggested that the use of QMC in the near future to tackle the energetics of systems as challenging as liquid binary iron alloys is not unthinkable [123].

B3.2.3.6 SUMMARY AND COMPARISONS

As we have outlined, a very wide variety of methods are available to calculate the electronic structure of solids. Empirical TB methods (such as discussed in [section B3.2.2](#)) are the least expensive, affording the calculation of unit cells with large numbers (e.g. 10^3) of atoms, or to provide cheap input to subsequent methods, at the price of quantitative accuracy. DFT methods ([section A1.3.5.4](#) and [section B3.2.3.3](#)), on the other hand, are responsible for many of the impressive results obtained in computational materials theory in recent years. The tradeoff for DFT is the opposite: its expense, except in the not-yet-general linear scaling methods, limits it typically to systems with at most a few hundred atoms. Once the $O(N)$ DFT methods become more general (for example, when orbital-free DFT can treat non-metallic systems), then the DFT method will be able routinely to treat systems as large as those treated now with TB.

The diversity of approaches based on HF ([section B3.2.3.4](#)) is small at present compared to the diversity found for DFT. For solids, HF appears to yield results inferior to DFT due to the neglect of electron correlation, but being a genuine many-particle theory it offers the possibility for consistent corrections, in contrast to DFT. Finally, the QMC techniques ([section B3.2.3.4](#)) hold promise for genuine many-particle calculations, yet they are still far from able to offer the same quantities for the same range of materials and geometries as the theories mentioned before. With this wide range of methods now introduced, we will look at their application to chemisorption on solid surfaces.

B3.2.4 QUANTUM STRUCTURAL METHODS FOR SOLID SURFACES

B3.2.4.1 INTRODUCTION

First-principles models of solid surfaces and adsorption and reaction of atoms and molecules on those surfaces range from *ab initio* quantum chemistry (HF; configuration interaction (CI), perturbation theory (PT), etc: for details see [chapter B3.1](#)) on small, finite clusters of atoms to HF or DFT on two-dimensionally infinite slabs. In between these

two extremes lie embedded cluster models, which recognize and attempt to correct the drastic approximation made by using a finite cluster to describe, for example, a metallic conductor whose electronic structure is inherently delocalized or an ionic crystal with long-range Coulomb interactions. Upon chemisorption, the binding of an atom or a molecule to a surface involves significant sharing of electrons in the bond between the

adsorbate and surface atoms and this breaking of the crystal symmetry will induce localization of the electrons. The attractive feature of the embedded cluster idea is that it preserves the strengths of the cluster approach, namely it allows one to describe the very local process of chemisorption to a high degree of accuracy by, for example, quantum chemical methods, while at the same time attempting to account for the presence of the rest of the surface and bulk. Surface reconstruction and molecular adsorption have been studied on a variety of surfaces, including insulators, semiconductors and metals. To illustrate these methods, we will focus on those used to examine adsorption of atoms and molecules on transition metal surfaces. This is not a comprehensive review of each approach; rather, we provide selected examples that demonstrate the range of techniques and applications, and some of the lessons learned.

B3.2.4.2 THE FINITE CLUSTER MODEL

The most straightforward molecular quantum mechanical approach is to treat adsorption on a small, finite cluster of transition metal atoms, ranging from as small as four atoms up to ~40 atoms. Though all-electron calculations can be performed, typically the core electrons of transition metal atoms are replaced by an effective core potential (ECP, the quantum chemistry version of a pseudopotential that accounts approximately for the core–valence electron interaction), while the valence electrons of each metal atom are treated explicitly within a HF, CI, PT, or DFT formalism. Typically, a few atoms in the chemisorption region contain the valence (or all) electrons explicitly, while surrounding atoms tend to be described more crudely with, for example, a one-electron ECP representation, model pseudopotentials or, in the case of ionic crystals, a finite array of point charges. Generally, the structure of the cluster is chosen to be a fixed fragment of the bulk. Examples of this type of approach include the early work of Upton and Goddard [124], who examined adsorption of electronegative and electropositive atoms on a Ni₂₀ cluster designed to mimic various low-index faces of Ni. In this model, only the 4s electrons on each Ni atom were treated explicitly, while the 3d electrons were subsumed into an ECP. They made predictions concerning preferred binding sites, geometries, vibrational frequencies and binding energies. Bagus *et al* [125] published an important comparison study showing that it is more accurate to treat metal atoms directly interacting with an adsorbate at an all-electron level, while it is sufficient to describe the surrounding metal atoms with ECPs. Panas *et al* [126] proposed the idea that a cluster should be ‘bond-prepared’, namely that one should study an electronic state of the finite cluster that has enough singly-occupied orbitals of the correct symmetry to interact with the incoming molecule to form the necessary covalent bonds between the adsorbate and the metal. In one of the first studies of a metal surface reaction, Panas *et al* [127] examined dissociative chemisorption pathways at the multi-reference CI level for O₂ on a Ni₁₃ cluster, generally using ECPs for all but the 4s electrons. Salahub and co-workers [128] used DFT-LDA with a Gaussian basis to examine chemisorption of C, O, H, CO and HCOO on Ni clusters containing up to 16 atoms meant to represent various low-index faces of Ni. Gradient corrections to the LDA scheme improved dramatically the binding energies for hydrogen bound to small Ni clusters, when compared to experimental results for Ni(111) and Ni(100) [129]. Multiple adsorbates were also studied by DFT-LDA: for example, in the case of hydrogen on Pd clusters modelling Pd(110) [130]. Diffusion barriers were also calculated by DFT-LDA for clusters containing up to 13 metal atoms of Pd, Rh, Sn, and Zn [131]. Other examples include HF calculations of K adsorbed on Cu clusters [132], HF and Møller–Plesset second-order PT (MP2) calculations of acetylene on Cu and Pd clusters [133], modified coupled pair functional (CPF) calculations for CO on Cu clusters [134], averaged CPF calculations of hydrogen adsorption on relaxed Cu clusters [135], HF, CASSCF (complete active space self-consistent field) and multireference CI and PT calculations for CO [136] and O [137] on Pt clusters, and spin-polarized DFT of *c*-CH₂N₂ on Pd and Cu tetramers [138] and of K and CO on Pd_{8,14} [139].

The advantage of the finite-cluster model is that one can systematically include high levels of electron correlation; this is to be balanced against the lack of a proper band structure, the presence of edge effects and the fact that it is generally limited to modelling low coverages. Next we outline current strategies for ameliorating some of these difficulties.

B3.2.4.3 FINITE-CLUSTER MODEL IN CONTACT WITH A CLASSICAL BACKGROUND

Several modifications of the finite-cluster model meant to account for the background Fermi sea of electrons and to compensate for the lack of a proper band structure have been developed. They rely on simple approximations of the surface/bulk, usually involving classical electrostatic interactions and usually applied to ionic crystals (see, for example, [140]). Of these, the model invented by Nakatsuji is the primary one that has considered adsorption on metal surfaces [141]. The so-called ‘dipped adcluster model’ [142] considers a small cluster plus an adsorbate as the ‘adcluster’ that is ‘dipped’ onto the Fermi sea of electrons of the bulk metal. A normal HF calculation on the small system is performed, in which electrons are added to or removed from the cluster in each calculation. By comparing the variation in the total energy with respect to the fractional electron transfer, dE/dn , to the work function of the metal, μ , the extent of electron transfer between the adcluster and the bulk metal can be established. Thus, charges on a small cluster are optimized and an image charge correction is also accounted for. In certain cases, integral charges are transferred between the cluster and the ‘surroundings’; then electron correlation calculations, for example CI, can be carried out. This is a purely classical electrostatic approach to accounting for the background electrons in an implicit, rather than explicit, manner. Nakatsuji has used this to study adsorption of ionic adsorbates on metals, and finds that one can describe the polarization of the metal reasonably well. We have worked briefly with this approach [143], but found that there is a problem with extending the method beyond two-dimensional clusters, because of an ambiguity of where to place the image plane. Indeed, Nakatsuji’s examples are always small one- or two-dimensional clusters. It is also likely that the wavefunction for such small clusters (typically ≤ 4 metal atoms) would not adequately represent a true metal surface wavefunction.

A simple, implicit means of describing the metallic band structure [144] was introduced by Rösch, using a Gaussian broadening of the cluster energy levels in order to determine a cluster Fermi level within DFT, originally by the X_α method (a simplified version of DFT-LDA; see section A1.3.3.3). Recent applications of this method have utilized more accurate forms of gradient-corrected spin-polarized DFT to look at adsorption of, for example, acetylene on $\text{Ni}_{14,20}$ clusters [145], CO adsorption on Ni, Pd and Pt clusters of eight or nine atoms [146] and NO adsorption on Ru [147].

B3.2.4.4 SLAB CALCULATIONS

The other extreme of modelling chemisorption is to use a slab described by DFT or HF. The slab is typically taken to be periodic in the directions parallel to the surface and contains a few atomic layers in the direction normal to the surface. For the adatoms not to influence each other, unless that is intended, the unit cell needs to be sufficiently large, parallel to the surface. For computational reasons, it is advantageous in some methods, namely plane wave techniques, to have periodicity in three dimensions. In the supercell geometry, this periodicity is gained by considering slabs which are periodic in the direction perpendicular to the surface but separated from each other by vacuum regions. The vacuum region has to be thick enough so that there is no influence between the surfaces facing each other (the same is true for the slab thickness). For a schematic description of several simulation model geometries, see [figure B3.2.12](#).

Figure B3.2.12. Schematic illustration of geometries used in the simulation of the chemisorption of a diatomic molecule on a surface (the third dimension is suppressed). The molecule is shown on a surface simulated by (A) a semi-infinite crystal, (B) a slab and an embedding region, (C) a slab with two-dimensional periodicity, (D) a slab in a supercell geometry and (E) a cluster.

Freeman and co-workers developed the FLAPW method (see B3.2.2) during the early 1980s [70, 148]. This was a major advance, because the conventional ‘muffin-tin’ potential was eliminated from their calculation allowing general-shape potentials to be evaluated instead. Freeman’s group first developed this for thin films and then for bulk metals. As mentioned before, the LAPW basis, along with the elimination of any shape approximations in the potential, allows for highly accurate calculations on transition metal surfaces, within the DFT-LDA and the generalized gradient approximation, GGA (see section A1.3.3.3). For the ‘stand-alone’ slab geometry, figure B3.2.12(C) the LAPW basis functions decay exponentially into the vacuum. The numerous interfacial systems examined by Freeman’s group include, for example, CO with K or S coadsorption on Ni(001) [149], adsorption of sulfur alone on Ni(001) [150], Fe monolayers on Ni(111) [151], Ag monolayers on MgO(001) [152], Au-capped Fe monolayers on MgO(001) [153], NO adsorption on Rh, Pd and Pt [154], and Li on Ru(001) [155]. Typical properties predicted are the equilibrium positions, magnetic moments, charge densities and surface densities of states.

More recently, other groups—primarily in Europe—have begun doing pseudopotential plane wave (often gradient-corrected) DFT supercell slab calculations (figure B3.2.12(D)) for chemisorption on metals. The groups of Nørskov [156], Scheffler [157], Baerends [158, 159] and Hafner and Kresse [160, 161] have been the most active. Adsorbate–metal surface systems examined include: alkalis and N₂ on Ru [156], NO on Pd [156], H₂ on Al [156], Cu [156, 158], Pd [157, 158] and sulfur-covered Pd [157], CO oxidation on Ru [157], CO on Ni, Pd and Pt [158], O on Pt [160], and H₂ on Rh, Pd and Ag [161].

An interesting study by te Velde and Baerends [159] compared slab- and cluster-DFT results for CO absorption on Cu(100). They found large oscillations in the chemisorption binding energy of CO to finite copper clusters as a function of cluster size. This suggests that the finite-cluster model (figure B3.2.12(E)) is likely to be inadequate, at least for modelling metal surfaces. By contrast, the slab calculations converge quickly with the number of Cu layers for the CO heat of adsorption and CO–CO distances.

The supercell plane wave DFT approach is periodic in three dimensions, which has some disadvantages: (i) thick vacuum layers are required so the slab does not interact with its images, (ii) for a tractably sized unit cell, only high adsorbate coverages are modelled readily and (iii) one is limited in accuracy by the form of the

exchange–correlation functional chosen. In particular, while DFT, especially using gradient-corrected forms of the exchange–correlation functional (GGA), has proven to be remarkably reliable in many instances, there are a number of examples for chemisorption in which the commonly used GGAs have been shown to fail dramatically (errors in binding energies of 1 eV or greater) [162, 163]. This naturally motivates the next set of approaches, namely the embedded cluster strategy.

B3.2.4.5 EMBEDDED-CLUSTER SCHEMES: CLUSTER IN CLUSTER

Whitten and co-workers developed a metal cluster embedding scheme appropriate for CI calculations during the 1980s [164]. In essence, the method consists of: (i) solving for a HF minimum basis set (one 4s orbital/atom) description of a large cluster (e.g., ~30–90 atoms); (ii) localizing the orbitals *via* exchange energy maximization with atomic basis functions on the periphery; (iii) using these localized orbitals to set up effective Coulomb and exchange operators for the electrons within the cluster to be embedded; (iv) improving the basis set on the atoms comprising the embedded cluster and (v) performing a small CI calculation ($O(10^3)$ configurations) within orbitals localized on the embedded cluster. This strategy provides an approximate way of accounting for nearby electrons outside the embedded cluster itself. Whitten and co-workers have applied it to a variety of adsorbates (H, N, O, C—containing small molecules) on, primarily, Ni surfaces. Duarte and Salahub recently reported a DFT-cluster-in-DFT-cluster variant of Whitten’s embedding, with a couple of twists on the original approach (for example, fractional orbital occupancies and charges, and an extra buffer region) [165]. Earlier, Sellers developed a related scheme for embedding a MP2 cluster within another cluster, where the background was modelled with screened ECPs [166]. Also, Ravenek and Geurts [167] and Fukunishi and Nakatsuji [168] extended the Green’s matrix method of Pisani [169] (who developed it mainly for ionic crystals) to again embed a cluster within a cluster by introducing a semiorthogonal basis and renormalizing the charge on the cluster. It was implemented within the X_α method in the former case [167], and by broadening each discrete energy level to mimic the bulk band structure within HF theory for the cluster in the latter case [168].

Pisani [169] has used the density of states from periodic HF (see B3.2.2.4) slab calculations to describe the host in which the cluster is embedded, where the applications have been primarily to ionic crystals such as LiF. The original calculation to derive the external Coulomb and exchange fields is usually done on a finite cluster and at a low level of *ab initio* theory (typically minimum basis set HF, one electron only per atom treated explicitly).

The main drawback of the cluster-in-cluster methods is that the embedding operators are derived from a wavefunction that does not reflect the proper periodicity of the crystal: a two-dimensionally infinite wavefunction/density with a proper band structure would be preferable. Indeed, Rösch and co-workers pointed out recently a series of problems with such cluster-in-cluster embedding approaches. These include the lack of marked improvement of the results over finite clusters of the same size, problems with the orbital space partitioning such that charge conservation is violated, spurious mixing of virtual orbitals into the density matrix [170], the inherent delocalized nature of metallic orbitals [171], etc.

B3.2.4.6 EMBEDDING OF CLUSTERS IN PERIODIC BACKGROUND

One of the first cluster embedding schemes was put forth by Ellis and co-workers [172]. They were interested in studying transition metal impurities in NiAl alloys, so they considered a TMAI_xNi_y cluster embedded in a periodic self-consistent crystal field appropriate for bulk β' -NiAl. The field was calculated via X_α calculations, as was the cluster itself. The idea was to provide a relatively inexpensive alternative to supercell DFT calculations.

Perhaps the most sophisticated embedding scheme for describing metal surfaces to date is the LDA-based

self-consistent Green's function method for semi-infinite crystals. Inglesfield, Benesh, and co-workers embed the near-surface layers using an embedding potential constructed from the bulk Green's function within an all-electron approach, using an LAPW basis [173]. Scheffler and co-workers developed a similar approach using a Gaussian basis for the valence electrons and pseudopotentials [174]. The formulation of the latter method is somewhat different from Inglesfield's and Benesh's, in that a reference system is chosen for which the Green's function and density are known (typically the bulk metal), and a Δ (Green's function) is solved for in order to get a Δ (embedding potential) and hence a Δ (density). This allows one to solve for the embedding potential locally in a small region around the adsorbate. These methods allow for an economical yet accurate calculation of the embedding density, which yields a trustworthy description of charge transfer and other equilibrium properties, though subject to the accuracy limitations inherent in DFT-LDA.

In the late 1980s, Feibelman developed his Green's function scattering method using LDA with pseudopotentials to describe adsorption on two-dimensionally infinite metal slabs [175], based on earlier work by Williams *et al* [176]. The physical basis for the technique is that the adsorbate may be considered a defect off which the Bloch waves of the perfect substrate scatter. The interaction region is short-range because of screening by the electron gas of the metal. Feibelman has used this technique to study, for example, the chemisorption of an H₂ molecule on Rh(001) [177], S adatoms on Al(331) [178] and Ag adatoms on Pt(111) [179]. Charge densities, relative energies for various adsites and diffusion barriers (the latter in good agreement with experiment) were the typical quantities predicted.

Krüger and Rösch implemented within DFT the Green's matrix approach of Pisani within an approximate periodic slab environment [180]. They were able to successfully extend Pisani's embedding approach to metal surfaces by smoothing out the step function that determines the occupation numbers near the Fermi level. Keys to the numerical success of their method included: (i) symmetric orthogonalization of the Bloch basis to produce a localized set of functions that yielded a balanced distribution of charge in the system and (ii) self-consistent evaluation of the Fermi energy by fixing the charge on the cluster to be neutral. The slab was described with a Slater basis at the DFT-LDA level, while the embedded cluster orbitals were expanded in terms of Gaussian functions at the DFT-LDA level. While some properties exhibited non-monotonic behaviour with increasing cluster size, the charge transfer between the metal surface and the adsorbate seemed to be well described. They concluded that properties are not well converged in this method if the cluster does not contain shells of metal atoms that are at least next-nearest-neighbours to the adsite metal atoms.

Head and Silva used occupation numbers obtained from a periodic HF density matrix for the substrate to define localized orbitals in the chemisorption region, which then defines a cluster subspace on which to carry out HF calculations [181]. Contributions from the surroundings also only come from the bare slab, as in the Green's matrix approach. Increases in computational power and improvements in minimization techniques have made it easier to obtain the electronic properties of adsorbates by supercell slab techniques, leading to the Green's function methods becoming less popular [182].

Cortona embedded a DFT calculation in an orbital-free DFT background for ionic crystals [183], which necessitates evaluation of kinetic energy density functionals (KEDFs). Wesolowski and Warshel [184] had similar ideas to Cortona, except they used a frozen density background to examine a solute in solution and examined the effect of varying the KEDF. Stefanovich and Truong also implemented Cortona's method with a frozen density background and applied it to, for example, water adsorption on NaCl(001) [185].

B3.2.4.7 EMBEDDING EXPLICIT CORRELATION METHODS IN A DFT BACKGROUND

In principle, DFT calculations with an ideal exchange–correlation functional should provide consistently accurate energetics. The catch is, of course, that the exact exchange–correlation functional is not known.

While various GGAs have been remarkably successful, there are notable exceptions [186, 187], including ones specific to surface adsorption mentioned earlier, where the binding-energy errors can be more than an eV [162, 163]. As another example, Louie and Cohen and co-workers found no systematic improvement over the LDA when gradient corrections were included in calculations of Al, Nb and Pd bulk properties, including the cohesive energy [186]. Indeed, the design of exchange–correlation functionals constitutes an active field of research (see, for example, [188]). The lack of completely systematic means to improve these functionals is an unappealing aspect of these calculations.

A first step towards a systematic improvement over DFT in a local region is the method of Aberenkov *et al* [189], who calculated a correlated wavefunction embedded in a DFT host. However, this is achieved using an analytic embedding potential function fitted to DFT results on an indented crystal. One must be cautious using a bare indented crystal to represent the surroundings, since the density at the surface of the indented crystal will have inappropriate Friedel oscillations inside and decay behaviour at the indented surface not present in the real crystal.

We have developed a different first-principles embedding theory that combines DFT with explicit correlation methods. We sought to develop a method for treating bulk or surface phases that is more accurate than current implementations of DFT. The idea is to provide more accurate predictions for local energetics, such as chemisorption binding energies and adsorbate electronic excitation energies. To achieve this, our theory improves upon the DFT description of electron correlation in a local region. This is accomplished by an embedding theory that treats a small region within an accurate quantum chemistry approach [190, 191], which interacts with its surroundings *via* an embedding potential, $v_{\text{embed}}(\mathbf{r})$. This $v_{\text{embed}}(\mathbf{r})$ is derived from a periodic DFT calculation on the total system. It is expressed purely in terms of orbital-free DFT (kinetic and potential energy) interaction terms between the embedded region and its surroundings *à la* Cortona and, in particular, purely in terms of functionals of the total density, ρ_{tot} , and the density of the embedded region, ρ_1 . We thus avoid construction of localized orbitals to describe the electrons in the surrounding environment. This is especially important for metal surfaces, where the extensive \mathbf{k} -point sampling required to get a well converged density makes localization impractical (very expensive). This way of expressing the embedding operator also eliminates problems that occur in other forms of embedding, such as those of matching conditions at the embedding boundary, or spurious charge transfer, since the electrostatic potential and the density are continuous by construction. Its only real disadvantage is that there is an arbitrariness associated with the choice of T_s . Development of optimal T_s functionals is an active area of research in our group [97, 98 and 99].

The self-consistent embedding cycle proceeds as follows. First, a well converged density, ρ_{tot} , is calculated for the extended metal surface in the presence of an adsorbate. This is accomplished within a standard pseudopotential plane wave DFT calculation (see [chapter A1.3](#)). Second, we partition the system into the region of interest (typically the adsorbate and neighbouring metal atoms at or near the surface) and its surroundings (all the other atoms in the periodic unit cell). The embedded region is defined by the integral number of electrons and nuclei within that region but not by

-29-

a particular physical, fixed boundary. This allows for the electron density from the embedded region to expand or contract variationally into the surroundings, thus affording some effective charge polarization to occur as needed.

The electron density, ρ_1 , of the embedded cluster/adsorbate atoms is calculated using quantum chemistry methods (HF, PT, multireference SCF, or CI). The initial step in this iterative procedure sets $v_{\text{embed}}(\mathbf{r})$ to zero, since ρ_1 is needed in order to calculate it. On subsequent iterations, the third step is to use ρ_1 and ρ_{tot} to calculate $v_{\text{embed}}(\mathbf{r})$, then insert it, as a one-electron operator expressed in matrix form in the atomic orbital basis of the adsorbate/cluster, into the quantum chemistry calculation of step two, and then ρ_1 is updated (*via* the wavefunction). We repeatedly update $v_{\text{embed}}(\mathbf{r})$ and then ρ_1 until full self-consistency is achieved, with

fixed ρ_{tot} . In this way, we variationally optimize both the quantum chemistry wavefunction and, implicitly, the density of the surroundings, subject to fixed ρ_{tot} . We tacitly assume that the DFT-slab density for the total system, ρ_{tot} , is in fact a good representation and does not need to be adjusted.

We have shown that our embedding total energies may be written in terms of the total energy obtained in step one (the DFT total energy for the entire system), plus a correction term, that subtracts out the DFT energy in the local region I and adds back in an *ab initio* total energy for that same region,

$$E_{\text{tot}}^{\text{embed}} = E_{\text{tot}}^{\text{DFT}} + (E_{\text{I}}^{\text{ab initio}} - E_{\text{I}}^{\text{DFT}}).$$

Thus, another way to think of the embedding is that the *ab initio* treatment of region I is *correcting* the DFT results in the same region, for the same self-consistent density. We expect, then, that such a treatment should reduce, for example, the famous LDA overbinding problem (LDA bond energies are generally significantly overestimated). We have indeed seen a smooth decrease in the LDA overbinding as a function of increasing electron correlation. We benchmarked the method against nearly exact calculations on a small system and then further corroborated it on experimentally well studied chemisorption systems: CO on transition metal surfaces. Our binding energies are in good agreement with nearly full configuration interaction in the former and experimental adsorbate binding energies in the latter. Very recently, we have demonstrated that excitation energies for adsorbed CO are dramatically improved compared to experiment upon inclusion of the embedding potential [192]. In the future, we hope this method will provide a general means for accurate predictions of the local electronic structure of condensed matter.

B3.2.5 OUTLOOK

Computational solid-state physics and chemistry are vibrant areas of research. The all-electron methods for high-accuracy electronic structure calculations mentioned in [section B3.2.3.2](#) are in active development, and with PAW, an efficient new all-electron method has recently been introduced. Ever more powerful computers enable more detailed predictions on systems of increasing size. At the same time, new, more complex materials require methods that are able to describe their large unit cells and diverse atomic make-up. Here, the new orbital-free DFT method may lead the way. More powerful techniques are also necessary for the accurate treatment of surfaces and their interaction with atoms and, possibly complex, molecules. Combined with recent progress in embedding theory, these developments make possible increasingly sophisticated predictions of the quantum structural properties of solids and solid surfaces.

ACKNOWLEDGMENTS

The authors would like to thank Professor P E Blöchl, Dr H Eckstein, Professor W Schattke, Professor K E Smith and T Strasser for making figures available for this publication. FS thanks Dr E E Krasovskii for introducing him to the LAPW method.

B3.3 Statistical mechanical simulations

Michael P Allen

B3.3.1 INTRODUCTION

Computer simulation, at the molecular level, has grown enormously in importance over the last 50 years. Affordable computer chips have historically doubled in power every 18 months, so the computer simulator, regarded as an experimentalist, has the unique advantage of rapidly improving apparatus. With the recent explosion in personal computing, there seems every prospect that this situation will continue, allowing computer simulation to become of even more practical value in fields such as the design of drugs and molecular materials. This provides a stimulus to develop simulation methods, and an industry has grown up marketing the necessary software.

This chapter concentrates on describing molecular simulation methods which have a connection with the statistical mechanical description of condensed matter, and hence relate to theoretical approaches to understanding phenomena such as phase equilibria, rare events, and quantum mechanical effects.

B3.3.1.1 THE AIMS OF SIMULATION

We carry out computer simulations in the hope of understanding bulk, macroscopic properties in terms of the microscopic details of molecular structure and interactions. This serves as a complement to conventional experiments, enabling us to learn something new; something that cannot be found out in other ways.

Computer simulations act as a bridge between microscopic length and time scales and the macroscopic world of the laboratory (see [figure B3.3.1](#)). We provide a guess at the interactions between molecules, and obtain ‘exact’ predictions of bulk properties. The predictions are ‘exact’ in the sense that they can be made as accurate as we like, subject to the limitations imposed by our computer budget. At the same time, the hidden detail behind bulk measurements can be revealed. Examples are the link between the diffusion coefficient and

velocity autocorrelation function (the former easy to measure experimentally, the latter much harder); and the connection between equations of state and structural correlation functions.

Simulations act as a bridge in another sense: between theory and experiment (see [figure B3.3.2](#) . We can test a theory using idealized models, conduct ‘thought experiments’, and clarify what we measure in the laboratory. We may also carry out simulations on the computer that are difficult or impossible in the laboratory (for example, working at extremes of temperature or pressure).

-2-

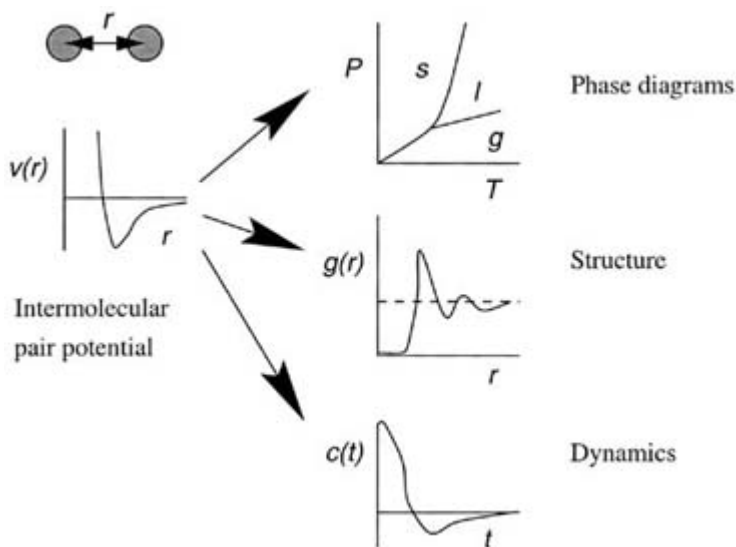

Figure B3.3.1. Simulations as a bridge between the microscopic and the macroscopic. We input details of molecular structure and interactions; we obtain predictions of phase behaviour, structural and time-dependent properties.

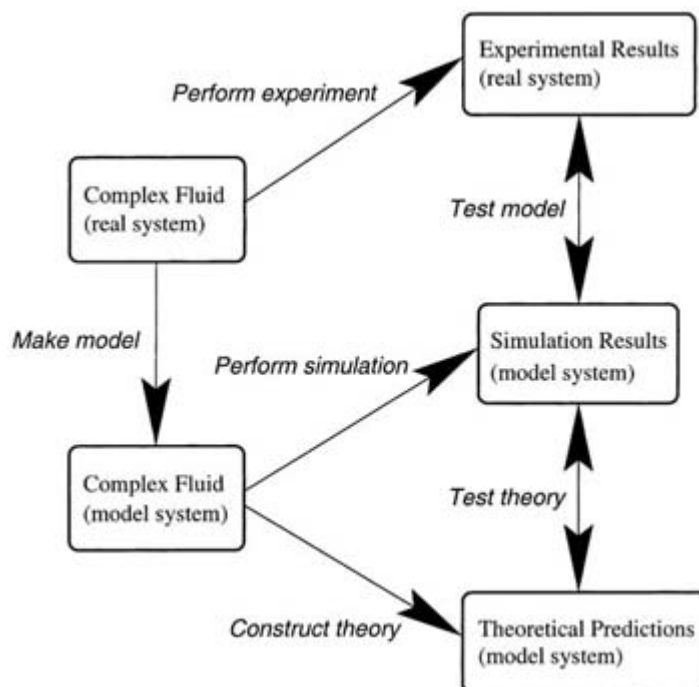

Figure B3.3.2. Simulation as a bridge between theory and experiment. We may test a theory by conducting a

simulation using the same model. We may test the model by comparing with experimental results.

-3-

Ultimately we may want to make direct comparisons with experimental measurements made on specific materials, in which case a good model of molecular interactions is essential. The aim of so-called *ab initio* molecular dynamics is to reduce the amount of fitting and guesswork in this process to a minimum. On the other hand, we may be interested in phenomena of a rather generic nature, or we may simply want to discriminate between good and bad theories. When it comes to aims of this kind, it is not necessary to have a perfectly realistic molecular model; one that contains the essential physics may be quite suitable.

The two main families of simulation technique are molecular dynamics (MD) and Monte Carlo (MC). Additionally, there is a whole range of hybrid techniques which combine features from both MC and MD.

B3.3.1.2 THE TECHNIQUES OF SIMULATION

Molecular dynamics consists of the brute-force solution of Newton's equations of motion. It is necessary to encode in the program the potential energy and force law of interaction between molecules; the equations of motion are solved numerically, by finite difference techniques. The system evolution corresponds closely to what happens in 'real life' and allows us to calculate dynamical properties, as well as thermodynamic and structural functions. For a range of molecular models, packaged routines are available, either commercially or through the academic community.

Monte Carlo can be thought of as a prescription for sampling configurations from a statistical ensemble. The interaction potential energy is coded into the program, and a random walk procedure adopted to go from one state of the system to the next. MC programs can be relatively easy to program; they allow us to calculate thermodynamic and structural properties, but not exact dynamics. It is relatively simple to specify external conditions (constant temperature, pressure etc.) and many tricks may be devised to improve the efficiency of the sampling.

Both MD and MC techniques evolve a finite-sized molecular configuration forward in time, in a step-by-step fashion. (In this context, MC simulation 'time' has to be interpreted liberally, but there is a broad connection between real time and simulation time (see [1, chapter 2].) Common features of MD and MC simulation techniques are that there are limits on the typical timescales and length scales that can be investigated. The consequences of finite size must be considered both in specifying the molecular interactions, and in analysing the results.

B3.3.2 SIMULATION AND STATISTICAL MECHANICS

Here we consider various aspects of statistical mechanics (see also [chapter A2.3](#) and [2, 3]) that have a direct bearing on computer simulation methodology.

B3.3.2.1 SIMULATION TIME AND LENGTH SCALES

Simulation runs are typically short ($t \sim 10^3 - 10^6$ MD or MC steps, corresponding to perhaps a few nanoseconds of real time) compared with the time allowed in laboratory experiments. This means that we need to test whether or not a simulation has reached equilibrium before we can trust the averages calculated in it. Moreover, there is a clear need to subject the simulation averages to a statistical analysis, to make a realistic estimate of the errors.

How long should we run? This depends on the system and the physical properties of interest. Suppose that we are interested in a variable X , defined such that its ensemble average $X = \langle \chi \rangle = 0$. (Here and throughout we use script letters for instantaneous dynamical variables, i.e., functions of coordinates and momenta, to distinguish them from averages and thermodynamic quantities.) A characteristic time, τ , may be defined, over which the correlations $\langle \chi(0)\chi(t) \rangle$ decay towards zero. The simulation run time t_{run} should be significantly longer than τ . The time scales of properties of interest will vary from one system to another; they may not be predictable in advance, and this will have a bearing on the length of simulation required.

Similar considerations apply to the size of system simulated. The samples involved are typically quite small on the laboratory scale. Most fall in the range $N \sim 10^3$ – 10^6 particles, thus imposing a restriction on the length scales of the phenomena that may be investigated, in the nanometre–submicron range. Indeed, in many cases, there is an overriding need to do a system-size analysis of simulation results, to quantify these effects.

How large a simulation do we need? Once more this depends on the system and properties of interest. From a spatial correlation function $\langle \chi(0)\chi(r) \rangle$ relating values computed at different points r apart, we may define a characteristic distance ξ over which the correlation decays. The simulation box size L should be significantly larger than ξ in order not to influence the results.

The ratios, t_{run}/τ and L/ξ , appear in expressions for estimating the errors on simulation-averaged quantities. Roughly speaking, a simulation sample can be regarded as a collection of $\sim(L/\xi)^3$ sub-samples, each making a statistically independent contribution to the average properties. Also, a simulation run may be regarded as a succession of $\sim t_{\text{run}}/\tau$ statistically independent sub-runs. Then, the usual rules for combining independent samples apply, and estimated error bars are inversely proportional to the square root of the run time. For further information see [4, 5, 6 and 7].

Near critical points, special care must be taken, because the inequality $L \gg \xi$ will almost certainly not be satisfied; also, critical slowing down will be observed. In these circumstances a quantitative investigation of finite size effects and correlation times, with some consideration of the appropriate scaling laws, must be undertaken. Examples of this will be seen later; one of the most encouraging developments of recent years has been the establishment of reliable and systematic methods of studying critical phenomena by simulation.

B3.3.2.2 PERIODIC BOUNDARY CONDITIONS

Small sample size means that, unless surface effects are of particular interest, periodic boundary conditions need to be used. Consider 1000 atoms arranged in a $10 \times 10 \times 10$ cube. Nearly half the atoms are on the outer faces, and these will have a large effect on the measured properties. Surrounding the cube with replicas of itself takes care of this problem. Provided the potential range is not too long, we can adopt the *minimum image convention* that each atom interacts with the nearest atom or image in the periodic array. In the course of the simulation, if an atom leaves the basic simulation box, attention can be switched to the incoming image. This is shown in [figure B3.3.3](#). Of course, it is important to bear in mind the imposed artificial periodicity when considering properties which are influenced by long-range correlations. Special attention must be paid to the case where the potential range is not short: for example, for charged and dipolar systems. Methods for handling this are discussed later.

Figure B3.3.3. Periodic boundary conditions. As a particle moves out of the simulation box, an image particle moves in to replace it. In calculating particle interactions within the cutoff range, both real and image neighbours are included.

B3.3.2.3 MOLECULAR INTERACTIONS

Let us denote a ‘state of the system’ by γ . For the purposes of discussion, we shall concentrate on a system composed of atoms, and for this γ represents the complete set of coordinates $\mathbf{r}^{(N)} = (r_1, r_2, \dots, r_N)$ and conjugate momenta $\mathbf{p}^{(N)} = (p_1, p_2, \dots, p_N)$. Then the energy, or Hamiltonian, may be written as a sum of kinetic and potential terms $\mathcal{H} = \mathcal{K} + \mathcal{V}$. For atomic systems, \mathcal{V} is a function of coordinates only and \mathcal{K} may be written as a function of momenta; in molecular systems represented as rigid bodies, or in terms of generalized coordinates, the kinetic energy may also depend on the coordinates [8].

Sticking, for simplicity, with a simple atomic system, the kinetic energy may be written

$$\mathcal{K}(\mathbf{p}_1, \mathbf{p}_2, \dots, \mathbf{p}_N) = \sum_{i=1}^N \sum_{\alpha=x,y,z} p_{i\alpha}^2 / 2m_i.$$

The potential energy \mathcal{V} is traditionally split into one-body, two-body, three-body . . . terms:

$$\mathcal{V}(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_N) = \sum_i v^{(1)}(\mathbf{r}_i) + \sum_i \sum_{j>i} v^{(2)}(\mathbf{r}_i, \mathbf{r}_j) + \sum_i \sum_{j>i} \sum_{k>j} v^{(3)}(\mathbf{r}_i, \mathbf{r}_j, \mathbf{r}_k) + \dots.$$

The $v^{(1)}$ term represents an externally applied potential field or the effects of the container walls; it is usually dropped for fully periodic simulations of bulk systems. Also, it is usual to neglect $v^{(3)}$ and higher terms (which in reality might be of order 10% of the total energy in condensed phases) and concentrate on $v^{(2)}$. For brevity henceforth we will just call this $v(r)$. There is an extensive literature on the way these potentials are determined experimentally, or modelled

theoretically (see, e.g., [9, 10 and 11]). In simulations, it is common to use the simplest models that faithfully represent the essential physics: the hard-sphere, square-well, and Lennard-Jones potentials have the longest

history. The latter has the functional form

$$v^{\text{LJ}}(r) = 4\varepsilon \left\{ \left(\frac{d}{r} \right)^{12} - \left(\frac{d}{r} \right)^6 \right\}$$

with two parameters: d , the diameter, and ε , the well depth. This potential was used, for instance, in the earliest studies of the properties of liquid argon [12, 13]. For molecular systems, we simply build the molecules out of site–site potentials of this, or similar, form (figure B3.3.4). If electrostatic charges are present, we add the appropriate Coulomb potentials

$$v^{\text{Coulomb}}(r) = \frac{Q_1 Q_2}{4\pi \epsilon_0 r}$$

where Q_1, Q_2 are the charges. We may also use rigid-body potentials which depend on centre of mass positions and orientations. An example is the Gay–Berne potential [14]

$$v^{\text{GB}}(r, \hat{\mathbf{u}}_1, \hat{\mathbf{u}}_2) = 4\varepsilon(\hat{\mathbf{r}}, \hat{\mathbf{u}}_1, \hat{\mathbf{u}}_2)[\varrho^{-12} - \varrho^{-6}]$$

with

$$\varrho = \frac{r - d(\hat{\mathbf{r}}, \hat{\mathbf{u}}_1, \hat{\mathbf{u}}_2) + d_0}{d_0}$$

which depends upon the molecular axis vectors $\hat{\mathbf{u}}_1$ and $\hat{\mathbf{u}}_2$, and on the direction $\hat{\mathbf{r}}$ and magnitude r of the centre–centre vector $\mathbf{r} = \mathbf{r}_1 - \mathbf{r}_2$. The parameter d_0 determines the smallest molecular diameter and there are two orientation-dependent quantities in the above shifted Lennard-Jones form: a diameter $d(\hat{\mathbf{r}}, \hat{\mathbf{u}}_1, \hat{\mathbf{u}}_2)$ and an energy $\varepsilon(\hat{\mathbf{u}}_1, \hat{\mathbf{u}}_2)$. Each quantity depends in a complicated way (not given here) on parameters characterizing molecular shape and structure. This potential has been extensively used in the study of molecular liquids and liquid crystals [15, 16, 17, 18, 19 and 20].

Figure B3.3.4. Lennard-Jones pair potential showing the r^{-12} and r^{-6} contributions.

It is common practice in classical computer simulations *not* to attempt to represent intramolecular bonds by terms in the potential energy function, because these bonds have very high vibration frequencies and should really be treated in a quantum mechanical way rather than in the classical approximation. Instead, the bonds are treated as being constrained to have fixed length, and some straightforward ways have been devised to incorporate these constraints into the dynamics (see later).

For a wide range of physical problems, a lattice spin system provides a useful, if very coarse-grained, description. The great advantage of such an approach is the speed with which such systems may be simulated, especially when a single spin may be taken to represent not just one molecule but a larger region of the physical system. The state γ of such systems may be specified by a set of discrete or continuous spin values $\sigma^{(N)} = (\sigma_1, \sigma_2, \dots, \sigma_N)$, where $\sigma_i = \pm 1$ for the archetypal Ising model, but takes other values for other models. For Ising-like systems, the energy may be written $\mathcal{H} = -J \sum_{\langle i,j \rangle} \sigma_i \sigma_j$, where $\sum_{\langle i,j \rangle}$ indicates a sum over nearest neighbour spins i, j and J is a coupling constant. Again, there is much flexibility in the nature of the energy function. There is an extensive literature on spin simulations [6, 21, 22 and 23] especially in relation to the theory of critical phenomena [24]. Spin models are not restricted to the obvious area of magnetic solids; it has proved possible to include, for instance, polymer liquids in this class [25], allowing the study of otherwise inaccessible behaviour.

B3.3.2.4 SIMULATIONS AND ENSEMBLES

One of the flexibilities of computer simulation is that it is possible to define the thermodynamic conditions corresponding to one of many statistical ensembles, each of which may be most suitable for the purpose of the study. A knowledge of the underlying statistical mechanics is essential in the design of correct simulation methods, and in the analysis of simulation results. Here we describe two of the most common statistical ensembles, but examples of the use of other ensembles will appear later in the chapter.

The microcanonical ensemble corresponds to an isolated system, with specified number of particles N ,

volume V , and energy E . The fundamental thermodynamic potential is the entropy, and it is related to statistical mechanical quantities as follows:

$$(B3.3.1)$$

Here, Ω_{NVE} is the number of states available to the system at given NVE , written as an integral over a thin energy shell; $\delta(\dots)$ is the Dirac delta function. The ensemble average $\langle \chi \rangle_{NVE}$ is defined in terms of the ensemble probability density function $Q_{NVE}(\Gamma)$.

The canonical ensemble corresponds to a system of fixed N and V , able to exchange energy with a thermal bath at temperature T , which represents the effects of the surroundings. The thermodynamic potential is the Helmholtz free energy, and it is related to the partition function Q_{NVT} as follows:

$$\begin{aligned} A &= E - TS = -kT \ln Q_{NVT} \\ Q_{NVT} &= \int d\Gamma e^{-\beta \mathcal{H}(\Gamma)} = \int dE \Omega_{NVE} e^{-\beta E} \\ Q_{NVT}(\Gamma) &= Q_{NVT}^{-1} e^{-\beta \mathcal{H}(\Gamma)} \\ \langle \mathcal{X} \rangle_{NVT} &= \int d\Gamma Q_{NVT}(\Gamma) \mathcal{X}(\Gamma). \end{aligned} \quad (B3.3.2)$$

Here $\beta=1/kT$. In a real system the thermal coupling with surroundings would happen at the surface; in simulations we avoid surface effects by allowing this to occur homogeneously. The state of the surroundings defines the temperature T of the ensemble.

Since $\mathcal{H}=\mathcal{K} + \mathcal{V}$, the canonical ensemble partition function factorizes into ideal gas and excess parts, and as a consequence most averages of interest may be split into corresponding ideal and excess components, which sum to give the total. In MC simulations, we frequently calculate just the excess or configurational parts: in this case, γ consists just of the atomic coordinates, not the momenta, and the appropriate expressions are obtained from equation b3.3.2 by replacing \mathcal{H} by the potential energy \mathcal{V} . The ideal gas contributions are usually easily calculated from exact

expressions, in which the integrations over atomic momenta have been carried out analytically.

B3.3.2.5 AVERAGES AND DISTRIBUTIONS

It is generally well known that, for most averages, differences between ensembles disappear in the thermodynamic limit. However, for finite-sized systems of the kind studied in simulations, it is necessary to consider the differences between ensembles, which will be significant for mean-squared values (fluctuations) and, more generally, for the probability distributions of measured quantities. For example, energy fluctuations in the constant- NVE ensemble are (by definition) zero, whereas in the constant- NVT ensemble they are not. Since these points have a bearing on various aspects of simulation methodology, we expand on them a little here.

It is a standard result in the canonical ensemble that energy fluctuations are related to the heat capacity $C_V = (\partial E / \partial T)_V$:

$$kT^2 C_V = \langle \mathcal{H}^2 \rangle - \langle \mathcal{H} \rangle^2 = \langle \delta \mathcal{H}^2 \rangle.$$

Since C_V and E are both extensive properties ($\propto N$), the root-mean-square energy fluctuations are smaller, by a factor $1/\sqrt{N}$, than typical average energies E . As the system size increases, the relative magnitude of fluctuations decreases, and the thermodynamic limit is achieved.

It is instructive to see this in terms of the canonical ensemble probability distribution function for the energy, $\mathcal{P}_{NVT}(E)$. Referring to [equation B3.3.1](#) and [equation \(B3.3.2\)](#), it is relatively easy to see that

$$\mathcal{P}_{NVT}(E) = \langle \delta(\mathcal{H}(\Gamma) - E) \rangle_{NVT} = \frac{\Omega_{NVE} e^{-E/kT}}{\mathcal{Q}_{NVT}}.$$

The product of a rapidly increasing function of energy, Ω_{NVE} , and a rapidly decreasing function $e^{-E/kT}$, gives a distribution of energies which is very sharply peaked about the most likely value, as shown in figure B3.3.5. A reasonable first approximation to $\mathcal{P}_{NVT}(E)$ is a Gaussian function, centred on this most probable value, with a width determined by C_V .

Figure B3.3.5. Energy distributions. The probability density is proportional to the product of the density of states and the Boltzmann factor.

-10-

In principle, these formulae may be used to convert results obtained at one state point into averages appropriate to a neighbouring state point. For any canonical ensemble average

$$\langle \mathcal{X} \rangle_{NVT_1} = \frac{\langle \mathcal{X} e^{-\delta\beta \mathcal{H}} \rangle_{NVT_0}}{\langle e^{-\delta\beta \mathcal{H}} \rangle_{NVT_0}} \quad (\text{B3.3.3})$$

$$\mathcal{P}_{NVT_1}(E) \equiv \langle \delta(\mathcal{H} - E) \rangle_{NVT_1} = \mathcal{P}_{NVT_0}(E) \frac{e^{-\delta\beta E}}{\langle e^{-\delta\beta \mathcal{H}} \rangle_{NVT_0}}. \quad (\text{B3.3.4})$$

where $\delta\beta = \beta_1 - \beta_0$. Choosing $\chi = \delta(\mathcal{H} - E)$ gives a way of re-weighting the energy distribution

Such histogram re-weighting techniques have a long history [26, 27, 28 and 29]. The usefulness of this equation depends sensitively on accurate sampling of energies in the region of interest, at T_1 , which may be far away from the maximum in \mathcal{P} . We have seen how the mean-squared fluctuations in E are related to the heat capacity; higher-order, non-Gaussian terms in $\mathcal{P}_{NVT}(E)$ are also related to thermodynamic derivatives [30, 31], but they are smaller, and so are hard to measure accurately. This limits the extension to nearby state points; a common theme of computer simulation is the devising of techniques to get around this problem, and we shall return to this later. Similar considerations apply to volume distributions in constant-pressure

ensembles, and indeed to other cases of thermodynamically conjugated pairs of variables.

Statistical mechanics may be used to derive practical microscopic formulae for thermodynamic quantities. A well-known example is the virial expression for the pressure, easily derived by scaling the atomic coordinates in the canonical ensemble partition function

$$PV = NkT - \frac{1}{3} \left\langle \sum_i \sum_{j \neq i} w_{ij} \right\rangle.$$

Here we assumed pairwise additivity $V = \sum_i \sum_{j \neq i} v_{ij}$, and defined $w(r) = r(dv(r)/dr)$. Also easily derived in the canonical ensemble is the general virial-like form, where q may be any coordinate or momentum,

$$\left\langle \mathcal{X} \frac{\partial \mathcal{H}}{\partial q} \right\rangle = kT \left\langle \frac{\partial \mathcal{X}}{\partial q} \right\rangle.$$

A well known example of this is obtained by setting $\chi = p_i \alpha$, $\alpha = x, y, z$, any component of momentum, giving the equipartition-of-energy relation

$$\left\langle \sum_{i\alpha} p_{i\alpha}^2 / 2m_i \right\rangle = \frac{3}{2} NkT.$$

This is commonly used to measure the temperature in a MD simulation. Less well known is the hypervirial relation

-11-

obtained by setting $\chi = -(\partial V / \partial r_{i\alpha}) = f_{i\alpha}$, a component of the force:

$$\left\langle \sum_{i\alpha} \left(\frac{\partial \mathcal{V}}{\partial r_{i\alpha}} \right)^2 \right\rangle = kT \left\langle \sum_{i\alpha} \left(\frac{\partial^2 \mathcal{V}}{\partial r_{i\alpha}^2} \right) \right\rangle$$

which relates the Laplacian of the potential with the mean-squared force. Butler et al [32] have suggested using this expression to measure the ‘configurational’ temperature (as a check) in MC simulations; they also provide a derivation of the corresponding expression in the microcanonical ensemble (see also [33]); it is surprising that this useful proposal has only been made so recently.

Finally, by considering increasing the number of particles by one in the canonical ensemble (looking at the excess, non-ideal, part), it is easy to derive the Widom [34] test-particle formula

$$\mu^{\text{ex}} \approx A_{N+1}^{\text{ex}} - A_N^{\text{ex}} = -kT \ln \langle e^{-\beta v_{\text{test}}} \rangle. \quad (\text{B3.3.5})$$

Here we have separated terms in the potential energy which involve the extra ‘test’ particle, $V_{N+1} = V_N + v_{\text{test}}$. The ensemble average here includes an unweighted average over inserted particle coordinates. In practice this means randomly inserting a test particle, many times, and averaging the Boltzmann factor of the associated energy change. More details of free energy calculations will be given later.

B3.3.2.6 TIME DEPENDENCE

A knowledge of time-dependent statistical mechanics is important in three general areas of simulation. First, in recent years there have been significant advances in the understanding of MD algorithms, which have arisen out of an appreciation of the formal operator approach to classical mechanics. Second, an understanding of equilibrium time correlation functions, their link with dynamical properties and especially their connection with transport coefficients, is essential in making contact with experiment. Third, the last decade has seen a rapid development of the use of nonequilibrium MD, with a better understanding of the formal aspects, particularly the link between the dynamical algorithm, dissipation, chaos and fractal geometry. Space does not permit a full description of this here: the interested reader should consult [35, 36] and references therein.

The Liouville equation dictates how the classical statistical mechanical distribution function $\varrho(\mathbf{r}^{(N)}, \mathbf{p}^{(N)}, t)$ evolves in time. (Also, quantum dynamics may be expressed in a formally equivalent way, but we shall concentrate exclusively on classical systems here.) From considerations of standard, Hamiltonian, mechanics [8] and the flow of representative systems in an ensemble through a particular region of phase space, it is easy to derive the Liouville equation

$$\frac{\partial \varrho}{\partial t} = - \left\{ \sum_{i\alpha} \dot{r}_{i\alpha} \frac{\partial}{\partial r_{i\alpha}} + \dot{p}_{i\alpha} \frac{\partial}{\partial p_{i\alpha}} \right\} \varrho \equiv -i\hat{L}\varrho$$

defining the Liouville operator \hat{L} . Compare this equation for ϱ with the time evolution equation for a dynamical variable $\chi(\mathbf{r}^{(N)}, \mathbf{p}^{(N)})$, which comes directly from the chain rule applied to Hamilton's equations

-12-

$$\dot{\chi} = \sum_{i\alpha} \dot{r}_{i\alpha} \frac{\partial \chi}{\partial r_{i\alpha}} + \dot{p}_{i\alpha} \frac{\partial \chi}{\partial p_{i\alpha}} \equiv i\hat{L}\chi.$$

The formal solutions of the time evolution equations are

$$\varrho(t) = e^{-i\hat{L}t} \varrho(0) \quad \text{and} \quad \chi(t) = e^{i\hat{L}t} \chi(0). \quad (\text{B3.3.6})$$

A number of manipulations are possible, once this formalism has been established. There are useful analogies both with the Eulerian and Lagrangian pictures of incompressible fluid flow, and with the Heisenberg and Schrödinger pictures of quantum mechanics [37, chapter 7], [38, chapter 11]. These analogies are particularly useful in formulating the equations of classical response theory [39], linking transport coefficients with both equilibrium and nonequilibrium simulations [35].

The Liouville equation applies to any ensemble, equilibrium or not. Equilibrium means that ϱ should be *stationary*, i.e., that

$$\partial \varrho / \partial t = 0.$$

In other words, if we look at any phase-space volume element, the rate of incoming state points should equal the rate of outflow. This requires that ϱ be a function of the constants of the motion, and especially $\varrho = \varrho(\mathcal{H})$. Equilibrium also implies $d\langle \chi \rangle / dt = 0$ for any χ . The extension of the above equations to nonequilibrium ensembles requires a consideration of entropy production, the method of controlling energy dissipation (thermostatting) and the consequent non-Liouville nature of the time evolution [35].

B3.3.3 MOLECULAR DYNAMICS

The solution of Newton's or Hamilton's equations on the computer

$$\dot{\mathbf{r}}_i = \mathbf{p}_i/m_i \quad \text{and} \quad \dot{\mathbf{p}}_i = \mathbf{f}_i$$

where m_i is the mass of atom i , and \mathbf{f}_i is the total force acting on it, is intrinsically a simple task. Many methods exist to perform step-by-step numerical integration of systems of coupled ordinary differential equations. Characteristics of these equations are: (a) they are 'stiff', i.e., there may be short and long time scales, and the algorithm must cope with both; (b) calculating the forces is expensive, typically involving a sum over pairs of atoms, and should be performed as infrequently as possible.

Also we must bear in mind that the advancement of the coordinates fulfils two functions: (i) accurate calculation of dynamical properties, especially over times as long as typical correlation times τ ; (ii) accurately staying on the constant-energy hypersurface, for much longer times t_{run} . Exact time reversibility is highly desirable (since the original equations

-13-

are exactly reversible). To ensure rapid sampling of phase space, we wish to make the time step as large as possible, consistent with these requirements. For these reasons, simulation algorithms have tended to be of *low order* (i.e., they do not involve storing high derivatives of positions, velocities etc): this allows the time step to be increased as much as possible without jeopardizing energy conservation. It is unrealistic to expect the numerical method to accurately follow the true trajectory for very long times t_{run} . The 'ergodic' and 'mixing' properties of classical trajectories, i.e., the fact that nearby trajectories diverge from each other exponentially quickly, make this impossible to achieve.

All these observations tend to favour the Verlet algorithm in one form or another, and we look closely at this in the following sections. For historical reasons only, we mention the more general class of predictor-corrector methods which have been optimized for classical mechanics simulations, [40, 41]; further details are available elsewhere [7, 42, 43].

B3.3.3.1 THE VERLET ALGORITHM

There are various, essentially equivalent, versions of the Verlet algorithm, including the original method employed by Verlet [13, 44] in his investigations of the properties of the Lennard-Jones fluid, and a 'leapfrog' form [45]. Here we concentrate on the 'velocity Verlet' algorithm [46], which may be written

$$\begin{aligned}\mathbf{r}_i(t + \delta t) &= \mathbf{r}_i(t) + \delta t \mathbf{p}_i(t)/m_i + \frac{1}{2} \delta t^2 \mathbf{f}_i(t)/m_i \\ \mathbf{p}_i(t + \delta t) &= \mathbf{p}_i(t) + \frac{1}{2} \delta t [\mathbf{f}_i(t) + \mathbf{f}_i(t + \delta t)].\end{aligned}$$

This advances the coordinates and momenta over a small time step δt . A piece of pseudo-code illustrates how this works:

```
call force(r,f)
do step = 1, nstep
  r = r + dt*p/m + (0.5*dt**2)*f/m
  p = p + 0.5*dt*f
  call force(r,f)
  p = p + 0.5*dt*f
enddo
```

The forces are calculated from the positions at the start of a simulation. They are used to advance the positions, and ‘half-advance’ the velocities or momenta. The new forces $\mathbf{f}(t+\delta t)$ are calculated, and these are used to complete the momentum update. At the end of the step, positions, momenta, and forces all conveniently refer to the same time point. Moreover, as we shall see shortly there is an interesting theoretical derivation of this version of the algorithm.

Important features of the Verlet algorithm are: (a) it is *exactly* time reversible; (b) it is *low* order in time, hence permitting long time steps; (c) it is easy to program.

-14-

B3.3.3.2 PROPAGATORS AND THE VERLET ALGORITHM

The velocity Verlet algorithm may be derived by considering a standard approximate decomposition of the Liouville operator which preserves reversibility and is *symplectic* (which implies that volume in phase space is conserved). This approach [47] has had several beneficial consequences.

The Liouville operator of equation b3.3.6 may be written [48]

$$e^{i\hat{L}t} = (e^{i\hat{L}\delta t})_{\text{approx}}^P + \mathcal{O}(P\delta t^3)$$

where $\delta t = t/P$ and an approximate propagator, correct at short time steps $\delta t \rightarrow 0$, appears in the parentheses. This is a formal way of stating what we do in MD, when we split a long time period t into a large number P of small time steps δt , using an *approximation* to the true equations of motion over each time step. It turns out that useful approximations arise from splitting \hat{L} into two parts

$$\hat{L} = \hat{L}_p + \hat{L}_r.$$

The following approximation

$$e^{i\hat{L}\delta t} = e^{(i\hat{L}_p + i\hat{L}_r)\delta t} \approx e^{i\hat{L}_p\delta t/2} e^{i\hat{L}_r\delta t} e^{i\hat{L}_p\delta t/2} \quad (\text{B3.3.7})$$

is asymptotically exact in the limit $\delta t \rightarrow 0$. For nonzero δt this is an approximation to $e^{i\hat{L}\delta t}$ because in general \hat{L}_p and \hat{L}_r do not commute, but it is still exactly time reversible. Tuckerman et al [47] set

$$i\hat{L}_p = \sum_{i\alpha} \dot{p}_{i\alpha} \frac{\partial}{\partial p_{i\alpha}} = \sum_{i\alpha} f_{i\alpha} \frac{\partial}{\partial p_{i\alpha}} \quad i\hat{L}_r = \sum_{i\alpha} \dot{r}_{i\alpha} \frac{\partial}{\partial r_{i\alpha}} = \sum_{i\alpha} (p_{i\alpha}/m) \frac{\partial}{\partial r_{i\alpha}}.$$

A straightforward derivation (not reproduced here) shows that the effect of the three successive steps embodied in equation (b3.3.7), with the above choice of operators, is precisely the velocity Verlet algorithm. This approach is particularly useful for generating multiple time-step methods.

B3.3.3.3 MULTIPLE TIME STEPS

An important extension of the MD method allows it to tackle systems with multiple time scales: for example, molecules which have very strong internal springs representing the bonds, while interacting externally through softer potentials, or molecules consisting of both heavy and light atoms. A simple MD algorithm will have to adopt a time step short enough to handle the fast-varying internal motions. Tuckerman et al [47] set

out methods for generating time-reversible Verlet-like algorithms using the Liouville operator formalism described above. Here we suppose that there are two types of force in the system: slow-moving external forces F_i and fast-moving internal forces f_i . The momentum satisfies $\dot{p} = f_i + F_i$. Then we break up the Liouville

-15-

operator $i\hat{L} = i\hat{L}_p + i\hat{\ell}$:

$$i\hat{L}_p = \sum_{i\alpha} F_{i\alpha} \frac{\partial}{\partial p_{i\alpha}} \quad i\hat{\ell} = \sum_{i\alpha} \dot{r}_{i\alpha} \frac{\partial}{\partial r_{i\alpha}} + f_{i\alpha} \frac{\partial}{\partial p_{i\alpha}} \equiv i\hat{\ell}_r + i\hat{\ell}_p.$$

The propagator approximately factorizes

$$e^{i\hat{L}\Delta t} \approx e^{i\hat{L}_p\Delta t/2} e^{i\hat{\ell}\Delta t} e^{i\hat{L}_p\Delta t/2}$$

where Δt represents a long time step. The middle part is then split again, using the conventional separation, and iterating over small time steps $\delta t = \Delta t/P$:

$$e^{i\hat{\ell}\Delta t} \approx [e^{i\frac{1}{2}\delta t\hat{\ell}_r} e^{i\delta t\hat{\ell}_p} e^{i\frac{1}{2}\delta t\hat{\ell}_r}]^P.$$

So the fast-varying forces must be computed many times at short intervals; the slow-varying forces are used just before and just after this stage, and they only need be calculated once per long time step.

This actually translates into a fairly simple algorithm, based closely on the standard velocity Verlet method. Written in a Fortran-like pseudo-code, it is as follows. At the start of the run we calculate both rapidly-varying (f) and slowly-varying (F) forces, then, in the main loop:

```

do STEP = 1, NSTEP
  p = p + 0.5*DT*F
  do step = 1, nstep
    r = r + dt*p/m + (0.5*dt**2)*f/m
    p = p + 0.5*dt*f
    call force(r,f)
    p = p + 0.5*dt*f
  enddo
  call FORCE(r,F)
  p = p + 0.5*DT*F
enddo

```

The entire simulation run consists of `NSTEP` long steps; each step consists of `nstep` shorter sub-steps. `DT` and `dt` are the corresponding time steps, `DT = nstep*dt`.

A particularly fruitful application, which has been incorporated into the computer code ORAC [49], is to split the interatomic force law into a succession of components covering different ranges: the short-range forces change rapidly with time and require a short time step, but advantage can be taken of the much slower time variation of the long-range forces, by using a longer time step and less frequent evaluation for these. Having said this, multiple time step algorithms are still under active study [50], and there is some concern that resonances may occur between the natural frequencies of the system under study, and the various time steps

used in schemes of this kind [51].

-16-

B3.3.3.4 CONSTRAINTS

Although, in principle, multiple time steps provide a method of integrating stiff degrees of freedom, such as intramolecular bonds, the alternative of rigidly constraining bond lengths is still very popular. In classical mechanics, constraints are introduced through the Lagrangian [8] or Hamiltonian [52] formalisms. Given a set of algebraic relations between atomic coordinates, for example, a fixed bond length b between atoms 1 and 2

$$\sigma(\mathbf{r}_1, \mathbf{r}_2) = (\mathbf{r}_1 - \mathbf{r}_2) \cdot (\mathbf{r}_1 - \mathbf{r}_2) - b^2 = 0$$

the constraint force between the atoms will have the following form

$$\mathbf{g}_1 = \lambda \frac{\partial \sigma}{\partial \mathbf{r}_1} \quad \text{and} \quad \mathbf{g}_2 = \lambda \frac{\partial \sigma}{\partial \mathbf{r}_2}$$

and it will appear in the equations of motion along with the normal forces. It is easy to derive an exact expression for the multiplier λ ; for many constraints, a system of equations (one per constraint) is obtained. In practice, since the equations of motion are only solved approximately, the constraints will be increasingly violated as the simulation proceeds. The breakthrough in this area came with the proposal of a scheme, SHAKE, to solve the equations for the constraint forces *approximately* (i.e., to the same level of approximation as the dynamical algorithm) in such a way that the constraints are satisfied exactly at the end of each time step [53, 54]; for a review see [55]. The appropriate version of this scheme for the velocity Verlet algorithm is called RATTLE [56].

It is important to realize that a simulation of a system with rigidly constrained bond lengths is not equivalent to a simulation with, for example, harmonic springs representing the bonds, even within the limit of very strong springs. One obvious point is that the momenta conjugated to the bond coordinates are nonzero and store some kinetic energy in the spring case, while they are zero by definition in the constrained case. A subtle, but crucial, consequence of this is that it has an effect on the distribution function for the other coordinates. If we obtain the configurational distribution function by integrating over the momenta, the difference arises because in one case a set of momenta is set to zero, and not integrated, while in the other an integration is performed, which may lead to an extra term depending on particle coordinates. This is frequently called the ‘metric tensor problem’; it is explained in more detail in [7, 57], and there are well-established ways of determining when the difference is likely to be significant [58] and how to handle it, if necessary [59].

Some people prefer to use the multiple time step approach to handle fast degrees of freedom, while others prefer to use constraints, and there are situations in which both techniques are applicable. Constraints also find an application in the study of rare events, where a system may be studied at the top of a free energy barrier (see later), or for convenience when it is desired to fix a thermodynamic order parameter or ordering direction [17].

B3.3.3.5 NEIGHBOUR LISTS

In the inner loops of MD and MC programs, we consider an atom i and loop over all atoms j to calculate the minimum image separations. If $r_{ij} > r_c$, the potential cutoff, the program skips to the end of the inner loop, avoiding expensive

calculations, and considers the next neighbour. In this method, the time to examine all pair separations is proportional to N^2 ; for every pair, one must compute at least r_{ij}^2 ; this still consumes a lot of time. Some economies result from the use of lists of nearby pairs of atoms.

Verlet [13] suggested a technique for improving the speed of a program by maintaining a list of neighbours. The potential cutoff sphere, of radius r_c , around a particular atom is surrounded by a 'skin', to give a larger sphere of radius r_{list} , as shown in figure B3.3.6. At the first step in a simulation, a list is constructed of all the neighbours of each atom, for which the pair separation is within r_{list} . Over the next few MD time steps, only pairs appearing in the list are checked in the force routine. From time to time the list is reconstructed: it is important to do this before any unlisted pairs have crossed the safety zone and come within interaction range. It is possible to trigger the list reconstruction automatically, if a record is kept of the distance travelled by each atom since the last update. The choice of list cutoff distance r_{list} is a compromise: larger lists will need to be reconstructed less frequently, but will not give as much of a saving on cpu time as smaller lists. This choice can easily be made by experimentation.

Figure B3.3.6. The Verlet list on its construction, later, and too late. The potential cutoff range, and the list range, are indicated. The list must be reconstructed before particles originally outside the list range have penetrated the potential cutoff sphere.

For larger systems ($N \geq 1000$ or so, depending on the potential range) another technique becomes preferable. The cubic simulation box (extension to noncubic cases is possible) is divided into a regular lattice of $n_c \times n_c \times n_c$ cells; see figure B3.3.7. These cells are chosen so that the side of the cell $r_{cell} = L/n_c$ is greater than the potential cutoff distance r_c . If there is a separate list of atoms in each of those cells, then searching through the neighbours is a rapid process: it is only necessary to look at atoms in the same cell as the atom of interest, and in nearest neighbour cells. The cell structure may be set up and used by the method of linked lists [45, 60]. The first part of the method involves sorting all the atoms into their appropriate cells. This sorting is rapid, and may be performed at every step. Then, within the force routine, pointers are used to scan through the contents of cells, and calculate pair forces. This approach is very efficient for large systems with short-range forces. A certain amount of unnecessary work is done because the search region is cubic, not (as for the Verlet list) spherical.

Figure B3.3.7. The cell structure. The potential cutoff range is indicated. In searching for neighbours of an atom, it is only necessary to examine the atom's own cell, and its nearest-neighbour cells.

B3.3.3.6 LONG-RANGE FORCES

Many realistic simulations will involve the Coulomb interaction between charges, which decreases with separation as r^{-1} , and the dipole–dipole interaction, which decreases as r^{-3} . These cannot be treated simply by applying a spherical cutoff: it is essential to consider the effects of the surrounding medium. Two somewhat different techniques have been used in the majority of computer simulations to handle long-range forces: the reaction field method and the Ewald sum.

In the reaction field method, the space surrounding a dipolar molecule is divided into two regions: (i) a cavity, within which electrostatic interactions are summed explicitly, and (ii) a surrounding medium, which is assumed to act like a smooth continuum, and is assigned a dielectric constant ϵ_r . Ideally, this quantity will be equal to the dielectric constant ϵ of the liquid itself, but calculating this, of course, is frequently one of the goals of the simulation, not one of the input parameters. The essence of the reaction field method is to calculate the total dipole moment of the molecules in the cavity, hence obtaining the polarization of the surrounding continuum, and to use this to work out the reaction field on the molecule at the centre. This supplements the direct electrostatic interaction with molecules in the cavity, in the calculation of the total energy. The reaction field method was used by Barker and Watts [61] in early simulations of water and has been discussed by Neumann and Steinhauser [62] and Patey et al [63].

In the Ewald method, a lattice sum is performed over charges within the periodically repeating simulation box. This is a subtle matter, since the sum, for Coulomb potentials, is only conditionally convergent: the result depends on the order of terms. Nonetheless, the procedure has been carefully analysed by de Leeuw et al [64] and Felderhof [65]. To make the summation a practical proposition, a trick is used: each point charge is screened by a surrounding, Gaussian, charge distribution, which makes the interactions short-ranged: these interactions are tackled in real space in the usual way. The contribution of an equal and opposite set of Gaussians is tackled in reciprocal space, using Fourier transforms. The choice of the width of the Gaussians is a parameter which may be varied to optimize the speed of calculation (for a given accuracy): Perram et al [66] have shown that the optimal choice leads to an algorithm whose expense grows as $N^{3/2}$.

When carried out properly, the results of the reaction field method and the Ewald sum are consistent [67]. Recently, the reaction field method has been recommended on grounds of efficiency and ease of programming [68, 69]. The

expense of the Ewald method, particularly as the system size grows, has led to the search for alternative formulations [see, e.g., 70]. Recently, the practical implementation of the Ewald method has been significantly improved. The smooth particle mesh Ewald method, inspired by the approach of [45], employs a mesh and an interpolation scheme to allow evaluation of the reciprocal space sums using fast Fourier transforms [71, 72]. This approach has been incorporated into a standard code [49] and seems very promising for large biomolecular systems. It has to be said that there are still some subtleties involved in the handling of long-range forces [see, e.g., 73] and the reader should consult carefully the references if approaching the simulation of such systems from the beginning.

B3.3.4 MONTE CARLO

It is important to realize that MC simulation does not provide a way of calculating the statistical mechanical partition function: instead, it is a method of sampling configurations from a given statistical ensemble and hence of calculating ensemble averages. A complete sum over states would be impossibly time consuming for systems consisting of more than a few atoms. Applying the trapezoidal rule, for instance, to the configurational part of Q_{NVT} , entails discretizing each atomic coordinate on a fine grid; then the dimensionality of the integral is extremely high, since there are $3N$ such coordinates, so the total number of grid points is astronomically high. The MC integration method is sometimes used to estimate multidimensional integrals by randomly sampling points. This is not feasible here, since a very small proportion of all points would be sampled in a reasonable time, and very few, if any, of these would have a large enough Boltzmann factor to contribute significantly to the partition function. MC simulation differs from such methods by sampling points in a nonuniform way, chosen to favour the important contributions.

B3.3.4.1 IMPORTANCE SAMPLING

MC simulation is a method of concentrating the sampled points in the important regions, namely the regions with high Boltzmann factor $e^{-\beta\mathcal{H}}$: a random walk is devised, moving from one point to the next, with a biasing probability chosen to generate the desired distribution. Unfortunately, a consequence of this approach is that it is no longer possible to estimate the partition function itself, merely *ratios* of sums over states, that is, ensemble averages. Suppose that we have succeeded in selecting states γ with probability proportional to $\varrho(\Gamma) = \exp\{-\beta\mathcal{H}(\Gamma)\}$. Then, if we have conducted N_t ‘observations’ or ‘steps’ in the process, the ensemble average becomes an average over steps

$$\langle \mathcal{X} \rangle_{NVT} = \sum_{\Gamma} \varrho(\Gamma) \mathcal{X}(\Gamma) = \frac{1}{N_t} \sum_{i=1}^{N_t} \mathcal{X}_i.$$

The Boltzmann weight appears *implicitly* in the way the states are chosen. The form of the above equation is like a time average as calculated in MD. The MC method involves designing a stochastic algorithm for stepping from one state of the system to the next, generating a trajectory. This will take the form of a *Markov chain*, specified by transition probabilities which are independent of the prior history of the system.

Write $\varrho(\Gamma) \equiv \varrho_{\Gamma}$ treating it as a component of a (very large) column vector. Consider an *ensemble* of systems all evolving at once. Specify a matrix whose elements $\pi_{\Gamma\leftarrow\gamma}$ give the probability of going to state Γ from state γ , for

every pair of states. The matrix must satisfy $\sum_{\Gamma'} \pi_{\Gamma' \leftarrow \Gamma} = 1$, to conserve probability. At each step, implement jumps with this transition matrix. This generates a *Markov chain* of states, i.e., one in which the transition probabilities do not depend on the history. Feller's theorem [74] tells us that, subject to some reasonable conditions, there exists a limiting (equilibrium) distribution of states and the system will tend towards this limiting distribution. (Recently [75], it has been shown that the Markov condition can be relaxed, and the system will still behave in this way.) A little thought shows that the limiting distribution will satisfy

$$Q_{\Gamma'} = \sum_{\Gamma} \pi_{\Gamma' \leftarrow \Gamma} Q_{\Gamma}$$

which is a matrix eigenvalue equation. The eigenvector is already known: it is the Boltzmann distribution. The MC method is specified by choosing a transition matrix which satisfies this equation. One way of guaranteeing this is to ensure that

$$\pi_{\Gamma \leftarrow \Gamma'} Q_{\Gamma'} = \pi_{\Gamma' \leftarrow \Gamma} Q_{\Gamma}$$

which is usually termed the *microscopic reversibility* condition. An immediate consequence of this is that the ratio of probabilities $Q_{\Gamma' \leftarrow \Gamma} / Q_{\Gamma \leftarrow \Gamma'}$ is equal to the ratio of transition matrix elements $\pi_{\Gamma' \leftarrow \Gamma} / \pi_{\Gamma \leftarrow \Gamma'}$. This relationship is analogous to that relating the equilibrium constant for a chemical reaction to the ratio of forward and backward rate constants.

The most commonly used prescription [76] is

$$\begin{aligned} \pi_{\Gamma' \leftarrow \Gamma} &= \alpha_{\Gamma' \leftarrow \Gamma} \min(1, Q_{\Gamma'} / Q_{\Gamma}) & \Gamma \neq \Gamma' \\ \pi_{\Gamma \leftarrow \Gamma} &= 1 - \sum_{\Gamma' \neq \Gamma} \pi_{\Gamma' \leftarrow \Gamma} & \text{otherwise.} \end{aligned}$$

Here, an underlying matrix, with elements $\alpha_{\Gamma' \leftarrow \Gamma}$, sets the probability of *attempting* a move like $\Gamma' \leftarrow \Gamma$, and the other factor gives the probability of *accepting* such a move. This scheme only requires a knowledge of the ratio $Q_{\Gamma' \leftarrow \Gamma} / Q_{\Gamma \leftarrow \Gamma'}$:

$$\min(1, Q_{\Gamma'} / Q_{\Gamma}) = \min(1, e^{-\beta(\mathcal{H}(\Gamma') - \mathcal{H}(\Gamma))}) = \min(1, e^{-\beta\delta\mathcal{H}}).$$

It does not require knowledge of the factor normalizing the Q , i.e., the partition function. For atomic and molecular systems, the partition function is split into a product of 'ideal' (exactly calculable) and 'excess' terms: the position and momentum distributions also factorize, and we wish to sample

$$Q_{NVT}(r) \propto \exp\{-\beta\mathcal{V}(r)\}.$$

The prescription for accepting or rejecting moves is exactly as written before, but with \mathcal{V} replacing \mathcal{H} . Assuming that the interaction potential is short-ranged, it is not necessary to perform a complete recalculation of \mathcal{V} every time an atom is moved: just the part involving that atom. For a given trial move, this is done twice: once before the attempted move and once after. Some improvement in efficiency may be obtained by using neighbour lists, as described earlier for MD.

Selecting trial moves in an unbiased way typically means (a) choose an atom 'randomly', with equal probability from the complete set; (b) displace it by random amounts in the x , y and z directions, chosen

independently and uniformly from a predefined range (symmetric about the origin). These choices use a random number generator; the quality of the random numbers may be an issue. A key aspect of move selection is that the probabilities for *attempting* forward and reverse moves must be equal, so $\alpha_{\Gamma \square \leftarrow \Gamma} = \alpha_{\Gamma \leftarrow \Gamma \square}$. For the above prescription, it should be evident that this is true, by considering the number of ways of selecting an atom, and the number of positions it might be moved to (assuming a fine discretization of space). In the case of a rigid molecule, move selection will include a procedure for randomly rotating a molecule in an unbiased way. The magnitudes of trial moves are parameters of the method, chosen to give a reasonable acceptance rate, traditionally 50% or so. There is no special reason for this value. Ideally, for every study, one would investigate which choice gives the most efficient sampling of phase space.

The analysis of Manousiouthakis and Deem [75] mentioned above has demonstrated that it is also correct to choose atoms sequentially rather than randomly: it has been tacitly assumed for many years that this violation of the Markovian restriction is acceptable, so a proof of this kind is very welcome.

B3.3.4.2 WEIGHTED AND BIASED SAMPLING

It is useful to write down here the basic formulae for sampling with an additional weight function applied, sometimes called non-Boltzmann or umbrella sampling, and for sampling when the selection of trial moves is done in a biased way, i.e., the α matrix is not symmetrical.

A weight factor $\mathcal{W}(\Gamma)$ may be introduced in the MC sampling algorithm, to generate a modified, or ‘weighted’, distribution,

$$q_{\mathcal{W}} \propto \mathcal{W}(\Gamma) \exp\{-\beta\mathcal{H}(\Gamma)\}.$$

The usual MC procedure is adopted, with trial moves $\Gamma' \leftarrow \Gamma$ selected as usual, but now accepted with probability

$$\min\left(1, \frac{\mathcal{W}(\Gamma')}{\mathcal{W}(\Gamma)} e^{-\beta\delta\mathcal{H}}\right).$$

In the calculation of ensemble averages, we correct for the weighting as follows

$$\langle \mathcal{X} \rangle = \frac{\langle \mathcal{X}/\mathcal{W} \rangle_{\mathcal{W}}}{\langle 1/\mathcal{W} \rangle_{\mathcal{W}}}$$

where $\langle \dots \rangle_{\mathcal{W}}$ represents the weighted simulation averages. This kind of sampling may be useful when the most important states for our purposes are not those which have the highest weights in the canonical ensemble: for example, when we wish to compute a free energy difference between two states. We will return to this later.

Biased move selection means that $\alpha_{\Gamma \square \leftarrow \Gamma} \neq \alpha_{\Gamma \leftarrow \Gamma \square}$. Suppose that we wish, nonetheless, to sample the canonical distribution. To do this, we need to calculate the ratio $\alpha_{\Gamma \square \leftarrow \Gamma} / \alpha_{\Gamma \leftarrow \Gamma \square}$ as well as $q_{\Gamma \square} / q_{\Gamma} = e^{-\beta\delta\mathcal{H}}$. Then we accept the move with probability

$$\min \left(1, \frac{\alpha_{\Gamma \leftarrow \Gamma'}}{\alpha_{\Gamma' \leftarrow \Gamma}} e^{-\beta \delta H} \right).$$

A consideration of the transition probabilities allows us to prove that microscopic reversibility holds, and that canonical ensemble averages are generated. This approach has greatly extended the range of simulations that can be performed. An early example was the preferential sampling of molecules near solutes [77], but more recently, as we shall see, polymer simulations have been greatly accelerated by this method.

B3.3.5 SIMULATION IN DIFFERENT ENSEMBLES

It is very convenient to be able to choose a nonstandard ensemble for a simulation. Generally, it is more straightforward to do this in MC, but MD techniques for various ensembles have been developed. We consider MC implementations first.

B3.3.5.1 MC IN DIFFERENT ENSEMBLES

The isothermal–isobaric ensemble corresponds to a system whose volume and energy can fluctuate, in exchange with its surroundings at specified NPT . The thermodynamic driving force is the Gibbs free energy $G = A + PV$. The configurational distribution function may be written

$$Q_{NPT}(\mathbf{s}^{(N)}, V) \propto V^N e^{-\beta PV} e^{-\beta \mathcal{V}}.$$

Here we have introduced scaled coordinates $\mathbf{s}^{(N)} = L^{-1} \mathbf{r}^{(N)}$ where L is the box length (assumed cubic).

This ensemble is a weighted superposition of NVT ensembles for different volumes. A typical MC sweep consists of N attempted single-particle moves, exactly as for constant- NVT MC, followed by one attempt to scale, homogeneously, the volume of the simulation box, together with the coordinates of all the particles in it. This is accepted or rejected so as to generate the above distribution. One prescription for selecting the volume move is to attempt to change $V \rightarrow V' = V + \delta V$ where δV is uniformly sampled from an interval $[-\delta V_{\max}, \delta V_{\max}]$. The new box length is computed, and all the particle coordinates scaled by an appropriate factor; then the new potential energy is computed. Assuming that the selection of δV is unbiased, the probability ratio to use in the Metropolis prescription is just the ratio of the two ensemble densities, $Q_{NPT}(V')/Q_{NPT}(V)$ and the move is accepted with probability

$$\min(1, e^{-\beta \delta \mathcal{W}}) \quad \text{where} \quad \delta \mathcal{W} = \delta \mathcal{V} + P \delta V - NkT \ln(V'/V).$$

Here $\delta \mathcal{V} = \mathcal{V}' - \mathcal{V}$ and $\delta V = V' - V$. The maximum attempted volume change is chosen to give a reasonable acceptance rate, traditionally 35–50% or so; there is no firm reason for this choice.

The above prescription for selecting volume changes is not unique. It may seem more natural to make random,

uniform, changes in the box length L ; some people prefer to sample V uniformly [78]. These choices are *not*

precisely consistent with the accept/reject procedure described above. They can be regarded as unbiased sampling of a variable different from V (in which case a simple transformation of variables is needed to convert Q_{NPT} into the new form, and additional powers of V will appear in it) or as biased sampling in V -space, in which case a small correction factor (the same extra powers of V) will appear in the accept/reject procedure. An analysis of the forward and backward transition probabilities will give the appropriate acceptance/rejection criterion in each case.

The grand canonical ensemble corresponds to a system whose number of particles and energy can fluctuate, in exchange with its surroundings at specified μ VT. The relevant thermodynamic quantity is the grand potential $\Omega = A - \mu N$. The configurational distribution is conveniently written

$$Q_{\mu VT}(s^{(N)}, N) \propto (N!)^{-1} V^N z^N \exp\{-\beta\mathcal{V}\}.$$

Here again we have introduced scaled coordinates $s^{(N)} = L^{-1}r^{(N)}$ where L is the box length (assumed cubic), $z = \exp\{\beta\mu\}/\Lambda^3$ is the activity, and $\Lambda = h/\Lambda = h/\sqrt{2\pi mkT}$ is the thermal de Broglie wavelength.

This ensemble is a weighted superposition of NVT ensembles with different values, of N . As a rule of thumb, a typical MC sweep consists of N attempted moves, each of which is chosen randomly to be (i) a displacement (handled exactly as in constant- NVT MC); (ii) the creation of a new particle at a randomly selected position; (iii) the destruction of a randomly selected particle from the system. The probabilities for attempting creation and destruction must be equal (for consistency with what follows), but they need not be equal to the probability for attempting displacement (although they often are).

For a creation attempt, a position is chosen uniformly at random within the box, and an attempt made to create a new particle there. The probability ratio for creation is:

$$\frac{Q_{\mu VT}(N+1)}{Q_{\mu VT}(N)} = \frac{zV}{N+1} \exp\{-\beta\delta\mathcal{V}\} \equiv \exp\{-\beta\delta\mathcal{Z}^{\text{create}}\}$$

where $\delta\mathcal{V} = \mathcal{V}' - \mathcal{V}$ is the potential energy change associated with inserting the new particle. In a Metropolis scheme, the creation attempt is accepted with probability $\min(1, \exp\{-\beta\delta\mathcal{Z}^{\text{create}}\})$.

For a destruction attempt, one of the existing N particles is selected at random, and an attempt made to destroy it. The probability ratio to use is

$$\frac{Q_{\mu VT}(N-1)}{Q_{\mu VT}(N)} = \frac{N}{zV} \exp\{-\beta\delta\mathcal{V}\} \equiv \exp\{-\beta\delta\mathcal{Z}^{\text{destroy}}\}$$

where $\delta\mathcal{V}$ is the potential energy change associated with removing the particle. In a Metropolis scheme, the destruction attempt is accepted with probability $\min(1, \exp\{-\beta\delta\mathcal{Z}^{\text{destroy}}\})$. These expressions can be shown to satisfy microscopic reversibility [57].

In a dense system, the acceptance rate of particle creation and deletion moves will decrease, and the number of attempts must be correspondingly increased: eventually, there will come a point at which grand canonical simulations are not practicable, without some tricks to enhance the sampling.

B3.3.5.2 MD IN DIFFERENT ENSEMBLES

In this section we discuss MD methods in the constant- NVT ensemble, and the constant- NPT ensemble.

There are three general approaches to conducting MD at constant temperature rather than constant energy. One method, simple to implement and reliable, is to periodically reselect atomic velocities at random from the Maxwell–Boltzmann distribution [79]. This is rather like an occasional random coupling with a thermal bath. The resampling may be done to individual atoms, or to the entire system; some guidance on the reselection frequency may be found in [79].

A second approach, due originally to Nos'e [80] and reformulated in a useful way by Hoover [81], is to introduce an extra ‘thermal reservoir’ variable into the dynamical equations:

$$\begin{aligned}\dot{\mathbf{r}}_i &= \mathbf{p}_i/m & \dot{\mathbf{p}}_i &= \mathbf{f}_i - \zeta \mathbf{p}_i \\ \dot{\zeta} &= \frac{\sum_{i\alpha} p_{i\alpha}^2/m - gkT}{Q} \equiv v_T^2 \left[\frac{\sum_{i\alpha} p_{i\alpha}^2/m}{gkT} - 1 \right] = v_T^2 \left[\frac{T}{T} - 1 \right].\end{aligned}$$

Here ζ is a friction coefficient which is allowed to vary in time; Q is a thermal inertia parameter, which may be replaced by v_T , a relaxation rate for thermal fluctuations; $g \approx 3N$ is the number of degrees of freedom. T stands for the instantaneous ‘mechanical’ temperature. It may be shown that the distribution function for the ensemble is proportional to $\exp\{-\beta\mathcal{H}'\}$ where $\mathcal{H}' = \mathcal{H} + \frac{1}{2}3NkT\zeta^2/v_T^2$. These equations lead to the following time variation of the system energy $\mathcal{H} = \sum_{i\alpha} p_{i\alpha}^2/2m + \mathcal{V}$, and for the variable \mathcal{H}' :

$$\dot{\mathcal{H}} = \sum_{i\alpha} p_{i\alpha} \dot{p}_{i\alpha}/m - \sum_{i\alpha} f_{i\alpha} \dot{r}_{i\alpha} = -\zeta \sum_{i\alpha} p_{i\alpha}^2/m \quad \dot{\mathcal{H}}' = -3NkT\dot{\zeta}.$$

If $T > T$, i.e., the system is too hot, then the ‘friction coefficient’ ζ will tend to increase; when it is positive the system will begin to cool down. If the system is too cold, the reverse happens, and the friction coefficient may become negative, tending to heat the system up again. In some circumstances, this approach generates non-ergodic behaviour, but this may be ameliorated by the use of chains of thermostat variables [82]. Tobias et al [83] give an example of the use of this scheme in a biomolecular simulation.

As an alternative to sampling the canonical distribution, it is possible to devise equations of motion for which the ‘mechanical’ temperature is constrained to a constant value [84, 85, 86]. The equations of motion are

$$\dot{\mathbf{r}}_i = \mathbf{p}_i/m \quad \dot{\mathbf{p}}_i = \mathbf{f}_i - \zeta \mathbf{p}_i \quad \zeta = \frac{\sum_{i\alpha} f_{i\alpha} p_{i\alpha}}{\sum_{i\alpha} p_{i\alpha}^2}.$$

-25-

Here the friction coefficient ζ is completely determined by the instantaneous values of the coordinates and momenta. It is easy to see that the kinetic energy $\mathcal{K} = \sum_{i\alpha} p_{i\alpha}^2/2m$ is now a constant of the motion:

$$\dot{\mathcal{K}} = \sum_{i\alpha} p_{i\alpha} \dot{p}_{i\alpha}/m_i = \sum_{i\alpha} p_{i\alpha} f_{i\alpha}/m_i - \zeta \sum_{i\alpha} p_{i\alpha}^2/m_i = 0.$$

It is possible to devise extended-system methods [79, 87] and constrained-system methods [88] to simulate the constant- NPT ensemble using MD. The general methodology is similar to that employed for constant-

NVT , and in the course of the simulation the volume V of the simulation box is allowed to vary, according to the new equations of motion. A useful variant allows the simulation box to change shape as well as size [89, 90]. It is also possible to extend the Liouville operator-splitting approach to generate algorithms for MD in these ensembles; examples of explicit, reversible, integrators are given by Martyna et al [91].

B3.3.6 FREE ENERGIES, CHEMICAL POTENTIALS AND WEIGHTED SAMPLING

A major drawback of MD and MC techniques is that they calculate *average* properties. The free energy and entropy functions cannot be expressed as simple averages of functions of the state point γ . They are directly connected to the logarithm of the partition function, and our methods do not give us the partition function itself. Nonetheless, calculating free energies is important, especially when we wish to determine the relative thermodynamic stability of different phases. How can we approach this problem?

B3.3.6.1 FREE ENERGY DIFFERENCES

It is possible to calculate *derivatives* of the free energy directly in a simulation, and thereby determine free energy differences by thermodynamic integration over a range of state points between the state of interest and one for which we know A exactly (the ideal gas, or harmonic crystal for example):

$$(\beta A)_2 - (\beta A)_1 = \int_{\beta_1}^{\beta_2} E \, d\beta \quad \text{or} \quad A_2 - A_1 = - \int_{V_1}^{V_2} P \, dV.$$

This is reliable and fairly accurate, if tedious. It was used, for example, by Hoover [92] to locate the melting parameters for soft-sphere systems. The only point to watch out for is that one should not cross any phase transitions in taking the path from 1 to 2: it must be *reversible*.

-26-

A free energy difference between two systems with energy functions \mathcal{H}_0 and \mathcal{H}_1 , respectively, may be written in a way analogous to [equation b3.3.3](#)

$$A_1 = A_0 - kT \ln \langle \exp\{-\beta \Delta \mathcal{H}\} \rangle_0$$

where $\langle \dots \rangle_0$ is an ensemble average for system 0 and $\Delta \mathcal{H} = \mathcal{H}_1 - \mathcal{H}_0$. In the extreme case $\mathcal{H}_0 \equiv \mathcal{H}_1$, this would give an unweighted estimate of the partition function of system 1, but would be extremely poorly sampled for the reasons discussed in [section b3.3.2](#). Reasonable estimates will result when the two systems do not differ ‘too much’, so that contributing values of the Boltzmann factor are given a significant weight by the sampling over states in system 0. One famous example of this is the test-particle insertion formula, [equation \(B3.3.5\)](#), for estimating the chemical potential, where system 1 contains an additional particle. Another example is where a molecule in the system can be mutated into another. The efficiency of the sampling may depend critically on the direction of the perturbation change: estimating μ^{ex} by particle *removal*, for instance, is formally possible but usually less accurate than particle insertion. Kofke and Cummings [93] have reviewed various approaches in this field and make the general recommendation that the change should take place in the direction of *decreasing entropy*.

B3.3.6.2 HISTOGRAM RE-WEIGHTING

A way of looking at the points raised in the previous section is to compare energy *distributions* in two systems whose free energies we wish to relate. In particular, consider measuring, in a simulation of system 0, the function $\mathcal{P}_0(\Delta E)$, i.e., the probability density per unit ΔE of configurations for which \mathcal{H}_0 and \mathcal{H}_1 differ by the prescribed amount ΔE . The distribution $\mathcal{P}_1(\Delta E)$ may be similarly calculated by simulating system 1. These two functions may be straightforwardly related [94]:

$$\ln \mathcal{P}_1(\Delta E) = \ln \mathcal{P}_0(\Delta E) + \beta \Delta A - \beta \Delta E.$$

Therefore, apart from an unknown constant $\beta \Delta A$, and a known linear term $\beta \Delta E$, these are the same function. Bennett [94] suggested two graphical methods for determining $\beta \Delta A$ from $\mathcal{P}_0(\Delta E)$ and $\mathcal{P}_1(\Delta E)$, which rely on the two distributions, at worst, nearly overlapping (i.e., being measurable, with good statistics, for the same or similar values of ΔE). To broaden the sampling into the wings of the distribution, thereby improving statistics and extending the overlap region, we may use weighted sampling as described in section b3.3.4.2. There are many related approaches, variously called umbrella [95], multicanonical [96] and entropic [97] sampling, simulated tempering [98] and expanded ensembles [99].

Windowing is a special case of umbrella sampling: the weight function is a constant inside a specified region of configuration space, and zero outside. In MC we simply reject moves which would take the system outside the window, and otherwise proceed as usual. This allows us to examine a distribution function, and hence a free energy curve, piece by piece, matching up the resulting curves afterwards. The way to do this combination of histograms has been discussed by Ferrenberg and Swendsen [100], and the statistical errors in histogram re-weighting have been discussed by Swendsen [101] and Ferrenberg et al [102]. Ultimately, this approach leads back to the idea of performing simulations in a (nearly)-*microcanonical* ensemble and relating the results at nearby energies, as we do in thermodynamic integration; as emphasized in the review of Dönweg [103], ‘for any thermodynamic integration procedure there is an equivalent multistage sampling or histogram procedure, and *vice versa*’.

B3.3.6.3 THE CHEMICAL POTENTIAL

The ensemble average in the Widom formula, $\langle\langle \exp\{-\beta v_{\text{test}}\} \rangle\rangle$, is sometimes loosely referred to as the ‘insertion probability’. It becomes very low for dense fluids. For example, for hard spheres, we can use the scaled-particle theory [104] or the Carnahan–Starling equation of state [105] to estimate it (see figure B3.3.8). The insertion probability falls below 10^{-4} , well before the freezing transition at $\eta \approx 0.49$. Similar estimates can be made for the Lennard-Jones fluid. The lower this factor becomes, the poorer the statistics, and the more unreliable will be the estimate of μ^{ex} . The problem is particularly acute for dense molecular fluids where, as a first guess, one could take the overall Boltzmann factor to be the *product* of the individual atomic values.

Figure B3.3.8. Insertion probability for hard spheres of various diameters (indicated on the right) in the hard sphere fluid, as a function of packing fraction η , predicted using scaled particle theory. The dashed line is a guide to the lowest acceptable value for chemical potential estimation by the simple Widom method.

A simple method of improving the efficiency of test particle insertion [106, 107, 108 and 109] involves dividing the simulation box into small cubic regions, and identifying those which would make a negligible contribution to the Widom formula, due to overlap with one or more atoms. These cubes are excluded from the sampling, and a correction applied afterwards for the consequent bias.

Another trick is applicable to, say, a two-component mixture, in which one of the species, A, is smaller than the other, B. From figure B3.3.8 for hard spheres, we can see that A need not be *particularly* small in order for the test particle insertion probability to climb to acceptable levels, even when insertion of B would almost always fail. In these circumstances, the chemical potential of A may be determined directly, while that of B is evaluated indirectly, relative to that of A. The related ‘semi-grand’ ensemble has been discussed in some detail by Kofke and Glandt [110].

This naturally leads to the idea of estimating μ^{ex} by gradual insertion [111, 112 and 113]. This can be thought of as a thermodynamic integration pathway, connecting the states with N and $N + 1$ particles via a set of intermediate points, characterized by a parameter λ , $0 \leq \lambda \leq 1$ which determines the degree to which the extra ‘ λ -particle’ is ‘switched on’. A MC scheme is constructed, which (in addition to the usual moves) allows λ to vary either continuously or in predefined discrete jumps. Then the chemical potential is expressed $\mu_{\text{ex}} = \Delta A_{\text{ex}} = A_{\text{ex}}(\lambda = 1) - A_{\text{ex}}(\lambda = 0)$. It is advantageous to apply a weighting function (see section b3.3.4.2) [112, 113], to ensure more or less uniform sampling of the different λ states. Consider the probability histogram $\mathcal{P}(\lambda)$ of the sampled values of λ during the runs. Without an external biasing potential this will be directly related to a Landau free energy

$$\mathcal{P}(\lambda) \propto \exp\{-\beta\mathcal{F}(\lambda)\}$$

where $\mathcal{F}(1) - \mathcal{F}(0) = \Delta A_{\text{ex}}$ is the desired free energy difference; to obtain a uniform distribution, a weight function $\mathcal{W}(\Gamma) \propto \exp\{-\beta\Psi(\lambda)\}$ with a biasing potential $\Psi(\lambda) = -\mathcal{F}(\lambda)$ would be used. This ideal weighting function is not known at the start of the simulation, but an initial guess may be iteratively refined from the measured $\mathcal{P}(\lambda)$ in a series of runs.

It is also advantageous to ensure that the λ -particle samples a wide range of positions in the fluid: this is achieved by attempting large-scale moves to new, randomly-selected positions from time to time, and also frequently attempting exchanges of position with a randomly-selected full-size particle. The former moves will have a high probability of success when λ is small, and the latter when λ is large. Camp et al [114] provide an example of this method in action, for a model of liquid crystals.

B3.3.6.4 FREE ENERGY OF SOLIDS

Early attempts to calculate solid-state free energies, and hence locate the melting transition, introduced the idea of conducting a thermodynamic integration along an artificial pathway [115, 116]. Each atom is artificially restricted to a single cell in space so that, as the density is lowered, the system converts more or less smoothly into a kind of ‘lattice gas’. More recently, Frenkel et al [117] proposed a method in which λ corresponds to switching between the true potential and a harmonic spring, which couples each atom at instantaneous position \mathbf{r}_i to its ideal lattice site $\mathbf{r}_i^{(0)}$:

$$\mathcal{V}(\lambda) = \lambda\mathcal{V}_1 + (1 - \lambda)\mathcal{V}_0.$$

Here \mathcal{V}_1 is the original, many-body potential energy function, while \mathcal{V}_0 is a sum of single-particle spring potentials proportional to $|\mathbf{r}_i - \mathbf{r}_i^{(0)}|^2$. As $\lambda \rightarrow 0$ the system becomes a perfect Einstein crystal, whose free energy is exactly calculable. Recently, a combination of approaches has been used [118]: first the solid is subjected to a set of one-particle spring potentials, and then the influence of the interparticle forces is reduced to zero by expanding the crystal. This method was used to locate the melting transition for a model of nitrogen at $T = 300$ K.

Density functional theory arguments [119, 120] suggest that the springs should be of the correct strength to produce the same mean-squared displacement in the Einstein limit as in the original crystal. More precisely, it is best to switch over to a one-body potential in such a way that the one-body density $\rho(\mathbf{r})$ is the same at all points along the integration path. Such a path is guaranteed not to traverse a first-order phase transition.

B3.3.7 CONFIGURATION-BIASED MC

The biased-sampling approach may be considerably generalized, to allow the construction of MC moves step-by-step, with each step depending on the success or failure of the last. Such a procedure is biased, but it is then possible to correct for the bias (by considering the possible reverse moves). The technique has dramatically speeded up polymer simulations, and is capable of wider application.

The idea may be illustrated by considering first a method for increasing the acceptance rate of moves (but at the expense of trying, and discarding, several other possible moves). Having picked an atom to move, calculate the new trial interaction energy v_t for a range of trial positions $t = 1 \dots k$. Pick the actual attempted move from this set, with a probability proportional to the Boltzmann factor. This biases the move selection, towards high-probability states, but we can calculate the contribution of the bias to $\alpha_{\Gamma \rightarrow \Gamma'}$. Then we must

calculate $\alpha_{\Gamma \leftarrow \Gamma'}$ for the hypothetical reverse move: we do this by selecting $k-1$ possible trial positions around the new position of the atom, plus the place it originally came from, making k in all. The ratio $\alpha_{\Gamma \leftarrow \Gamma'}/\alpha_{\Gamma' \leftarrow \Gamma}$ is used in the accept/reject decision, along with the relevant Boltzmann factors (see [section b3.3.4.2](#)). For $k=1$ this gives the usual Metropolis prescription; for $k \rightarrow \infty$ it is easy to show that the acceptance rate tends to unity, but the method becomes very expensive, since all the work has gone into calculating the biasing factors.

The expense is justified, however, when tackling polymer chains, where reconstruction of an entire chain is expressed as a succession of atomic moves of this kind [[121](#)]. The first atom is placed at random; the second selected nearby (one bond length away), the third placed near the second, and so on. Each placement of an atom is given a greater chance of success by selecting from multiple locations, as just described. Biasing factors are calculated for the whole multi-atom move, forward and reverse, and used as before in the Metropolis prescription. For further details see [[122](#), [123](#), [124](#), [125](#)]. A nice example of this technique is the study [[126](#), [127](#)] of the distribution of linear and branched chain alkanes in zeolites.

B3.3.8 PHASE TRANSITIONS

Here we discuss the exploration of phase diagrams, and the location of phase transitions. See also [[128](#), [129](#), [130](#), [131](#)] and [[22](#), chapters 8–14]. Very roughly we classify phase transitions into two types: first-order and continuous. The fact that we are dealing with a finite-sized system must be borne in mind, in either case.

B3.3.8.1 FIRST-ORDER AND CONTINUOUS TRANSITIONS

At a continuous phase transition, a correlation length ξ (see [section b3.3.2.1](#)) diverges and an order parameter, typically the ensemble average of the corresponding dynamical variable, becomes macroscopically large. The divergence heralding the transition is describable in terms of universal exponent relations. Effects of finite size close to continuous phase transitions are well studied [[24](#), [132](#)]. By contrast, a first-order phase transition is abrupt, as one phase becomes thermodynamically more stable than another; there are no transition precursors. In the thermodynamic limit, there is a step-function discontinuity in most properties, including thermodynamic derivatives of the free energy. Again it is possible to describe the effects of finite size [[132](#), [133](#)].

For both first-order and continuous phase transitions, finite size *shifts* the transition and *rounds* it in some way. The shift for first-order transitions arises, crudely, because the chemical potential, like most other properties, has a finite-size correction $\mu(N) - \mu(\infty) \sim \mathcal{O}(1/N)$. An approximate expression for this was derived by Siepmann et al [[134](#)]. Therefore, the line of intersection of two chemical potential surfaces $\mu_I(T,P)$ and $\mu_{II}(T,P)$ will shift, in general, by an amount $\mathcal{O}(1/N)$. The rounding is expected because the partition function only has singularities (and hence produces discontinuous or divergent properties) in the limit $L \rightarrow \infty$; otherwise, it is analytic, so for finite N the discontinuities must be smoothed out in some way. The shift for continuous transitions arises because the transition happens when $\xi \rightarrow L$ for the finite system, but when $\xi \rightarrow \infty$ in the infinite system. The rounding happens for the same reason as it does for first-order phase transitions: whatever the nature of the divergence in thermodynamic properties (described, typically, by critical exponents) it will be limited by the finite size of the system.

In either case, first-order or continuous, it is useful to consider the probability distribution function for variables averaged over a spatial block of side L ; this may be the complete simulation box (in which case we

must specify the ensemble and boundary conditions) or it may be a sub-system. For purposes of illustration we shall not distinguish these possibilities.

B3.3.8.2 CONTINUOUS PHASE TRANSITIONS

Here we discuss only briefly the simulation of continuous transitions (see [132, 135] and references therein). Suppose that the transition is characterized by a non-vanishing order parameter X and a corresponding divergent correlation length ξ . We shall be interested in the block average value $X_L \equiv \langle \chi \rangle_L$, where the L reminds us of the system size. In a magnetic system, X is the magnetization; in a fluid it might be the density. The basic idea of finite size scaling analysis is that the values of properties of the system are dictated by the ratio ξ/L , and that no other length scales enter the problem, near a critical point. Any property can be written

$$X_L = X \times \Phi(\xi/L)$$

where X is the average value in the infinite system limit and Φ is some scaling function. There will be exponent laws dictating the behaviour of X in the vicinity of the phase transition, and more scaling laws stating how ξ behaves inside the function Φ . We can apply a scaling analysis to the distribution function $\mathcal{P}(X_L)$ [136, 137]. Actually at the critical point, the distribution can be calculated by simulation, or predicted by renormalization group theory [136, 137, 138 and 139]; different universal forms will be seen for different universality classes. Examination of these functions is a powerful way of locating and characterizing critical points, and in the critical region the histogram reweighting method is a particularly useful way of maximizing the information obtained from individual simulations. For example, the prewetting critical point has been shown to lie in the $d = 2$ Ising universality class in this way [139]. A further example is the study of the critical point of the $d = 2$ Lennard-Jones fluid [140, 141]. For this, long runs of order 10^6 – 10^8 sweeps were needed, but the system sizes were relatively small: $N \approx 100$ and 400.

B3.3.8.3 FIRST-ORDER PHASE TRANSITIONS

Consider simulating a system in the canonical ensemble, close to a first-order phase transition. In one phase, $\mathcal{P}_{NVT}(E)$ is essentially a Gaussian centred around a value E_I , while in the other phase the peak is around E_{II} . Far from the transition, one or other of these will apply. Close to the phase transition we will see contributions from both Gaussians, and a double-peaked distribution. The weight of each Gaussian changes as the temperature is varied. Thus, a smooth

-31-

crossover occurs from one branch of the equation of state $E(T) = \langle \mathcal{H} \rangle_{NVT}$ to the other. In the transition region we may expect to see anomalies such as an increased specific heat: the double-peaked distribution is wider than its constituent single-peaked ones, and recall that C_V is linked to $\langle \delta \mathcal{H}^2 \rangle$. The corresponding Landau free energy

$$\mathcal{F}_{NVT}(E) = -kT \ln \mathcal{P}_{NVT}(E)$$

has two minima separated by a barrier. The high-probability, low free energy values correspond to the single phase configurations; the intermediate values are for mixtures of the two phases, with an interfacial free energy penalty.

In the microcanonical ensemble, the signature of a first-order phase transition is the appearance of a ‘van der Waals loop’ in the equation of state, now written as $T(E)$ or $\beta(E)$. The $\beta(E)$ curve switches over from one

branch, phase I, of the equation of state to the other, phase II, tracing out a loop in the transition region. This loop is a finite-size effect, due to the interfacial free energy contributions in the transition region, just mentioned. For a larger system size the loop will flatten out, becoming a horizontal line in the thermodynamic limit, joining the two coexisting energies at the transition temperature; for $N \rightarrow \infty$ the interfacial properties contribute a negligible amount to the total free energy. (Calling it a ‘van der Waals loop’ is therefore misleading: it has no connection with the loop in the approximate van der Waals equation of state for fluids, which in any case is independent of system size.) It is possible to inter-relate the form of this loop, and the double-peaked structure of the energy distribution, with the thermodynamic coexistence conditions [[1](#), [132](#), [142](#), [143](#), [144](#), [145](#)].

The previous discussions translate directly over into pressure–volume variables, if we compare the constant- NVT and constant- NPT ensembles. Double-peaked distributions of volumes are seen near a transition at constant pressure.

Direct coexistence of solid and fluid phases of hard spheres and disks was observed in the early simulations of Wood and Jacobson [[146](#)] and Alder and Wainwright [[147](#), [148](#)]; the appearance of a ‘van der Waals loop’ in the equation of state was explained in some detail shortly afterwards [[142](#), [149](#), [150](#)]. Very detailed analyses of this situation, especially in relation to spin systems, have appeared in recent years [[143](#), [144](#), [145](#), [151](#) and [152](#)]. Histogram reweighting can be useful here [[153](#), [154](#)] and measuring the height of the interfacial free energy barrier as a function of system size has been recommended as a test for first-order behaviour [[155](#)]. A nice example of this approach for a spin model of a liquid crystal, which exhibits a tricky *weak* first-order transition, is the work of Zhang et al [[156](#), [157](#)], following on from earlier work by Fabbri and Zannoni [[158](#)]. An example for a *strong* first-order transition is the study of melting and nucleation barriers in the Lennard-Jones system [[159](#)] and models of metallic systems [[160](#)]. This approach used windowing and biased sampling techniques.

Recently, Orkoulas and Panagiotopoulos [[161](#)] have shown that it is possible to use histogram reweighting and multicanonical simulations, starting with individual simulations near the critical point, to map out the liquid–vapour coexistence curve in a very efficient way.

Simulations in the Gibbs ensemble attempt to combine features of Widom’s test particle method with the direct simulation of two-phase coexistence in a box. The method of Panagiotopoulos et al [[162](#), [163](#)] uses two fully-periodic boxes, I and II.

In the simplest version, a one-component system is simulated at a given temperature T in both boxes; particles in different boxes do not interact directly with each other; however, volume moves and particle creation and deletion

moves are coupled such that the total volume V and the total number of particles N are conserved. With appropriate acceptance/rejection probabilities for the volume exchange and particle exchange moves, together with the usual MC procedure for moving particles around within the two boxes, the thermodynamic conditions for mechanical and chemical equilibrium between the boxes are ensured. A typical MC cycle would consist of: one attempted move per particle in each box; one attempt to exchange volumes between boxes; a predetermined number of attempts to exchange particles. The technique has been reviewed by Panagiotopoulos [[131](#), [164](#), [165](#)] and Smit [[129](#)]. The partition function for the two-box system is simply the usual canonical sum over all possible states, including a sum over all the distributions of particles between the boxes such that $N_I + N_{II} = N$, and an integral over all box volumes such that $V_I + V_{II} = V$. The probability distribution function for the ensemble, and the acceptance and rejection rules for particle and volume

exchanges, are easily derived.

The characteristic feature of the technique is the behaviour of the system if the overall density N/V lies in a two-phase region. For a single simulation box, both phases would appear, with an interface between them; in the Gibbs ensemble, the interface free energy penalty can be avoided by the system arranging to have each phase entirely in its own box. This phase separation happens automatically during the equilibration stage of the simulation.

The great advantages of the technique are its avoidance of interfacial properties, and the semi-automatic way that it converges on the coexisting densities without the need to input chemical potentials or guess equations of state. Unavoidably, it suffers from the same problems as the Widom test-particle method: at high density the particle exchange moves are accepted with very low probability, and special techniques are required to overcome this. It is essential to monitor the success rate of exchanges, and carry out enough of them to ensure that a few percent of molecules are exchanged at each step.

The Gibbs ensemble method has been outstandingly successful in simulating complex fluids and mixtures. For a multicomponent system, it is possible to simulate at constant pressure rather than constant volume, as separation into phases of different compositions is still allowed. The method allows one to study straightforwardly phase equilibria in confined systems such as pores [166]. Configuration-biased MC methods can be used in combination with the Gibbs ensemble. An impressive demonstration of this has been the determination by Siepmann et al [167] and Smit et al [168] of liquid–vapour coexistence curves for *n*-alkane chain molecules as long as 48 atoms.

As we have seen, insertion of small molecules can be dramatically easier than large ones; this leads to a ‘semi-grand’ version of the Gibbs ensemble [131, 169, 170]: the smaller particles are exchanged between the boxes, while moves that interconvert particle species are carried out within the boxes. The ideas seen before for computing the chemical potential by gradual insertion [111, 112, 113] can be naturally generalized to the Gibbs ensemble: at each stage a given molecule may be in an intermediate state of transfer between one box and another. As an example, Escobedo and de Pablo [171] use an expanded Gibbs ensemble for polymers, and Nath et al [172] have computed the liquid–vapour envelopes for long-chain alkanes, using different potential models and comparing with previous work [167, 168].

B3.3.8.5 THERMODYNAMIC METHODS

The alternative to direct simulation of two-phase coexistence is the calculation of free energies or chemical potentials together with solution of the thermodynamic coexistence conditions. Thus, we must solve (say) $\mu_I(P) = \mu_{II}(P)$ at constant T . A reasonable approach [173, 174, 175 and 176] is to conduct constant- NPT simulations, measure μ by test-particle insertion, and also to note that the simulations give the derivative $\partial\mu/\partial P = \langle V \rangle / N$ directly. Thus, conducting

one or two simulations may be enough for a preliminary fit to the equations of state $\mu_I(P)$, $\mu_{II}(P)$ allowing one to home in on the intersection point quite quickly.

Once a point on the coexistence line has been found, one can trace out more of it using the approach of Kofke [177, 178] to numerically integrate the Clapeyron equation

$$\left(\frac{dP}{d\beta}\right)_\sigma = -\frac{\Delta h}{\beta\Delta v}.$$

Here, $\Delta h = h_\beta - h_\alpha$ is the difference in molar enthalpies of the coexisting phases, and Δv is the difference in molar volumes; the suffix σ indicates that the derivative is to be evaluated along the coexistence line.

The method consists of solving the above equation in a standard step-by-step manner, for example using a predictor–corrector algorithm. The right-hand side is calculated by simulating both phases at constant T and P in separate, uncoupled boxes. At intervals, a small change in T (the independent variable) is made in both boxes, and this is accompanied by a change in P (the dependent variable) as dictated by the differential equation solver. The approach relies on a starting point at which the two phases are at thermodynamic equilibrium, $\Delta\mu = 0$; thereafter the Clapeyron equation, if solved accurately, should guarantee that equilibrium is maintained. The method has been applied to the liquid–vapour coexistence curve [177, 178] and to the melting and sublimation curves [179] for the Lennard-Jones system; it was also extended by Agrawal and Kofke [180] to study the melting transition of a large family of soft-sphere systems, showing the emergence of the bcc phase as being stable relative to fcc for high enough softness parameters. Various technical details of this approach have been discussed [178, 179] and possible sources of inaccuracy considered.

An example of the use of this method in a complex situation is the study by Bolhuis and Kofke [181, 182] of the freezing of polydisperse hard spheres (a system in which there is a distribution of atomic diameters). A semi-grand ensemble imposes a distribution of chemical potential differences (for different hard-sphere diameters) on the system: the width of this distribution controls the polydispersity. The same chemical potentials (for all the different species) apply in two coexisting phases. The thermodynamic integration technique may then be used to map out the freezing–melting line in the pressure–polydispersity plane, starting from the monodisperse limit (simple hard spheres). The resulting phase diagram, in volume fraction–polydispersity variables, is shown in figure B3.3.9. An important result is that fractionation between the two phases allows a highly polydisperse fluid to precipitate a solid which is only slightly polydisperse—never higher than 5.7% in terms of the average sphere diameter.

-34-

Figure B3.3.9. Phase diagram for polydisperse hard spheres, in the volume fraction (ϕ)–polydispersity (s) plane. Some tie-lines are shown connecting coexisting fluid and solid phases. Thanks are due to D A Kofke and P G Bolhuis for this figure. For further details see [181, 182].

B3.3.8.6 STUDIES OF INTERFACES

Simulation of both bulk phases in a single box, separated by an interface, is closest to what we do in real life. It is necessary to establish a well defined interface, most often a planar one between two phases in ‘slab’ geometry. A large system is required, so that one can characterize the two phases far from the interface, and read off the corresponding bulk properties. Naturally, this is the approach of choice if the interfacial properties (for example, the surface tension) are themselves of interest. The first stage in such a simulation is to prepare bulk samples of each phase, as close to the coexisting densities as possible, in cuboidal periodic boundaries, using boxes whose cross sections match. The two boxes are brought together, to make a single longer box, giving the desired slab arrangement with two planar interfaces. There must then follow a period of equilibration, with mass transfer between the phases if the initial densities were not quite right.

Equilibration of the interface, and the establishment of equilibrium between the two phases, may be very slow. Holcomb et al [183] found that the density profile $\rho(z)$ equilibrated much more quickly than the profiles of normal and transverse pressure, $P_N(z)$ and $P_T(z)$, respectively. The surface tension is proportional to the z -integral of $P_N(z)-P_T(z)$. The bulk liquid in the slab may continue to contribute to this integral, indicating lack of equilibrium, for very long times if the initial liquid density is chosen a little too high or too low. A recent example of this kind of study, is the MD simulation of the liquid–vapour surface of water at temperatures between 316 and 573 K by Alexandre et al [184].

B3.3.9 RARE EVENTS

By definition, rare events happen infrequently, but this does not mean that they happen slowly. Accordingly, molecular simulations may contribute greatly to our understanding of such events, but some special sampling tricks will be needed since the ‘natural’ timespans of simulations are already very short. The simplest example is where the system crosses a free energy barrier from one region to another in phase space, and a single ‘reaction coordinate’ can be identified to characterize the two stable regions and the transition state. The statistical mechanical background to barrier crossing rates, in terms of linear response theory, has been given by Chandler [2, 185]. The transition rate is typically a product of two factors: the equilibrium probability density for finding the system at the top of the barrier, and a dynamical quantity, essentially the inverse of a relaxation time for the system to settle from the barrier into one or other stable region.

We have already discussed weighted sampling methods for exploring regions of high free energy, so the first part of this problem is tractable. The calculation of time-dependent functions, which start from the barrier top, is facilitated by the so-called ‘blue-moon’ ensemble [186] in which a constraint is applied to keep the system exactly on the desired hypersurface. This allows sampling of the starting conditions with good statistics; then the constraint may be released and subsequent dynamics accumulated. (Metric tensor factors associated with the constraint are discussed elsewhere [187, 188].) To compute the time-dependent part of the barrier-crossing rate, special approaches have been developed to suppress transient behaviour and statistical noise [187].

In many cases, it may not be possible to identify a single reaction coordinate. A good example of a free-energy surface depending on two variables is found in the study by ten Wolde and Frenkel [189] of the mechanism of protein crystal nucleation, and the possible influence of fluctuations induced by a nearby metastable critical point. Here, the relevant variables are ‘density’ and ‘crystallinity’, as illustrated in [figure B3.3.10](#). At high levels of supercooling, well away from the hidden critical point, nucleation follows a route whereby a crystalline nucleus forms from the start: this involves a high free energy barrier. Close to the critical point, a different mechanism operates: critical fluctuations encourage formation of a liquid-like nucleus, and only after this has grown to a certain size does a crystal start to form. This pathway involves a

much lower free energy barrier. This work is an example of the insight obtainable from simulations into a previously poorly understood area, namely the art of obtaining good protein crystals for structure determination, as well as illustrating the qualitatively different mechanisms that may operate under different conditions.

-36-

Figure B3.3.10. Contour plots of the free energy landscape associated with crystal nucleation for spherical particles with short-range attractions. The axes represent the number of atoms identifiable as belonging to a high-density cluster, and as being in a crystalline environment, respectively. (a) State point significantly below the metastable critical temperature. The nucleation pathway involves simple growth of a crystalline nucleus. (b) State point at the metastable critical temperature. The nucleation pathway is significantly curved, and the initial nucleus is liquidlike rather than crystalline. Thanks are due to D Frenkel and P R ten Wolde for this figure. For further details see [189].

The more general problem of finding a transition pathway when the relevant reaction coordinates are not obvious, has recently been tackled [190, 191]. The basic idea [192] is to generate chains of states linking the two stable states, through a weighted sampling procedure which makes no assumptions about the mechanism. The method is very general, but inevitably expensive.

B3.3.10 QUANTUM SIMULATION USING PATH INTEGRALS

In this section we look briefly at the problem of including quantum mechanical effects in computer simulations. We shall only examine the simplest technique, which exploits an isomorphism between a quantum system of atoms and a classical system of ring polymers, each of which represents a path integral of the kind discussed in [193]. For more details on work in this area, see [22, 194] and particularly [195, 196, 197].

The coordinate representation of the density matrix, in the canonical ensemble, may be written

-37-

$$\mathcal{Q}(\mathbf{r}^{(N)}, \mathbf{r}^{(N')}) = \mathcal{Q}_{NVT}^{-1}(\mathbf{r}^{(N)}) |e^{-\beta \hat{H}}| \mathbf{r}^{(N')}$$

and correspondingly for the partition function

$$\mathcal{Q}_{NVT} = \int d\mathbf{r}^{(N)} (\mathbf{r}^{(N)} | e^{-\beta \hat{H}} | \mathbf{r}^{(N)}).$$

Here we have adopted a Dirac bracket notation ($\dots | \dots \rangle$) which should be distinguished from the ensemble average $\langle \dots \rangle$. Actually evaluating this is tricky, because the Hamiltonian is the sum of the kinetic and potential energy operators, $\hat{H} = \hat{K} + \hat{V}$, which do not commute. Hence

$$e^{-\beta(\hat{K}+\hat{V})} \neq e^{-\beta\hat{K}} e^{-\beta\hat{V}}.$$

When the exponent is small (e.g., at high temperature), reasonable approximations exist. This problem is attacked in a manner similar to that used to derive expressions for the propagator $e^{i\hat{L}t}$, as a succession of small time step propagators, in [section b3.3.3.2](#): we split the exponential up into smaller pieces. So, we write

$$e^{-\beta\hat{H}} = [e^{-\beta\hat{H}/P}]^P$$

and insert this into the expression for the partition function

$$\mathcal{Q}_{NVT} = \int d\mathbf{r}^{(N)} (\mathbf{r}^{(N)} | e^{-\beta\hat{H}/P} e^{-\beta\hat{H}/P} \dots e^{-\beta\hat{H}/P} | \mathbf{r}^{(N)}).$$

Now we do one of the standard quantum mechanical tricks, inserting the identity operator as a complete sum of states in the coordinate representation:

$$\hat{1} = \int d\mathbf{r}^{(N')} | \mathbf{r}^{(N')} \rangle \langle \mathbf{r}^{(N')} |$$

in between each exponential. This will introduce $P - 1$ additional integrations over coordinates. Each of the contributions $(\mathbf{r}^{(N)} | e^{-\beta\hat{H}/P} | \mathbf{r}^{(N')})$ is an un-normalized, off-diagonal, density matrix $\mathcal{Q}(\mathbf{r}^{(N)}, \mathbf{r}^{(N')})$ evaluated at a temperature a factor P higher than the temperature of the real system. For more background on this approach to quantum mechanics, see [\[193\]](#).

As in the case of the propagator, we shall be applying a symmetrical version of the Trotter formula [\[48\]](#) to the high-temperature density matrix

$$(\mathbf{r}^{(N)} | e^{-\beta\hat{H}/P} | \mathbf{r}^{(N')}) \approx (\mathbf{r}^{(N)} | e^{-\frac{1}{2}\beta\hat{V}/P} e^{-\beta\hat{K}/P} e^{-\frac{1}{2}\beta\hat{V}/P} | \mathbf{r}^{(N')}).$$

The potential energy part is diagonal in the coordinate representation, and we drop the hat indicating an operator henceforth. The kinetic energy part may be evaluated by transforming to the momentum representation and carrying out a Fourier transform. The result is

$$Q_{NVT} \approx \left(\frac{Pm}{2\pi\beta\hbar^2} \right)^{dP/2} \int \dots \int d\mathbf{r}_1^{(N)} \dots d\mathbf{r}_P^{(N)} e^{-\beta\mathcal{V}_{\text{qu}}} e^{-\beta\mathcal{V}_{\text{cl}}}$$

$$\mathcal{V}_{\text{qu}} = -\frac{Pm}{2\beta^2\hbar^2} (|\mathbf{r}_1^{(N)} - \mathbf{r}_2^{(N)}|^2 + |\mathbf{r}_2^{(N)} - \mathbf{r}_3^{(N)}|^2 + \dots + |\mathbf{r}_P^{(N)} - \mathbf{r}_1^{(N)}|^2)$$

$$\mathcal{V}_{\text{cl}} = \frac{1}{P} (\mathcal{V}(\mathbf{r}_1^{(N)}) + \mathcal{V}(\mathbf{r}_2^{(N)}) + \dots + \mathcal{V}(\mathbf{r}_P^{(N)}))$$

This is better understood with a picture: see figure B3.3.11. The discretized path-integral is isomorphic to the classical partition function of a system of N ring polymers each having P atoms. Each atom in a given ring corresponds to a different ‘imaginary time’ point $p = 1 \dots P$. $\mathcal{V}(\mathbf{r}^{(N)})$ represents the interatomic interactions (for example, Lennard-Jones) between the atoms of the real system. This couples together only *correspondingly labelled* atoms, i.e., atoms with the same index p . So, between each pair of the original atoms, there are P such interactions, each one weaker than the true potential by a factor $1/P$. In addition, harmonic quantum ‘springs’ couple together successively indexed atoms within a ring polymer. We may simulate this classical ring polymer system by conventional MC or MD.

Figure B3.3.11. The classical ring polymer isomorphism, for $N=2$ atoms, using $P=5$ beads. The wavy lines represent quantum ‘spring bonds’ between different imaginary-time representations of the same atom. The dashed lines represent real pair-potential interactions, each diminished by a factor P , between the atoms, linking corresponding imaginary times.

Temperature appears in the partition function in an unusual way. The average energy takes the form

$$E = \frac{3}{2}NPkT + \langle \mathcal{V}_{\text{cl}} \rangle - \langle \mathcal{V}_{\text{qu}} \rangle.$$

As P is increased, the partial cancellation between the kinetic part and the spring part may worsen the statistics on E . This has led to suggestions of alternative ways of estimating E [198]. As P goes up, the springs become stronger, the interactions in \mathcal{V}_{cl} become (individually) weaker, and this leads to sampling problems. In MD, one needs to use multiple time step methods to ensure proper handling of the spring vibrations, and there is a possible physical bottleneck in the transfer of energy between the spring system and the other degrees of freedom which must be handled properly [199]. In MC, one needs to use special methods to sample configuration space efficiently [200, 201].

For fermions (especially) and bosons there are additional problems. Let \hat{P} be one of the $N!$ permutations of particle labels. Then the fermion density matrix ϱ_F has the symmetry

$$\varrho_F(\mathbf{r}^{(N)}, \mathbf{r}^{(N')}) = (-1)^{\hat{P}} \varrho_F(\hat{P}\mathbf{r}^{(N)}, \mathbf{r}^{(N')}) = (-1)^{\hat{P}} \varrho_F(\mathbf{r}^{(N)}, \hat{P}\mathbf{r}^{(N')}).$$

It is possible to relate this to the ‘Boltzmann’ (i.e., distinguishable particle) density matrix $\varrho(\mathbf{r}^{(N)}, \mathbf{r}^{(N')})$ by

$$\varrho_F(\mathbf{r}^{(N)}, \mathbf{r}^{(N')}) = \frac{1}{N!} \sum_{\hat{P}} (-1)^{\hat{P}} \varrho(\hat{P}\mathbf{r}^{(N)}, \mathbf{r}^{(N')}).$$

It is necessary to sum over these permutations in a path integral simulation. (The same sum is needed for bosons, without the sign factor.) For fermions, odd permutations contribute with negative weight. Near-cancelling positive and negative permutations constitute a major practical problem [196].

B3.3.11 CAR–PARRINELLO SIMULATIONS

Car and Parrinello [202] proposed a technique for efficiently solving the Schrödinger equation which has had an enormous impact on materials simulation (for reviews, see [203, 204, 205, 206]). The technique is an *ab initio* one, i.e., free of empirical parameters, and is based on the use of a quantum mechanical orthonormal basis set $\psi^{(n)} \equiv \psi_i(\mathbf{r})$ to describe the electronic degrees of freedom. Specifically, the aim is to obtain the electron density $\rho(\mathbf{r})$; the total energy of the system may then be written as a functional of this density, whose minimization yields the ground state energy [207]. Pseudopotentials [208] represent the effects of the atomic cores on the valence electrons, allowing some economies. The energy functional is written

$$E[\psi^{(n)}, \mathbf{R}^{(N)}] = \sum_i (\psi_i | \hat{\mathcal{K}} + \hat{\mathcal{V}}_{\text{ps}} | \psi_i) + \frac{1}{2} \int d\mathbf{r} d\mathbf{r}' \frac{\rho(\mathbf{r})\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} \quad (\text{B3.3.8})$$

$$+ E_{\text{xc}}[\rho] + \frac{1}{2} \sum_{i \neq j} \frac{Q_i Q_j}{|\mathbf{R}_i - \mathbf{R}_j|}. \quad (\text{B3.3.9})$$

Here we distinguish between nuclear coordinates \mathbf{R} and electronic coordinates \mathbf{r} ; $\hat{\mathcal{K}}$ is the single-particle kinetic energy operator, and $\hat{\mathcal{V}}_{\text{ps}}$ is the total pseudopotential operator for the interaction between the valence electrons and the combined nucleus + frozen core electrons. The electron–electron and nucleus–nucleus Coulomb interactions are easily recognized, and the remaining term $E_{\text{xc}}[\rho]$ is the electronic exchange and correlation energy functional. This is usually treated in the local density approximation, using ground-state data for the homogeneous electron gas [209]; the most promising improvements seem to be based on the addition of gradient corrections [205, 206].

For each configuration of the nuclei, minimization of the total energy with respect to the electron density yields the instantaneous value of a potential energy function $\mathcal{V}(\mathbf{R}^{(N)})$, and the corresponding forces on the nuclei. In principle,

assuming an adiabatic separation between nuclear and electronic motion, Newton's equations for the nuclei may be solved in the usual way, while the electrons are allowed to evolve according to Schrödinger's equations, remaining on the instantaneous ground-state surface. This turns out to be very inefficient in practice, and the breakthrough came with the suggestion [202] that a classical dynamical evolution of the electronic configuration could be used to stay in the ground state. A Lagrangian, involving both nuclear and electronic degrees of freedom, is written down; the electrons are given fictitious masses, and minimization of the electronic energy may be performed by introducing a friction coefficient.

The Car–Parrinello method has found wide applicability, especially for studying systems in which structure and bonding are inseparable, or for materials under extreme conditions for which empirical potential would be unreliable. Examples are the studies by Alfe and Gillan [210] and de Wijs et al [211] of iron in the Earth's core, at temperatures of several thousand Kelvin and pressures sufficient to compress the metal to about half its normal volume. It was concluded that the liquid iron in the core is not exceptionally viscous (as has been suggested by some seismic measurements) and that dissolved sulphur atoms show no tendency to form clusters or chains (which might have a large effect on viscosity). This is shown in figure B3.3.12. Additionally, the simulations suggest that the solid part of the core has the hcp crystal structure, contrary to that inferred from experiments at lower pressure and temperature.

Figure B3.3.12. Sulphur atoms in liquid iron at the Earth's core conditions, simulated by first-principle Car–Parrinello molecular dynamics. (a) Initial conditions, showing a manually-prepared initial cluster of sulphur atoms. (b) A short time later, indicating spontaneous dispersal of the sulphur atoms, which mingle with the surrounding iron atoms. Thanks are due to D Alfe and M J Gillan for this figure. For further details see [210, 211].

A similar approach, in spirit, has been proposed [212] for the study of two-component classical systems, for example polyelectrolytes, which consist of mesoscopic, highly-charged, polyions, and microscopic,

oppositely-charged, counterions. This time, an ‘effective free energy’, depending parametrically on the polyion coordinates \mathbf{R} , arises by integration over the counterion coordinates \mathbf{r} . A unified dynamical scheme, in which the counterions are given fictitious masses, allows the counterion density to adjust adiabatically to the slower motion of the polyions, and hence permits the free energy to be minimized as the system evolves.

B3.3.12 PARALLEL SIMULATIONS

MD programs may be efficiently parallelized, that is, the computational work divided between many processors to result in faster execution. Well established message-passing standards and software make it relatively easy to write portable and efficient codes. The algorithm to advance positions and momenta is trivially handled, with each processor being responsible for a subset of the atoms. The critical considerations are (i) the parallelization of the time-consuming force calculation, and (ii) the overheads associated with communicating information between processors. Two general methodologies seem to be most promising. In the *replicated data* method, all the processors hold copies of all the atomic coordinates; however, in the double loop over pair interactions, each processor deals with a subset of pairs. Some care needs to be taken to balance the load between processors, and the results of the force calculations must be broadcast to all other processors, which may be time-consuming, but perhaps the biggest drawback is the memory requirement of holding copies of all data on all nodes. Nonetheless, this method is easy to program and reasonably efficient for many purposes [213, 214, 215]. In the *domain decomposition* method, the simulation box is split into (usually) cubic regions, and each processor is responsible only for the atoms in a given region; there is some communication of information from neighbouring domains before the force calculation, and also some redistribution of atoms as they move around the system. This approach may be integrated with the link-cell approach of section b3.3.3.5, and is especially efficient for systems with short-range forces [213, 215, 216, 217, 218]. An example of the capabilities of such an approach on a massively parallel supercomputer is the study by Holian and Lomdahl [219] of shock waves in a fcc crystal of 10 million atoms, as illustrated in figure B3.3.13. In this case, a shock is generated by reflecting atoms at a piston face, i.e., imposing a momentum mirror. A system of this size was essential to ensure that the periodic boundaries do not limit the plastic flow induced by the shock: this can be seen in the randomly-spaced plaid pattern of the figure. The wave propagates back about 60 lattice spacings, generates a large number of stacking faults distributed randomly on the four {111} slip systems, and eventually produces a nonplanar propagation front.

-42-

Figure B3.3.13. Intersecting stacking faults in a fcc crystal at the impact plane induced by collision with a momentum mirror for a square cross section of side 100 unit cells. The shock wave has advanced half way to the rear (~250 planes). Atom shading indicates potential energy. Thanks are due to B Holian for this figure.

For further details see [219].

Although this section has concentrated on MD, it should not be forgotten that lattice-based MC codes may be parallelized very efficiently; for more information on parallel simulation methods see [220, 221, 222 and 223] and references therein.

B3.3.13 OUTLOOK

With the rapid development of computer power, and the continual innovation of simulation methods, it is impossible to predict what may be achieved over the next few years, except to say that the outlook is very promising. The areas of rare events, phase equilibria, and quantum simulation continue to be active.

An easily recognizable trend is the increasing application of simulation methods to problems of direct practical benefit to industry [224]. A pointer to this kind of use is provided by the synthesis of a small-pore microporous material, using a structure-directing template molecule designed by computer [225]. The aim is to promote formation of a desired material (here a cobalt aluminophosphate catalyst in the so-called CHA structure) without generating competing microporous phases. The simulation procedure allows molecular entities to be grown from a seed molecule by adding standard fragments, under the control of a cost function to minimize non-bonded overlaps with the surrounding CHA framework. Likely templates are ranked by binding energy, which measures how well they fit in the pore. The result is illustrated in [figure B3.3.14](#). This led to a successful synthetic route: the suggested template molecule forms the desired pure mesoporous material in 4 h at 180°C, without the formation of competing structures which are found with other templates.

-43-

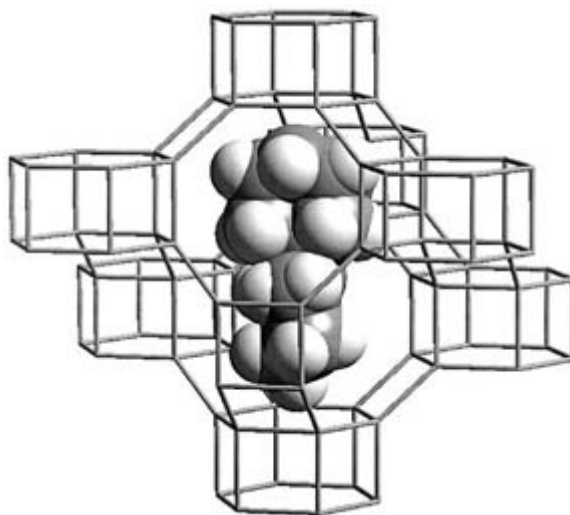

Figure B3.3.14. Template molecule in a zeolite cage. The CHA structure (periodic in the calculation but only a fragment shown here) is drawn by omitting the oxygens which are positioned approximately halfway along the lines shown connecting the tetrahedral silicon atoms. The molecule shown is 4-piperidinopiperidine, which was generated from the dicyclohexane motif suggested by computer. Thanks are due to D W Lewis and C R A Catlow for this figure. For further details see [225].

A further theme is the development of techniques to bridge the length and time scales between truly molecular-scale simulations and more coarse-grained descriptions. Typical examples are dissipative particle dynamics [226] and the lattice-Boltzmann method [227]. Part of the motivation for this is the recognition that

brute-force molecular simulation will always be limited in time scale by achievable chip speeds, even if increased use of parallel computers allows one to tackle larger length scales. Nonetheless, there will always be the need to relate such work to underlying molecular parameters, through statistical mechanics. A more detailed discussion of these techniques would take us beyond the scope of this chapter.

B3.4.1 INTRODUCTION

The study of quantum effects associated with nuclear motion is a distinct field of chemistry, known as quantum molecular dynamics. This section gives an overview of the methodology of the field; for further reading, consult [[1](#), [2](#), [3](#), [4](#) and [5](#)].

The importance of non-classical behaviour in molecular dynamics has its origins in the inherently quantal nature of atomic motion. The de Broglie wavelengths of atoms are small but non-vanishing. For example, hydrogen has a de Broglie wavelength that can be as high as $\approx 1.0 \text{ \AA}$ at room temperature. Specific quantum effects in atomic and molecular motion include: zero-point motion, most notably for hydrogen which has a zero-point energy of $\sim 10 \text{ kcal mol}^{-1}$ in many of its covalent interactions; interference resonances, which are spikes in reaction or pre-dissociation probabilities associated with quasi-bound states of molecules [[6](#), [7](#), [8](#) and [9](#)]; and tunnelling of nuclei which is important in many catalytic reactions [[10](#), [11](#), [12](#), [13](#) and [14](#)].

In its most fundamental form, quantum molecular dynamics is associated with solving the Schrödinger equation for molecular motion, whether using a single electronic surface (as in the Born–Oppenheimer approximation— [section B3.4.2](#) or with the inclusion of multiple electronic states, which is important when discussing non-adiabatic effects, in which the electronic state is changed [[15](#), [16](#), [17](#), [18](#) and [19](#)].

[Section B3.4.3](#), [Section B3.4.4](#), [Sections B3.4.5](#) describe methods of solving the Schrödinger equation for scattering events. [Sections B3.4.6](#) and [Sections B3.4.7](#) proceed to discuss photo-dissociation and bound states.

As these methods are explored, it is quickly realized that the numerical effort in the theoretical description grows prohibitively large with the number of atoms in a molecule. The difficulty lies in precisely what makes molecular motion fundamentally quasi-classical, i.e. the large molecular masses (relative to the mass of the electron). Consequently, a molecular wavefunction has many oscillations and is difficult to model numerically. There have been many attempts at developing alternate approaches for representing quantum wavefunctions and observables without the use of large grids or basis sets, ranging from approximations to path-integral descriptions. The basics of these approaches are described in [Sections B3.4.8](#). Later, [Sections B3.4.9](#) describes the issues involved in the study of non-adiabatic phenomena.

Finally, [Sections B3.4.10](#) touches on the application of quantum molecular dynamics to a very exciting field: laser interactions with molecules. This field presents, in principle, the opportunity to influence chemistry by lasers rather than to simply observe it.

The scope of this section restricts the discussion. One omitted topic is the collision and interaction of molecules with surfaces (see [[20](#), [21](#)] and [section A3.9](#)). This topic connects quantum molecular dynamics in gas and condensed phases. Depending on the time scales of the interaction of a molecule with a surface, the

reactions are similar to those

-2-

in one phase or the other. If the collision is fast, so that one may neglect the motion of the surface molecules and treat them as frozen, it is effectively a gas-phase reaction. On the other extreme, if the motion of the adsorbate is slow or comparable in time to the motion of surface and subsurface molecules, then the collision problem becomes very similar to the interaction of molecules in condensed phases. The latter is a subject of a separate [Sections C3.5](#).

Another modern and highly exciting topic, omitted here due to lack of space, is the motion of very cold molecules [[22](#), [23](#) and [24](#)], which can have de Broglie wavelengths that are as large or larger than the distances between the molecules. The simplest examples are essentially extensions of floppy van der Waals structures, but at the extreme, when the wavelength is extremely large and there are many molecules per molecular wavelength, one ends up with Bose–Einstein condensates (where the wavefunctions of the molecules coalesce to form one giant coherent molecular function) and even molecular lasers (i.e. lasers where the fundamental particles are atoms or molecules rather than photons [[25](#)]) can be made. [Sections C1.4](#) provides an overview of this new field.

As in any field, it is useful to clarify terminology. Throughout this section an ‘atom’ more specifically refers to its nuclear centre. Also, for most of the section the $\hbar=1$ convention is used. Finally, it should be noted that in the literature the label ‘quantum molecular dynamics’ is also sometimes used for a purely classical description of atomic motion under the potential created by the electronic distribution.

Finally, this section is related to several others, especially [Sections A3.11](#) on formal scattering, which should be carefully consulted.

B3.4.2 QUANTUM MOTION ON A SINGLE ELECTRONIC SURFACE

A corner-stone of a large portion of quantum molecular dynamics is the use of a single electronic surface. Since electrons are much lighter than nuclei, they typically adjust their wavefunction to follow the nuclei [[26](#)]. Specifically, if a collision is started in which the electrons are in their ground state, they typically remain in the ground state. An exception is non-adiabatic processes, which are discussed later in this section.

The single-surface assumption, known also as the Born–Oppenheimer approximation, implies that the nuclei are described by a single wavefunction ($\psi(\mathbf{x},t)$ where \mathbf{x} is a multi-dimensional vector describing the nuclear position). The time-dependent equation for the evolution of the wavefunction is simply

$$i\frac{\partial\psi}{\partial t} = \hat{H}\psi \equiv [\hat{K} + V(\mathbf{x})]\psi \quad (\text{B3.4.1})$$

where \hat{H} is the Hamiltonian governing the motion of the nuclei (or the atomic motion, as typically denoted), \hat{K} is the kinetic term (a sum of terms of the form $-(1/2m_j)(\partial^2/\partial\mathbf{x}_j^2)$ for each atom j) and V is the Born–Oppenheimer potential which is defined as the electronic ground-state energy for nuclear configuration $\bar{\mathbf{x}}$, including the nuclear–nuclear repulsion.

As a word of caution, the Born–Oppenheimer assumption is not universally valid. There are many reactions in which,

for example, non-adiabatic curve-crossing processes occur. In these cases, two electronic potentials—e.g., the ground state and an excited state—are locally equal to one another at some configuration. Curve-crossing effects are highly non-trivial and can affect the nuclear dynamics even at energies which are way below the curve crossing. These points are briefly discussed in [Sections B3.4.9](#).

B3.4.3 SCATTERING

B3.4.3.1 COLLINEAR MOTION

[Equation \(B3.4.1\)](#) is general and applies to both scattering and bound state spectroscopy. Scattering will be considered first. For simplicity, the discussion uses the collinear model for the $\mathbf{A} + \mathbf{BC} \rightarrow \mathbf{AB} + \mathbf{C}$ reaction (i.e. assuming all particles lie on a line). This model is easy to visualize and embodies most elements of three-dimensional (3D) scattering of larger molecules.

After removal of centre-of-mass motion, there are two independent distances which need to be considered for a collinear problem, r_{BA} ($\equiv r_{\text{B}} - r_{\text{A}}$, where r_{B} and r_{A} denote the positions of A and B on the line) and r_{CB} , which is similarly defined. Unfortunately, the kinetic energy is not conveniently described with these coordinates; therefore, alternate systems are used. The most convenient one is reactant Jacobi coordinates (r, R) , where $r = r_{\text{CB}}$, and R is the distance between A and the centre of mass of B and C [27]. In these coordinates, the kinetic energy gets a simple and separable form so that the Schrödinger equation is

$$i \frac{\partial \psi}{\partial t} = \left[-\frac{1}{2M} \frac{\partial^2}{\partial R^2} - \frac{1}{2\mu} \frac{\partial^2}{\partial r^2} + V(R, r) \right] \psi \quad (\text{B3.4.2})$$

where μ is the reduced mass associated with the BC vibration, and M is the mass associated with the A–BC motion.

[Figure B3.4.1](#) shows the potential surface for a simple collinear reaction, $\mathbf{D} + \mathbf{H}_2 \rightarrow \mathbf{HD} + \mathbf{H}$. The most notable aspect of this potential is the angle between the products and reactant arrangement. Below breakup ($\mathbf{D} + \mathbf{H}_2 \rightarrow \mathbf{D} + \mathbf{H} + \mathbf{H}$, which can occur only at several electronvolts above the reaction threshold), the potential surface has three relevant regions: the reactants ($\mathbf{D} + \mathbf{H}_2$) asymptote (arrangement) at large R and small r ; the products ($\mathbf{H} + \mathbf{DH}$) asymptote; and a strong interaction region where all three atoms are closely spaced. The strong-interaction region is extended over a region of $\approx 1 \text{ \AA} \times 1 \text{ \AA}$, containing several oscillations of the full (DH_2) wavefunction. Since the potential is not separable in R and r , upon reaction the particles would exchange vibrational and translational energy (and in the three-dimensional case, also rotational energy).

Figure B3.4.1. The potential surface for the collinear $D + H_2 \rightarrow DH + H$ reaction (this potential is the same as for $H + H_2 \rightarrow H_2 + H$, but to make the products and reactants identification clearer the isotopically substituted reaction is used). The $D + H_2$ reactant arrangement and the $DH + H$ product arrangement are denoted. The coordinates are r , the H_2 distance, and R , the distance between the D and the H_2 centre of mass. Distances are measured in angströms; the potential contours shown are 4.7 eV, -4.55 eV, . . ., -3.8 eV. (The potential energy is zero when the particles are far from each other. Only the first few contours are shown.) For reference, the zero-point energy for H_2 is -4.47 eV, i.e. 0.27 eV above the H_2 potential minimum (-4.74 eV); the room-temperature thermal kinetic energy is approximately 0.03 eV. The graph uses the accurate Liu–Seigbahn–Truhlar–Horowitz (LSTH) potential surface [195].

The collinear model does not include bifurcation, i.e. the possibility of *several* product channels which the system can access. A model potential surface for an $A + BC \rightarrow AB + C$, $AC + B$ reaction is shown in figure B3.4.2. Both of these examples will be used in the discussion below.

Figure B3.4.2. (a) A schematic potential surface showing bifurcation for a triatomic reactive system. (b) By blocking the products' arrangement with an absorbing potential (shaded area) the reactive system is reduced to one arrangement; this scheme enables calculation of both total reactivities and state-to-state information. Reprinted from [46] with permission.

B3.4.3.2 BOUNDARY CONDITIONS

The eventual goal in scattering calculations is essentially to obtain the scattering matrix, S (see Section A3.11 and equation (B3.4.4) below). The scattering matrix can be obtained by reference to the solution of the time-independent Schrödinger equation, fulfilling

$$(\hat{H} - E)\psi = 0 \quad (\text{B1.4.3})$$

which is the Fourier transform of [equation B3.4.1](#). However, this wavefunction must obey the appropriate boundary conditions. It should have components associated with a single ‘incoming’ channel (an incoming wave associated with the translational $\mathbf{A} + \mathbf{BC}$ motion, e^{-ikR} , multiplied by a wavefunction for BC at a specific initial target state, $\phi_{n_0}(r)$). In addition, there are components associated with all ‘outgoing’ channels. (See [Section A3.11](#) and [\[27\]](#).) For example, for the bifurcating potential case where three asymptotic arrangements are formally possible, the wavefunction (with an index n_0 attached) is

$$\begin{aligned} \psi_{n_0}(\mathbf{x}, E) = & \phi_{n_0}(r) \frac{e^{-ik_{n_0}R}}{\sqrt{k_{n_0}/M}} - \sum_n \phi_n(r) \frac{e^{ik_n R}}{\sqrt{k_n/M}} S_{nn_0} \\ & - \sum_{\bar{n}} \phi_{\bar{n}}(\bar{r}) \frac{e^{ik_{\bar{n}} \bar{R}}}{\sqrt{k_{\bar{n}}/M}} S_{\bar{n}n_0} - \sum_{\bar{\bar{n}}} \phi_{\bar{\bar{n}}}(\bar{\bar{r}}) \frac{e^{ik_{\bar{\bar{n}}} \bar{\bar{R}}}}{\sqrt{k_{\bar{\bar{n}}}/\bar{M}}} S_{\bar{\bar{n}}n_0} \end{aligned} \quad (\text{B3.4.4})$$

where ϕ_n is the n th vibrational state of the BC diatomic and k_n is the translational momentum of A when BC is in the n th state ($k_n^2/2M = E - \epsilon_n$). Quantities with a $(\bar{r}, \bar{R}, \text{etc})$ refer to the product channel $\mathbf{AB} + \mathbf{C}$, so \bar{R} is the distance between $\mathbf{AB} + \mathbf{C}$, etc. In addition, for cases in which the $\mathbf{AC} + \mathbf{B}$ channel is open, a double-bar notation is used ($\bar{\bar{n}}, \bar{\bar{r}}, \text{etc}$). $S_{\bar{n}n_0}$ is the scattering matrix associated with the amplitude of the system to emerge at product channel \bar{n} when it is initially at reactant channel n_0 . The equality sign is in quotes to denote that this relation is only valid in the asymptote where the system is separated into an atom and a diatom.

B3.4.3.3 SCATTERING TECHNIQUES

The presence of the multiple arrangements make molecular scattering very challenging theoretically. After much trial and error, several techniques have been developed. These techniques generally fall into two broad categories:

- methods which aim at treating all possible arrangements simultaneously;
- arrangement-decoupling approaches [\[28, 29, 30 and 31\]](#) where an absorbing potential is used to convert multiple-arrangement problems to inelastic-scattering (or even bound-state-like) problems. In recent years, these approaches have become very powerful for large-scale applications.

B3.4.3.4 ALL-ARRANGEMENT METHODS

(A) WAVEFUNCTION EXPANSION

The conceptually simplest approach to solve for the S -matrix elements is to require the wavefunction to have the form of [equation \(B3.4.4\)](#), supplemented by a bound function which vanishes in the asymptote [\[32, 33, 34 and 35\]](#) This approach is analogous to the full configuration-interaction (CI) expansion in electronic structure calculations, except that now one is expanding the nuclear wavefunction. While successful for intermediate size problems, the resulting matrices are not very sparse because of the use of multiple coordinate systems, so that this type of method is prohibitively expensive for diatom–diatom reactions at high energies.

(B) CLOSE COUPLING

Alternatively, one can use close-coupling methods. These methods are easiest to understand for single arrangement problems (i.e. when both the **AB** + **C** and **AC** + **B** product arrangements are very high in energy so that only the **A** + **BC** reactant arrangement can be accessed). Then one writes

$$\psi_{n_0}(R, r, E) = \sum_n a_{nn_0}(R) \phi_n(r) \quad (\text{B3.4.5})$$

and it is readily shown that the Schrödinger equation can be written as

$$\frac{\partial^2}{\partial R^2} a_{nn_0} = 2M \sum_m (U_{nm}(R) - E \delta_{mn}) a_{mn_0} \quad (\text{B3.4.6})$$

where

$$U_{nm}(R) = \int \phi_n(r) \left(-\frac{1}{2\mu} \frac{\partial^2}{\partial r^2} + V(R, r) \right) \phi_m(r) dr. \quad (\text{B3.4.7})$$

Equation (B3.4.6) is solved by starting at a small value of R , denoted by R_{start} , where the potential is high and the wavefunction is exponentially vanishing, and picking random values for a_{nn_0} and $\delta a_{nn_0}/\delta R$. Then, the equations are propagated towards larger R . Eventually, $\psi(R, r)$ is resolved at a large value of R to yield the S -matrix [36]. In practice, one has to avoid linear dependence between the solutions associated with different initial conditions. This is achieved by simple stabilization approaches.

The close-coupling approach works readily and simply if the reaction is purely ‘inelastic’. The method can also be made to work very simply for a single product arrangement (as in collinear reactions), by using a ‘twisted’ coordinate system, most conveniently reaction path coordinates [37, 38 and 39] as shown in [figure B3.4.3](#).

Figure B3.4.3. A schematic figure showing, for the DH_2 collinear system, a reaction-path coordinate Q connecting continuously the reactants and the single products asymptote. Also shown are the cuts denoting the coordinate perpendicular to Q .

The complications which occur with bifurcation, i.e. when more than one product arrangement is accessible, can be solved by various methods. Historically, the first close-coupling approaches for multiple product channels employed fitting procedures [40], where the close-coupling equations are simultaneously propagated from each of the asymptotes inwards and then are fitted together at a dividing surface. This approach has been replaced in recent calculations by two methods. One is based on using absorbing potentials to turn the reactive problem into an inelastic one, as explained later. The other is to use hyperspherical coordinates for carrying out the close-coupling propagation [41, 42, 43, 44 and 45]. The hyperspherical coordinates consist of a single radius ρ , which is zero at the origin (when all nuclei are stuck together) and increases outwards, and a set of angles. For the collinear problem as well as the atom-diatom problem (involving three independent distances) the hyperspherical coordinates are typically just the regular spherical coordinates. Close-coupling propagation starts at $\rho = 0$ and moves outward until a large value of ρ is reached. When the asymptote are reached one fits the wavefunction to have the form of [equation \(B3.4.4\)](#) and thus obtains the scattering matrix.

B3.4.4 ARRANGEMENT DECOUPLING BY ABSORBING POTENTIALS

A simplifying approach to scattering is to eliminate all the product asymptote. This can be done efficiently and rigorously [28, 30, 31, 46] by inserting in the Hamiltonian a negative-imaginary potential (or more generally a complex potential with a negative imaginary term) [30, 47, 48 and 49]. This potential, denoted as $-iV_{\lambda}(R,r)$, acts to ‘chop’ away the product arrangements, while retaining the correct form of the wavefunction (see [figure B3.4.4](#)).

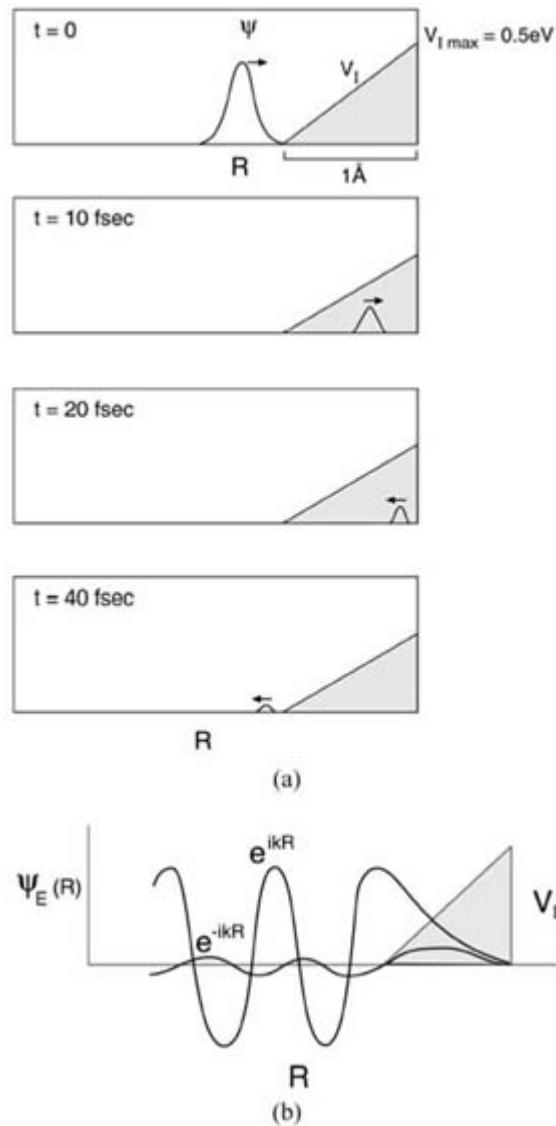

Figure B3.4.4. (a) Schematic evolution in a 1D problem of a wavepacket impinging on an absorbing potential with typical parameters (shaded). The width and magnitude of the absorbing potential must be sufficiently large so that a wavepacket impinging on it would eventually be completely absorbed, with very little reflected. (b) In time-independent language, the absorbing potential forces the wavefunction in the region preceding it to have an outgoing (e^{ikR}) form, with very little reflected (e^{-ikR}) component.

To understand this unique feature of the negative imaginary potential it is easiest to refer to the time-dependent language, discussed later in the section. Heuristically, note that the time-dependent propagator, $e^{-i(\hat{H}-iV_I)t}$ essentially contains a $e^{-V_I t}$ term which decays the wavefunction in regions where V_I is positive. The negative imaginary potential therefore prevents reflection and thus imposes ‘outgoing boundary conditions’ [31] on the wavefunctions to which they are applied.

There is considerable freedom in the choice of absorbing potentials; they are simply required [30] to be sufficiently extended to absorb any wavefunction which impinges on them, while not rising too sharply to avoid reflection from their rising slopes before the wave gets absorbed. This implies that they typically need to extend only over approximately one to two de Broglie wavelengths, which is usually short enough to add

only a negligible overhead to the size of the required grids.

The negative imaginary potentials can be applied in any scattering formalism. In close coupling, they can be implemented to block any product arrangement [31] (see figure B3.4.2) and this thereby converts the reactive problem to an inelastic one; the only cost is the propagation of a complex matrix, a_{nn_0} rather than a real one.

Alternately, absorbing potentials can also be applied to convert scattering to a bound-state-like problem. One method is to write the Schrödinger wavefunction as a sum of two terms $\psi_{n_0}(E) = \chi_{n_0}(E) + \zeta_{n_0}(E)$, where ζ_{n_0} includes the known incoming wave term, and χ includes the unknown outgoing wave part (see figure B3.4.5). The final equation is then [28]

$$(E - (\hat{H} - iV_I))\chi_{n_0} = (\hat{H} - E)\zeta_{n_0} \quad (\text{B3.4.8})$$

where the absorbing potentials are inserted to impose the correct boundary conditions on χ_{n_0} .

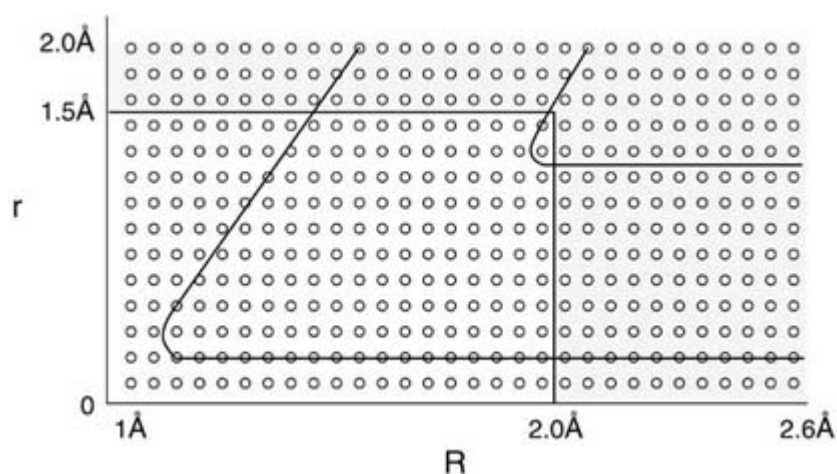

Figure B3.4.5. Schematic plot of a two-dimensional potential surface for $D + H_2$ restricted by an absorbing potential (shaded area). The absorbing potential $iV_I(R, r)$ (shaded region) rises gently outward towards the edges of the grid. In practice, the grid needs to be extended only by $\approx 0.5\text{--}1 \text{ \AA}$, or less for heavier mass systems. The absorbing potential imposes the correct boundary condition on the wavefunction in the inner region. This basic paradigm of a small grid (denoted by dots), used in the strong-interaction region to describe the main part of the wavefunction, applies in several different formulations: time-independent arrangement-decoupling scattering, where the time-independent wavefunction $\chi_{n_0}(R, r, E)$ is placed on this grid (supplemented by a function describing the initial wavefunction); time-dependent scattering (where it is used to describe the non-elastic part of the wavefunction, and the elastic part is

represented on a separate grid); flux-flux studies, and photodissociation. All desired scattering information can be obtained from the information on the wavefunction in the strong-interaction region.

This approach has one key advantage [30]. Although when solving for χ one needs to invert $(E - \hat{H} + iV_I)$ (more precisely calculate the action of the so-called Green's function $(E - \hat{H} + iV_I)^{-1}$ on the initial state), the operator is defined in a finite region so that the wavefunction can be written on a single small grid covering the small-interaction region (as no asymptotic regions are involved). This makes the operation by \hat{H} very rapid

(formally, \hat{H} is then very sparse) so that efficient iterative methods can be used [50, 51, 52, 53 and 54]. It is then possible to handle grid sizes of more than a million points. Thus systems like $\mathbf{AB} + \mathbf{CD}$ rearrangement scattering, with six or more floppy distances (and ≈ 10 points per degree of freedom) are now routinely done with arrangement decoupling approaches based on absorbing potentials. The most widely applied iterative method with absorbing potentials and arrangement decoupling was developed within a time-dependent formulation, and is discussed below.

B3.4.4.1 THE TIME-DEPENDENT METHOD

The approaches discussed so far are generally called time-independent methods, since they start from the time-independent Schrödinger equation, $(\hat{H}-E)\psi_{n_0}$. An alternative is to use the time-dependent Schrödinger equation [28, 29, 50, 55, 56, 57, 58, 59, 60, 61, 62, 63 and 64]. Conceptually, the time-dependent approach is very simple: prepare an initial wavepacket on an appropriate grid; propagate the initial wavepacket for a sufficiently long time; and analyse the results. The approach is efficient, since propagation of a wavepacket is relatively cheap and since results on scattering at many energies are extracted at once. Correct boundary conditions have a very simple meaning in time-dependent approaches: the scattered component of the wavepacket is not returned from the edges of the grid. This is done by adding an absorbing potential to the Hamiltonian, which absorbs any component of the wavefunction that reaches the edge of the grid.

In more detail, in time-dependent approaches an initial wavepacket associated with the separate parts of the colliding system is prepared. The most efficient approach for a grid construction is to use two grids. Thus, the total wavefunction is divided into two parts [30, 65], a simple one which defines the initial wavefunction and a more complicated part, represented (for collinear scattering) on a two-dimensional grid of R, r values, which is used to carry most of the wavefunction (essentially the scattered part) and which is padded with absorbing potentials (see figure B3.4.5). With this approach and with methods which reduce the number of grid points (in a given region) to at most two per oscillation [50, 66, 67], the total number of grid points can be reduced to 150–800 for collinear scattering involving hydrogen with energies of up to 2 eV.

Once the grid (or two grids) are prepared, there are two similar types of approaches to propagate the initial wavefunction forward with time. One approach is split-operator methods, [59] where the short-time propagator is divided into a kinetic and potential parts so that

$$|\psi_{n_0}(t+dt)\rangle \approx \exp\left[-i\frac{(V-iV_I)dt}{2}\right] \exp\left[-i\left(\frac{P^2}{2M} + \frac{p^2}{2\mu}\right)dt\right] \exp\left[-\frac{i(V-iV_I)dt}{2}\right] |\psi_{n_0}(t)\rangle \quad (\text{B 3.4.9})$$

-11-

where a bra-ket notation is used. The action by the potential is trivial, since it is local in coordinate space, and amounts to multiplication of $\psi_{n_0}(R, r, t)$ by $\exp(-iV(R,r)dt/2)$, and by a damping term, $\exp(-V_I(R,r)dt/2)$.

The action by the kinetic term is only slightly more complicated: the coordinate grid wavefunction, $\psi_{n_0}(R, r)$, undergoes a fast Fourier transform (FFT) to convert it to momentum space:

$$\psi_{n_0}(P, p, t) = \sum_{R,r} e^{-i(pr+PR)} \psi_{n_0}(R, r, t). \quad (\text{B 3.4.10})$$

The function is then multiplied by $\exp(-i((P^2/2M) + (p^2/2\mu))dt)$ and then returned to coordinate space by the

inverse of equation (B3.4.10).

The key to this method is thus to act with each operator (exponential of the potential or kinetic term) in the representation (coordinate or momentum grid) in which it is local [50, 66, 67].

An alternative to split operator methods is to use iterative approaches. In these methods, one notes that the wavefunction is formally $|\psi_{n_0}(t)\rangle = \exp(-i\hat{H}t)|\psi_{n_0}\rangle$, and the action of the exponential operator is obtained by repetitive application of H on a function (i.e. on the computer, by repetitive applications of the sparse matrix H on wavefunction vectors). The simplest iterative method is the Taylor expansion of $e^{-i\hat{H}t}|\psi_{n_0}\rangle$ as $\sum_n ((-i)^n t^n / n!) \hat{H}^n |\psi_{n_0}\rangle$. On the computer, this expansion would be performed by acting with \hat{H} on ψ_{n_0} , then acting with \hat{H} on the resulting vector, etc, and adding the contribution to the sum at each stage. The action by \hat{H} on a vector is straightforward, as in the split operator approach: the potential is local, and the kinetic energy is evaluated by Fourier transforming back and forth onto the momentum grid.

The Taylor series by itself is not numerically stable, since the individual terms can be very large even if the result is small, but other polynomials which are highly convergent can be found, e.g. Chebyshev [50, 62, 63 and 64] or Lancosz polynomials [51, 68].

The wavepacket is propagated until a time where it is all scattered and is away from the interaction region. This time is short (typically 10–100 fs) for a direct reaction. However, for some types of systems, e.g. for reactions with wells, the system can be trapped in resonances which are quasi-bound states (see section B3.4.7). There are efficient ways to handle time-dependent scattering even with resonances, by propagating for a short time and then extracting the resonances and adding their contribution [69].

The last stage is the extraction of energy-resolved information, obtained automatically and simultaneously at many energies, by Fourier transforming the wavefunction to produce an energy-resolved state:

$$\psi_{n_0}(R, r, E) = \frac{1}{a_E} \int_{-\infty}^{\infty} \psi_{n_0}(R, r, t) e^{iEt} dt \quad (\text{B 3.4.11})$$

-12-

where a_E is related to the energy content of the initial wavepacket. It is easy to show that $\psi(R, r, E)$ fulfills the time-independent Schrödinger equation. (In practice, ψ is known analytically prior to $t = 0$, so that the wavefunction only needs to be propagated forward in time.) The scattering matrix is then obtained from either of several formulae, all of the form [46, 65, 70, 71, 72, 73 and 74]

$$S_{\bar{n}n_0} = \langle \xi_{\bar{n}} | \psi_{n_0}(E) \rangle \quad (\text{B 3.4.12})$$

where $\xi_{\bar{n}}$ is a simple function which is associated with the final state \bar{n} . These formulae extract long-range scattering information from the wavefunction values in the strong-interaction region. Scattering information can therefore be extracted even when absorbing potentials are used to remove the asymptotic regions.

An interesting side point is that it is possible to recast the time-dependent approach, as described here, in a purely time-independent fashion, since from the equations above it follows that [74]

$$\psi_{n_0}(E) = \text{constant} \frac{1}{E - \hat{H} + iV_I} \psi_{n_0}.$$

The time-dependent approach is thus just one technique for evaluating the action of the Green's function on the initial wavepacket.

B3.4.4.2 LARGE-SCALE APPLICATIONS

Both close-coupling approaches (hyperspherical or with absorbing potentials) and iterative/time-dependent absorbing-potential arrangement-decoupling approaches are readily extended to three-dimensional atom-molecule and molecule-molecule scattering. The wavefunction representation becomes more complicated and includes rotational matrices, but the essence and application of the method remains analogous [58, 65, 75, 76].

Iterative approaches, including time-dependent methods, are especially successful for very large-scale calculations because they generally involve the action of a very localized operator (the Hamiltonian) on a function defined on a grid. The effort increases relatively mildly with the problem size, since it is proportional to the number of points used to describe the wavefunction (and not to the cube of the number of basis sets, as is the case for methods involving matrix diagonalization). Present computational power allows calculations with optimized grids with sizes of 10^5 – 10^7 points or more. This enables efficient simulations of four-body reactions involving six independent distances and up to two overall rotational coordinates. Thus far there have been several four-body reactions reported using this method, including $\text{H}_2 + \text{OH} \rightleftharpoons \text{H}_2\text{O} + \text{H}$ [75, 76, 77 and 78] and $\text{CO} + \text{HO} \rightleftharpoons \text{CO}_2 + \text{H}$ [79, 80], as well as surface reactions [58, 81] (see figure B3.4.6 for an example).

-13-

Figure B3.4.6. Reaction probabilities for the initial-state-selected process $\text{H}_2(v=0, j=0) + \text{OH}(v, j=0) \rightarrow \text{H}_2\text{O} + \text{H}$, for zero total angular momentum. Taken from [75] with permission.

B3.4.5 COARSE INFORMATION

The methodology presented so far allows the calculations of state-to-state S -matrix elements. However, often one is not interested in this high-level of detail but prefers instead to find more average information, such as the initial-state selected reaction probability, i.e. the probability of rearrangement given an initial state n_0 . In general, this probability is

$$P_{n_0}(E) = \sum_{\bar{n}} |S_{\bar{n}n_0}(E)|^2. \quad (\text{B 3.4.13})$$

For example, for the collinear reaction A+BC this would be the probability that if initially the diatom BC is in a vibrational state $\phi_{n_0}(r)$, then after the reaction a diatom AB is formed (in *any* product vibrational state). In practice, the initial-state selected probability is easily calculated from the flux of the wavefunction $\psi_{n_0}(R, r, E)$ calculated at the product arrangement (e.g., at a large value of r , the B–C separation).

At times, however, even the information presented by P_{n_0} is too detailed. If one wants to rigorously calculate the thermal rate of rearrangement reactions, the initial vibrational state is not important. The relevant quantity is the sum of the initial-state-selected probabilities

$$N(E) = \sum_{n_0} P_{n_0}(E) = \sum_{n_0 \bar{n}} |S_{\bar{n}n_0}(E)|^2. \quad (\text{B 3.4.14})$$

-14-

$N(E)$ is called the cumulative reaction probability. It is directly related to the thermal reaction rate $k(T)$ by

$$k(T) = \frac{\int N(E) e^{-E/kT} dE}{Q} \quad (\text{B 3.4.15})$$

where T is the temperature and Q is the reactants' partition function.

A major achievement [71, 82, 83, 84, 85, 86, 87 and 88] was the development of a simple quantum ('flux-flux') expression for the cumulative reaction probability, $N(E)$, with the final result [88]

$$N(E) \propto \text{Im Tr}(FGFG^*) \quad (\text{B 3.4.16})$$

where the Green's function is, as mentioned earlier,

$$G(E) = \frac{1}{E - (\hat{H} + iV_I)} \quad (\text{B 3.4.17})$$

and F is the flux operator. In this expression, the trace is evaluated over a small grid region. In principle, the grid has to contain only a small-interaction region, in which the system 'decides' its final arrangement (i.e. with what probability to react). This expression does not refer to the scattering matrix and therefore the asymptotic region does not have to be included in the grid.

The flux-flux expression and its extensions have been used to calculate reaction probabilities for several important reactions, including $\text{H}_2 + \text{O}_2 \rightarrow \text{H} + \text{H}_2\text{O}$, by explicit calculation of the action of G in a grid representation with absorbing potentials. The main power of the flux-flux formula over the long run will be the natural way in which approximations and semi-classical expressions can be inserted into it to treat larger systems.

B3.4.6 PHOTO-DISSOCIATION

The time-dependent approach has the advantage that it is easy to visualize the propagation of a simple wavepacket and make intuitive sense of a large body of chemical phenomena. This is especially powerful in photo-initiated processes. As a result of a photon absorption, the ground-state wavefunction is ‘jumped’ to a higher potential energy surface of a different electronic state and propagates on this new surface. The initial excitation is, by the Frank–Condon principle, essentially vertical (i.e. the nuclear position and momentum do not change, only the electronic state). The subsequent process (see [figure B3.4.7](#)) is the response of the nuclear coordinates to the change in the electronic state.

-15-

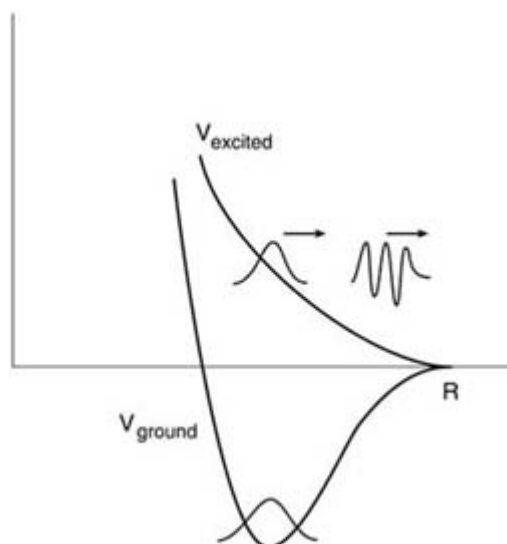

Figure B3.4.7. Schematic example of potential energy curves for photo-absorption for a 1D problem (i.e. for diatomics). On the lower surface the nuclear wavepacket is in the ground state. Once this wavepacket has been excited to the upper surface, which has a different shape, it will propagate. The photoabsorption cross section is obtained by the Fourier transform of the correlation function of the initial wavefunction on the excited surface with the propagated wavepacket.

For two Born–Oppenheimer surfaces (the ground state and a single electronic excited state), the total photo-dissociation cross section for the system to absorb a photon of energy ω , given that it is initially at a state $|\chi\rangle$ with energy E_0 can be shown, by simple application of second-order perturbation theory, to be [89]

$$\sigma(\omega) = \text{constant} \cdot \int e^{i(\omega+E_0)t} c(t) dt \quad (\text{B 3.4.18})$$

where the correlation function is defined as

$$c(t) = \langle \Phi | e^{-i\hat{H}_{\text{exc}}t} | \Phi \rangle \quad (\text{B 3.4.19})$$

$\Phi = \mu\chi$, μ is the dipole moment and χ is the initial vibrational state on the ground surface (with energy E_0). \hat{H}_{exc} is the excited-state potential energy. This expression has a clear physical meaning. Take an initial wavepacket, χ , multiply it by the dipole moment, and use the resulting packet ($\Phi \equiv \mu\chi$) as an initial function so that it is propagated under the excited-state potential ($\Phi(t) \equiv e^{-i\hat{H}_{\text{exc}}t} \Phi$).

equation (B3.4.18) makes a very powerful statement: absorption is only related to the Fourier transform of the

correlation function. All that is needed is to know how the wavepacket propagates in time on the upper surface. Keeping in mind the time–energy uncertainty principle, one can then qualitatively understand the spectral features in

-16-

photo-absorption [89]. Referring to figure B3.4.8 the correlation function starts at 1 at $t = 0$, then undergoes a period of decay over a time scale denoted by T_1 . This initial decay is more rapid if the excited potential surface is steep, slower if it is shallow. This is the shortest time scale in the correlation function, so it corresponds to the broadest feature in the energy spectrum, i.e. the envelope in figure B3.4.9. In figure B3.4.8, the correlation peaks every time the wavepacket returns to the initial placement (denoted by T_2). In the energy picture, the peak spacing is $2\pi/T_2$. The correlation peaks are decreasing in magnitude over time T_3 as the wavepacket either decays to other modes or moves to another region of the potential energy surface. T_3 is therefore the peak's width in the energy spectrum.

Figure B3.4.8. The correlation function $c(t) = \langle \psi_0 | \psi(t) \rangle$ as a function of time for photodissociation in a collinear (or three-dimensional) polyatomic case. There are three relevant time scales; T_1 , which measures how rapidly the initial wavefunction dephases; T_2 , which measures how long it takes this initial wavefunction to regroup; and T_3 which measures how long the wavefunction takes to ‘leak’ to other degrees of freedom. In practice, photodissociation experiments may yield spectra which are more blurred, if T_1, T_2 and/or T_3 are not well separated.

-17-

Figure B3.4.9. The Fourier transform of the correlation function, from [figure B3.4.8](#), which gives the absorption spectrum as a function of frequency.

This time-dependent method allows one to nicely connect the theoretical and experimental observations. As mentioned earlier, the correlation function and its generalizations yield the spectra for a large number of other photospectroscopy processes, such as Raman processes [[90](#)], as well as molecular scattering [[73](#), [74](#)].

B3.4.7 BOUND STATES AND RESONANCES—EXTRACTION

B3.4.7.1 RESONANCES—FORMALISM

The quantum dynamics of bound and scattered systems is closely correlated through the concept of resonances which are, heuristically, quasi-bound states in which the system can spend time [[6](#), [7](#), [8](#) and [9](#), [91](#), [92](#), [93](#) and [94](#)]. More formally, resonances are poles of the S -matrix. (See section A3.11.) In a scattering process, the cross section typically exhibits peaks as a function of the scattering energy, exactly at (or near) the energy of the resonances. For example, in a one-dimensional scattering off a double well, the scattering probabilities exhibit sharp peaks when the collision energy matches the energy of the quasi-bound states in the well ([figure B3.4.10](#)). (See [figure B3.4.11](#) for a realistic example.)

Figure B3.4.10. Schematic figure of a 1D double-well potential surface. The reaction probabilities exhibit peaks whenever the collision energy matches the energy of the resonances, which are here the quasi-bound states in the well (with their energy indicated). Note that the peaks become wider for the higher energy resonances—the high-energy resonance here is less bound and ‘leaks’ more toward the asymptote than do the low-energy ones.

-19-

Figure B3.4.11. (a) Reaction probability for a 4D study of the dissociation of incident H_2 on CO. The probability exhibits sharp peaks whenever the energy matches that of a resonance wavefunction. (b) Plot of

the resonance wavefunction associated with one of the peaks, as well as (c) a 2D cut of the potential surface. Note that the resonance wavefunction decays near the end of the grid, due to the use of an absorbing potential, which localizes its effects to the strong-interaction region. Taken from [196], with permission.

The classical counterpart of resonances is periodic orbits [91, 95, 96, 97 and 98]. For example, a purely classical study of the $\mathbf{H}+\mathbf{H}_2$ collinear potential surface reveals that near the transition state for the $\mathbf{H}+\mathbf{H}_2\rightarrow\mathbf{H}_2+\mathbf{H}$ reaction there are several trajectories (in R and r) that are periodic. These trajectories are not stable but they nevertheless affect strongly the quantum dynamics. A study of the resonances in $\mathbf{H}+\mathbf{H}_2$ scattering as well as many other triatomic systems (see, e.g., [99]) reveals that the scattering peaks are closely related to the frequencies of the periodic orbits and the resonance wavefunctions are large in the regions of space where the periodic orbits reside.

Theoretically, resonances are essentially solutions of the Schrödinger equation at complex energies. These specific solutions have the property that they are mainly concentrated in the strong-interaction region and at the asymptote are outgoing waves. For one-dimensional predissociation (figure B3.4.12) where the coordinate is labelled R , the resonance wavefunction is asymptotically (i.e. for large positive R) the following outgoing wave:

-20-

$$\psi_{\text{Res}}(R) \approx a e^{ikR} \quad (\text{B 3.4.20})$$

where a is a constant here and k is the energy-dependent wavevector, $k^2/2m = E$. The existence of such a resonance function seems to be baffling, since graduate level quantum mechanical texts [100] prove that the only bound solutions to the Schrödinger equation are those with real energies and zero flux. Heuristically, the solution to this difficulty is that the formal resonance energies are complex. Thus, k is complex and e^{ikR} blows up when R is very large. Therefore, resonance functions are not bound functions and the regular proofs do not apply to them.

Figure B3.4.12. A schematic 1D vibrational pre-dissociation potential curve (wide full line) with a superimposed plot of the two bound functions and the resonance function. Note that the resonance wavefunction is associated with a complex wavevector and is slowly increasing at very large values of R . In practice this increase is avoided by using absorbing potentials, complex scaling, or stabilization.

The key to practical calculations of resonances is to limit the extent of the grids used for describing the wavefunctions. In the original approach, called ‘stabilization’ [92, 93 and 94], a finite grid or basis set is used and the Hamiltonian is diagonalized on that grid (or for that basis set). Those few eigenvalues which change very little when the grid size is modified are associated with the wavefunction of the resonances. (The resonances are concentrated in the interaction region, so that they are not sensitive to the details of the grid end points.) The main difficulty with this approach is that it necessitates many diagonalizations of the Hamiltonian matrix, one for each grid size.

An alternate and formally very powerful approach to resonance extraction is complex scaling [7, 101, 102, 103, 104, 105, 106 and 107] whereby a new Hamiltonian is solved. In this Hamiltonian, the grid’s multi-dimensional coordinate (e.g., \mathbf{x}) is multiplied by a complex constant α . The kinetic energy gains a constant complex factor ($\partial^2/\partial\mathbf{x}^2 \rightarrow (1/\alpha^2)(\partial^2/\partial\mathbf{x}^2)$), while the potential needs to be evaluated at points with a complex argument $V(\alpha\mathbf{x})$. In a typical calculation, one diagonalizes the resulting complex Hamiltonian for several complex values of α , and the complex resonances are

-21-

those which do not change appreciably with respect to α (analogous to the stabilization approach). Complex scaling has been applied mostly to analytical potentials [7, 101, 102, 103 and 104]; however, it could also be used for numerically– derived potentials [105, 106 and 107].

Finally, the simplest approach to extract resonances is to add to the Hamiltonian an absorbing potential [8, 48, 108, 109], and then look for the complex eigenvalues of the Hamiltonian $\hat{H}-iV_f$. The absorbing potential ensures that the resonance wavefunction has the correct form (is outgoing) in the asymptotic region immediately preceding V_f (see figure B3.4.4). Again, resonance functions are found by varying the parameters (the length and magnitude of V_f).

B3.4.7.2 NUMERICALLY EXTRACTING BOUND STATES AND RESONANCE FUNCTIONS

As explained above, the practical extraction of resonance eigenfunctions and eigenvalues (in complex scaling or with absorbing potentials) amounts to extraction of eigenvalues of a complex Hamiltonian and is thus completely equivalent to extraction of bound states. One method for extracting the complex eigenstates of the Hamiltonian is simply to expand it in terms of a fixed basis set, and diagonalize directly the resulting matrix. This approach works for small- and intermediate-scale problems and/or low-energy eigenstates.

An alternative is to use iterative methods. The simplest iterative technique for calculating bound state or resonances is to pick a random initial wavefunction $\psi_0(\mathbf{x})$ and propagate it forward in time, producing a wavepacket:

$$\psi(\mathbf{x}, t) = e^{-i\hat{H}t} \psi_0(\mathbf{x}). \quad (\text{B 3.4.21})$$

\hat{H} refers here to the complex Hamiltonian, i.e. after complex scaling or inclusion of an absorbing potential; \mathbf{x} is the grid (or basis set) used to represent ψ . Fourier transform ψ with respect to E

$$\psi(\mathbf{x}, E) = \int_0^T e^{iEt} \psi(\mathbf{x}, t) dt \quad (\text{B 3.4.22})$$

where T is a large time. It is clear that the squared norm of $\psi(\mathbf{x}, E)$ (i.e. $\int |\psi(\mathbf{x}, E)|^2 d\mathbf{x}$) has a peak whenever E is

near a resonance or bound-state energy, ϵ_n , since $\psi(x,t)$ has contributions varying as $e^{-i\epsilon_n t}$ from each eigenenergy ϵ_n .

This ‘direct filter’ technique is very powerful [56, 59] in extracting highly excited states, since only the propagation of a wavepacket is required. However, it is inefficient when there are closely-lying eigenvalues (T needs to be larger than the inverse level spacing, $|\epsilon_{n+1} - \epsilon_n|^{-1}$, as a manifestation of Heisenberg’s uncertainty relation) or ϵ_n is a wide resonance (i.e. its imaginary eigenvalue is large in absolute magnitude compared with the level spacing, so that its contribution to the wavepacket, $e^{-i\epsilon_n t}$, is washed out rapidly as a function of time).

To avoid these difficulties an alternate approach, labelled filter diagonalization, was developed [110, 111, 112, 113, 114, 115, 116 and 117]. The approach is powerful for extracting highly excited energies. Mechanistically, filter diagonalization is simple (see figure B3.4.13). The initial wavepacket is propagated for a short time T , and the filtered functions $\psi(x, E)$ are prepared as in equation (B3.4.22) but using a short time T . The filtering is carried out for several

(typically ≈ 50) closely spaced energies which could be way above the ground-state energy. The key is to note that even after a short propagation time, T , the $\psi(x, E)$ functions would only contain contributions from eigenstates within a narrow strip of sampled energies. Thus, the filtered functions $\psi(x, E)$ are an excellent basis for eigenstates and eigenvalues within the filtered energy range. The true eigenvalues within this range are then found by diagonalizing the small (e.g., 50×50) matrix of the Hamiltonian operator within the $\psi(x, E)$ basis. The advantage of filter diagonalization is that it avoids the long propagation times of the pure filter approach as well as the large matrix diagonalizations associated with pure diagonalization.

Figure B3.4.13. The basic premise in filter diagonalization is to filter a wavefunction for a short time at several energies, E_1, E_2, \dots , so that, in energy space, the resulting set of several filtered functions (denoted by full bell-shapes) spans the eigenstates (short bars) in the energy range of interest. The short-time filtered wavefunctions can therefore be used to extract the eigenstates at the desired energy range, with a modest cost, since only short-time filter and small-matrix diagonalizations are used.

As a side note, filter diagonalization is also useful in a more general context. It can be shown that it is an efficient approach for extracting frequencies from a short-time segment of a general signal [112, 113 and 114, 118, 119], so that it is not even necessary to use a wavepacket! All one needs is a signal. This feature is very important in semi-classical and path integral simulations discussed below, where all the information is extracted from a time-dependent correlation function, because the quality of the simulations degrades as a function of time (the number of trajectories is typically increased exponentially as the time is increased); therefore, information must be extracted from the shortest time possible.

The formalism outlined in the previous sections is very useful for small systems, but is, as explained, impractical for more than six to ten strongly interacting degrees of freedom. Thus, alternate approaches are required to represent dynamics for large systems. Currently, there are many new approaches developed and tested for this purpose, and these approaches are broadly classified as follows:

- frozen and zero-point approximations;
- mean-field methods and their extensions;

-23-

- Gaussian-wavepacket-based techniques;
- path-integral and semi-classical approaches.

These approaches are generally interwoven, and some of the most exciting developments in chemical dynamics have been associated with their combinations. This section very briefly describes the motivation behind and the application of these techniques.

B3.4.8.1 FROZEN AND ZERO-POINT APPROXIMATIONS

Often a degree of freedom moves very slowly; for example, a heavy-atom coordinate. In that case, a plausible approach is to use a ‘sudden’ approximation, i.e. fix that coordinate and do reduced dimensionality quantum-dynamics simulations on the remaining coordinates. A common application of this technique, in a three-dimensional case, is to fix the angle of approach to the target [120, 121] (see figure B3.4.14).

Figure B3.4.14. The infinite-order-sudden approximation for $A + BC \rightarrow AB + C$. In this approximation, the BC molecule does not rotate until reaction occurs.

The sudden approach has been applied widely, starting with atom-diatom calculations and continuing today for diatom-diatom calculations [79, 122, 123]. This approach and a related approximation (coupled states or CS, which involves the neglect of Coriolis coupling terms in three dimensions [120, 121, 124, 125]) are much more powerful when combined with the arrangement decoupling with absorbing potentials approach discussed earlier. The reason is that approximations are typically much easier to formulate and apply, and are more valid, for single-arrangement approaches. For an example of the successful merging of approximations and arrangement decoupling, see [126].

A related and particularly simple approximation is J -shifting [127, 128]. This method is a simple (and

generally useful) trick for calculating reaction probabilities in three dimensions from a single calculation with zero total angular momentum ($J = 0$), by approximating the effect of the non-zero angular momentum as shifting a transition state:

-24-

$$P_J(E) = (2J + 1)P_{J=0}(E - C_J) \quad (\text{B 3.4.23})$$

where C_J is determined from the contribution of angular degrees of freedom to the transition state energy.

A related type of approximation is the reaction path method [[122](#), [123](#), [129](#), [130](#), [131](#) and [132](#)], in which the coordinates are divided into those which are relatively rigid during the reaction and are typically associated with harmonic oscillators, and the remaining coordinates (reaction coordinates) which undergo significant change during the reaction. The contribution of those degrees of freedom which are replaced by harmonic oscillators can be taken, for low-energy reactions, simply by the zero point energy of the harmonic oscillators. More sophisticated treatments, appropriate for higher temperatures, are actively developed now in the area of liquid reaction dynamics where they are used to describe effects of solvents (see section C3.5 for details and further references). In addition, proper inclusion of rotational states of the fragments was recently shown to yield accurate results in a molecular multi-dimensional reaction-path-like approach [[133](#)].

B3.4.8.2 MEAN-FIELD METHODS AND THEIR EXTENSIONS

The mean field technique is one of the most robust and simple methods used to handle larger molecules in gas and liquid environments [[50](#), [134](#), [135](#) and [136](#)]. The basic premise of all mean-field methods is that the full wavefunction represents N very weakly coupled modes (Q_i) and can be approximated as

$$\psi(\{Q_i\}; t) = \prod_{i=1}^N \chi(Q_i, t). \quad (\text{B 3.4.24})$$

The result of this approximation is that each mode is subject to an effective average potential created by all the expectation values of the other modes. Usually the modes are propagated self-consistently. The effective potentials governing the evolution of the mean-field modes will change in time as the system evolves. The advantage of this method is that a multi-dimensional problem is reduced to several one-dimensional problems.

The fundamental disadvantage of the mean-field method is that it does not allow modes to respond in a correlated manner to each other. This problem can be somewhat alleviated by a good definition of the relevant coordinate system [[134](#), [136](#)]. (An extension of mean-field methods that does allow for coupling [[137](#), [138](#) and [139](#)] will be discussed later.)

If one is interested in low-lying eigenvalues or low-energy scattering a CI-like approach can be applied, in which one uses zero-order eigenfunctions of a simple Hamiltonian to expand the wavefunction. Spectroscopic calculations including up to 20 to 30 degrees of freedom have been carried out using such an approach [[140](#), [141](#), [142](#) and [143](#)].

B3.4.8.3 GAUSSIAN-WAVEPACKET BASED TECHNIQUES

Gaussian wavepackets are very special functions which, in a sense, bridge the gap between classical and quantum

descriptions [89, 144]. They are defined as

$$\psi(\mathbf{x}, t) = \text{constant} \times \exp(-(\mathbf{x} - \bar{\mathbf{x}}(t))^2 / 2\sigma^2) \exp(i\bar{\mathbf{p}}(t) \cdot \mathbf{x}) \quad (\text{B 3.4.25})$$

where $\bar{\mathbf{x}}(t)$, σ and $\bar{\mathbf{p}}(t)$ are the average position, width and momentum of the packet, respectively. A Gaussian wavepacket represents the ground state of a harmonic oscillator, shifted in position and momentum. (Gaussian wavepackets are also known as Glauber or ‘coherent’ states—although the latter definition is sometimes applied to more general functions.)

The primary property of Gaussian wavepackets is that on a harmonic potential surface they are solutions of the time-dependent Schrödinger equation. Specifically, if one places a Gaussian wavepacket at $t = 0$ on a harmonic oscillator with an arbitrary average position and momentum, $\bar{\mathbf{x}}(t = 0)$ and $\bar{\mathbf{p}}(t = 0)$, the resulting wavefunction will remain a Gaussian. The average position and momentum change in time exactly like a classical particle would.

From this basic fact, several related approaches have emerged. First, a technique in which one propagates classical trajectories forward in time, and uses a single or multiple sets of Gaussian wavepackets (one for each classical trajectory) as an ansatz for the full wavefunction is introduced. For each Gaussian the position and momentum are specified by the classical trajectory [144]. This technique is already able to account for much of the zero-point energy effects. In addition, interference and tunnelling effects can be partially accounted for by adding several multi-dimensional Gaussians [144, 145, 146 and 147]. The method has been shown recently to be very powerful for non-adiabatic coupling problems (see [section B3.4.9](#)).

Gaussian wavepackets have also found use in a new approach that improves on mean-field techniques [137, 138 and 139, 148]. In this method, the degrees of freedom are divided into those which change strongly during the reaction (the ‘system’ coordinates), which are treated by an explicit wavepacket; the remaining ‘bath’ coordinates are treated by Gaussians. The parameters for the bath Gaussians are dependent on the system state, and this introduces explicitly a correlation between the system and bath modes (the bath responds differently to different parts of the system). Use of this technique in multi-dimensional reactions involving tunnelling has shown it to be significantly superior to mean-field techniques, while requiring modest numerical effort even for multi-dimensional systems.

B3.4.8.4 PATH INTEGRAL AND SEMI-CLASSICAL DYNAMICS

In the 1940s, Feynmann realized that quantum mechanics can be recast in a simple form which is very reminiscent of classical mechanics [149, 150]. This approach, path integrals, has been heavily researched in chemical dynamics since, if properly convergent, it could allow calculations on very large systems. Even earlier, van Vleck [151] postulated a semi-classical approach, i.e. a method which (like the Wentzel–Kramers–Brillouin (WKB) approximation) captures quantum interference effects and is accurate when the masses or energies are large so that \hbar can be considered small. This section briefly describes Feynmann’s approach, semi-classical dynamics, and recent developments and improvements.

For concreteness, assume that we consider several particles described together by a multi-dimensional coordinate \mathbf{x} and assume that the kinetic energy is the usual $(-1/2M)(\partial^2/\partial\mathbf{x}^2)$, where M is a single relevant mass. (Hamiltonians in

quantum dynamics can usually be brought to this form upon rescaling of the coordinates by constants.) The basic ingredient in Feynmann's approach is the correlation function for a general function ψ :

$$\langle \psi | \psi(\tau) \rangle = \langle \psi | e^{-i\hat{H}\tau} | \psi \rangle = \int \psi^*(\mathbf{x}'') G(\mathbf{x}'', \mathbf{x}', \tau) \psi(\mathbf{x}', \tau) d\mathbf{x}' d\mathbf{x}'' \quad (\text{B 3.4.26})$$

where the time-dependent Green's function G is very simple:

$$G(\mathbf{x}'', \mathbf{x}', \tau) = \text{constant} \cdot \sum_{\text{path}} e^{iS(\text{path})/\hbar}. \quad (\text{B 3.4.27})$$

In this section, we insert \hbar explicitly. The sum has the following meaning: for each pair of points \mathbf{x}' and \mathbf{x}'' draw a path $\mathbf{x}(t)$ that starts at \mathbf{x}' ($\mathbf{x}(t=0) = \mathbf{x}'$) and ends at \mathbf{x}'' ($\mathbf{x}(t=\tau) = \mathbf{x}''$). This path need not be a classical path (see figure B3.4.15). Each such path contributes $e^{iS/\hbar}$, where S is the action of the path. S (unrelated to the scattering matrix) is calculated very simply as

$$S = \int \left[\frac{M}{2} \left(\frac{dx}{dt} \right)^2 - V(x(t)) \right] dt \quad (\text{B 3.4.28})$$

where V is the potential. This, in principle, gives a very simple prescription. All one has to do in order to calculate quantum mechanical properties is to sum over 'many' quantum trajectories.

Figure B3.4.15. A possible Feynmann path trajectory for a 1D variable as a function of time. This trajectory carries an oscillating $e^{iS/\hbar}$ component with it, where S is the action of the trajectory. The trajectory is highly fluctuating; its values at each time step ($x(dt), x(2dt), \dots$, etc) are not correlated.

Unfortunately, this simple approach is not plausible numerically. The integral, as presented, will not converge, even for short times. The problem is that even trajectories which are 'wild', i.e. highly fluctuating, contribute,

per path, the same as trajectories that are ‘gentle’. The key to introducing convergence is to realize that highly fluctuating trajectories or trajectories that lie in regions of high potential energy give contributions that are cancelled by those of other nearby trajectories. Thus, a *bundle* of highly fluctuating trajectories gives only a very weak contribution. The only trajectories that give very strong contribution are *classical* trajectories (for example, if there is no potential, the classical trajectory would run with constant velocity from \mathbf{x}' to \mathbf{x}''). This realization is the key to the development of semi-classical approaches, i.e. approaches in which the exact calculation of the time-dependent Green’s function is replaced by the sum of contributions of classical trajectories. The basic semi-classical expression is [151, 152, 153, 154, 155, 156, 157 and 158]

$$\langle \psi | \psi(t) \rangle = \text{constant} \int \sum_{\text{path}} \frac{e^{iS_{\text{path}}/\hbar}}{\sqrt{|\partial \mathbf{p}''/\partial \mathbf{x}'|}} \psi^*(\mathbf{x}'') \psi(\mathbf{x}') d\mathbf{x}'' d\mathbf{x}'. \quad (\text{B 3.4.29})$$

Note the meaning of this expression: for each choice of the initial and final position \mathbf{x}' and \mathbf{x}'' , calculate the classical path that takes you from \mathbf{x}' to \mathbf{x}'' in time t . Specifically, calculate the momentum along the path and the final momentum, \mathbf{p}'' , and find out how \mathbf{p}'' varies with the initial position. This would give, for a multi-dimensional problem, a matrix $\partial \mathbf{p}''/\partial \mathbf{x}'$; whose absolute determinant needs to be inverted.

There is a simple physical explanation to the inverse determinant in equation (B3.4.29). Each classical trajectory has a ‘volume’ of quantum trajectories nearby which have similar phases to it. Beyond that volume, the phases are becoming random. Thus, the larger that volume, the greater contribution would that bundle give to the final semi-classical ‘propagator’. If \mathbf{p}'' varies slowly when \mathbf{x}' is changed (and $|\partial \mathbf{p}''/\partial \mathbf{x}'|$ is small), the action’s phase varies slowly under a change in the end-point position, so the volume of the quantum trajectories that surround the classical trajectory is also large, and a large contribution is expected from the semi-classical propagator.

Expression (B3.4.29) is still not well suited for classical simulations due to several reasons. First, $|\partial \mathbf{p}''/\partial \mathbf{x}'|$ can vanish at specific times, which leads to infinities in the result. (In classical scattering this is related to the existence of ‘scattering rainbows’.) This is easily circumvented by changing integration parameters, from \mathbf{x}'' to \mathbf{p}' (i.e. from the final position to the initial momentum)

$$d\mathbf{x}' d\mathbf{x}'' = \left| \frac{\partial \mathbf{x}''}{\partial \mathbf{p}'} \right| d\mathbf{x}' d\mathbf{p}' \quad (\text{B 3.4.30})$$

leading to [156, 157]

$$\langle \psi | \psi(t) \rangle = \int \left| \frac{\partial \mathbf{p}''}{\partial \mathbf{x}'} \right|^{\frac{1}{2}} \psi^*(\mathbf{x}'') \psi(\mathbf{x}') e^{iS(\mathbf{x}', \mathbf{p}', t)/\hbar} d\mathbf{x}' d\mathbf{p}'. \quad (\text{B 3.4.31})$$

This transform also solves the boundary value problem, i.e. there is no need to find, for an initial position \mathbf{x}' and final position \mathbf{x}'' , the trajectory that connects the two points. Instead, one simply picks the initial momentum and position \mathbf{p}', \mathbf{x}' and calculates the classical trajectories resulting from them at all times. Such methods are generally referred to as initial variable representations (IVR).

Finally, one problem still remains. There are complex terms which need to be associated with the determinant. The complex terms (Maslov indices) have to do with the square root of the determinant, which may be negative, and also appear in the related WKB approximation. They can be calculated, albeit with difficulty

[152, 153, 154, 155, 156, 157 and 158].

Even expression (B3.4.31), although numerically preferable, is not the end of the story as it does not fully account for the fact that nearby classical trajectories (those with similar initial conditions) should be averaged over. One simple methodology for that averaging has been through the division of phase space into parts, each of which is ‘covered’ by a set of Gaussians [159, 160]. This is done by recasting the initial wavefunction as

$$\psi(\mathbf{x}) = \iint d\bar{\mathbf{x}} d\bar{\mathbf{p}} (g_{\bar{\mathbf{x}}\bar{\mathbf{p}}}|\psi\rangle g_{\bar{\mathbf{x}}\bar{\mathbf{p}}}(\mathbf{x})) \quad (\text{B 3.4.32})$$

where $g_{\bar{\mathbf{x}}\bar{\mathbf{p}}}(\mathbf{x})$ is the Gaussian that is centred at point $\bar{\mathbf{x}}$ with momentum $\bar{\mathbf{p}}$

$$g_{\bar{\mathbf{x}}\bar{\mathbf{p}}}(\mathbf{x}) = \text{constant} e^{-(\mathbf{x}-\bar{\mathbf{x}})^2/2\sigma^2} e^{i\bar{\mathbf{p}}\cdot\mathbf{x}/\hbar} \quad (\text{B 3.4.33})$$

and σ is arbitrary. By applying these formulae two times, using the semi-classical approximation and eventually summing again over phases, the following expression results [161, 162 and 163]:

$$\langle\psi|\psi(t)\rangle = \int d\mathbf{x}' d\mathbf{p}' e^{iS(\mathbf{x}',\mathbf{p}',t)/\hbar} F(\mathbf{x}',\mathbf{p}',t). \quad (\text{B 3.4.34})$$

where the exact form of F is given clearly in [163].

The resulting expression is not difficult to numerically propagate.

Numerical applications of the formalism have been very successful lately [162, 163, 164, 165, 166 and 167]. This technique is very powerful for situations where short-time propagation is sufficient. For long-time processes, where the number of required trajectories is large, it is necessary to introduce other ingredients, such as methods for reducing the total propagation time—for example, the filter diagonalization method discussed above which was applied recently to the semi-classical approximation [113, 165], or backward-forward propagation schemes which tend to make the semiclassical integrand much smoother [168].

B3.4.9 NON-ADIABATIC EFFECTS

B3.4.9.1 FORMALISM

The discussion in the previous sections assumed that the electron dynamics is adiabatic, i.e. the electronic wavefunction follows the nuclear dynamics and at every nuclear configuration only the lowest energy (or more generally, for excited states, a single) electronic wavefunction is relevant. This is the Born–Oppenheimer approximation which allows the separation of nuclear and electronic coordinates in the Schrödinger equation.

This assumption breaks down in many molecules, especially upon photo-excitation, since excited states are often close to each other or even cross one another (i.e. have the same electronic energy at a given nuclear position). Thus, the full Schrödinger wavefunction needs to be considered:

$$\Psi(\mathbf{x}, \mathbf{r}_e, t) = \sum_n \psi_n(\mathbf{x}, t) \Phi_n(\mathbf{r}_e; \mathbf{x}) \quad (\text{B 3.4.35})$$

where n is now the index of the electronic states and \mathbf{r}_e is the position of the electron. Φ_n are eigensolutions, for each position of \mathbf{x} , of the electronic part of the Hamiltonian (every part of the electron–nuclear Hamiltonian except for the nuclear kinetic energy). The associated eigenvalues are labelled u_n , and are the adiabatic ground- and excited-state energies. From this expansion there follows an equation for the nuclear wavefunction [15, 16, 17 and 18, 169]. A complication is that the adiabatic electronic states, $\Phi_n(\mathbf{r}_e; \mathbf{x})$, depend themselves on the nuclear coordinate \mathbf{x} . Thus, the nuclear kinetic-energy terms in the Schrödinger equation, which have derivatives in them ($\partial^2/\partial\mathbf{x}^2$), also operate on Φ_n . The resulting time-dependent Schrödinger equation is then straightforwardly shown to be

$$-\frac{1}{2M} \frac{\partial^2}{\partial\mathbf{x}^2} \psi_n + \sum_m \frac{\tau_{nm}^1}{2M} \frac{\partial}{\partial\mathbf{x}} \psi_m + \sum_m \frac{\tau_{nm}^2}{2M} \frac{\partial^2}{\partial\mathbf{x}^2} \psi_m + u_n \psi_n = i \frac{\partial}{\partial t} \psi_n \quad (\text{B 3.4.36})$$

where the matrices τ^1 and τ^2 are

$$\tau_{nm}^1(\mathbf{x}) = \int \Phi_n(\mathbf{r}_e; \mathbf{x}) \frac{\partial}{\partial\mathbf{x}} \Phi_m(\mathbf{r}_e; \mathbf{x}) d\mathbf{r}_e \quad (\text{B 3.4.37})$$

$$\tau_{nm}^2(\mathbf{x}) = \int \Phi_n(\mathbf{r}_e; \mathbf{x}) \frac{\partial^2}{\partial^2\mathbf{x}} \Phi_m(\mathbf{r}_e; \mathbf{x}) d\mathbf{r}_e. \quad (\text{B 3.4.38})$$

The effect of τ^2 is usually negligible, due to the $1/M$ factor. However, τ^1 is fundamentally important, yet mathematically difficult to treat. Specifically, it can be shown that τ_{nm}^1 is proportional to the inverse of the energy difference between

electronic states n and m so its value can become infinite. Several ways to simplify the equation have been developed, starting with the work of Baer [15, 16, 17 and 18, 26, 169, 170]. The mathematical theory is too intricate to discuss here in detail; it is sufficient to say that one does a ‘gauge’ transform, i.e. a transformation from adiabatic wavefunctions (the ψ_n) to a new set of ‘diabatic functions’ for which the derivative coupling (i.e. the τ^1 coefficient of $\partial/\partial\mathbf{x}$) is minimized or completely absent. Instead, a new part of the potential appears as a coupling of the electronic states (i.e. an off-diagonal potential). This coupling potential introduces a new ‘phase’ problem. The difficulty is that the diabatic functions (i.e. the functions which are obtained after the transformation) are defined in terms of a linear combination (sometimes complex) of the adiabatic functions. [169] These linear combinations are non-unique. Consider the generic example of two crossing potential surfaces in two (nuclear) dimensions (see figure B3.4.16). When the nuclei move around the potential contours, the linear combination changes. Upon return to the same starting point, the phase of the states need not be the same! Thus the nuclear diabatic functions are not uniquely defined. This is a very important effect (called the molecular phase or Berry phase [15, 16 and 17, 19, 26, 171]), since it would appear even at low energies, way below the energies in which the conical interaction appears, i.e. way below the energies of the excited states! This phenomenon has been recently shown to be important in scattering of $\mathbf{H}+\mathbf{H}_2$ and its isotopic analogy [19]. (A simple interpretation of the molecular phase phenomenon in a $\mathbf{H}+\mathbf{H}_2$ type reaction system is that the full wavefunction is symmetric under exchange of any of the two hydrogen atoms and it is antisymmetric under electron–electron exchange, so that the nuclear part of it should be antisymmetric under a change of any pair of the three nuclei. This modifies the Schrödinger equation for the atomic motion.) In

addition, it was shown in a model system that they can affect state-to-state transition probabilities in a reactive system [172].

Figure B3.4.16. A generic example of crossing 2D potential surfaces. Note that, upon rotating around the conic intersection point, the phase of the wavefunction need not return to its original value.

The molecular phase effects are especially important when the system has some type of symmetry. Nevertheless, the typical treatment of non-adiabatic effects ignores the adiabatic phase, although, as cautioned, this is a problematic step.

In the remainder of this section, we will follow this simplifying (and problematic) assumption, and postulate that, upon the adiabatic to diabatic transformation, the Schrödinger equation has the form:

$$i \frac{\partial \psi_n}{\partial t} = -\frac{1}{2M} \frac{\partial^2}{\partial x^2} \psi_n + \sum_m V_{mn} \psi_m \quad (\text{B3.4.39})$$

where V_{nm} is called the diabatic potential matrix. (Note that if we were to use a finite set of molecular valence orbitals, $\Phi_n(\mathbf{r}_e)$, that do not depend on the nuclear orbitals, and expand the Schrödinger wavefunction in terms of Φ_n , we would automatically obtain this equation. Such a basis would be automatically diabatic.)

To see physically the problem of motion of wavepackets in a non-diagonal diabatic potential, we plot in figure B3.4.17 a set of two adiabatic potentials and their diabatic counterparts for a 1D problem, for example, vibrations in a diatom (as in metal–metal complexes). As figure B3.4.17 shows, if a wavepacket is started away from the ‘crossing’ point, it would slide towards this crossing point (where $V_{11} = V_{22}$) where it would branch; a part of it would continue on the same *adiabatic* state (i.e. shift to a different diabatic state) and the other part would ‘jump’ to a different adiabatic state.

Figure B3.4.17. When a wavepacket comes to a crossing point, it will split into two parts (schematic Gaussians). One will remain on the same adiabat (different diabat) and the other will hop to the other adiabat (same diabat). The adiabatic curves are shown by full lines and denoted by ‘ground’ and ‘excited’; the diabatic curves are shown by dashed lines and denoted 1, 2.

The problem of branching of the wavepacket at crossing points is very old and has been treated separately by Landau and by Zener [15, 173, 174]. The model problem they considered has the following diabatic coupling matrix:

$$V = \begin{pmatrix} -F(R - R_0) & \Gamma \\ \Gamma & F(R - R_0) \end{pmatrix} \quad (\text{B3.4.40})$$

where $2F$ is the difference in slope of the potentials (i.e. the difference in force felt in each state), Γ is the coupling element and R_0 is the crossing point. Landau and Zener showed that, in such a case, the probability for the wavefunction to transfer from the higher adiabatic level to the lower one (i.e. to remain on the same diabat) is

$$\rho_{\text{non-adiabatic}} = \exp\left(\frac{-\pi|\Gamma|^2}{v|F|}\right) \quad (\text{B3.4.41})$$

-32-

while the probability to remain on the same adiabatic level is

$$\rho_{\text{adiabatic}} = 1 - \rho_{\text{non-adiabatic}} \quad (\text{B3.4.42})$$

where v is the velocity of the wavepacket at the crossing point. Note two things about this formula: the steeper the difference is in the potentials, the higher the probability of a non-adiabatic transfer; in addition, if the mass is large (i.e. the velocity is low), then the motion is adiabatic ($\rho_{\text{adiabatic}} \approx 1$).

B3.4.9.2 NUMERICAL APPROACHES FOR SIMULATING NON-ADIABATIC PROCESSES

The simplest approach to simulating non-adiabatic dynamics is by surface hopping [175, 176]. In its simplest form, the approach is as follows. One carries out classical simulations of the nuclear motion on a specific adiabatic electronic state (ground or excited) and at any given instant checks whether the diabatic potential associated with that electronic state is intersecting the diabatic potential on another electronic state. If it is, then a decision is made as to whether a ‘jump’ to the other adiabatic electronic state should be performed,

based on the values for $\rho_{\text{adiabatic}}$ and $\rho_{\text{non-adiabatic}}$ (when $\rho_{\text{non-adiabatic}}$ is close to 1, a jump to the other electronic state is made with a high probability so that the particle remains on the same *diabatic* potential). If a jump is made, the particle continues its motion along the new adiabatic potential surfaces, with the same instantaneous position and momentum.

This approach is very simple and powerful. It has been used in numerous studies (for references see [176, 177]) and generally captures the essentials of the adiabatic versus non-adiabatic branching. It is especially useful in circumstances where the nuclear motion is essentially classical (i.e. zero point motion and tunnelling can be ignored).

This basic hopping model has a major disadvantage, however, as it fails to say much about the phases of the wavefunction. Consider a case where the wavefunction visits a region where surface hopping occurs, so a part of it hops, and at some later time it re-visits this region and again a part of it undergoes hopping. These two parts would interfere together and the interference may be constructive or destructive, but the hopping model does not specify this information.

To remedy this difficulty, several approaches have been developed. In some methods, the phase of the wavefunction is specified after hopping [178]. In other approaches, one expands the nuclear wavefunction in terms of a limited number of basis-set functions and works out the quantum dynamical probability for jumping. For example, the quantum dynamical basis functions could be a set of Gaussian wavepackets which move forward in time [147]. This approach is very powerful for short and intermediate time processes, where the number of required Gaussians is not too large.

The ultimate approach to simulate non-adiabatic effects is through the use of a full Schrödinger wavefunction for both the nuclei and the electrons, using the adiabatic–diabatic transformation methods discussed above. The whole machinery of approaches to solving the Schrödinger wavefunction for adiabatic problems can be used, except that the size of the wavefunction is now essentially doubled (for problems involving two-electronic states, to account for both states). The first application of these methods for molecular dynamical problems was for the charge-transfer system

-33-

Here quantum-mechanical vibrational state-to-state differential cross sections were calculated for a translational energy of $E_{\text{tr}} = 20$ eV and compared with experiments, with very good agreement between experiment and theory. In another application of this approach, state-selected integral cross sections were calculated for the $(\text{Ar} + \text{H}_2)^+$ system. Reactive (exchange), charge-transfer and spin transitions processes were treated simultaneously in one single calculation, and they compared very well with experiments [179, 180].

Finally, semi-classical approaches to non-adiabatic dynamics have also been formulated and successfully applied [167, 181]. In an especially transparent version of these approaches [167], one employs a mathematical ‘trick’ which converts the non-adiabatic surfaces to a set of coupled oscillators; the number of oscillators is the same as the number of electronic states. This method is also quite accurate, except that the number of required trajectories grows with time, as in any semi-classical approach.

B3.4.10 CONTROLLING MOLECULAR MOTION

The preceding sections were concerned with the description of molecular motion. An ambitious goal is to proceed further and influence molecular motion. This lofty goal has been at the centrepiece of quantum dynamics in the past decade and is still under intense investigation [182, 183, 184, 185, 186, 187, 188, 189, 190, 191, 192, 193 and 194]. Here we will only describe some general concepts and schemes.

The basic Hamiltonian describing the motion of atoms and molecules under a strong laser is simple in the dipole approximation,

$$\hat{H} = \hat{H}_0 - \mu \cdot E(t) \quad (\text{B3.4.43})$$

where $E = E(t)$ is the time-dependent electric field at the molecule, while \hat{H}_0 is the Hamiltonian of the static system; μ is the transition dipole operator, which typically connects different electronic states.

There are several different possible goals in controlling molecular dynamics. One goal can be the localization of excitations to a specific bond in a molecule, and the molecule could be broken along that bond [188]. Alternatively, one can try to transfer the molecule completely to an excited electronic state [186]. Another is the control of alignment (so that a molecule would point in a certain direction) [189, 190]. Still another goal would be the control of branching ratios; for example, in a reaction of an atom with a diatom, $A + BC$, one may want to control the branching into

-34-

products [182, 183 and 184]:

Finally, one may want to control the emission of light from molecules.

The conceptually simplest approach towards controlling systems by laser field is by ‘teaching’ the field [188, 191, 192 and 193]. Typically, the field is experimentally prepared as, for example, a sum of Gaussian pulses with variable height and positions. Each experiment gives an outcome which can be quantified. Consider, for example, an $A + BC$ reaction where the possible products are $AB + C$ and $AC + B$; if the $AB + C$ product is preferred one would seek to optimize the branching ratio

$$P_{\text{branch}} \equiv \frac{P(A + BC \rightarrow AB + C)}{P(A + BC \rightarrow AB + C, AC + B)}. \quad (\text{B3.4.44})$$

In a purely experimental (non-theory) approach [188, 191, 192 and 193] the branching ratio can be controlled by repeating the experiment many times, each with a randomly chosen set of pulse magnitudes and start times. One can repeat the experiment, varying the electrical field somewhat each time until the best outcome is achieved. This approach maybe the most appropriate one for large systems where little is known about the underlying dynamics and it has recently been demonstrated to work very well on dissecting large molecules [188].

Closely related to these ‘experimental’ approaches are optimal control procedures, in which one simulates

theoretically the effects of the electric field on the system, and then modifies the electric field to give the best objective, i.e. a desired output (in this case: a high branching ratio) [182, 183]. The optimal control algorithm can be recast in a very powerful mathematical form which makes the calculation converge rapidly to give an excellent field for any objective, if it is possible to simulate the system motion theoretically.

A different set of approaches uses simple physical properties to control the system [184]. To demonstrate this type of problem, consider an even simpler branching problem where, upon excitation, two possible degenerate products are simultaneously produced. An example would be to photo-dissociate a diatom AB and produce different states of the system: one state labelled $A + B^*$, in which B is electronically excited and A is receding away slowly; and another state, labelled $A + B$, in which B is in the ground state and A is receding rapidly (so that the total energy is in both cases equal). The simplest method of controlling the $A + B^*$ versus $A + B$ production rate would be to mix two different pathways for obtaining $A + B$ and $A + B^*$; for example, mixing a field of frequency ω with a phase-lagged third harmonic of a field which is three times lower in frequency (see figure B3.4.18):

$$E_1 \cos \omega t + E_3 \cos \left(\frac{\omega t}{3} + \phi \right). \quad (\text{B3.4.45})$$

-35-

Other possible choices are to use two pairs of frequencies which together have the same energies. The key point is that quantum interference between the two pathways can be used to control the branching ratio. This coherent-control approach is very general and can be used in virtually any branch of molecular dynamics, including scattering and photo-dissociation.

Figure B3.4.18. A schematic use of coherent control in $AB \rightarrow A + B, A + B^*$ dissociation: use of a single high-frequency photon (ω) or three low-intensity ($\omega/3$) photons would lead to emerging wavefunctions in both arrangements. However, by properly combining the amplitudes and phases of the single- and three-photon paths, the wavefunction would emerge in a single channel.

B 3.5 Optimization and reaction path algorithms

Peter Pulay and Jon Baker

B 3.5.1 INTRODUCTION

A quantum mechanical treatment of molecular systems usually starts with the Born–Oppenheimer approximation, i.e., the separation of the electronic and nuclear degrees of freedom. This is a very good approximation for well separated electronic states. The expectation value of the total energy in this case is a function of the nuclear coordinates and the parameters in the electronic wavefunction, e.g., orbital coefficients. The wavefunction parameters are most often determined by the variation theorem: the electronic energy is made stationary (in the most important ground-state case it is minimized) with respect to them. The

optimized energy, calculated as a function of the nuclear coordinates, is known as the potential energy surface (PES). Finding its (local) minimum gives the calculated equilibrium structure. The latter, although experimentally not directly accessible, is perhaps the most satisfactory definition of molecular geometry, and serves as the best starting point for a treatment of molecular vibrations. A large part of the total effort expended in quantum chemical calculations is spent in optimizing either electronic parameters or molecular geometries; the latter task is dominant in empirical force field calculations. The optimization of electronic wavefunctions is usually treated separately from the optimization of molecular geometries; however, there are enough similarities between the two problems to discuss them together.

Both the electronic and the geometry optimization problem, particularly the latter, may have more than one solution. For small, rigid molecules, the approximate molecular geometry is chemically obvious, and the presence of multiple minima is not a serious concern. For large, flexible molecules, however, finding the absolute minimum, or a complete set of low-lying equilibrium structures, is only a partially solved problem. This topic will be discussed in the last section of this chapter. The rest of the article deals with local optimization, i.e., finding a minimum from a reasonably close starting point. We will also discuss the determination of other stationary points—most importantly saddle points—constrained optimization, and reaction paths. Several reviews have been published on geometry optimization [1, 2]. The optimization of SCF-type wavefunctions is often highly nonlinear, particularly for the multiconfigurational case, and this has received most attention [3, 4].

The most important consideration affecting the choice of the method for locating minima, or stationary points in general, is the availability of analytical derivatives of the object function, in our case the energy. Zeroth-order (energy only) methods can be used for a few variables but are notoriously inefficient for a larger number of degrees of freedom. First-order methods, which use both energy and gradient (first-derivative) information, are particularly useful in quantum chemistry because the extra effort needed to evaluate all first derivatives is usually comparable to the calculation of the energy itself and may be less, particularly for the electronic degrees of freedom [5]. Second-order methods, which use second derivatives, further improve the convergence of the optimization process. However, calculating second derivatives tends to be much more expensive than calculating the gradient, and full second-order methods are usually cost efficient only when first-order methods have severe convergence problems. Derivatives higher than the second have been used occasionally, but they are not generally available and are expensive to calculate. Consequently, this article will mainly concentrate on first- and second-order methods.

-2-

The electronic energy W in the Born–Oppenheimer approximation can be written as $W = W(\mathbf{q}, \mathbf{p})$, where \mathbf{q} is the vector of nuclear coordinates and the vector \mathbf{p} contains the parameters of the electronic wavefunction. The latter are usually orbital coefficients, configuration amplitudes and occasionally nonlinear basis function parameters, e.g., atomic orbital positions and exponents. The electronic coordinates have been integrated out and do not appear in W . Optimizing the electronic parameters leaves a function depending on the nuclear coordinates only, $E = E(\mathbf{q})$. We will assume that both $W(\mathbf{q}, \mathbf{p})$ and $E(\mathbf{q})$ and their first derivatives are continuous functions of the variables q_i and p_j .

B 3.5.2 OVERVIEW OF TECHNIQUES FOR LOCAL OPTIMIZATION

B3.5.2.1 CHARACTERIZATION OF STATIONARY POINTS

In this section, we will discuss general optimization methods. Our example is the geometry optimization problem, i.e., the minimization of $E(\mathbf{q})$. However, the results apply to electronic optimization as well. There are a number of useful monographs on the minimization of continuous, differentiable functions in many variables [6, 7].

For a point on the potential energy surface to be a stationary point, all its first derivatives, $\partial E/\partial q_i$, must vanish, and thus the whole gradient vector $\mathbf{g} = \{\partial E/\partial q_i, i = 1, n\}$ should be zero. The character of a stationary point, i.e., whether it is a local minimum, maximum or saddle point, can be determined by examining the second derivatives. Expanding the energy change in the neighbourhood of a stationary point \mathbf{q}^0 in a power series in terms of displacement coordinates from the stationary point, $\delta q_i = q_i - q_i^0$, gives

$$E(\mathbf{q}) - E(\mathbf{q}^0) = \sum_i (\partial E/\partial q_i)|_{\mathbf{q}^0} \delta q_i + 1/2 \sum_{i,j} (\partial^2 E/\partial q_i \partial q_j)|_{\mathbf{q}^0} \delta q_i \delta q_j + \text{higher terms.} \quad (\text{B3.5.1})$$

As \mathbf{q}^0 is a stationary point, the linear terms $(\partial E/\partial q_i)|_{\mathbf{q}^0} \delta q_i$ in equation B3.5.1 vanish, and higher-order terms do not have to be considered for local characterization of stationary points, because lower-order terms (quadratics in this case) always dominate for sufficiently small displacements. Introducing the force constant, or Hessian matrix, i.e., the matrix of second derivatives \mathbf{H} , $H_{ij} = (\partial^2 E/\partial q_i \partial q_j)|_{\mathbf{q}^0}$, the above equation can be written in a convenient matrix notation as

$$\Delta E = E(\mathbf{q}) - E(\mathbf{q}^0) = \frac{1}{2} \delta \mathbf{q}^\dagger \mathbf{H} \delta \mathbf{q}. \quad (\text{B3.5.2})$$

Let us express the displacement coordinates as linear combinations of a set of new coordinates \mathbf{y} : $\delta \mathbf{q} = \mathbf{U}\mathbf{y}$; then $\Delta E = \mathbf{y}^\dagger \mathbf{U}^\dagger \mathbf{H} \mathbf{U} \mathbf{y}$. \mathbf{U} can be an arbitrary non-singular matrix, and thus can be chosen to diagonalize the symmetric matrix \mathbf{H} : $\mathbf{U}^\dagger \mathbf{H} \mathbf{U} = \Lambda$, where the diagonal matrix Λ contains the (real) eigenvalues of \mathbf{H} . In this form, the energy change from the stationary point is simply $\Delta E = \frac{1}{2} \sum_i \Lambda_i y_i^2$. It is clear now that a sufficient condition for a minimum is that all eigenvalues of \mathbf{H} be positive, i.e., \mathbf{H} must be a positive definite matrix. Otherwise choosing $y_i \neq 0$, all other $y_j = 0$, where Λ_i is a negative eigenvalue, will decrease the energy, i.e., the stationary point cannot be a minimum. Zero eigenvalues of the Hessian (inflection points) need not be considered because their probability in the general case is

-3-

vanishingly small. Stationary points with only one negative Hessian eigenvalue are called first-order saddle points. They have considerable importance as transition states in chemical reactions. The energy difference between a transition state and the reactant(s) is the barrier corresponding to the reaction path passing through that transition state. Stationary points with two or more negative eigenvalues are far less important, as in this case there is always a reaction path with lower barrier which determines the reaction probability (however, in symmetrical systems higher-order saddle points may be preferred reference geometries[8]).

The simplest smooth function which has a local minimum is a quadratic. Such a function has only one, easily determinable stationary point. It is thus not surprising that most optimization methods try to model the unknown function with a local quadratic approximation, in the form of [equation \(B3.5.1\)](#).

B3.5.2.2 ENERGY-ONLY METHODS

As noted in the introduction, energy-only methods are generally much less efficient than gradient-based techniques. The simplex method [9] (not identical with the similarly named method used in linear programming) was used quite widely before the introduction of analytical energy gradients. The intuitively most obvious method is a sequential optimization of the variables (sequential univariate search). As the optimization of one variable affects the minimum of the others, the whole cycle has to be repeated after all variables have been optimized. A one-dimensional minimization is usually carried out by finding the

minimum of a parabola fitted to three points obtained by varying one of the variables (keeping the others constant), changing values so as to bracket the minimum, and zeroing in on the minimum by diminishing the step size [6]. Generalized to any vector direction on the surface, this is called a line search. The convergence rate of the sequential univariate search can be exceedingly slow if the variables are strongly coupled and, thus, this method is not recommended. A better alternative is to convert gradient methods, covered in the next section, to energy-only methods by calculating the gradients numerically. One of the most widely used energy-only methods is the modified Fletcher–Powell method described by Schlegel [1]; perhaps better is the numerical version of Baker’s Eigenvector Following (EF) algorithm (see later) [10]. In spite of these ingenious algorithms, the general consensus among researchers in the field is that energy-only methods are simply not cost effective for systems with more than a few degrees of freedom.

B3.5.2.3 GRADIENT METHODS

All efficient optimization methods require the gradient vector, i.e., the first derivatives of the function to be optimized. As the quantum mechanical energy as a function of nuclear coordinates is the result of an iterative procedure, and ordinary first-order perturbation theory is inapplicable in the usual case where the basis functions move with the nuclei, this is not a trivial problem. The introduction of analytical energy derivatives (forces on the atoms in the context of geometry optimization) of the SCF energy [11], and later generalizations to more complex wavefunctions (for reviews see, e.g., [5, 12]) improved the efficiency of geometry optimizations by one or two orders of magnitude, depending on the molecular size, making possible structure optimization for large polyatomic molecules.

(A) NEWTON’S METHOD

Most gradient optimization methods rely on a quadratic model of the potential surface. The minimum condition for the

-4-

quadratic energy expression

$$E(\mathbf{q}) = E(\mathbf{q}^0) + \delta\mathbf{q}^\dagger \mathbf{g} + \frac{1}{2} \delta\mathbf{q}^\dagger \mathbf{H} \delta\mathbf{q}$$

using the symmetry of \mathbf{H} , leads to

$$\mathbf{g} + \mathbf{H} \delta\mathbf{q} = \mathbf{0} \text{ and } \delta\mathbf{q} = -\mathbf{H}^{-1} \mathbf{g}. \quad (\text{B3.5.3})$$

Here \mathbf{g} is the gradient vector at \mathbf{q}^0 , $\mathbf{g}_i = (\partial E / \partial q_i)|_{\mathbf{q}^0}$. The minimizer $\mathbf{q}^0 + \delta\mathbf{q}$ is exact on a quadratic surface and requires only the solution of a linear system of equations. For a nonlinear surface, this method has to be iterated. Near the solution, the iterative procedure is quadratically convergent. In practice, this means that three or four iterations usually suffice for locating the minimum to high accuracy. This is the basic Newton (or Newton–Raphson) method. Despite its rapid convergence for nearly quadratic surfaces, it suffers from a number of shortcomings and in its original form is seldom used for geometry optimization. It has some importance for difficult cases of wavefunction optimization. The principal defect of Newton’s method is that it requires the Hessian (second-derivative) matrix at every iteration. Second derivatives are typically much more expensive than gradients in quantum chemistry applications. Another problem is that far from the minimum the Hessian may not be positive definite. The energy change in a Newton–Raphson cycle is $\delta\mathbf{q}^\dagger \mathbf{g} = -\frac{1}{2} \mathbf{g}^\dagger \mathbf{H}^{-1} \mathbf{g}$ in the quadratic approximation. Thus the energy does not necessarily decrease, even for small steps, unless \mathbf{H} (and obviously its inverse) is positive definite.

(B) SIMPLE RELAXATION

Both defects of the Newton method can be eliminated by replacing the exact inverse Hessian \mathbf{H}^{-1} by a (fixed) positive definite approximation to it, \mathbf{F} . This method is known as simple relaxation. In both geometry and wavefunction optimization, it is usually possible to construct a fairly good approximate Hessian. For geometry optimization, this can be based on the molecular connectivity and transferability of potential parameters, or on previous low-level calculations. For wavefunction optimization, a guess based on orbital energy differences is often reasonably accurate. Far from the minimum, approximate Hessian methods using positive definite matrices are preferable to the Newton method, as they have the descent property, i.e., the energy decreases for sufficiently small steps. However, they lack the quadratic terminal convergence rate of the Newton method. Instead, the residual error vector (the distance from the accurate minimum) is given by $\mathbf{r}^{(n)} = (\mathbf{I} - \mathbf{FH})^n \mathbf{r}^{(0)}$ on a quadratic surface. Here \mathbf{I} is the unit matrix and $^{(n)}$ denotes the n th cycle. The ultimate convergence rate is governed by the magnitude of the largest eigenvalue of the matrix $(\mathbf{I} - \mathbf{FH})$. This will be small if \mathbf{F} is a good approximation to \mathbf{H}^{-1} . To show this, we introduce new variables, through a linear transformation of the old ones, which diagonalize \mathbf{FH} . Using these coordinates, the k th component of the residue in step n is $\lambda_k^n \mathbf{r}_k^{(0)}$ where λ_k is the k th eigenvalue of $(\mathbf{I} - \mathbf{FH})$. This explains a common property of simple relaxation: it usually shows good initial convergence but slows down later as the surviving components of the residuum take on directions in which the Hessian is poorly estimated. If one of the eigenvalues of $(\mathbf{I} - \mathbf{F}^{-1}\mathbf{H})$ exceeds 1 in absolute magnitude then simple relaxation without a line search will ultimately diverge.

If there is no approximate Hessian available, then the unit matrix is frequently used, i.e., a step is made along the gradient. This is the steepest descent method. The unit matrix is arbitrary and has no invariance properties, and thus the

-5-

resulting step may be made arbitrarily large or small by scaling the coordinates. Therefore, steepest descent methods require a line search for a minimum along the direction of the gradient vector. Line searches are often recommended in general optimization texts. However, they tend to be less efficient in quantum chemistry, as the evaluation of the gradient vector costs roughly the same as the calculation of the energy for a wide range of methods, and supplies much more information. Nevertheless, they may be necessary for strongly non-quadratic functions (or, what is essentially the same thing, at points far from the minimum). A good compromise which requires no additional energy evaluations was suggested by Schlegel [13]: a polynomial is fitted to the energies at two points, and to the gradients projected on the line connecting them, and its minimum is located. The polynomial can be cubic or, as recommended by Schlegel, a special quartic with only one minimum. If a line search is used, the energy of simple relaxation and steepest descent steps should always decrease, and they should ultimately converge. However, convergence may be very slow if \mathbf{F} is a poor approximation to the inverse Hessian \mathbf{H}^{-1} , as is usually the situation in the steepest descent method. In this case, illustrated in figure B3.5.1 the optimization takes a zigzag path converging slowly to the minimum.

Figure B3.5.1. Contour line representation of a quadratic surface and part of a steepest descent path zigzagging toward the minimum.

In simple relaxation (the fixed approximate Hessian method), the step does not depend on the iteration history. More sophisticated optimization techniques use information gathered during previous steps to improve the estimate of the minimizer, usually by invoking a quadratic model of the energy surface. These methods can be divided into two classes: variable metric methods and interpolation methods.

(C) VARIABLE METRIC METHODS

In these methods, also known as quasi-Newton methods, the approximate Hessian is improved (updated) based on the results in previous steps. For the exact Hessian and a quadratic surface, the quasi-Newton equation $\Delta \mathbf{g}^{(n)} = \mathbf{H} \Delta \mathbf{q}^{(n)}$ and its analogue $\mathbf{H}^{-1} \Delta \mathbf{g}^{(n)} = \Delta \mathbf{q}^{(n)}$ must hold (where $\Delta \mathbf{g}^{(n)} = \mathbf{g}^{(n+1)} - \mathbf{g}^{(n)}$, and similarly for $\Delta \mathbf{q}^{(n)}$). These equations, which have only n components, are obviously insufficient to determine the $n(n+1)/2$ independent components of the Hessian or its inverse. Therefore, the updating is arbitrary to a certain extent. It is desirable to have an updating scheme that converges to the exact Hessian for a quadratic function, preserves the quasi-Newton conditions obtained in previous steps, and—for minimization—keeps the Hessian positive definite. Updating can be performed on either \mathbf{F} or its inverse, the approximate Hessian. In the former case repeated matrix inversion can be avoided. All updates use dyadic products, usually built from $\Delta \mathbf{q}^{(n)}$ and $\mathbf{F} \Delta \mathbf{g}^{(n)}$. Fletcher [6] gives a detailed description of various update techniques. The most important update formulae are the Murtagh–Sargent update [14]:

-6-

$$\mathbf{F}^{(n+1)} = \mathbf{F}^{(n)} + (\Delta \mathbf{q}^{(n)} - \mathbf{F}^{(n)} \Delta \mathbf{g}^{(n)}) (\Delta \mathbf{q}^{(n)} - \mathbf{F}^{(n)} \Delta \mathbf{g}^{(n)})^T / \{ (\Delta \mathbf{q}^{(n)} - \mathbf{F}^{(n)} \Delta \mathbf{g}^{(n)})^T \Delta \mathbf{g}^{(n)} \}$$

the Davidon–Fletcher–Powell (DFP) update [15]:

and the Broyden–Fletcher–Goldfarb–Shanno (BFGS) update [6]:

$$\mathbf{F}^{(n+1)} = \mathbf{F}^{(n)} + s(1 + s \Delta \mathbf{g}^{(n)T} \mathbf{F}^{(n)} \Delta \mathbf{g}^{(n)}) \Delta \mathbf{q}^{(n)} \Delta \mathbf{q}^{(n)T} - s(\Delta \mathbf{q}^{(n)} \Delta \mathbf{g}^{(n)T} \mathbf{F}^{(n)} + \mathbf{F}^{(n)} \Delta \mathbf{g}^{(n)} \Delta \mathbf{q}^{(n)T})$$

where $s = 1/(\Delta \mathbf{q}^{(n)T} \Delta \mathbf{g}^{(n)})$. A linear combination of these updates is also possible. Both the DFP and BFGS updates preserve positive definite \mathbf{F} matrices provided $\Delta \mathbf{q}^{(n)T} \Delta \mathbf{g}^{(n)} > 0$; current opinion is that the latter is the best update to use for general minimization.

For transition state searches, none of the above updates is particularly appropriate as a positive definite Hessian is not desired. A more useful update in this case is the Powell update [16]:

$$\mathbf{H}^{(n+1)} = \mathbf{H}^{(n)} + \{ \mathbf{v} \Delta \mathbf{q}^{(n)T} + \Delta \mathbf{q}^{(n)} \mathbf{v}^T - (\mathbf{v}^T \Delta \mathbf{q}^{(n)T}) (\Delta \mathbf{q}^{(n)} \Delta \mathbf{q}^{(n)T}) / t \} / t$$

where $\mathbf{v} = \Delta \mathbf{g}^{(n)} - \mathbf{H}^{(n)} \Delta \mathbf{q}^{(n)}$ and $t = (\Delta \mathbf{q}^{(n)T} \Delta \mathbf{q}^{(n)})$. The Powell update allows the signature of the Hessian, i.e., the number of negative eigenvalues, to change, which is necessary if the region of the potential energy surface is inappropriate for the stationary point being sought. Perhaps the best Hessian update for transition state searches is a linear combination of the Powell and Murtagh–Sargent updates proposed by Bofill [17, 18].

For a very large number of variables, the question of storing the approximate Hessian or inverse Hessian \mathbf{F} becomes important. Wavefunction optimization problems can have a very large number of variables, a million or more. Geometry optimization at the force field level can also have thousands of degrees of freedom. In these cases, the initial inverse Hessian is always taken to be diagonal or sparse, and it is best to store the

upgrade vectors and associated scalars and generate the inverse Hessian *in situ*, rather than store the full updated inverse Hessian itself.

A more general update method, widely used in the Gaussian suite of programs [19], is due to Schlegel [13]. In this method, the Hessian in the n -dimensional subspace spanned by taking differences between the current $\mathbf{q}^{(n)}$ and previous geometries $\mathbf{q}^{(n-1)}, \dots, \mathbf{q}^{(0)}$ is calculated numerically. This is possible (although not terribly accurate), as the $n \Delta \mathbf{q}$ and $n \Delta \mathbf{g}$ values suffice for the calculation of an n -dimensional Hessian by forward differences. The Hessian in the small subspace is then projected back to the full space. A line search along the new correction vector is avoided by using the constrained quartic interpolation scheme described above.

(D) INTERPOLATION METHODS

For a quadratic surface, the gradient vector is a linear function of the coordinates. An alternative way of using

-7-

information gathered during the optimization is to interpolate among the coordinate vectors obtained in the preceding cycles. The basic interpolation method is the preconditioned conjugate gradient (CG) method [20]. Although usually formulated in a different way, it is equivalent to first making a simple relaxation step using an approximate inverse Hessian \mathbf{F} , called the preconditioner, and replacing the calculated displacement by a linear combination of the current and all previous coordinate displacement vectors $\Delta \mathbf{q}^{(i)}$:

$$\Delta \mathbf{q}^{(n+1)} = -\mathbf{F} \mathbf{g}^{(n+1)} + \sum_{i=1}^n \beta_i \Delta \mathbf{q}^{(i)}.$$

The coefficients β_i are chosen so that, on a quadratic surface, the interpolated gradient becomes orthogonal to all $\Delta \mathbf{q}^{(i)}$. This condition is equivalent to minimizing the energy in the space spanned by the displacement vectors. In the quadratic case, a further simplification can be made as it can be shown that all β_i with the exception of β_n vanish. The latter is given by

$$\beta_n = \mathbf{g}^{(n+1)\text{T}} \mathbf{F} \mathbf{g}^{(n+1)} / (\mathbf{g}^{(n)\text{T}} \Delta \mathbf{q}^{(n)})$$

although there are several forms which are equivalent for a quadratic function but not in general [6], e.g., the Polak–Ribiere form [21]. The gradient at the (interpolated) new point is not recalculated but is itself interpolated. For very large problems, the conjugate gradient method has the advantage that it needs to store only a few vectors (the preconditioner is usually diagonal or sparse, and must be positive definite).

A similar method, direct inversion in the iterative subspace (DIIS) [22, 23] tries to minimize the norm of the error vector (in most cases the gradient) by interpolating in the subspace spanned by the previous vectors. Unlike the CG method, DIIS is able to converge to saddle points. DIIS is now the standard method for the SCF optimization problem. It is also useful for geometry optimization [24]. It does not have the conjugate property and therefore requires the storage of previous coordinate and gradient vectors (in practice, usually restricted to about 20 or fewer). However, not using the CG property, which is valid for quadratic surfaces only, probably adds to the stability of the method.

To derive the DIIS equations, let us consider a linear combination of coordinate vectors $\mathbf{q}^{(1)}, \dots, \mathbf{q}^{(n)}$, $\mathbf{q} = \sum_i^n c_i \mathbf{q}^{(i)}$. On a quadratic surface, the gradient (or any linear function of the gradient) is an analogous linear combination if the coefficients sum to unity:

$$\mathbf{g} = \sum_i^n c_i \mathbf{g}^{(i)}. \quad (\text{B3.5.4})$$

Minimizing the square of the gradient vector under the condition $\sum_i^n c_i = 1$ yields the following linear system of equations

-8-

$$\begin{pmatrix} B_{11} & \dots & B_{1n} & -1 \\ \vdots & & \vdots & \vdots \\ B_{n1} & \dots & B_{nn} & -1 \\ -1 & \dots & -1 & 0 \end{pmatrix} \begin{pmatrix} c_1 \\ \vdots \\ c_n \\ \lambda \end{pmatrix} = \begin{pmatrix} 0 \\ \vdots \\ 0 \\ -1 \end{pmatrix}$$

where $B_{ij} = \mathbf{g}^{(i)\text{T}} \mathbf{g}^{(j)}$. Due to the wide dynamic range of the B_{ij} coefficients, it is best to normalize the diagonal elements of this equation to 1. This procedure yields an extrapolated geometry and [gradient B3.5.4](#). The next step is calculated by relaxing the extrapolated gradient with the approximate inverse Hessian and adding it to the extrapolated geometry. Hessian updating can be combined with DIIS, but the method works well even with a static Hessian. Any linear function of the gradient can be used instead of the gradient. This changes the weighting of the error somewhat.

B3.5.2.4 SECOND-ORDER METHODS

As mentioned in the introduction, full second-order methods (e.g., the Newton method) are usually not cost efficient, particularly for geometry optimization, due to the high cost of Hessian evaluation. For wavefunction optimization, the explicit evaluation of the full Hessian is not practicable due to the large number of degrees of freedom. Second-order methods can still be utilized by using direct methods, i.e., finding the solution of the Newton–Raphson equation $\mathbf{H}\delta\mathbf{q} = -\mathbf{g}$ without explicitly constructing and inverting \mathbf{H} . In such a case, second-order methods are competitive, and in difficult cases superior to first-order methods in the quadratic region, i.e., close to the minimum. Optimization of transition states also frequently requires the explicit evaluation of the Hessian or a submatrix of it.

B3.5.2.5 DAMPING METHODS

Particularly in the early stages of an optimization, when the gradient is large and Hessian information is inaccurate, the computed step size may be too great; using such large steps may lead to divergence or convergence to unwanted minima. Methods which incorporate a line search are usually immune to this problem; however, as discussed above, line searches are inefficient in quantum chemistry because the evaluation of the full gradient vector can often take *less* time than the evaluation of a single energy.

The simplest way to deal with large, potentially disastrous steps is to limit the step size, either its maximum component or its norm. For geometry optimization, 0.2 to 0.3 Å or rad appears to be a reasonable value for a maximum single component; 0.3 rad is also appropriate for the maximum orbital rotation component in wavefunction optimization. A better method than simply scaling the displacement is to use a trust radius. The idea behind the trust radius is to restrict the step taken so that it lies in the local region of the energy surface where the truncation of the original power series expansion ([equation \(B3.5.1\)](#)) to quadratic terms only is valid. The neighbourhood about the current point where quadratic behaviour holds is called the trust region.

If the computed step size exceeds the trust radius, t , its direction is reoptimized under the condition that $|\Delta\mathbf{q}| = t$, i.e., the Lagrangian

$$E(\mathbf{q}, d) = E(\mathbf{q}^0) + \Delta\mathbf{q}^T \mathbf{g} + \frac{1}{2} \Delta\mathbf{q}^T \mathbf{H} \Delta\mathbf{q} + \frac{1}{2} d (|\Delta\mathbf{q}|^2 - t^2)$$

-9-

is minimized. The solution is $\Delta\mathbf{q} = -(\mathbf{H} + d\mathbf{I})^{-1} \mathbf{g}$ where the positive denominator shift d is a complex function of t and is usually determined iteratively from the condition $|\Delta\mathbf{q}| = t$. The trust radius can be adjusted based on the accuracy of the energy difference predicted by the quadratic model, compared with the actual energy difference [2, 6]. One problem with the trust radius method, and other methods which limit $|\Delta\mathbf{q}|$, is that they do not scale properly with the system size: they are not ‘size consistent’. For instance, if n identical, non-interacting molecules are optimized simultaneously, the maximum displacement norm for each decreases like $n^{-1/2}$. For this reason, it is perhaps best to limit the maximum component, rather than the norm of the displacement [6].

An alternative, and closely related, approach is the augmented Hessian method [25]. The basic idea is to interpolate between the steepest descent method far from the minimum, and the Newton–Raphson method close to the minimum. This is done by adding to the Hessian a constant shift matrix which depends on the magnitude of the gradient. Far from the solution the gradient is large and, consequently, so is the shift d . One can, e.g., choose d to be proportional to the expected energy lowering, $d = -\alpha^2 \mathbf{g}^T \Delta\mathbf{q}$ (note that $\mathbf{g}^T \Delta\mathbf{q}$ is negative for minimization and thus d is positive), and solve the damped equation

$$(\mathbf{H} + d\mathbf{I})\Delta\mathbf{q} = -\mathbf{g}.$$

This is equivalent to finding the lowest eigenvalue λ (which is always negative and approaches zero at convergence) of the generalized eigenvalue equation

$$\begin{pmatrix} \mathbf{H} & \mathbf{g} \\ \mathbf{g}^T & 0 \end{pmatrix} \begin{pmatrix} \Delta\mathbf{q} \\ 1 \end{pmatrix} = \lambda \begin{pmatrix} \alpha^2 \mathbf{I} \\ \mathbf{0}^T \end{pmatrix} \begin{pmatrix} \mathbf{0} & \Delta\mathbf{q} \\ 1 & 1 \end{pmatrix}. \quad (\text{B3.5.5})$$

Equation B3.5.5 is, in turn, equivalent to the minimum condition on the rational function

$$E(\mathbf{q}) = E(\mathbf{q}^0) + (\mathbf{g}^T \Delta\mathbf{q} + \frac{1}{2} \Delta\mathbf{q}^T \mathbf{H} \Delta\mathbf{q}) / (1 + \alpha^2 \Delta\mathbf{q}^T \Delta\mathbf{q}).$$

For $\alpha = 0$, minimization of this expression yields the Newton–Raphson formula for $\Delta\mathbf{q}$. For large values of α , $\Delta\mathbf{q}$ becomes asymptotically $\alpha^{-1} \mathbf{g}/|\mathbf{g}|$, i.e., the steepest descent formula with a step length $1/\alpha$. The augmented Hessian method is closely related to eigenvector (mode) following, discussed in [section B3.5.5.2](#). The main difference between rational function and trust radius optimizations is that, in the latter, the level shift is applied only if the calculated step exceeds a threshold, while in the former it is imposed smoothly and is automatically reduced to zero as convergence is approached.

B 3.5.3 THE OPTIMIZATION OF WAVEFUNCTIONS

The basic self-consistent field (SCF) procedure, i.e., repeated diagonalization of the Fock matrix [26], can be viewed, if sufficiently converged, as local optimization with a fixed, approximate Hessian, i.e., as simple relaxation. To show this, let us consider the closed-shell case and restrict ourselves to real orbitals. The SCF orbital coefficients are not the

best set of coordinates to work with because, being constrained to be orthonormal, they are not independent. A better set of parameters can be chosen as the above-diagonal elements of an antisymmetric matrix \mathbf{K} , used to build an orthogonal matrix \mathbf{U} by $\mathbf{U} = \exp(\mathbf{K})$ [27] or, alternatively $\mathbf{U} = 2(\mathbf{I} - \frac{1}{2}\mathbf{K})^{-1} - \mathbf{I}$ (see, e.g., [23]). \mathbf{U} describes a generalized rotation between the orbitals. We start with an orthonormal set of orbitals \mathbf{C}_0 , defined as $\varphi^T = \chi^T \mathbf{C}_0$, where φ^T and χ^T are row vectors of molecular orbitals and atomic basis functions, respectively. All possible orthonormal orbital sets can be expressed as $\mathbf{C} = \mathbf{C}_0 \mathbf{U}$. Not all elements of \mathbf{K} are relevant. Rotations between virtual orbitals can obviously be omitted, and rotations between two occupied orbitals have no effect on the energy because the determinantal wavefunction is invariant against such rotations. Therefore, only rotations between occupied and virtual orbitals, i.e., the elements K_{ia} , $i \leq n$, $a > n$ are needed if, as usual, the n occupied orbitals φ_i precede the virtual ones φ_a .

The gradient and second derivative components of the SCF energy can be expressed for both kinds of parametrization (see [28]) as

$$\frac{1}{4} \partial E / \partial K_{ia} = F_{ia} \quad (\text{B3.5.6})$$

$$\frac{1}{4} \partial^2 E / \partial K_{ia} \partial K_{jb} = F_{ab} \delta_{ij} - F_{ij} \delta_{ab} + 4(ia|jb) - (ij|ab) - (ib|ja) \quad (\text{B3.5.7})$$

where, e.g., $(ij|ab)$ is a two-electron integral in the usual Mulliken notation. In a typical SCF iteration near convergence, the Fock matrix is nearly diagonal, and the orbital rotation parameter corresponding to a small occupied-virtual (Brillouin-violating) element F_{ia} is, from first-order perturbation theory, $K_{ia} = F_{ia} / (\epsilon_a - \epsilon_i)$. Comparing this with (B3.5.7) and noting that in a canonical orbital basis $F_{ii} = \epsilon_i$, $F_{aa} = \epsilon_a$ and the off-diagonal elements of \mathbf{F} are zero, it is clear that the ordinary SCF iteration is equivalent to neglecting the two-electron integrals in the electronic Hessian, equation (B3.5.7). This explains the observation that straight SCF iteration frequently slows down as the SCF procedure progresses, cf. [B3.5.2.3](#).

For ordinary SCF problems, interpolation methods are particularly suitable, as they require the storage of only a limited amount of information. The standard method for closed-shell or simple open-shell problems is DIIS (direct inversion in the iterative subspace) [22, 23]. Equation (B3.5.6) is not appropriate for the error vector because each error vector is expressed in a different basis. Transforming the occupied-virtual block of the orbital Fock matrix to a common basis, e.g., to the atomic orbital basis, yields the commutator $\mathbf{SDF} - \mathbf{FDS}$, arranged as a vector, for the gradient [22, 23]. DIIS usually converges well for closed shell systems from a reasonable starting wavefunction. Several modifications of this method have been proposed [29, 30]. For unrestricted (UHF) wavefunctions, DIIS is widely used but it is less appropriate. As it is a gradient norm minimization technique, it has a tendency to converge to the closest stationary point. For an even number of electrons, the closed-shell wavefunction is a formal solution of the UHF equations, and DIIS, unless started close to the expected minimum, may converge uphill to the closed-shell solution. The preconditioned conjugate gradient method (the preconditioner being the SCF approximation to the Hessian) is probably more appropriate in this case. Similarly, in density functional calculations with a plane wave basis set, the basis set is often huge, and the conjugate gradient method, with its limited storage requirement, is preferable [31, 32].

Due to the large number of variables in wavefunction optimization problems, it may appear that full second-order methods are impractical. For example, the storage of the Hessian for a modest closed-shell wavefunction with 500

basis functions and 200 electrons requires more than $(100 \times 400)^2/2 = 8 \times 10^8$ words. However, as shown by Bacskay [28] for closed- and open-shell SCF, and Lengsfeld and Liu for MC-SCF [33], using techniques analogous to direct configuration interaction [34], the solution of the linear system of equations (B3.5.3) can be accomplished iteratively, each micro-iteration (to be distinguished from the SCF iterations, which are called macro-iterations) taking about the same effort as an SCF cycle. For closed- and open-shell SCF, the resulting doubly iterative algorithm is comparable in efficiency with DIIS [35] but it is more complex, and thus less widely used.

The situation is different for the multi-configurational SCF (MC-SCF) case. Although DIIS has been used successfully for simpler cases [36], the strong coupling between orbital rotations and configuration interaction (CI) coefficients mandates the use of second-order or approximate second-order methods (see the reviews [3, 4] and references therein). As the signature of the Hessian is frequently incorrect, the augmented Hessian (rational function) method, which forces a step in the right direction, is generally employed. Perhaps the most efficient method is that proposed by Werner and Meyer [37] and further expanded by Werner and Knowles [38]. In this method, an approximate MC-SCF energy expression is defined, which is accurate to second order in terms of the orbital coefficients **C** and not the unitary parameters **K**. Through this change of variables, the effect of orthonormality and the periodicity of the orbitals as functions of the orbital rotations are taken into account correctly, resulting in a large increase of the radius of convergence of the Newton–Raphson method.

B 3.5.4 OPTIMIZATION OF MOLECULAR GEOMETRIES

This section discusses techniques specific to the optimization of molecular geometries.

There are four main factors that influence the rate of convergence of molecular structure optimizations: (1) the initial guess geometry; (2) the optimization algorithm; (3) the quality of the Hessian matrix and (4) the coordinate system. The first of these is obvious; the closer the starting geometry is to the final converged geometry, the fewer optimization cycles it should take to get there. Optimization algorithms will not be discussed here, as with a reasonable starting geometry and Hessian, most standard methods (see section B3.5.2) perform well. The choice of algorithm is, however, much more crucial for transition states, and one method, the Eigenvector Following algorithm, will be described in the section dealing with transition state optimization. The third point can also be dealt with briefly. Most current optimization algorithms use approximate second-derivative (Hessian) information with updating to help predict the next step. Assuming that the surface can be adequately modelled by a quadratic function, the more reliable the initial Hessian information and the updating is, the better will be the predicted step and the fewer cycles it should take to converge. Lower-level calculations, force fields and simple universal force constant [39, 40 and 41] formulae can be employed to generate the initial Hessian. The fourth factor, the coordinates used to carry out the optimization, is now recognized as being vitally important and it is the choice of coordinates that is largely responsible for the efficiency of modern geometry optimization algorithms.

B3.5.4.1 THE COORDINATE SYSTEM

As noted above, the coordinate system is now recognized as being of fundamental importance for efficient geometry optimization; indeed, most of the major advances in this area in the last ten years or so have been due to a better choice of coordinates. This topic is seldom discussed in the mathematical literature, as it is in general not possible to choose simple and efficient new coordinates for an abstract optimization problem. A nonlinear molecule with N atoms and no

symmetry needs $3N - 6$ internal coordinates to specify its geometry. Unless symmetry or other constraints fix the values of some coordinates, it is not possible to omit coordinates. However, it is possible, and sometimes

useful to use more. The coordinates are then not independent, a situation called redundancy.

The two key factors that make a good set of coordinates are to minimize the degree of coupling between them, and make the potential energy surface more quadratic. In general, the less coupling the better, as variation of one particular coordinate will then have minimal impact on the other coordinates. Coupling manifests itself primarily as relatively large mixed partial derivative terms between different coordinates. For example, a strong harmonic coupling between two different coordinates, i and j , results in a large off-diagonal element, H_{ij} , in the Hessian matrix. Cubic and higher-order couplings are even more deleterious for optimization, as they cannot be eliminated by a linear transformation.

Cartesian coordinates are an obvious choice as they can be defined for all systems, and gradients and second derivatives are calculated directly in Cartesians. Unfortunately, they normally make a poor coordinate set for optimization as they are fairly heavily coupled, their only advantage being their simplicity and completely general nature. If the quadratic model holds, i.e., for very small displacements, and if the gradient and Hessian are properly transformed, Cartesians are equivalent to any other coordinate set [42]. Of course, the source of good Hessian data is often a force field expressed in valence coordinates, so the latter are used implicitly. A further minor inconvenience of Cartesians is that the Hessian is singular, due to the presence of translational degrees of freedom (interestingly, rotations cause singularity of the force constant matrix—and zero vibrational frequencies—only at stationary points, a problem first discussed in [12] and rediscovered many times since). Cartesian optimization is used almost exclusively in molecular mechanics, despite its inefficiency, as it requires no transformation of the coordinates and derivatives. While the computational effort required by these transformations is negligible in *ab initio* work, it becomes significant in force field methods with energy and gradient computation being so rapid. Recent work promises to improve the efficiency of methods using valence internal coordinates [43, 44 and 45].

Z-matrix coordinates are widely used to define molecular geometries. A Z matrix specifies the molecular geometry in a treelike manner, by connecting each new atom in the system to those that have been defined previously. The first three atoms in the Z matrix are unique, with the first atom at the origin, the second lying on the Z axis (connected to the first by a single stretch) and the third lying in the XZ plane (connected to either the first or second atom via a stretch and defining a bend with the unconnected atom). Each new atom after the third is defined with respect to atoms previously defined in the Z matrix using, for example, one stretch, one bend and one torsion. An example of a typical Z matrix (for fluoroethylene) is shown in [figure B3.5.2](#).

-13-

C1						
C2	C1	L1				
F	C1	L2	C2	A1

A2		118.0				
A3		120.0				
A4		120.0				

Figure B3.5.2. Example Z matrix for fluoroethylene. Notation: for example, line 4 of the Z matrix means that a H atom is bonded to carbon atom C1 with bond length L3 (ångströms), making an angle with carbon atom C2 of A3 (degrees) and a dihedral angle with the fluorine atom of 180.0° . All parameters given lettered variable names (L1, A1 etc) will be optimized; the dihedral angles are given explicitly as these are fixed by symmetry (the molecule is planar). Simple constraints can be imposed by removing parameters from the optimization list.

Initially, the Z matrix was utilized simply as a means of geometry input. It was subsequently found that optimization was generally more efficient in Z -matrix coordinates than in Cartesians, especially for acyclic systems. This is not always the case, and care must be taken in constructing a suitable Z matrix. A short discussion on good Z -matrix construction strategy is given by Schlegel [39].

The first *ab initio* gradient geometry optimizations were performed in what are now called natural internal coordinates [46], although they were formally defined only later [47]. These coordinates are derived from vibrational spectroscopy and are appropriate for covalent (mainly organic) molecules. They include all individual bond stretching coordinates, but only non-redundant linear combinations of bond angles and torsions as deformational coordinates. Suitable linear combinations of bends and torsions (the two are considered separately) are selected using group theoretical arguments based on approximate local symmetry. The major advantage of natural internal coordinates in geometry optimization is that they significantly reduce the coupling, both harmonic *and* anharmonic, between the various coordinates. Compared to natural internals, Z -matrix coordinates arbitrarily omit some angles and torsions—to prevent redundancy—and this can induce strong anharmonic coupling between the coordinates, especially with a poorly constructed Z matrix. Successful minimizations can be carried out in natural internals with only an approximate (e.g., diagonal) Hessian provided at the starting geometry but a good starting Hessian is still needed for a transition state search. Using a suitable set of internal coordinates can reduce the number of cycles required to converge compared to the corresponding Cartesian optimization by an order of magnitude or more, depending on the system.

-14-

Despite their clear advantages, natural internals have only become popular relatively recently, principally because in early programs they had to be user defined, a tedious and error-prone procedure for large molecules. This situation changed with the development of algorithms capable of generating natural internals automatically from input Cartesians [48, 49]. For minimization, natural internals and their successors have become the coordinates of choice [50, 51].

However, there are some disadvantages to natural internal coordinates. Their automatic construction proceeds by an exhaustive topological analysis involving thousands of lines of code and, for molecules with a complex structure, e.g., multiply fused rings and cages, the algorithm may be unable to generate a suitable non-redundant set of coordinates. Additionally, *more* coordinates than the $3N - 6$ (where N is the number of atoms) required may be generated. The redundancies can be removed by eliminating some coordinates, but this is arbitrary and may negatively influence convergence.

Various methods have been suggested for dealing with redundant coordinates. The normal coordinate optimization method [52] can use a force field defined in redundant coordinates, but is restricted to rectilinear coordinates. A general force field, expressed in redundant coordinates, can be transformed to a non-redundant set [13]. The current method of choice is to carry out the optimization directly in the redundant coordinate space [53] using the concept of a generalized inverse. If the total number of internal coordinates, including redundancies, is $n > 3N - 6$, then one constructs and diagonalizes the $n \times n$ matrix $\mathbf{G} = \mathbf{B}\mathbf{B}^T$ where \mathbf{B} is the first-order transformation matrix from Cartesians to internal coordinates, $\Delta\mathbf{q} = \mathbf{B}\Delta\mathbf{x}$. Diagonalization of \mathbf{G} results in two sets of eigenvectors; a set of $m = 3N - 6$ eigenvectors with eigenvalues $\lambda > 0$, and a set of $n - m$ eigenvectors with eigenvalues $\lambda = 0$ (to numerical precision). The eigenvalue equation for \mathbf{G} can be written

$$\mathbf{G}(\mathbf{UR}) = (\mathbf{UR}) \begin{pmatrix} \Lambda & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{pmatrix} \quad (\text{B3.5.8})$$

and the generalized inverse of \mathbf{G} , \mathbf{G}^- , involves inverting the non-zero eigenvalues only and back-transforming

$$\mathbf{G}^- = \mathbf{U}\Lambda^{-1}\mathbf{U}^T.$$

In this way the optimization can be cast in terms of the original coordinate set, including the redundancies. Exactly the same transformations between Cartesian and internal coordinate quantities hold as for the non-redundant case (see the next section), but with the generalized inverse replacing the regular inverse.

The redundant optimization scheme [53] can be applied to natural internal coordinates, which are sometimes redundant for polycyclic and cage compounds. It can also be applied directly to the underlying primitives. This has the disadvantage that the coordinate space is larger, and contains many redundancies, but it is simpler to implement than a full natural internal coordinate scheme and can handle essentially any molecule, regardless of the topology, thus avoiding any failure in the generating algorithm. The well known Gaussian *ab initio* program [19] now uses, as a default, this type of algorithm [54].

-15-

As originally implemented, the redundant optimization scheme involved solution of equation (B3.5.8) at the beginning of *every* optimization cycle, which may be expensive in semiempirical or force field methods. A scheme which involves a *single* diagonalization was introduced by Baker *et al* [55]. Diagonalization of the \mathbf{G} matrix partitions the original coordinate space into two subspaces, a redundant subspace spanned by the set of vectors in \mathbf{R} and a non-redundant subspace spanned by \mathbf{U} . Since \mathbf{R} is redundant, it can be discarded and the set of vectors in \mathbf{U} defines a complete, non-redundant coordinate set which can be retained throughout the entire optimization. Unlike natural internals, which are linear combinations of just a few of the primitives localized in small regions of the molecule, each vector in \mathbf{U} is potentially a linear combination of *all* of the primitives and is delocalized over the entire molecule; they are known as *delocalized internal coordinates* [55]. Despite their apparent complexity, delocalized internals perform in practice as well as natural internals.

We present in [table B3.5.1](#) a comparison of Cartesian, *Z*-matrix and delocalized internal coordinate optimizations, using the semiempirical PM3 method [56] on ten typical medium-sized organic molecules. All optimizations were started with a unit Hessian and used the EF algorithm (see later) [57] with a BFGS Hessian update [6] to compute the optimization step; the only difference is in the coordinate system. The final column shows our best results using an initial non-unit Hessian matrix, diagonal in the space of *primitive* internals, with diagonal force constants estimated using the recipe of Schlegel [39]. The results, in terms of the number of cycles required for convergence, clearly show the advantages of using a good set of coordinates combined with a reliable estimate of the corresponding force constants.

-16-

Table B3.5.1 Number of cycles to converge for geometry optimizations of some typical organic molecules using Cartesian, *Z*-matrix and delocalized internal coordinates^a.

Molecule	Formula	Symmetry	Cycles to converge			
			CART ^b	ZMAT ^b	INT ^b	INT ^c

azulene	C ₁₀ H ₈	C _{2v}	24	13	16	10
lumazine	C ₆ H ₄ N ₄ O ₂	C _s	26	18	14	8
dichloropropane (<i>gauche</i>)	C ₃ H ₆ Cl ₂	C ₁	48	24	33	7

cyanomethyl methyl ether	C ₃ H ₅ NO	C ₁	45	25	33	9
salicylic acid	C ₇ H ₆ O ₃	C _s	32	45 ^d	13	10
isoxanthopterin	C ₆ H ₅ N ₅ O ₂	C _s	36	18	12	9
pyrroloquinoline quinone anion (3-)	C ₁₄ H ₃ N ₂ O ₈	C ₁	167 ^e	F ^f	109	36
2,5-bis-(4-aminophenyl)-1,3,4-oxadiazol	C ₁₄ H ₁₂ N ₄ O	C _{2v}	27	F ^f	14	7
permethyl-nonasilane (<i>gauche</i> conformer)	Si ₉ (CH ₃) ₂₀	C ₁	355 ^e	113 ^g	213	47

^a Calculations using the semiempirical PM3 method with standard convergence criteria of 0.0003 au on the maximum component of the gradient vector and *either* an energy change from the previous cycle of $< 10^{-6}$ hartree *or* a maximum predicted displacement for the next step of < 0.0003 au.

^b Started with a unit Hessian matrix.

^c Started with a Hessian diagonal in the space of *primitive* internals using the recipe of Schlegel [39].

^d Poor *Z* matrix.

^e Converged prematurely with too high energy due to small energy changes between steps.

^f *Z* matrix generated using Cartesian \rightarrow *Z*-matrix conversion program. Severe converge problems with energy oscillation; halted after 90 cycles with energy higher than at starting geometry.

^g Acyclic system; good *Z* matrix.

B3.5.4.2 TRANSFORMATION BETWEEN COORDINATE SYSTEMS

This section deals with the transformation of coordinates and forces [11, 47] between different coordinate systems. In particular, we will consider the transformation between Cartesian coordinates, in which the geometry is ultimately specified and the forces are calculated, and internal coordinates which allow efficient optimization.

(A) TRANSFORMATION OF FIRST AND SECOND DERIVATIVES

Let us consider the energy expanded through second order in two sets of displacement coordinates $\Delta\mathbf{x}$ and $\Delta\mathbf{q}$. The two coordinate systems are related by

-17-

$$\Delta q_i = \sum_a B_{ia} \Delta x_a + \frac{1}{2} \sum_{a,b} C_{ab}^i \Delta x_a \Delta x_b + \dots \quad (\text{B3.5.9})$$

The potential energy is given as

$$\begin{aligned}
E &= E_0 + \sum_i \Delta q_i g_i + \frac{1}{2} \sum_{i,j} H_{ij} \Delta q_i \Delta q_j + \dots \\
&= E_0 + \sum_a \Delta x_a f_a + \frac{1}{2} \sum_{a,b} K_{ab} \Delta x_a \Delta x_b + \dots
\end{aligned}
\tag{B3.5.10}$$

or, in matrix notation,

$$E = E_0 + \Delta \mathbf{q}^T \mathbf{g} + \frac{1}{2} \Delta \mathbf{q}^T \mathbf{H} \Delta \mathbf{q} + \dots = E_0 + \Delta \mathbf{x}^T \mathbf{f} + \frac{1}{2} \Delta \mathbf{x}^T \mathbf{K} \Delta \mathbf{x} + \dots$$

where \mathbf{g} and \mathbf{H} are the gradient and the force constant matrix, respectively, in internal coordinates, and \mathbf{f} and \mathbf{K} are the same in Cartesians. Substituting (B3.5.9) into equation (B3.5.10) and equating equal powers one obtains

$$\begin{aligned}
\mathbf{f} &= \mathbf{B}^T \mathbf{g} \\
\mathbf{K} &= \mathbf{B}^T \mathbf{H} \mathbf{B} + \sum_i \mathbf{C}^i g_i.
\end{aligned}$$

If the two coordinate systems are connected by a non-singular transformation then, defining $\mathbf{A} = (\mathbf{B}^T)^{-1}$, the more important inverse transformations are given by

$$\begin{aligned}
\mathbf{g} &= \mathbf{A} \mathbf{f} \\
\mathbf{H} &= \mathbf{A} \mathbf{K} \mathbf{A}^T - \sum_i g_i \mathbf{A} \mathbf{C}^i \mathbf{A}^T.
\end{aligned}
\tag{B3.5.11}$$

Thus the transformation matrix for the gradient is the inverse transpose of that for the coordinates. In the case of transformation from Cartesian displacement coordinates ($\Delta \mathbf{x}$) to internal coordinates ($\Delta \mathbf{q}$), the transformation is singular because the internal coordinates do not specify the six translational and rotational degrees of freedom. One could augment the internal coordinate set by the latter but a simpler approach is to use the generalized inverse [58]

$$\mathbf{A} = (\mathbf{B} \mathbf{M} \mathbf{B}^T)^{-1} \mathbf{B} \mathbf{M}$$

where \mathbf{M} is any non-singular $3N \times 3N$ matrix, in the simplest case the $3N$ -dimensional unit matrix.

The second term in equation B3.5.11 deserves comment. This term shows that Hessian (second-derivative) matrices

in different coordinate systems are not related simply by a similarity transformation, except at stationary points. In particular, its signature (number of negative eigenvalues) does not have to be the same in different coordinate systems. Properly chosen internal coordinates tend to make the Hessian positive definite, and are probably one of the reasons why internal coordinates are preferable for molecular geometry optimization.

When working with any coordinate system other than Cartesians, it is necessary to transform finite displacements between Cartesian and internal coordinates. Transformation from Cartesians to internals is seldom a problem as the latter are usually geometrically defined. However, to transform a geometry displacement from internal coordinates to Cartesians usually requires the solution of a system of coupled nonlinear equations. These can be solved by iterating the first-order step [47]

$$\Delta \mathbf{x} = \mathbf{A}^T \Delta \mathbf{q}$$

where $\Delta \mathbf{q}$ is the difference between the current internal coordinates and their desired values, calculated to full accuracy from the Cartesians. If $\Delta \mathbf{q}$ is large, it may be better to proceed in stages, converging $\Delta \mathbf{x}$ roughly between each stage.

B3.5.4.3 CONSTRAINED OPTIMIZATION

Constrained optimization refers to optimizations in which one or more variables (usually some internal parameter such as a bond distance or angle) are kept fixed. The best way to deal with constraints is by elimination, i.e., simply remove the constrained variable from the optimization space. Internal constraints have typically been handled in quantum chemistry by using Z matrices; if a Z matrix can be constructed which contains all the desired constraints as individual Z -matrix variables, then it is straightforward to carry out a constrained optimization by elimination.

The situation is more complicated in molecular mechanics optimizations, which use Cartesian coordinates. Internal constraints are now relatively complicated, nonlinear functions of the coordinates, e.g., a distance constraint between atoms i and j in the system is $R_{ij} = \sqrt{\{(x_i - x_j)^2 + (y_i - y_j)^2 + (z_i - z_j)^2\}} = R_0$, and this cannot be handled by simple elimination. There are two main approaches if elimination is not possible, penalty functions and Lagrange multipliers.

The general constrained optimization problem can be considered as minimizing a function of n variables $F(\mathbf{x})$, subject to a series of m constraints of the form $C_i(\mathbf{x}) = 0$. In the penalty function method, additional terms of the form $\frac{1}{2}\sigma_i C_i(\mathbf{x})^2$, $\sigma_i > 0$, are formally added to the original function, thus

$$F(\mathbf{x})^{\text{pen}} = F(\mathbf{x}) + \sum \frac{1}{2}\sigma_i C_i(\mathbf{x})^2$$

with the summation over all m constraints. If the constraint is satisfied, the additional term is zero, but if not then the value of the function increases in proportion to the square of the deviation, i.e., the additional term penalizes any geometries that do not satisfy the constraint. In practice, the value of the function is left unaltered and what is done is to modify the gradient according to

-19-

$$\partial F(\mathbf{x})^{\text{pen}} / \partial x_j = \partial F(\mathbf{x}) / \partial x_j + \sum \sigma_i \partial C_i(\mathbf{x}) / \partial x_j.$$

Exactly the same types of step as for an unconstrained optimization can then be taken, using the modified as opposed to the regular gradient.

The performance of the penalty function algorithm is heavily influenced by the value chosen for σ_i . The larger the value of σ_i , the better the constraints are satisfied but the slower the rate of convergence. Optimizations with very high values of σ_i encounter severe convergence problems. However, the method is very general and

easy to apply.

A better approach is the method of Lagrange multipliers. This introduces the Lagrangian function [59]

$$L(\mathbf{x}, \lambda) = F(\mathbf{x}) - \sum \lambda_i C_i(\mathbf{x})$$

which replaces the function $F(\mathbf{x})$ in the unconstrained case. Here the λ_i are the so-called Lagrange (or unknown) multipliers, one for each constraint. Differentiating with respect to \mathbf{x} and λ gives

$$\partial F(\mathbf{x})^{\text{pen}} / \partial x_j = \partial F(\mathbf{x}) / \partial x_j + \sum \sigma_i \partial C_i(\mathbf{x}) / \partial x_j.$$

and

$$\partial L(\mathbf{x}, \lambda) / \partial \lambda_i = -C_i(\mathbf{x}).$$

At a stationary point of the Lagrangian function, we have $\nabla L = \mathbf{0}$, i.e., all $\partial L / \partial x_j = 0$ and all $\partial L / \partial \lambda_i = 0$. This latter condition means that all $C_i(\mathbf{x}) = 0$ and so all constraints are satisfied. Hence finding a set of values (\mathbf{x}, λ) for which $\nabla L = \mathbf{0}$ gives a solution to the constrained optimization problem in exactly the same way as finding an \mathbf{x} for which $\nabla F = \mathbf{0}$ gives a solution to the corresponding unconstrained problem.

A major difference between the penalty function and Lagrange multiplier methods is that in the latter the unknown multipliers are part of the optimization space and are treated essentially as additional variables. The Lagrange multiplier method usually converges significantly faster than the penalty function method and has the further advantage that constraints are satisfied essentially exactly. Note that, in both methods, constraints do not need to be satisfied in the starting geometry, but are instead satisfied at convergence. An efficient algorithm (within the context of Cartesian optimization) for imposing constraints in Cartesian coordinates, which incorporates both penalty functions and Lagrange multipliers, was presented by Baker in 1992 [60], with further improvements in the following year [61].

By combining the Lagrange multiplier method with the highly efficient delocalized internal coordinates, a very powerful algorithm for constrained optimization has been developed [62]. Given that delocalized internal coordinates are potentially linear combinations of *all* possible primitive stretches, bends and torsions in the system, cf. *Z*-matrix coordinates which are *individual* primitives, it would seem very difficult to impose any constraints at all; however, as

shown in the original reference [55], any desired internal constraint can be imposed using a relatively simple Schmidt orthogonalization procedure. By projecting unit vectors (with unit components corresponding to particular primitives) onto the non-redundant subspace \mathbf{U} (see equation (B3.5.8)) and Schmidt orthogonalizing the resultant vectors against all other vectors in \mathbf{U} , it is possible to isolate individual primitives in a consistent manner into *single* vectors. By removing these vectors from the optimization space, optimizations can be carried out in which the primitives involved retain their initial values throughout the optimization. The resulting algorithm has all the advantages of redundant internal coordinate optimizations in terms of efficiency, combined with the advantage of the Lagrange multiplier method that desired constraints do not have to be satisfied in the starting geometry. As constraints do become satisfied, they can simply be eliminated from the optimization space (this cannot be done with Cartesian optimizations due to the form of the constraints). By starting with an appropriate constraint vector, it is possible to impose constraints on linear

combinations of variables rather than on individual primitives. It is also possible to perform constrained transition state searches. For more details see [55] and [62].

There are alternative methods for imposing constraints, but they are less satisfactory than those discussed above. One commonly used alternative is to use projection techniques [12, 63]. In this approach, components in directions that would result in motion that would violate the constraints are projected out of the gradient vector and Hessian matrix before calculating the next step. Unfortunately, while projection works fine for constraints that are linear in the coordinates (the standard method for imposing the Eckart conditions is by projection), nonlinear constraints have to be linearized, and consequently ‘feasibility corrections’ [63] must be applied to prevent deviations from the desired constraints increasing as the optimization progresses. The interesting method of Taylor and Simons [64] for combining linearized geometrical constraints with mode following also suffers from this drawback.

Another way of attempting to constrain variables without eliminating them from the optimization space is to set the appropriate force constants to very large values. This is what is currently done in Schlegel’s redundant internal coordinate algorithm to prevent motion in the redundant subspace [54]. Perhaps a better method is to set the corresponding rows and columns in the inverse Hessian to zero. This method must begin with a geometry that satisfies the constraints.

B 3.5.5 OPTIMIZATION OF TRANSITION STATES

Searching for transition states poses additional difficulties compared to minimization. The first problem is the starting geometry. There is a host of structural information that can be called upon to provide a good estimate of the likely geometry of a local minimum. Far less knowledge is available about transition state geometries. Second is the structure of the Hessian. In the region of a transition structure, the Hessian must have one, and only one, negative eigenvalue. Unlike the situation for a minimum search, there is no simple and cheap method for guessing a reasonable starting Hessian with the appropriate eigenvalue structure. Even if you calculate an exact initial Hessian, if your starting geometry is poor, its eigenstructure will probably be inappropriate. One thing that is often done for transition states is to calculate a few rows and columns of the Hessian—those corresponding to variables in the ‘active site’ where most of the geometrical changes are expected—by finite difference on the gradient, and guess diagonal Hessian matrix elements for the rest of the system in the same way one would do for a minimum search. The starting Hessian will then hopefully have an appropriate negative eigenvalue.

-21-

In addition to the problem of generating a starting Hessian with the correct signature, there are problems in retaining it. The Hessian updates commonly used for minimization generally retain positive definiteness (see section B3.5.2.3); there are no such guarantees for retaining a negative eigenvalue during a transition state search. Once the desired region of the potential energy surface (PES) has been reached, quasi-Newton techniques can be used to refine the geometry; however they must be able to correct for the occasional bad update which may destroy the Hessian eigenstructure. Transition state searches can thus be separated into two parts; first find the correct region on the PES and then home in onto the transition state. Many of the methods described below for locating approximate transition states have the advantage that they require no second-derivative information.

B3.5.5.1 LOCATING THE CORRECT NEIGHBOURHOOD

(A) COORDINATE DRIVING

A commonly used approach is coordinate driving. Here an appropriate internal coordinate, or a linear combination of coordinates, is chosen as a reaction coordinate. At various intervals along this coordinate, between its value in the reactants and in the products, all the other variables are optimized. This then defines a minimum energy path. The energy maximum on this path can be shown to be the transition state geometry. Usually, however, the maximum on the path is located only approximately. Coordinate driving involves several minimizations in $(n - 1)$ variables; consequently it is quite expensive. Moreover, its success depends on a good definition of the reaction coordinate; it should be roughly parallel with the true reaction path. If, at any point along the path, the reaction coordinate becomes nearly perpendicular to the reaction path, the latter may become discontinuous. The minimum energy path defined in this way has little physical significance, as different choices of reaction coordinate can produce different pathways.

(B) SYNCHRONOUS TRANSIT

Another approach requiring less intuition is the synchronous transit method [65]. Here the path between reactants and products is interpolated linearly between the reactant and the product. The interpolation can be carried out in Cartesians, internal coordinates or, perhaps best, in terms of distance coordinates [66]; the results depend somewhat on the interpolation method. A maximum is first found along this linear synchronous transit path. This is followed by alternate minimization along directions *orthogonal* to the original direction, combined with maximum searches along a parabolic path (the quadratic synchronous transit) joining the reactant, the product and the current estimate of the transition state. For very curved reaction paths the quadratic synchronous transit path may be a poor approximation, and the reaction path may have to be approximated piecewise. A similar algorithm, which involves minimization in a space *conjugate* to the maximum search direction, was developed by Bell and Crighton [67]. This last reference also contains a good discussion of various transition-state search strategies.

Both of the above methods can be considered as approximations to the Fukui reaction path, discussed later in this article. The maximum of the Fukui reaction path also yields the transition state, although usually at significantly more expense than coordinate driving or the synchronous transit method. A more modern development of these ideas has been given by Ionova and Carter [68].

(C) WALKING UPHILL

These algorithms try to walk up to transition states from minima, usually along the shallowest path, i.e., along the

-22-

eigenvector of the Hessian which has the lowest eigenvalue [69, 70 and 71]. They are more important when the transition state has already been located approximately and will be discussed in the next section.

(D) BRACKETING THE TRANSITION STATE

These methods try to bracket the transition state from both the reactant and the product side [72, 73]. For example, in the method of Dewar *et al* [73], two structures, one in the reactant valley and one in the product valley, are optimized simultaneously. The lower-energy structure is moved to reduce the distance separating the two structures by a small amount, e.g. by 10%, and its structure is reoptimized under the constraint that the distance is fixed. This process is repeated until the distance between the two structures is sufficiently small.

(E) SEAM CROSSING

Here the transition state is approximated by the lowest crossing point on the seam intersecting the *diabatic* (non-interacting) potential energy surfaces of the reactant and product. The method was originally developed

for excited state surfaces [74], and has subsequently been used to locate approximate transition states [75, 76].

B3.5.5.2 REFINING THE TRANSITION STATE

It is usually not efficient to use the methods described above to refine the transition state to full accuracy. Starting from a qualitatively correct region on the potential surface, in particular one where the Hessian has the right signature, efficient gradient optimization techniques, with minor modifications, are usually able to zero in on the transition state quickly.

(A) DIRECT INVERSION IN THE ITERATIVE SUBSPACE

One of the methods which is appropriate is DIIS applied to geometry optimization [24]; being a gradient norm minimization method, it will converge to any stationary point. This is, however, one of its problems as it may converge to the wrong point. The convergence radius of augmented Hessian type methods is larger. One of these methods, the eigenvector following (EF) method [57], is generally useful for both transition states and minima and will be described here as an example of a modern optimization algorithm.

(B) EIGENVECTOR FOLLOWING

The EF algorithm [57] is based on the work of Cerjan and Miller [69] and, in particular, Simons and coworkers [70, 71]. It is closely related to the augmented Hessian (rational function) approach [25]. We have seen in [section B3.5.2.5](#) that this is equivalent to adding a constant level shift (damping factor) to the diagonal elements of the approximate Hessian \mathbf{H} . An appropriate level shift effectively makes the Hessian positive definite, suitable for minimization.

Although a single shift parameter can also be used to find a transition state, the eigenvector following algorithm utilizes *two* level shifts: one for the Hessian (transition state) mode along which the energy is to be maximized and the other for modes for which it is minimized. In terms of a diagonal Hessian representation, transforming the gradient appropriately, we have the two eigenvalue equations

-23-

$$\begin{pmatrix} b_2 & \dots & 0 & g'_2 \\ & \ddots & & \\ 0 & & b_n & g'_n \\ g'_2 & & g'_n & 0 \end{pmatrix} \begin{pmatrix} \Delta q_2 \\ \vdots \\ \Delta q_n \\ 1 \end{pmatrix} = \lambda_n \begin{pmatrix} \Delta q_2 \\ \vdots \\ \Delta q_n \\ 1 \end{pmatrix} \quad (\text{B3.5.12})$$

and

$$\begin{pmatrix} b_1 & g'_1 \\ g'_1 & 0 \end{pmatrix} \begin{pmatrix} \Delta q_1 \\ 1 \end{pmatrix} = \lambda_p \begin{pmatrix} \Delta q_1 \\ 1 \end{pmatrix}. \quad (\text{B3.5.13})$$

In these two equations, the b_i are the eigenvalues of \mathbf{H} ($b_1 < b_2 < \dots < b_n$), \mathbf{g}' is the gradient vector transformed to the basis of the eigenvectors \mathbf{U} of \mathbf{H} : $\mathbf{g}' = \mathbf{U}^T \mathbf{g}$, and we have (arbitrarily) set the factor α in [equation \(B3.5.5\)](#) to unity. Note that λ_n is the lowest eigenvalue of equation (B3.5.12) (it is always negative and approaches zero at convergence), while λ_p is the highest eigenvalue of equation (B3.5.13) (it is always positive and again approaches zero at convergence). Once suitable values of λ_p and λ_n have been determined, the final step is given by

$$\Delta \mathbf{q} = -\mathbf{g}'_1 \mathbf{u}_1 / (b_1 - \lambda_p) - \sum \mathbf{g}'_i \mathbf{u}_i / (b_i - \lambda_n) \quad (i = 2, \dots, n)$$

where it is assumed that we are maximizing along the lowest Hessian mode \mathbf{u}_1 , and minimizing along all the others. This holds *regardless* of the Hessian eigenvalue structure (unlike the Newton–Raphson step), and so the algorithm can handle Hessian matrices with the wrong signature.

It is also possible to maximize along modes other than the lowest and, in this way perhaps, locate transition states for alternative rearrangements/dissociations from the same initial starting point. For maximization along the k th mode (instead of the lowest), b_1 would be replaced by b_k , and the summation would now exclude the k th mode but include the lowest. Since what was originally the k th mode is the mode along which the negative eigenvalue is required, then this mode will eventually become the lowest mode at some stage of the optimization. To ensure that the original mode is being followed smoothly from one cycle to the next, the mode that is actually followed is the one with the greatest overlap with the mode followed on the previous cycle. This procedure is known as mode following. For more details and some examples, see [57]. Mode following can work well for small systems, but for larger, flexible molecules there are usually a number of soft modes which lead to transition states for conformational rearrangements and not to the more interesting reaction saddle points. Moreover, each eigenvector can be followed in two opposite directions and frequently only one leads to a reaction.

Although it was originally developed for locating transition states, the EF algorithm is also efficient for minimization and usually performs as well as or better than the standard quasi-Newton algorithm. In this case, a single shift parameter is used, and the method is essentially identical to the augmented Hessian method.

B 3.5.6 SIMULTANEOUS OPTIMIZATION OF GEOMETRIES AND WAVEFUNCTIONS

So far, we have considered the optimization of wavefunction and geometry parameters separately. In view of the much shorter timescale and higher energy associated with the former, this is reasonable. However, additional savings can be potentially obtained by optimizing the wavefunction and the geometry simultaneously. This was first proposed for density functional methods [77] and later for traditional quantum chemistry techniques [78]. With the large increase of computing speed compared to disk input/output speed, direct techniques [79] were generally adopted. In direct methods, the large disparity between calculating the gradients of the molecular energy with respect to electronic parameters (the Fock matrix in SCF theory) and nuclear coordinates disappeared; gradients are now only a few times more expensive than a Fock matrix evaluation, making simultaneous wavefunction-geometry optimization much more attractive. In spite of this, such methods are not yet widely used, except in the crude form of relaxing the SCF convergence criteria if the geometry parameters are far from convergence.

The molecular dynamics method introduced by Car and Parrinello [80], though not strictly an optimization method, has many features in common with simultaneous optimization of the wavefunction and geometry. In this method, the electronic wavefunction and energy are close to, but not identical with, the Born–Oppenheimer energy. The basic idea is to consider the electronic degrees of freedom as dynamical variables, along with the nuclear coordinates. The Lagrangian contains the kinetic energy of the nuclei, the potential energy as a function of both the nuclear and electronic degrees of freedom and a fictitious kinetic energy term which is the square of the time derivative of the electronic wavefunction multiplied by a small mass. The inertia of this fictitious electronic mass causes the wavefunction to deviate slightly from the Born–Oppenheimer surface. The Car–Parrinello method is most efficient for plane wave basis sets, as the

calculation of the nuclear gradient is very inexpensive in this method, but it has also been introduced into SCF theory [81, 82].

B 3.5.7 REACTION PATH ALGORITHMS

The reaction path is defined by Fukui [83] as the line $\mathbf{q}(s)$ leading down from a transition state along the steepest descent direction

$$\partial \mathbf{q}(s) / \partial s = -\mathbf{g}(s) / |\mathbf{g}(s)|. \quad (\text{B3.5.14})$$

Here s is the path length, $ds = (dq_1^2 + \dots + dq_n^2)^{1/2}$. The reaction path is, unfortunately, dependent on the coordinate system. This should perhaps be emphasized more than is generally the case. Scaling one coordinate by a factor $\alpha > 1$ increases the coordinate value but decreases the corresponding gradient component, so that if the reaction path was antiparallel to the gradient before the scaling it will not be so after scaling. For qualitative studies of chemical reactions, there is little to recommend one particular reaction path over another. However, for dynamical studies, the intrinsic reaction coordinate (IRC) [83], defined as the path length along the reaction path in mass-weighted Cartesian coordinates, $\xi_i = m_i^{1/2} x_i$, has advantages over other definitions (for example the kinetic energy matrix is the unit

-25-

matrix). Here m_i is the atomic mass corresponding to the Cartesian coordinate x_i , making the reaction path isotope dependent. A major difficulty with reaction paths is that to decide whether a given point is on the path the whole path must be constructed; local information (energy, gradient, force constants etc.) is insufficient.

B3.5.7.1 FOLLOWING THE REACTION PATH DOWNHILL

The most widely used methods try to follow the gradient downhill starting from a transition state. At the transition state itself, the gradient vanishes and the first step must be made along the imaginary eigenvector of the Hessian in the proper coordinates, i.e., mass-weighted Cartesians for the IRC path. As pointed out by Schlegel [1, 2], (B3.5.14) is a stiff differential equation and its integration by simply making small downhill steps along the gradient, a method equivalent to Euler's method, requires very small steps and consequently much effort. Otherwise, the calculated reaction path diverges from the true one, at first slowly and then more rapidly. To deal with this problem requires either constrained minimization steps at each point on the path, or alternatively second-order (both gradient and Hessian) information. This increases the cost of the individual steps but allows much larger steps to be taken.

The method of Ishida *et al* [84] includes a minimization in the direction in which the path curves, i.e. along $(\mathbf{g}/|\mathbf{g}| - \mathbf{g}'/|\mathbf{g}'|)$, where \mathbf{g} and \mathbf{g}' are the gradient at the beginning and the end of an Euler step. This technique, called the stabilized Euler method, performs much better than the simple Euler method but may become numerically unstable for very small steps. Several other methods, based on higher-order integrators for differential equations, have been proposed [85, 86].

Page *et al* [87] use a local quadratic model for the surface. This requires the Hessian, but once it is available, the reaction path can be inexpensively determined for a quadratic (or even higher-order) analytical surface (see also [88]). Gonzales and Schlegel [89, 90] approximate the reaction path by an arc of a circle. They first make a step along the gradient of length half the current stepsize to an intermediate point. From this, they make another half step so that the energy is minimized, subject to the stepsize constraint. The wavefunction

and the gradient need not be evaluated at the intermediate point. This method is implemented in the Gaussian series of programs [19] and is widely used. It does not need the exact Hessian, but a good estimate should be available so that the many local optimizations converge rapidly. An advantage of this method is that it yields the curvature of the reaction path at the transition state correctly.

B3.5.7.2 APPROACHING THE REACTION PATH FROM THE SIDE

These methods, which probably deserve more attention than they have received to date, simultaneously optimize the positions of a number of points along the reaction path. The method of Elber and Karplus [91] was developed to find transition states. It furnishes, however, an approximation to the reaction path. In this method, a number (typically 10–20) equidistant points are chosen along an approximate reaction path connecting two stationary points **a** and **b**, and the average of their energies is minimized under the constraint that their spacing remains equal. This is obviously a numerical quadrature of the integral $S^{-1} \int_a^b E(q(s))$ where S is the path length between the points **a** and **b**. The Euler equation to this variation problem yields the condition for the reaction path, [equation \(B3.5.14\)](#). A similar method has been proposed by Stachó and Bán [92].

B3.5.7.3 BIFURCATION OF THE REACTION PATH AND VALLEY–RIDGE INFLECTION POINTS

As shown by Valtazanous and Ruedenberg [93], steepest descent paths (e.g., the Fukui intrinsic reaction coordinate)

-26-

can bifurcate, i.e., split in two, only at stationary points. Thus, the intuitive notion of a reaction path forking, e.g., upon ascent in a valley to two different transition states, or, starting down from a transition state to two different minima, is impossible. This should be regarded as an inherent limitation of the standard definition of a reaction path, not as a physical impossibility. Such cases, in which a valley floor is gradually transformed into a ridge are, in fact, quite common. Mathematically, they are characterized by fact that one of the eigenvalues of the Hessian in the subspace perpendicular to the path changes from positive to negative. The point at which the eigenvalue is zero is called the valley–ridge inflection point. The reaction path, started at a stationary point, will run directly along the ridge and thus becomes non-physical past a valley–ridge inflection point. The actual reaction, of course, will not follow the reaction path in this case, not even qualitatively. Steepest descent paths started a little away from the reaction path will veer away from the latter after passing the valley–ridge inflection point. Baker and Gill [94] have devised a method for locating valley–ridge inflection points (which they call branching points). The reader is reminded, however, that the signature of the Hessian at non-stationary points depends strongly on the coordinate system. Thus, the location of a valley–ridge inflection point may be quite different in Cartesians or mass-weighted Cartesians than in internal coordinates. In particular, the Hessian in Cartesian coordinates may have spurious negative eigenvalues corresponding to rotational coordinates.

B 3.5.8 GLOBAL OPTIMIZATION

For our purposes, global optimization refers to the location of the *lowest* minimum on a given potential energy surface. As mentioned in the introduction, this is currently only a partially solved problem. The number of conformational minima, e.g., for a large protein, increases enormously with the size of the system, and the only way to be *absolutely* sure that the lowest-energy structure has been found is to do an exhaustive search of the entire energy surface; for large molecules this is essentially impossible. Even if the lowest-energy structure were successfully located, this would likely have only limited chemical significance, as there would be many structures energetically close to the global minimum (within a kcal or so) which would need to be

considered for an accurate treatment of the thermodynamics. It is almost a certainty (though the authors are unaware of a formal proof) that finding the global minimum on molecular potential energy surfaces is computationally NP complete, and thus scales factorially with the size of the problem. Such problems are generally regarded as insoluble (however, this does not exclude their solution in a given case).

With systematic PES searches excluded, random (stochastic) methods have become the most common techniques for global minimization. The two most popular methods are simulated annealing [95] and genetic algorithms [96]. The former method derives its name from the annealing process in condensed matter physics in which a solid is melted in a bath and the temperature is then slowly decreased; the particles are expected to settle into their lowest-energy states, provided the initial temperature is sufficiently high and the cooling rate is sufficiently low. In practical optimizations, cooling is represented by local minimizations and heating by random jumps, i.e., random displacements of some or all of the atoms. After a ‘sufficient number’ of local minimization/random jump cycles, the procedure is terminated with the lowest-energy structure found so far taken as the global minimum.

The genetic algorithm method takes its name from the trading of genetic information in chromosomes between parents to produce an offspring. A random population of individuals (geometrical structures for the system in question) is created, and local minimizations are performed on each individual. Selected structural components (genes) from mostly the lowest-energy individuals are allowed to exchange, producing a new set of individuals for the next round of local

-27-

minimizations. After a sufficiently large number of rounds, the global minimum should be located.

Both of these global optimization methods require a very large number of essentially full local optimizations and, consequently, are normally restricted to moderate-sized systems described using mechanics force fields. A somewhat different approach has been developed by Piela and coworkers [97], utilizing the diffusion or heat conduction equation. In this method, a surface containing multiple local minima is smoothly deformed in such a way that wells on the surface gradually disappear, with shallower wells vanishing faster than deeper, lower-energy wells. Eventually a surface will be derived which has just one minimum, related to the lowest-energy, global minimum on the original surface. By carefully reversing the procedure, keeping track of the minimum as it evolves, one is (hopefully) led back to the global minimum as the original surface is reformed.

Other deterministic methods for global optimization have also been developed (see, e.g., [98]).

B3.6 Mesoscopic and continuum models

Marcus Müller

B3.6.1 INTRODUCTION

Many systems in physical chemistry exhibit structure on length scales that greatly exceed the atomic dimensions. Systems containing surfactants—detergents or milk, for instance—often consist of droplets of one component dissolved in another phase. The size of these droplets exceeds the extension of the molecular constituents by far. Very generally, mesoscopic and continuum models describe the properties of materials on length scales larger than the atomic dimensions by incorporating the details of the underlying atomic structure only in terms of a reduced number of effective variables. In this very broad sense, the Navier–Stokes equation

[1], which describes the motion of a fluid via a density, energy, and velocity field and elasticity theory [2], and which describes solids in terms of stress and displacement fields, also belongs to this class of model. In both approaches, the subject of the model is not the properties of individual atoms (e.g., their position or quantum state) but rather their average properties (like the density or velocity) in a small coarse-graining volume. Usually the coarse graining is not performed explicitly, but it is understood that the averaging volume is large enough to result in a continuous spatial variation of the variables of the mesoscopic model and yet still be smaller than the characteristic length scale of the phenomena under consideration.

In the following entry we shall restrict ourselves to discussing mesoscopic and continuum models for complex fluids in chemical physics. The wide span of time and length scales in these materials is illustrated in [figure B3.6.1](#) for a blend of two polymers. On the atomistic scale each polymer consists of chemical repeat units joined together to form the chain molecule. The length scale is set by the distance between the atoms along the backbone of the polymer, typically in the range of 1–2 Å. The vibrations of the atoms occur on the timescale of picoseconds. In a dense melt, the flexible chain molecules adopt a random-walk-like conformation. The ‘step length’ of the random walk, or persistence length b , is typically of the order of a few nanometres. Since several thousands of repeat units form a polymer, the overall size of a single molecule, as specified by its radius of gyration, exceeds the persistence length by 1–3 orders of magnitude. On this range of length scales the structure of the polymer is self-similar. If the two components of the blend are not miscible, as it is generally the case, one species forms droplets that are dispersed in a matrix of the other species. The size of the droplets is in the micrometre range. On even larger length scales (say 1 mm) the material appears homogeneous. Clearly the properties on the mesoscopic length scale are important for application properties. A decrease of the droplet size or even the formation of a connected morphology (i.e. a microemulsion) improves the mechanical properties of the composite material. A similar span of time and length scales is encountered in many other systems (e.g., mixtures of oil, water and surfactant or glassy materials) and this behaviour is rather typical for complex fluids.

Figure B3.6.1. Illustration of the wide span of length scale in a binary polymer blend. (See the text for further explanation.)

A unified model that describes the structure from the atomistic length scale up to macroscopic properties is not analytically tractable. Even state-of-the-art supercomputers cannot cope with such a broad spread of time and length scales in numerical simulations. Today's largest simulated systems in thermal equilibrium comprise about 10^7 particles and, hence, span about 2–3 decades in length scales. With the increase of computing power and progress in simulation methodology, simulating larger and larger system sizes will become feasible, but computer modelling from atomic to macroscopic scales in the framework of a single, unified model is not feasible at present or in the near future.

Another caveat for the modelling from the atomistic level up to the macroscopic level is the requirement of sufficiently accurate interaction potentials. Minor inaccuracies in calculations on small length scales can give rise to pronounced effects on the mesoscopic scale. Consider, for instance the self-assembly of amphiphilic molecules (see section B3.6.3) into a spatially ordered structure. The free-energy difference between the different morphologies can be as small as $10^{-4}kT$ per molecule. The *ab initio* prediction of such a small free-

energy difference is certainly a formidable task.

Mesoscopic and continuum models do not attempt to describe large-scale phenomena starting from the smallest atomic length scale, but rather incorporate the local structure via a small number of effective parameters. Mesoscopic models lump a small number of atoms into an effective particle. These particles interact via coarse-grained interactions. By this coarse-graining procedure much of the atomistic detail is lost, and only those interactions pertinent to the phenomena on the mesoscopic length scales are retained. Even if the interactions on the microscopic scale are extremely complex (e.g., hydrophobic interactions [3] in lipid water mixtures), they can often be captured by simple expressions on the mesoscopic length scale. Coarse-grained models thus yield valuable insights into the structure on large length scales. For specific examples the effective interactions are derived by eliminating the degrees of freedom on the smallest (atomistic) length scales, retaining only those on larger length scales; for some systems (e.g., polymer chains in the gas phase) this coarse-graining procedure has a formal justification due to the self-similar structure on a large range of length scales; for other systems the mapping between the atomistic/microscopic level and the mesoscopic description is rather a concept than a practicable procedure. In this latter case, the application of mesoscopic models rests on the observation that different systems (e.g., diblock copolymers and lipid water mixtures) share a common behaviour on mesoscopic scales. Universal mesoscopic behaviour that does not depend on the details on the atomistic level in a qualitative way is the subject of mesoscopic models.

Continuum models go one step further and drop the notion of particles altogether. Two classes of models shall be discussed: field theoretical models that describe the equilibrium properties in terms of spatially varying fields of mesoscopic quantities (e.g., density or composition of a mixture) and effective interface models that describe the state of the system only in terms of the position of interfaces. Sometimes these models can be derived from a mesoscopic model (e.g., the Edwards Hamiltonian for polymeric systems) but often the Hamiltonians are based on general symmetry considerations (e.g., Landau–Ginzburg models). These models are well suited to examine the generic universal features of mesoscopic behaviour.

Mesoscopic and continuum models bridge the gap between atomistic realistic simulations and the description on the macroscopic level, (e.g., elasticity theory). The objectives of mesoscopic models are twofold. On the one hand they help identify interactions that are necessary to bring about the phenomena on a mesoscopic scale (e.g., phase separation or self-assembly) and they aid in investigating the dependence of the mesoscopic behaviour on the effective interactions. This information also yields some qualitative insight into how the microscopic parameters influence mesoscopic behaviour (e.g., the dependence of the structure in a self-assembled system on the architecture/shape of the amphiphilic molecules). On the other hand, this class of models elucidates universal behaviour on the mesoscopic scale (e.g., identifying various morphologies into which systems can self-assemble, the relation between confinement and phase behaviour, or the consequences of fluctuations) and establishes a relation between behaviour on large length scales and experimentally accessible (mesoscopic) quantities (e.g., Flory–Huggins parameter, interfacial tension, or bending rigidity of membranes).

The hierarchy of models is complemented by a variety of methods and techniques. Mesoscopic models that incorporate some fluid-like packing (e.g., spring–bead models for polymer solutions) are investigated by Monte Carlo

simulations, molecular dynamics or density functional techniques. Lattice models are studied by Monte Carlo simulations. The larger the span of length scales considered, the larger the computational effort required. Models without pronounced packing effects (e.g., the Edwards Hamiltonian) are investigated by self-consistent field techniques. Continuum models are often analytically tractable, at least in the mean field approximation, and simple analytical expressions for various quantities (e.g., interfacial tension between two immiscible polymers) can be obtained in some limiting cases. The effect of fluctuations has been assessed by computer simulations, transfer matrix calculations and renormalization group techniques.

At the heart of mesoscopic and continuum models lies the question: Which degrees of freedom are to be retained as relevant and which can be ignored? The answer depends on the specific problem. By comparing different models the degree of universality and the relevance of interactions can be gauged. This yields much insight into the mechanisms which underly the phenomena. Mesoscopic and continuum models make contact with chemical models on the atomistic level as well as with the macroscopic descriptions. Effort is being made to incorporate more chemical realism into the models as well as to extend them to larger length scales.

In the following we shall describe various applications of mesoscopic models to complex fluids. The examples extend from applications that are quite close to the atomistic level (e.g., coarse-grained polymer models) to highly idealized models (e.g., effective interface Hamiltonians or Ginzburg–Landau models). Moreover, we restrict ourselves mainly to the description of thermodynamic equilibrium. The remainder of this entry is organized as follows. In section B3.6.2 we discuss applications of coarse-grained models to systems involving homopolymers. Mesoscopic models for the description of self-repelling chains, polymer solutions, polymer melts and binary blends are introduced. From these models, more coarse-grained descriptions can be derived in terms of Ginzburg–Landau expansions or effective interface Hamiltonians. [Section B3.6.3](#) then considers amphiphilic molecules. Their co-operative behaviour on the supramolecular level has been explored in the framework of models with various degrees of detail. Chain models retain the salient features of the amphiphile’s architecture while lattice models or continuum models yield a description in terms of a spatially varying concentration. On even larger scales, the statistical mechanics of interfaces has been investigated via random interface models. This article closes with a brief look at the application of mesoscopic and continuum models to dynamical phenomena.

B3.6.2 POLYMERIC SYSTEMS

B3.6.2.1 POLYMER SOLUTIONS

Coarse-grained models have a longstanding history in polymer science. Long-chain molecules share many common mesoscopic characteristics which are independent of the atomistic structure of the chemical repeat units [4, 5 and 6]. The self-similar structure [7, 8, 9 and 10] on large length scales is only characterized by a single length scale, the chain extension R .

The important interactions in polymer solutions are the connectivity of the segments along the chain molecules and interactions between segments. The solvent molecules are often not treated explicitly, but their effect is incorporated into the effective interactions between polymer segments. A good solvent corresponds to an effective repulsion between segments and the polymer chains adopt a swollen configuration. A bad solvent gives rise to an attraction between the polymer segments and leads to a collapse.

The observation of the universality and self-similarity of the large-length-scale properties has a theoretical basis. In 1972 de Gennes [11] related the structure of a polymer chain in a good solvent to a field theory of a n component vector model in the limit $n \rightarrow 0$. This class of models (see the entry on phase transitions and critical phenomena; A2.5) exhibits a continuous phase transition and the properties close to this critical point have been investigated extensively with renormalization group calculations [8, 9 and 10]. The inverse chain length plays the role of the distance from the critical point of the $n = 0$ component vector model. As in the theory of critical phenomena, the behaviour in the vicinity of this critical point (i.e. $1/N \ll 1$) is governed by a universal scaling behaviour that is brought about by only a few relevant interactions. The relation between the behaviour of polymer chains in the limit of $N \rightarrow \infty$ and the critical behaviour justifies the use of highly coarse-grained models that incorporate only two relevant interactions: connectivity along the chain and binary segmental interactions.

Lattice models of polymer solutions are a particularly simple and computationally efficient realization, and therefore have attracted abiding interest [12]. In simple lattice models, a small group of atomistic repeat units is represented by a site on a simple cubic lattice. Segments along a polymer occupy neighbouring lattice sites and multiple occupation of lattice sites is forbidden (excluded volume). The latter constraint corresponds to the repulsive binary interaction under good solvent conditions. Isolated chains on the lattice adopt configurations of self-avoiding walks. The polymer's end-to-end distance R scales with the chain length like $R \sim N^\nu$. The exponent $\nu = 0.588$ has been calculated using renormalization group techniques [9, 10], enumeration techniques for short chain lengths and Monte Carlo simulations [13].

The application of lattice models to study the behaviour of multi-chain systems (i.e. dilute and semi-dilute solutions, and dense melts) is straightforward in principle. The equilibration of dense multi-chain systems is, however, a challenging problem for computer simulations, and simple lattice models have been a testing bed for many algorithms. Some methods are tailored to isolated chains or very dilute systems (e.g., the pivot algorithm [13] or the construction of a chain via the pruned-enriched Rosenbluth method [14]); other methods provide an effective relaxation of the overall chain dimensions in dense systems (e.g., configurational bias Monte Carlo [15, 16] or the recoil growth algorithm [17]).

Though these simple lattice models reproduce the universal features of polymer solutions, it is difficult to incorporate details of the chain architecture. The simple lattice model allows only for two bond angles which makes the investigation of orientational effects prone to lattice artefacts. Moreover the particles in real fluids arrange to form neighbouring shells. This local packing structure of the fluid does not affect the universal scaling behaviour but it is pertinent to the relation between the coarse-grained effective interactions and the underlying microscopic potentials. Since the vacancies on the lattice and the polymer segments have the same size, packing effects in the density correlation function are largely absent. More sophisticated lattice models (e.g., the bond fluctuation model [18]), in which monomers are represented by extended objects (e.g., a whole unit cube) on the lattice, have been explored. These models exhibit packing effects and a large number of bond angles while still retaining the computational advantages of lattice models. They also allow for a diffusive dynamics of the polymers on the lattice which consists of random local displacements of the monomers. Moreover, the bond vectors can be chosen such that the excluded volume constraint prevents bonds from crossing through each other in the course of these local displacements. This non-crossability takes account of topological effects which are important for the dynamical properties of linear chains [19] and influence the conformational statistics of ring polymers [20, 21 and 22] (e.g., in order to avoid topological interactions rings collapse in a concentrated solution).

Off-lattice models enjoy a growing popularity. Again, a particle corresponds to a small number of atomistic repeat units

along the backbone of the polymer. Off-lattice models allow simulations at constant pressure or the calculation of the pressure via the virial expression. This yields direct access to the pVT behaviour. By modelling polymers as a sequence of tangent hard spheres in continuous space, computer simulators have investigated the equation of state in polymer solutions and the detailed packing structure of polymer solutions in contact with a hard wall. This class of model is particularly suited for comparing the results to analytical theories (e.g., Wertheim's theory [23] or density functional approaches [24, 25 and 26]) because of the existence of elaborated analytical descriptions for the corresponding hard-sphere monomer fluid.

Hard-sphere models lack a characteristic energy scale and, hence, only entropic packing effects can be investigated. A more realistic modelling has to take hard-core-like repulsion at small distances and an attractive interaction at intermediate distances into account. In non-polar liquids the attraction is of the van der Waals type and decays with the sixth power of the interparticle distance r . It can be modelled in the form of a Lennard-Jones potential $V_{LJ}(r)$ between segments

$$V_{\text{LJ}}(\mathbf{r}) = 4\epsilon \left\{ \left(\frac{\sigma}{r} \right)^{12} - \left(\frac{\sigma}{r} \right)^6 \right\} \quad (\text{B3.6.1})$$

where the exponent of the first, repulsive term is chosen for computational convenience. The Lennard-Jones radius σ sets the microscopic length scale and ϵ sets the energy scale. In many simulational applications the potential is truncated and shifted so as to yield a continuous, finite ranged potential. This does not alter the qualitative behaviour but shifts the temperature and density of the liquid–vapour critical point. The Lennard-Jones particles are tied together to form chain molecules. The constraint of fixed bond length or an harmonic bonding potential has been employed. Another popular choice is the FENE potential [27, 28]. It takes the form

$$V_{\text{FENE}}(r) = -\frac{k}{2} R_0^2 \ln \left(1 - \frac{r^2}{R_0^2} \right) \quad \text{with} \quad R_0 = 1.5\sigma. \quad (\text{B3.6.2})$$

The parameter k tunes the stiffness of the potential. It is chosen such that the repulsive part of the Lennard-Jones potential makes a crossing of bonds highly improbable (e.g., $k = 30$). This off-lattice model has a rather realistic equation of state and reproduces many experimental features of polymer solutions. Due to the attractive interactions the model exhibits a liquid–vapour coexistence, and an isolated chain undergoes a transition from a self-avoiding walk at high temperatures to a collapsed globule at low temperatures. Since all interactions are continuous, the model is tractable by Monte Carlo simulations as well as by molecular dynamics. Generalizations of the Lennard-Jones potential to anisotropic pair interactions are available: e.g., the Gay–Berne potential [29]. This latter potential has been employed to study non-spherical particles that possibly form liquid crystalline phases.

In the limit that the number of effective particles along the polymer diverges but the contour length and chain dimensions are held constant, one obtains the Edwards model of a polymer solution [9, 30]. Polymers are represented by random walks that interact via zero-ranged binary interactions of strength v . The partition function of an isolated chain is given by

-7-

$$\mathcal{Z} = \int \mathcal{D}[\mathbf{r}(t)] \exp \left(-\frac{3}{2b^2} \int_0^N dt \left(\frac{d\mathbf{r}}{dt} \right)^2 \right) \exp \left(- \int d\mathbf{r} d\mathbf{r}' \hat{\rho}(\mathbf{r}) v \delta(\mathbf{r} - \mathbf{r}') \hat{\rho}(\mathbf{r}') \right) \quad (\text{B3.6.3})$$

where the density field $\hat{\rho}$ is related to the configuration $\mathbf{r}(t)$ of the polymer via

$$\hat{\rho}(\mathbf{r}') = \int_0^N dt \delta(\mathbf{r}' - \mathbf{r}(t)). \quad (\text{B3.6.4})$$

The path integral \mathcal{D} sums over all polymer conformations $\mathbf{r}(t)$, where $0 \leq t \leq N$ denotes the contour parameter along the polymer. The second term represents the connectivity along the molecule and b denotes the persistence length (i.e. the ‘step length’ of the random walk). In the absence of the third term, the partition function describes a Gaussian chain with the end-to-end distance $\mathbf{R} = b\sqrt{N}$ (Gaussian chain model). This is the only length scale in the problem. Very much like in quantum mechanics, the path integral results in a diffusion equation (i.e. the polymer analogue of Schrödinger’s equation for the propagator) for the probability of finding a chain’s segment after t steps along the chain at position \mathbf{r} in space. The third term describes the interactions: if segments t and t' are located at the same position they interact with the strength v .

This model is very popular for analytical calculations and generalizations to multi-chain systems are straightforward. Properties of polymer solutions have been obtained via renormalization group techniques [8, 9 and 10]. Similar to the simple lattice model the Edwards model includes only the chain connectivity and binary segmental interactions: the detailed structure of the underlying fluid is omitted. For $\nu = 0$ the self-similar Gaussian statistics persist on all length scales and there is no rod-like behaviour on smaller scales. Generalizations of thread-like models to stiff polymers and orientational interactions, however have been explored. The most popular one is the wormlike chain model, in which the second term in the Edwards Hamiltonian (B3.6.3) is replaced by [31]

$$\exp\left(-\frac{\eta}{2}\int_0^N dt\left(\frac{du}{dt}\right)^2\right) \quad (\text{B3.6.5})$$

where $u(t) = dr/dt$ denotes the tangent vector along the path with unit norm. The parameter η controls the local stiffness of the path. On small distances along the chain the tangent vectors u are highly correlated and the stiffness parameter η controls the decay of orientational correlations along the chain's contour: $\langle u(t)u(t') \rangle = \exp(-|t-t'|/\eta)$. On large length scales, however, the Gaussian behaviour is recovered and the end-to-end distance is given by $R^2 = 2\eta N$.

B3.6.2.2 POLYMER BLENDS

The above models can be generalized to multicomponent systems by modifying the segmental interactions. Most applications deal with a binary blend in a common solvent. The excluded volume interaction between segments limits density fluctuations in a dense polymer liquid. Therefore many models of dense multicomponent systems neglect the finite compressibility and model the excluded volume interactions by enforcing a uniform segment density. In 1941, Flory [32] and Huggins [33] employed a simple lattice model to calculate the phase diagram for a dense binary polymer blend in mean field approximation. The two polymer species—denoted A and B—are modelled as walks on a lattice,

-8-

and the binary interactions of strengths ϵ_{AA} , ϵ_{AB} and ϵ_{BB} act between neighbours on the lattice. Since all lattice sites are occupied, only the difference of the segmental interactions (the Flory–Huggins parameter)

$$\chi_{FH} = \frac{z}{kT} \left(\epsilon_{AB} - \frac{\epsilon_{AA} + \epsilon_{BB}}{2} \right) \quad (\text{B3.6.6})$$

determines the phase diagram. Here, $z = 6$ denotes the coordination number of the simple cubic lattice. Typical experimental values of the Flory–Huggins parameter χ are in the range 10^{-2} – 10^{-5} for partially compatible blends while the individual interactions between the segments ϵ_{ij} ($i, j = A, B$) are of the order of $k_B T$. This illustrates that the phase behaviour is governed by a delicate cancellation of interactions. Starting from a model with atomistic details and performing an *ab initio* calculation of the packing structure and the effective segmental interactions in a binary blend would require extremely accurate interatomic potentials as input and a very high numerical quality of the calculation. Therefore, predicting the value of the Flory–Huggins parameter on an *ab initio* basis is virtually impossible. The concept of describing the effective incompatibility of two polymer species by a single mesoscopic parameter χ_{FH} has proven remarkably successful, however. When χ_{FH} is used as an adjustable parameter the mean field theory of Flory and Huggins is quite successful in describing many experimental observations. The values of the χ_{FH} parameter of various pairs of polymers have been extracted from a comparison between theory and experiment and are compiled in, for example, [34]. In the framework of the mean field theory, the excess free energy of mixing per segment

takes a particularly simple form:

$$\frac{\Delta F}{\rho V k T} = \frac{\phi_A}{N_A} \ln \phi_A + \frac{\phi_B}{N_B} \ln \phi_B + \chi_{FH} \phi_A \phi_B \quad (\text{B3.6.7})$$

where N_A and N_B denote the chain length of the two polymer species and ϕ_A and ϕ_B denote the relative amount of A or B segments, respectively. $\phi_A + \phi_B = 1$. The first term represents the translational entropy of mixing. Due to the connectivity of the segments it is reduced by a factor $1/N_A$ or $1/N_B$, respectively. The second term describes the repulsion between unlike segments. The chain conformations are assumed to be independent of the composition. Therefore the conformational entropy does not give any contribution to the free energy of mixing in the Flory–Huggins treatment. Most notably, the theory rationalizes the fact that long macromolecules tend to demix, because a small repulsion is sufficient to far outweigh the entropy of mixing, which is reduced by the factor $1/N$. This expression for the excess free energy of mixing also forms the basis for self-consistent field models of spatially inhomogeneous systems.

In order to gain qualitative insight into how to relate the Flory–Huggins parameter to the architectural properties of the components, mesoscopic models with various degrees of structural detail have been investigated. Complex lattice models allow monomeric units to occupy more than one lattice site. In the lattice cluster model of Freed and co-workers [35] the effect of explicit monomer structure has been explored. The partition function of the model is expressed in a systematic double expansion with respect to the inverse temperature and the inverse coordination number of the underlying lattice. To zero order the approach recovers the results of the original Flory–Huggins theory. Higher-order terms account for geometric packing on the monomer scale and non-random mixing effects. This approach has been successful in predicting various subtle influences of the monomer architecture, including the occurrence of entropic contributions to the Flory–Huggins parameter.

-9-

Similar questions can be addressed by the P-RISM (polymer reference interaction site model) theory of Curro and Schweizer [36]. This integral equation theory generalizes the Ornstein–Zernike equation to polymeric systems in order to account for the fluid-like packing structure. Details of the molecular architecture enter via the single-chain structure factor. The P-RISM approach yields a detailed description of the phase behaviour and the local structure and has been applied to models with various degrees of structural detail. In the limit that the chains are modelled as infinitely thin Gaussian paths the results are very similar to the Flory–Huggins theory. The theory has been applied to fairly realistic chain models taking the experimentally measured single-chain structure factors as input. More recently, this approach has been applied self-consistently to calculate the change of the molecular conformation upon blending.

The bond fluctuation model [37] and off-lattice [38, 39] models have been used to investigate the binary polymer blends within Monte Carlo simulations. Attention has focused on rather different topics: (i) Monte Carlo simulations appropriately account for the effect of composition fluctuations. They are important in the vicinity of the critical temperature of the unmixing transition. When the chain length is increased, this fluctuation-dominated region shrinks and one observes a crossover between the 3D Ising universality class and mean field critical behaviour [40]. (ii) The relation between the polymer architecture and the Flory–Huggins parameter has been explored in simulations. Disparities in the architecture on the scale of the coarse-grained monomers (e.g., different local stiffness of the chains or different monomer shapes) alter the packing structure and give rise to enthalpic and entropic contributions to the Flory–Huggins parameter [37, 39]. When comparing experimental data to the predictions of the mean field theory, deviations from the simple proportionality $\chi_{FH} \sim 1/T$ of the Flory–Huggins parameter are rather the rule than an exception. (iii) Monte Carlo simulations reveal that the chains in the minority phase shrink. By reducing their size, they increase the local density of their own monomers and reduce the number of unfavourable contacts with the opposite species. The latter effect is, however, not captured in simple mean field theories. (iv) Off-lattice models have

been employed to study binary blends at constant pressure and to explore the effect of compressibility on the miscibility behaviour [38, 39].

These coarse-grained approaches investigate the generic behaviour and the qualitative dependence on the chain architecture. Again it should be pointed out that these simulations and analytical methods cannot predict the absolute value of the Flory–Huggins parameter of a specific pair of polymers. However by a careful choice of the coarse-grained model, they help in identifying relevant parameters for the miscibility on a coarse-grained scale.

B3.6.2.3 SELF-CONSISTENT FIELD APPROACH AND GINZBURG–LANDAU MODELS

Long polymers tend to demix and the properties of the interfaces between the coexisting phases have attracted longstanding interest. Using the Gaussian chain model, Helfand and Tagami [41] investigated the interfacial properties in the self-consistent field theory. Within the mean field approximation the problem of interacting polymers is formulated in terms of a single-chain problem in an effective, external field. This effective, external field replaces the interactions with the surrounding polymers in the binary A/B blend. The effective field

$$w_A(\mathbf{r}) = \xi(\mathbf{r})\{\phi_A(\mathbf{r}) + \phi_B(\mathbf{r}) - 1\} + \chi\phi_B(\mathbf{r}) \quad (\text{B3.6.8})$$

acts on a monomer of species A at position \mathbf{r} with ϕ_A and ϕ_B denoting the local composition of the blend. A similar equation holds for w_B . The first term enforces the incompressibility; the factor ξ is adjusted to comply with the constraint $\phi_A(\mathbf{r}) + \phi_B(\mathbf{r}) = 1$ everywhere. The second term describes the repulsion between different species parameterized by χ . The local composition, in turn, depends on the fields and is obtained as the Boltzmann average of

-10-

isolated A and B chains in the fields w_A and w_B , respectively. For Gaussian chains, described by the first part of the Hamiltonian (B3.6.3), this leads to a diffusion equation in the external potential w_A and w_B . Since the fields depend on the local composition the equations have to be solved self-consistently.

Helfand and Tagami calculated the composition profiles across the interface and determined the interfacial tension. In general, the self-consistent field equations have to be solved numerically. Different schemes in real space [42], on lattices [43] and in Fourier representation [44] have been devised. There are, however, two interesting limits in which simple analytical expressions for the interfacial width and the interfacial tension can be obtained. The limit in which the width of the interface is much smaller than the extension of the polymer and yet larger than the persistence length b is called the strong segregation limit. It corresponds to the range $1 \gg \chi \gg 1/N$ of incompatibility. This strong segregation limit is only accessible for long chain lengths N and corresponds to truly polymeric behaviour. The interfacial width w and tension γ are described by the simple forms

$$w = b/\sqrt{6\chi} \quad \text{and} \quad \gamma = \rho b\sqrt{\chi/6} \quad (\text{B3.6.9})$$

where ρ denotes the monomer density. The leading corrections to the strong segregation behaviour are of the order $1/\chi N$ and have been the subject of much investigation [45, 46 and 47]. Of course, the Gaussian chain model cannot describe the structure on length scales smaller than or comparable to the persistence length b of the polymer. This restricts the application of this mesoscopic model to the range $\chi \ll 1$.

The binary polymer blend exhibits a second-order unmixing transition. Close to the critical temperature the

concentration of the two coexisting phases does not differ very much and the characteristic length scale of composition fluctuations ξ or the interfacial width w are large compared with the size R of the polymer coil. In this weak segregation limit polymer blends behave very similarly to mixtures of small molecules in the vicinity of the critical point. The difference between the composition of the coexisting phases and the composition of the mixture at the critical point defines the order parameter m of the unmixing transition (see the entry on phase transitions and critical phenomena; A2.5). It increases with a universal power law upon cooling the system below the critical temperature T_c :

$$m \sim t^\beta \quad \text{with} \quad t = \frac{T_c - T}{T_c} > 0. \quad (\text{B3.6.10})$$

β is the critical exponent and t denotes the reduced distance from the critical temperature. In the vicinity of the critical point, the free energy can be expanded in terms of powers and gradients of the local order parameter $m(\mathbf{r}) = \phi_A(\mathbf{r}) - \phi_B(\mathbf{r})$:

$$\frac{F[m(\mathbf{r})]}{\rho k T} \sim \int d^3 \mathbf{r} \left\{ f(m) + \frac{l^2}{2} (\nabla m)^2 \right\} \quad \text{with} \quad f(m) = -\frac{t}{2} m^2 + \frac{1}{12} m^4. \quad (\text{B3.6.11})$$

This form is called a Ginzburg–Landau expansion. The first term $f(m)$ corresponds to the free energy of a homogeneous (bulk-like) system and determines the phase behaviour. For $t > 0$ the function f exhibits two minima at $m = \pm\sqrt{3t}$. This value corresponds to the composition difference of the two coexisting phases. The second contribution specifies the cost of an inhomogeneous order parameter profile. l sets the typical length scale.

-11-

The general form of the expansion is dictated by very general symmetry considerations; the specific coefficients for the example of a polymer blend can be derived from the self-consistent field theory. For a binary blend this yields $l^2 = b^2 N / 18$. In mixtures of small molecules the coefficient is determined by the range of the interactions; in polymeric systems the coefficient is associated with the conformational entropy. It is the shape of the extended molecule and its deformation at a spatial inhomogeneity that gives rise to the free energy cost.

Ginzburg–Landau models constitute a widely used example of continuum models. This class of continuum models describes the generic behaviour of all binary mixtures close to the unmixing transition. The properties of the specific model enter only via the coefficients of the expansion which set the energy scale and length scale. Extensions to different transitions (e.g., first-order transitions or microemulsion) are available (see also [section B3.6.3](#)). This approach, however, does not incorporate any structural detail of the underlying systems and hence becomes quantitatively inaccurate at lower temperatures, where the coexisting phases differ more strongly in their composition or the characteristic length scale (i.e. the correlation length ξ) becomes comparable to the size of the molecules.

Within this continuum approach Cahn and Hilliard [48] have studied the universal properties of interfaces. While their elegant scheme is applicable to arbitrary free-energy functionals with a square gradient form we illustrate it here for the important special case of the Ginzburg–Landau form. For an ideally planar interface the profile depends only on the distance z from the interfacial plane. In mean field approximation, the profile $m(z)$ minimizes the free-energy functional (B3.6.11). This yields the Euler–Lagrange equation

$$\frac{\delta \mathcal{F}}{\delta m} = 0 \quad \Rightarrow \quad -tm + \frac{1}{3} m^3 - l^2 \frac{d^2 m}{dz^2} = 0 \quad (\text{B3.6.12})$$

which, in turn, is solved by a simple function

$$m = \pm\sqrt{3}l^{1/2} \tanh\left(\frac{z}{w}\right) \quad \text{with} \quad w = \frac{\sqrt{2}l}{l^{1/2}}. \quad (\text{B3.6.13})$$

In the vicinity of the critical point (i.e. $|t| \ll 1$) the interfacial width w is much larger than the microscopic length scale l and the Landau–Ginzburg expansion is applicable.

Both Monte Carlo simulations of lattice models [49, 50] and spring–bead models [51] have been employed to study interfaces in polymeric systems. The simulations yield insight into the local properties of the polymeric fluid. Unlike in the Landau–Ginzburg expansion, the notion of polymers is retained and the orientation of the extended molecules at the interface or the enrichment of end segments have been studied. Moreover, the simulations incorporate fluctuations, which are ignored in the mean field approximation. In the vicinity of the critical temperature composition fluctuations are important. The mean field treatment overestimates the critical point and the binodals are flatter in the simulations which exhibit 3D Ising critical behaviour ($\beta = 0.324$) than in the mean field case ($\beta = 1/2$). The importance of composition fluctuations can be gauged by the Ginzburg criterion [52]: The neglect of fluctuations is justified when the order parameter fluctuations in one ‘correlation volume’ of size ξ^3 are small compared with the order parameter itself. In the case of a symmetric binary polymer blend this condition yields

-12-

$$\frac{\chi - \chi_c}{\chi_c} \gg \frac{N^2}{\rho^2 R^6} \sim \frac{1}{N}. \quad (\text{B3.6.14})$$

Ultimately, in the vicinity of the critical point, composition fluctuations are important, but the region in which these fluctuations dominate the behaviour decreases with the chain length N . Qualitatively, the behaviour can be understood as follows: long-chain molecules do not fill space and strongly interdigitate; the number of other chains in the volume of a reference chain increases like \sqrt{N} with chain length. This large number of interaction partners results in a strong suppression of fluctuations in the interactions on the level of a whole molecule and, hence, replacing the interactions by a non-fluctuating mean field is a good approximation.

Another important difference between the mean field treatment and the simulations or experiments are fluctuations of the local interfacial position. While the mean field treatment assumes a perfectly flat, planar interface right from the outset, the local interfacial position fluctuates in experiments and simulations. A typical snapshot of the local interface position, as obtained from a Monte Carlo simulation of a binary polymer blend is depicted in [figure B3.6.2](#). On not too small length scales the local position of the interface is smooth and without bubbles or overhangs. The system configuration can be described by two ingredients: the position $u(\mathbf{r}_{\parallel})$ of the centre of the interface as a function of the lateral coordinates \mathbf{r}_{\parallel} and the local structure described by profiles across the interface. The latter quantities depend only on the coordinate normal to the interface. In many applications the coupling between the long-wavelength fluctuations of the local interfacial position u and the intrinsic profile is neglected. In this case the intrinsic profiles describe the variation of quantities across an ideally planar interface. The apparent interfacial profile $p_{\text{app}}(z)$, which is averaged over fluctuations of the local interfacial position in experiments or simulations, can be approximated by a convolution of the intrinsic profile $p_{\text{int}}(z)$ and the distribution $P(u)$ of the local interface position [53]

$$p_{\text{app}}(z) = \int du P(u) p_{\text{int}}(z - u) \quad (\text{B3.6.15})$$

If one is only interested in the properties of the interface on scales much larger than the width of the intrinsic profiles, the interface can be approximated by an infinitely thin sheet and the properties of the intrinsic profiles can be cast into a few effective parameters. Using only the local position of the interface, effective interface Hamiltonians describe the statistical mechanics of fluctuating interfaces and membranes.

-13-

Figure B3.6.2. Local interface position in a binary polymer blend. After averaging the interfacial profile over small lateral patches, the interface can be described by a single-valued function $u(\mathbf{r}_{\parallel})$. (Monge representation). Thermal fluctuations of the local interface position are clearly visible. From Werner et al [49].

B3.6.2.4 EFFECTIVE INTERFACE HAMILTONIANS

The fluctuations of the local interfacial position increase the effective area. This increase in area is associated with an increase of free energy \mathcal{H} which is proportional to the interfacial tension γ . The free energy of a specific interface configuration $u(\mathbf{r}_{\parallel})$ can be described by the capillary wave Hamiltonian:

$$\mathcal{H}[u(\mathbf{r}_{\parallel})] = \gamma \int dx dy \left\{ \sqrt{1 + \left(\frac{du}{dx}\right)^2} \sqrt{1 + \left(\frac{du}{dy}\right)^2} - 1 \right\} \approx \frac{\gamma}{2} \int d^2 \mathbf{r}_{\parallel} (\nabla u)^2. \quad (\text{B3.6.16})$$

The functional $\mathcal{H}[u]$ can be diagonalized via a Fourier transformation with respect to the lateral coordinates \mathbf{r}_{\parallel} . This results in

$$\mathcal{H}[u_q] = \frac{\gamma}{2} \sum_q q^2 |u_q|^2. \quad (\text{B3.6.17})$$

In this Fourier representation the Hamiltonian is quadratic and the equipartition theorem yields for the thermal

fluctuations: $\langle u^2(\mathbf{q}) \rangle = k_B T / \gamma q^2$. This spectrum corresponds to a Gaussian distribution of the local interface position:

$$P(u) = \frac{1}{\sqrt{2\pi s^2}} \exp\left(-\frac{u^2}{2s^2}\right) \quad \text{with} \quad (B3.6.18)$$

$$s^2 = \frac{1}{4\pi^2} \int d^2 q_{\parallel} \langle u^2(q_{\parallel}) \rangle = \frac{kT}{2\pi\gamma} \ln\left(\frac{q_{\max}}{q_{\min}}\right)$$

where a short and long wave length scale cut-off q_{\max} and q_{\min} have to be introduced to avoid the divergence at $q \rightarrow \infty$ and $q \rightarrow 0$.

The interfacial fluctuations broaden laterally averaged profiles. Within the convolution approximation (B3.6.15) one obtains a profile with the shape of the erfc function [49]:

$$w_{\text{app}}^2 = w_{\text{int}}^2 + \frac{kT}{4\gamma} \ln\left(\frac{q_{\max}}{q_{\min}}\right). \quad (B3.6.19)$$

Thus, the apparent interfacial width w_{app} , which is measured in simulations or experiments, is larger than the intrinsic width w_{int} and depends via the wavevector cut-offs on the geometry considered. This can actually be used to measure the interfacial tension in computer simulations.

For a free interface the cut-off at large length scales is determined by the lateral patch size on which the interface is observed. In simulations this is set by the size of the simulation cell. In scattering experiments (e.g., neutron reflectivity) it is associated with the lateral coherence length of the beam. If the coexisting phases differ in density, gravitation will give rise to a large-scale cut-off for capillary waves [54]

$$q_{\max} = \sqrt{\frac{g\Delta\rho}{\gamma}} \quad (B3.6.20)$$

where $\Delta\rho$ is the density difference and g the gravitational constant. Similarly, interactions with boundaries (e.g. van der Waals forces) limit fluctuations and give rise to a large length scale cut-off. In this case the cut-off depends on the distance between the interface and the wall and the cut-off imparts a dependence of the apparent interfacial width on the distance between the wall and the interface.

On short length scales the coarse-grained description breaks down, because the fluctuations which build up the (smooth) intrinsic profile and the fluctuations of the local interface position are strongly coupled and cannot be distinguished. The effective interface Hamiltonian can describe the properties only on length scales large compared with the width $1/q_{\max} \sim w$ of the intrinsic profile. The absolute value of the cut-off is difficult to determine: the apparent profiles are experimentally accessible, but in order to use equation (B3.6.19) the width of an hypothetically flat interface without fluctuations has to be known. Polymer blends are suitable candidates for investigating this problem. Since the self-consistent field theory gives an accurate description of the interface profile except for

fluctuations, it yields a quantitative description of the intrinsic, ideally flat, profile. The comparison with

Monte Carlo simulations, which include fluctuations, then yields q_{max} . Simulations of a coarse-grained polymer blend by Werner *et al* find $q_{max} = 1.65/w_{int}$ [49] in the strong segregation limit, in rather good agreement with the value $q_{max} = 2/w_{int}$ suggested by analytical theory [55].

An important application of effective interface Hamiltonians are wetting phenomena. If a binary mixture is confined, the wall of the container will favour one component of the mixture, say A. This component forms an enrichment layer at the wall, while the B component is expelled from the wall region. Rather than describing the detailed composition profile at the wall, the effective interface Hamiltonian specifies the system configuration solely by the distance between the A-rich enrichment layer at the wall and the B component further away. This coarse graining concept is sketched in [figure B3.6.3](#). The profile is distorted in the vicinity of the wall and this gives rise to a short-range effective interaction between the wall and the interface. The length scale of the interaction is set by the characteristic length scale of the (free) interface profile. Dispersion forces give rise to an additional long-ranged effective interaction, which decays like a power-law with the distance l . The effective interfacial Hamiltonian takes the form:

$$\mathcal{H}[l(\mathbf{r}_1)] = \int d^2\mathbf{r}_1 \left\{ \frac{\gamma(l)}{2} (\nabla l)^2 + g(l) \right\} \quad (\text{B3.6.21})$$

where $g(l)$ denotes the effective interaction between the wall and a portion of the interface at a distance l . The first term corresponds to the capillary wave Hamiltonian. In general, the coefficient $\gamma(l)$ in front of the square gradient depends on the distance between the wall and the interface [56], because the intrinsic profile is distorted in the presence of the wall. Only for large distances $l \rightarrow \infty$ does the effective interfacial tension $\gamma(l)$ tend to its macroscopic value. The second term describes the effective interface potential between the wall and the interface. Depending on the shape of the interface potential $g(l)$ different situations are encountered [57]: if the effective potential exhibits a minimum in the vicinity of the wall, the interface is bound to the wall. This corresponds to a microscopically thin layer of the preferred component A at the wall. One says: A does not wet the wall. If $g(l)$ has a minimum at infinite distance $l \rightarrow \infty$ there is a macroscopically thick layer of A at the wall: component A wets the wall. The transition between both states is the wetting transition, which can be continuous (i.e. the thickness of the enrichment layer diverges upon approaching the transition temperature) or (most often) discontinuous (i.e. the thickness of the layer jumps from a microscopic value to a macroscopic one).

Figure B3.6.3. Sketch of the coarse-grained description of a binary blend in contact with a wall. (a) Composition profile at the wall. (b) Effective interaction $g(l)$ between the interface and the wall. The different potentials correspond to complete wetting, a first-order wetting transition and the non-wet state (from above to below). In case of a second-order transition there is no double-well structure close to the transition, but $g(l)$ exhibits a single minimum which moves to larger distances as the wetting transition temperature is approached from below. (c) Temperature dependence of the thickness l of the enrichment layer at the wall. The jump of the layer thickness indicates a first-order wetting transition. In the case of a continuous transition the layer thickness would diverge continuously upon approaching T_{wet} from below.

In the mean field considerations above, we have assumed a perfectly flat interface such that the first term in the Hamiltonian (B3.6.21) is ineffective. In fact, however, fluctuations of the local interface position are important, and its consequences have been studied extensively [57, 58].

B3.6.3 AMPHIPHILIC MODELS

Another important class of materials which can be successfully described by mesoscopic and continuum models are amphiphilic systems. Amphiphilic molecules consist of two distinct entities that like different environments. Lipid molecules, for instance, comprise a polar head that likes an aqueous environment and one or two hydrocarbon tails that are strongly hydrophobic. Since the two entities are chemically joined together they cannot separate into macroscopically large phases. If these amphiphiles are added to a binary mixture (say, water and oil) they greatly promote the dispersion of one component into the other. At low amphiphile

concentrations the molecules enrich at the interface so as to place their different ends into the corresponding phases. This displaces the water and the oil from the oil/water interface and greatly reduces the interfacial tension. At larger concentration of amphiphiles the molecules self-assemble into complex morphologies. These might either be isotropic (i.e. a microemulsion) or possess liquid crystalline order. The spatial structure is selected by a balance to minimize the contacts between the different entities and to fill space. Some of the possible morphologies are displayed in figure B3.6.4. Analogous morphologies are encountered in polymeric systems involving block copolymers.

Figure B3.6.4. Illustration of three structured phases in a mixture of amphiphile and water. (a) Lamellar phase: the hydrophilic heads shield the hydrophobic tails from the water by forming a bilayer. The amphiphilic heads of different bilayers face each other and are separated by a thin water layer. (b) Hexagonal phase: the amphiphiles assemble into a rod-like structure where the tails are shielded in the interior from the water and the heads are on the outside. The rods arrange on a hexagonal lattice. (c) Cubic phase: amphiphilic micelles with a hydrophobic centre order on a BCC lattice.

The relation between the architecture of the molecules and the spatial morphology into which they assemble has attracted longstanding interest because of their importance in daily life. Lipid molecules are important constituents of the cell membrane. Amphiphilic molecules are of major importance for technological applications (e.g., in detergents and the food industry).

The large length scale on which the self-assembly occurs and the universality of the morphologies borne out in experiments on a large variety of different systems make mesoscopic and continuum models suitable tools for investigating the underlying universal mechanism. Experiments suggest that many of the generic features can be captured by the amphiphilicity of the molecules. The models that have been employed can be broadly divided into models that aim at correlating the molecular architecture with the morphology and those models which investigate the generic phase behaviour and the influence of fluctuations.

B3.6.3.1 CHAIN MODELS

The architecture of the lipid molecules or the diblock copolymers results in the typical amphiphilic properties, like surface activity and self-assembly. On the most qualitative level, understanding of the self-assembly in lipid systems [3] is provided by a characterization of the molecules as a simple geometrical object (‘wedge’) parameterized by its volume, the maximum chain length and the area per head group. The different phases result from simple geometric packing considerations. Similar arguments on the balance between chain stretching and interfacial tension yield the qualitative features of the phase diagrams in systems containing diblock copolymers [59].

Chain models capture the basic elements of the amphiphilic behaviour by retaining details of the molecular architecture. Ben-Shaul *et al* [60] and others [61] explored the organization of the hydrophobic portion in lipid micelles and bilayers by retaining the conformational statistics of the hydrocarbon tail within the RIS (rotational isomeric state) model [4, 5] while representing the hydrophilic/hydrophobic interface merely by an

effective tension. By invoking a mean field approximation and calculating the properties of the tails by an enumeration of a large sample of conformations, they investigated the packing effects inside the hydrocarbon core for various detailed chain architectures. This mean field technique has been extended, for example, to include a modelling of the hydrophilic head and to study the self-assembly of lipids in aqueous solutions [62] or to investigate the absorption of proteins at surfaces covered with a polymer brush [63].

Many simulation approaches use a coarse-grained description of the amphiphiles by representing them via short-chain molecules on a lattice. The lattice is there only for computational convenience but is assumed to play no role otherwise. Typically, the number of lattice sites to model the amphiphiles is small and does not exceed 32. Each site is conceived as a small number of atomistic units along the amphiphilic molecule. A particularly popular model has been suggested by Larson [64]. There are two types of sites: hydrophilic and hydrophobic. Hydrophobic sites correspond to the oil or the hydrocarbon tail of the amphiphiles; hydrophilic sites represent the polar head of the amphiphiles or water. Oil and water are modelled as single-site entities. There is a short-range repulsion between unlike segments. The phase diagram of ternary oil/amphiphiles/water and binary amphiphile/water mixtures has been investigated by Monte Carlo simulations. Many phases observed in experiments (disordered, lamellar, hexagonal and even the gyroid phase) can be obtained as a function of temperature, composition and architecture of the amphiphile. Of course, special care has to be devoted to the study of finite-size effects. Typically, only a small number of unit cells of the spatially periodic structure fit into a simulation cell. If the size of the simulation box is close to a multiple of the unit cell size the stability of the phase might be greatly enhanced; if the size of the simulation box is incompatible with the spatially periodic structure the morphology is strongly distorted and its stability reduced. Very similar effects occur in nature if a spatially periodic structure is confined into a thin film.

A multitude of different variants of this model has been investigated using Monte Carlo simulations (see, for example [65]). The studies aim at correlating the phase behaviour with the molecular architecture and revealing the local structure of the aggregates. This type of model has also proven useful for studying rather complex structures (e.g., vesicles or pores in bilayers).

For structures with a high curvature (e.g., small micelles) or situations where orientational interactions become important (e.g., the gel phase of a membrane) lattice-based models might be inappropriate. Off-lattice models for amphiphiles, which are quite similar to their counterparts in polymeric systems, have been used to study the self-assembly into micelles [66], or to explore the phase behaviour of Langmuir monolayers [67] and bilayers. In those systems, various phases with a nematic ordering of the hydrophobic tails occur.

Since the amphiphilic nature is essential for the phase behaviour, systems of small molecules (e.g., lipid water mixtures) and polymeric systems (e.g., homopolymer copolymer blends) share many common features. Within the mean field approximation, the phase behaviour of block-copolymer models can conveniently be explored in the framework of the Gaussian chain model. The investigation of the self-assembly into various complex phases takes advantage of a Fourier decomposition of the spatially varying densities. The phase diagrams for pure diblock copolymers, binary blends of diblock copolymers and binary and ternary solutions have been investigated [44, 48]. These calculations reveal a rich variety of different morphologies as a function of the incompatibility, architecture and amount of homopolymer 'solvent'. In binary and ternary solutions, highly swollen phases are found in which the periodicity of the structure far exceeds the radius of gyration. An example of the possible phases in a ternary blend of two homopolymers and a symmetric diblock copolymer is presented in figure B3.6.5. At a fixed incompatibility one finds a complex phase diagram, including disordered homopolymer-rich phases, a symmetric lamellar phase L and asymmetric swollen lamellar phases L_A and L_B , which accommodate different amounts of the homopolymer components. Note that very similar phase diagrams are found in ternary oil water amphiphile mixtures. In the self-consistent field calculations not only the phase behaviour but also effective properties of the internal interfaces (e.g., the interfacial tension of bending moduli) are accessible [69]. The latter information might serve as input to

effective interface Hamiltonians.

Figure B3.6.5. Phase diagram of a ternary polymer blend consisting of two homopolymers, A and B, and a symmetric AB diblock copolymer as calculated by self-consistent field theory. All species have the same chain length N and the figure displays a cut through the phase prism at $\chi N = 11$ (which corresponds to weak segregation). The phase diagram contains two homopolymer-rich phases A and B, a symmetric lamellar phase L and asymmetric lamellar phases, which are rich in the A component L_A or rich in the B component L_B , respectively. From Janert and Schick [68].

Figure B3.6.6. Illustration of the two principal radii of curvature for a membrane.

In general, the self-consistent field calculations are accurate for long polymers; for short chains however, fluctuations become important. Self-consistent field calculations and simulations of polymeric models show for example, that the bending rigidity of copolymer-laden interfaces might be quite small for short chain lengths. In a region where the self-consistent field theory predicts a highly swollen lamellar phase, the lamellar order is unstable with respect to interfacial fluctuations and a microemulsion forms [70]. Polymeric microemulsions have been observed in simulations [71] and experiments [72], but they are much more common in small molecular amphiphilic systems. Similarly, fluctuations easily destroy the body-centred cubic arrangement of micelles found in the self-consistent field theory and lead to formation of a micellar solution.

These chain models are well suited to investigate the dependence of the phase behaviour on the molecular architecture and to explore the local properties (e.g., enrichment of amphiphiles at interfaces, molecular conformations at interfaces). In order to investigate the effect of fluctuations on large length scales or the shapes of vesicles, more coarse-grained descriptions have to be explored.

B3.6.3.2 LATTICE MODELS

A further step in coarse graining is accomplished by representing the amphiphiles not as chain molecules but as single site/bond entities on a lattice. The characteristic architecture of the amphiphile—the hydrophilic head and hydrophobic tail—is lost in this representation. Instead, the interaction between the different lattice sites, which represent the oil, the water and the amphiphile, have to be carefully constructed in order to bring about the amphiphilic behaviour.

As early as 1969, Wheeler and Widom [73] formulated a simple lattice model to describe ternary mixtures. The bonds between lattice sites are conceived as particles. A bond between two positive spins corresponds to water, a bond between two negative spins corresponds to oil and a bond connecting opposite spins is identified with an amphiphile. The contact between hydrophilic and hydrophobic units is made infinitely repulsive; hence each lattice site is occupied by either hydrophilic or hydrophobic units. These two states of a site are described by a spin variable s_i , which can take the values +1 and -1. Obviously, oil/water interfaces are always completely covered by amphiphilic molecules. The Hamiltonian of this Widom model takes the form

$$\mathcal{H} = -h \sum_i s_i - J \sum_{\langle ij \rangle} s_i s_j - 2M \sum_{\langle\langle ij \rangle\rangle} s_i s_j - M \sum_{\langle\langle\langle ij \rangle\rangle\rangle} s_i s_j \quad (\text{B3.6.22})$$

where $\langle ij \rangle$, $\langle\langle ij \rangle\rangle$, and $\langle\langle\langle ij \rangle\rangle\rangle$ denote nearest, next-nearest and fourth-nearest neighbours on the lattice, respectively. The first two terms correspond to the Ising Hamiltonian. h acts as a chemical potential which favours positive spins, while J controls the incompatibility between water and oil. If only these two terms were present the model would describe a simple binary mixture. The additional terms have to be incorporated to bring about the amphiphilic properties. The case of negative M has been much investigated. In this case, the third term imparts some kind of bending rigidity to the oil/water interface, while the fourth term favours sequences of the form $(\dots + + - - + + - - \dots)$. This leads to the formation of lamellar phases which are not directly tied to the lattice spacing.

Slightly more complex models treat the water, the amphiphile and the oil as three distinct variables corresponding to the spin variables $S = +1, 0$, and -1 . The most general Hamiltonian with nearest-neighbour interactions has the form

$$\mathcal{H} = - \sum_{\langle ij \rangle} \{J S_i S_j + K S_i^2 S_j^2 + C(S_i^2 S_j + S_j^2 S_i)\} - \sum_i \{H S_i - \Delta S_i^2\}. \quad (\text{B3.6.23})$$

This Blume–Emery–Griffiths (BEG) model [74] has been studied both by mean field calculations as well as by simulations. There is no pronounced difference between the amphiphile molecules $S = 0$, the oil or the water. Indeed, the model was first suggested in a quite different context. An extension of the model by Schick and Shih [75] includes an additional interaction of the form

$$(\text{B3.6.24})$$

$$\Delta\mathcal{H} = -L \sum_{(ijk)} S_i(1 - S_j^2)S_k$$

where $(i j k)$ denotes three sites in a line. For negative values of L the term favours local conformations in which the amphiphile sits between the water and the oil. The model exhibits an oil-rich phase, a water-rich phase, a lamellar phase and a disordered phase, which exists between the lamellar phase and the oil–water coexistence. The disordered phase consists of water and oil domains separated by amphiphile sheets. It is homogeneous on large length scales, but shows—for certain parameter regions—oscillating structure on smaller length scales. These two length scales are associated with the structure of a microemulsion. The period of the oscillations characterize the local domain size in the microemulsion, while this nearly liquid-crystalline order ‘dephases’ on larger length scales. This defines the persistence length ξ . The latter length scale is mesoscopic (i.e. of the order of 100 Å), while the former is roughly the size of the molecules.

Lattice models have been studied in mean field approximation, by transfer matrix methods and Monte Carlo simulations. Much interest has focused on the occurrence of a microemulsion. Its location in the phase diagram between the oil-rich and the water-rich phases, its structure and its wetting properties have been explored [76]. Lattice models reproduce the reduction of the surface tension upon adsorption of the amphiphiles and the progression of phase equilibria upon increasing the amphiphile concentration. Spatially periodic (lamellar) phases are also describable by lattice models. However, the structure of the lattice can interfere with the properties of the periodic structures.

-22-

B3.6.3.3 CONTINUUM MODELS

An even coarser description is attempted in Ginzburg–Landau-type models. These continuum models describe the system configuration in terms of one or several, continuous order parameter fields. These fields are thought to describe the spatial variation of the composition. Similar to spin models, the amphiphilic properties are incorporated into the Hamiltonian by construction. The Hamiltonians are motivated by fundamental symmetry and stability criteria and offer a unified view on the general features of self-assembly. The universal, generic behaviour—the possible morphologies and effects of fluctuations, for instance—rather than the description of a specific material is the subject of these models.

An important example is the one-order-parameter model invented by Gompper and Schick [77], which describes a ternary mixture in terms of the density difference ϕ between water and oil:

$$\mathcal{F}[\phi(\mathbf{r})] = \int d\mathbf{r} \{ f(\phi) + g(\phi)|\nabla\phi|^2 + c|\Delta\phi|^2 \}. \quad (\text{B3.6.25})$$

The first two terms resemble the Ginzburg–Landau Hamiltonian for the polymeric systems. $f(\phi)$ describes the bulk free energy and there is a gradient square term to account for the free-energy costs of a spatially varying order parameter profile. In principle, the functions f , g and c of this Ginzburg–Landau expansion can be derived from a more microscopic model (e.g., the lattice models of the previous section). Such a derivation serves to relate the input parameters of the Ginzburg–Landau theories to microscopic parameters (e.g., length of the amphiphile) of the underlying model. The coefficients f , g and c are also related to the scattering intensity and, hence, some guidance from the experiment is available on how to choose them. Though the amphiphiles do not occur explicitly in the description, they determine the density dependence of the functions f and g . In order to model three-phase coexistence between an oil-rich phase, a water-rich phase and a microemulsion with roughly equal amounts of oil and water, the function f has to exhibit three minima. The amphiphiles decrease the free-energy cost of interfaces. This is modelled by a negative value of g in some

intermediate composition range. This favours the formation of interfaces and, therefore, the third term (with $c > 0$) is required to ensure thermodynamic stability.

By virtue of their simple structure, some properties of continuum models can be solved analytically in a mean field approximation. The phase behaviour interfacial properties and the wetting properties have been explored. The effect of fluctuations is investigated in Monte Carlo simulations as well as non-equilibrium phenomena (e.g., phase separation kinetics). Extensions of this one-order-parameter model are described in the review by Gompper and Schick [76]. A very interesting feature of these models is that effective quantities of the interface—like the interfacial tension and the bending moduli—can be expressed as a functional of the order parameter profiles across an interface [78]. These quantities can then be used as input for an even more coarse-grained description.

B3.6.3.4 RANDOM INTERFACE MODELS

Most characteristics of amphiphilic systems are associated with the alteration of the interfacial structure by the amphiphile. Addition of amphiphiles might reduce the free-energy costs by a dramatic factor (up to 10^{-2} dyn cm^{-1} in the oil/water/amphiphile mixture). Adding amphiphiles to a solution or a mixture often leads to the formation of a microemulsion or spatially ordered phases. In many aspects these systems can be conceived as an assembly of internal interfaces. The interfaces might separate oil and water in a ternary mixture or they might be amphiphilic bilayers in

-23-

binary solutions. Random interface models study the large-scale structure of amphiphilic systems by describing the configuration of the local, instantaneous interfacial position.

The effective free energy of the system of interfaces takes the general form [79, 80 and 81]

$$\mathcal{H} = \int dS \{ \gamma + \lambda_s H + 2\kappa H^2 + \bar{\kappa} K \} \quad (\text{B3.6.26})$$

where dS denotes the surface element, H the local mean curvature and K the local Gaussian curvature of the interface. The latter two quantities are related to the two principal radii of curvature via $2H = 1/R_1 + 1/R_2$ and $K = 1/R_1 R_2$. The interfacial tension γ controls the area of the interface. λ_s describes a spontaneous curvature of the interface, which is related to an asymmetry of the interface. This might occur even in a bilayer, when it is composed of an amphiphilic mixture and the two sheets have different compositions. The coefficients κ and $\bar{\kappa}$ characterize the bending rigidity and the saddle-splay modulus respectively. If the interface is closed, the Gauss–Bonnet theorem relates $\int dS K = 2\pi \chi_E$ to the Euler characteristic χ_E . Since this quantity is a topological invariant, the last term in the Hamiltonian can be omitted if the topology of the interface does not change (e.g., in the case of a vesicle).

One can regard the Hamiltonian (B3.6.26) above as a phenomenological expansion in terms of the two invariants K and H of the surface. To establish the connection to the effective interface Hamiltonian (b3.6.16) it is instructive to consider the limit of an almost flat interface. Then, the local interface position u can be expressed as a single-valued function of the two lateral parameters $u(\mathbf{r}_{\parallel})$. In this Monge representation the interface Hamiltonian can be written as

(B3.6.27)

$$\mathcal{H} = \int d^2r_{\parallel} \left\{ \frac{\gamma}{2} |\nabla u|^2 + \frac{\kappa}{2} |\Delta u|^2 \right\}.$$

Among the different problems which have been tackled with random interface Hamiltonians are the following. (i) The phase diagram of the random interface Hamiltonian has been explored by Huse and Leibler [82]. The phase diagram comprises a droplet phase, in which the minority component is dissolved into the matrix of the majority component, disordered phases and lamellar phases. (ii) Much interest has focused on the role of fluctuations. In the presence of a wall or another interface, the fluctuations of the local interface position are restricted. This gives rise to an entropic repulsion between the fluctuating interface and confining boundaries (Helfrich interaction [83]). (iii) In order to avoid the free-energy cost of a rim, membranes close up to form vesicles. The shapes of vesicles as a function of the bending rigidity and the pressure difference between the vesicle's interior and the outside have been mapped out [84].

B3.6.4 APPLICATIONS TO DYNAMIC PHENOMENA

Though this entry has focused on equilibrium properties, mesoscopic and continuum models in chemical physics can also describe non-equilibrium phenomena, and we shall mention some techniques briefly.

Mesoscopic models can often be treated by molecular dynamics simulations. This method generates a realistic

-24-

(Hamiltonian) trajectory in the phase space of the model from which information about the equilibrium dynamics can readily be extracted. The application to non-equilibrium phenomena (e.g., the kinetics of phase separation) is, in principle, straightforward.

Exploring the hydrodynamic behaviour of complex fluids with conventional molecular dynamics models poses a challenge to computational resources, because the hydrodynamic behaviour appears only on large time and length scales. Coarse-grained models [85, 86 and 87] have been explored in which a particle does not correspond to a molecule or a small number of atoms but rather to a fluid element. These 'fluid particles' [86] interact with an extremely soft potential, which does not diverge as two effective particles approach each other (see the Lennard-Jones potential (B3.6.1)) but increases only linearly with the interparticle distance. This very soft repulsive potential allows for very large time steps in a molecular dynamics simulation. As the particles correspond to coarse-grained fluid elements they do not conserve energy when they collide. This provides a motivation for a dissipative friction force and a random force. The strength of the friction and the noise are related by a fluctuation-dissipation theorem, which ensures that the equilibrium distribution corresponds to the canonical ensemble. Unlike the standard implementation of noise and friction forces in molecular dynamics schemes, noise and friction in the dissipative particle dynamics do not act on the velocity of a single particle but on pairs of particles. In this way momentum is conserved. The macroscopic behaviour is not diffusive but hydrodynamic (note, however, that the energy is not conserved and there is no transport equation of the energy). This method promises to be an efficient way to study dynamic effects on the mesoscopic scale of complex fluids. An application of dissipative particle dynamics to a binary homopolymer blend is described in [87].

Monte Carlo schemes generate a stochastic trajectory through phase space (see the entry about statistical mechanical simulations; B3.3). If the Monte Carlo moves resemble the configurational changes in a realistic dynamics (e.g., the conformations evolve via small displacements of particles) some dynamical information can be gained. Since there is no momentum in Monte Carlo simulations the dynamics is diffusive. However, many Monte Carlo algorithms employ moves that involve rather large changes in the system conformation (e.g., deletion of a molecule and subsequent insertion at a random position). These 'unphysical' moves are

extremely efficient in propagating the system through configuration space, but they do not allow for a dynamic interpretation of the trajectory.

A lattice scheme which does capture hydrodynamic behaviour is the lattice Boltzmann method [88, 89, 90 and 91]. This method has been devised as an effective numerical technique of computational fluid dynamics. The basic variables are the time-dependent probability distributions $f_\alpha(\mathbf{x}, t)$ of a velocity class α on a lattice site \mathbf{x} . This probability distribution is then updated in discrete time steps using a deterministic local rule. A careful choice of the lattice and the set of velocity vectors minimizes the effects of lattice anisotropy. This scheme has recently been applied to study the formation of lamellar phases in amphiphilic systems [92, 93].

Analytic techniques often use a time-dependent generalization of Landau–Ginzburg free-energy functionals. The different universal dynamic behaviours have been classified by Hohenberg and Halperin [94]. In the simple example of a binary fluid (model B) the concentration difference can be used as an order parameter m . A gradient in the local chemical potential $\mu(\mathbf{r}) = \delta F / \delta m(\mathbf{r})$ gives rise to a current \mathbf{j}

$$\mathbf{j} = -\Lambda \nabla \frac{\delta F}{\delta m(\mathbf{r})} \quad (\text{B3.6.28})$$

-25-

which strives to minimize the free energy. The kinetic coefficient Λ denotes a phenomenological constant which sets the time scale. In complex fluids (e.g., polymer blends) the relation between the gradient of the chemical potential and the current is non-local and the kinetic coefficient has to be generalized [95]. If the order parameter is conserved (e.g., in the demixing of a binary mixture) the change of the order parameter and the current are related by the continuity equation

$$\frac{\partial m(\mathbf{r}, t)}{\partial t} = \nabla \cdot \mathbf{j} = -\nabla \cdot \Lambda \nabla \frac{\delta F}{\delta m(\mathbf{r})}. \quad (\text{B3.6.29})$$

This time development of the order parameter is completely deterministic; when the equilibrium $\mu(\mathbf{r}) = \text{const}$ is reached the dynamics comes to rest. Noise can be added to capture the effect of thermal fluctuations. This leads to a Langevin dynamics for the order parameter.

Time-dependent Ginzburg–Landau models can be generalized to models with or without conserved order parameters. Also, the effect of additional conservation laws (for example, the inclusion hydrodynamic effects) has been explored. More complicated forms of the free-energy functional can be used to incorporate more details of the systems and alleviate the restriction to small order parameters inherent in the Ginzburg–Landau expansion. Shi and Noolandi [96] have used the free energy functional of the self-consistent field theory to explore fluctuations in spatially structured phases of diblock copolymers. A similar free-energy functional is employed by Fraaije and co-workers [97] to study the kinetics of self-assembly in amphiphilic systems. Extensions of the time-dependent Ginzburg–Landau equation to a formal scheme for the time evolution of non-equilibrium systems in terms of a set of coarse-grained variables have been explored [98].

C1.1 Clusters

Lai-Sheng Wang

C1.1.1 CLUSTERS

C1.1.1.1 INTRODUCTION

As we divide and subdivide a piece of bulk crystal, its properties will not change dramatically until we reach the nanometre scale. As particle size approaches molecular dimensions, all properties of a material change. Particles consisting of a few to a few thousand atoms are called *clusters*. These particles often show unique electronic, magnetic and chemical properties with dramatic size and shape dependence. The field of cluster research involves the elucidation of these unique size-dependent properties and how they evolve from the molecular to the bulk as more and more atoms are added. A wide variety of clusters have been made and investigated, including metals, semiconductors, ionic solids, noble gases and small molecules. The discovery of C₆₀ and fullerenes [1], as a result of studying carbon clusters (see [chapter C1.2](#)), represents the best yield from cluster research. Curl, Kroto and Smalley were awarded the 1996 Nobel Prize in Chemistry for this remarkable discovery.

Clusters are intermediates bridging the properties of the atoms and the bulk. They can be viewed as novel molecules, but different from ordinary molecules, in that they can have various compositions and multiple shapes. Bare clusters are usually quite reactive and unstable against aggregation and have to be studied in vacuum or inert matrices. Interest in clusters comes from a wide range of fields. Clusters are used as models to investigate surface and bulk properties [2]. Since most catalysts are dispersed metal particles [3], isolated clusters provide ideal systems to understand catalytic mechanisms. The versatility of their shapes and compositions make clusters novel molecular systems to extend our concept of chemical bonding, structure and dynamics. Stable clusters or passivated clusters can be used as building blocks for new materials or new electronic devices [4] and this aspect has now led to a whole new direction of research into nanoparticles and quantum dots (see [chapter C2.17](#)). As the size of electronic devices approaches ever smaller dimensions [5], the new chemical and physical properties of clusters will be relevant to the future of the electronics industry.

Cluster research is a very interdisciplinary activity. Techniques and concepts from several other fields have been applied to clusters, such as atomic and condensed matter physics, chemistry, materials science, surface science and even nuclear physics. While the dividing line between clusters and nanoparticles is by no means well defined, typically, nanoparticles refer to species which are passivated and made in bulk form. In contrast, clusters refer to unstable species which are made and studied in the gas phase. Research into the latter is discussed in the current chapter.

C1.1.2 TECHNIQUES FOR CLUSTER GENERATION AND DETECTION IN THE GAS PHASE

C1.1.2.1 CLUSTER GENERATION IN THE GAS PHASE

The formation of clusters in the gas phase involves condensation of the vapour of the constituents, with the exception of the electrospray source [6], where ion-solvent clusters are produced directly from a liquid solution. For rare gas or molecular clusters, supersonic beams are used to initiate cluster formation. For nonvolatile materials, the vapours can be produced in one of several ways including laser vaporization, thermal evaporation and sputtering.

SUPERSONIC EXPANSION SOURCE

Supersonic expansion is an indispensable tool in modern chemical physics and physical chemistry [7]. It is an effective technique to produce weakly bonded clusters from gaseous species. Supersonic expansion of a gas sample through a small orifice cools the gas sample adiabatically to very low temperatures. Cluster growth is initiated through three-body collisions. A number of parameters (nozzle size, shape and backing pressure) can be varied to produce cold clusters and to tune cluster size distributions. Clusters with very low rotational and vibrational temperatures (a few kelvins) can be produced using the seeded beam technique, where a small amount of condensing gas is seeded in a helium beam to promote cluster formation and cooling. Clusters of rare gases and other small molecules are all produced and studied using the supersonic beam technique.

LASER VAPORIZATION SUPERSONIC CLUSTER SOURCE

Laser vaporization is one of the most popular and powerful techniques to produce metal and semiconductor clusters in the gas phase. [Figure C1.1.1](#) shows a schematic of a generic laser vaporization supersonic cluster beam source, first developed by Smalley and coworkers [8]. In this technique, an intense pulsed laser beam is focused onto a target. The rapid electronic to vibrational energy transfer allows the laser beam to heat the radiated spot to up to $\approx 10\,000$ K, producing a plasma with both neutral and charged atomic species. A pulsed high pressure carrier gas (usually helium) is delivered in coincidence with the laser pulse, and the rapid cooling due to the carrier gas initiates the cluster growth. The nascent clusters are entrained in the carrier gas and undergo a supersonic expansion to be further cooled. Both neutral and charged clusters can be produced. The laser vaporization technique is very versatile and it can produce clusters from any metal and semiconductor elements in the periodic table. Mixed clusters can be produced either by using an alloy target or adding a reactive gas in the carrier gas. A two-laser vaporization source has also been used to produce alloy clusters [9, 10].

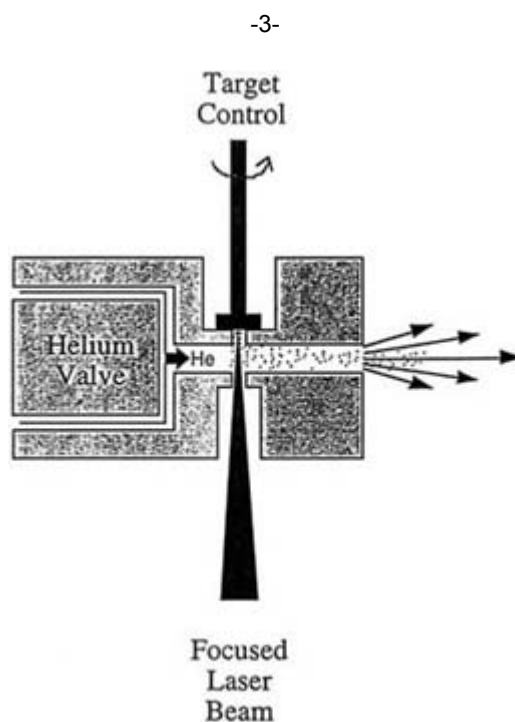

Figure C1.1.1. Schematic of a typical laser vaporization supersonic metal cluster source using a pulsed laser and a pulsed helium carrier gas.

THERMAL EVAPORATION SOURCE

The thermal evaporation source was the earliest used to produce metal clusters in the gas phase [11, 12 and 13], mostly for clusters of the alkalis and other low melting point materials. In this technique, a bulk sample is simply

heated in an oven to produce the atomic vapour. The vapour is entrained in a low-pressure gas flow where nucleation and cluster growth take place. Clusters of sodium atoms with more than 20 000 atoms have been made with this source [14]. A high-pressure carrier gas can also be used to produce a supersonic beam of clusters with the thermal evaporation source.

SPUTTERING SOURCE

Sputtering of a target surface with energetic particles can produce clusters. The energetic particles are typically ion beams of the rare gases or cesium. Clusters are lifted from the target surface by the energetic impact. Cluster sizes produced in this technique are generally limited and the cluster temperatures are high [15]. Intense continuous beams of cluster ions can be produced by sputtering and have been used for size-selected cluster deposition [16]. A related technique is a cold cathode discharge in a flowing rare gas. The discharge ionizes the rare gas, which then sputter metal atoms off the target (cathode). Cluster ions are formed through aggregation in the flowing gas stream. Continuous beams of small cluster ions can be effectively produced with this technique [17].

-4-

ELECTROSPRAY SOURCE

Electrospray was originally invented as a soft ionization technique for biological mass spectrometry [6, 18]. In electrospray, a liquid solution containing the molecules of interest is sprayed through a syringe needle under high voltage. Highly charged droplets produced in this fashion are broken down and desolvated to produce the ions of interest. Electrospray can also be used effectively to produce ion-solvent clusters and weakly bonded complexes [19]. Electrospray is a fairly new technique and is beginning to be used by physical chemists to produce novel gas phase clusters and complexes [20, 21].

C1.1.2.2 CLUSTER DETECTION IN THE GAS PHASE

The whole arsenal of physical chemistry methods has been utilized to investigate clusters. The development of cluster research is driven largely by new techniques to generate clusters and by new experimental tools to probe them. Mass spectrometry is the most useful tool in gas-phase cluster research because the first information one wants to know is the cluster's mass and size. All gas-phase investigations of clusters rely on mass spectrometry one way or the other. Since more stable clusters tend to be more abundant, a mass distribution of clusters contains valuable information about cluster stabilities, revealing 'magic numbers'—clusters with significantly higher abundance than their neighbours. Some of the most important discoveries of cluster science were based on the mass distribution of clusters, for example, the shell structure of free electron metal clusters [22] and C_{60} [1]. There are several ways to perform mass spectrometry, all using charged particles and measuring the mass/charge ratios of clusters. Mass separation of neutral clusters is still a challenging task [23]. The general assumption is that charged clusters also reflect the stability or distribution of the neutral clusters, although that is not always the case.

The most popular mass spectrometric technique is the 'time-of-flight' method [24], in which cluster mass information is obtained by measuring the flight times of a cluster ion beam in a given distance. The time-of-flight method is particularly suitable with pulsed laser vaporization cluster sources, and has high efficiency because the whole mass range is measured for a given laser shot. The time-of-flight technique has moderate mass resolution, but high resolution can be achieved by using a reflection [25, 26]. Ion cyclotron resonance mass spectrometry is another powerful technique used in cluster research [27]. Ions are confined and stored in a three-dimensional trap formed by a strong uniform magnetic field (\mathbf{B}) in the x - y directions and an electrostatic potential well in the z direction. The ion cyclotron frequency is $\omega_c = q\mathbf{B}/m$, so that highly accurate masses (m/q) can be obtained by measuring the cyclotron frequencies. Chemical reaction and fragmentation experiments are routinely performed with the stored ions [28, 29].

There are other techniques for mass separation such as the quadrupole mass filter and Wien filter. Another mass spectrometry technique is based on ion chromatography, which is also capable of measuring the shapes of clusters [30, 31]. In this method, cluster ions of a given mass are injected into a drift tube with well-defined entrance and exit slits and filled with an inert gas. The clusters drift through this tube under a weak electric potential. Since the

cluster mobility depends on collision cross sections with the inert gas, different isomers of a given cluster size are spatially separated in the drift tube. Structural information can be obtained for clusters whose isomers exhibit significantly different shapes, such as carbon and silicon clusters [32].

C1.1.3 METAL CLUSTERS

Metal clusters are bonded by strong covalent or metallic bonds. Clusters of the low melting point metallic elements are produced using the thermal evaporation technique. With the laser vaporization technique, metal clusters from all the metallic elements in the periodic table can be made. Simple metal clusters include those main group elements whose cluster properties are dominated by the delocalized nature of their valence electrons. In contrast to the simple metal clusters, transition-metal clusters are extremely complicated. Because of the unfilled d orbitals, transition-metal clusters possess a high density of electronic states. Transition-metal clusters possess both metallic and covalent bonding characters and exhibit interesting chemical, magnetic and electronic properties. Studies of transition-metal clusters are directly relevant to heterogeneous catalysis, surface science, metal cluster chemistry and metal–metal bonding in inorganic chemistry [33]. Although accurate theoretical descriptions of transition-metal clusters still pose a tremendous challenge, improved experimental and theoretical techniques are expected to make significant progress in the investigation of transition-metal clusters.

C1.1.3.1 SIMPLE METAL CLUSTERS AND THE ELECTRON SHELL MODEL

The simple metal clusters are among the earliest cluster species experimentally investigated [34]. They include those clusters from elements of the main groups IA–IIIA. Clusters of the IB and IIB elements with filled d-shells can also be categorized as simple metal clusters because their properties are largely dominated by the free electron nature of the valence s electrons. The relative ease of their formation through the thermal evaporation source and their relatively simple electronic structure made many experimental and theoretical investigations possible [34, 35 and 36]. In 1984, Knight and coworkers first observed from mass spectra of sodium clusters that clusters with 8, 20, 40, 58 and 92 atoms are more abundant than other clusters [22], as shown in [figure C1.1.2](#). They explained this observation in terms of a one-electron shell model [3], in which the valence electrons of the constituent atoms are completely delocalized within the volume of the cluster.

Figure C1.1.2. (a) Mass spectrum of sodium clusters (Na_N), $N = 4-75$. The inset corresponds to $N = 75-100$. Note the more abundant clusters at $N = 8, 20, 40, 58$, and 92 . (b) Calculated relative electronic stability, $\Delta(N+1) - \Delta(N)$ versus N using the spherical electron shell model. The closed shell orbitals are labelled, which correspond to the more abundant clusters observed in the mass spectrum. Knight W D, Clemenger K, de Heer W A, Saunders W A, Chou M Y and Cohen M L 1984 *Phys. Rev. Lett.* **52** 2141, figure 1.

In the shell model [37, 38], the jellium approximation is used to replace the positive cores with a uniform background potential. The valence electrons are treated as a quantized Fermi gas moving in the jellium potential and bounded by the cluster surface. The effective one-electron wavefunctions of a spherically symmetric potential are characterized by a main quantum number, n , and an angular momentum quantum l with degeneracy $2(2l+1)$, including spin. A closed shell system is obtained when all the levels for a given l are occupied with valence electrons. A closed shell system exhibits an enhanced stability because there exists a large energy gap to the next empty level (see figure C1.1.2(b)). The ordering of the levels depends on the shape of the potential. It turns out that the potential form for the metal clusters is analogous to that used in nuclear physics with similar shell structures. Therefore, the quantum numbers in

metal cluster physics follow the nuclear physics convention and there is no restriction on the angular quantum number l (unlike the filling of angular momentum shells in atomic physics underlying the periodic table of the elements). The nuclear shell model was developed in the 1940s to explain particularly stable nuclei. Thus concepts and ideas have been borrowed from nuclear physics to cluster physics and there is an interesting cross fertilization of two very different fields [39]. Besides the idea of shell closing, collective excitations [40, 41 and 42], fission [43, 44 and 45], and scattering [46]—concepts familiar in nuclear physics—have also been studied for the simple metal clusters.

The spherical shell model can only account for the major shell closings. For open shell clusters, ellipsoidal distortions occur [47], leading to subshell closings which account for the fine structures in [figure C1.1.2\(a\)](#). The electron shell model is one of the most successful models emerging from cluster physics. The electron shell effects are observed in many physical properties of the simple metal clusters, including their ionization potentials, electron affinities, polarizabilities and collective excitations [34].

C1.1.3.2 TRANSITION-METAL CLUSTERS: CHEMISTRY

The microscopic understanding of the chemical reactivity of surfaces is of fundamental interest in chemical physics and important for heterogeneous catalysis. Cluster science provides a new approach for the study of the microscopic mechanisms of surface chemical reactivity [48]. Surfaces of small clusters possess a very rich variation of chemisorption sites and are ideal models for bulk surfaces. Chemical reactivity of many transition-metal clusters has been investigated [49]. Transition-metal clusters are produced using laser vaporization, and the chemical reactivity studies are carried out typically in a flow tube reactor in which the clusters interact with a reactant gas at a given temperature and pressure for a fixed period of time. Reaction products are measured at various pressures or temperatures and reaction rates are derived. It has been found that the reactivity of small transition-metal clusters with simple molecules such as H₂ and NH₃ can vary dramatically with cluster size and structure [48, 49, 50, 51 and 52].

[Figure C1.1.3](#) shows a plot of the chemical reactivity of small Fe, Co and Ni clusters with H₂ as a function of size (full curves) [53]. The reactivity changes by several orders of magnitudes simply by changing the cluster size by one atom. Both geometrical and electronic arguments have been put forth to explain such reactivity changes. It is found that the reactivity correlates with the difference between the ionization potential (IP) and the electron affinity (EA) for a given cluster, corrected by a Coulomb energy, e^2/R , where R is the radius of the cluster ([figure C1.1.3](#)), dashed lines). This observation is interpreted using a model in which the probability of H₂ chemisorption is proportional to the magnitude of an entrance channel barrier caused by Pauli repulsion between H₂ and the cluster. This barrier is assumed to be proportional to the energy gap between the highest occupied and lowest unoccupied orbitals, characterized by the difference between the IP and EA of the cluster. [Figure C1.1.3](#) demonstrates the importance of the cluster electronic structures on the cluster reactivity.

Figure C1.1.3. Relative reactivity of transition-metal clusters with H_2 (full curves, log scale) and the promotion energy $EP(N) = IP(N) - EA(N) - e^2/R(N)$, where IP, EA, and R represent the cluster ionization potential, electron affinity, and radius, respectively. The top figure is for Fe_N ($N = 8-20$), the middle figure is for Co_N ($N = 4-26$), and the lower figure is for Ni_N ($N = 7-20$). Conceicao J, Laaksonen R T, Wang L S, Guo T, Nordlander P and Smalley R E 1995 *Phys. Rev. B* **51** 4668, figure 3.

Cluster chemisorption experiments have been used extensively to probe the geometric structure of transition-metal clusters by Riley and coworkers [54, 55 and 56]. Since most of the atoms of a cluster are on the cluster surface, the available surface sites contain information about the underlying cluster structure. By measuring the maximum uptake of molecules, one can gain an insight into the cluster packing geometry. These studies have been mainly focused on clusters of Fe, Co, Ni and Cu and have found that icosahedral packing is the dominating structural feature of these clusters [54, 55 and 56]. There is ample evidence that multiple structural isomers exist for many of these clusters. For Cu clusters, evidence is provided for both electron shell behaviour and icosahedral geometrical structure [56].

The reactivity of size-selected transition-metal cluster ions has been studied with various types of mass spectrometric techniques [15]. Fourier-transform ion cyclotron resonance (FT-ICR) is a particularly powerful technique in which a cluster ion can be stored and cooled before experimentation. Thus, multiple reaction steps can be followed in FT-ICR, in addition to its high sensitivity and mass resolution. Many chemical reaction studies of transition-metal clusters with simple reactants and hydrocarbons have been carried out using FT-ICR [49, 57, 58]. A special reactive channel is cluster fragmentation induced either by photoabsorption or collisions with an inert gas. Measuring cluster fragmentation pathways and energetics provides information about both the cluster structures and bonding energies. Strong size-dependent bonding energies are found for small transition-metal cluster ions, and the bonding energy approaches the bulk cohesive energy smoothly for large clusters [59, 60].

C1.1.3.3 TRANSITION-METAL CLUSTERS: ELECTRONIC STRUCTURE

The diverse chemical and physical properties of the transition-metal clusters derive from their rich electronic structure. Thus probing the electronic structure of transition-metal clusters is of special interest. Transition metal dimers have been extensively studied by resonance two-photon ionization (R2PI) spectroscopy [61, 62, 63 and 64]. However, the high density of low-lying electronic states, characteristic of the transition-metal clusters, prevents the R2PI technique being used for larger clusters. Single photon photofragmentation spectroscopy of clusters bound with rare gas atoms has been used to probe the electronic structure of larger transition-metal clusters [65, 66]. Photoionization experiments have been used extensively to measure the IPs of transition-metal clusters [67, 68]. Recently, ZEKE (zero kinetic energy) spectroscopy has been applied to small neutral transition-metal clusters [69].

A more powerful experimental technique to probe the electronic structure of transition-metal clusters is size-selected anion photoelectron spectroscopy (PES) [70, 71, 72, 73, 74, 75 and 76]. In PES experiments, a size-selected anion cluster is photodetached by a fixed wavelength photon and the kinetic energies of the photoemitted electrons are measured. PES experiments provide direct measure of the electron affinity and electronic energy levels of neutral clusters. This technique has been used to study many types of clusters over a large cluster size range and can probe how the electronic structures of transition-metal clusters evolve from molecular to bulk [77, 78, 79, 80 and 81]. Research has focused on the 3d transition-metal clusters, for which there have also been many theoretical studies [82, 83, 84, 85, 86, 87, 88 and 89]. It is found that the electronic structure of the small transition-metal clusters is molecular in nature, with discrete electronic states. However, the electronic structure of the transition-metal clusters approaches that of the bulk rapidly. Figure C1.1.4 shows that the electronic structure of vanadium clusters with 65 atoms is already very similar to that of bulk vanadium [90]. Other 3d transition-metal clusters also show bulk-like electronic structures in similar size range [78].

-10-

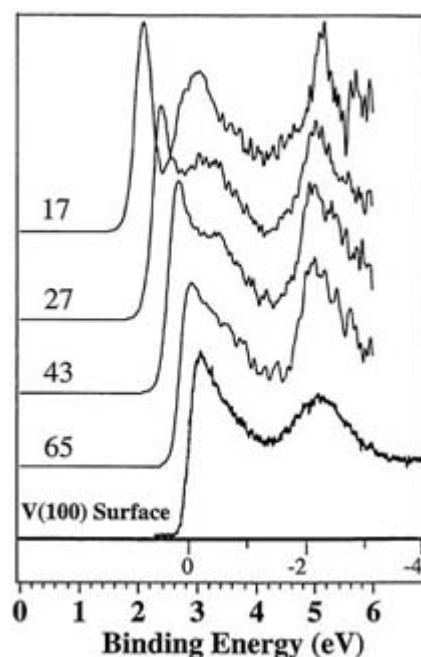

Figure C1.1.4. Photoelectron spectra of V_N^- ($N = 17, 27, 43,$ and 65) at 6.42 eV photon energy, compared to the bulk photoelectron spectrum of V(100) surface at 21.21 eV photon energy. The cluster spectra reveal the appearance of bulk features at V_{17} and how the cluster spectral features evolve toward the bulk. The bulk spectrum is referenced to the Fermi level. Wu H, Desai S R and Wang L S 1996 *Phys. Rev. Lett.* **77** 2436, figure 2.

C1.1.3.4 TRANSITION-METAL CLUSTERS: MAGNETISM

One of the interesting aspects of transition-metal clusters is their novel magnetic properties [91, 92, 93 and 94].

Although most transition-metal atoms have unpaired d-electrons and are magnetic, very few bulk transition-metal crystals are magnetic. Therefore, it is of great interest to understand how the magnetic properties of transition metals develop (diminish) as cluster size increases. The magnetic properties of transition-metal clusters have been investigated using the Stern–Gerlach molecular beam deflection method. Magnetic properties of clusters of the three bulk ferromagnetic materials, Fe, Co and Ni have been extensively studied [95, 96, 97, 98 and 99]. These clusters are found to be superparamagnetic with strong size-dependent magnetic moments. Figure C1.1.5 shows the measured magnetic moments of small Ni clusters as a function of size [99]. The dramatic size dependence of the cluster magnetic moments is interpreted to be due to a surface enhancement: the minima correspond to clusters with closed geometrical shells and maxima to clusters with relatively open structures. Small clusters generally possess much higher moments than the bulk materials, and the moments approach bulk values in the size range of about 500 atoms. Magnetism has also been detected in clusters of those elements whose bulk crystals are nonmagnetic [100].

-11-

Figure C1.1.5. Nickel cluster magnetic moment per atom (μ) as a function of cluster size, at temperatures between 73 and 198 K. Apsel S E, Emmert J W, Deng J and Bloomfield L A 1996 *Phys. Rev. Lett.* **76** 1441, figure 1.

C1.1.4 SEMICONDUCTOR CLUSTERS

Since silicon is the most important semiconductor material, clusters of silicon have been most extensively studied, both theoretically and experimentally. The electronic structure [101, 102, 103 and 104], geometrical structure [105, 106, 107, 108, 109 and 110] and chemical reactivity [111] of silicon clusters have been investigated. The structures of small silicon clusters assume three-dimensional structures different from both that of the bulk crystal and that of its group IV neighbour, carbon. Ion mobility experiments have been very effective in providing experimental structural information for silicon clusters, and confirm that many structural isomers exist for silicon clusters because of their strong covalent bonding and relatively open structures [106, 110]. Ion mobility results show that silicon clusters up to ~27 atoms follow a prolate growth sequence, resulting in geometries with an aspect ratio of ~3 [106]. Larger clusters appear to assume more spherical geometries. The structures of medium-sized silicon clusters with 12–26 atoms have been studied recently by theoretical calculations using density functional theory in combination with ion mobility experiments [110]. Figure C1.1.6 shows the calculated structures of silicon clusters containing 12–20 atoms. The clusters with less than 18 atoms can be visualized as stacked Si_9 tricapped trigonal prisms, whereas global minima of Si_{19} and Si_{20} assume more spherical structures.

Figure C1.1.6. Minimum energy structures for neutral Si_n clusters ($n = 12\text{--}20$) calculated using density functional theory with the local density approximation. Cohesive energies per atom are indicated. Note the two nearly degenerate structures of Si_{16} . Ho K M, Shvartsburg A A, Pan B, Lu Z Y, Wang C Z, Wachter J G, Fye J L and Jarrold M F 1998 *Nature* **392** 582, figure 2.

Other semiconductor clusters have also been studied, such as germanium clusters [101, 112] and mixed clusters of the III–V semiconductors GaAs [113, 114 and 115] and InP [116, 117]. Of particular interest is the evolution and emergence of the energy band gap in these clusters. Infrared and visible absorption spectroscopy has been performed on indium phosphide clusters (In_xP_y) with $x + y$ up to 14 [116]. An optical-gap-like feature with an onset close to the band gap of bulk crystalline indium phosphide is already observed for the even clusters in this size range. This is surprising, because according to the model of quantum confinement these tiny clusters are expected to have band gaps much larger than that of the bulk crystal. Photoelectron spectroscopy experiments on size selected gallium arsenide cluster anions (Ga_xAs_y^-) showed that the electron affinity of the neutral clusters with $x + y$ around 50 already approached that of the bulk [113], quite different from the behaviour of metal clusters. Even though the electronic structure of

transition-metal clusters already approaches that of the bulk in a similar size regime, their electron affinity is still smaller than that of the bulk by more than 1 eV [77, 78, 79, 80 and 81]. These observations indicate the importance of charge localization in semiconductor clusters [118]. For bulk GaAs and InP, surface reconstruction creates shallow traps for conduction-band electrons. The wavefunction for a trapped electron is localized and is not subjected to the same quantum confinement effects as the delocalized orbital of a conduction-band electron. Thus,

quantum confinement effects are expected to be less important in clusters, where charge localization dominates, as should be the case for small clusters of GaAs and InP. The nature of charge localization suggests that such molecular-sized clusters may be ideal models for studying the surface behaviours of bulk semiconductors.

C1.1.5 IONIC CLUSTERS AND MIXED CLUSTERS

C1.1.5.1 IONIC CLUSTERS

Ionic clusters, such as alkali halide clusters, were among the earliest cluster species experimentally investigated [119]. The binding in ionic clusters is dominated by classical electrostatic effects, and simple interaction potentials can give fairly accurate descriptions of these clusters. One characteristic of the ionic clusters is that they mimic the structures of the bulk ionic crystals even at relatively small sizes, making ionic clusters attractive targets for both experimental and theoretical investigations. Nonstoichiometric alkaline halide clusters or clusters with excess electrons have been used as models to study bulk defects [120, 121 and 122]. Recent investigations have found facile structural transformation in alkaline halide clusters with rather low activation energies [123, 124].

Oxide clusters are another class of important ionic clusters because of the important roles that oxide materials play in both chemical catalysis and advanced materials applications. Oxide clusters of the main group I–III elements are dominated by the electrostatic interactions [125, 126 and 127]. Oxide clusters of the transition metals become more complicated with both ionic and covalent characters [128]. Oxide clusters of the late main group elements, such as silicon, are more dominated by covalent bonding. Oxide clusters are relatively less well characterized. Chemical reactivity of a number of transition-metal oxide clusters has been studied in a fast flow reactor with laser vaporization [129]. Antimony and bismuth oxide clusters have been recently produced, and magic number clusters characteristic of bulk compositions are observed [130, 131]. Photoelectron spectroscopy of size-selected anions has been carried out on a number of oxide cluster series [126, 132, 133 and 134]. The electronic structure evolution from that of a bare cluster to that of an oxide is monitored as the cluster is oxidized step-by-step by oxygen. [Figure C1.1.7](#) shows the structures of a series of Si_3O_y ($y = 1-6$) clusters [134], which can be viewed as a sequential oxidation of a Si_3 cluster. The local Si–O bonding structure from Si_3O to Si_3O_3 mimic that of the initial oxidation of a silicon surface, whereas the larger clusters (Si_3O_4 to Si_3O_6) with a SiO_4 unit begins to mimic that of bulk silicon oxide.

Figure C1.1.7. MP2/6-311 + G* optimized structures of the Si_3O_y ($y = 1-6$) clusters. All bond lengths are in Å. Note that for $y = 1-4$, all the O atoms are bridge bonded to two Si. Wang L S, Nicholas J B, Dupuis M, Wu H and Colson S D 1997 *Phys. Rev. Lett.* **78** 4450, figure 2.

C1.1.5.2 CARBIDE CLUSTERS

Metal-carbide clusters are relevant to the formation of both endohedral fullerenes and carbon nanotubes [135]. There also exists a class of apparently stable metal-carbide cluster ions, $\text{M}_8\text{C}_{12}^+$ ($\text{M} = \text{Ti}, \text{V}, \text{Cr}, \text{Zr}$ and Hf), called metallocarbohedrenes (met-car), first discovered by Castleman and coworkers [136]. The formation mechanisms of these novel clusters and nanostructures are still not elucidated [137]. Understanding the chemical bonding and structures of small metal-carbide clusters provides important insight into their growth mechanisms and can help design more efficient techniques for their bulk synthesis. For example, annealing of LaC_n^+ clusters in the gas phase converts them into endohedral fullerenes, and suggests that the La atom acts as a nucleation centre and the carbon rings arrange themselves around the La atom to form the final products [138]. Met-cars have not been isolated in bulk form and their structures have not been determined despite extensive experimental and theoretical investigations [137]. Many

questions still remain about the structure and bonding of metal-carbide clusters and the met-cars. Detailed characterization of the small carbide clusters will be key to understanding the formation of met-cars and endohedral fullerenes, as well as the catalytic effects in carbon nanotube growth. Mixed clusters in general provide interesting gas phase systems because not only their size, but also their composition, can be systematically varied. Clusters with tailored chemical or physical properties may be designed with the mixed clusters.

C1.1.6 RARE-GAS CLUSTERS AND OTHER WEAKLY BONDED MOLECULAR CLUSTERS

Rare-gas clusters can be produced easily using supersonic expansion. They are attractive to study theoretically because the interaction potentials are relatively simple and dominated by the van der Waals interactions. The Lennard–Jones pair potential describes the structures of the rare-gas clusters well and predicts magic clusters with icosahedral structures [139, 140]. The first five icosahedral clusters occur at 13, 55, 147, 309 and 561 atoms and are observed in experiments of Ar, Kr and Xe clusters [141]. Small helium clusters are difficult to produce because of the extremely weak interactions between helium atoms. Due to the large zero-point energy, bulk helium is a quantum fluid and does not solidify under standard pressure. Large helium clusters, which are liquid-like, have been produced and studied by Toennies and coworkers [142]. Recent experiments have provided evidence of superfluidity in ^4He clusters for as few as 60 atoms [143]. Helium clusters provide an ultracold environment, which can be used as a matrix to trap other molecules. Currently there is considerable interest in using large helium clusters as ‘nanocryostats’ to trap metal clusters and other molecular species for high-resolution spectroscopy investigations [144, 145].

Molecular clusters are weakly bound aggregates of stable molecules. Such clusters can be produced easily using supersonic expansion, and have been extensively studied by both electronic and vibrational spectroscopy [146, 147]. Hydrogen-bonded clusters are an important class of molecular clusters, among which small water clusters have received a considerable amount of attention [148, 149]. Solvated cluster ions have also been produced and studied [150, 151]. These solvated clusters provide ideal model systems to obtain microscopic information about solvation effect and its influence on chemical reactions.

C1.1.7 OUTLOOK

Gas-phase investigations of clusters over the past two decades have provided major advances of our fundamental understanding of these microscopic species and how their physical and chemical properties change with size. With new and continuously improved experimental and theoretical techniques, more discoveries and deeper understanding can be expected. Clusters provide the flexibility in size, shape, and composition in making new molecular species, which will enrich our concept of chemical structure and bonding. With new species that do not follow the classical valency, new chemical bonding theories and ideas will need to be developed to predict their physical and chemical properties. To understand the molecular details of the evolution from small clusters to nanocrystals will continue to be a challenge to both experimental and theoretical investigations. The diverse topics and systems afforded by clusters will make this field continue to be exciting and challenging for the new millennium to come.

C1.2 Fullerenes

Dirk M Guldi

INTRODUCTION

The scope of the following article is to survey the physical and chemical properties of the third modification of carbon, namely [60]fullerene and its higher analogues. The enthusiasm that was triggered by these spherical carbon allotropes resulted in an epidemic-like number of publications in the early to mid-1990s. In more recent years the field of fullerene chemistry is, however, dominated by the organic functionalization of the highly reactive fullerene

core, yielding literally thousands of fullerene derivatives with new and, in part, even more intriguing properties than pristine fullerenes. This still growing field is the subject of a new number of excellent review articles and books. The beginning of the current review deals with the fullerenes' structural and electronic configurations, followed by a detailed description of their undoped/doped thin films and a discussion of fullerene-based polymers and Langmuir–Blodgett films. In addition, the properties of fullerenes in condensed media, ranging from electrochemical redox reactions and photoexcited states to electron transfer processes, are elucidated. This account will end with a final section regarding metal incorporated endohedral complexes.

C1.2.1 STRUCTURE

The initial report regarding the existence and characterization of [60]fullerenes (figure C1.2.1) by Kroto *et al* is an important landmark for the chemistry and physics of fullerenes [1]. The importance of this discovery was acknowledged with the Nobel Prize in 1996. It took, however, a few more years until Krätschmer *et al* reported a method describing the arc discharge of carbon rods with the prospect of synthesizing large quantities of fullerene materials (figure C1.2.2) [2]. In parallel, the laser evaporation cluster beam technique has been employed by Smalley and coworkers to vaporize graphite in a helium atmosphere and, thus, to mimic the appropriate fullerene nucleation conditions [3]. With gram quantities at hand, scientists began to investigate the unique chemical and physical properties of this spherical carbon allotrope.

The fundamental concept proposed for the composition of three-dimensional fullerene structures is the introduction of five-membered (i.e. pentagon) rings, which are primarily responsible for the curvature [4]. They function like defects in a graphite structure and lead to nonplanarity of the π -electronic structure. However, the strain energy will only be minimized when the pentagons are as far apart as possible. This 'isolated pentagon' principle [5] has best been achieved in [60]fullerene, which consists of 12 regularly implanted five-membered (i.e. pentagon) and 20 six-membered (i.e. hexagon) rings and, therefore, differs most markedly from two-dimensional carbon structures (i.e. graphite). As a direct result of the 12 pentagonal faces, [60]fullerene shows, in contrast to graphitic sheets, an anisotropic electron distribution. In [60]fullerene, the pentagons are most evenly distributed, but not as far apart as possible.

Figure C1.2.1. Structure of [60] fullerene (I_h), [70] fullerene (D_{5h}), [76] fullerene (D_2), [78] fullerene (C_{2v}) and [84] fullerene (D_2).

More important, the surface curvature of the carbon network exerts a profound impact on the reactivity of the fullerene core [6, 7]. In this context, the most striking consequence emerges from the pyramidalization of the individual carbon atoms. Influenced by the curvature, the sp^2 hybrids which exist in truly two-dimensional planar

carbon networks and hydrocarbons adopt an $sp^{2.278}$ hybridization with p orbitals that possess an s character of 0.085. Accordingly, the exterior surface is much more reactive than planar analogues, and is comparable to those of electron deficient polyolefins. This, in turn, rationalizes the high reactivity of the fullerene core towards photolytically and radiolytically generated carbon- and heteroatomic-centred radicals and also other neutral or ionic species [8]. The interior, in contrast, is shown to be practically inert [9]. Despite these surface related effects, the $sp^{2.278}$ character of the carbon atoms is expected to have a stabilizing effect on carbon-centred radical ions as well as carbanions and carbocations.

The first fullerene to be characterized was the I_h [60] fullerene, which was originally identified by its four-band IR absorption spectrum [2]. The proposed cage-like structure of [60] fullerene, with a diameter of 7.1 Å, was unequivocally confirmed by the detection of a single ^{13}C NMR resonance, stemming from the equivalency of all the carbon atoms in this molecule [10]. X-ray crystal structures reveal two different types of C–C bond, i.e. short 6–6 bonds, with a high double bond character and long 6–5 bonds, possessing low double bond character [3]. In contrast, the ^{13}C NMR spectrum of [70] fullerene exhibits five lines, again in perfect agreement with a closed sphere. Also ionization experiments helped to characterize the fullerene structure [11, 12 and 13]. The C_{60}^{++} carbon clusters, produced upon ionization, have large internal energies and cool via the sequential emission of C_2 molecules. The latter route arises predominantly from a combination of the high stability of the even-membered C_2 clusters and their relatively high binding energy of ~ 3.6 eV. This makes the C_2 loss mechanism energetically more favourable than separating two individual carbon atoms.

-3-

Figure C1.2.2. Diagram of the apparatus used to produce fullerenes from graphite rods.

In addition to the most abundant fullerene, namely [60]fullerene, a number of higher fullerenes have also been isolated and characterized, including [70] (point group D_{5h}), chiral [76] (point group D_2), the D_3 and C_{2v} isomers

of [78] and an equilibrated mixture of [84]fullerene of D_2 and D_{2d} symmetry (see [figure C1.2.1](#)) [14, 15, 16, 17 and 18]. Large crystalline quantities of these higher fullerenes are scarce, while there is a greater complexity associated with the lower symmetry of the molecule. In addition to their relatively small synthetic amounts, the presence of more than a single isomer which satisfies the isolated-pentagon rule results in further complications with respect to separation of these isomeric mixtures.

C1.2.2 CRYSTAL STRUCTURE

Below 90 K, [60]fullerene freezes into an orientational glass in which it adopts a simple cubic structure [19]. This low temperature structure can be traced to the anisotropic electronic structure. Alignment of the electron rich regions of

-4-

one molecule over the electron deficient regions of its neighbouring molecule optimizes the electrostatic contribution to the predominantly van der Waals intermolecular bonding and, in turn, governs the overall stability of this glass phase. Above 90 K, the structure is a primitive cubic structure (space group T_{6h} or $Pa3$) [20]. In this temperature regime, molecular motions are no longer restricted and, accordingly, the molecules start to move freely between two distinct nearly degenerate orientations, differing in energy by ~ 11.4 meV. In principle, this phase of residual rotational motion is followed by a first-order phase transition at 261 K yielding a face-centred cubic (fcc) structure $Fm3m$, characterized by rapid isotropic reorientational motion of the molecules [21]. In this phase transition, from an orientationally ordered to an orientationally disordered phase, a competition dominates between an entropy gain by rotation and an energy gain by intermolecular attraction.

[70]fullerene, with a D_{5h} symmetry, on the other hand, crystallizes in two phases, namely, centred cubic (ccp, [figure C1.2.3](#)) and hexagonal close packed structures (hcp, [figure C1.2.4](#)), which differ, in essence, only in their stacking sequence. Heating experiments on the pure hcp phase (ABAB), by means of dilatometry, in the 200–400 K temperature window give rise to two phase transitions: first to a deformed hcp and secondly to a monoclinic structure. Structural studies on a ccp crystal revealed a transition to an fcc ($Fm3m$) at high temperature and, upon cooling, a phase transition to a rhombohedral phase ($R3m$) (ABCABC) [22, 23, 24 and 25].

-5-

Figure C1.2.4. Hexagonal packing (ABA) of [60]fullerene.

C1.2.3 ELECTRONIC CONFIGURATION

[60]fullerene has a truncated-icosahedral form, with a point group symmetry I_h which allows a degeneracy as high as five. The 30 filled $p\pi$ orbitals host 60 π electrons, in a structural pattern closely resembling that of free particles on the surface of a sphere and, in turn, evoke an equal net atomic charge distribution on each carbon [26]. All 60 carbon atoms have equivalent symmetry, but the bonds fall into two sets, namely, hexagon–pentagon and hexagon–hexagon edges. The 60 Hückel molecular orbitals give rise to the reducible representation: $2A_g + 3T_{1g} + 4T_{2g} + 6G_g + 8H_g + 1A_u + 4T_{1u} + 5T_{2u} + 6G_u + 7H_u$. Only the A_g and the H_g modes are Raman active while the T_{1u} modes are solely IR active [27].

In essence, the 60 MOs split into 30 bonding and 30 antibonding π molecular orbitals with the h_u and t_{1u} broadening into the valence and conduction bands of the solid, respectively [28]. Because of the presence of both pentagonal and hexagonal rings in the fullerene cage, there are six t_{1u} band electrons in addition to the more common σ and π electrons [26]. For example, graphite consists only of hexagons and, hence, only the σ and π electrons are present. Molecular calculations regarding the electronic configuration have determined that this threefold degenerate LUMO (t_{1u}) is separated by ~ 1.8 eV from a lower lying fivefold degenerate HOMO (h_u) and from a higher lying threefold degenerate LUMO + 1 (t_{1g}) (figure C1.2.5) [29, 30]. The moderate optical energy gap not only underlines the remarkable electron accepting features of these carbon spheres, but it emphasizes, in combination with the optical conductivity, the semiconducting characteristics of solid fullerene, comparable to hydrogenated amorphous semiconductor silicon (a-Si:H).

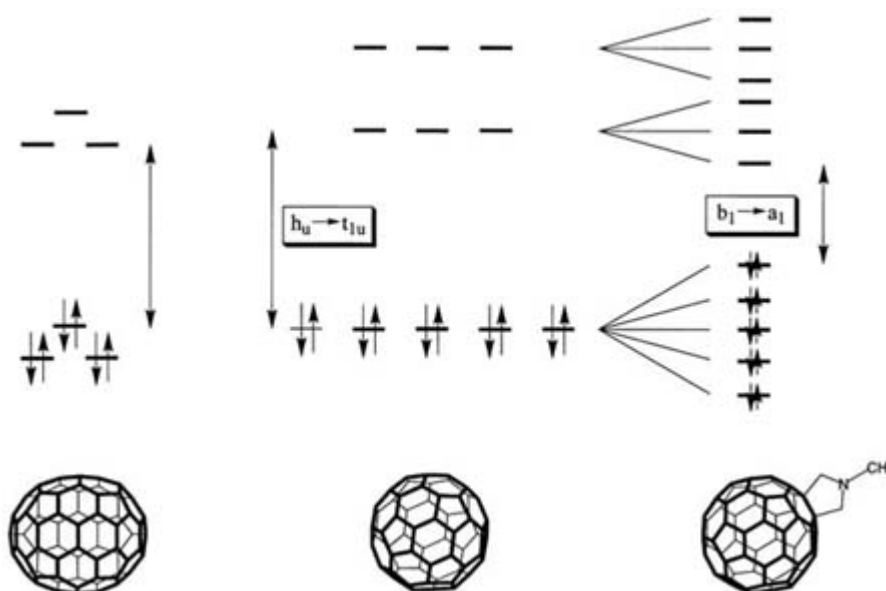

Figure C1.2.5. Illustration of the π orbital energy levels in [60]fullerene, [70]fullerene and monofunctionalized pyrrolidino[60]fullerene [26].

In light of oxidative processes, the high degree of resonance stabilization that arises from the maximally occupied HOMO (10 electrons), makes it an extremely difficult task to remove an electron from the HOMO level [31]. Thus, [60]fullerene can be considered mostly an electronegative entity which is much more easily reduced than oxidized.

The electronic configuration of higher fullerenes, e.g. [70] (figure C1.2.5) [76], [78] and [84]fullerene, is in essence similar to that known for [60]fullerene with, however, one fundamental difference. Their HOMO–LUMO energy gap decreases gradually with increasing number of carbon atoms [32]. On the other hand, recent calculations regarding the smallest so far isolated fullerene species, namely [36]fullerene, indicate also a substantially reduced energy gap of ~ 0.2 eV [33]. From the even stronger constrained curvature, relative to [60]fullerene, stems the fundamental consequence that the carbon atoms in [36]fullerene become so reactive that rapid polymerization occurs, preventing a systematic detailed investigation of any other properties of [36]fullerene.

The most important classes of functionalized [60]fullerene derivatives, e.g. methanofullerenes [34], pyrrolidinofullerenes [35], Diels–Alder adducts [34] and aziridinofullerene [36], all give rise to a cancellation of the fivefold degeneration of their HOMO and threefold degeneration of their LUMO levels (figure C1.2.5). This stems in a first order approximation from a perturbation of the fullerene's π -electron system in combination with a partial loss of the delocalization.

C1.2.4 THIN FILMS

The growth of a well ordered fullerene monolayer, by means of molecular beam epitaxy, has been used for the controlled nucleation of single crystalline thin films. The quality and stability of molecular thin films has been shown

to depend strongly on the interaction between the molecules and the substrates chosen for their growth [37, 38]. It is important to note that fullerenes give rise to much stronger intermolecular interactions relative to conventional organic molecules. Thus, their utilization for molecular thin films, by means of organic molecular beam epitaxy, has been vigorously investigated. In essence, parameters such as the character and also the strength of the interaction between the fullerene core and the substrate determine the morphology and regularity of the film growth. In the case of strong interactions the mobility of the chemisorbed fullerene molecule is limited and

successive deposition leads to the growth of polycrystalline grains with typically small diameters. In clear contrast, substrates such as {001} KBr [39, 40], {0001} MoS₂ [41], {0001} GaSe [41] {111} CaF [42], {111} Si [42, 43], {111} GeS [44], GaAs [45], freshly cleaved mica [46, 47] and layered materials [38], induce sufficiently strong van der Waals interaction between the fullerene molecules and, in turn, overpower the interaction between the substrate and individual fullerene molecules. This leads to a high effective surface mobility of the physisorbed fullerene molecules for fairly large grains. Predominantly a fcc structure with a series of close-packed planes {111} oriented with respect to the substrate plane, or a hcp structure, with {0001} close-packed planes, is found. Also good single-domain epitaxy structure was reported on Au(110), Ag(110) and Ni(110), while multi-domain growth predominates on Cu(111), Au(111), Ag(111) and Pt(111). Charge transfer into the fullerene's LUMO is deemed to be the dominant effect that leads to a strong interaction with the substrate and reduces the effective surface mobility, as has been observed for Au{110} and a variety of metals including Ag, Mg, Cr and Bi [48,49,50,51 and 52].

Consequently, deposition of the first monolayer is the most important factor, determining the growth of the subsequent layers and, consequently, the crystallinity of the resulting multilayered films. General information regarding the strength of the fullerene–substrate bond can be derived from the thermal stability of the fullerene layer. This has been impressively documented via the observation of the principally different crystallinity of [60] fullerene films on semiconductor surfaces such as Si. Depending on the Si surface, being either hydrophobic (passivated) and hydrophilic (non-passivated), films were crystalline with a fcc structure and a noticeable {111} texture, or of amorphous nature, respectively. The amorphous character has been ascribed to the fullerene's interaction with the hydrophilic substrate, where [60]fullerene is mobile and diffuses freely even at temperatures as low as 100 K [37].

C1.2.5 DOPING OF FULLERENES AND SUPERCONDUCTIVITY

The crystal structure of [60]fullerene reveals characteristics of a fcc packing with the molecules located at the lattice points and four fullerene molecules per unit cell [26]. According to the fcc lattice constant, $a = 14.15 \text{ \AA}$ the intramolecular centre-to-centre distance ($a/\sqrt{2}$) is exactly 10.01 \AA . The close packing of the nanometre-sized fullerenes creates two types of interstitial site, sufficiently large to host small-sized molecules or atoms without distorting the crystal [53]. In particular, one octahedral site and two tetrahedral sites per [60]fullerene are present with radii of 2.06 \AA and 1.12 \AA , respectively. It was shown that the respective tetrahedral and octahedral vacancies of the fullerene crystal may be filled with a wide variety of dopants [54,55,56 and 57]. These range from various alkali (Li, Na, K, Rb, Cs), earth alkali metals (Ca, Sr, Ba) and rare-earth metals (Yb, Sm, Eu) to organic donors, such as ferrocene and tetrakis(dimethylamino) ethylene. Metal diffusion in fullerene films and single crystals or vapour transport diffusion are the most widely applied methodologies for fabricating [60]fullerene–metal intercalation composites. On the other hand, intercalation of compounds that have low diffusion coefficients in C₆₀ necessitates sublimation in a UHV chamber.

The occupation of each tetrahedral and octahedral site in these regularly oriented arrays of cavities by, for example, alkali atoms results in the transfer of a single electron to the fullerene's conduction band (t_{1u}) [58]. Consequently,

via stoichiometric alkali metal doping, intercalation structures were fabricated ranging from A₁C₆₀ and A₃C₆₀ to terminally reacted A₆C₆₀ phases and A₁₂C₆₀/A'₆C₆₀ (A = Li and A' = Sr, Ba; full occupation of the LUMO (t_{1u}) and LUMO + 1 (t_{1g}) levels) (figure C1.2.6) [54, 55, 56 and 57]. It was shown that the stability of the alkali A₃C₆₀ and A₆C₆₀ composite structures is mainly governed by the Madelung potential.

Figure C1.2.6. Summary of fcc [60]fullerene structure and alkali-intercalation composites of [60]fullerene.

-9-

The half-filled molecular conduction band (t_{1u}) in A_3C_{60} gives rise to a maximized density of states at the Fermi level. It is interesting to note that this metallic phase becomes a superconductor at low temperatures, while the A_6C_{60} phase proves to be mainly insulating (figure C1.2.6). The resulting A_3C_{60} compounds are typically ionic $[A^+]_3[C_{60}^{3-}]$ and form fcc lattices which positions the icosahedral fullerene cores in sites of local cubic symmetry with a lattice parameter ($a = 14.24 \text{ \AA}$) that is only slightly expanded from that of fcc dopant free [60]fullerene [54].

Raman scattering is the key technique for probing the doping process in fullerites [59]. Specifically, the position of the $A_g(2)$ pinch mode, which is a characteristic fingerprint for the charge transfer in these alkali doped systems, has been employed with great success to identify the various doped phases. Fundamental experiments have been performed with the scope to identify the nature of the superconductivity in these classes of materials including interpretation of the phase diagram as a function of composition, pressure and magnetic field, structure determination, magnetic susceptibility and, finally, NMR relaxation measurements in the normal state [60]. Specifically, band structure calculations on A_3C_{60} composites indicate that the charge transfer is nearly complete and that the electrons are used to half fill the conduction band [54]. Consequently, a simple charge transfer concept, from the cations to the LUMO of the fullerene, yielding a metallic state, has been proposed for a qualitative rationalization of the electronic properties.

In pristine [60] fullerene, the t_{1u} band is completely empty while, in contrast, the A_6C_{60} phase (bcc lattice) has a completely filled conduction band. In the intermediately doped A_4C_{60} phase (bct lattice), the density of states at the Fermi level is, however, nearly zero. These considerations are consistent with the absence of high temperature superconductivity in [60]fullerene, A_4C_{60} and A_6C_{60} . In conclusion, the superconducting behaviour strongly depends on the concentration of conduction band electrons, on the lattice constant and the degree of orientational order, yielding composites which display T_C values between 2 and 40 K. The highest T_C values that are reported are those of K- (33 K), Rb- (33 K) and Cs- (40 K, stabilized under hydrostatic pressure) doped A_3C_{60} composites (figure C1.2.7). Their properties may be best understood on the basis of a high average phonon frequency in combination with weak intermolecular interactions and strongly scattering intramolecular modes.

Also, novel magnetic properties have been reported in mixed fullerene composites, in which the fullerene is limited to a single negative charge. For instance, the tetrakis(dimethylamino) ethylene/[60]fullerene salt, namely, $[TDAE^+][C_{60}^-]$, has been described as a soft ferromagnet with a Curie temperature of 16 K [61, 62].

-10-

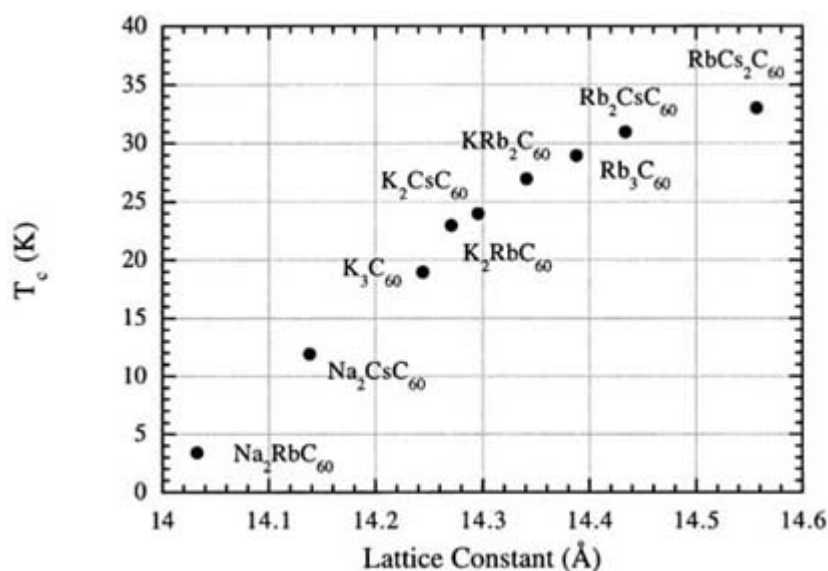

Figure C1.2.7. Superconducting transition temperature plotted as a function of the a lattice parameter for a variety of A_3C_{60} phases [55].

C1.2.6 FULLERENE POLYMERS

Several studies have demonstrated the successful incorporation of [60]fullerene into polymeric structures by following two general concepts: (i) in-chain addition, so called pearl necklace type polymers or (ii) on-chain addition pendant polymers. Pendant copolymers emerge predominantly from the controlled mono- and multiple functionalization of the fullerene core with different amine-, azide-, ethylene propylene terpolymer, polystyrene, poly(oxyethylene) and poly(oxypropylene) precursors [63,64,65,66,67 and 68]. On the other hand, $(-C_{60}Pd-)_n$ polymers of the pearl necklace type were formed via the periodic linkage of [60]fullerene and Pd monomer units after their initial reaction with the p -xylylene diradical [69,70 and 71].

An alternative approach envisages the stimulating idea to produce an all-carbon fullerene polymer in which adjacent fullerenes are linked by covalent bonds and align in well characterized one-, two- and three-dimensional arrays. Polymerization of [60]fullerene, with the selective formation of covalent bonds, occurs upon treatment under pressure and relatively high temperatures, or upon photopolymerization in the absence of a triplet quencher, such as molecular oxygen, using an Ar^+ ion laser at intensities of 50 mW mm^{-2} [72,73,74,75,76,77 and 78]. The synthesis of at least three polymer phases is reported with characteristics ranging from those of rhombohedral and

orthorhombic to tetragonal phases (figure C1.2.8). Typically, in these oligomer and polymer composites the interfullerene C–C linkage evolves from a [2+2] cycloaddition between neighbouring fullerene cores, which results in the formation of four-membered carbon rings (D_{2h} symmetry), fusing together adjacent molecules. Photopolymerization is hindered below the ordering transition of [60]fullerene as the probability of short carbon–carbon bonds approaching intermolecular contact diminishes.

Figure C1.2.8. Orthorhombic 1D and rhombohedral 2D structure of polymerized [60]fullerene.

The C–C linkage in the polymeric [60]fullerene composite is highly unstable and, in turn, the reversible [2+2] phototransformation leads to an almost quantitative recovery of the crystalline fullerene. In contrast the similarly conducted illumination of [70]fullerene films results in an irreversible and randomly occurring photodimerization. The important aspect which underlines the markedly different reactivity of the [60]fullerene polymer material relative to, for example, the analogous [36]fullerene composites, is the reversible transformation of the former back to the initial fcc phase.

C1.2.7 LANGMUIR–BLODGETT FILMS

Well ordered two-dimensional monolayered films are of great interest because of the valuable insights they provide regarding molecule interactions and their potential application to important technologies related to coatings and surface modifications. The optical and electrical properties of [60]fullerene films are strongly affected by the deposition conditions, by impurities or disordered structures. Thus, the exploration of these properties requires the controlled incorporation of fullerenes in well defined two-dimensional arrays and three-dimensional networks. Extensive efforts have been undertaken, ranging from modifying the deposition conditions to applying amphiphilic host molecules, with the scope to generate stable and well ordered monolayered fullerene films [79,80,81,82,83,84,85,86,87,88,89,90,91 and 92]. The strong π – π interaction and the resulting tendency to form aggregates precludes, however, formation of stable monolayers and Langmuir–Blodgett films at the air–water interface and solid substrates, respectively. In essence, the currently available data suggest three promising approaches to overcome these fundamental difficulties: (i) amphiphilic functionalization of the hydrophobic fullerene core via covalent attachment of hydrophilic groups [93,94,95,96,97,98,99,100,101,102,103 and 104], (ii) reducing the hydrophobic surface via controlled multiple

functionalization [105,106 and 107] or (iii) self-assembly via electrostatic attractions of oppositely charged species [108].

The controlled functionalization of the fullerene core, at one or more positions by addends of different hydrophobicities, has been demonstrated to provide a viable alternative to control the supermolecular structures formed upon their spreading on the water surface. It was unequivocally demonstrated that choosing an adequate hydrophobic–hydrophilic balance is a fundamental aspect with regard to forming stable and monolayered fullerene composites. In particular, functionalization with hydrophilic addends, such as cryptates, triethyleneglycol monomethyl ether, benzocrowns, N-acetyl pyrrolidine derivatives, carboxylic acid groups and oxygen ($C_{60}O$), leads to the important promotion of the amphiphilic character of the fullerene core. A simple picture helps to rationalize the success of this concept: The hydrophilic or water-soluble head groups enhance the interaction with the aqueous subphase and, in turn, allow a two-dimensional fixation of the fullerene core at the air–water interface.

C1.2.8 ELECTROCHEMISTRY

One aspect that reflects the electronic configuration of fullerenes relates to the electrochemically induced reduction and oxidation processes in solution. In good agreement with the threefold degenerate LUMO, the redox chemistry of [60]fullerene, investigated primarily with cyclic voltammetry and Osteryoung square wave voltammetry, unravels six reversible, one-electron reduction steps with potentials that are equally separated from each other. The separation between any two successive reduction steps is $\sim 450 \pm 50$ mV. The low reduction potential (only -0.44 V *versus* SCE) of the process, that corresponds to the generation of the π -radical anion [31,109,110,111 and 112], deserves special attention.

In contrast to the relative ease of reduction, oxidation of fullerenes requires more severe conditions [113, 114]. Not only does the resonance stabilization raise the level of the corresponding oxidation potential (1.26 V *versus* Fc/Fc^+), but also the reversibility of the underlying redox process is affected [115].

This behaviour also stands for functionalized [60]fullerene derivatives, with, however, a few striking differences. The most obvious parameter is the negative shift of the reduction potentials, which typically amounts to ~ 100 mV. Secondly, the separation of the corresponding reduction potentials is clearly different. While the first two reduction steps follow closely the trend noted for pristine [60]fullerene, the remaining four steps display an enhanced separation. This has, again, a good resemblance to the HOMO–LUMO calculations, namely, a cancellation of the degeneration for functionalized [60]fullerenes [31, 116, 117].

The electrochemical features of the next higher fullerene, namely, [70]fullerene, resemble the prediction of a doubly degenerate LUMO and a LUMO + 1 which are separated by a small energy gap. Specifically, six reversible one-electron reduction steps are noticed with, however, a larger splitting between the fourth and fifth reduction waves. It is important to note that the first reduction potential is less negative than that of [60]fullerene [31]. Parallel to the shift that the reduction of higher fullerenes shows, oxidation of the latter is also made easier (D_{5h} [70] fullerene: $+1.20$ V *versus* Fc/Fc^+). The underlying HOMO LUMO gap in D_{5h} [70]fullerene (2.22 V) is, therefore, markedly decreased relative to [60]fullerene (2.32 V). This trend is further extended in D_2 [76]fullerene (1.64 V) C_{2v} [78]fullerene (1.72 V) and D_2/D_{2d} [84]fullerene (1.6 V) [32, 118]. In conclusion, higher fullerenes are better electron accepting and, at the same time, better electron donating materials relative to their smaller cousin, [60] fullerene.

Thin films of fullerenes, which were deposited on an electrode surface via, for example, drop coating, were largely heterogeneous, due to the entrapping of solvent molecules into their domains. Consequently, their electrochemical behaviour displayed different degrees of reversibility and stability depending on the time of electrolysis and the

number of consecutive redox cycles scanned. Langmuir–Blodgett films of pristine [60]fullerene, upon electrochemical reduction, formed insoluble films which stem from the immobilization of charge compensating counter-cations into the film. The large separation between the cathodic and anodic waves, indicative of a high degree of irreversibility, has been attributed to structural rearrangements upon the reduction and reoxidation process and documents the high disordering of the fullerene cores in LB films [91, 119, 120, 121, 122, 123 and 124].

C1.2.9 SOLUBILITY

The quasi-aromatic structure of fullerenes affects the solubility of these hydrophobic moieties. Typical representatives are nonpolar organic solvents, such as toluene, benzene and chlorinated hydrocarbons [25]. In toluene, benzene and o-xylene the solubility of [60]fullerene exhibits, surprisingly, a negative temperature dependence, along with a maximum of solubility around 280 K. On the other hand, polar solvents including alcohols and aqueous systems are of impractical use for investigating the physical and chemical properties of fullerenes [126, 127]. For example, in polar solutions the hydrophobic fullerene core aggregates spontaneously, yielding clusters with indefinite aggregate sizes and unknown properties that vary, in part, quite significantly from those of true fullerene monomers [128, 129]. This fullerene clustering has been monitored directly through dynamic light scattering and gel exclusion chromatography. An elegant route to overcome, in particular, the water-insolubility of fullerenes, is their incorporation into water-soluble superstructures. In this context, cyclodextrins [130, 131], calixarenes [132], various micellar [133, 134, 135 and 136] and vesicular host structures [137, 138, 139 and 140] were successfully utilized and the resulting complexes were studied under the aspect of photo-induced cytotoxicity and, if ^{14}C radiolabelled, as potential biochemical tracers [141].

C1.2.10 PHOTOEXCITED STATES

Another interesting physical feature relates to the chromophoric character of fullerenes. Based on the symmetry prohibitions, solutions of [60]fullerene absorb predominantly in the UV region, with distinct maxima at 220, 260 and 330 nm. In contrast to extinction coefficients on the order of $10^5 \text{ M}^{-1} \text{ cm}^{-1}$ at these wavelengths, the visible region shows only relatively weak transitions (λ_{max} at 536 nm; $\epsilon = 710 \text{ M}^{-1} \text{ cm}^{-1}$) [142].

Similar to the fullerene ground state the singlet and triplet excited state properties of the carbon network are best discussed with respect to the three-dimensional symmetry. Surprisingly, the singlet excited state gives rise to a low emission fluorescence quantum yield (Φ_{FLU}) of 1.0×10^{-4} [143]. Despite the highly constrained carbon network, the low Φ value relates to the combination of a short lifetime (1.8 ns) [144], a quantitative intersystem crossing ($\Phi_{\text{ISC}} = 1$) [145] and, finally, the symmetry forbidden nature of the lowest energy transition. To the same extent, also the phosphorescence quantum yield ($\Phi_{\text{PHO}} < 10^{-6}$) [146] is strongly impacted by the spherical structure.

Concerning transient absorption, laser or light excitation throughout the UV–visible region leads to the generation of the singlet excited state. The latter gives rise to a characteristic singlet–singlet absorption, maximizing around 920 nm [144], whose lowest vibrational state has an energy of 1.99 eV. Once formed, the singlet excited state undergoes

a rapid and, more importantly, a quantitative intersystem crossing to the energetically lower lying triplet excited state. The lowest triplet excited state has an energy of $\sim 1.57 \text{ eV}$ [147, 148]. In the case of [60]fullerene, this intersystem crossing takes place with a lifetime of 1.8 ns, governed by a large spin–orbit coupling which makes this process much faster than those known for two-dimensional rigid hydrocarbons. On the other hand, the fast ISC rate and the weak fluorescence provide the means for a triplet quantum yield (Φ_{TRIPLET}) close to unity.

The triplet–triplet absorption spectrum reveals, similar to the singlet–singlet features, a maximum in the near-IR

region around 750 nm [149]. In the absence of alternative deactivation processes, such as triplet–triplet annihilation and also ground-state quenching, the triplet lifetime amounts to ~100 μ s and is, again, much shorter than the triplet lifetime of comparable planar hydrocarbons [150, 151]. In this context, it is interesting to note that the highly constrained carbon network, particularly that of [60]fullerene, prohibits any vibrational motion, C–C bond elongation, or even changes of the dipole moment that may accelerate the deactivation of the singlet or triplet excited states. This argument is further substantiated by a small Stokes effect [152], which correlates to the energetic adaptation of the excited state to a new solvent environment, and also insignificant resonance Raman shifts [153] upon reduction of the fullerene core.

In aerated or oxygen saturated solutions, the fullerene triplet lifetime suffers a marked reduction [147, 148]. Luminescence studies (at 1365 nm) helped to identify singlet oxygen ($^1\text{O}_2$) as a product evolving from a bimolecular, Dexter-type energy transfer reaction. Particularly promising is the quantum yield for the singlet oxygen formation, which is near unity [147, 148]. In other words, the fullerene triplet excited state is quantitatively converted into this biologically important oxygen species. Corresponding experiments with functionalized [60] fullerene derivatives that display sufficient water solubility in the absence of a host structure, such as $\text{C}_{60}[\text{C}(\text{COO}^-)_2]_2$, $\text{C}_{60}[\text{C}(\text{COO}^-)_2]_3$, $\text{C}_{60}[(\text{CH}_2)_4\text{SO}_3\text{Na}]_6$ and $\text{C}_{60}(\text{OH})_{18}$, corroborated the efficient formation of singlet oxygen also in aqueous solutions [154, 155]. This, of course, evoked a tremendous interest to probe fullerenes as a potential agent for photodynamic therapy. Encouraging results stem from the strong cytotoxicity to L929 upon visible light irradiation as a result of superoxide production [141].

There are, indeed, many biological implications that have been triggered by the advent of fullerenes. They range from potential inhibition of HIV-1 protease, synthesis of drugs for photodynamic therapy and free radical scavenging (antioxidants), to participation in photo-induced DNA scission processes [156, 157, 158, 159, 160, 161, 162 and 163]. These examples unequivocally demonstrate the particular importance of water-soluble fullerenes and are summarized in a few excellent reviews [141, 175].

Another application is optical limiting [164, 165]. This is performed by materials whose transmittance strongly and quickly drops as the intensity of a laser pulse traversing them increases beyond a saturation level. The reverse saturable absorption mechanism is assumed to be the major parameter that determines the optical limiting. This mechanism plays an active role when an excited state, that is efficiently populated by optical excitation, has an absorption cross-section larger than that of the ground state at the excitation wavelength. In this light, the weak broad absorption of [60]fullerene throughout the UV–visible spectrum is beneficial to excite the ground state. Most importantly, both excited states, e.g. the singlet and triplet state, display cross sections significantly larger than that of the singlet ground state all over the accessible visible and near-IR spectrum. Consequently, the reverse saturable absorption that occurs with samples of pristine [60]fullerenes and functionalized [60]fullerene derivatives during the picosecond time regime and also on the nano-/microsecond time scales is attributed to emerging from the lowest singlet and triplet excited state, respectively. In particular, sol–gel films of [60]fullerene and some derivatives exhibit a marked enhancement in the red spectral region.

C1.2.11 π -RADICAL ANIONS

The most important species among the reduced fullerenes (π -radical anions to hexa-anions) are the one-electron reduced forms. In general, various techniques were employed for their characterization, ranging from transient absorption spectroscopy [166, 167 and 168] to transient electron spin resonance spectroscopy [111, 112, 167, 169, 170, 171 and 172]. The absorption features of [60], [70], [76], [78] and [84]fullerene π -radical anions, which lie predominantly in the near-IR region, are unmistakably confirmed [173]. For example, the [60]fullerene π -radical anion shows a narrow band around 1080 nm which serves as a diagnostic probe for the identification of this one-electron reduced species and, furthermore, allows an accurate analysis of inter- and intramolecular ET dynamics in [60]fullerene containing systems. This cannot be concluded for the interpretation of the ESR signals, which are still subject to a controversially conducted discussion favouring either a narrow or, alternatively, a broad ESR feature [111, 112, 167, 169, 170, 171 and 172]. A recent hypothesis proposes, in essence, a narrow ESR line for the π -radical anion which, upon rapid dimerization, undergoes a significant line broadening [169, 170]. It remains,

however, to be shown by different techniques such as, for example, time-resolved pulse radiolysis coupled with an ESR detector which assumption can be trusted.

C1.2.12 ELECTRON TRANSFER REACTIONS

The combination of a high degree of electron delocalization within the fullerene's π -system and their effective sizes prompts the application of this carbon material as new electron accepting moieties (figure C1.2.9). More importantly, the total reorganization energy upon reduction has been shown to be relatively small [174]. Hence, fullerenes became very appealing spheres for inter- and intramolecular electron transfer processes under the aspect of energy conversion and energy storage [175, 176 and 177].

A specific case that attracted a lot of attention encompasses the intermolecular electron transfer from a series of arene radical cations to [76] and [78]fullerene [178]. The high degree of charge and energy delocalization within the fullerene moiety is expected to exert an effect in the desired direction as it minimizes vibrational differences between the reaction partners in the ground and transition state. The corresponding relation between the rate constant and the thermodynamic driving force follows the features of a parabola, i.e. the electron transfer rates increase only to a maximal value before they decrease noticeably at higher driving forces. This kinetic study made use of the unequally sized reaction partners, namely, a large-sized electron donor and small-sized electron acceptor couple, elevating the diffusion-controlled limit. Furthermore, the relatively low reorganization energy is clearly beneficial for the possibility to establish a Marcus-inverted behaviour which facilitates reaching the maximum of the exothermic electron transfer process at lower $-\Delta G$ and, in turn, reaching the inverted region at lower energy. This example is one of the rare cases that establish a 'Marcus-inverted' region in a bimolecular electron transfer, beside those reports on the geminate recombination of photolytically generated radical pairs.

Figure C1.2.9. Schematic representation of photoinduced electron transfer events in fullerene based donor-acceptor arrays (i) from a TTF donor moiety to a singlet excited fullerene and (ii) from a ruthenium excited MLCT state to the ground state fullerene.

The redox properties of pristine fullerenes and monofunctionalized fullerene derivatives in their ground and excited states have drawn much attention for the design of devices such as molecular switches, receptors, photoconductors and photoactive dyads [175, 176 and 177]. These applications are generally based on the implication of fullerenes as a multifunctional electron storage moiety. The excellent electron accepting properties of fullerenes, together with their low reorganization energy, makes [60]fullerene and its derivatives good candidates for building blocks of systems employable for solar energy conversion, batteries and photovoltaics. The concept of linking fullerenes to a number of interesting electro- or photoactive species offers new opportunities in the preparation of materials with building blocks having highly symmetrical and coordinating geometries.

-17-

The chemically simplest case encompasses the covalent attachment of addends that lack any visible absorption and are as such redox inactive, but may indirectly influence electron or energy transfer reactions. Of increasing complexity are arrays carrying electroactive addends, e.g. in *N,N* dimethylaniline (DMA) [179, 180], ferrocene (Fc) [181] or tetrathiofulvalene (TTF) (figure C1.2.10) [182]. In these multicomponent supermolecules, the fullerene core is implemented as a photosensitizer that sequentially accepts an electron from the adjacent electroactive moiety. Accordingly, these systems can be classified as electroactive, but due to their insignificant visible absorption characteristics, photoinactive dyads. Considering the moderate absorption features of [60]fullerene in the visible region, functionalization with antenna molecules, such as metalloporphyrins [183, 184, 185, 186, 187, 188, 189, 190, 191, 192, 193 and 194] or MLCT transition metal complexes [195, 196 and 197], have developed as important objectives to promote the visible absorption characteristics of the resulting dyads and, most importantly, to improve the light harvesting efficiency of the fullerene core (figure C1.2.10). As a direct consequence, the role of the fullerene is significantly changed. Under these circumstances fullerenes operate exclusively as either electron or energy acceptor moieties. For details, the reader is directed to a series of excellent review articles, which appeared during recent years [175, 176 and 177].

C1.2.13 ENDOHEDRAL FULLERENES

Finally, endohedral fullerenes are discussed. They attracted considerable attention for their potential use as superconductors, organic ferromagnets and magnetic resonance imaging agents (MRI). The enthusiasm that has arisen is based, in part, on the fact that the carbon network of each fullerene surrounds a large empty space which, in turn, renders it capable of encapsulating atomic particles. Furthermore, these novel materials created the stimulating possibility to fine-tune the fullerene's physical and chemical properties via systematic substitution of the embedded metal species. In general, two approaches are pursued to incorporate the metal into the fullerene's interior. The first one implies the synergetic utilization of the arc discharge method of carbon rods in the presence of metal carbides [198, 199]. Thus, the metal is present during the genesis of the fullerene network and can be scavenged by the closing sphere. In contrast to this approach, the second alternative involves the chemically induced opening of the carbon network, stuffing of the vacant interior with metals, and, in the last step, the subsequent re-closing of the open sphere [200]. It should be emphasized that the latter concept is a very challenging endeavour from the standpoint of synthesis. In fact, so far only the first route has led to isolable yields of endohedral fullerenes.

Metallofullerenes are commonly found with [74], [76], [80] and [82] fullerene and span composites that have a single ($M@C_{82}$), two ($M_2@C_{82}$) or even three metal atoms ($M_3@C_{82}$) encapsulated. The first type of metallofullerene extracted from fullerene soot was lanthanum fullerene $La@C_{82}$ followed a short time later by the detection of scandium fullerene $Sc@C_{82}$ and yttrium fullerene $Y@C_{82}$ [201, 202 and 203]. These have been completed by essentially all alkali metals, alkali-earth metals, noble gases and rare-earth metals (figure C1.2.11) [204, 205, 206, 207, 208, 209, 210, 211, 212, 213, 214, 215, 216, 217, 218, 219 and 220].

Figure C1.2.11. Synthesized and isolated endohedral fullerenes.

There has been a long dispute on the endo- or exohedral nature of such metallofullerenes. Experimental evidence including scanning tunnelling microscopy, extended x-ray absorption fine structure and transmission electron microscopy confirmed unequivocally the endohedral structure of these fullerene composites [204, 205, 206, 207, 208, 209, 210, 211, 212, 213, 214, 215, 216, 217 and 218]. On the other hand, ESR has been proven to be the method of choice to investigate the electronic state [210, 221, 222 and 223]. Spectral evidence from the latter technique demonstrates that the encaged metal atom transfers a significant amount of charge to the carbon cage.

The most recent success in light of stuffing the fullerene's interior and using it as a carrier is the stabilization of atomic nitrogen and phosphorus inside [60]fullerene [9, 224]. Particularly, the remarkable stability of the $N@C_{60}$ system led the researchers to postulate a Faraday-cage-like property of the carbon network. EPR and ENDOR experiments, in combination with the stability of the system in air, clearly demonstrate that the nitrogen is incorporated into the fullerene interior and that, furthermore, it sustains completely its atomic ground state configuration [9]. The spherical symmetry of $N@C_{60}$, as, for example, derived from the absence of anisotropic hyperfine interaction, is interpreted as a strong indicator for the fixation of the nitrogen in the centre of [60] fullerene. In addition, the centre position is substantiated by potential energy calculations suggesting that the highly reactive nitrogen atom is trapped and shielded from the surroundings.

The noble-gas fullerene compounds have no chemical bond between the gas atom and the carbon atoms, yet they are also extremely stable, since the gas atom simply cannot escape from the fullerene cage. In this light, the recently introduced ^3He NMR spectroscopy of endohedral $\text{He}@C_{60}$ is bound to become a major experimental tool to study the structure and reactions of fullerenes [225, 226].

C1.2.14 CONCLUDING REMARKS

Recently, considerable advances have been made in the production of a different class of nanoscopic carbon structures, namely, carbon nanotubes, which stimulated fundamental research exploring the structure–property relationship of these materials [227]. In their simplest form carbon nanotubes are composed of only a single cylindrical graphene shell with a central hollow internal cavity. These structurally uniform cylinders are invariably sealed at both ends by bended carbon caps, which contain both five- and six-membered rings similar to the structures of fullerenes. Based on their similarity with highly graphitized carbonaceous materials, nanotubes have low chemical reactivity. Therefore, the chemistry of carbon nanotubes is mainly focused on opening reactions at its

caps to enable filling of the hollow cavity with electron conducting material. In contrast, the tubewalls are practically nonreactive. These materials are promising candidates for future applications ranging from catalysis to separation and storage technology to electronics and accordingly warrant appropriate attention.

C1.3 Van der Waals molecules

Jeremy M Hutson

C1.3.1 INTRODUCTION

The attractive forces between pairs of atoms or molecules are almost always strong enough to support bound vibrational states. The resulting molecular complexes, or *Van der Waals molecules*, are very weakly bound, and are easily destroyed by collisions with other molecules. They exist in small but significant concentrations in gases and gas mixtures: for example, in Ar gas at 120 K and 1 bar, about 0.4% of the atoms are present as bound dimers [1]. The dimer concentrations decrease with increasing temperature, but are larger for systems with stronger attractive forces, such as most systems containing polar molecules.

Van der Waals complexes can be observed spectroscopically by a variety of different techniques, including microwave, infrared and ultraviolet/visible spectroscopy. Their existence is perhaps the simplest and most direct demonstration that there are attractive forces between stable molecules. Indeed the spectroscopic properties of Van der Waals complexes provide one of the most detailed sources of information available on intermolecular forces, especially in the region around the potential minimum. The measured rotational constants of Van der Waals complexes provide information on intermolecular distances and orientations, and the frequencies of bending and stretching vibrations provide information on how easily the complex can be distorted from its equilibrium conformation. In favourable cases, the whole of the potential well can be mapped out from spectroscopic data.

Studies of Van der Waals complexes have provided a wealth of information on the properties of weak non-chemical bonds. They have allowed the determination of complete potential energy surfaces for small systems, and have thrown considerable light on the nature of the hydrogen bond. Studies of larger clusters have begun to provide information of relevance to the liquid state, and to explain the behaviour of hydrogen-bonded networks. Studies of clusters containing reactive species are now starting to throw new light on the dynamics of chemical reactions. All these examples will be discussed in more detail below.

C1.3.2 TYPES OF SPECTROSCOPY

The spectroscopic signatures of Van der Waals complexes were first observed by Vodar and co-workers in the late 1950s [2], as broad features in the ‘missing Q-branch’ regions of the spectra of hydrogen halides and their mixtures at high pressures. Rank *et al* [3] subsequently observed irregular but fairly sharp features between the monomer vibration–rotation lines at lower pressures. The lines were attributed to dimers because their intensity increased quadratically with the gas pressure. Many attempts were made to obtain resolved spectra that could be analysed reliably. However, the basic problem at the time was that, at the pressures needed to obtain substantial concentrations of dimers, there was so much pressure broadening that the monomer lines swamped the spectra of the dimers. As the pressure was reduced, the dimer lines became somewhat sharper and the accessible region between the monomer lines increased, but the dimer spectra soon became too weak to observe above the noise.

-2-

Greater success was achieved for complexes formed from homonuclear diatoms such as H_2 and N_2 , for which monomer infrared transitions are forbidden by dipole selection rules. Complexes containing such molecules do have an infrared spectrum, because the quadrupole moment of the homonuclear monomer creates an electric field, which induces a dipole moment in the attached atom or molecule. In particular, rotationally resolved spectra were obtained for several complexes formed from H_2 and rare gases [4, 5]; these complexes have unusually large rotational constants because of the presence of H_2 . Spectra were also obtained for analogous complexes containing D_2 and HD. They were used to obtain a succession of intermolecular potentials for H_2 –Ar, H_2 –Kr and H_2 –Xe, of steadily increasing sophistication and accuracy [6, 7 and 8]. It was possible to determine not only the radial dependence of the potential, but also its dependence on intermolecular angle θ (anisotropy) and on the monomer bond length r .

A major breakthrough in the spectroscopy of Van der Waals complexes came in 1972, when Dyke, Howard and Klemperer [9] succeeded in measuring the microwave spectrum of $(HF)_2$ in a molecular beam. Such experiments are described in detail in the chapter on *Jet Spectroscopy*. In a typical molecular beam spectroscopy experiment, gas at around 1 bar pressure is expanded into a vacuum through a nozzle of aperture around 50 μm . Under these conditions, the gas molecules undergo many collisions during the expansion, and the collisions equalize the velocities of the different molecules. This is often referred to as a *supersonic* expansion. At the end of the expansion, nearly all of the random thermal energy of the gas molecules has been converted into ordered translational motion of the beam; all the molecules have almost the same velocity, and the relative velocities are very low. The beam itself, beyond the expansion region, is a nearly collision-free environment. The low relative velocities correspond to very low effective translational temperatures: temperatures of 1–10 K are common in molecular beam spectroscopy experiments. The populations of rotational and vibrational levels do not relax as fast as translation; rotational and vibrational distributions are sometimes characterized by higher temperatures, or may

not follow a Boltzmann distribution at all. In most cases, the rotational distribution is nearly as cold as the translational distribution, while the vibrational temperature is somewhere between the translational temperature and the source temperature. In any case, the effective temperature of the beam is low enough for large concentrations of complexes to be formed, and the complexes are mostly in their ground vibrational state.

C1.3.2.1 MICROWAVE SPECTROSCOPY

Klemperers' early microwave experiments on Van der Waals complexes used molecular beam electric resonance (MBER) spectroscopy, which relies on the fact that a beam of molecules with permanent dipole moments can be focused by an inhomogeneous electric field. Because of the Stark effect, the energy of a dipolar molecule in an electric field depends on the field strength. A MBER spectrometer usually uses a quadrupolar field; the beam is passed down the centre of a set of four parallel rods with alternating positive and negative voltages. This arrangement gives no electric field along the central axis, but the field increases linearly away from the axis. For a molecule in a state with a positive quadratic Stark effect, the energy thus increases quadratically with displacement from the centre; this creates a linear restoring force, so that a beam of such molecules is focused by the rods.

A MBER spectrometer is shown schematically in [figure C1.3.1](#). The technique relies on using two inhomogeneous electric fields, the A and B fields, to focus the beam. Since the Stark effect is different for different rotational states, the A and B fields can be set up so that a particular rotational state (with a positive Stark effect) is focused onto the detector. In MBER spectroscopy, the molecular beam is irradiated with microwave or radiofrequency radiation in the

-3-

central region (C field); any molecule which undergoes a rotational transition to a state with a negative Stark effect will not be focused by the B field, and will not reach the detector. Thus a transition is detected by monitoring the molecular beam flux as a function of the irradiation frequency. A mass spectrometer is usually used as the beam detector, allowing straightforward discrimination between monomers and Van der Waals complexes.

Figure C1.3.1. Schematic diagram of a molecular beam electric resonance spectrometer. (Taken from [60].)

An enormous range of complexes has been observed by MBER spectroscopy. Almost any pair of volatile compounds can be expanded through a nozzle and made to form complexes. In spectroscopic experiments, it is common to use around 1% of the sample gases in a buffer gas such as Ar, in order to minimize the formation of trimers and larger complexes. The restrictions on the technique are that the constituent molecules must be volatile and that the complex must have a dipole moment. In addition, for very large complexes, even the temperature of a molecular beam is high enough that a large number of rotational states are populated. The sensitivity of MBER relies on being able to deplete the beam intensity significantly by removing the molecules in a single rotational state. Thus, if the rotational partition function is very high, MBER may not be sensitive enough for spectra to be detected.

A few Van der Waals complexes have been observed using the analogous technique of molecular beam *magnetic* resonance, in which the molecules are focused using a magnetic rather than an electric field.

An alternative approach to obtaining microwave spectroscopy is Fourier transform microwave (FTMW) spectroscopy in a molecular beam [10]. This may be considered as the microwave analogue of Fourier transform NMR spectroscopy. The molecular beam passes into a Fabry–Perot cavity, where it is subjected to a short microwave pulse (of a few milliseconds duration). This creates a macroscopic polarization of the molecules. After the microwave pulse, the time-domain signal due to coherent emission by the polarized molecules is detected and Fourier transformed to obtain the microwave spectrum.

Microwave studies in molecular beams are usually limited to studying the ground vibrational state of the complex. For complexes made up of two molecules (as opposed to atoms), the intermolecular vibrations are usually of relatively low amplitude (though there are some notable exceptions to this, such as the ammonia dimer). Under these circumstances, the methods of classical microwave spectroscopy can be used to determine the structure of the complex. The principal quantities obtained from a microwave spectrum are the rotational constants of the complex, which are conventionally designated A , B and C in decreasing order of magnitude: there is one rotational constant B for a linear complex, two constants (A and B or B and C) for a complex that is a symmetric top and three constants (A , B and C) for an

-4-

asymmetric top. The rotational constants are related to the moments of inertia of the complex. For a rigid complex, the rotational constants are simply

$$A = \frac{h^2}{2I_A} \quad B = \frac{h^2}{2I_B} \quad C = \frac{h^2}{2I_C} \quad (\text{C1.3.1})$$

where I_A , I_B and I_C are the moments of inertia of the complex about its three principal axes. If the structures of the free monomers are assumed to be unchanged in the complex, then the number of coordinates required to define a ‘structure’ varies from one (for an atom–atom complex) to six (for a complex formed from two nonlinear molecules) as shown in figure C1.3.2. The rotational constants obtained for a single isotopic species are thus not usually enough to determine the structure of the complex, and it is usual to measure spectra for several isotopically substituted species.

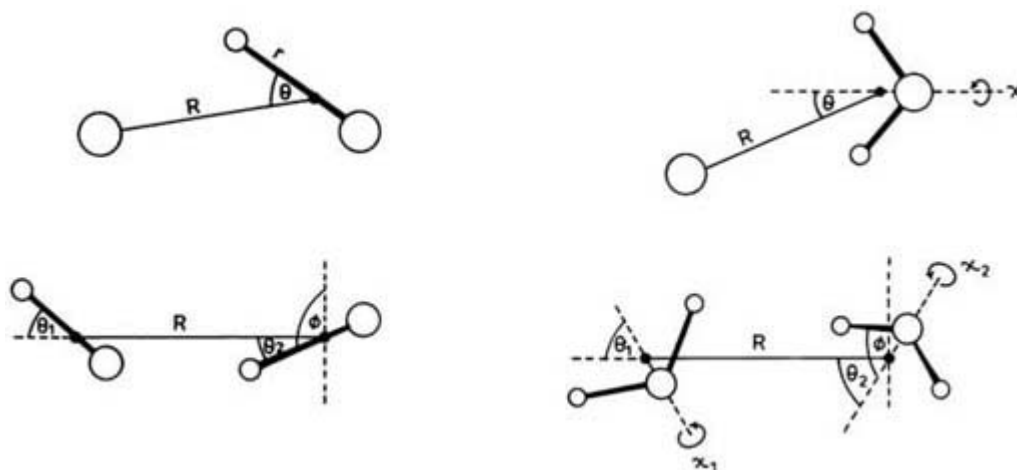

Figure C1.3.2. Coordinate systems used for intermolecular potential energy surfaces. (Taken from [60].)

The use of isotopic substitution to determine structures relies on the assumption that different isotopomers have the same structure. This is not nearly as reliable for Van der Waals complexes as for chemically bound molecules. In particular, substituting D for H in a hydride complex can often change the amplitudes of bending vibrations substantially; under such circumstances, the idea that the complex has a single ‘structure’ is no longer appropriate and it is necessary to think instead of motion on the complete potential energy surface; a well defined equilibrium structure may still exist, but knowledge of it does not constitute an adequate description of the complex.

There are other important properties that can be measured from microwave and radiofrequency spectra of complexes. In particular, the dipole moments and nuclear quadrupole coupling constants of complexes may contain useful information on the structure or potential energy surface. This is most easily seen in the case of the dipole moment. The dipole moment of the complex is a vector, which may have components along all the principal inertial axes.

-5-

Measurements of Stark splittings in microwave and radiofrequency spectra allow these components to be determined. The main contribution to the dipole moment of the complex arises from the permanent dipole moment vectors of the monomers, which project along the axes of the complex according to simple trigonometry (cosines). Thus, measurements of the dipole moment convey information about the orientation of the monomers in the complex. It is of course necessary to take account of effects due to induced dipole moments and to consider whether the effects of vibrational averaging are important.

The argument for nuclear quadrupole coupling constants is similar, except that they are second-rank tensors rather than vectors and so different angular functions (involving second Legendre polynomials, or squares of cosines) are involved in the projections. Nuclear quadrupole coupling constants have the advantage that induced effects are usually very small, so that they contain uncontaminated angular information.

When a complex rotates, it stretches slightly and may also undergo other small structural changes. These changes are reflected in centrifugal distortion constants, which can be extracted from microwave (or other) spectra. The centrifugal distortion constants contain useful information on intermolecular forces, because they measure how easily the complex is distorted; in essence, they reflect the force constants for the bending and stretching vibrations.

It is also possible to measure microwave spectra of some more strongly bound Van der Waals complexes in a gas cell rather than a molecular beam. Indeed, the first microwave studies on molecular clusters were of this type, on carboxylic acid dimers [11]. The resolution that can be achieved is not as high as in a molecular beam, but bulk gas studies have the advantage that vibrational satellites, due to pure rotational transitions in complexes with intermolecular bending and stretching modes excited, can often be identified. The frequencies of the vibrational satellites contain information on how the vibrationally averaged structure changes in the excited states, while their intensities allow the vibrational frequencies to be estimated.

C1.3.2.2 INFRARED SPECTROSCOPY

As described above, classical infrared spectroscopy using grating spectrometers and gas cells provided some valuable information in the early days of cluster spectroscopy, but is of limited scope. However, the advent of tunable infrared lasers in the 1980s opened up the field and made rotationally resolved infrared spectra accessible for a wide range of species. As for microwave spectroscopy, tunable infrared laser spectroscopy has been applied both in gas cells and in molecular beams. In a gas cell, the increased sensitivity of laser spectroscopy makes it possible to work at much lower pressures, so that strong monomer absorptions are less troublesome.

The intermolecular bending and stretching vibrations of Van der Waals complexes typically have wave-numbers between 20 cm^{-1} and 200 cm^{-1} . At the temperatures used in gas cells, usually between 77 K and 300 K, many complexes are in excited vibrational states. In addition, since most complexes (other than those of He and H_2) have rotational constants that are 0.1 cm^{-1} or less, very long rotational progressions (up to $J = 100$) are often observed. Spectra obtained in gas cells can thus be very congested and quite difficult to assign reliably. Nevertheless, the large number of excited states produces a very rich spectrum, and it is sometimes possible to characterize excited states that would not otherwise be accessible.

Infrared spectroscopy can also be carried out in molecular beams. The primary advantages of beam spectroscopy are that it dispenses almost entirely with monomer absorptions that overlap regions of interest, and that the complexes are

internally cold, so that the spectrum is very much simplified. The latter advantage is illustrated in figure C1.3.3 which compares infrared spectra of Ar-HF obtained in a gas cell and in a molecular beam, using a tunable difference frequency laser as the light source in each case.

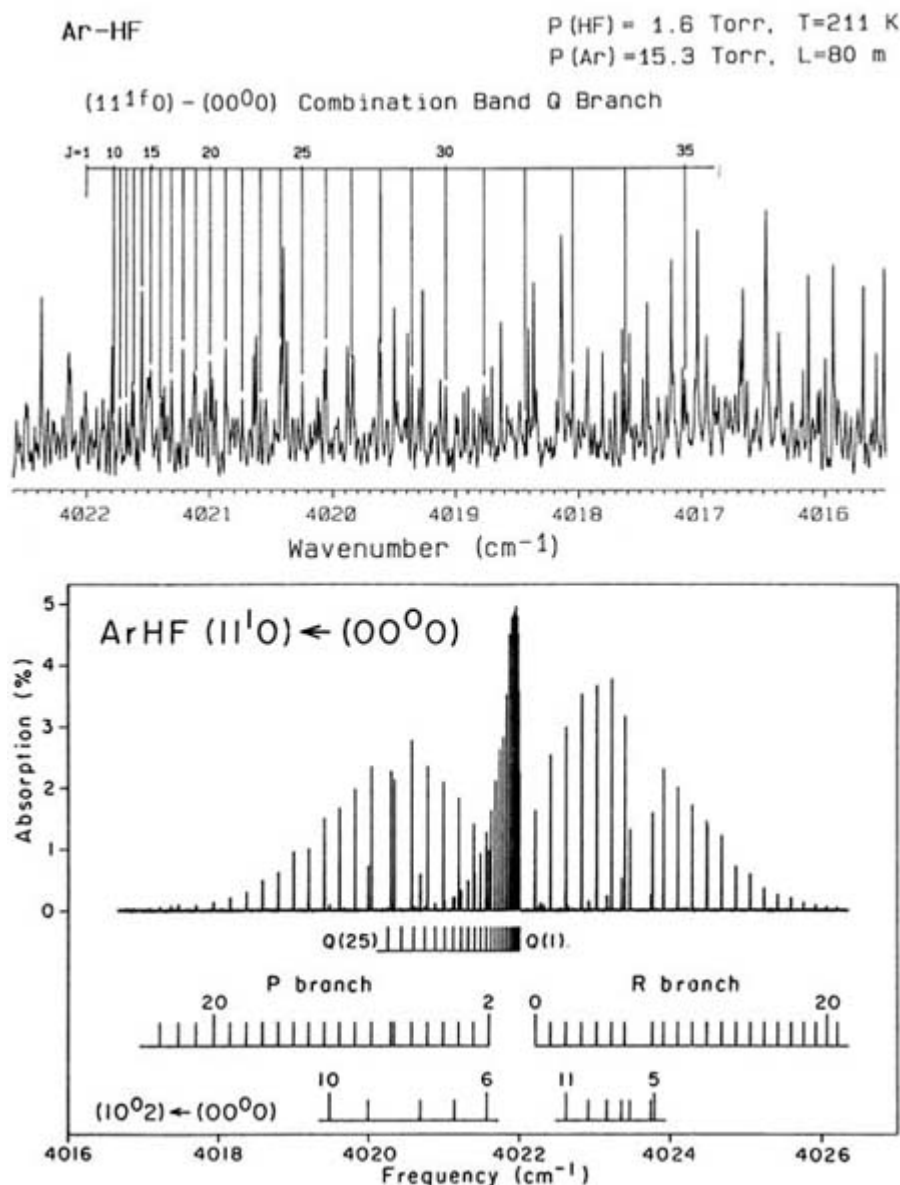

Figure C1.3.3. Comparison between infrared spectra for the p bend combination band of Ar-HF obtained in the gas phase and in a slit jet. (a) The gas-phase spectrum (Taken from [36]). (b) The slit jet spectrum (Taken from [61]).

The earliest molecular beam infrared experiments on Van der Waals complexes used photodissociation spectroscopy: a molecular beam is irradiated with a tunable infrared laser and the molecular beam intensity is measured as a function of

laser frequency [12]. The original experiments did not use state selection, and monitored the beam intensity using a bolometer, which measures the total energy that is deposited by the molecules that reach it. Since complexes in vibrationally excited states usually undergo fast vibrational predissociation, and the recoil velocities are such that the fragments are ejected from the beam and do not reach the detector, transitions involving complexes are detected

as a *decrease* in the energy flux reaching the bolometer. This allows complexes to be distinguished from monomers, which reach the detector undissociated, and produce a positive signal because the energy absorbed from the photon is deposited on the bolometer. Photodissociation experiments have proved to be a very rich source of information, not only on energy levels but also on predissociation dynamics, because the fragments that leave the beam can be detected and their internal states inferred.

One problem with molecular beam techniques is that, although the concentration of complexes is high, the available path length is very low. For some time this precluded the observation of spectra in molecular beams by the conventional spectroscopic approach of monitoring the attenuation in the laser beam intensity caused by absorption. In order to overcome this, Nesbitt and co-workers [13] developed techniques using molecular beams expanded through a slit rather than a circular hole. This provides much longer path lengths, and makes it possible to carry out direct absorption experiments, monitoring the depletion in laser beam intensity (as in a normal spectrometer) rather than the molecular beam intensity.

Most infrared spectroscopy of complexes is carried out in the mid-infrared, which is the region in which the monomers usually absorb infrared radiation. Van der Waals complexes can absorb mid-infrared radiation either with or without simultaneous excitation of intermolecular bending and stretching vibrations. The mid-infrared bands that contain the most information about intermolecular forces are *combination bands*, in which the intermolecular vibrations are excited. Such spectra map out the vibrational and rotational energy levels associated with monomers in excited vibrational states and, thus, provide information on interaction potentials involving excited monomers, which may be slightly different from those for ground-state molecules.

It is thus of great interest to carry out experiments that excite the intermolecular bending and stretching vibrations directly, without exciting the monomers as well. These transitions lie deep in the far infrared, typically in the 20–200 cm^{-1} region, and this has traditionally been a very difficult region for spectroscopy. Fourier transform spectroscopy in gas cells can be applied to obtain rotationally resolved spectra of complexes in this region [14], and it is also possible to measure far-infrared spectra in molecular beams. Early work [15, 16] used laser Stark spectroscopy, in which the molecules were tuned into resonance with the laser by applying a Stark field. However, this was superseded by methods using tunable far-infrared lasers, based on nonlinear mixing of fixed-frequency molecular lasers with microwave radiation [17]; these make it possible to obtain zero-field far-infrared spectra of complexes, which are much easier to interpret than laser Stark spectra.

Mid-infrared combination bands and far-infrared spectra of Van der Waals complexes map out the pattern of energy levels associated with intermolecular bending and stretching vibrations. The principal quantities that can be observed are vibrational frequencies and rotational constants, though once again subsidiary quantities such as centrifugal distortion constants, dipole moments and nuclear quadrupole coupling constants may sometimes be extracted. In addition, observation of line broadening due to predissociation can sometimes provide very direct measurements of binding energies (and hence of the depths of potential wells).

For chemically bound molecules, it is usual to analyse the vibrational energy levels in terms of *normal modes*: a non-linear (or linear) molecule with N atoms has $3N - 6$ (or $3N - 5$) vibrational degrees of freedom. There is a

-8-

fundamental frequency ν_i associated with each degree of freedom i . The vibrational energy levels may be labelled with a quantum number v_i for each normal mode and, to a first approximation, the energy is given by the harmonic expression

$$E_v = \sum_{i=1}^{3N-6(\text{or } 5)} h\nu_i (v_i + \frac{1}{2}). \quad (\text{C1.3.2})$$

For quantitative work, it is necessary to include anharmonic corrections and coupling between the normal modes, but the general picture suffices to handle the lower vibrational levels of most near-rigid molecules.

Unfortunately, the normal-mode picture is quite inadequate for many Van der Waals complexes, even in their lowest few levels. This may be illustrated by considering the bending levels of Ar–HCl, which are shown in [figure C1.3.4](#). The equilibrium geometry of Ar–HCl is linear, so it has one doubly degenerate bending mode. In a normal-mode picture, the vibrational levels would be labelled by a bending quantum number ν and a vibrational angular momentum l (or K). The normal-mode energy level pattern is shown on the right-hand side of [figure C1.3.4](#). The ground state has $\nu^K = 0^0$, while the first excited state has $\nu^K = 1^{\pm 1}$. The $\nu = 2$ excited states lie at about twice the energy of the $1^{\pm 1}$ states and are split into components with $\nu^K = 2^0$ and $2^{\pm 2}$. The actual levels of the complex clearly have a quite different pattern; in particular, the lowest excited state with $K = 0$ lies *below* the lowest $K = \pm 1$ level, not above it. The pattern observed in the complex is in fact much closer to that expected for an HCl molecule undergoing nearly free internal rotation in the complex, shown in the centre of [figure C1.3.4](#). In the free-rotor limit, the HCl energy levels are simply $bj(j + 1)$, where b is the rotational constant of HCl and j is the rotational quantum number for HCl internal rotation (not overall rotation of the complex). In the presence of potential anisotropy, j becomes quantized along the intermolecular axis with a projection quantum number K , which can take integer values up to $\pm j$. In a complex such as Ar–HCl, the splittings between the different K levels for a given value of j are substantial, but the general picture of hindered internal rotation is considerably closer to the truth than the normal-mode picture of low-amplitude vibrations about an equilibrium geometry. A full analysis of the energy level pattern can provide very detailed information on the anisotropic potential energy surface [18].

-9-

Figure C1.3.4. The real pattern of intermolecular bending energy levels for Ar–HCl (left) compared with the pattern expected for a free internal rotor (centre) and a near-rigid bender (right). The allowed transitions are shown in each case. (Taken from [19].)

The quantum numbers that are appropriate to describe the vibrational levels of a quasilinear complex such as Ar–HCl are thus the monomer vibrational quantum number ν , an intermolecular stretching quantum number n and two quantum numbers j and K to describe the hindered rotational motion. For more rigid complexes, it becomes appropriate to replace j and K with normal-mode vibrational quantum numbers, though there is an awkward intermediate regime in which neither description is satisfactory: see [3] for a discussion of the transition between the two cases. In addition, there is always a quantum number J for the total angular momentum (excluding nuclear spin). The total parity (symmetry under space-fixed inversion of all coordinates) is also a conserved quantity that is spectroscopically important.

C1.3.2.3 PHOTODISSOCIATION AND PREDISSOCIATION

The binding energy of a Van der Waals complex is usually considerably less than the energy of a mid-infrared photon. Accordingly, Van der Waals complexes containing vibrationally excited monomers usually have enough energy to dissociate, by converting the vibrational energy into relative translational energy of the fragments. This process is referred to as *vibrational predissociation*.

For complexes such as Ar-H₂, Ar-HF and Ar-HCl, vibrational predissociation is a very slow process and does not cause appreciable broadening of the lines in the infrared spectrum. Indeed, for Ar-HF, Huang *et al* [20] showed that

-10-

vibrationally excited molecules survive for at least 0.3 ms, and reach a bolometric beam detector undissociated. However, for heavier monomers and more strongly bound complexes, vibrational predissociation can be much faster and lead to observable line broadening in the spectrum. The predissociation lifetime τ and linewidth γ (full width at half maximum, in energy units) are related by

$$\tau = \frac{\hbar}{\gamma}. \quad (\text{C1.3.3})$$

Spectra of two different bands of (HF)₂, showing the difference between predissociated and undissociated spectra [21], are shown in figure C1.3.5

The occurrence of predissociation opens up a new family of observable quantities. It is possible to measure not only linewidths or lifetimes, but also the internal state distributions of the fragments. All these quantities are sensitive to the intermolecular potential and can be used to test or refine proposed potential surfaces.

Figure C1.3.5. Spectra of two different infrared bands of HF dimer, corresponding to excitation of the 'bound' (lower panel) and 'free' (upper panel) HF monomers in the complex. Note the additional line width for the 'bound' HF, caused by vibrational predissociation with a lifetime of about 0.8 ns. (Taken from [21].)

-11-

C1.3.2.4 VISIBLE AND ULTRAVIOLET SPECTROSCOPY

Tunable visible and ultraviolet lasers were available well before tunable infrared and far-infrared lasers. There are many complexes that contain monomers with visible and near-UV spectra. The earliest experiments to give detailed dynamical information on complexes were in fact those of Smalley *et al* [22], who observed laser-induced fluorescence (LIF) spectra of He-I₂ complexes. They excited the complex in the I₂ B ← X band, and were able to produce excited-state complexes containing B-state I₂ in a wide range of vibrational states. From line widths and dispersed fluorescence spectra, they were able to study the rates and pathways of dissociation. Such work was subsequently extended to many other systems, including the rare gas-Cl₂ systems, and has given quite detailed information on potential energy surfaces [23].

The homonuclear rare gas pairs are of special interest as models for intermolecular forces, but they are quite difficult to study spectroscopically. They have no microwave or infrared spectrum. However, their vibration-rotation energy levels can be determined from their electronic absorption spectra, which lie in the vacuum ultraviolet (VUV) region of the spectrum. In the most recent work, Herman *et al* [24] have measured vibrational and rotational frequencies to great precision. In the case of Ar-Ar, the results have been incorporated into a multiproperty analysis by Aziz [25] to develop a highly accurate pair potential.

C1.3.2.5 OTHER SPECTROSCOPIC METHODS

Far-infrared and mid-infrared spectroscopy usually provide the most detailed picture of the vibration-rotation energy levels in the ground electronic state. However, they are not always possible and other spectroscopic methods are also important.

It is often difficult to observe direct infrared transitions from the ground state to highly excited intermolecular bending and stretching states, because the spectroscopic intensities are very low. One technique that circumvents this difficulty is stimulated-emission pumping (SEP) spectroscopy. Molecules (or complexes) are first promoted to an excited electronic state by a pump laser, and then emission is stimulated by a second tunable laser (the dump laser) at slightly lower frequency. Meanwhile, the population of the excited state is monitored in some way (perhaps by observing the spontaneous emission signal). When the dump laser is resonant with a transition back down to an excited vibrational level of the ground electronic state, it causes an observable dip in the population of the excited state. SEP spectroscopy has been applied with great success to map out the energy levels of the open-shell complex Ar-OH in its ground electronic state [26], and the resulting spectra have been used to obtain potential energy surfaces for the interaction [27].

C1.3.3 EXAMPLES

C1.3.3.1 BINARY COMPLEXES: AR-HCL AND AR-HF

The Ar-HCl and Ar-HF Van der Waals complexes were among the first to be detected experimentally, by the observation of weak peaks lying between the vibration-rotation lines of HCl and HF in mixtures with rare gases as

-12-

described above. The first measurements were made at a time when very little was known about intermolecular forces involving molecules and it was clear from the beginning that, if high-resolution spectra could be measured, they would contain an immense amount of valuable information. It was also clear that atom–molecule complexes would be much easier to treat theoretically than molecule–molecule complexes. Accordingly, when MBER spectroscopy (see above) was developed in the early 1970s, Ar–HCl [28] and Ar–HF [29] were among the first systems studied.

The early MBER spectra were of two types: first, pure rotational (microwave) transitions and, secondly, radiofrequency transitions between different hyperfine levels; the latter were observable only for Ar–HCl, because both ^{35}Cl and ^{37}Cl have nuclear quadrupole moments while ^{19}F has none. In addition, the rotational levels of both complexes could be split by applying an electric field (Stark effect) and the dipole moment could be determined from the size of the splittings. It turned out that Ar–HCl and Ar–HF were ‘pseudo-linear’ molecules: their rotational energy levels could be interpreted entirely in terms of a single rotational constant B and centrifugal distortion constant D_J . Nevertheless, the spectra contained signatures that showed that they were *not* rigid linear species: the dipole moments of the complexes were only about two-thirds of those of the HCl and HF monomers, and the nuclear quadrupole coupling constants of Ar–HCl were only about one-third of those of the corresponding HCl isotopomers. Both these fractions would have been close to one for a rigid linear species.

The Ar–HCl and Ar–HF complexes became prototypes for the study of intermolecular forces. Holmgren *et al* [30] produced an empirical potential energy surface for Ar–HCl fitted to the microwave and radiofrequency spectra, showing that the equilibrium geometry is linear, Ar–HCl, with a well depth of around 175 cm^{-1} . However, it turned out that this surface gave a poor account of properties that were sensitive to the shape of the repulsive wall, such as the pressure broadening of HCl vibration–rotation lines in the gas phase [31]. This is a general problem with intermolecular potentials determined solely from the spectra of complexes; the spectra do not contain enough information to determine the shape of the repulsive wall. Conversely, the potential energy surface determined from the pressure broadening [31] gave a very poor account of the spectra of the complexes [32].

Hutson and Howard [33] combined the Van der Waals spectra with pressure-broadening data and virial coefficients to produce an improved surface. However, even then, they showed that the microwave spectra determined the potential quite accurately between $\theta = 0$ and 90° , around the absolute minimum, but could not determine whether there was a secondary minimum around $\theta = 180^\circ$, the linear Ar–ClH structure. This again illustrates a general limitation: microwave spectra do not usually sample geometries far from equilibrium. Hutson and Howard [34] suggested that the best way to probe the Ar–ClH region would be to measure mid-infrared or far-infrared spectra, exciting intermolecular bending bands, and gave predictions for such spectra for potential surfaces with and without secondary minima.

Laser techniques capable of obtaining rotationally resolved infrared spectra of complexes came along fairly quickly [12]. For Ar–HCl, Marshall *et al* [15] and Ray *et al* [16] developed laser Stark methods for measuring far-infrared spectra in a molecular beam with fixed-frequency lasers. The laser Stark results were extended by Busarow *et al* [17], who used a tunable far-infrared laser for the first time. High-resolution mid-infrared spectra for Ar–HCl and Ar–HF were measured in both gas cells [35, 36] and slit jets [13, 37] using tunable difference-frequency lasers. Hutson [38] used the new spectra to develop an improved potential energy surface for Ar–HCl, establishing definitively that there is a secondary minimum around the linear Ar–ClH geometry, about 30 cm^{-1} shallower than the primary minimum at the Ar–HCl geometry.

Over the next few years, both the mid-infrared and the far-infrared spectra for Ar–HF and Ar–HCl were extended to numerous other bands and to other isotopic species (most importantly those containing deuterium). In 1992, Hutson [18, 39] combined all the available spectroscopic data to produce definitive potential energy surfaces that included both the angle dependence and the dependence on the HF/HCl monomer vibrational quantum number v (actually through the mass-reduced vibrational quantum number [40], $\eta = (v + \frac{1}{2})/\sqrt{\mu_{\text{HX}}}$). The resulting Ar–HF potential (designated H6(4,3,2)) is shown in figure C1.3.6. The potentials have since been used to calculate

numerous properties, including pressure-broadening coefficients, inelastic scattering integral cross sections, differential cross sections and the spectra of HF and HCl in rare gas clusters and matrices. They have proved to be remarkably reliable. They have also been used extensively as testing grounds for new *ab initio* electronic structure methods.

Figure C1.3.6. Contour plot of the H6(4,3,2) potential for Ar--HF, which was fitted principally to data from far-infrared and mid-infrared spectroscopy of the Ar--HF Van der Waals complex. The contours are labelled in cm^{-1} . (Taken from [39].)

C1.3.3.2 LARGER CLUSTERS: $(\text{H}_2\text{O})_N$

The most important molecular interactions of all are those that take place in liquid water. For many years, chemists have worked to model liquid water, using molecular dynamics and Monte Carlo simulations. Until relatively recently, however, all such work was done using ‘effective potentials’ [41], designed to reproduce the condensed-phase properties but with no serious claim to represent the true interactions between a pair of water molecules.

The advent of cluster spectroscopy offered the opportunity to place studies of liquid water and aqueous solutions on a

much firmer footing, by learning first about the water dimer and the true water–water pair potential and then exploring how the interactions change for larger clusters.

There has been considerable progress in this direction. The water dimer has been the subject of intense spectroscopic study, especially by far-infrared vibration–rotation–tunnelling spectroscopy (FIR-VRTS) [42]. Many different bands have been observed, involving intermolecular bending and stretching vibrations and tunnelling motions. The potential energy surface is six-dimensional (one distance and five angles) even when intramolecular vibrations of the water monomer are neglected. Because of this, developing a purely empirical potential surface from the spectroscopic observations is a difficult task. Nevertheless, Fellers *et al* [43] have used the spectra to fit the parameters of a functional form due to Millot and Stone [44].

Larger water clusters, including the trimer, tetramer, pentamer and hexamer, have also been studied spectroscopically. The equilibrium geometries of some of them are shown in [figure C1.3.7](#). A characteristic feature of the water clusters, and of many others, is that they have large numbers of equivalent minima on their potential energy surfaces, with relatively low barriers that allow tunnelling motions between the different minima. There are often low-lying subsidiary minima as well, which also affect the spectroscopy. Assigning and interpreting the spectra is a complex task involving permutation-inversion symmetry as well as sophisticated potential energy surfaces and many-dimensional bound-state calculations. The behaviour of the clusters cannot be explained in terms of small excursions from an equilibrium structure: it really becomes necessary to talk of ‘spectroscopy beyond structure’.

-15-

Figure C1.3.7. Equilibrium geometries of some water clusters from *ab initio* calculations. (Taken from [62].)

The equilibrium geometry of the water trimer is chiral, with fast tunnelling between the enantiomers [45]. There are actually 48 right-handed and 48 left-handed forms, all with the same energy. The tetramer is cyclic, but non-chiral, and with many fewer equivalent minima [46]. The pentamer is also cyclic [47], but the hexamer has a cage structure [48]. Higher clusters have also been studied, though at lower resolution, by infrared spectroscopy on beams of mass-selected clusters [49]. The octamer is particularly interesting, because it is believed to have dynamical cubic symmetry. Many other spectroscopic techniques have been used as well.

The ultimate reason for studying water clusters is of course to understand the interactions in bulk water (though clusters are interesting in their own right, too, because finite-size systems can have special properties). There has been

a vast amount of work on simulating the water clusters, both classically and quantumly. Quantum simulations are particularly challenging, because of the high dimensionality of the systems. Nevertheless, calculations on the lowest vibrational states of systems as large as water octamer have been carried out using quantum Monte Carlo methods.

The intermolecular forces between water molecules are strongly non-additive. It is not realistic to expect any pair potential to reproduce the properties of both the water dimer and the larger clusters, let alone liquid water. There has therefore been a great deal of work on developing potential models with explicit pairwise-additive and non-additive parts [44, 50, 51]. It appears that, when this is done, the energy of the larger clusters and ice has a non-additive contribution of about 30%.

An important area that has yet to be fully explored is the effect of the flexibility of water molecules. The intermolecular forces in water are large enough to cause significant distortions from the gas-phase monomer geometry. In addition, the flexibility is crucial in any description of vibrational excitation in water.

C1.3.3.3 REACTIVE SPECIES: H_2-OH

One of the motivations for studying Van der Waals complexes and clusters is that they are floppy systems with similarities to the transition states of chemical reactions. This can be taken one stage further by studying clusters that actually are precursors for chemical reactions, and can be broken up to make more than one set of products. A good example of this is H_2-OH , which can in principle dissociate to form either $H_2 + OH$ or $H_2O + H$. Indeed, dissociation to $H_2O + H$ is energetically favoured: the reaction $H_2 + OH \rightarrow H_2O + H$ is exothermic by about 5000 cm^{-1} , and plays a key role in combustion. It has been extensively studied both in the gas phase and in crossed molecular beams. The only reason that the H_2-OH complex can be observed at all is that there is a barrier to reaction of more than 2000 cm^{-1} , and the transition state has a quite different geometry from the complex.

OH is an open-shell molecule with a $^2\Pi$ ground state. In the complex, the Π state splits into two states of A' and A'' symmetry. *Ab initio* calculations [52] gave a well depth of 188 cm^{-1} (relative to free $OH + H_2$) for the A'' state, in a symmetric $O-H-H_2$ geometry. The first excited state, by contrast, has a well at least 2300 cm^{-1} deep. The first spectroscopic observations of H_2-OH [53], using laser-induced fluorescence, were carried out in parallel with bound-state calculations [54]. The early experiments showed broad peaks because the levels of the excited electronic state are very short-lived; they confirmed the existence of bound H_2-OH complexes, but provided only limited information on the interactions between ground-state molecules. Nevertheless, they opened the way to much higher-resolution studies using infrared overtone pumping to excite the OH vibration [55] and stimulated Raman spectroscopy to excite the H_2 vibration in the complex [56].

The vibrationally excited states of H_2-OH have enough energy to decay either to H_2 and OH or to cross the barrier to reaction. Time-dependent experiments have been carried out to monitor the non-reactive decay (to $H_2 + OH$), which occurs on a timescale of microseconds for H_2-OH but nanoseconds for D_2-OH [57, 58]. Analogous experiments have also been carried out for complexes in which the H_2 vibration is excited [59]. The reactive decay products have not yet been detected, but it is probably only a matter of time. Even if it proves impossible for H_2-OH , there are plenty of other 'pre-reactive' complexes that can be produced. There is little doubt that the spectroscopy of such species will be a rich source of information on reactive potential energy surfaces in the fairly near future.

C1.4 Atom traps and studies of ultracold systems

John Weiner

C1.4.1 INTRODUCTION

Just over a decade ago the first successful experiments and theory demonstrating that light could be used to cool and confine atoms to sub-milliKelvin temperatures [1, 2] opened several exciting new chapters in chemical physics and in atomic, molecular and optical (AMO) physics. Atom optics and interferometry [5, 6], holography [7], optical lattices [8] and Bose–Einstein condensation in dilute gases all exemplify startling new physics where atoms cooled with light play a pivotal role. The nature of the interactions between these cold particles has become the subject of intensive study not only because of their importance to these new areas of AMO physics but also because their investigation has led to new insights into how association spectroscopy of the colliding species can lead to precision measurements of atomic and molecular parameters and how radiation fields can manipulate the outcome

of a collision itself. As a general orientation [figure C1.4.1](#) shows how a typical atomic de Broglie wavelength varies with temperature and where various physical phenomena are situated along the scale. With de Broglie wavelengths of the order of a few thousandths of a nanometre, conventional gas-phase chemistry can usually be interpreted as the interaction of classical nuclear point particles moving along potential surfaces defined by their associated electronic charge distribution. At one time liquid helium was thought to define a regime of cryogenic physics, but it is clear from [figure C1.4.1](#) that optical and evaporative cooling have created ‘cryogenic’ environments below liquid helium by many orders of magnitude. At the level of Doppler cooling and optical molasses the de Broglie wavelength becomes comparable to or longer than the chemical bond, approaching the length of the cooling optical light wave. Here we can expect wave and relativistic effects such as resonances, interferences and interaction retardation to become important. Following Suominen [9], we will term the Doppler cooling and optical molasses temperature range, roughly between 1 mK and 1 μ K, the regime of cold collisions. Most collision phenomena at this level are studied in the presence of one or more light fields used to confine the atoms and to probe their interactions. Excited quasimolecular states often play an important role. Below about 1 μ K, where evaporative cooling and Bose–Einstein condensation (BEC) become the focus of attention, the de Broglie wavelength grows to a scale comparable to the mean distance separating atoms in a dilute gas; quantum degenerate states of the atomic ensemble begin to appear. In this regime ground-state collisions only take place through radial (not angular) motion and are characterized by a phase shift, or scattering length, of the ground-state wave function. Since the atomic translational energy now lies below the kinetic energy transferred to an atom by recoil from a scattered photon, cooling with light fields can be of no further use; and collisions occurring in a temperature range from 1 μ K to 0 must be ground-state interactions.

-2-

Figure C1.4.1. The situation of various physical phenomena along a scale of temperature plotted against de Broglie wavelength.

C1.4.2 THE PHYSICS OF NEUTRAL-ATOM TRAPS

C1.4.2.1 ATOM TRAPS

(A) LIGHT FORCES AND DOPPLER-LIMIT COOLING

It is well known that a light beam carries momentum and that the scattering of light by an object produces a force. This property of light was first demonstrated by Frisch [10] through the observation of a very small transverse deflection (3×10^{-5} rad) in a sodium atomic beam exposed to light from a resonance lamp. With the invention of the laser, it became easier to observe effects of this kind because the strength of the force is greatly enhanced by the use of intense and highly directional light fields, as demonstrated by Ashkin [11] with the manipulation of transparent dielectric spheres suspended in water. Although the results of Frisch and Ashkin rekindled interest in using light forces

-3-

to control the motion of neutral atoms, the basic groundwork for the understanding of light forces acting on atoms was not laid out before the end of the decade of the 1970s. Unambiguous experimental demonstration of atom cooling and trapping was not accomplished before the mid-80s. In this section we discuss some fundamental aspects of light forces and schemes employed to cool and trap neutral atoms.

The light force exerted on an atom can be of two types: a dissipative, *spontaneous force* and a conservative, *dipole force*. The spontaneous force arises from the impulse experienced by an atom when it absorbs or emits a quantum of photon momentum. When an atom scatters light, the resonant scattering cross section can be written as $\sigma_0 = \lambda_0^2/2\pi$ where λ_0 is the on-resonant wavelength. In the optical region of the electromagnetic spectrum the wavelengths of light are of the order of several hundreds of nanometres, so resonant scattering cross sections become quite large, $\sim 10^{-9}$ cm². Each photon absorbed transfers a quantum of momentum $\hbar k$ to the atom in the direction of propagation (\hbar is the Planck constant divided by 2π , and $k = 2\pi / \lambda$ is the magnitude of the wave vector associated with the optical field). The spontaneous emission following the absorption occurs in random directions; and, over many absorption–emission cycles, it averages to zero. As a result, the *net* spontaneous force acts on the atom in the direction of the light propagation, as shown schematically in the diagram of figure C1.4.2. The saturated rate of photon scattering by spontaneous emission (the reciprocal of the excited-state lifetime) fixes the upper limit to the force magnitude. This force is sometimes called *radiation pressure*.

Figure C1.4.2. Spontaneous emission following absorption occurs in random directions, but absorption from a light beam occurs along only one direction.

The dipole force can be readily understood by considering the light as a classical wave. It is simply the time-averaged force arising from the interaction of the transition dipole, induced by the oscillating electric field of the light, with the gradient of the electric field amplitude. Focusing the light beam controls the magnitude of this gradient and detuning the optical frequency below or above the atomic transition controls the sign of the force acting on the atom. Tuning the light below resonance attracts the atom to the centre of the light beam while tuning above resonance repels it. The dipole force is a stimulated process in which no net exchange of energy between the

field and the atom takes place, but photons are absorbed from one mode and reappear by stimulated emission in another. Momentum conservation requires that the change of photon propagation direction from initial to final mode imparts a net recoil to the atom. Unlike the spontaneous force, there is in principle no upper limit to the magnitude of the dipole force since it is a function only of the field gradient and detuning.

-4-

We can bring these qualitative remarks into focus by considering the amplitude, phase and frequency of a classical field interacting with an atomic transition dipole in a two-level atom. A detailed development of the following results is beyond the scope of the present article, but can be found elsewhere [12, 13]. The usual approach is semiclassical and consists in treating the atom as a two-level quantum system and the radiation as a classical electromagnetic field [14]. A full quantum approach can also be employed [15], but it will not be discussed here. What follows immediately is sometimes called the Doppler cooling model. It turns out that atoms with hyperfine structure in the ground state can be cooled below the Doppler limit predicted by this model; and, to explain this unexpected sub-Doppler cooling, models involving interaction between a slowly moving atom and the polarization gradient of a standing wave have been invoked. We will sketch briefly in the next section the physics of these polarization gradient cooling mechanisms.

The basic expression for the interaction *energy* is

$$U = -\boldsymbol{\mu}\mathbf{E} \quad (\text{C1.4.1a})$$

where $\boldsymbol{\mu}$ is the transition dipole and \mathbf{E} is the electric field of the light. The *force* is then the negative of the spatial gradient of the potential,

$$\mathbf{F} = -\nabla_{\mathbf{R}}U = \boldsymbol{\mu}\nabla_{\mathbf{R}}\mathbf{E} \quad (\text{C1.4.2})$$

where we have set $\nabla_{\mathbf{R}}\boldsymbol{\mu}$ equal to zero because there is no spatial variation of the dipole over the length scale of the optical field. The optical-cycle average of the force is expressed as

$$\langle \mathbf{F} \rangle = \langle \boldsymbol{\mu}\nabla_{\mathbf{R}}\mathbf{E} \rangle = \boldsymbol{\mu}[(\nabla_{\mathbf{R}}E_0)u - (E_0\nabla_{\mathbf{R}}(k_{\mathbf{R}}R))v] \quad (\text{C1.4.3})$$

where u and v arise from the steady-state solutions of the optical Bloch equations,

$$u = \frac{\Omega}{2} \frac{\Delta\omega_{\mathbf{L}}}{(\Delta\omega_{\mathbf{L}})^2 + (\Gamma/2)^2 + \Omega^2/2} \quad (\text{C1.4.4})$$

and

$$v = \frac{\Omega}{2} \frac{\Gamma/2}{(\Delta\omega_{\mathbf{L}})^2 + (\Gamma/2)^2 + \Omega^2/2}. \quad (\text{C1.4.5})$$

In equations (C1.4.4) and (C1.4.5) $\Delta\omega_{\mathbf{L}} = \omega - \omega_{\mathbf{R}}$ is the detuning of the optical field from the atomic transition frequency $\omega_{\mathbf{R}}$, Ω is the natural width of the atomic transition and ω is termed the Rabi frequency and reflects the

-5-

strength of the coupling between field and atom,

$$\Omega = -\frac{\mu E_0}{\hbar}. \quad (\text{C1.4.6})$$

In writing [equation \(C1.4.3\)](#) we have made use of the fact that the time-average dipole has in-phase and in-quadrature components,

$$\langle \boldsymbol{\mu} \rangle = 2\mu(u \cos \omega_L t - v \sin \omega_L t) \quad (\text{C1.4.7})$$

and the electric field of the light is given by the classical expression,

$$E = E_0[\cos(\omega t - k_L R)]. \quad (\text{C1.4.8})$$

The time-averaged force, [equation \(C1.4.3\)](#), consists of two terms: the first term is proportional to the gradient of the electric field amplitude; the second term is proportional to the gradient of the phase. Substituting [equation \(C1.4.4\)](#) and [equation \(C1.4.5\)](#) into [equation \(C1.4.3\)](#), we have for the two terms,

$$\begin{aligned} \langle \mathbf{F} \rangle = & \mu(\nabla_{\mathbf{R}} E_0) \frac{\Omega}{2} \left[\frac{\Delta\omega_L}{(\Delta\omega_L)^2 + (\Gamma/2)^2 + \Omega^2/2} \right] \\ & - \mu(E_0 \nabla_{\mathbf{R}}(-k_L R)) \frac{\Omega}{2} \left[\frac{\Gamma/2}{(\Delta\omega_L)^2 + (\Gamma/2)^2 + \Omega^2/2} \right]. \end{aligned} \quad (\text{C1.4.9})$$

The first term is the dipole force, sometimes called the trapping force, F_T , because it is a conservative force and can be integrated to define a trapping potential for the atom:

$$F_T = \mu(\nabla_{\mathbf{R}} E_0) \frac{\Omega}{2} \left[\frac{\Delta\omega_L}{(\Delta\omega_L)^2 + (\Gamma/2)^2 + \Omega^2/2} \right] \quad (\text{C1.4.10})$$

and

$$U_T = - \int F_T dR = \frac{\hbar \Delta\omega_L}{2} \ln \left[1 + \frac{\Omega^2/2}{(\Delta\omega_L)^2 + (\Gamma/2)^2} \right]. \quad (\text{C1.4.11})$$

-6-

The second term is the spontaneous force, sometimes called the cooling force, F_C , because it is a dissipative force and can be used to cool atoms,

$$F_C = \mu E_0 k_L \frac{\Omega}{2} \left[\frac{\Gamma/2}{(\Delta\omega_L)^2 + (\Gamma/2)^2 + \Omega^2/2} \right]. \quad (\text{C1.4.12})$$

Note that in [equation \(C1.4.10\)](#), the line-shape function in square brackets is dispersive and changes sign as the detuning $\Delta\omega_L$ changes sign from negative (red detuning) to positive (blue detuning). In [equation \(C1.4.12\)](#), the

line-shape function is absorptive, peaks at zero detuning and exhibits a Lorentzian profile. These two equations can be recast to bring out more of their physical content. The dipole force can be expressed as

$$F_T = -\frac{1}{2\Omega^2} \nabla \Omega^2 \hbar \Delta\omega_L \left[\frac{s}{1+s} \right] \quad (\text{C1.4.13a})$$

where s , the *saturation parameter*, is defined to be

$$s = \frac{\Omega^2/2}{(\Delta\omega_L)^2 + (\Gamma/2)^2}. \quad (\text{C1.4.14})$$

In equation (C1.4.14) the saturation parameter essentially defines a criterion to compare the time required for stimulated and spontaneous processes. If $s \ll 1$ then spontaneous coupling of the atom to the vacuum modes of the field is fast compared to the stimulated Rabi coupling and the field is considered weak. If $s \gg 1$ then the Rabi oscillation is fast compared to spontaneous emission and the field is said to be strong. Setting s equal to unity defines the saturation condition

$$\Omega_{\text{sat}} = \sqrt{2} \left(\frac{\Gamma}{2} \right) \quad (\text{C1.4.15})$$

and, as can be seen from the line-shape factor in equation (C1.4.12), the resonance line width is power broadened by a factor of $\sqrt{2}$. With the help of the definition of the Rabi frequency, [equation \(C1.4.6\)](#), and the light beam intensity,

$$I = \frac{1}{2} \epsilon_0 c E_0^2 \quad (\text{C1.4.16})$$

-7-

[equation \(C1.4.13a\)](#) can be written in terms of the gradient of the light intensity, the saturation parameter and the detuning,

$$F_T = -\frac{1}{4I} (\nabla I) \hbar \Delta\omega_L \left[\frac{s}{1+s} \right]. \quad (\text{C1.4.17})$$

Note that negative $\Delta\omega_L$ (red detuning) produces a force attracting the atom to the intensity maximum while positive $\Delta\omega_L$ (blue detuning) repels the atom away from the intensity maximum. The spontaneous force or cooling force can also be written in terms of the saturation parameter and the spontaneous emission rate,

$$F_C = \frac{\hbar k_L \Gamma}{2} \left[\frac{s}{1+s} \right] \quad (\text{C1.4.18})$$

which shows that this force is simply the rate of absorption and reemission of momentum quanta $\hbar k_L$ carried by a photon in the light beam. Note that as s increases beyond unity, F_C approaches $\frac{\hbar k_L \Gamma}{2}$, the maximum photon scattering rate. Furthermore, from the previous definitions of I, Ω and Ω_{sat} , we can write

$$(\text{C1.4.19})$$

$$\frac{I}{I_{\text{sat}}} = \frac{\Omega^2}{\Gamma^2/2}$$

and

$$F_C = \frac{\hbar k_L \Gamma}{2} \left[\frac{I/I_{\text{sat}}}{(\frac{2\Delta\omega_L}{\Gamma})^2 + I/I_{\text{sat}} + 1} \right]. \quad (\text{C1.4.20})$$

Now if we consider the atom moving in the $+z$ direction with velocity v_z and counterpropagating to the light wave detuned from resonance by $\Delta\omega_L$, the *net* detuning will be

$$\Delta\omega = \Delta\omega_L + k_L v_z \quad (\text{C1.4.21})$$

where the term $k_L v_z$ is the Doppler shift. The force F_- acting on the atom will be in the direction opposite to its motion. In general,

$$F_{\pm} = \pm \frac{\hbar k_L \Gamma}{2} \left[\frac{I/I_{\text{sat}}}{(\frac{2(\Delta\omega_L \mp k v_z)}{\Gamma})^2 + I/I_{\text{sat}} + 1} \right] \quad (\text{C1.4.22})$$

-8-

Suppose we have two fields propagating in the $\pm z$ directions and we take the net force $F = F_+ + F_-$. If $k v_z$ is small compared to Γ and $\Delta\omega_L$, then we find

$$F \simeq 4\hbar k \frac{I}{I_{\text{sat}}} \frac{k v_z (2\Delta\omega_L / \Gamma)}{[1 + (2\Delta\omega_L / \Gamma)^2]^2}. \quad (\text{C1.4.23})$$

This expression shows that if the detuning $\Delta\omega_L$ is negative (i.e. red detuned from resonance), then the cooling force will oppose the motion and be proportional to the atomic velocity. The one-dimensional motion of the atom, subject to an opposing force proportional to its velocity, is described by a damped harmonic oscillator. The Doppler damping or friction coefficient is the proportionality factor,

$$\alpha_d = -4\hbar k^2 \frac{I}{I_{\text{sat}}} \frac{(2\Delta\omega_L / \Gamma)}{[1 + (2\Delta\omega_L / \Gamma)^2]^2} \quad (\text{C1.4.24})$$

and the characteristic time to damp the kinetic energy of the atom of mass m to $1/e$ of its initial value is

$$\tau = \frac{m}{2\alpha_d}. \quad (\text{C1.4.25})$$

However, the atom will not cool indefinitely. At some point the Doppler cooling rate will be balanced by the heating rate coming from the momentum fluctuations of the atom absorbing and re-emitting photons. Setting these two rates equal and associating the one-dimensional kinetic energy with $\frac{1}{2}k_B T$, we find

$$k_B T = \frac{\hbar \Gamma}{4} \frac{1 + (2\Delta\omega_L/\Gamma)^2}{2|\Delta\omega_L|/\Gamma}. \quad (\text{C1.4.26})$$

This expression shows that T is a function of the laser detuning, and the minimum temperature is obtained when $\Delta\omega_L = -\frac{\Gamma}{2}$. At this detuning,

$$k_B T = \hbar \frac{\Gamma}{2} \quad (\text{C1.4.27})$$

which is called the Doppler-cooling limit. This limit is typically, for alkali atoms, on the order of a few hundred microKelvin. For example the Doppler cooling limit for Na is $T = 240$ microKelvin. In the early years of cooling and trapping, prior to 1988, the Doppler limit was thought to be a real physical barrier. Then the experimental measurements of Lett *et al* [16] showed that in fact Na atoms could be cooled well below the Doppler limit. Although the physics of this sub-Doppler cooling in three dimensions is still not fully understood, the essential role played by the hyperfine structure of the ground state has been worked out in one-dimensional models which we describe here.

-9-

(B) SUB-DOPPLER COOLING

Two principal mechanisms which cool atoms to temperatures below the Doppler limit rely on spatial polarization gradients of the light field through which the atoms move [17]. These two mechanisms, however, invoke very different physics, and are distinguished by the spatial polarization dependence of the light field. Two parameters, the friction coefficient and the velocity capture range, determine the significance of these cooling processes. In this section we compare expressions for these quantities in the sub-Doppler regime to those found in the conventional Doppler cooling model of one-dimensional optical molasses.

In the first case two counterpropagating light waves with orthogonal polarization form a standing wave. This arrangement is familiarly called the ‘lin–perp–lin’ configuration. [Figure C1.4.3](#) shows what happens. We see from the figure that if we take as a starting point a position where the light polarization is linear ϵ_1 , it evolves from linear to circular over a distance of $\lambda/8$ (σ_-). Then over the next $\lambda/8$ interval the polarization again changes to linear but in the direction orthogonal to the first (ϵ_2). Then from $\lambda/4$ to $3\lambda/8$ the polarization again becomes circular but in the sense opposite (σ_+) to the circular polarization at $\lambda/8$, and finally after a distance of $\lambda/2$ the polarization is again linear but antiparallel to (ϵ_1). Over the same half-wavelength distance of the polarization period, atom–field coupling produces a periodic energy (or light) shift in the hyperfine levels of the atomic ground state. To illustrate the cooling mechanism we assume the simplest case, a $J_g = \frac{1}{2} \rightarrow J_e = \frac{3}{2}$ transition. As shown in [figure C1.4.4](#) the atom moving through the region of z around $\lambda/8$, where the polarization is primarily σ_- , will have its population pumped mostly into $J_g = -\frac{1}{2}$. Furthermore the Clebsch–Gordan coefficients controlling the transition dipole coupling to $J_e = \frac{3}{2}$ impose that the $J_g = -\frac{1}{2}$ level couples to σ_- light three times more strongly than does the $J_g = +\frac{1}{2}$ level. The difference in coupling strength leads to the light shift splitting between the two ground states shown in [figure C1.4.4](#). As the atom continues to move to $+z$, the relative coupling strengths are reversed around $3\lambda/8$ where the polarization is essentially σ_+ . Thus the relative energy levels of the two hyperfine ground states oscillate ‘out of phase’ as the atom moves through the standing wave. The key idea is that the optical pumping rate, always redistributing population to the lower-lying hyperfine level, lags the light shifts experienced by the two atom ground-state components as the atom moves through the field. The result is a ‘Sisyphus effect’ where an atom cycles through a period in which it spends most of its time climbing a potential hill, converting kinetic energy to potential energy, subsequently dissipating the accumulated potential energy into the empty modes of the radiation field and simultaneously transferring population back to the lower lying of the two ground-state levels. [Figure C1.4.5](#) illustrates the optical pumping phase lag. In order for this cooling mechanism to work, the optical pumping time, controlled by the light intensity, must be less than the light-shift time, controlled essentially by the velocity of the atom. Since the atom is moving slowly, having been previously cooled by the Doppler mechanism, the light

field must be weak in order to slow the optical pumping rate so that it lags the light-shift modulation rate. This physical picture combines the conservative optical dipole force, whose space integral gives rise to the potential hills and valleys over which the atom moves and the irreversible energy dissipation of spontaneous emission required to achieve cooling. We can make the discussion more precise and obtain simple expressions for the friction coefficient and velocity capture by establishing some definitions. As in the Doppler cooling model we define the friction coefficient $\alpha_{|p|}$ to be the proportionality constant between the force F and the atomic velocity v .

-10-

Figure C1.4.3. Schematic diagram of the ‘lin–perp–lin’ configuration showing spatial dependence of the polarization in the standing-wave field (after [17]).

Figure C1.4.4. Schematic diagram showing how the two $\pm\frac{1}{2}$ levels of the ground state couple to the spatially varying polarization of the ‘lin–perp–lin’ standing wave light field (after [17]).

Figure C1.4.5. Population modulation as the atom moves through the standing wave in the ‘lin–perp–lin’ one dimensional optical molasses. The population lags the light shift such that kinetic is converted to potential energy then dissipated into the empty modes of the radiation field by spontaneous emission (after [17]).

$$F = -\alpha_{|p|} v. \quad (C1.4.28)$$

We assume that the light field is detuned to the red of the $J_g \rightarrow J_e$ atomic resonance frequency,

$$\Delta_L = \omega_L - \omega_R \quad (C1.4.29)$$

and term the light shifts of the $J_g = \pm \frac{1}{2}$ levels Δ_{\pm} respectively. At the position $z = \lambda/8$, $\Delta_- = 3\Delta_+$ and at $z = 3\lambda/8$, $\Delta_+ = 3\Delta_-$. Since the applied field is red detuned, all Δ have negative values. Now in order for the cooling mechanism to be effective the optical pumping time τ_p should be comparable to the time required for the atom with velocity v to travel from the bottom to the top of a potential hill, $\frac{\lambda/4}{v}$,

$$\tau_p \simeq \frac{\lambda/4}{v} \quad (C1.4.30)$$

or

$$\Gamma' \simeq kv \quad (C1.4.31)$$

where $\Gamma' = 1/\tau_p$ and $\lambda/4 \simeq 1/k$, with $k = \frac{2\pi}{\lambda}$ the magnitude of the optical wave vector. Now the amount of energy W dissipated in one cycle of hill climbing and spontaneous emission is essentially the average energy splitting of the two light-shifted ground states, between, say, $z = \lambda/8$ and $3\lambda/8$ or $W \simeq -\hbar\Delta$. Therefore the *rate* of energy dissipation is

$$\frac{dW}{dt} = -\Gamma' \hbar \Delta. \quad (C1.4.32)$$

However in general the time-dependent energy change of a system can be always be expressed as $\frac{dW}{dt} = Fv$ so in this one-dimensional model and taking into account equation (C1.4.28) we can write

$$\frac{dW}{dt} = -\alpha_{|p|} v^2 = -\Gamma' \hbar \Delta \quad (C1.4.33)$$

so that

$$\alpha_{|p|} = -\frac{k\hbar\Delta}{v} = -\frac{k^2\hbar\Delta}{\Gamma'}. \quad (C1.4.34)$$

Note that since $\Delta < 0$, α_{lp1} is a positive quantity. Note also that at far detunings ($\Delta_L \gg \Gamma$) [equation \(C1.4.11\)](#) shows that $\Delta = \frac{\Omega^2}{4\Delta_L}$. It is also true that for light shifts large compared to the natural linewidth ($\Delta \gg \Gamma$), $\Gamma/\Gamma' = \frac{\Delta_L^2}{\Omega^2}$ so the sub-Doppler friction coefficient can also be written

$$\alpha_{\text{lp1}} = -\frac{k^2 \hbar \Delta_L}{4\Gamma'} \quad (\text{C1.4.35})$$

Equation (C1.4.35) yields two remarkable predictions: first, that the sub-Doppler friction coefficient can be a big number compared to α_d since at far detuning Δ_L/Γ is a big number; and second, that α_{lp1} is independent of the applied field intensity. This last result contrasts sharply with the Doppler friction coefficient which is proportional to field intensity up to saturation (see [equation \(C1.4.24\)](#)). However, even though α_{lp1} looks impressive, the range of atomic velocities over which it can operate are restricted by the condition that $\Gamma' \simeq kv$. The ratio of the capture velocities for Doppler versus sub-Doppler cooling is therefore only $v_{\text{lp1}}/v_d \simeq \frac{4\Delta}{\Delta_L}$. [Figure C1.4.6](#) illustrates graphically the comparison between the Doppler and the ‘lin-perp-lin’ sub-Doppler cooling mechanism. The dramatic difference in capture range is evident from the figure. Note also that the slopes of the curves give the friction coefficients for the two regimes and that, within the narrow velocity capture range of its action, the slope of the sub-Doppler mechanism is markedly steeper.

Figure C1.4.6. Comparison of capture velocity for Doppler cooling and ‘lin-perp-lin’ sub-Doppler cooling. Notice that the slope of the curves, proportional to the friction coefficient, is much steeper for the sub-Doppler mechanism. (After [17].)

The second mechanism operates with the two counterpropagating beams circularly polarized in opposite senses. When the two counterpropagating beams have the same amplitude, the resulting polarization is always linear and orthogonal to the propagation axis, but the tip of the polarization axis traces out a helix around the propagation axis with a pitch of λ . [Figure C1.4.7](#) illustrates this case. The physics of the sub-Doppler mechanism does not rely on hill-climbing and spontaneous emission, but on an imbalance in the photon scattering rate from the two counterpropagating light waves as the atom moves along the z axis. This imbalance leads to a velocity-dependent restoring force acting on the atom. The essential factor leading to the differential scattering rate is the creation of *population orientation* along the z axis among the sublevels of the atom *ground state*. Those sublevels with more population scatter more photons. Now it is evident from a consideration of the energy level diagram and the

Clebsch–Gordan coefficients coupling ground and excited levels that $J_g = \frac{1}{2} \leftrightarrow J_e = \frac{3}{2}$ transitions coupled by linearly polarized light cannot produce a population orientation in the ground state. In fact the simplest system to exhibit this effect is $J_g = 1 \leftrightarrow J_e = 2$, and a measure of the orientation is the magnitude of the $\langle J_z \rangle$ matrix element between the $J_{gz} = \pm$ sublevels. If the atom remained stationary at $z = 0$, interacting with the light polarized along y , the light shifts Δ_0, Δ_1 of the three ground-state sublevels would be

$$\Delta_{+1} = \Delta_{-1} = \frac{3}{4} \Delta_0 \quad (\text{C1.4.36})$$

and the steady-state populations 4/17, 4/17 and 9/17 respectively. Evidently, linearly polarized light will not produce a net steady-state orientation, $\langle J_z \rangle$. As the atom begins to move along z with velocity v , however, it sees a linear polarization precessing around its axis of propagation with an angle $\varphi = -kz = -kvt$. This precession gives rise to a new

-14-

term in the Hamiltonian, $V = kvJ_z$. Furthermore, if we transform to a rotating coordinate frame, the eigenfunctions belonging to the Hamiltonian of the moving atom in this new ‘inertial’ frame become linear combinations of the basis functions with the atom at rest. Evaluation of the steady-state orientation operator, J_z , in the inertial frame is now nonzero,

$$\langle J_z \rangle = \frac{40 \hbar kv}{17 \Delta_0} = \hbar[\Pi_{+1} - \Pi_{-1}]. \quad (\text{C1.4.37})$$

Notice that the orientation measure is only nonzero when the atom is moving. In equation (C1.4.37) we denote the populations of the $|\pm\rangle$ sublevels as Π_{\pm} , and we interpret the nonzero matrix element as a direct measure of the population difference between the $|\pm\rangle$ levels of the ground state. Note that since Δ_0 is a negative quantity (red detuning), equation (C1.4.37) tells us that the Π_- population is greater than the Π_+ population. Now, if the atom travelling in the $+z$ direction is subject to two light waves, one with polarization σ_- (σ_+) propagating in the $-z$ ($+z$) direction, the preponderance of population in the $|- \rangle$ level will result in a higher scattering rate from the wave travelling in the $-z$ direction. Therefore the atom will be subject to a net force opposing its motion and proportional to its velocity. The differential scattering rate is $\frac{40 kv}{17 \Delta_0} \Gamma'$ and, with an $\hbar k$ momentum quantum transferred per scattering event, the net force is

$$F = -\frac{40 \hbar k^2 v \Gamma'}{17 \Delta_0}. \quad (\text{C1.4.38})$$

The friction coefficient α_{cp} is evidently

$$\alpha_{cp} = -\frac{40}{17} \hbar k^2 \frac{\Gamma'}{\Delta_0} \quad (\text{C1.4.39})$$

which is a positive quantity since Δ_0 is negative from red detuning. Contrasting α_{cp} with α_{lpl} we see that α_{cp} must be much smaller since the assumption has been all along that the light shifts Δ were much greater than the line widths Γ' . It turns out, however [17], that the heating rate from recoil fluctuations is also much smaller so that the ultimate temperatures reached from the two mechanisms are comparable.

Figure C1.4.7. Spatial variation of the polarization from the field resulting from two counterpropagating, circularly polarized fields with equal amplitude but polarized in opposite senses. Note that the polarization remains linear but that the axis rotates in the x - y plane with a helical pitch along the z axis of length λ .

Although the Doppler cooling mechanism also depends on a scattering imbalance from oppositely travelling light waves, the imbalance in the scattering rate originates from a difference in the scattering probability per photon due to the Doppler shift induced by the moving atom. In the sub-Doppler mechanism the scattering probabilities from the two light waves are equal but the ground-state populations are not. The state with the greater population experiences the greater rate.

(C) THE MAGNETO-OPTICAL TRAP (MOT)

Basic notions. [18] originally suggested that the spontaneous light force could be used to trap neutral atoms. The basic concept exploited the internal degrees of freedom of the atom as a way of circumventing the optical Earnshaw theorem (OET) proved by [19]. This theorem states that if a force is proportional to the light intensity, its divergence must be null because the divergence of the Poynting vector, which expresses the directional flow of intensity, must be null through a volume without sources or sinks of radiation. This null divergence rules out the possibility of an inward restoring force everywhere on a closed surface. However, when the internal degrees of freedom of the atom are considered, they can change the proportionality between the force and the Poynting vector in a position-dependent way such that the OET does not apply. Spatial confinement is then possible with spontaneous light forces produced by counterpropagating optical beams. Using these ideas to circumvent the OET, Raab *et al* [20] demonstrated a trap configuration that is currently the most commonly employed. It uses a radial magnetic field gradient produced by a quadrupole field and three pairs of circularly polarized, counterpropagating optical beams, detuned to the red of the atomic transition and intercepting at right angles in the position where the magnetic field is zero. The magneto-optical trap exploits the position-dependent Zeeman shifts of the electronic levels when the atom moves in the radially increasing magnetic field. The use of circularly polarized light, red-detuned $\sim\Gamma$ results in a spatially dependent transition probability whose net effect is to produce a restoring force that pushes the atom toward the origin.

To make clear how this trapping scheme works, consider a two-level atom with a $J = 0 \rightarrow J = 1$ transition moving along the z direction. We apply a magnetic field $B(z)$ increasing linearly with distance from the origin. The Zeeman shifts of the electronic levels are position dependent, as shown in [figure C1.4.8\(a\)](#). We also apply counterpropagating optical fields along the $\pm z$ directions carrying oppositely circular polarization and detuned to the red of the atomic

transition. It is clear from [figure C1.4.8](#) that an atom moving along $+z$ will scatter σ^- photons at a faster rate than

σ^+ photons because the Zeeman effect will shift the $\Delta M_J = -1$ transition closer to the light frequency.

Figure C1.4.8. (a) An energy level diagram showing the shift of Zeeman levels as the atom moves away from the $z = 0$ axis. The atom encounters a restoring force in either direction from counterpropagating light beams. (b) A typical optical arrangement for implementation of a magneto-optical trap.

$$F_{1z} = -\frac{\hbar k}{2} \Gamma \frac{\Omega^2/2}{(\Delta + kv_z + \frac{\mu_B}{\hbar} \frac{dB}{dz} z)^2 + (\Gamma/2)^2 + \Omega^2/2}. \quad (\text{C1.4.40})$$

Similarly, if the atom moves along $-z$ it will scatter σ^+ photons at a faster rate from the $\Delta M_J = +1$ transition.

$$F_{2z} = +\frac{\hbar k}{2} \Gamma \frac{\Omega^2/2}{(\Delta - kv_z - \frac{\mu_B}{\hbar} \frac{dB}{dz} z)^2 + (\Gamma/2)^2 + \Omega^2/2}. \quad (\text{C1.4.41})$$

The atom will therefore experience a net restoring force pushing it back to the origin. If the light beams are red detuned $\sim \Gamma$, then the Doppler shift of the atomic motion will introduce a velocity-dependent term to the restoring force such that, for small displacements and velocities, the total restoring force can be expressed as the sum of a term linear in velocity and a term linear in displacement,

$$F_{\text{MOT}} = F_{1z} + F_{2z} = -\alpha\dot{z} - Kz.$$

Equation (C1.4.42) expresses the equation of motion of a damped harmonic oscillator with mass m ,

$$\ddot{z} + \frac{2\alpha}{m}\dot{z} + \frac{K}{m}z = 0. \quad (\text{C1.4.43})$$

The damping constant α and the spring constant K can be written compactly in terms of the atomic and field parameters as

$$\alpha = \hbar k \Gamma \frac{16|\Delta'|(\Omega')^2(k/\Gamma)}{[1 + 2(\Omega')^2]^2 [1 + \frac{4(\Delta')^2}{1+2(\Omega')^2}]^2} \quad (\text{C1.4.44})$$

and

$$K = \hbar k \Gamma \frac{16|\Delta'|(\Omega')^2(\frac{d\omega_0}{dz})}{[1 + 2(\Omega')^2]^2 [1 + \frac{4(\Delta')^2}{1+2(\Omega')^2}]^2} \quad (\text{C1.4.45})$$

where Ω', Δ' and $\frac{d\omega_0}{dz} = \frac{(\mu_B/\hbar)(\frac{dB}{dz})}{\Gamma}$ are Γ -normalized analogues of the quantities defined earlier. Typical MOT operating conditions fix $\Omega' = 1/2$, $\Delta' = 1$, so α and K reduce to

$$\alpha \simeq (0.132)\hbar k^2 \quad (\text{C1.4.46})$$

and

$$K \simeq (1.16 \times 10^{10})\hbar k \frac{dB}{dz}. \quad (\text{C1.4.47})$$

The extension of these results to three dimensions is straightforward if one takes into account that the quadrupole field gradient in the z direction is twice the gradient in the x, y directions, so that $K_z = 2K_x = 2K_y$. The velocity dependent damping term implies that kinetic energy E dissipates from the atom (or collection of atoms) as $E/E_0 = e^{-\frac{2\alpha}{m}t}$ where m is the atomic mass and E_0 the kinetic energy at the beginning of the cooling process. Therefore, the dissipative force term cools the collection of atoms as well as combining with the displacement term to confine them. The damping time constant $\tau = \frac{m}{2\alpha}$ is typically tens of microseconds. It is important to bear in mind that an MOT is anisotropic since the restoring force along the z axis of the quadrupole field is twice the restoring force in the x - y plane. Furthermore, an MOT provides a dissipative rather than a conservative trap and it is therefore more accurate to characterize the maximum capture velocity rather than the trap ‘depth’.

Early experiments with MOT-trapped atoms were carried out by initially slowing an atomic beam to load the trap [20, 21]. Later, a continuous uncooled source was used for that purpose, suggesting that the trap could be loaded with the slow atoms of a room-temperature vapour [22]. The next advance in the development of magneto-optical trapping was the introduction of the vapour-cell magneto-optical trap (VCMOT). This variation captures cold atoms directly from the low-velocity edge of the Maxwell–Boltzmann distribution always present in a cell

background vapour [23]. Without the need to load the MOT from an atomic beam, experimental apparatus became simpler and now many groups around the world use the VCMOT for applications ranging from precision spectroscopy to optical control of reactive collisions.

Densities in an MOT. The VCMOT typically captures about a million atoms in a volume less than a millimetre in diameter, resulting in densities $\sim 10^{10} \text{ cm}^{-3}$. Two processes limit the density attainable in an MOT: (1) collisional trap loss and (2) repulsive forces between atoms caused by reabsorption of scattered photons from the interior of the trap [21, 24]. Collisional loss in turn arises from two sources: hot background atoms that knock cold atoms out of the MOT by elastic impact and binary encounters between the cold atoms themselves. Trap loss due to cold collisions is the topic of section C1.4.3. The ‘photon-induced repulsion’ or photon trapping arises when an atom near the MOT centre spontaneously emits a photon which is reabsorbed by a another atom before the photon can exit the MOT volume. This absorption results in an increase of $2\hbar k$ in the relative momentum of the atomic pair and produces a repulsive force proportional to the product of the absorption cross section for the incident light beam and scattered fluorescence. When this outward repulsive force balances the confining force, further increase in the number of trapped atoms leads to larger atomic clouds, but not to higher densities.

(D) DARK SPOT

In order to overcome the ‘photon-induced repulsion’ effect, Ketterle *et al* [25] proposed a method that allows the atoms to be optically pumped to a ‘dark’ hyperfine level of the atom ground state that does not interact with the trapping light. In a conventional MOT one usually employs an auxiliary ‘repumper’ light beam, copropagating with the trapping beams but tuned to a neighbouring transition between hyperfine levels of ground and excited states. The repumper recovers population that leaks out of the cycling transition between the two levels used to produce the MOT. As an example, figure C1.4.9 shows the trapping and repumping transitions usually employed in an Na MOT. The scheme, known as a dark spontaneous-force optical trap (dark SPOT), passes the repumper through a glass plate with a small black dot shadowing the beam such that the atoms at the trap centre are not coupled back to the cycling transition but spend most of their time ($\sim 99\%$) in the ‘dark’ hyperfine level. Cooling and confinement continue to

function on the periphery of the MOT but the centre core experiences no outward light pressure. The dark SPOT increases density by almost two orders of magnitude.

Figure C1.4.9. Usual cooling (carrier) and repumping (sideband) transitions when optically cooling Na atoms. The repumper frequency is normally derived from the cooling transition frequency with electro-optic modulation.

Dashed lines show that lasers are tuned about one natural linewidth to the red of the transition frequencies.

(E) THE FAR-OFF RESONANCE TRAP (FORT)

Although an MOT functions as a versatile and robust ‘reaction cell’ for studying cold collisions, light frequencies must tune close to atomic transitions and an appreciable steady-state fraction of the atoms remain excited. Excited-state trap-loss collisions and photon-induced repulsion limit achievable densities.

A far-off resonance trap (FORT), in contrast, uses the dipole force rather than the spontaneous force to confine atoms and can therefore operate far from resonance with negligible population of excited states. A hybrid MOT/dipole-force trap was used by a NIST–Maryland collaboration [26] to study cold collisions, and a FORT was demonstrated by Miller *et al* [27] for ^{85}Rb atoms. The FORT consists of a single, linearly polarized, tightly focused Gaussian-mode beam tuned far to the red of resonance. The obvious advantage of large detunings is the suppression of photon absorption. Note from [equation \(C1.4.12\)](#) that the spontaneous force, involving absorption and reemission, falls off as the square of the detuning, while [equation \(C1.4.11\)](#) shows that the potential derived from the dipole force falls off only as the detuning itself. At large detunings and high field gradients (tight focus) [equation \(C1.4.11\)](#) becomes

$$U \simeq \frac{\hbar\Omega^2}{4\Delta\omega_L} \tag{C1.4.48}$$

which shows that the potential becomes directly proportional to light intensity and inversely proportional to detuning. Therefore, at far detuning but high intensity the depth of the FORT can be maintained but most of the atoms will not absorb photons. The important advantages of FORTs compared to MOTs are (1) high density ($\sim 10^{12} \text{ cm}^{-3}$) and (2) a well defined polarization axis along which atoms can be aligned or oriented (spin polarized). The main disadvantage is the small number of trapped atoms due to small FORT volume. The best number achieved is about 10^4 atoms [28].

(F) MAGNETIC TRAPS

Pure magnetic traps have also been used to study cold collisions and they are critical for the study of dilute gas-phase Bose–Einstein condensates (BECs) in which collisions figure importantly. We anticipate, therefore, that magnetic traps will play an increasingly important role in future collision studies in and near BEC conditions.

The most important distinguishing feature of all magnetic traps is that they do not require light to provide atom containment. Light-free traps reduce the rate of atom heating by photon absorption to zero, an apparently necessary condition for the attainment of BEC. Magnetic traps rely on the interaction of atomic spin with variously shaped magnetic fields and gradients to contain atoms. The two governing equations are

$$U = -\mu_S B = -\frac{g_S \mu_B}{\hbar} \mathbf{S} B = -\frac{g_S \mu_B}{\hbar} M_S B \tag{C1.4.49}$$

and

$$\mathbf{F} = -\frac{g_S \mu_B}{\hbar} M_S \nabla B. \tag{C1.4.50}$$

If the atom has nonzero nuclear spin I then $\mathbf{F} = \mathbf{S} + \mathbf{I}$ substitutes for \mathbf{S} in equation (C1.4.49), the g-factor generalizes to

$$g_F \cong g_S \frac{F(F+1) + S(S+1) - I(I+1)}{2F(F+1)} \quad (\text{C1.4.51})$$

and

$$\mathbf{F} = -\frac{g_F \mu_B}{\hbar} M_F \nabla B. \quad (\text{C1.4.52})$$

Depending on the sign of U and F , atoms in states whose energy increases or decreases with magnetic field are called ‘weak-field seekers’ or ‘strong-field seekers’, respectively. One could, in principle, trap atoms in any of these states,

-21-

needing only to produce a minimum or a maximum in the magnetic field. Unfortunately only weak-field seekers can be trapped in a static magnetic field because such a field in free space can only have a minimum. Dynamic traps have been proposed to trap both weak- and strong-field seekers [29]. Even when weak-field seeking states are not in the lowest hyperfine levels they can still be used for trapping because the transition rate for spontaneous magnetic dipole emission is $\sim 10^{-10} \text{ s}^{-1}$. However, spin-changing collisions can limit the maximum attainable density. The first static magnetic field trap for neutral atoms was demonstrated by Migdall *et al* [30]. An anti-Helmholtz configuration, similar to an MOT, was used to produce an axially symmetric quadrupole magnetic field. Since this field design always has a central point of vanishing magnetic field, nonadiabatic Majorana transitions can take place as the atom passes through the zero point, transferring the population from a weak-field to a strong-field seeker and effectively ejecting the atom from the trap. This problem can be overcome by using a magnetic bottle with no point of zero field [31, 32, 33 and 34]. The magnetic bottle, also called the Ioffe–Pritchard trap, was recently used to achieve BEC in a sample of Na atoms pre-cooled in an MOT [35]. Other approaches to eliminating the zero-field point are the time-averaged orbiting potential (TOP) trap [36] and an optical ‘plug’ [37] that consists of a blue-detuned intense optical beam aligned along the magnetic trap symmetry axis and producing a repulsive potential to prevent atoms from entering the null-field region. Trap technology continues to develop and the recent achievement of BEC will stimulate more robust traps containing greater numbers of atoms. At present $\sim 10^7$ atoms can be trapped in a BEC loaded from an MOT containing $\sim 10^9$ atoms.

C1.4.3 INELASTIC EXOERGIC COLLISIONS IN MOTS

An exoergic collision converts internal atomic energy to kinetic energy of the colliding species. When there is only one species in the trap (the usual case) this kinetic energy is equally divided between the two partners. If the net gain in kinetic energy exceeds the trapping potential or the ability of the trap to recapture, the atoms escape; and the exoergic collision leads to trap loss.

Of the several trapping possibilities described in the last section, by far the most popular choice for collision studies has been the magneto-optical trap (MOT). An MOT uses spatially dependent resonant scattering to cool and confine atoms. If these atoms also absorb the trapping light at the initial stage of a binary collision and approach each other on an excited molecular potential, then during the time of approach the colliding partners can undergo a fine-structure-changing collision (FCC) or relax to the ground state by spontaneously emitting a photon. In either case, electronic energy of the quasimolecule converts to nuclear kinetic energy. If both atoms are in their electronic ground states from the beginning to the end of the collision, only elastic and hyperfine changing (HCC) collisions

can take place. Elastic collisions (identical scattering entrance and exit states) are not exoergic but figure importantly in the production of Bose–Einstein condensates (BECs). At the very lowest energies only s waves contribute to the elastic scattering and in this regime the collisional interaction is characterized by the scattering length. The sign of the scattering length determines the properties of a weakly interacting Bose gas and the magnitude controls the rate of evaporative cooling needed to achieve BEC. The HCC collisions arise from ground-state splitting of the alkali atoms into hyperfine levels due to various orientations of the nonzero nuclear spin. A transition from higher to lower molecular hyperfine level during the collisional encounter releases kinetic energy. In the absence of external light fields HCCs often dominate trap heating and loss.

-22-

If the collision starts on the excited level, the long-range dipole–dipole interaction produces an interatomic potential varying as $\pm C_3/R^3$. The sign of the potential, attractive or repulsive, depends on the relative phase of the interacting dipoles. For the trap-loss processes that concern us in this chapter we concentrate on the attractive long-range potential, $-C_3/R^3$. Due to the extremely low energy of the collision, this long-range potential acts on the atomic motion even when the pair are as far apart as $\lambda/2\pi$ (the inverse of the light-field wave vector k). Since the collision time is comparable to or greater than the excited-state lifetime, spontaneous emission can take place during the atomic encounter. If spontaneous emission occurs, the quasimolecule emits a photon red shifted from atomic resonance and relaxes to the ground electronic state with some continuum distribution of the nuclear kinetic energy. This conversion of internal electronic energy to external nuclear kinetic energy can result in a considerable increase in the nuclear motion. If the velocity is not too high, the dissipative environment of the MOT is enough to cool this radiative heating, allowing the atom to remain trapped. However, if the transferred kinetic energy is greater than the recapture ability of the MOT, the atoms escape the trap. This process constitutes an important trap-loss mechanism termed radiative escape (RE), and was first pointed out by Vigué [38]. For alkalis there is also another exoergic process involving excited–ground collisions. Due to the existence of fine structure in the excited state ($P_{3/2}$ and $P_{1/2}$), the atomic encounter can result in FCC, releasing Δ_{FS} of kinetic energy, shared equally between both atoms. For example in sodium $\frac{\Delta E_{FS}}{2} \simeq 12 \text{ K}$, which can easily cause the escape of both atoms from the MOT, typically 1 K deep.

These three effects, HCC, RE and FCC, are the main exoergic collisional process that take place in an MOT. They are the dominant loss mechanisms which usually limit the maximum attainable density and number in MOTs. They are not, however, the only type of collision in the trap.

C1.4.3.1 PHOTOASSOCIATION AT AMBIENT AND ULTRACOLD TEMPERATURES

The first measurement of a free–bound photoassociative absorption appeared long before the development of optical cooling and trapping, about two decades ago, when Scheingraber and Vidal [39] reported the observation of photoassociation in collisions between magnesium atoms. In this experiment fixed UV lines from an argon ion laser excited free–bound transitions from the thermal continuum population of the ground $X^1X^1\Sigma_g^+$ state to bound levels of the $A^1A^1\Sigma_u^+$ state of Mg_2 . Scheingraber and Vidal analysed the subsequent fluorescence to bound and continuum states from which they inferred the photoassociative process. The first unambiguous photoassociation *excitation spectrum*, however, was measured by Inoue *et al* [40] in collisions between Xe and Cl at 300 K. In both these early experiments the excitation was not very selective due to the broad thermal distribution of populated continuum ground states. Jones *et al* [41], with a technically much improved experiment, reported beautiful free–bound vibration progressions in KrF and XeI $X \rightarrow B$ transitions; and, from the intensity envelope modulation, were able to extract the functional dependence of the transition moment on the internuclear separation. Although individual vibrational levels of the B state were clearly resolved, the underlying rotational manifolds were not. Jones *et al* [41] simulated the photoassociation structure and line shapes by assuming a thermal distribution of rotational levels at 300 K. Photoassociation and dissociation processes prior to the cold and ultracold epoch have been reviewed by Tellinghuisen [42].

A decade after Schenigraber and Vidal reported the first observation of photoassociation, Thorsheim *et al* [43]

proposed that high-resolution free-bound molecular spectroscopy should be possible using optically cooled and confined atoms. Figure C1.4.10 shows a portion of their calculated $X \rightarrow A$ absorption spectrum at 10 mK for sodium atoms. This figure illustrates how cold temperatures compress the Maxwell-Boltzmann distribution to the point where

-23-

individual rotational transitions in the free-bound absorption are clearly resolvable. The marked differences in peak intensities indicate scattering resonances, and the asymmetry in the line shapes, tailing off to the red, reflect the thermal distribution of ground-state collision energies at 10 mK. Figure C1.4.11 plots the photon-flux-normalized absorption rate coefficient for singlet $X^1X^1\Sigma_g^+ \rightarrow A^1A^1\Sigma_u^+$ and triplet $a^3A^1\Sigma_u^+ \rightarrow 1^3X^1\Sigma_g^+$ molecular transitions over a broad range of photon excitation, red detuned from the Na ($^2S \rightarrow ^2P$) atomic resonance line. The strongly modulated intensity envelopes are called Condon modulations, and they reflect the overlap between the ground-state continuum wavefunctions and the bound excited vibrational wavefunctions. We shall see later that these Condon modulations reveal detailed information about the ground state scattering wave function and potential from which accurate s-wave scattering lengths can be determined. Thorsheim *et al* [44], therefore, predicted all the notable features of ultracold photoassociation spectroscopy later to be developed in many experiments: (1) precision measurement of vibration-rotation progressions from which accurate excited-state potential parameters can be determined, (2) line profile measurements and analysis to determine collision temperature and threshold behaviour and (3) spectral intensity modulation from which the ground-state potential, the scattering wave function and the s-wave scattering length can be characterized with great accuracy.

Figure C1.4.10. Calculated free-bound photoassociation spectrum at 10 mK.

Figure C1.4.11. Calculated absorption spectrum of photoassociation in Na at 10 mK, showing Condon fluctuations.

An important difference distinguishes ambient-temperature photoassociation in rare-gas halide systems and sub-milliKelvin temperature photoassociation in cooled and confined alkali systems. At temperatures found in MOTs and FORTs (and within selected velocity groups in atomic beams) the collision dynamics are controlled by long-range electrostatic interactions, and Condon points R_C are typically at tens to hundreds of a_0 . In the case of the rare-gas halides the Condon points are in the short-range region of chemical binding and, therefore, free-bound transitions take place at much smaller internuclear distances, typically less than ten a_0 . For the colliding A,B quasimolecule the pair density n as a function of R is given by

$$n = n_A n_B 4\pi R^2 e^{-\frac{V(R)}{kT}} \quad (\text{C1.4.53})$$

so the density of pairs varies as the square of the internuclear separation. Although the pair-density R dependence favours long-range photoassociation, the atomic reactant pressures are quite different with the $n_A n_B$ product of the order of 10^{35} cm^{-6} for rare-gas halide photoassociation and only about 10^{22} cm^{-6} for optically trapped atoms. Therefore the effective pair density available for rare-gas halide photoassociation greatly exceeds that for cold alkali photoassociation, permitting fluorescence detection and dispersion by high-resolution (but inefficient) monochromators.

C1.4.3.2 ASSOCIATIVE AND PHOTOASSOCIATIVE IONIZATION

Conventional associative ionization (AI) occurring at ambient temperature proceeds in two steps: excitation of isolated atoms followed by molecular autoionization as the two atoms approach on excited molecular potentials. In sodium for example [44]

The collision event lasts a few picoseconds, fast compared to radiative relaxation of the excited atomic states (\sim tens of nanoseconds). Therefore the incoming atomic excited states can be treated as stationary states of the system Hamiltonian, and spontaneous radiative loss does not play a significant role. In contrast, cold and ultracold photoassociative ionization (PAI) must always start on ground states because the atoms move so slowly that radiative lifetimes become short compared to collision duration. The partners must be close enough at the Condon point, where the initial photon absorption takes place, so that a significant fraction of the excited scattering flux survives radiative relaxation and goes on to populate the final inelastic channel. Thus PAI is also a two-step process: (1) photoexcitation of the incoming scattering flux from the molecular ground-state continuum to specific vibration-rotation levels of a bound molecular state and (2) subsequent photon excitation either to a doubly excited molecular autoionizing state or directly to the molecular photoionization continuum. For example, in the case of sodium collisions the principal route is through doubly excited autoionization [45]

whereas for rubidium atoms the only available route is direct photoionization in the second step [46]

Collisional ionization can play an important role in plasmas, flames and atmospheric and interstellar physics and chemistry. Models of these phenomena depend critically on the accurate determination of absolute cross sections and rate coefficients. The rate coefficient is the quantity closest to what an experiment actually measures and can be regarded as the cross section averaged over the collision velocity distribution,

$$K = \int_0^\infty v\sigma(v)f(v)dv. \quad (\text{C1.4.58})$$

The velocity distribution $f(v)$ depends on the conditions of the experiment. In cell and trap experiments it is usually a Maxwell–Boltzmann distribution at some well defined temperature, but $f(v)$ in atomic beam experiments, arising from optical excitation velocity selection, deviates radically from the normal thermal distribution [47]. The actual signal count rate, $\frac{d(X_2^+)}{dt}$, relates to the rate coefficient through

$$\frac{1}{V\alpha} \frac{d(X_2^+)}{dt} = K[X]^2 \quad (\text{C1.4.59})$$

where V is the interaction volume, α the ion detection efficiency and $[X]$ the atom density. If rate constant or cross section measurements are carried out in crossed or single atomic beams [44, 47, 48] special care is necessary to determine the interaction volume and atomic density.

PAI was the first measured collisional process observed between cooled and trapped atoms [26]. The experiment was performed with atomic sodium confined in a hybrid laser trap, utilizing both the spontaneous radiation pressure and the dipole force. The trap had two counterpropagating, circularly polarized Gaussian laser beams brought to separate foci such that longitudinal confinement along the beam axis was achieved by the spontaneous force and transversal confinement by the dipole force. The trap was embedded in a large (~1 cm diameter) conventional optical molasses loaded from a slowed atomic beam. The two focused laser beams comprising the dipole trap were alternately chopped with a 3 μs ‘trap cycle’, to avoid standing-wave heating. This trap cycle for each beam was interspersed with a 3 μs ‘molasses cycle’ to keep the atoms cold. The trap beams were detuned about 700 MHz to the red of the $3s^2 S_{1/2}(F=2) \rightarrow 3p^2 P_{3/2}(F=3)$ transition while the molasses was detuned only about one natural line width (~10 MHz). The atoms captured from the molasses (~ 10^7 cm^{-3}) were compressed to a much higher excited atom density (~ $5 \times 10^9 \text{ cm}^{-3}$) in the trap. The temperature was measured to be about 750 μK . Ions formed in the trap were accelerated and

focused toward a charged-particle detector. To assure the identity of the counted ions, Gould *et al* [26] carried out a time-of-flight measurement; the results of which, shown in [figure C1.4.12](#) clearly establish the Na_2^+ ion product. The linearity of the ion rate with the square of the atomic density in the trap supported the view that the detected Na_2^+ ions were produced in a binary collision. After careful measurement of ion rate, trap volume and excited atom density, the value for the rate coefficient was determined to be $K = (1.1_{-0.5}^{+1.3}) \times 10^{-11} \text{ cm}^3 \text{ s}^{-1}$. Gould *et al* [26], following conventional wisdom, interpreted the ion production as originating from collisions between two *excited* atoms,

$$\frac{dN_1}{dt} = K \int n_e^2(\mathbf{r}) d^3\mathbf{r} = K \bar{n}_e N_e \quad (\text{C1.4.60})$$

where $\frac{dN_1}{dt}$ is the ion production rate, $n_e(\mathbf{r})$ the excited-state density, N_e the number of excited atoms in the trap ($= \int n_e(\mathbf{r}) d^3(\mathbf{r})$) and \bar{n}_e the ‘effective’ excited-state trap density. The value for K was then determined from these measured parameters. Assuming an average collision velocity of 130 cm s^{-1} , equivalent to a trap temperature of $750 \mu\text{K}$, the corresponding cross section was determined to be $\sigma = (8.6^{+10.0}_{-3.8}) \times 10^{-14} \text{ cm}^2$. In contrast the cross section at $\sim 575 \text{ K}$ had been previously determined to be $\sim 1.5 \times 10^{-16} \text{ cm}^2$ [49, 50 and 51]. Gould *et al* [26] rationalized the difference in cross section size by invoking the difference in de Broglie wavelengths, the number of participating partial waves and the temperature dependence of the ionization channel probability. The quantal expression for the cross section in terms of partial wave contributions l and inelastic scattering probability S_{12} is

$$\sigma_{12}(\epsilon) = \left(\frac{\pi}{k^2}\right) \sum_{l=0}^{\infty} (2l+1) |S_{12}(\epsilon, l)|^2 \cong \pi \left(\frac{\lambda_{\text{dB}}}{2\pi}\right)^2 (l_{\text{max}} + 1)^2 P_{12} \quad (\text{C1.4.61})$$

where λ_{dB} is the entrance channel de Broglie wavelength and P_{12} is the probability of the ionizing collision channel averaged over all contributing partial waves of which l_{max} is the greatest. The ratio of $(l_{\text{max}} + 1)^2$ between 575 K and $750 \mu\text{K}$ is about 400 and the de Broglie wavelength ratio factor varies inversely with temperature. Therefore, in order that the cross section ratio be consistent with low- and high-temperature experiments, $\frac{\sigma_{12}(575 \text{ K})}{\sigma_{12}(750 \mu\text{K})} \sim 1.7 \times 10^{-3}$, Gould *et al* [26] concluded that P_{12} must be about three times greater at 575 K than at $750 \mu\text{K}$.

-27-

Figure C1.4.12. Time-of-flight spectrum clearly showing that the ions detected are Na_2^+ and not the atomic ion.

However, it soon became clear that the conventional picture of associative ionization, starting from the excited atomic states, could not be appropriate in the cold regime. Julienne [52] pointed out the essential problem with this picture. In the molasses cycle the optical field is only red detuned by one line width, and the atoms must therefore be excited at very long range, near $1800 a_0$. The collision travel time to the close internuclear separation where associative ionization takes place is long compared to the radiative lifetime, and most of the population decays to the ground state before reaching the autoionization zone. During the trap cycle, however, the excitation takes place at much closer internuclear distances due to a 70 line-width red detuning and high-intensity field dressing. Therefore, one might expect excitation survival to be better on the trap cycle than on the molasses cycle, and the NIST group set up an experiment to test the predicted cycle dependence of the ion rate.

Lett *et al* [53] performed a new experiment using the same hybrid trap. This time, however, the experiment measured ion rates and fluorescence separately as the hybrid trap oscillated between ‘trap’ and ‘molasses’ cycles. The results from this experiment are shown in figure C1.4.13. While keeping the total number and density of atoms (excited atoms plus ground-state atoms) essentially the same over the two cycles and while the excited state fraction changed only by about a factor of two, the ion rate increased in the trapping cycle by factors ranging from 20 to 200 with most observations falling between 40 and 100. This verified the predicted effect qualitatively even if the magnitude was smaller than the estimated 10^4 factor of Julienne [52]. This modulation ratio is orders of magnitude more than would be expected if excited atoms were the origin of the associative ionization signal. Furthermore, by detuning the trapping lasers over 4 GHz to the red, Lett *et al* continued to measure ion production at rates comparable to those measured near the atomic resonance. At such large detunings, reduction in atomic excited-state population would have led to reductions in ion rate by over four orders of magnitude, had the excited atoms been the origin of the collisional ionization. Not only did far off-resonance trap cycle detuning maintain the ion production rate, but Lett *et al* [53] observed evidence of peak structure in the ion signal as the dipole trap cycle detuned to the red.

-28-

Figure C1.4.13. Trap modulation experiment showing much greater depth of ion intensity modulation (by more than one order of magnitude) than fluorescence or atom number modulation, demonstrating that excited atoms are not the origin of the associative ionizing collisions.

To interpret this experiment, Julienne and Heather [45] proposed a mechanism that has become the standard picture for cold and ultracold photoassociative ionization. Figure C1.4.14 details the model.

Figure C1.4.14. Photoassociative ionization (PAI) in Na collisions.

Two colliding atoms approach on the molecular ground-state potential. During the molasses cycle with the optical fields detuned only about one line width to the red of atomic resonance, the initial excitation occurs at very long range, around a Condon point at $1800 a_0$. A second Condon point at $1000 a_0$ takes the population to a 1_u doubly excited potential that, at shorter internuclear distance, joins adiabatically to a $3 \Sigma_u^+$ potential, thought to be the principal short-range entrance channel to associative ionization [54, 55]. More recent calculations suggest other entrance channels are important as well [56]. The long-range optical coupling to excited potentials in regions with little curvature implies that spontaneous radiative relaxation will depopulate these channels before the approaching partners reach the region of small internuclear separation where associative ionization takes place. The overall probability for collisional ionization during the molasses cycle remains therefore quite low. In contrast, during the trap cycle the optical fields are detuned 60 line widths to the red of resonance, the first Condon point occurs at $450 a_0$; and, if the trap cycle field couples to the 0_g^- long-range molecular state [57], the second Condon point occurs at $60 a_0$. Survival against radiative relaxation improves greatly because the optical coupling occurs at much shorter range where excited-state potential curvature accelerates the two atoms together. Julienne and Heather [45] calculate about a three-orders-of-magnitude enhancement in the rate constant for collisional ionization during the trap cycle. The dashed and solid arrows in figure C1.4.14 indicate the molasses-cycle and trap-cycle pathways, respectively. The strong collisional ionization rate constant enhancement in the trap cycle calculated by Julienne and Heather [45] is roughly consistent with the measurements of Lett *et al* [53], although the calculated modulation ratio is somewhat greater than what was actually observed. Furthermore, Julienne and Heather calculate structure in the trap detuning spectrum. As the optical fields in the dipole trap tune to the red, a rather congested series of ion peaks appear, which Julienne and Heather ascribed to free-bound association resonances corresponding to vibration-rotation bound levels in the 1_g or the 0_g^- molecular excited states. The density of peaks corresponded roughly to what Lett *et al* [53] had observed; these two tentative findings together were the first evidence of a new photoassociation spectroscopy. In a subsequent full paper expanding on their earlier report, Heather and Julienne [58] introduced the term ‘photoassociative ionization’ to distinguish the two-step optical excitation of the quasimolecule from the conventional associative ionization collision between excited atomic states. In a very recent paper, Pillet *et al* [59] have developed a perturbative quantum approach to the theory of photoassociation, which can be applied to the whole family of alkali homonuclear molecules. This study presents a useful table of photoassociation rates which reveals an important trend toward lower rates of molecule formation as the alkali mass increases and provides a helpful guide to experiments designed to detect ultracold molecule production.

C1.5 Single molecule spectroscopy

Anne Myers Kelley

C1.5.1 INTRODUCTION

Until the late 1980s, virtually all molecular spectroscopic measurements involved observing a signal having contributions from a large number of different molecules, ‘large’ meaning much greater than one. While spectroscopists have long had the ability to detect and count individual photons or ions each originating from a single molecule, the statistical averaging required to make a meaningful measurement generally required observing many such events from many different molecules. Only recently have experimental techniques been developed that allow interrogation of fundamentally quantum mechanical entities on a one-by-one basis. These developments are driving revolutionary changes in the way molecular scientists make and interpret physical measurements. For example, simple organic molecules that are chemically identical, distinguished only by slightly different local environments within a solid, have been shown to have distinctly different electronic and vibrational spectra, linewidths, electric field and pressure-induced spectral shifts, and fluorescence lifetimes and quantum yields. The ability to correlate these various spectroscopic properties on a molecule-by-molecule basis is providing powerful insight into the details of intermolecular interactions. Single-molecule techniques have also shown that apparently pure, homogeneous enzyme preparations contain molecules having a wide range of catalytic activities and that an

individual enzyme's catalytic activity retains a 'memory' of its past history. This new information is stimulating a re-evaluation of established models for the chemical kinetics of biological systems. Single-molecule experiments involve sequential measurements of a given observable on the same molecule at different times and, if a time average is equivalent to an ensemble average (the ergodic hypothesis), no additional information is gained by probing individual members. The value of single-molecule measurements lies precisely in the fact that in many systems of interest, different members of the ensemble remain distinct on time scales much longer than that required to perform an experiment.

A wide variety of measurements can now be made on single molecules, including electrical (e.g. scanning tunnelling microscopy), magnetic (e.g. spin resonance), force (e.g. atomic force microscopy), optical (e.g. near-field and far-field fluorescence microscopies) and hybrid techniques. This contribution addresses only those techniques that are at least partially optical. Single-particle electrical and force measurements are discussed in the sections on scanning probe microscopies (B1.19) and surface forces apparatus (B1.20).

C1.5.2 HISTORY

The approach to, and finally the achievement of, detection and spectroscopy of single molecules proceeded almost independently from three separate directions.

C1.5.2.1 SPECTRAL SELECTION IN CRYOGENIC SOLIDS

The development of tunable, narrow-bandwidth dye laser sources in the early 1970s gave spectroscopists a new tool for selectively exciting small subsets of molecules within inhomogeneously broadened ensembles in the solid state. The technique of fluorescence line-narrowing [1, 2 and 3] takes advantage of the fact that relatively rigid chromophoric

-2-

molecules in dilute mixed solids at low temperatures often have very narrow electronic origin transitions even when the bulk absorption spectrum is severely broadened by an inhomogeneous distribution of spectrally distinct environments. By tuning a narrow-band excitation source into resonance with the low-energy side of the absorption band, only those molecules that absorb at that precise frequency can be excited. This subensemble, having a well defined electronic origin frequency, will then produce spectrally sharp emissions. As the sample is made increasingly dilute, and/or the excitation is tuned progressively farther toward the red edge of the absorption spectrum, the number of molecules on resonance with the laser decreases, eventually becoming either zero or one.

The first clearly demonstrated optical detection of single *chromophores* was published by Moerner's group at IBM Almaden 1989 on the mixed crystal system pentacene in *p*-terphenyl at 1.6 K [4, 5]. They utilized a double-modulation direct absorption technique employing frequency modulation of the laser source coupled with electric field or ultrasonic strain modulation of the absorption line. Direct absorption is not known for its high sensitivity, and these preliminary experiments achieved only modest signal-to-noise ratios. Shortly thereafter, Orrit's group at Bordeaux demonstrated single-molecule detection in the same system with the fundamentally much more sensitive technique of fluorescence excitation—fluorescence line-narrowing carried to the extreme of a single resonant chromophore at a time (figure C1.5.1) [6]. Fluorescence excitation has since been the technique of choice for nearly all single-molecule optical experiments, although some refinements in direct absorption detection have recently been demonstrated [7].

Figure C1.5.1. (A) Schematic diagram showing the principle of single-molecule spectral selection in solids at low temperatures. The inhomogeneously broadened electronic origin is composed of a superposition of the Lorentzian profiles of individual molecules, with a Gaussian distribution of centre frequencies caused by random strains and defects in the surrounding environment. (B) The number of dopant molecules in the probed volume on resonance with a narrow-band laser can be controlled by tuning the laser wavelength to the red side of the inhomogeneous band. C1.5.2.2 FLUORESCENCE STATISTICS IN LIQUID SOLUTIONS

Fluorescence, because of its essentially background-free nature, has long been appreciated by both analytical and physical chemists for its high sensitivity. Photon counting techniques allow detection of single photons each emitted by a single molecule, although under normal conditions the total signal is composed of photons arising from many different molecules. Hirschfeld was apparently the first to demonstrate that individual molecules (in his case, large antibodies each tagged with 80–100 fluorophores) in a highly dilute solution could be detected by the burst of fluorescence emitted by each molecule as it diffused through the observation volume of an optical microscope [8]. The Keller [9] and Mathies [10] groups subsequently combined this idea with a more detailed analysis of the photon burst statistics to detect single molecules of the highly fluorescent multichromophoric protein phycoerythrin. The first demonstration of genuine single-*chromophore* detection in liquid solution was published by Shera and co-workers in 1990 on the laser dye rhodamine 6G in water [11], using pulsed excitation and time-gated detection to reduce background counts. Somewhat later, Nie *et al* [12] demonstrated that with some modifications to the detection system, a commercial laser confocal microscope could also be made sensitive enough to detect single chromophores diffusing in and out of the detection volume.

C1.5.2.3 SPATIAL SELECTION IN SOLIDS AND ON SURFACES

A third approach to single-molecule optical detection began with the development of near-field scanning optical microscopy (NSOM) in the 1980s (see section 1.19). NSOM allows optical measurements on surfaces to be made with a resolution approaching $\lambda/40$ in the best cases [13], which for visible light is comparable to the size of single large molecules such as proteins and polymers. The first observation of single molecules by NSOM was reported in

1993 by Betzig and Chichester [14]. Shortly thereafter, several groups demonstrated that the techniques of ordinary far-field fluorescence microscopy, if coupled with highly sensitive, low-noise detectors, can also detect single molecules as long as they are spaced far enough apart that the limiting resolution of about $\lambda/2$ is adequate. Far-field fluorescence microscopy is technically simpler than NSOM and has the advantage of not being restricted to surfaces, and has become the technique of choice for spatial selection of single molecules as long as the sample can be made sufficiently dilute that the additional resolution of the near-field technique is not needed.

C1.5.3 PRINCIPLES AND TECHNIQUES OF SINGLE-MOLECULE OPTICAL

C1.5.3.1 FLUORESCENCE

The vast majority of single-molecule optical experiments employ one-photon excited spontaneous fluorescence as the spectroscopic observable because of its relative simplicity and inherently high sensitivity. Many molecules fluoresce with quantum yields near unity, and spontaneous fluorescence lifetimes for chromophores with large oscillator strengths are a few nanoseconds, implying that with a sufficiently intense excitation source a single molecule should be able to absorb and emit of the order of 10^8 photons per second. Additionally, in most molecules much of the emitted light is sufficiently red-shifted from the excitation frequency to allow detection against a nominally near-zero background.

A number of experimental and physical realities cloud this rosy picture. Inevitably many emitted photons are lost due to the finite solid angle over which the fluorescence is collected, losses at the various filters, lenses, windows, and other

-4-

optical elements between the sample and the detector, and the quantum efficiency of the photodetector. Most experimental configurations actually detect emitted photons with an overall efficiency of only a few per cent. All molecules have nonzero, if small, quantum yields for forming long-lived metastable states (often triplet states), reducing the number of absorption–emission cycles that can be accomplished per second. The intensity of the excitation source has to be kept low enough that it does not induce undesired nonlinear optical effects (section B1.1 and section B1.5). Finally, all known molecules undergo photochemical degradation with some nonzero yield, and this photobleaching is generally the limiting factor in determining the total number of photons that can be collected from a single molecule. Nevertheless, it is routinely possible with strongly fluorescent chromophores to detect 10^3 – 10^4 photons per second. The challenging part of performing single-molecule fluorescence detection is not the absolute size of the signal, which is huge compared with that typical of many conventional ensemble-averaged spectroscopies such as Raman, but rather ascertaining that the signal arises from only one molecule, reducing the background count level, and obtaining a statistically significant amount of data from the molecule under observation before it photobleaches.

(A) SPECTRAL SELECTION

The spectral selection approach [15, 16 and 17] is based on the fact that purely lifetime-limited line widths for electronic transitions of molecules rarely exceed 10–20 MHz, whereas the apparent width of the electronic origin in condensed-phase molecular spectra is typically orders of magnitude greater even in single crystals and certainly in polymers and glasses. At temperatures below 4 K, where little thermal population of phonons is possible, this additional width is ascribed to slightly different local environments for different chromophores, each giving rise to a slightly different spectral shift. When a spectrally narrow laser (bandwidth on the order of the intrinsic lifetime-limited width) is tuned through the ensemble-broadened electronic origin, only those chromophores on resonance with that particular laser frequency can absorb, and as the laser is tuned into the wings of the spectral line, the number of molecules on resonance approaches either zero or one (figure C1.5.1) and figure C1.5.2. In practice this works best when tuning to the red side of the electronic origin; on the blue side, the zero-phonon lines (pure

electronic origin transitions) of blue-shifted molecules are degenerate with the much broader phonon sidebands (electronic excitation of the chromophore coupled with excitation of low-frequency matrix or intermolecular vibrations) of redder-shifted molecules. Typically the emission is collected with mirror or lens systems placed inside the cryostat to collect light over the largest possible solid angle, and observed with a high quantum efficiency detector, either a photomultiplier tube or an avalanche photodiode, through one or more long-pass or bandpass filters to block scattered or transmitted laser light. Alternatively, the emitted light may be dispersed with a spectrograph and detected with a high-efficiency array photodetector, generally a CCD.

Figure C1.5.2. Fluorescence excitation spectra (cps = counts per second) of pentacene in *p*-terphenyl at 1.5 K. (A) Broad scan of the inhomogeneously broadened electronic origin. The spikes are repeatable features each due to a different single molecule. The laser detuning is relative to the line centre at 592.321 nm. (B) Expansion of a 2 GHz region of this scan showing several single molecules. (C) Low-power scan of a single molecule at 592.407 nm showing the lifetime-limited width of 7.8 MHz and a Lorentzian fit. Reprinted with permission from Moerner [198]. Copyright 1994 American Association for the Advancement of Science.

The criterion that single molecules are being observed is often taken to be the appearance in a fluorescence excitation frequency scan of well separated peaks that have about the same intensity and width, separated by regions of flat background. However, one cannot be certain that a given peak does not arise from two molecules with accidentally degenerate resonant frequencies. Stronger evidence is provided by observing that when spontaneous or photoinduced spectral jumps or photobleaching occur, the fluorescence excitation feature jumps to a new frequency or disappears entirely from the scanned region in a quantized, all-or-nothing manner. Probably the best evidence for single-molecule observation comes from the statistics of photon emission on short time scales. Since a single molecule must experience a nonzero time interval between successive photon emissions (after emitting a photon, it must absorb one prior to its next emission), the probability of emitting two photons with zero time delay goes to zero for a single molecule, the phenomenon known as photon antibunching.

The requirement of a very sharp and strong electronic origin absorption line limits the technique to strongly absorbing and fluorescing, relatively rigid chromophores and matrices having little Franck–Condon activity in low-frequency

vibrations. The requirement that the electronic origin be spectrally quite stable limits the technique to very low temperatures and to chromophore–matrix combinations in which spectral diffusion and photophysical hole-burning processes are slow. Thus, while the intrinsically high spectral resolution of this technique allows detailed spectroscopic and dynamical studies on individual molecules, the number of material systems to which it can be applied seems to be quite limited.

(B) SPATIAL SELECTION WITH NEAR-FIELD OPTICS

The development of near-field scanning optical microscopy (NSOM) as a viable experimental technique opened up the possibility of performing optical measurements with spatial resolution on molecular scales, just as scanning tunnelling microscopy (STM) allows imaging through electrical measurements down to the atomic level. By forcing the excitation light to pass through a metallized tip with an aperture much smaller than the wavelength of the light, and placing the sample in the near field of the tip (much less than a wavelength away), a variety of optical microscopies can be performed at a resolution much better than the classical far-field limit of $\approx\lambda/2$ [13, 14, 15, 16, 17 and 18]. Apertureless variants of NSOM have also been described [19 and 20]. The NSOM technique in general is described in more detail in [section B1.20](#).

NSOM in fluorescence mode can easily detect single molecules that are spatially separated by tens of nanometres or more, as long as they are sufficiently photostable to withstand the necessary number of excitation–emission cycles [14, 15, 16, 17, 18, 19, 20 and 21]. The usual criterion for single-molecule observation is the appearance of single isolated spots in the NSOM fluorescence image ([figure C1.5.3](#)), although two or more molecules that are accidentally in very close proximity are not always resolvable. The quantized nature of photobleaching events is another good criterion for single-molecule observation in spatially as well as spectrally selected techniques. NSOM is difficult to perform at low temperatures, but cryogenic near-field microscopes have been described [22] and demonstrated at the single-molecule level [23 and 24]. A significant limitation is that the chromophore of interest must be at or very near a surface to allow the tip to be brought into close proximity. The tips are notoriously difficult to fabricate in a reproducible manner, particularly when a very small aperture is desired, and can become quite hot during operation due to the laser power dissipated in the metal coating. The proximity of the metal tip to the chromophore can induce artifacts that have been discussed in some detail [25, 26 and 27]. In applications where sub-diffraction-limited optical resolution is needed, for example in studying biological or engineered supermolecular structures, NSOM is the only viable technique. If, however, the goal is merely to study single molecules and the samples can be prepared such that the molecules are spaced arbitrarily far apart, conventional far-field fluorescence microscopies are technically more straightforward and less subject to artifacts.

Figure C1.5.3. Near-field fluorescence image (4.5 μm square) of single oxazine 720 molecules dispersed on the surface of a PMMA film. Each peak (fwhm 100 nm) is due to a single molecule. The different intensities are due to different molecular orientations and spectra. Reprinted with permission from Xie [122]. Copyright 1996 American Chemical Society.

An intriguing alternative to NSOM is to engineer a tip bearing a single fluorescent molecule that can be excited at one wavelength, emitting light at a Stokes-shifted wavelength to be used as a highly spatially localized probe light source [28 and 29].

(C) SPATIAL SELECTION WITH FAR-FIELD OPTICS

Confocal scanning laser fluorescence microscopy is a well established optical technique (see section B1.19) that combines the transverse resolution common to any optical microscopy with a high degree of depth resolution that comes from requiring the fluorescence emission to follow the same optical path as the exciting laser light and pass through a pinhole conjugate to a pinhole through which the exciting laser was focused. A three-dimensional fluorescence image is mapped out by raster scanning either the exciting laser beam or the sample in the transverse plane and stepping the focusing lens to sample distance along the depth axis. If the fluorescence collection and detection systems are efficient enough, this technique can be sufficiently sensitive to detect emission from single molecules [12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29 and 30]. The limiting transverse resolution is determined by the numerical aperture of the laser focusing lens but cannot exceed about $\lambda/2$, while the resolution along the depth axis is typically of the same order. Thus, for single molecules to be resolved directly they must be separated on average by roughly 0.2–0.5 μm or more, although sub-diffraction resolution may be achieved through subsequent numerical processing of the images [31] or by making clever use of optical interference effects [32, 33]. Figure C1.5.4 compares near-field and far-field images of the same set of single molecules at a surface. Once a strong feature due to a single molecule has been identified, the centre of the focused spot can be moved to that molecule and more detailed spectroscopic or kinetic measurements made. The low resolution makes it difficult to be certain that a fluorescent spot truly arises from a single molecule, and it is useful to have other evidence such as photon emission statistics and/or quantized jumping or photobleaching to verify single-molecule observation.

-8-

Figure C1.5.4. Comparison of near-field and far-field fluorescence images, spectra and lifetimes for the same set of isolated single molecules of a carbocyanine dye at a PMMA–air interface. Note the much higher resolution of the near-field image. The spectrum and lifetime of the molecule indicated with the arrow were recorded with near-field excitation and with far-field excitation at two different excitation powers. Reproduced with permission from Trautman and Macklin [125].

Forming an image by scanning the laser spot across the sample, or vice versa, minimizes the light dose received by each molecule and reduces photobleaching. The tradeoff is that it requires some time to gather an image. A fluorescent image can be obtained much more rapidly by irradiating a larger area in the transverse plane and imaging the emission from the entire area at once onto a two-dimensional photodetector. This approach is most useful for highly-photostable molecules at low temperatures [34, 35 and 36]. Photobleaching can be further reduced by employing an automatic positioning system with feedback to locate and centre the excitation on a single molecule as rapidly as possible [37] and also by excluding oxygen [38] and/or working at very low temperatures where most chromophores are more stable, although the latter adds considerable complexity to the experimental configuration [39, 40 and 41].

(D) STATISTICAL DETECTION METHODS

The statistics of the detected photon bursts from a dilute sample of chromophores can be used to count, and to some degree characterize, individual molecules passing through the illumination and detection volume. This can be achieved either by flowing the sample rapidly through a narrow fluid stream that intersects the focused excitation beam or by allowing individual chromophores to diffuse into and out of the beam. If the sample is sufficiently dilute that

chromophores pass through the beam effectively one at a time, repetitive excitation and emission of each molecule during its passage time generates a burst of emitted photons, superimposed on a random background count level due to stray room and laser light, Raman scattering from the solvent, etc [9, 10 and 11, 42, 43, 44, 45 and 46]. Figure C1.5.5 shows representative data from a configuration allowing free diffusion of chromophores into and out of the beam. A variety of statistical analyses of the photon bursts can be performed to improve the fidelity of detection and/or to discriminate between chromophores of different chemical species based on spectral and/or temporal features of the emission [44, 45, 47, 48, 49, 50, 51 and 52]. These statistical methods are employed mainly for counting molecules in analytical applications. The comparatively short observation time for each molecule limits the extent to which photophysical, spectroscopic or dynamic properties can be examined at the single-molecule level.

Figure C1.5.5. Time-dependent fluorescence signals observed from liquid solutions of rhodamine 6G by confocal fluorescence microscopy. Data were obtained with 514.5 nm excitation and detected through a 540–580 nm bandpass filter. The integration time is 1 ms per point. (A) Blank. (B) 2×10^{-11} M rhodamine 6G in water. Each peak represents detection of a single molecule diffusing into and then out of the detection volume. The inserts are close up views of the peaks indicated, showing the multiple detection of a single molecule. (C) 5×10^{-11} M rhodamine 6G in ethanol. Reprinted with permission from Nie *et al* [12]. Copyright 1994 American Association for the Advancement of Science.

C1.5.3.2 RAMAN SCATTERING

Raman scattering (section B1.3) is a notably weak process. In most experimental configurations no more than one in 10^{10} laser photons is scattered into a given Raman line. While resonance enhancement may improve this to one in 10^6 , Raman would still appear to be a highly unpromising technique for single-molecule detection. Nevertheless, at least four different groups have recently claimed single-molecule sensitivity using surface-enhanced Raman scattering (SERS), an enhancement mechanism whose physical basis is still subject to some controversy. Nie and Emory [53] examined rhodamine 6G dye molecules bound to particles of colloidal silver that were immobilized on a substrate such that they could be imaged via confocal microscopy. Using very low dye concentrations and exciting with 514.5 nm light, they observed Raman scattering from only a very few particles that they attributed to particularly stable and highly surface-enhanced ‘hot’ binding sites (figure C1.5.6) and figure C1.5.7. The apparent enhancement is of the order of 10^{14} over ordinary unenhanced Raman, whereas generally accepted values for SERS enhancements from ordinary bulk experiments are around 10^6 . More recent work by Brus *et al* essentially confirms and extends these observations 54. Kneipp *et al* examined crystal violet and a cyanine dye on colloidal silver with excitation in the near-infrared, away from both molecular electronic resonances and the principal particle plasmon resonance. They probed the particles in free solution and based their claim of single-chromophore detection on the excitation volume, dye-to-silver concentration ratio, and detection statistics [55, 56]. Finally, Käll *et al* examined the SERS spectra of haemoglobin attached to silver nanoparticles and concluded that single-molecule SERS is possible only for protein molecules situated between and bound to more than one silver particle

Figure C1.5.6. Single Ag nanoparticles imaged with evanescent-wave excitation. (A) Unfiltered photograph showing scattered laser light (514.5 nm) from Ag particles immobilized on a polylysine-coated surface. (B) Bandpass filtered (540–580 nm) photograph taken from a blank Ag colloid sample incubated with 1 mM NaCl and no dye. (C) and (D) Filtered photographs taken from an Ag colloid sample incubated with 2×10^{-11} M rhodamine 6G. Each image shows at least one Raman scattering particle. (E) and (F) Filtered photographs of Ag colloid incubated with higher concentrations of rhodamine 6G (2×10^{-10} M and 2×10^{-9} M, respectively). Each image shows several Raman scattering particles. Figure C1.5.7. Surface-enhanced Raman spectra of a single rhodamine 6G particle on silver recorded at 1 s intervals. Over 300 spectra were recorded from this particle before the signals disappeared. The nine spectra displayed here were chosen to highlight several as yet unexplained sudden changes in both frequency and intensity. Reprinted with permission from Nie and Emory [53]. Copyright 1997 American Association for the Advancement of Science.

It now seems clear that, under certain conditions, massive enhancements of what is normally a very weak process can be achieved. The ability to obtain vibrational spectra would be a great advance in the characterization of single molecules if methods could be found to reproducibly observe all molecules in a sample, not only those that happen to bind to special sites on the colloid.

C1.5.3.3 MULTIPHOTON EXCITATION

Electronic excitation to a fluorescent state can be accomplished not only by direct one-photon absorption to that state, but also by the ‘simultaneous’ absorption of two or more photons whose energy sums to that of the excited state. Multiphoton absorption cross sections are sufficiently small that these processes are negligibly weak with cw light sources, but two- and three-photon absorption become viable processes for single-molecule detection at the high peak intensities provided by focusing femtosecond pulses to diffraction-limited spot sizes. In particular, the development of Ti:sapphire lasers reliably delivering femtosecond pulses in the far-red and near-infrared regions of the spectrum has enabled two- and three-photon excited fluorescence microscopy of blue and ultraviolet chromophores [58, 59]. Multiphoton absorption is sometimes referred to as ‘intrinsically confocal’ since the probability of absorbing two or three photons depends on the second or third power of the laser intensity, respectively, greatly enhancing the

contribution to the signal from molecules at the beam focus over those outside the focus, even without any additional aperturing. The transverse resolution can be somewhat enhanced for the same reason, although this advantage is partially offset by the larger focused spot size imposed by the longer wavelength of the laser. In addition, the negligible absorption of the unfocused red or infrared light by many samples, particularly biological samples, allows probing at comparatively great depths within samples that often absorb strongly in the UV.

Two-photon excited fluorescence detection at the single-molecule level has been demonstrated for chromophores in cryogenic solids [60], room-temperature surfaces [61], membranes [62] and liquids [63, 64 and 65]. Although multiphoton excited fluorescence has been embraced with great enthusiasm as a technique for both ordinary confocal microscopy and single-molecule detection, it is not a panacea; in particular, photochemical degradation in multiphoton excitation may be more severe than with ordinary linear excitation, probably due to absorption of more than the desired number of photons from the intense laser pulse (e.g. triplet excited state absorption) [61].

C1.5.4 SYSTEMS AND PHENOMENA

C1.5.4.1 SPECTROSCOPY AND PHOTOPHYSICS

(A) CRYOGENIC STUDIES

Studies of single molecules in cryogenic solids, while limited to a relatively small number of chromophore/ matrix combinations (and small variations thereupon), have covered a wide range of spectroscopic and dynamic processes [66, 67].

The spectral and temporal characteristics of the fluorescence excitation spectra have been examined for several chromophores in a variety of single crystalline, Sh'polskii, and amorphous matrices. Two distinct methods are employed in these studies: direct measurements in which the laser frequency is scanned repetitively across a single-molecule electronic origin while counting emitted photons, and correlation techniques in which the laser frequency is fixed and the autocorrelation statistics of emitted photons measured. Both techniques can provide information about the dynamics of fluctuations in the electronic origin frequency of a single molecule, although the correlation techniques are useful over a broader range of time scales. The direct technique also permits the electronic origin linewidths for different single molecules to be measured, with the limitation that the time required to accurately characterize the lineshape by scanning the laser frequency ranges from fractions of a second to minutes, and any fluctuations occurring on faster time scales are folded into the apparent linewidth. In all systems examined to date, at least some molecules exhibit time-dependent fluctuations in electronic origin frequency ranging from a few MHz to many GHz or more. These occur on time scales from microseconds to hours, and may be apparently spontaneous (usually denoted 'spectral diffusion') and/or light-induced (often called 'hole burning'). In general the narrowest lines, as narrow as the lifetime limit based on the fluorescence lifetime measured in bulk experiments, and most stable spectra are observed in single crystals: pentacene [6, 68 and 69] and terrylene [70, 71] in *p*-terphenyl, and terrylene [72], dibenzoterrylene [73] and dibenzanthanthrene [74] in naphthalene. These and closely related chromophores in *n*-alkane Sh'polskii matrices (terrylene in *n*-alkanes [75, 76, 77 and 78], perylene in *n*-nonane [79], dibenzanthanthrene [80] and terrylenediimide [81] in *n*-hexadecane) tend to show more spectral diffusion and a broader distribution of apparent linewidths, up to several times the lifetime limit. Even more spectral lability is observed in amorphous (polymer) matrices; the electronic origin linewidths measured over any finite period of time often exceed the lifetime limit by more than an order of

magnitude, and a rich variety of spectral diffusion and spectral jumping behaviours are observed (see figure C1.5.8 [78, 81, 82, 83, 84, 85, 86 and 87]). The spontaneous spectral diffusion that persists even down to 1.5 K is attributed to tunnelling between 'two-level systems', different configurations of the matrix separated by small barriers that are nearly isoenergetic for the chromophore in its ground electronic state but have significantly different energies in the excited electronic state, thus shifting the electronic transition frequency. Considerable theoretical work has been and continues to be performed to understand the physical origin of these two-level systems and to interpret the observed linewidth distributions and dynamics of the spectral diffusion [88, 89, 90, 91, 92, 93, 94 and 95].

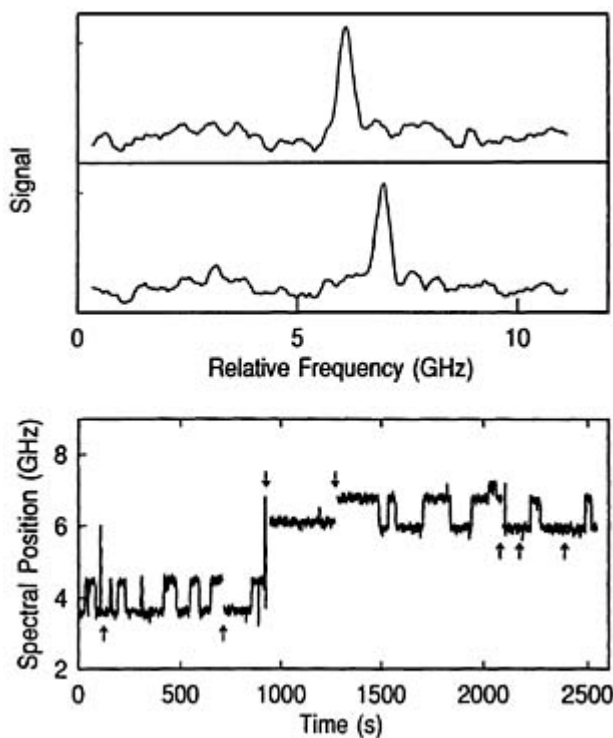

Figure C1.5.8. Spectral jumping of a single molecule of terrylene in polyethylene at 1.5 K. The upper trace displays fluorescence excitation spectra of the same single molecule taken over two different 20 s time intervals, showing the same molecule absorbing at two distinctly different frequencies. The lower panel plots the peak frequency in the fluorescence excitation spectrum as a function of time over a 40 min trajectory. The molecule undergoes discrete jumps among four (briefly five) different resonant frequencies during this time period. Arrows represent scans during which the molecule had jumped entirely outside the 10 GHz scan window. Adapted from [199].

The Stark effect (shifting of the absorption frequency in response to an external electric field) has been measured for nominally centrosymmetric single molecules both in mixed crystals (pentacene in *p*-terphenyl) [96] and in amorphous solids (terrylene in polyethylene) [97]. In the former system the energy shifts are dominated by the term quadratic in applied field as expected for a centrosymmetric system, but in the latter the Stark shifts are dominated by the linear term and vary widely in both magnitude and sign among different molecules. This is excellent evidence for large and variable dipole moments induced in nominally centrosymmetric chromophores by the disorder in the environment, and dramatically demonstrates the strength of the local electric fields produced by even the moderately polar bonds of a simple hydrocarbon environment.

-15-

Line shifts as a function of pressure have been studied for pentacene and terrylene in *p*-terphenyl [98, 99]. Both exhibited linear and reversible spectral red shifts with increasing pressure. Modest variations (factors of 1.3–1.6) in the pressure shifts among molecules were attributed to slightly different local environments.

Fluorescence lifetimes have been measured directly by time-correlated single-photon counting for pentacene in *p*-terphenyl [100]. This experiment requires careful selection of the laser pulse characteristics such that the pulse duration is short enough to resolve the 23 ns decay time, yet has a bandwidth narrow enough to allow spectral selection of individual molecules. Four different molecules had the same lifetime to within experimental uncertainty, indicating that the principal contributions to the S_1 state decay (radiation and internal conversion to S_0) are not strongly sensitive to the local environment in this relatively homogeneous crystalline matrix.

The polarization properties of single-molecule fluorescence excitation spectra have been explored and utilized to determine both the molecular transition dipole moment orientation and the depth of single pentacene molecules in a *p*-terphenyl crystal, taking into account the rotation of the polarization of the excitation light by the birefringent

crystal [101, 102].

Dispersed fluorescence spectra showing resolution of the ground-state vibrations have been reported for single molecules of pentacene in *p*-terphenyl [103, 104], terrylene in *p*-terphenyl [71] and terrylene in polyethylene [105, 106 and 107]. In the former system all molecules were found to have quite similar spectra, but the small variations between crystallographically distinct O₁ and O₂ sites were shown to be reproducible enough to distinguish between sites [104], and other small variations due to either natural abundance isotopic substitution or local defect induced redistributions of intensity were noted [104]. Terrylene in both crystalline and amorphous matrices exhibits significant spectral variations among molecules (see figure C1.5.9). The two distinct types of spectra observed in polyethylene were suggested to arise from terrylene molecules in two very different local environments, perhaps amorphous and crystalline, although the possibility of a chemical impurity could not be ruled out at the time and has since been suggested as the correct explanation [108]. These experiments highlight the promise of low-temperature single-molecule spectroscopy for making very detailed spectroscopic measurements probing correlations among various spectroscopic observables, e.g., electronic and vibrational frequencies. They also suggest the possibility that single-molecule spectroscopy could provide the vibrational frequencies of ¹³C substituted isotopomers, essential in classical vibrational analysis, without the need to synthesize specifically labelled material.

-16-

Figure C1.5.9. Vibrationally resolved dispersed fluorescence spectra of two different single molecules of terrylene in polyethylene. The excitation wavelength for each molecule is indicated and the spectra are plotted as the difference between excitation and emitted wavenumber. Each molecule's spectrum was recorded on a CCD detector at two different settings of the spectrograph grating to examine two different regions of the emission spectrum. 'Type 1' and 'type 2' spectra were tentatively attributed to terrylene molecules in very different local environments, although the possibility that type 2 spectra arise from a chemical impurity could not be ruled out. Further details are given in Tchénio [105–107].

A long-range goal of some single-molecule work is to engineer single-molecule optical devices. Toward this, two groups have demonstrated the ability to use light to drive single molecules of terrylene among two or more stable states in a predictable manner—a single-molecule optical 'switch' [77, 109]. The optical properties of terrylene in *n*-octane have been modified by exciting nearby triphenylene molecules to their triplet state [110], and this idea has been extended to probe the dynamics of triplet excitons in isotopically mixed naphthalene crystals using frequency shifts of single molecules of terrylene as a local environmental probe [111].

Finally, the ability to optically address single molecules is enabling some beautiful experiments in quantum optics. The non-Poissonian photon arrival time distributions expected theoretically for single molecules have been observed directly, both antibunching at short times [112] and bunching on longer time scales [6, 112 and 113]. The fluorescence excitation spectra of single molecules bound to spherical microcavities have been examined as a probe

of the optical resonances of small particles [114]. A variety of nonlinear optical effects have been observed at high laser intensities, including the AC Stark effect and Rabi oscillations, and exceptional agreement with theoretical predictions has been shown (see figure C1.5.10) [115, 116, 117 and 118]. In a particularly exciting application of quantum optics with single molecules, dibenzanthanthrene in *n*-hexadecane has been made to act as a triggered source of single photons by using the method of adiabatic following to prepare a single molecule in its fluorescent state [119].

-17-

Figure C1.5.10. Normalized fluorescence intensity correlation function for a single terrylene molecule in *p*-terphenyl at 2 K. The solid line is the theoretical curve. Regions of deviation from the long-time value of unity due to photon antibunching (the finite lifetime of the excited singlet state), Rabi oscillations (absorption-stimulated emission cycles driven by the laser field) and photon bunching (dark periods caused by intersystem crossing to the triplet state) are indicated. Reproduced with permission from Plakhotnik *et al* [66], adapted from [118].

(B) ROOM TEMPERATURE STUDIES

Spatial selection techniques, both near-field and far-field, have been employed to examine a variety of spectroscopic and photophysical properties of single molecules at room temperature. Near-field and far-field images, fluorescence spectra, and lifetimes have been compared and found to be consistent under appropriate conditions (see figure C1.5.11), although the close proximity of the metallic tip used in near-field experiments can also alter fluorescence lifetimes as discussed above. While most of these studies involve dye molecules that have considerably more conformational flexibility than the rigid aromatics used in the low-temperature spectral selection experiments, single-molecule data over the full range from superfluid helium to room temperature have been obtained for a few chromophore/matrix combinations [81, 120]. The spectral linewidths (integrated over the required accumulation times of milliseconds or more) as well as the observed spectral jumps are orders of magnitude larger in the room temperature experiments, but similar phenomena of highly variable linewidths and resonant frequencies among different molecules, spontaneous and light-induced spectral jumping and ‘blinking’ of the fluorescence when exciting at a fixed frequency are observed [26, 121, 122, 123, 124, 125, 126, 127, 128 and 129]. Photon bunching in the emission correlation function due to triplet state formation has also been observed at room temperature [129, 130].

-18-

Figure C1.5.11. Far-field fluorescence images (A and D), corresponding fluorescence spectra (B and E), and fluorescence decays (C and F) for two different molecules of a carbocyanine dye at a PMMA–air interface. Lifetimes were fitted to a single exponential (dotted curves) with decay times of 2.56 ns ($\chi^2 = 1.05$) in (C) and 3.20 ns ($\chi^2 = 1.16$) in (F). For comparison, an ensemble measurement averaged over several hundred molecules is shown in (G) and (H). A single exponential fit to the lifetime yields a decay time of 2.70 ns ($\chi^2 = 6.7$). The larger χ^2 indicates a deviation from single-exponential behaviour, reflecting the ensemble average over a distribution of lifetimes. Reprinted with permission from Macklin *et al* [126]. Copyright 1996 American Association for the Advancement of Science.

The three-dimensional orientation of a single molecule's transition dipole has been determined using near-field optics, taking advantage of the longitudinal component of the electric field near the tip [14]. Similar determinations have been made using far-field optics with a 'donut mode' laser beam [123] and by analysing the intensity patterns from far-field fluorescence images under slightly aberrating conditions [131]. The far-field techniques in particular should prove invaluable for following orientational motions of single molecules in environments that permit such motion, as discussed briefly below.

C1.5.4.2 MAGNETIC RESONANCE OF CHROMOPHORES IN SOLIDS

Magnetic resonance techniques, while powerful spectroscopic probes of molecular structure (sections B1.12–B1.16), typically have quite low sensitivities, and direct detection of single nuclear or electron spins has yet to be demonstrated. However, electron spin resonance at the single-molecule level has been demonstrated through the indirect technique of optically detected magnetic resonance. The original experiments exploited the dependence of the time-averaged fluorescence intensity on the rate of intersystem crossing from the fluorescent singlet to the essentially nonemissive triplet state. The splittings among the magnetic components of the triplet state were detected by sweeping the RF field while measuring the total fluorescence intensity from a single molecule selected out of the inhomogeneous ensemble by its fluorescence excitation frequency [132, 133]. This idea has subsequently been extended to examine isotope effects on the rf resonant linewidths [134, 135] and to demonstrate single-spin coherence and spin echo phenomena [136, 137].

C1.5.4.3 CHEMICAL REACTIONS

Chemical reactions can be studied at the single-molecule level by measuring the fluorescence lifetime of an excited state that can undergo reaction in competition with fluorescence. Reactions involving electron transfer (section C3.2) are among the most accessible via such techniques, and are particularly attractive candidates for study as a means of testing relationships between charge-transfer optical spectra and electron-transfer rates. If the physical parameters that determine the reaction probability, such as overlap between the donor and acceptor orbitals,

thermodynamic driving force for the reaction and nuclear reorganization energies, are not constant across the ensemble, different molecules will exhibit different electron transfer ‘rates’, as defined through multiple measurements on the same molecule. A very broad distribution of lifetimes, and thereby electron transfer rates, was observed for excited cresyl violet molecules transferring an electron to an indium tin oxide surface (figure C1.5.12) [138]. In contrast, a study of the Os(VIII) ion-catalysed redox reaction between Ce(IV) and As(III), producing a fluorescent Ce(III) product, found uniform catalytic activities for different Os(VIII) ions [139]. Single-molecule rate measurements coupled with spectroscopy hold great promise for allowing the factors that dictate electron transfer and other chemical reactions to be teased apart.

Figure C1.5.12.(A) Fluorescence decay of a single molecule of cresyl violet on an indium tin oxide (ITO) surface measured by time-correlated single photon counting. The solid line is the fitted decay, a single exponential of 480 ± 5 ps convolved with the instrument response function of 160 ps fwhm. The decay, which is considerably faster than the natural fluorescence lifetime of cresyl violet, is due to electron transfer from the excited cresyl violet (D^*) to the conduction band or energetically accessible surface electronic states of ITO. (B) Distribution of lifetimes for 40 different single molecules showing a broad distribution of electron transfer rates. Reprinted with permission from Lu and Xie [138]. Copyright 1997 American Chemical Society.

C1.5.4.4 TRANSLATIONAL AND ROTATIONAL MOTIONS

While translational and rotational diffusion are very well understood at the bulk level, there are advantages to being able to observe trajectories of individual molecules, particularly in nonhomogeneous materials. Fluorescence microscopy has been used to follow single-molecule translation over long time scales in hindered and/or anisotropic environments such as polymers [140, 141], gels [142], engineered submicrometre channels [143] and lipid membranes [144], as well as in aqueous solution [145] and to quantify the ‘optical tweezers’ effect whereby a polarizable molecule is attracted into the focus of an intense light source [146, 147]. The three-dimensional rotational motions of chromophores bound to polymers can be monitored by the intensity distribution patterns in confocal fluorescence microscopy (figure C1.5.13) figure C1.5.14 and figure C1.5.15 [148, 149]. Polarization modulation techniques have been employed to probe rotational motions for chromophores on surfaces and bound to polymers [127, 150 and 151] and near-field excitation with two polarization detection channels has been used to

examine rotation of dye molecules on glass surfaces and in polymers [141]. These techniques seem likely to find broad applicability as probes of local motion in nano- and mesostructured materials, as well as in monitoring the conformational dynamics of biopolymers such as DNA and proteins.

Figure C1.5.13. Schematic diagram of an experimental set-up for imaging 3D single-molecule orientations. The excitation laser with either s- or p-polarization is reflected from the polymer/water boundary. Molecular fluorescence is imaged through an aberrating thin water layer, collected with an inverted microscope and imaged onto a CCD array. Aberrated and unaberrated emission patterns are observed for z- and xy-orientated molecules, respectively. Reprinted with permission from Bartko and Dickson [148]. Copyright 1999 American Chemical Society.

Figure C1.5.14. Fluorescence images of three different single molecules observed under the imaging conditions of figure C1.5.13. The observed dipole emission patterns (left column) are indicative of the 3D orientation of each molecule. The right-hand column shows the calculated fit to each observed intensity pattern. Molecules 1, 2 and 3 are found to have polar angles of $(\theta, \phi) = (4.5^\circ, -24.6^\circ)$, $(-5.3^\circ, 51.6^\circ)$ and $(85.4^\circ, -3.9^\circ)$, respectively. Reprinted with permission from Bartko and Dickson [148]. Copyright 1999 American Chemical Society.

Figure C1.5.15. Molecular orientational trajectories of five single molecules. Each step in the trajectory is separated by 300 ms and is obtained from the fit to the dipole emission pattern such as is shown in figure C1.5.14. The radial component is displayed as $\sin \theta$ and the angular variable as ϕ . The lighter dots around the average orientation represent ± 1 standard deviation. C1.5.4.5 CONJUGATED POLYMERS, CHROMOPHORE AGGREGATES, AND MICROHETEROGENEOUS MATERIALS

Materials that possess fundamental optical inhomogeneities are among the most appealing candidates for single-molecule techniques. These include conjugated polymers such as poly(phenylenevinylene) and its relatives, in which different polymer chains differ not only in their physical length but also in their effective electronic conjugation length, and noncovalent structures such as submicroscopic crystals and the J-aggregates formed by certain cyanine dyes, in which different ‘supermolecules’ differ in both numbers of chromophores and their spatial relationships. Large reversible fluorescence intensity fluctuations observed in far-field single-molecule studies on conjugated polymers have been interpreted in terms of excited-state quenching by a photochemically produced charge-separated state [129, 152 and 153]. Near-field techniques are particularly valuable in these systems, which have a functionally important structure on nanometre length scales. Near-field scanning optical microscopy, including analysis of the excitation and emission polarization properties, has been used to probe spatial relationships between excitation and emission in J-aggregates, providing information about the degree of order in the aggregate and the spatial extent of exciton migration [154, 155 and 156]. NSOM has also been applied to small molecular crystals to examine spatial inhomogeneities, energy transfer, and excitation trapping [156, 157 and 158].

Single molecules also have promise as probes for local structure when doped into materials that are themselves nonfluorescent. Rhodamine dyes in both silicate and polymer thin films exhibit a distribution of fluorescence maxima indicative of considerable heterogeneity in local environments, particularly for the silicate material [159]. A bimodal distribution of fluorescence intensities observed for single molecules of crystal violet in a PMMA film has been suggested to result from high and low viscosity local sites within the polymer that give rise to slow and fast internal conversion, respectively [160].

C1.5.4.6 METALLIC AND SEMICONDUCTOR NANOPARTICLES

Metallic and semiconductor ‘nanoparticles’ or ‘nanocrystals’—chunks of matter intermediate in size and physical properties between single atoms and the macroscopic bulk materials—are of great interest both for their

fundamental properties and for technological applications (section C2.17). Although methods have been developed to synthesize some of these materials with high monodispersity, even the best preparations have significant variations from particle to particle in the number of atoms and/or the geometry of the particle, making the ability to interrogate single particles particularly valuable. Generally these materials can be prepared such that the individual particles are spaced arbitrarily far apart, making far-field microscopy the optical technique of choice.

Size-dependent optical properties of single silver and gold nanoparticles have been studied [161, 162], as have the surface Raman enhancements of organic molecules bound to these nanoparticles, as discussed above [53]. Several beautiful spectroscopic studies have been carried out on single II–VI semiconductor nanocrystals, revealing very well resolved low-temperature fluorescence spectra having well defined phonon substructures [163, 164 and 165] (see figure C1.5.16), large Stark shifts in these spectra [166], pronounced spectral diffusion [164, 166, 167] and dramatic intensity-dependent effects on the spectra [165]. The spectral diffusion was interpreted as being due to randomly fluctuating local electric fields caused by charge carriers trapped at surface defects [166]. Recently, single-particle techniques have also been used to resolve luminescence from the individual ‘chromophores’ of nanostructured porous silicon [168].

-23-

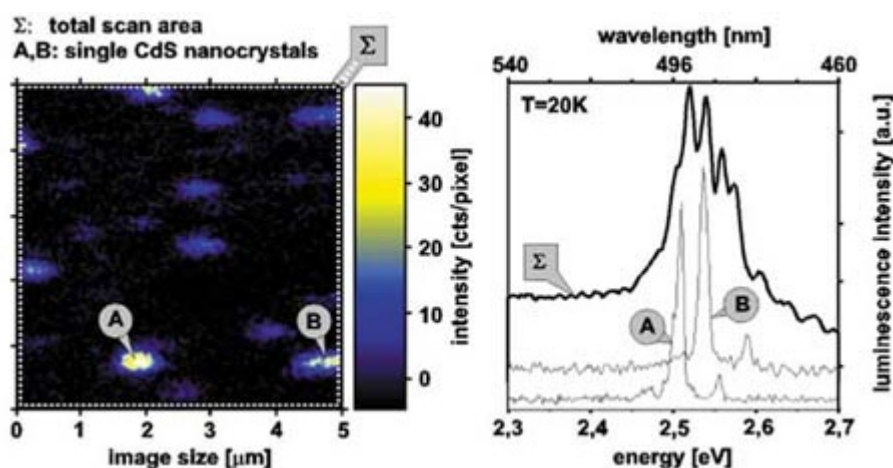

Figure C1.5.16. Spatial selection of single CdS nanocrystals on a quartz cover slip. Left: fluorescence image of isolated CdS nanocrystals recorded via scanning in a low-temperature confocal microscope ($T=20$ K). Total fluorescence was excited at 442 nm. Fifty-five per cent of the fluorescence was directed to a spectrometer during the scan, resulting in the Σ spectrum on the right. Spectra A and B were taken after moving the scanner to the bright spots marked in the fluorescence image, reducing the excitation intensity and increasing the acquisition time. Under these conditions both spectra show a second emission line shifted 5 meV (40 cm^{-1}) to the blue of the main peak. Reprinted with permission from Koberling *et al* [165]. Copyright 1999 by the American Physical Society.

C1.5.4.7 BIOLOGICAL SYSTEMS

The application of single molecule optical techniques to biological phenomena is an area currently seeing explosive growth [169].

The most obvious biological studies to undertake with optical techniques at the level of single functional units (generally not single *chromophores*) involve probing the photophysics of systems whose function, whether naturally evolved or engineered by man, involves responding to light. Photosynthetic light-harvesting complexes from green algae were imaged by near-field techniques at room temperature and fluorescence lifetimes measured with picosecond time resolution [170]. Subsequently, far-field microscopy has been used to obtain fluorescence excitation spectra of single bacterial light-harvesting complexes at 1.2 K [171, 172] and as a function of temperature [173] providing detailed information about individual chromophores’ site energies and energetic disorder, dipolar couplings between chromophores and spectral diffusion. Confocal fluorescence microscopy of single light-harvesting complexes at room temperature showed that photobleaching of just one bacteriochlorophyll

molecule of the 18-member assembly provides an energy trap that effectively quenches fluorescence from the entire assembly [174]. Single molecules of green fluorescent protein, widely used as a fluorescent tag in molecular biology, exhibit pronounced on-off 'blinking' effects whose origin has yet to be understood [175, 176].

Single-molecule optical methods have also been adapted to probe biological systems whose function is unrelated to light. Much of the research on single-molecule detection in liquids and gels is directed toward rapid DNA sequencing, utilizing either intrinsic fluorescence or, more likely, exogenous dyes bound to specific DNA bases [44, 45, 64, 177 and 178]. Single-molecule optical techniques are being used to study a variety of chemical and physical properties of

-24-

oligonucleotides, RNA and DNA including base pairing [179], electron transfer between dyes and DNA bases [180], ligand-induced conformational changes in RNA [181] and conformational dynamics in oligonucleotides [127, 150, 182, 183, 184 and 185], as well as to selectively cleave DNA [186]. Conformational dynamics in proteins that may have functional significance are being accessed through polarization studies, fluorescence quenching and energy transfer techniques carried out at the single-molecule level [187, 188]. Total internal reflection fluorescence microscopy has been used to visualize the motions of single molecules of fluorescently labelled kinesin, the motor protein that powers organelle transport along microtubules [189]. Dunn and co-workers are applying single-molecule techniques to study the morphology and dynamics of microenvironments in model biological membranes [190, 191].

Perhaps the most exciting application of single-molecule techniques in biology is the probing of enzymatic reactions at the level of individual turnovers [192, 193], utilizing systems in which either enzyme or substrate or both undergo large changes in optical properties (e.g. switching from fluorescent to nonfluorescent states) during the course of the reaction. These studies allow the possibility of heterogeneity in reaction rates among nominally identical enzyme molecules to be assessed, and make it possible to probe 'memory' effects, the extent to which an enzyme's binding constant or turnover rate depends upon its previous reaction history. Generally the enzyme is either bound to a surface [194] or confined within the pores of a gel [142] or nanoengineered structure [139, 143], and the substrate and product molecules allowed to diffuse toward and away from the immobilized enzyme. The catalytic activity among different molecules of nominally identical lactate dehydrogenase enzyme was found to vary by up to a factor of four, an observation tentatively attributed to the presence of multiple stable conformers of the enzyme [195]. A detailed study of single molecules of mammalian alkaline phosphatase revealed even more pronounced heterogeneities among different molecules (more than tenfold differences in turnover rate and more than two-fold differences in activation energy), which were attributed at least in part to post-translational modification producing chemically nonidentical enzyme molecules [196]. In contrast, single molecules of highly purified bacterial alkaline phosphatase have indistinguishable enzymatic activities [137]. Lengthy turnover trajectories of cholesterol oxidase, a flavoprotein that catalyses the oxidation of cholesterol by oxygen (figure C1.5.17), have been analysed to obtain the distribution of 'on' and 'off' times in the Michaelis-Menten catalytic mechanism, and also revealed evidence for memory effects probably due to slow conformational fluctuations in the protein [192, 193].

-25-

Figure C1.5.17.(A) Enzymatic cycle of cholesterol oxidase, which catalyses the oxidation of cholesterol by molecular oxygen. The enzyme's naturally fluorescent FAD active site is first reduced by a cholesterol substrate, generating a nonfluorescent FADH⁻, and then re-oxidized by molecular oxygen. (B) Structure of FAD. (C) Fluorescence intensity trajectory of an individual cholesterol oxidase enzyme, immobilized in an agarose gel, undergoing reaction with cholesterol and oxygen. Each on-off cycle of emission corresponds to one enzymatic turnover. (D) Distribution of emission on-times derived from the intensity trajectory. The nonexponential distribution reflects the fact that the forward reaction is not a single elementary step but involves an intermediate enzyme-substrate complex as shown in the inset. The solid line is a curve simulated by convolving two exponential distributions with $k_1[S]=2.5 \text{ s}^{-1}$ and $k_2[S]=15.3 \text{ s}^{-1}$. Reproduced with permission from Xie and Trautman [123]

C1.5.5 CONCLUSION

The ability to make optical measurements on individual molecules and submicroscopic aggregates, one at a time, is a valuable new tool in several areas of molecular science. By eliminating inhomogeneous broadening it allows pure spectroscopy to be performed with unprecedented precision in certain condensed phase systems. As an analytical method it permits the rapid detection of certain analytes with unmatched sensitivity. Finally, it is revolutionizing our

understanding of the relationships among nominally identical members of molecular ensembles. The deepest and most lasting contribution of this technique is likely to be in its application to complex systems such as biological macromolecules, polymers, and engineered nanostructures, where ensembles of members that are 'identical' to the best of nature's or man's efforts still exhibit differences on time scales that are of functional importance.

The techniques and applications of single molecule spectroscopy are currently in a state of rapid development, making this a difficult field to summarize at any given time. This contribution is, at best, a single frame of a movie

featuring plenty of action, improvisation, and unexpected plot twists.

ACKNOWLEDGMENTS

I am grateful to W E Moerner, Sunney Xie, Taras Plakhotnik, Felix Koberling, Shuming Nie, Dehong Hu, and Rob Dickson for providing the figures used in this contribution and/or for communicating preprints of their work prior to publication, and to Professor Dan Higgins for his comments on an early version of this chapter.

C2.1 Polymers

Pierre Robyr

C2.1.1 INTRODUCTION

Polymers are substances consisting of large molecules also known as macromolecules. The molecules are built up of many subunits called monomers which are linked together, usually by covalent bonds. In a polymer, the number of subunits is generally larger than 100 [1]. Assemblies of less than 100 subunits are often referred to as oligomers. Macromolecules make up many of the materials in living organisms, as for example cellulose, lignin, proteins and nucleic acids. The latter two have highly specific roles in life. Proteins control many biochemical processes and nucleic acids store genetic information. Many polymers are man-made materials, and are therefore called synthetic polymers. These polymers have a great industrial importance because they offer an attractive compromise between ease of processability and final mechanical and thermal properties. This article focuses on the general properties of polymers, without dealing with the specific roles of natural polymers, such as proteins and nucleic acids.

In contrast to low-molecular-weight compounds and polymers with specific roles in biochemical processes, most polymers consist of similar molecules with different molecular weights. The mean value and the distribution of the molecular weight depend on the preparation conditions and decisively influence the material properties. Both quantities can be obtained from different techniques such as light scattering, viscosity measurements or gel permeation chromatography. However, each technique provides a different average molecular weight [2]. The most important ones are the *number* average molecular weight

$$M_n = \frac{\sum_i n_i M_i}{\sum_i n_i}$$

where n_i is the number of molecules with molecular weight M_i , and the *weight* average molecular weight:

$$M_w = \frac{\sum_i n_i M_i M_i}{\sum_i n_i M_i}$$

The ratio M_w / M_n is one for a strictly uniform molecular-weight distribution and larger than one for molecular-weight distributions with finite widths. The variance of the molecular weight distribution is $(M_w/M_n - 1)M_n^2$ [3], therefore $M_w / M_n - 1$ is often mentioned as a measure for molecular-weight dispersion.

In polymers made of dis-symmetric monomers, such as, for example, poly(propylene), the structure may be irregular and constitutional isomerism can occur as shown in [figure C2.1.1\(a\)](#). The succession of the relative configurations of the asymmetric centres can also vary between stretches of the chain. Configuration isomerism is characterized by the succession of dyads which are named either *meso*, if the two asymmetric centres have the same relative configurations, or *racemo* if the configurations differ ([figure C2.1.1\(b\)](#)). A polymer is called isotactic if it contains only one type of dyad and syndiotactic if the dyad sequence strictly alternates between the *meso* and *racemo* forms.

Polymers without configurational regularity are called atactic. Configurationally regular polymers can form crystalline structures, while atactic polymers are almost always amorphous. Many polymers consist of linear molecules, however, nonlinear chain architectures are also important ([figure C2.1.2](#)).

Figure C2.1.1. (a) Constitutional isomerism of poly (propylene). The upper chain has a regular constitution. The lower one contains a constitutional defect. (b) Configurational isomerism of poly(propylene). Depending on the relative configurations of the asymmetric carbons of two successive monomer units, the corresponding dyad is either *meso* or *racemo*.

Figure C2.1.2. Polymers with linear and nonlinear chain architectures. The nonlinear polymers can have *branched* chains. Short chains of oligomers can be *grafted* to the main chain. The chains may form a *star*-like structure. The chains can be cross-linked and form a *network*.

Most properties of linear polymers are controlled by two different factors. The chemical constitution of the monomers determines the interaction strength between the chains, the interactions of the polymer with host molecules or with interfaces. The monomer structure also determines the possible local conformations of the polymer chain. This relationship between the molecular structure and any interaction with surrounding molecules is similar to that found for low-molecular-weight compounds. The second important parameter that controls polymer properties is the molecular weight. Contrary to the situation for low-molecular-weight compounds, it plays a fundamental role in polymer behaviour. It determines the slow-mode dynamics and the viscosity of polymers in solutions and in the melt. These properties are of utmost importance in polymer rheology and condition their processability. The mechanical properties, solubility and miscibility of different polymers also depend on their molecular weights.

The successful preparation of polymers is achieved only if the macromolecules are stable. Polymers are often prepared in solution where entropy destabilizes large molecular assemblies. Therefore, monomers have to be strongly bonded together. These links are best realized by covalent bonds. Moreover, reaction kinetics favourable to polymeric materials must be fast, so that high-molecular-weight materials can be produced in a reasonable time. The polymerization reaction must also be fast compared to side reactions that often hinder or preclude the formation of the desired product.

Polymerization reactions are generally divided into two main categories according to the mechanism of chain growth [4]. In the first category, called chain polymerization, chain growth proceeds exclusively by reaction between a monomer and the reactive site on the polymer chain with regeneration of the reactive site at the end of each growth step and possible production of a side-product L:

Chain polymerization involves at least two steps: initiation, i.e. formation of reactive sites, which are generally radicals or ions; and propagation, through which the chains grow. In most practical conditions termination reactions play an important role. Depropagation, i.e. the reduction of the degree of polymerization by one unit is also possible. In termination reactions, one or two reactive sites vanish and chain growth is stopped. The possibility of growth termination of a chain exists at every addition step and, therefore, the probability of termination increases with the degree of polymerization. This increase leads to the flattening of the average molecular weight as a function of the degree of monomer conversion, as shown in [figure C2.1.3](#) [5]. In the limiting situation of fast initiation, irreversible propagation and the absence of termination, the molecular weight increases linearly with the degree of conversion ([figure C2.1.3](#)). These conditions are approached in some ionic chain polymerizations performed under very clean conditions. Such reactions are called living polymerizations. Radical chain polymerization and also many chain polymerizations with simple ions as reactive sites produce polymers with irregular configuration. To prepare highly-regular polymers special catalysts have been developed. Two types widely used are Ziegler--Natta catalysts [6] and metallocene-based catalysts [7].

-4-

Figure C2.1.3. Schematic dependence of the molecular weight of a polymer as a function of the degree of monomer conversion for different polymerization reactions.

The second category of polymerization reactions does not involve a chain reaction and is divided into two groups: polyaddition and polycondensation [4]. In both reactions, the growth of a polymer chains proceeds by reactions between molecules of all degrees of polymerization. In polycondensations a low-molecular-weight product L is eliminated, while polyadditions occur without elimination:

In polycondensation reactions, the equilibrium can be easily shifted to the side of the higher molecular-weight compounds by allowing the eliminated compound to escape the reaction vessel or by actively removing it. Since molecules of all degrees of polymerization can react with each other, the average molecular weight grows faster with a higher degree of conversion (figure C2.1.3). Consequently, the preparation of polymers with high molecular weights requires a large degree of conversion [5].

Copolymerization involves the reaction of at least two different monomers A and B. In the case of chain copolymerization, the reactivity ratios r_A and r_B are important, $r_A = k_{AA}/k_{AB}$ and $r_B = k_{BB}/k_{BA}$, where k_{YX} is the rate constant of the reaction of a free monomer Y with a chain ending with a unit X [5]. Three different situations can be envisaged. (i) If $r_A r_B = 1$, $k_{AA}/k_{AB} = k_{BA}/k_{BB}$. The ratio of the probabilities of adding a monomer A or B to a chain end A is equal to the ratio of the probabilities of adding a monomer A or B to the chain end B. Consequently, the probabilities of adding a monomer A or B are independent of the chain end. This type of copolymerization is called ideal or Bernoullian copolymerization. (ii) If $r_A r_B < 1$, the sequence of the monomers tends to alternate. In the limiting case where $r_A = r_B = 0$, the monomer sequence strictly alternates. (iii) If $r_A r_B > 1$, the two types of monomers tend to sequence and build block structures along the chain.

We have tacitly assumed that the rate constants depend only on the last unit of the chain. In such a situation, the copolymerization is called a Markov copolymerization of first order. The special case (i), $r_A r_B = 1$, is a Markov copolymerization of order zero. If reactivity also depends on the penultimate unit of the chain, the polymerization is a Markov copolymerization of second order.

C2.1.3 CONFORMATION OF A SINGLE CHAIN

C2.1.3.1 INTRODUCTION

Polymer chains possess a huge number of degrees of freedom, which can be divided into two categories: on the one hand, bond angles and bond lengths and, on the other hand, torsional angles. Those of the first category undergo fast oscillations on the 10–100 fs time scale and vary little from one monomer to the other. Torsional angles are much softer degrees of freedom and set the conformation of the polymer chain. Two conformations are often encountered: random coils and helices. Random coils are found in polymer solutions, melts, and polymer glasses. Denatured proteins also adopt random coil structures. Helical structures often occur in crystalline polymer or as subunits in folded proteins.

The energy difference between the *trans* and *gauche* conformations in alkanes was investigated with Raman scattering [9]. It was found that the difference between the two energy minima in solution is 2–3 kJ mol⁻¹ and that the energy barrier is about 12 kJ mol⁻¹ (figure C2.1.4). Consequently, at room temperature the torsional angles of an alkane chain are most of the time either in the *gauche* or the *trans* state with roughly equal probabilities, and from time to time a chain segment collects sufficient thermal energy so that a conformational change can occur.

Figure C2.1.4. Potential energy as a function of the rotation about the central C–C bond in butane. The sketches show the projection of the molecule along the central C–C bond.

-6-

C2.1.3.2 GAUSSIAN CHAINS

At first sight, one might think that any treatment of the properties of a polymer chain has to emanate from its microscopic chemical structure since it determines the populations of the different rotational isomeric states of a given torsional angle. However, in polymers without well defined conformations, the correlation between the torsional angles along the chain decays rapidly. Beyond that length scale, typically a few nanometres and referred to as persistence length [10], one can think of the chain as a succession of jointed sticks, with unrestricted angles at the junctions. Such a chain with a large number of segments is called Gaussian. It can be easily shown [11] that for a chain consisting of N_s segments of length a_s the root mean square of the distance between the two chain ends averaged over all possible conformations is

$$\sqrt{\langle R^2 \rangle} = N_s^{1/2} a_s. \quad (\text{C2.1.1})$$

This relation also applies to any portion of the chain segments as long as the number of segments in the portion is sufficient. Therefore, if one proceeds n_s segmental steps, starting from a point in the interior of the chain, the resulting average displacement is of the order of $\sqrt{n_s} a_s$. Conversely, the number of monomers contained in a sphere of radius r scales as $n \propto n_s \propto r^2$. Thus, the Gaussian chain fills only partially a three-dimensional space and its fractal dimension is two. The mean monomer density c_m in a volume of size V as a function of the degree of polymerization N scales as

$$c_m(N) \propto \frac{N}{\langle R^2 \rangle^{3/2}} \propto N^{-1/2}. \quad (\text{C2.1.2})$$

The mean monomer density decreases with the increasing degree of polymerization.

It is not possible to apply (C2.1.1) down to the level of monomers and replace N_s by the degree of polymerization N and a_s^2 by the sum of the squares of the bond lengths in the monomer a_b^2 , because the chemical constitution imposes some stiffness to the chain on the length scale of a few monomer units. This effect is accounted for by introducing the characteristic ratio C_∞ defined as $C_\infty = \langle R^2 \rangle / (N a_b^2)$. The characteristic ratio can be determined from viscosity or scattering measurements.

Light scattering techniques play an important role in polymer characterization. In very dilute solution, where the polymer chains are isolated from one another, the inverse of the scattering function $S(q)$ can be expressed in the limit of vanishing scattering vector $q \rightarrow 0$ as [12]

$$\frac{1}{S(q)} = N^{-1} \left(1 + q^2 \frac{\langle R^2 \rangle}{18} + \dots \right). \quad (\text{C2.1.3})$$

Thus, by plotting S^{-1} as a function of q^2 in the limit of small q the mean square of the end-to-end distance can be obtained. For large value of q , $q^2 \langle R^2 \rangle \gg 1$,

-7-

$$S(q)q^2 = \frac{12N}{\langle R^2 \rangle} = \frac{12}{C_\infty a_b^2} \quad (\text{C2.1.4})$$

so that the characteristic ratio can be evaluated from the plateau value of $S(q)q^2 a_b^2$ at large q [12].

C2.1.3.3 EXCLUDED-VOLUME EFFECTS

The Gaussian chain model considers only the interactions between neighbouring monomers along the chains, which determine the characteristic ratio, but neglects the fact that two monomers distant along the chain by more than the persistence length cannot occupy the same volume. At first sight this shortcoming might seem intolerable. However, exactly this situation, where excluded-volume effects between distant monomers vanish, holds in poor solvents and in the melt. In a poor solvent, the interactions between the solvent molecules and the monomers are not favourable and the chain tends to contract onto itself. Solutions in which the poorness of the solvent exactly compensates for the excluded-volume effects are called theta solutions, or solutions at Θ conditions [13, 14].

Theta conditions in dilute polymer solutions are similar to the state of van der Waals gases near the Boyle temperature. At this temperature, excluded-volume effects and van der Waals attraction compensate each other, so that the second virial coefficient of the expansion of the pressure as a function of the concentration vanishes. On dealing with solutions, the quantity of interest becomes the osmotic pressure Π rather than the pressure. Its virial expansion may be written as

$$\Pi = RTc_w \left(\frac{1}{M_n} + \tilde{A}_2 c_w + \tilde{A}_3 c_w^2 + \dots \right) \quad (\text{C2.1.5})$$

where c_w is the weight concentration of the polymer. Since the interactions between the monomers and the solvent are temperature dependent, the conditions at which the second virial coefficient vanishes can be found by varying the temperature. The Θ conditions of a dilute solution of polystyrene in cyclohexane occur at $T = 35^\circ\text{C}$ and ambient pressure (figure C2.1.5).

Figure C2.1.5. Reduced osmotic pressure $\Pi M_n / (RTc_w)$ as a function of the weight concentration c_w of polystyrene ($M_n = 130\,000\text{ g mol}^{-1}$) in cyclohexane at different temperatures. At $T = 35\text{ }^\circ\text{C}$ and ambient pressure, the solution is at the Θ conditions. (Figure from [74], reprinted by permission of EDP Sciences.)

-8-

C2.1.3.4 EXPANDED CHAINS

Polymer chains at low concentrations in good solvents adopt more expanded conformations than ideal Gaussian chains because of the excluded-volume effects. A suitable description of expanded chains in a good solvent is provided by the ‘self-avoiding random walk’ model. Flory [15] showed, using a mean field approximation, that the root mean square of the end-to-end distance of an expanded chain scales as

$$\sqrt{\langle R^2 \rangle} = N_s^{3/5} a_s = C_\infty^{1/2} N^{3/5} a_F \quad (\text{C2.1.6})$$

where $a_F = a_b$ in the Θ state. These results were later put on a firmer theoretical basis by de Gennes [16]. Using the same arguments as in the case of Gaussian chains, the fractal dimension of expanded chain is found to be five-thirds and the scaling behaviour of the scattering function for $q\sqrt{\langle R^2 \rangle} \gg 1$ is

$$S(q) \propto \frac{1}{q^{5/3}} \quad (\text{C2.1.7})$$

compared to $S(q) \propto q^{-2}$ in the case of Gaussian chains (equation (C2.1.4))

The neutron scattering data of figure C2.1.6 show that if the excluded volume effects are activated by increasing the temperature from the Θ point, and thus increasing the goodness of the solvent, the transition from the Gaussian chain behaviour into that of an expanded chain depends on the length scale. The transition from the regime $S^{-1} \propto q^2$ to $S^{-1} \propto q^{5/3}$ occurs first for low values of q , i.e. for long distances, while below a temperature-dependent length, referred to as the thermic correlation length, the chain is still Gaussian. The whole chain may be seen as a self-avoiding walk of Gaussian blobs (figure C2.1.7).

as an expanded chain on longer length scales. The cross-over distance corresponds to the size of the pearls.

C2.1.3.5 ROTATIONAL ISOMERIC STATE MODELS

The quantitative description of many properties of polymer chains, such as energy, entropy and detailed conformation, necessitates the consideration of the monomer structure and its influence on the possible states of the torsional angles. The rotational isomeric state (RIS) theory focuses on such detailed descriptions of a polymer chain [9, 17, 18]. The RIS theory takes into account only the interactions between nearest-neighbour monomers and assumes that each torsional angle can take only a few possible conformations. The nearest-neighbour interactions control the populations of the few allowed conformations. Using these approximations, the statistical weight of a given chain conformation can be calculated from the sum of the pair interactions; by summing over all the conformations, the partition function of a polymer chain can be obtained. From the partition function and the conformational Helmholtz energy, estimates of the conformational entropy and internal energy can be calculated. The RIS theory also provides a simple way to calculate quantities such as the characteristic ratios C_∞ , the mean square end-to-end distance $\langle R^2 \rangle$ and the scattering curves.

C2.1.3.6 POLYELECTROLYTES

The polymers considered hitherto were electrically neutral molecules in neutral solvents. If the monomers contain functional groups that can dissociate into ions in polar solvents, the behaviour of the polymer chain is significantly influenced by the long-range Coulombic interactions [19]. For example, if the ionic strength of the solvent is increased by adding some salt, the repulsive interaction between the equivalent charges along the polyelectrolyte chain are reduced and the polymer shrinks. Concomitantly, the viscosity of the solution which largely depends on the overall polymer dimension, diminishes drastically. Polyelectrolytes have also attracted much attention as ionic conductors in the development of light and efficient dry batteries [20].

C2.1.4 SOLUTION, MELT AND GLASS

C2.1.4.1 DILUTE AND SEMI-DILUTE SOLUTIONS

In dilute solutions, the polymer chains are isolated from one another and only interact during brief encounters. With increasing polymer concentration, a point is reached where the chains start to overlap, this point c_m^* is referred to as the critical concentration of monomers at the overlap limit and can be approximated as $c_m^* = N/R_F^3$ with $R_F = \sqrt{\langle R^2 \rangle}$ in a good solvent. Using equation (C2.1.6), the volume fraction of the polymer at the overlap limit is $\phi^* < N^{-4/5}$ [21]. Thus, for a polymer with $N = 10^4$, the chains are isolated in solution only if the polymer volume fraction is less than about 0.001.

In discussion of the solution behaviour, the osmotic pressure is a quantity of primary interest. According to equation (C2.1.5), the osmotic pressure at very low concentrations is inversely proportional to the molecular weight of the polymer. This behaviour is indeed observed in figure C2.1.8. With increasing polymer concentration, the dependence of the osmotic pressure on the molecular weight vanishes and only the weight concentration of the polymer is relevant. In this regime the chains strongly overlap and the osmotic pressure scales as $\Pi/RT \propto c_w^{9/4}$.

Figure C2.1.8. Reduced osmotic pressure $\Pi/(RTc_w)$ as a function of the polymer weight concentration c_w for solutions of poly(α -methylstyrene) in toluene at 25 °C. The molecular weight of poly(α -methylstyrene) varies between $M_n = 7 \times 10^4 \text{ g mol}^{-1}$ (uppermost curve) and $M_n = 7.47 \times 10^6 \text{ g mol}^{-1}$ (lowest curve). (Figure from [76], reprinted by permission of the American Chemical Society.)

-12-

The inverse scattering function of dilute polymer solutions for small scattering wavenumber ($qR_F \ll 1$) obeys the so-called Zimm relation [22]:

$$\frac{1}{S(q, c_w)} = \frac{1}{N} \left(1 + q^2 \frac{R_F^2}{18} + \dots \right) (1 + 2\tilde{A}_2 M_n c_w + \dots). \quad (\text{C2.1.8})$$

By extrapolating the measurement of $1/S(q, c_w)$ to $q \rightarrow 0$ and $c_w \rightarrow 0$, \tilde{A}_2 and R_F can be measured. The behaviour of the osmotic pressure and that of the scattering function can be satisfactorily explained in the dilute regime, the cross-over region and the semi-dilute range by using only three parameters, namely, the polymer concentration c_w , the Flory radius R_F and the thermic correlation length. Beyond the semi-dilute range, about $\phi > 0.1$, the description based on the three parameters only is no longer valid.

C2.1.4.2 MELTS AND SCREENING EFFECT

Consider the monomer-density distribution for a single chain averaged over all possible conformations. The distribution has a bell-like shape with its middle point at the gravity centre of the chain. With this picture in mind, the excluded-volume effect encountered in good solvents can be understood as an entropic force which acts on the monomers in the direction of lower concentration. Overall, these forces lead to an expansion of the polymer chain. In the melt, the monomer density is constant since the monomers of the other chains compensate for the density gradient of a particular chain. This compensation is referred to as the ‘screening effect’ and is responsible for the Gaussian behaviour of chains in the melt. These qualitative arguments [23] are expressed quantitatively in the fact that, in polymer melts, the second virial coefficient of the local osmotic pressure scales as $1/N$ and thus vanishes for long chains [24].

In summary, we see now how the change from the expanded chains in dilute solutions to the ideal chains in a melt is accomplished. With increasing polymer concentration, the chain overlap increases and the length scale over

which excluded-volume effects are screened decreases. As the screening length decreases to the thermic correlation length, all excluded-volume effects disappear. Simultaneously, the polymer shrinks to the size of a Gaussian chain.

C2.1.4.3 GLASSY STATE

Upon cooling the melt of a polymer that cannot crystallize, the system becomes glassy, i.e. hard and void of long-range order. In (figure C2.1.9(a)) the specific volume of poly (vinyl acetate) is plotted as a function of the temperature. The specific volume is measured upon heating the sample after having quenched it at $-20\text{ }^{\circ}\text{C}$. Clearly, near $T = 30\text{ }^{\circ}\text{C}$ the slope of the graphs changes. The change in slope from the glassy region to the melt is not accompanied by a discontinuity, as in the case of the fusion of crystalline materials. This type of transition, with continuous specific volume or heat capacity, is typical of glassy materials and the temperature at which the linear extrapolations of the measured quantity cross defines the glass temperature T_g . However, the exact value of the glass transition temperature depends on the rate of temperature change at which the measurement is performed. This dependence on the measurement kinetics supports the view that no real phase transition occurs, but rather that the system ‘freezes’ in a non-equilibrium state.

Figure C2.1.9. Specific volume of poly(vinyl acetate) as a function of the temperature measured during heating two samples which were preliminary quenched from the melt to $-20\text{ }^{\circ}\text{C}$. One sample was stored for 1 min and the other for 100 h at $-20\text{ }^{\circ}\text{C}$ before heating. (Figure from [77], reprinted by permission of John Wiley and Sons Inc).

The variation of the specific volume as a function of heating in figure C2.1.9 is plotted for two samples which were stored for different times after a quench to $-20\text{ }^{\circ}\text{C}$. The specific volume in the glassy region and the glass temperature depend on storage time. This dependence shows that, on a practical time scale, glassy polymers are not in equilibrium. A second point of interest about the structure of glassy polymers is the presence of local order. Some experimental results suggest the occurrence of more local order in the glass than that found in the melt, where the chains behave as Gaussian with hardly any specific order between each other. However, many investigations support the view that very little difference exists between the average conformation of polymer chain in the glass and that in the melt [25].

Several interpretations of the glass transition have been put forward. They can be grouped into three main categories [26]. First, some theories are based on the concept of the free volume in the form of voids as a requirement for the onset of cooperative motion. Upon cooling of the melt, the free volume is continuously squeezed out of the system. The transition into the glassy state occurs when no free-volume is left. Second, kinetic theories of the glass transition relate the onset of the segmental motion of the polymer to the transition from the glassy state to the melt. Third, thermodynamic theories are based on the extrapolation to the glass transition at infinitely long measurement times. In this hypothetical regime, T_g becomes independent of the experimental procedure and a second-order transition occurs between two phases at equilibrium. Each of the theories can predict some of the observed changes at the glass temperature. However, none can explain them all [26].

C2.1.5 THERMODYNAMICS AND PHASE TRANSITION OF POLYMER MIXTURES

Often it is difficult to achieve the desired mechanical properties with a system made of a single polymer. Polystyrene, for example, possesses a good stiffness but has a low impact strength, it is a brittle material. By mixing small amounts of polybutadiene with polystyrene, a tough material is obtained which retains satisfactory stiffness. Blending polystyrene with a small amount of polybutadiene results in a two-phase structure, in which polybutadiene droplets are embedded in the polystyrene matrix. Other binary systems with good mechanical properties, like blends of polystyrene and poly(dimethylphenylene oxide), form homogeneous structures. In order to correlate the mechanical properties with the structures of the blend, it is of primary interest to understand the formation of the different types of structures.

C2.1.5.1 FLORY–HUGGINS THEORY

The Flory–Huggins theory of polymer mixtures [15, 27] is based on two main assumptions: first, the screening of excluded-volume effects renders all polymer chains effectively Gaussian; second, the interaction between the monomers of different chains can be treated using a mean field approximation, i.e. all monomers feel, on average, the same environment. These assumptions allow the derivation of the Gibbs energy of mixing of a binary polymer system:

$$\Delta G_{\text{mix}} = RTn_c \left(\frac{\phi_A}{N_A} \ln \phi_A + \frac{\phi_B}{N_B} \ln \phi_B + \chi \phi_A \phi_B \right) \quad (\text{C2.1.9})$$

where n_c is the number of reference units, approximately equal to the number of monomers, ϕ_A and ϕ_B are the volume fractions of polymers A and B, N_A and N_B are the degrees of polymerization. The quantity χ is the Flory–Huggins parameter; it is dimensionless and determines in an empirical manner the change of the local Gibbs energy per reference unit upon mixing [15, 27]. The first two terms in the parentheses arise from the increase of the translational entropy of the centres of mass of the chains after mixing, the third from the interactions between the chain segments.

The gain of translational entropy in mixing macromolecules is small compared to that achieved in mixing low-molecular-weight compounds. This poor gain manifests itself in the occurrence of the degrees of polymerization in the denominators of the two entropy terms in equation (C2.1.9). Consequently, homogeneous mixing occurs only when χ is negative, or positive but small. In [figure C2.1.10\(a\)](#) the Gibbs energy of mixing of two polymers with the same degrees of polymerization N is plotted for different values of the product χN . If $\chi N \leq 2$, mixing occurs at any ϕ_A value. For $\chi N > 2$, the shape of ΔG_{mix} as a function of ϕ_A changes. Consider the curve for $\chi N = 2.4$ at $\phi_A = 0.4$; the system can lower its Gibbs energy by separating into two homogeneous phases with volume fractions ϕ'_A and ϕ''_A . A similar behaviour occurs for all values of χ with $\chi N > 2$. The ensemble of volume fractions resulting from the phase separation form the binodal ([figure C2.1.10\(b\)](#)) [28]. Within the binodal, the system has a two-phase structure. If the condition $N_A = N_B = N$ is released, the graphs in [figure C2.1.10](#) become asymmetric, but the essential features qualitatively remain.

Figure C2.1.10. (a) Gibbs energy of mixing as a function of the volume fraction of polymer A for a symmetric binary polymer mixture $N_A = N_B = N$. The curves are obtained from [equation \(C2.1.9\)](#). (b) Phase diagram of a symmetric polymer mixture $N_A = N_B = N$. The full curve is the binodal and delimits the homogeneous region from that of the two-phase structure. The broken curve is the spinodal.

In many applications the phase structure as a function of the temperature is of interest. The discussion of this issue requires the knowledge of the temperature dependence of the Flory–Huggins parameter $\chi(T)$. If the interactions between the different monomers weakly depend on temperature, χ is proportional to T^{-1} because of the prefactor RT in [\(C2.1.9\)](#). In this situation, the axis in [figure C2.1.10\(b\)](#) indicates decreasing temperature and the region where the separation into a two-phase structure occurs is referred to as the ‘lower miscibility gap’. In some cases, χ increases with increasing temperature with a sign change from negative to positive. Such a temperature dependence of the Flory–Huggins parameter leads to the existence of an ‘upper miscibility gap’.

It is not always possible to describe the variations of $\Delta G_{\text{mix}}(\phi_A, T)$ with χ depending only on temperature. For some systems, the dependence of χ on the volume fraction must be considered too. However, the Flory–Huggins theory provides a very useful insight into structural behaviour of polymer mixtures.

C2.1.5.2 MECHANISMS OF PHASE SEPARATION

Phase separation of a polymer mixture is induced when the conditions change from the one-phase region into a miscibility gap. Usually, phase separation is provoked by a change in temperature. Two mechanisms of phase separation are known: ‘nucleation and growth’ and ‘spinodal decomposition’ [29]. Nucleation and growth processes start with the formation of the nuclei of a new composition. Subsequently, domains of the new composition grow from these nuclei. Systems that undergo spinodal decomposition behave differently. The sizes of the domains with the new compositions do not vary much until the latter stages of the phase separation process. In contrast, the compositions of the new phases change continuously.

The occurrence of one or the other phase-separation mechanisms can be predicted from the consideration of the change of the local Gibbs energy, δg , associated with a spontaneous fluctuation of the local composition about the composition of the homogeneous mixture ϕ_{A0} . If ϕg is positive, restoring forces will bring back the system to the homogeneous composition. In this regime, phase separation has to overcome an energy barrier, this is achieved in the nucleation step before the growth of the domains with a new composition. If ϕg is negative, no restoring force exists and the amplitude of the composition fluctuation grows so that the system separates into different phases spontaneously. Approximately, the sign of ϕg is given by that of the second derivative of $\Delta G_{\text{mix}}(\phi_A)$ at ϕ_{A0} . Therefore, the locus of the values ϕ_A with a vanishing second derivative of ΔG_{mix} delimits the region of the miscibility gap in which spinodal decomposition occurs. This locus is referred to as the spinodal ([figure C2.1.10 \(b\)](#)). The length scale of the concentration fluctuations at the beginning of the separation process is controlled by

the distance from the spinodal. If a system is brought into the region between the spinodal and the binodal, phase separation follows the nucleation and growth mechanism.

C2.1.5.3 BLOCK COPOLYMERS

In block copolymers [8, 30], long segments of different homopolymers are covalently bonded to each other. A large part of synthesized compounds are di-block copolymers, which consist only of two blocks, one of monomers A and one of monomers B. Tri- and multi-block assemblies of two types of homopolymer segments can be prepared. Systems with three types of blocks are also of interest, since in ternary systems the mechanical properties and the material functionality may be tuned separately.

Similarly to polymer mixtures, block copolymers can form an homogeneous phase but also separate into phases of different compositions. However, the presence of covalent bonds between the different blocks has important consequences on the structural arrangement after phase separation. Each of the different types of monomer segregate and almost pure domains are formed, but the domains have mesoscopic dimensions corresponding to the sizes of the blocks. Furthermore, since the block lengths usually have uniform sizes, the arrangement of the different domains are ordered. In the case of di-block copolymers the type of order depends on the ratio of the degree of polymerizations of block A and block B (figure C2.1.11). Tri- and multi-block binary systems exhibit qualitatively the same phase behaviour as di-block polymers. Changes occur for ternary systems. Their structures still exhibit periodic order, but the lattices are more complex [30].

Figure C2.1.11. Morphologies of a microphase-separated di-block copolymer as function of the volume fraction of one component. The values here refer to a polystyrene–polyisoprene di-block copolymer and ϕ_{PS} is the volume fraction of the polystyrene blocks. OBDD denotes the ordered bicontinuous double diamond structure. (Figure from [78], reprinted by permission of Annual Reviews.)

C2.1.6 PARTIALLY CRYSTALLINE POLYMERS

C2.1.6.1 SEMI-CRYSTALLINE STRUCTURES

Polymers with a regular configuration can crystallize. However, because of the presence of chain entanglements, chain defects and chains with different molecular weights, only partial crystallization occurs and an amorphous part always subsists. Semi-crystalline polymers exhibit a hierarchical structure. On the molecular level, the chains are fully stretched or form regular helices which pack parallel to each other into lamellar crystallites. The chain axes are perpendicular to the lamellar plane and the lamellar thickness is of the order of 10 nm. In single-polymer crystals prepared from highly dilute solutions, the chain folds back in a regular manner and builds the adjacent helix. In most of the systems, however, the chain may also re-enter the same lamella at a distant position or leave it definitively and possibly participate in another lamella after crossing an amorphous layer. Many lamellae form larger spherical assemblies with amorphous interstices called spherulites (figure C2.1.12). These assemblies have sizes from a few micrometres up to centimetres. The directions of the polymer chains or helices are always perpendicular to the radius of the spherulite.

Figure C2.1.12. Schematic drawing of the cross section through a spherulite. The lines indicate the connectivity of the crystalline lamellae. The inner structure of a lamella is also shown and consists of parallel polymer chains with their axes perpendicular to the spherulite radius.

The content of crystalline material in a system can be characterized by several techniques. Density measurements provide the volume fraction occupied by the crystallites. Measuring the heat of fusion provides the weight fraction of the crystalline domains. More details on the structure of semi-crystalline polymers can be obtained from electron microscopy, scattering techniques, Raman spectroscopy and NMR [31]. It is important to realize that the formation of crystalline polymeric structures is hindered because of the length of the chains and the presence of entanglements. Therefore, structure formation is governed by kinetical criteria rather than equilibrium thermodynamics: the structure that develops at a given temperature is that with the maximal growth rate rather than that with the lowest Gibbs energy.

-18-

C2.1.6.2 PRIMARY CRYSTALLIZATION

The usual and therefore most important situation where polymers crystallize is in melts cooled below the point of the fusion of a crystallite of infinite dimensions. Then, crystallization occurs by the nucleation and growth of spherulites. Another crystallization process is sometimes encountered in oriented melts and glasses. In such systems, the crystallization seems to occur at once in the whole sample and not at the interface between the growing crystallites and the amorphous matrix. Despite numerous studies, the crystallization process is not fully understood. Scattering measurements suggest a preliminary spinodal decomposition of the undercooled isotropic melt in phases with and without chain ends and chain defects before the formation of the crystallites [32].

In supercooled isotropic melts, crystallite growth occurs after nucleation. Initially, the lateral size of the lamellae increases at a constant rate, but as soon as the spherulites start to touch each other, the growth rate decreases. Overall, the sigmoidal time dependence of volume fraction of the crystalline regions is well described by the Avrami equation: $\phi_c \propto 1 - \exp(-(zt)^\beta)$, in which z is related to the rate constant of the lateral growth of the lamellae and β is a phenomenological parameter called the 'Avrami exponent'. The rate constant of the lateral growth is controlled by the balance of two factors; namely, the thermodynamic driving force of crystallization and the mobility of the chain segments. The former increases with undercooling, the latter decreases, so that a maximal rate of crystallization exists at a given undercooling. The minimal thickness of the lamellae also depends on the undercooling: it decreases with increasing undercooling.

The study of the crystallization of oriented melts and glasses shows that density variations on the length scale of tens of nanometres, as measured with small-angle x-ray scattering, occur before Bragg peaks appear in wide-angle x-ray scattering measurements [33]. These observations exclude a lateral growth of crystalline lamellae and support a continuous phase separation of the whole sample into crystalline and amorphous domains. This process is similar to that found in spinodal decomposition of polymer mixtures. The reason for this alternative crystallization mechanism might be related to an increased mobility of defects along the preoriented chains.

C2.1.6.3 SECONDARY CRYSTALLIZATION

After completion of the primary crystallization at a given temperature, crystallization does not come to an end, but resumes upon cooling. Two modes of secondary crystallization have been identified [34]. The more common one consists of the ‘insertion’ of new crystallites between those formed during primary crystallization. The inserted crystallites have a smaller thickness because they are formed at a lower temperature. The second mode is called ‘surface crystallization’. The increase of the thickness with decreasing temperature is possible if the mobility is still high enough so that the defects concentrated at the crystal surface after primary crystallization can move further into the amorphous domains. Then, because of the higher thermodynamic driving force to crystallization due to the lower temperature, crystal thickness augments.

C2.1.7 POLYMER DYNAMICS AND MECHANICAL BEHAVIOUR

Polymers have found widespread applications because of their mechanical behaviour. They combine the mechanical properties of elastic solids and viscous fluids. Therefore, they are regarded as viscoelastic materials. Viscoelastic

-19-

behaviour does not mean a simple superposition of the two properties, but includes a new phenomenon called anelasticity in which elastic response and viscous flow are coupled. When a load is applied, part of the deformation, although reversible, requires a certain time to occur.

C2.1.7.1 MICROSCOPIC DYNAMICAL MODELS

(A) ROUSE MODEL

A polymer chain can be approximated by a set of balls connected by springs. The springs account for the elastic behaviour of the chain and the beads are subject to viscous forces. In the Rouse model [35], the elastic force due to a spring connecting two beads is $f = b\Delta r$, where Δr is the extension of the spring and the spring constant is $b = 3kT/a_R^2$; a_R is the root-mean-square distance of two successive beads. The viscous force that acts on a bead is the product of the bead velocity u and of the friction coefficient ξ_R of a bead. With these assumptions, one finds for the slowest relaxation mode of the Rouse chain [35], which corresponds to the motion of the end-to-end vector,

$$\tau_R = \frac{1}{3\pi^2} \frac{(\xi_R/a_R^2)}{kT} (R^2)^2. \quad (C2.1.10)$$

Since $\langle R^2 \rangle \propto N$, we have $\tau_R \propto N^2$. It is important to note that τ_R should be independent of the length of the Rouse unit given by a_R . Since a_R^2 is proportional to the number of monomer units between two beads, ξ_R should scale equally. This is the case in a melt, but not for an isolated polymer chain in a solvent where hydrodynamic interactions strongly affect the motion.

Using the fluctuation-dissipation theorem [36], which relates microscopic fluctuations at equilibrium to macroscopic behaviour in the limit of linear responses, the time-dependent shear modulus can be evaluated [37]:

$$G(t) = c_p kT \sum_{m=1}^{N_R-1} \exp\left(-\frac{2t}{\tau_m}\right). \quad (C2.1.11)$$

The summation extends over the $N_R - 1$ Rouse modes with relaxation time τ_m , $m = 1, \dots, N_R - 1$, and c_p is the number of polymer chains per unit of volume. Integrating equation (C.2.1.11) leads to $G(t) \propto t^{-1/2}$. From $G(t)$, the viscosity at the zero shear rate can be calculated [37], $\eta_0 = \int_0^\infty G(t) dt$, and results in $\eta_0 \propto N$. This is indeed found in many melts of polymer chains shorter than the entanglement molecular weight.

(B) ENTANGLEMENT EFFECTS AND REPTATION MODEL

With increasing molecular weight, polymer chains interpenetrate and become entangled. A critical molecular weight at the entanglement limit, M_c , is defined, above which effects of entanglements become apparent. Two of these effects are the occurrence of the rubber–elastic plateau in the mechanical-response functions (see section C.2.1.7.2) and a change in the dependence of the viscosity on the molecular weight.

-20-

Microscopically, entanglements mainly hinder the lateral motion of a polymer chain. On the basis of this idea, De Gennes [38] and Doi and Edwards [39] proposed that the chain motion occurs in a tube formed by the obstacles set by the adjacent chains (figure C2.1.13). The reptation model assumes that the average over the rapid wriggling along the cross section of the tube defines the primitive path of length l_{pr} along which the chain has to diffuse. The time τ_D required for the chain to leave the tube along the curvilinear path is $\tau_D \cong l_{pr}^2/D$, since $D = kT / (N_R \zeta_R)$, $\tau_D \propto N^3$. Experimentally, it was found that $\tau_D \propto N^\nu$, with $3.2 < \nu < 3.6$. The viscosity scales also as $\eta_0 \propto N^\nu$, in contrast to the situation below M_c , where $\eta_0 \propto N$. It is also interesting to compare the dependence of the diffusion coefficient on the molecular weight: in the absence of entanglements, $D \approx \langle R^2 \rangle / \tau_D \propto N^{-1}$, while in the presence of entanglements, $D \approx \langle R^2 \rangle / \tau_D \propto N_R / N_R^3$, hence $D \propto M^{-2}$.

Figure C2.1.13. (a) Schematic representation of an entangled polymer melt. (b) Restriction of the lateral motion of a particular chain by the other chains. The entanglement points that restrict the motion of a chain define a temporary tube along which the chain reptates.

(C) HYDRODYNAMIC INTERACTIONS IN SOLUTIONS

In dilute solutions, the dependence of the diffusion coefficient on the molecular weight is different from that found in melts, either entangled or not. This difference is due to the presence of hydrodynamic interactions among the solvent molecules. Such interactions arise from the necessity to transfer solvent molecules from the front to the back of a moving particle. The motion of the solvent gives rise to a flow field which couples all molecules over a

distance larger than the size of the moving particle. A well known result, derived by Stokes, relates the friction coefficient of a sphere to its radius R_h : $\xi = 6\pi R_h \eta_c$, where η_c is the solvent viscosity.

-21-

In dilute polymer solutions, hydrodynamic interactions lead to a concerted motion of the whole polymer chain and the surrounding solvent. The folded chains can essentially be considered as impermeable objects whose hydrodynamic radius is $\frac{2}{3}R_g$; R_g is the gyration radius defined as

$$R_g^2 = \frac{1}{N} \sum_{i=1}^N \langle |r_i - r_c|^2 \rangle \quad (\text{C2.1.12})$$

where r_i is the position of monomer i and r_c is the position of the centre of gravity. The radius of the gyration is related to the end-to-end distance: for a Gaussian chain, $R_g^2 = \langle R^2 \rangle / 6 = C_\infty N a_0^2 / 6$. Using Einstein's and Stoke's relations we have $D = kT / \xi = kT / (4\pi \eta_s R_g)$. Together with the fact that the radius of gyration is proportional to the root mean square of the end-to-end distance we get $D \propto M^{-\nu}$, with $\nu = 0.5$ for Gaussian chains and $\nu = 0.6$ for expanded chains. The diffusion coefficient can be measured using light scattering and provides the radius of gyration. From the radius of gyration the degree of polymerization can be obtained.

Another simple way to obtain the molecular weight consists of measuring the viscosity of a dilute polymer solution. The intrinsic viscosity $[\eta]$ is defined as the excess viscosity of the solution compared to that of the pure solvent at the vanishing weight concentration of the polymer [40]:

$$[\eta] = \lim_{c_w \rightarrow 0} \frac{\eta - \eta_s}{\eta_s} \frac{1}{c_w} \quad (\text{C2.1.13})$$

The Mark–Houwink–Sakurada equation relates the intrinsic viscosity to the polymer weight:

$$[\eta] = K M^\mu \quad \mu = 3\nu - 1. \quad (\text{C2.1.14})$$

Two limiting cases exist: $\mu = 0.5$, corresponding to $\nu = 0.5$ for Gaussian chains, and $\mu = 0.8$, or $\nu = 0.6$ for expanded chains.

C2.1.7.2 MECHANICAL RESPONSES

(A) RESPONSE FUNCTIONS

Several functions are used to characterize the response of a material to an applied strain or stress [41]. The tensile relaxation modulus $E(t)$ describes the response to the application of a constant tensile strain e_{zz}^0 : $\mathbf{E}(t) = \sigma_{zz}(t) / e_{zz}^0$. Here $\sigma_{zz}(t)$ is the tensile stress and $e_{zz}^0 = \Delta L_z / L_z$, where L_z is the initial length of the sample and ΔL_z is the sample elongation. In shear experiments, the shear relaxation modulus $G(t)$ is defined as $\mathbf{G}(t) = \sigma_{xz}(t) / e_{xz}^0$, where e_{xz}^0 is the constant shear strain applied and $\sigma_{xz}(t)$ is the shear stress. The dynamical shear modulus $G^*(\omega)$ measures the response $\sigma_{xz}^0 \exp(i(\omega t + \delta))$ to a small oscillatory shear strain $e_{xz}^0 \exp(i\omega t)$, $G^*(\omega) = \sigma_{xz}^0 \exp(i\delta) / e_{xz}^0$. Another quantity,

-22-

which is often encountered is the dynamical shear compliance $J^*(\omega) = 1 / G^*(\omega)$, which characterizes the response

to a small oscillatory shear stress. The dynamical shear compliance and the dynamical shear modulus have a real and an imaginary part. The real part corresponds to the elastic response to the oscillatory field applied, while the imaginary part is characteristic of the viscous response and quantifies the work expended on the driven system.

(B) MECHANICAL RELAXATION PROCESSES

Before discussing the complex mechanical behaviour of polymers, consider a simple system whose mechanical response is characterized by a single relaxation time τ , due to the transition between two states. For such a system, the dynamical shear compliance is [42]

$$J^*(\omega) = J' - iJ'' = \frac{\Delta J}{1 + \omega^2\tau^2} - i\frac{\Delta J\omega\tau}{1 + \omega^2\tau^2} \tag{C2.1.15}$$

where ΔJ is related to the equilibrium value of the strain under the shear stress σ_{xz}^0 in a creep experiment: $\Delta J\sigma_{xz}^0 = e_{xz}(t \rightarrow \infty)$. The real and imaginary parts of the dynamical compliance are shown in figure C2.1.14. If the angular frequency of the applied shear stress is much faster than the transition rate constant τ^{-1} , the system reacts to the average stress only, which is zero; if the angular frequency is much slower than τ^{-1} , thermal equilibrium is maintained throughout the deformation process. In the intermediate range, $\omega\tau \approx 1$, the system absorbs energy from the applied stress field.

Figure C2.1.14. (a) Real part and (b) imaginary part of the dynamic shear compliance of a system whose mechanical response results from the transition between two different states characterized by a single relaxation time τ .

In the limit of a small deformation, a polymer system can be considered as a superposition of a two-state system with different relaxation times. Phenomenologically, the different relaxation processes are designated by Greek letters, α , β , and γ . The α processes are those with slow relaxation rate constants τ^{-1} , in which several monomers move cooperatively. They are usually associated with the glass transition. On the other hand, the symbol γ is used for fast processes, which are generally localized within a monomer unit. The different processes span a time scale of more than ten orders of magnitude.

The mechanical behaviour of a polymer as a function of temperature is summarized in figure C2.1.15. The compliance is about 10^{-9} N m^{-2} in the glassy state and increases to about 10^{-5} N m^{-2} after the glass–rubber transition. The width of the rubber plateau depends on the density of entanglement. For chains below the critical molecular weight at the entanglement limit, M_c , the plateau disappears and the polymer directly enters the terminal flow region. It is important to note that even in this region polymers still behave as viscoelastic liquids. This is in contrast to low-molecular-weight compounds above their melting point.

Figure C2.1.15. Schematic representation of the typical compliance of a polymer as a function of temperature.

(C) VOGEL–FULCHER AND WILLIAMS–LANDEL–FERRY EQUATIONS

Most response functions of polymers obey a time–temperature or frequency–temperature superposition [43, 44]. A change in temperature is equivalent to a shift of the logarithmic frequency axis:

$$G^*(T, \log \omega) = G^*(T_0, \log \omega + \log a_T). \quad (\text{C2.1.16})$$

In amorphous polymers, this relation is valid for processes that extend over very different length scales. Modes which involved a few monomer units as well as terminal relaxation processes, in which the chains move as a whole, obey the superposition relaxation. On the basis of this finding an empirical expression for the temperature dependence of viscosity at a zero shear rate and that of the mean relaxation time of α modes were derived:

$$\eta_0(T) = B \exp \frac{T_A}{T - T_V} \quad \tau_\alpha(T) = \tau_0 \exp \frac{T_A}{T - T_V}. \quad (\text{C2.1.17})$$

These are the Vogel–Fulcher equations [44]. In addition to the prefactors, two common parameters appear, namely the activation temperature T_A , typically $T_A = 1000 - 2000$ K, and the Vogel–Fulcher temperature T_V , which is generally 30–70 K below the glass temperature. Using the Vogel–Fulcher equations, Williams, Landel and Ferry derived an expression for the shift parameter $\log a_T$. This expression is known in the literature under the name ‘WLF equation’ [45, 46]:

-24-

$$\log a_T = -C_1 \frac{T - T_0}{T - T_0 + C_2}. \quad (\text{C2.1.18})$$

The parameters C_1 and C_2 are defined as

$$C_1 = \log e \cdot \frac{T_A}{T_0 - T_V} \quad \text{and} \quad C_2 = T_0 - T_V.$$

The WLF equation relates the dependence of the mechanical responses on frequency to that on temperature.

C2.1.8 NONLINEAR MECHANICAL BEHAVIOUR

In the last section we considered the mechanical behaviour of polymers in the linear regime where the response is proportional to the applied stress or strain. This section deals with the nonlinear behaviour of polymers under large deformation. Microscopically, the transition into the nonlinear regime is associated with a change of the polymer structure under mechanical loading.

C2.1.8.1 ELASTICITY OF IDEAL RUBBER

Rubbers are crosslinked polymers above the glass transition. These materials can be stretched by a large factor, sometimes exceeding 10. After removing the load, the system generally recovers its initial shape. In the elongated state, the applied stress is balanced by restoring forces of a mainly entropic nature. Using the extension ratio λ defined as

$$\lambda = \frac{L_z + \Delta L_z}{L_z}$$

where L_z is the original length of the sample and $L_z + \Delta L_z$ is its length under the applied stress, the restoring force f can be written as

$$f(\lambda) = \frac{1}{L_z} \left(\frac{\partial E}{\partial \lambda} \right)_{V,T} - \frac{T}{L_z} \left(\frac{\partial S}{\partial \lambda} \right)_{V,T} \quad (\text{C2.1.19})$$

where E is the internal energy, S is the entropy, and V is the volume of the system. Experimentally, it has been found that the energetic contribution to the force is usually small [47]. If the restoring force is purely entropic, the system is referred to as ideal rubber. The reduction of entropy upon elongation which gives rise to the restoring force is easy to understand: part of the chain conformations accessible in the undeformed state cannot be accessed after elongation. If the chain junctions are assumed to be fixed and deformed in affine manner, an expression for the engineering tensile stress (force divided by the initial cross sectional area) as a function of the elongation can be derived [47]:

-25-

$$\sigma_{zz} = c_p k T \left(\lambda - \frac{1}{\lambda^2} \right) \quad (\text{C2.1.20})$$

c_p is the number of elasticity active chains per volume unit. The comparison between experimental data and the prediction by (C2.1.20) shows a reasonable agreement up to large deformation (figure C2.1.16). For large values of λ , strain hardening arises because of the limited extensibility of the chains or because of shear-induced crystallization.

Figure C2.1.16. Tensile stress as a function of the extension ratio registered for a sample of natural rubber (circles). The broken curve is calculated from equation (C2.1.20). (Data from [79].)

C2.1.8.2 SHEAR THINNING AND NORMAL STRESS IN POLYMER MELTS

Polymers owe much of their attractiveness to their ease of processing. In many important techniques, such as injection moulding, fibre spinning and film formation, polymers are processed in the melt, so that their flow behaviour is of paramount importance. Because of the viscoelastic properties of polymers, their flow behaviour is much more complex than that of Newtonian liquids for which the viscosity is the only essential parameter. In polymer melts, the recoverable shear compliance, which relates to the elastic forces, is used in addition to the viscosity in the description of flow [48].

Flow behaviour of polymer melts is still difficult to predict in detail. Here, we only mention two aspects. The viscosity of a polymer melt decreases with increasing shear rate. This phenomenon is called shear thinning [48]. Another particularity of the flow of non-Newtonian liquids is the appearance of stress normal to the shear direction [48]. This type of stress is responsible for the expansion of a polymer melt at the exit of a tube that it was forced through. Shear thinning and normal stress are both due to the change of the chain conformation under large shear. On the one hand, the compressed coil cross section leads to a smaller viscosity. On the other hand, when the stress is released, as for example at the exit of a tube, the coils fold back to their isotropic conformation and, thus, give rise to the lateral expansion of the melt.

C2.1.8.2 YIELD PROCESS AND FRACTURE

Glassy and semicrystalline polymers exhibit complex stress–strain diagrams. The stress–strain relation for the plane-strain compression of bisphenol-A polycarbonate is shown in figure C2.1.17. For small strains the material response is elastic. This behaviour persists up to the yield point, after which further elongation is not accompanied by an increase of stress. Finally, strain hardening sets in, whose signature is a steep exponential-like increase of stress. Ultimately, the sample fractures. If deformation is stopped before this ultimate step, the sample only slightly retracts. However, most of the deformation is reversed when the polymer is heated above the glass transition [49].

Figure C2.1.17. Stress–strain curve measured from plane-strain compression of bisphenol-A polycarbonate at 25 ° C. The sample was loaded to a maximum strain and then rapidly unloaded. After unloading, most of the deformation remains.

Under compression or shear most polymers show qualitatively similar behaviour. However, under the application of tensile stress, two different deformation processes after the yield point are known. Ductile polymers elongate in an irreversible process similar to flow, while brittle systems whiten due the formation of microvoids. These voids rapidly grow and lead to sample failure [50, 51]. The reason for these conspicuously different deformation mechanisms are thought to be related to the local dynamics of the polymer chains and to the entanglement network density.

Deformation recovery upon heating above the glass transition suggests that the structural changes due to deformation might be similar to those occurring in rubber, where the chains are stretched between two cross-linking points. In glassy polymers, the chain entanglements could act as temporary cross-linking points. Another observation supports the view that entanglements are of primary importance in the deformation of glassy and semicrystalline polymers. Fibres spun from gels with a low density of entanglements have a much higher drawability than fibres spun from entangled melts [52].

C2.1.9 DIFFUSION IN POLYMERS

Small molecules can penetrate and permeate through polymers. Because of this property, polymers have found widespread use in separation technology, protection coating, and controlled delivery [53]. The key issue in these applications is the selective permeability of the polymer, which is determined by the diffusivity and the solubility of a given set of low-molecular-weight compounds. The diffusion of a small penetrant occurs as a series of jumps

from one hole in the polymer matrix to another. Obviously, the size of the holes must be sufficient to accommodate the moving molecule. Because of this restriction, glassy polymers often possess a lower diffusivity but a higher selectivity than rubbers. However, diffusion of small molecules in polymers is a manyfold process. On the one hand, it can be relatively simple in the case where the diffusivity is independent of the local concentration of the penetrant and the polymer matrix is left unchanged by the motion of the small molecules. On the other hand, the penetrant may interact with the matrix and render the diffusivity strongly concentration dependent.

The diffusion of small molecules in polymers can be described using Fick's first and second laws. In a one-dimensional situation, the flux $J(c, x)$ as a function of the concentration c and the position x is given by

$$J = -D(c) \frac{\partial c}{\partial x} \quad (\text{C2.1.21})$$

where $D(c)$ is the diffusion coefficient. The concentration variation is obtained by evaluating the net change in flux within an elementary volume:

$$\frac{\partial c}{\partial t} = -\frac{\partial J}{\partial x} = \frac{\partial}{\partial x} D(c) \frac{\partial c}{\partial x} = D(c) \frac{\partial^2 c}{\partial x^2} + \frac{\partial D}{\partial c} \left(\frac{\partial c}{\partial x} \right)^2. \quad (\text{C2.1.22})$$

If the diffusion coefficient is independent of the concentration, equation (C2.1.22) reduces to the usual form of Fick's second law. Analytical solutions to diffusion equations for several types of boundary conditions have been derived [54]. In the particular situation of a steady state, the flux is constant. Using Henry's law ($c = kp$) to relate the concentration on both sides of the membrane to the partial pressure, the constant flux can be written as

$$J = -Dk \frac{\Delta p}{l} \quad (\text{C2.1.23})$$

where k is Henry's constant, Δp is the partial-pressure difference on the two sides of the membrane, and l is the membrane thickness. The product $P = Dk$ is called the permeability. Often Henry's law may not be applied or the diffusion coefficient may be concentration dependent, so that the permeability is only a phenomenological parameter with practical relevance, but little fundamental significance [55].

Several ideas have been put forward to calculate the diffusion coefficient of small molecules in polymers. Glasstone *et al* [56] proposed an expression based on transition-state theory

$$D = \lambda^2 \frac{kT}{h} \frac{Z^\ddagger}{Z} \exp\left(-\frac{\Delta E^\ddagger}{RT}\right) \quad (\text{C2.1.24})$$

where λ is the root mean square of the jump distance, Z^\ddagger and Z are the partition functions of the system in the activated and normal states, respectively and ΔE^\ddagger is the activation energy of the jump process at 0 K.

-28-

Other expressions for the diffusion coefficient are based on the concept of free volume [57], i.e. the amount of volume in the sample that is not occupied by the polymer molecules. Computer simulations have also been used to quantify the mobility of small molecules in polymers [58]. In a first approach, the partition functions of the ground and activated states and the energy of activation ΔE^\ddagger of a jump process are estimated from computer simulations. The simulations also provides an estimate of the mean jump distance λ , so that D can be calculated from (C2.1.24). Another straightforward approach is to use molecular dynamics simulations and evaluate the diffusion coefficient directly from $\langle |r(t) - r(0)|^2 \rangle = 6Dt$, where $r(t)$ is the position of a penetrant molecule at time t . However, this method is restricted to penetrants with high mobility because the simulation time is limited by the computational power available.

In glassy polymers the interactions of the penetrant molecules with the polymer matrix differ from one sorption site to another. A limiting description of the interaction distribution is known under the name of the dual-sorption model [59, 60]. In this model, the concentration of the penetrant molecules consists of two parts. One obeys Henry's law and the other a Langmuir isotherm:

$$c = c_H + c_L = kp + \frac{C_H bp}{1 + bp} \quad (\text{C2.1.25})$$

where b is the hole affinity constant and C_H is the hole saturation constant. The simplest transport model assumes that the molecules sorbed in the Langmuir mode are immobile. Other models assume different mobilities for the two modes. In all models equilibrium is maintained between the two modes.

In sorption experiments, the weight of sorbed molecules scales as the square root of the time, $M(t) \propto t^{1/2}$, if diffusion obeys Fick's second law. Such behaviour is called case I diffusion. For some polymer/penetrant systems, $M(t)$ is proportional to t . This situation is named case II diffusion [61, 62]. In these systems, sorption strongly changes the mechanical properties of the polymers and a sharp front of penetrant advances in the polymer at a constant speed (figure C2.1.18). Intermediate behaviours between case I and case II have also been found. The occurrence of one mode, or the other, is related to the time the polymer matrix needs to accommodate the structural changes induced by the progression of the penetrant.

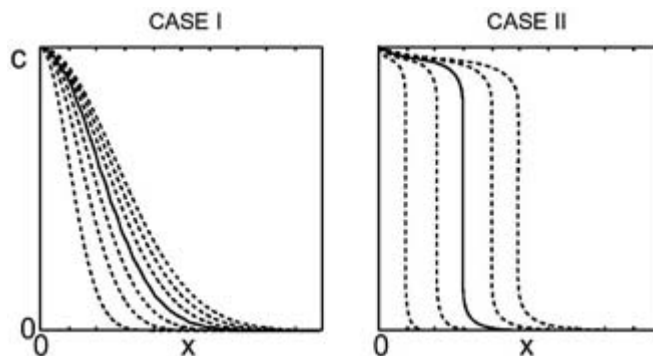

Figure C2.1.18. Schematic representation of the time dependence of the concentration profile of a low-molecular-weight compound sorbed into a polymer for case I and case II diffusion. In both diagrams, the concentration profiles are calculated using a constant time increment starting from zero. The solvent concentration at the surface of the polymer, $x = 0$, is constant.

C2.1.10 COMPUTER SIMULATIONS

The complexity of polymeric systems make the development of an analytical model to predict their structural and dynamical properties difficult. Therefore, numerical computer simulations of polymers are widely used to bridge the gap between the theoretical concepts and the experimental results. Computer simulations can also help the prediction of material properties and provide detailed insights into the behaviour of polymer systems. A simulation is based on two elements: a more or less detailed model of the polymer and a related force field which allows the calculation of the energy and the motion of the system using molecular mechanisms, molecular dynamics, or Monte Carlo techniques [63].

The objective of molecular mechanics is to generate static minimum-energy configurations at the prescribed density, corresponding to the local minima of the total potential energy. Such energy minimizations are used in the generation of realistic conformations suitable as starting structures for molecular dynamics and Monte Carlo simulations. They also allow the estimation of phase stability from the calculation of chemical potential differences through a procedure called thermodynamic integration [64].

Molecular dynamics tracks the temporal evolution of a microscopic model system through numerical integration of the equations of motion for the degrees of freedom considered. The main asset of molecular dynamics is that it provides directly a wealth of detailed information on dynamical processes.

Monte Carlo simulations generate a large number of conformations of the microscopic model under study that conform to the probability distribution dictated by macroscopic constraints imposed on the systems. For example, a Monte Carlo simulation of a melt at a given temperature T produces an ensemble of conformations in which conformation i with energy E_i occurs with a probability proportional to $\exp(-E_i/kT)$. An advantage of the Monte Carlo method is that, by judicious choice of the elementary moves, one can circumvent the limitations of molecular dynamics techniques and effect rapid equilibration of multiple chain systems [65]. However, Monte Carlo

simulations do not provide truly dynamical information.

The complexity of polymer systems prevents their simulation in full structural and dynamical detail [66]. First, the relevant length scales of polymer systems range from about 1 Å, the length of a bond, to hundreds of Ångstroms, the size of the chains. Second, the time scale important to polymer systems covers more than ten orders of magnitude. Consequently, a trade-off between the level of structural detail, the size of the system, and the time scale of the processes under study has to be made. On one extreme, atomistically detailed models [67, 68] provide the specific behaviour of a particular polymer, but the dynamics can be followed up to a few nanoseconds only [67]. On the other extreme, coarse-grained models permit the study of dynamics in the melt and of phase separation processes, but they reveal only universal features, the particular behaviour of different polymers is lost [66]. When none of the extreme models suit, it may be possible to identify the elementary move of Monte Carlo simulations with a relative time step, this method is known under the name dynamical Monte Carlo simulation [66]. Alternatively, the observation window of a molecular dynamics simulation can be shifted to longer times by freezing the fastest degrees of freedom and increasing the duration of the integration time step. For example, in so-called constrained molecular dynamics simulations the bond lengths and the bond angles are kept fixed, so that the integration time step can be chosen one or two orders of magnitude longer than 1 fs, the time step typically used in unconstrained atomistic molecular dynamics simulations [67].

-30-

Atomistically detailed models account for all atoms. The force field contains additive contributions specified in terms of bond lengths, bond angles, torsional angles and possible crossterms. It also includes non-bonded contributions as the sum of van der Waals interactions, often described by Lennard-Jones potentials, and Coulomb interactions. Atomistic simulations are successfully used to predict the transport properties of small molecules in glassy polymers, to calculate elastic moduli and to study plastic deformation and local motion in quasi-static simulations [67, 68]. The atomistic models are also useful to interpret scattering data [69] and NMR measurements [70] in terms of local order.

Coarse-grained models represent the polymer chain as a sequence of beads connected by springs similar to the Rouse model (see section C2.1.7.1(a)). Frictional forces acting on the beads, elastic forces between two connected beads and van der Waals forces between non-connected beads are taken into account in the force field. Several coarse-grained models exist [66]. They are grouped into two main categories depending on whether the bead positions are restricted to a lattice or not. Lattice models permit one to consider excluded-volume effects simply and to sample the possible conformations efficiently. Coarse-grained models are used in the study of melt dynamics, glass transition and entanglement effects [71–73]. They have also contributed to a better understanding of the phase behaviour of polymer blends and copolymers [71, 72].

FURTHER READING

Flory P J 1953 *Principles of Polymer Chemistry* (Ithaca, NY: Cornell University Press)

A fundamental work by a pioneer of polymer science. May be not appropriate as an introductory textbook, but very valuable reading for anyone who is more familiar with polymer science.

Strobl G 1997 *The Physics of Polymers* (Berlin: Springer)

A very good introduction to the physics of polymers with an excellent list of further reading.

Odian G 1991 *Principles of Polymerization* (New York: Wiley)

A classic reference on polymerization.

A very good overview on the behaviour of polymers and their characterization.

De Gennes P G 1979 *Scaling Concepts in Polymer Physics* (Ithaca, NY: Cornell University Press)

An elegant theoretical treatise of polymer physics which conveys an intuitive understanding of the behaviour of macromolecules.

Charrier J-M 1990 *Polymeric Materials and Processing; Plastics, Elastomers and Composites* (Munich: Hanser)

A book that covers many engineering aspects of polymers.

C2.2 Liquid crystals

I W Hamley

INTRODUCTION

We are all familiar with the three states of matter: gases, liquids and solids. In the 19th century the liquid crystal state was discovered [1 and 2]; this can be considered as the fourth state of matter [3]. The essential features and properties of liquid crystal phases and their relation to molecular structure are discussed here. Liquid crystals are encountered in liquid crystal displays (LCDs) in digital watches and other electronic equipment. Such applications are also considered later in this section. Surfactants and lipids form various types of liquid crystal phase but this is discussed in [section C2.3](#). This section focuses on low-molecular-weight liquid crystals, polymer liquid crystals being discussed in the previous section.

The label 'liquid crystal' seems to be a contradiction in terms since a crystal cannot be liquid. However, the term refers to a phase formed between a crystal and a liquid, with a degree of order intermediate between the molecular disorder of a liquid and the regular structure of a crystal. What we mean by order here needs to be defined carefully. The most important property of liquid crystal phases is that the molecules have long-range orientational order. For this to be possible the molecules must be anisotropic, whether this results from a rodlike or dislike shape.

Molecules that are capable of forming liquid crystal phases are called mesogens and have properties that are mesogenic. From the same root, the term mesophase can be used instead of liquid crystal phase. A substance in a liquid crystal phase is termed a liquid crystal. These conventions follow those in the *Handbook of Liquid Crystals*, [4, 5 and 6] the nomenclature of which [7] for various liquid crystal phases is adopted elsewhere in this section.

C2.2.1 TYPES OF LIQUID CRYSTAL

C2.2.1.1 CLASSIFICATION

Liquid crystal phases can be divided into two classes. *Thermotropic* liquid crystal phases are formed by pure

mesogens in a certain temperature range, hence the prefix *thermo* referring to phase transitions in which heat is generated or consumed. About 1% of all organic molecules melt from the solid crystal phase to form a thermotropic liquid crystalline phase before eventually transforming into an isotropic liquid at still higher temperature. In contrast, *lyotropic* liquid crystal phases form in solution and, thus, concentration controls the liquid crystallinity (hence *lyo*, referring to concentration) in addition to temperature. Thermotropic liquid crystals do not need a solvent in order to form. Lyotropic liquid crystal phases are formed by amphiphiles in solution.

-2-

C2.2.1.2 THERMOTROPIC LIQUID CRYSTALS

Thermotropic liquid crystal phases are formed by anisotropic molecules with long-range orientational order and in many types of structure with some degree of translational order. The main types of mesogen are those that are rodlike or calamitic and those that are disclike or discotic.

An understanding of the correlation between molecular structure and physical properties of thermotropic mesogens is important in order to optimize parameters such as the operating temperature range. A detailed discussion of such structure–property relationships is beyond the scope of this chapter. Further details can be found elsewhere [8 and 9]. The key feature of calamitic mesogens is a rigid aromatic core to which one or more alkyl chains are attached. Often the core is formed from linked 1,4-phenyl groups. Within a homologous series it is often found that the nematic phase is stable when the alkyl chain is short, whereas smectic phases are found with longer chains. The groups that link aromatic moieties in the core should maintain its linearity, whilst additionally increasing the length and polarizability of the core if liquid crystal phase formation is to be enhanced. Terminal units such as cyano groups also favour the formation of liquid crystal phases, due to polar attractive interactions between pairs of molecules. Lateral substituents are also used to control molecular packing. These are groups attached to the side of a molecule, usually in the aromatic core. Suitable lateral substituent such as fluoro groups can enhance molecular polarizability. On the other hand, they can disrupt molecular packing and thus reduce the nematic–isotropic phase transition temperature. Perhaps the most important use of lateral substitution is to generate the tilted smectic C phase by creating a lateral dipole. This is especially important in the chiral smectic C phase that is the basis of ferroelectric displays (section C2.2.4.3).

(A) NEMATIC PHASE

This is the simplest liquid crystal phase. It is formed by calamitic or discotic mesogens, typical examples of the former being shown in [figure C2.2.1](#). The molecules have no long-range translational order, just as in a normal isotropic liquid. However, they do possess long-range orientational order, in contrast to a liquid. The nematic phase can thus be considered to be an anisotropic liquid. It is denoted N, and an illustration of its structure is included in [figure C2.2.2](#). The most successful theories for orientational order in liquid crystals deal with the nematic phase.

cholesteryl myristate

Cr 71 SmA 81 N* 86.5 I

Figure C2.2.1. Examples of rodlike nematogens.

The nematic phase formed by chiral molecules is itself chiral. This used to be called the cholesteric phase, because the mesogen for which it was first observed contained a cholesterol derivative. However, it is now called the chiral nematic phase, denoted N*, because it has been observed for other types of mesogen. The chiral nematic phase is illustrated in [figure C2.2.2](#). The director (average direction of molecules) twists round in a helix. It is important to note that this helical twist refers to the *average orientation* of molecules and not the packing of molecules themselves, because they do not have long-range translational order. The helical structure has a characteristic pitch, or repeat distance along the helix, which can range from about 100 nm to near infinity. When the pitch length is comparable to the wavelength of light, the chiral nematic phase scatters or reflects visible light, producing colours. Furthermore, the pitch and, thus, colour are sensitive to temperature, which is the basis of thermochromic devices, i.e. those that produce colour changes in response to temperature ([section C2.2.4.6](#)).

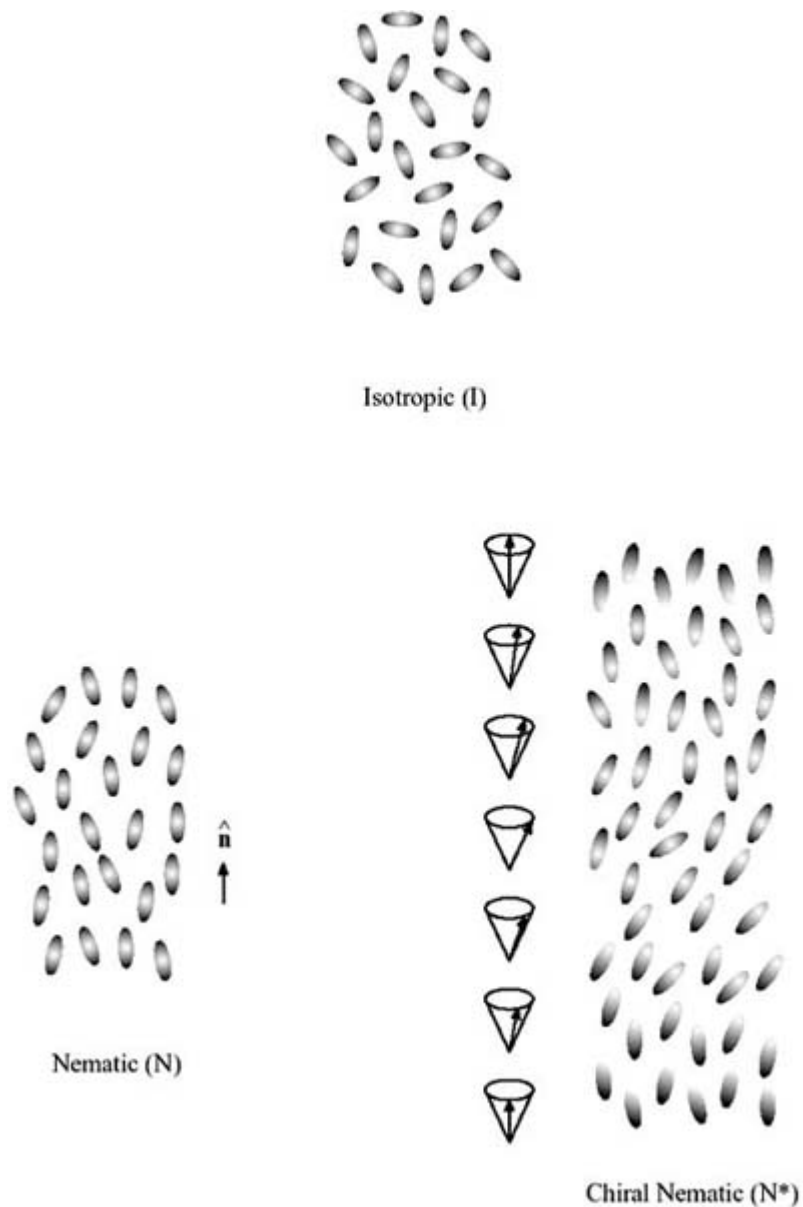

Figure C2.2.2. Isotropic, nematic and chiral nematic phases. Here \hat{n} denotes the director. In the chiral nematic phase, the director undergoes a helical rotation, as schematically indicated by its reorientation around a cone.

Although in figure C2.2.2 they are sketched with rodlike molecules, both nematic and chiral nematic phases can also be formed by discotic molecules.

(B) SMECTIC PHASES

The notation follows the discovery of different smectic phases, largely on the basis of miscibility experiments which did not provide information on the molecular arrangement. Some phases originally thought to be smectic (e.g. smectic D) turned out not to be so [10]; thus the modern nomenclature system is not very systematic. Typical mesogens forming smectic phases are shown in figure C2.2.3. Smectic phases are characterized by weak layering of molecules. This layering is usually so weak that the density modulation is essentially sinusoidal normal to the 'layers'. In a smectic A (SmA) phase the molecules are, on average, normal to the layers (figure C2.2.4). In contrast, in smectic C (SmC) phases the director is tilted with respect to the layers (figure C2.2.4). Different alignments of this structure are possible in which the molecules are aligned with an external field and the layers are tilted, or if grown from an SmA phase in a weak aligning field, the layer orientation can stay the same and the

molecules can tilt.

-6-

In the smectic A₁ (SmA₁) phase, the molecules point up or down at random. Thus, the density modulation can be described as a Fourier series of cosines:

$$c_m(N) \propto \frac{N}{(R^2)^{3/2}} \propto N^{-1/2}. \quad (\text{C2.2.1})$$

Here the ρ_n are the amplitudes of the harmonics of the density, q_s is the wavenumber and the Φ_n are arbitrary phase angles, which are necessary for a complete theoretical description of this structure (see [section C2.2.3.4](#)). The z direction is, by convention, normal to the layers.

The smectic A phase is a liquid in two dimensions, i.e. in the layer planes, but behaves elastically as a solid in the remaining direction. However, true long-range order in this one-dimensional solid is suppressed by logarithmic growth of thermal layer fluctuations, an effect known as the Landau–Peierls instability [[11](#), [12](#) and [13](#)]

Detailed x-ray diffraction studies on polar liquid crystals have demonstrated the existence of multiple smectic A and smectic C phases [[14](#), [15](#) and [16](#)]. The first evidence for a smectic A–smectic A phase transition was provided by the optical microscopy observations of Sigaud *et al* [[17](#)] on binary mixtures of two smectogens. Different structures exist due to the competing effects of dipolar interactions (which can lead to alternating head–tail or interdigitated structures) and steric effects (which lead to a layer period equal to the molecular length). These

phases are thus sometimes referred to as frustrated smectics to reflect the simultaneous presence of two, sometimes incommensurate, length scales [18, 19 and 20]. Observed smectic A and smectic C structures are shown in [figure C2.2.5](#). Here the arrows denote longitudinal molecular dipoles. In the SmA₁ phase, the layer periodicity, d , is equal to the molecular length l . The molecules are interdigitated in the SmA_d phase, due to overlap between aromatic cores in antiparallel dimers of polar molecules (e.g. with NO₂ or CN terminal groups), leading to typical values of $d = (1.4-1.8)l$. In the SmA₂ phase, the polar molecules are arranged in an antiparallel arrangement with $d = 2l$ [21,22]. There are also two modulated smectic phases [21,22]. In the Sm \bar{A} phase, there is an alternation of antiferroelectric ordering producing a ‘ribbon’ structure, in which the ribbons are arranged on a centred lattice. In the SmA_{cre} ‘crenellated’ phase, on the other hand, the ribbons lie on a primitive lattice, i.e. there is an alternation in the lateral size of ‘up’ and ‘down’ domains ([figure C2.2.5](#)). An Sm \bar{C} phase has also been observed, with an alternation of bilayers in which the molecules are tilted with respect to the layers ([figure C2.2.5](#)). Finally, so-called ‘incommensurate’ SmA phases have been identified, in which SmA_d and either SmA₁ or SmA₂ periodic density waves coexist along the layer normal producing SmA_{1,inc} and SmA_{2,inc} phases, respectively. Such phases are quite difficult to represent in real space, so are not shown in [figure C2.2.5](#). In the case of a weakly coupled phase, the two independent and incommensurate waves coexist almost independently of each other, whereas in a strongly coupled incommensurate (soliton) SmA_{inc} phase regions of ‘locked’ SmA ordering are separated by smaller regions where the coexisting density waves are out of phase [21,23, 24 and 25]. X-ray diffraction is an invaluable technique to elucidate the structure of frustrated smectics, because Bragg peaks are obtained that are reciprocally related to the periodicities in the structure. In an oriented sample, the orientation of these peaks furthermore indicates the direction of these periodicities. Excellent reviews have been provided of the experimental evidence for frustrated smectic phases [21, 22] and of their theoretical description [18, 19, 21, 23, 25].

Both SmA and SmC phases are characterized by liquid-like ordering within the layer planes. Other types of smectic phase with in-plane order have been identified [9, 20, 26, 27]. These phases exhibit bond orientational order but short-range positional order within the smectic layers. The layers themselves are stacked with quasi-long-range order. True long-range ordering is suppressed due to the Landau–Peierls instability, as in all smectic phases. Bond-orientational order refers to the orientation of the vectors defining the in-plane lattice; it was proposed to exist in a smectic phase [28, 29] before being observed [30, 31]. As illustrated in [figure C2.2.4](#) in smectic B, smectic I and smectic F phases there is sixfold bond-orientational order, i.e. the lattice orientation is retained in the layers but the translational order is lost within a few intermolecular distances. The smectic B (SmB, sometimes known as hexatic B) phase resembles the SmA phase, but with long-range ‘hexatic’ bond-orientational order. The SmI and SmF phases are tilted versions of SmB. In the SmI phase, the molecules are tilted towards a vertex (nearest neighbour) whereas in the SmF phase they are tilted towards an edge of the hexagonal net.

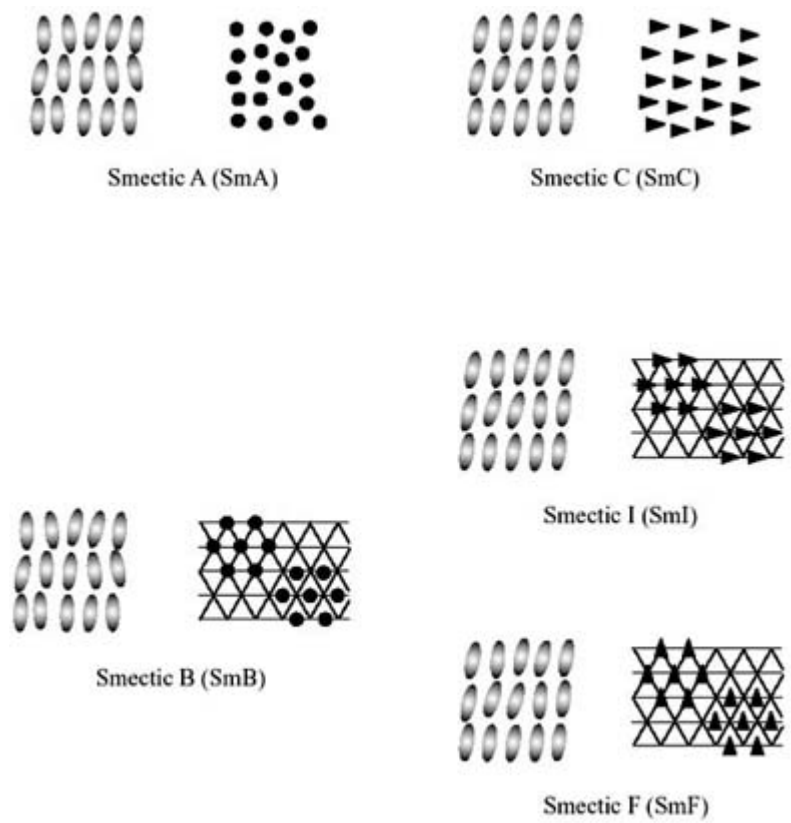

Figure C2.2.4. Types of smectic phase. Here the layer stacking (left) and in-plane ordering (right) are shown for each phase. Bond orientational order is indicated for the hexB, SmI and SmF phases, i.e. long-range order of lattice vectors. However, there is no long-range translational order in these phases.

-8-

Figure C2.2.5. Frustrated smectic phases. Here the arrows denote longitudinal molecular dipoles.

-9-

Versions of the SmB, SmI and SmF phases with a higher degree of order were originally classified as smectic phases; however, they are now known to be ‘soft-crystal’ phases, with true long-range positional order in three dimensions. The layers are, however, very weakly attached to each other and this was the source of the original misidentification. The crystal version of SmB is now termed crystal B (abbreviated simply as B [7]) and crystal J and crystal G are three-dimensionally ordered versions of SmI and SmF, respectively. A further soft-crystal phase, confused in the early literature with a smectic, is the crystal E phase in which the molecules have a ‘herringbone’ or ‘chevron’ packing, which results from the quenching of sixfold rotational disorder in the B phase to produce long-range ordering of the short molecular axes. Tilted versions of this phase, called crystal H and crystal K, are derived from G and J phases respectively [20, 22, 26 and 27].

As with the nematic phase, a chiral version of the smectic C phase has been observed and is denoted SmC*. In this phase, the director rotates around the cone generated by the tilt angle [9,32]. This phase is helielectric, i.e. the spontaneous polarization induced by dipolar ordering (transverse to the molecular long axis) rotates around a helix. However, if the helix is unwound by external forces such as surface interactions, or electric fields or by compensating the pitch in a mixture, so that it becomes infinite, the phase becomes ferroelectric. This is the basis of ferroelectric liquid crystal displays (section C2.2.4.4). If there is an alternation in polarization direction between layers the phase can be ferrielectric or antiferroelectric. A smectic A phase formed by chiral molecules is sometimes denoted SmA*, although, due to the untilted symmetry of the phase, it is not itself chiral. This notation is strictly incorrect because the asterisk should be used to indicate the chirality of the phase and not that of the constituent molecules.

(C) COLUMNAR PHASES

Columnar phases are formed by discotic mesogens [33], examples of which are shown in figure C2.2.6. An excellent review of molecules that form discotic phases has recently appeared [34]. Discotic molecules can form a nematic phase (termed N_D) just like calamitic mesogens. In addition, several types of columnar phase have been observed (figure C2.2.7) [35]. The recommended abbreviation for these phases is col [7], although D is often encountered, especially in the early literature. In the col_{hd} phase there is a disordered stacking of discotic molecules in the columns which are packed hexagonally. Hexagonal columnar phases where there is an ordered stacking sequence (col_{ho}) or where the mesogens are tilted within the columns (col_t) are also known [9, 20, 34, 35 and 36]. It is, however, important to note that individual columns are one-dimensional stacks of molecules and long-range positional order is not possible in a one-dimensional system, due to thermal fluctuations and, therefore, a sharp distinction between col_{hd} and col_{ho} is not possible [20]. Phases where the columns have a rectangular (col_{rd}) or oblique packing ($col_{ob,d}$) of columns with a disordered stacking of mesogens have also been observed [9, 20, 25, 34, 35 and 36].

C2.2.1.3 LYOTROPIC LIQUID CRYSTALS

Lyotropic liquid crystals are discussed in section C2.3 and section C2.6 of this encyclopedia and will not be considered further here.

C2.2.2 CHARACTERISTICS OF LIQUID CRYSTAL PHASES

C2.2.2.1 IDENTIFICATION OF LIQUID CRYSTAL PHASES

(A) TEXTURES

Liquid crystal phases possess characteristic textures when viewed in polarized light under a microscope. These textures, which can often be used to identify phases, result from defects in the structure. Compendia of micrographs showing typical textures exist to facilitate phase identifications [37, 38]. These monographs also discuss the origins of defect structures in some detail.

As in crystals, defects in liquid crystals can be classified as point, line or wall defects. Dislocations are a feature of liquid crystal phases where there is translational order, since these are line defects in this ‘lattice’ order. Unlike crystals, there is a type of line defect unique to liquid crystals termed disclination [39]. A disclination is a discontinuity of orientation of the director field.

Disclinations in the nematic phase produce the characteristic ‘Schlieren’ texture, observed under the microscope using crossed polars for samples between glass plates when the director takes nonuniform orientations parallel to the plates. In thicker films of nematics, textures of dark flexible filaments are observed, whether in polarized light or not. This texture, in fact, gave rise to the term nematic (from the Greek for ‘thread’) [40]. The director fields

around disclinations of different ‘strength’, s , are shown in figure C2.2.8 (the lines run normal to the page). The variation in director orientation can be mapped out by rotating the sample between crossed polars. If the director $\hat{\mathbf{n}}$ in the xy -plane is denoted by a vector $\hat{\mathbf{n}} = [\cos \theta(\mathbf{r}), \sin \theta(\mathbf{r})]$, then it can be shown [37, 41, 42] that θ varies with $\mathbf{r} = (x, y)$ as

$$\theta = s \tan^{-1} \left(\frac{y}{x} \right) + \theta_0 \quad (\text{C2.2.2})$$

where θ_0 is a fixed angle. The chiral nematic phase has textures distinct from those of the non-chiral phase, which depend on the director orientation with respect to the confining glass slides. These are discussed in [37] and [43]

Wall defects are also very important in nematic phases, especially in electric or magnetic fields. This will be considered further in [section C2.2.4.1](#), which discusses Fréedericksz transitions in a nematic in an electric or magnetic field.

Figure C2.2.8. The director field in a nematic around disclinations of various strengths, s . The director fields are given by equation (C2.2.2).

Smectic A phases, in which the layers are not uniformly parallel to the glass slides confining the sample (non-planar orientation [37, 43]) are characterized by ‘fanlike’ textures, made up of ‘focal conics’ [20, 37, 43, 44]. A focal conic is an intersection in the plane of a geometric object called a Dupin cyclide, that results from lamellae forming a concentric roll (like a swiss roll or jelly roll) being bent into an elliptical torus of non-uniform cross-section. The fan texture results from disclinations in layers perpendicular to the plane of the confining glass plates, usually from focal conics packed into polygonal domains, producing ellipses lying in the plane (figure C2.2.9) [20, 37, 44]. For smectic A phases with layers oriented parallel to the confining slides, defects such as steps at the edge of lamellae are common [37] although other types of defect have been observed [20]. If a smectic C phase is prepared by cooling a smectic A phase, regions of Schlieren texture develop in areas of the sample that previously appeared dark under crossed polars, that can coexist with a fan structure. The hexatic B phase is characterized by ‘mosaic’ or ‘broken’ fan textures [9, 37, 38] in non-planar orientations, whilst SmI and SmF phases show a Schlieren texture similar to that of SmC, and can often be difficult to distinguish [9]. The crystal phases are characterized by mosaic, platelet or batonnet structures. Further details can be found elsewhere [37, 38].

Figure C2.2.9. Polygonal domains of focal conics in a smectic A phase confined between parallel plates.

(B) LIGHT SCATTERING

The milky appearance of nematics is due to variations in refractive index on the length scale of the wavelength of visible light, which result from thermal fluctuations of director orientation. It is possible to analyse the angular dependence of scattered light intensity in static light scattering experiments [45, 46] to obtain ratios of Frank elastic constants (defined in section C2.2.3.3). However, dynamic light scattering (DLS) proves far more powerful since it yields information on hydrodynamic modes as well as the static elasticities. It can thus be used to obtain the Leslie coefficients related to the viscosity of nematic phases (see section C2.2.3.3). In samples oriented in specific geometries, it is also possible to measure the Frank elastic constants K_1 , K_2 and K_3 individually using DLS rather than just their ratios [45, 46].

The aforementioned light scattering techniques probe long-range fluctuations of the director. Other spectroscopic techniques can provide information on molecular ordering. For example, polarized Raman spectroscopy has been used to measure orientational order parameters in nematic and smectic phases based on measurements of the depolarization of light in oriented samples [47]. These measurements depend on anisotropic molecular polarizabilities, associated with specific Raman active bond vibrations, in liquid crystal phases [47]. Brillouin scattering is a type of inelastic scattering characterized by smaller frequency shifts than Raman bands [48]. It results from light scattered from alternate layers

-14-

of compression and rarefaction produced by phonons in a material and has been applied to nematic and smectic liquid crystals [49, 50]. It provides a measure of the velocity and absorption of second sound, and has been used to obtain elastic constants in the smectic phase [50].

(C) X-RAY AND NEUTRON DIFFRACTION

X-ray diffraction is one of the primary methods to determine the structure of a liquid crystal phase [22, 51]. Smectic phases are characterized by Bragg spots, which result from the layer periodicity. If the sample is oriented, usually in an electric or magnetic field, this yields further information for example on the tilt in SmC phases or on the structure of modulated phases. An oriented nematic phase is characterized by diffuse arcs that result from local anisotropic intermolecular interactions. Orientated smectic and nematic phases are characterized by wide-angle scattering arcs which result from the side-to-side packing of molecules. The anisotropy of these arcs is related to the extent of orientational ordering; indeed, the azimuthal angular dependence of the scattered intensity can be used to obtain an orientational order parameter [52]. However, this analysis does not provide information on the single molecule orientational distribution function (section C2.2.3.1). A powerful method to obtain this exploits the contrast variation possible in small-angle neutron scattering using deuterium labelling. A mixture of normal and deuterated mesogens produces purely single-molecule scattering at low angles, and this can be directly analysed to provide order parameters and to reconstruct the orientational distribution function [53, 54]. In fact, diffraction is capable of providing, in principle, the full distribution function, unlike spectroscopic methods [55]. Neutron scattering has also been used to probe molecular diffusive motions (rotational and translational), via incoherent quasi-elastic neutron scattering [54].

(D) SPECTROSCOPIC TECHNIQUES

Of spectroscopic techniques, nuclear magnetic resonance (NMR) has been most widely used to measure orientational ordering in liquid crystals [56, 57 and 58]. Most commonly, changes of line splittings in the spectra of deuterium-labelled molecules are used, specifically ^2H quadrupolar splittings or intermolecular dipole–dipole couplings between pairs of protons. If molecules are partially deuterated then information on the ordering of the labelled segments can be obtained. In addition, the dipolar spectra are easier to analyse than those of fully protonated molecules, when deuterium decoupling techniques are exploited. Further details are provided in [57]. Another method to obtain spectra that can easily be interpreted is to use rigid solutes dissolved in the liquid crystal phase [57]. If the structure of the solute molecules is not too complicated, the dipolar couplings can be analysed to provide orientational order parameters. Of course, the method only provides information on orientational ordering in liquid crystal–solute mixtures. However, since the form of the anisotropic interactions should be the same as in the pure liquid crystal phase, studies on solutes can provide indirect information on the ordering of the mesogens. The analysis of chemical shift anisotropies has recently been exploited to probe orientational ordering [56].

NMR is not the best method to identify thermotropic phases, because the spectrum is not directly related to the symmetry of the mesophase, and transitions between different smectic phases or between a smectic phase and the nematic phase do not usually lead to significant changes in the NMR spectrum [56]. However, the nematic–isotropic transition is usually obvious from the discontinuous decrease in orientational order. NMR can, however, be used to identify lyotropic liquid crystal phases, using ^2H NMR on solutions in D_2O . Cubic, hexagonal and lamellar phases can be distinguished due to different averages of the quadrupolar interaction which result from differences in the curvature and symmetry of the amphiphile–water interface [56, 57 and 58].

-15-

(E) DIFFERENTIAL SCANNING CALORIMETRY

This method is used to locate phase transitions via measurements of the endothermic enthalpy of phase transition. Details of the technique are provided elsewhere [25, 58]. Typically, the enthalpy change associated with transitions between liquid crystal phases or from a liquid crystal phase to the isotropic phase is much smaller than the melting enthalpy. Nevertheless, it is possible to locate such transitions with a commercial DSC, since typical enthalpies are $1\text{--}5\text{kJ mol}^{-1}$ [9]. These relatively small values indicate that transitions between liquid crystal phases and between these and the isotropic phase involve much more delicate structural changes than those that accompany the crystal–liquid crystal melting transition. Most liquid crystal phase transitions are first order (discontinuous in enthalpy), although some, such as the SmC to SmA transition can be second order (continuous). The latter can be difficult to locate, because the heat capacity is small and it is then necessary to turn to a higher-resolution technique such as adiabatic scanning calorimetry [59].

C2.2.3 THEORY

Thermotropic liquid crystal phases are formed by rodlike or disclike molecules. However, in the following we consider orientational ordering of rodlike molecules for definiteness, although the same parameters can be used for discotics. In a liquid crystal phase, the anisotropic molecules tend to point along the same direction. This is known as the director, which is a unit vector denoted \hat{n} .

C2.2.3.1 DEFINITION OF AN ORIENTATIONAL ORDER PARAMETER

Long-range orientational order of the constituent molecules is the defining characteristic of liquid crystals. It is therefore important to be able to quantify the degree of orientational order. To do this, an orientational order parameter is introduced, which describes the average orientation of the molecules. In general, the orientational distribution for a rigid molecule is a function of the three Euler angles $\Omega = (\alpha, \beta, \gamma)$ with respect to \hat{n} . However, for a uniaxial phase of cylindrically symmetric molecules, only the polar angle β is relevant. The orientational

distribution function then describes the probability for molecules to be oriented at an angle β with respect to the average, i.e. with respect to the director. It is usually denoted by $f(\beta)$ and in terms of the anisotropic potential of mean torque, $U(\beta)$, is defined as

$$f(\beta) = Z^{-1} \exp[-U(\beta)/kT] \quad (\text{C2.2.3})$$

where Z is the orientational partition function

$$Z = \int \exp[-U(\beta)/kT] d(\cos \beta). \quad (\text{C2.2.4})$$

Typical shapes of the orientation distribution function are shown in [figure C2.2.10](#). In a liquid crystal phase, the more highly oriented the phase, the more $f\beta$ tends to be sharply peaked near $\beta=0$. However, in the isotropic phase, a molecule has an equal probability of taking on any orientation and then $f\beta$ is constant.

An orientational order parameter can be defined in terms of an ensemble average of a suitable orthogonal polynomial. In liquid crystal phases with a mirror plane of symmetry normal to the director, orientational ordering is specified,

-16-

to lowest order, by the order parameter

$$\bar{P}_2 = \overline{\frac{3}{2} \cos^2 \beta - \frac{1}{2}}. \quad (\text{C2.2.5})$$

Here the bar indicates an average over the orientational distribution function. Here $P_2(\cos \beta) = (\frac{3}{2} \cos^2 \beta - \frac{1}{2})$ is the second rank Legendre polynomial. This average takes the value $\bar{P}_2 = 0$ for an isotropic phase. For a completely oriented phase $\bar{P}_2 = 1$. The order parameter is sometimes denoted by the symbol S [20]. The average in equation (C2.2.5) can be written explicitly in terms of the orientational distribution function:

$$\bar{P}_2 = \int P_2(\cos \beta) f(\beta) d(\cos \beta). \quad (\text{C2.2.6})$$

To completely specify the orientational ordering, the complete set of orientational order parameters, $\bar{P}_L, L = 0, 2, 4, \dots$, is required. Only the even rank order parameters are non-zero for phases with a symmetry plane perpendicular to the director (e.g. N and SmA phases).

Figure C2.2.10. Orientational distribution functions for (a) a highly oriented liquid crystal phase, (b) a less well

oriented liquid crystal phase and (c) an isotropic phase.

C2.2.3.2 THEORIES FOR ORIENTATIONAL ORDER

There are basically two types of theory for orientational ordering in liquid crystals. The first considers long-range attractive dispersion interactions. The Maier–Saupe theory for orientational ordering in nematic phases belongs to this category. The second type of theory assumes that orientational order results from short-range steric interactions. The first example of this type of theory was the Onsager model, in which the excluded volume for rodlike particles is calculated as a function of their volume fraction. At sufficiently large volume fractions, the theory is able to predict a nematic phase.

We consider first the Maier–Saupe theory and its variants. In its original formulation, this theory assumed that orientational order in nematic liquid crystals arises from long-range dispersion forces which are weakly anisotropic [60, 61 and 62]. However, it has been pointed out [63] that the form of the Maier–Saupe potential is equivalent to one in

-17-

which there are both long-range attractive and short-range attractive contributions to the intermolecular potential. The general form of this potential is

$$U(\cos \beta) = \bar{u}_2 \bar{P}_2 P_2(\cos \beta). \quad (\text{C2.2.7})$$

This can be inserted in equation (C2.2.3) to give the orientational distribution function, and thus into equation (C2.2.6) to determine the orientational order parameters. These are determined self-consistently by variation of the interaction ‘strength’ \bar{u}_2 in equation (c2.2.7). As pointed out by de Gennes and Prost [20] it is possible to obtain the Maier–Saupe potential from a simple variational, maximum entropy method based on the lowest-order anisotropic distribution function consistent with a nematic phase.

A generalization of the Maier–Saupe theory to account for terms higher than second rank in the potential was presented by Humphries *et al* [64]. The model has also been extended to account for the orientational ordering of non-cylindrically symmetric (biaxial) nematogens [65]. Exploiting the rotational isomeric state model [66] to generate conformers, a molecular field theory for the orientational order of flexible nematogens has been developed, where the orientational ordering of each segment of a molecule is described by a second-rank tensor [67, 68]. The ability of such models to describe the orientational order of nematogens containing terminal alkyl chains has been assessed by making comparisons with order parameters extracted from NMR experiments [69, 70]. An odd–even variation of segmental orientational order parameters with the number of carbon atoms in the chain is one of the observed features that these theories can reproduce. The nematic–isotropic phase transition temperature and entropy also show an odd–even variation [67, 69].

The Maier–Saupe theory was developed to account for ordering in the smectic A phase by McMillan [71]. He allowed for the coupling of orientational order to the translational order, by introducing a translational order parameter which depends on an ensemble average of the first harmonic of the density modulation normal to the layers as well as \bar{P}_2 . This model can account for both first- and second-order nematic–smectic A phase transitions, as observed experimentally.

Turning now to theories for the nematic phase based on short-range repulsive intermolecular interactions, we consider first the Onsager model [72]. This theory has been used to describe nematic ordering in solutions of rodlike macromolecules such as tobacco mosaic virus or poly(γ -benzyl-L-glutamate). Here, the orientational distribution is calculated from the volume excluded to one hard cylinder by another. The theory assumes that the rods cannot interpenetrate. Denoting the length of rods by L and the diameter by D , it is assumed that the volume fraction $\Phi = c \frac{1}{4} \pi L D^2$ (c =concentration) is much less than unity and that the rods are very long $L \gg D$. It is found that the nematic phase exists above a volume fraction $\Phi_c = 4.5D/L$ [20]. The Onsager theory predicts jumps in density and order parameter \bar{P} at the isotropic–nematic phase transition on cooling, that are much larger than those

observed for thermotropic liquid crystals [20]. It is an athermal model so that quantities like the transition density are independent of temperature. For these reasons, it has not proved very successful for thermotropic liquid crystals, for which the (thermal) Maier–Saupe theory and its extensions are more suitable.

It has not proved possible to develop general analytical hard-core models for liquid crystals, just as for normal liquids. Instead, computer simulations have played an important role in extending our understanding of the phase behaviour of hard particles. Frenkel and Mulder found that a system of hard ellipsoids can form a nematic phase for ratios $L/D > 2.5$ (rods) or $L/D < 0.4$ (discs) [73]; however, such a system cannot form a smectic phase, as can be shown by a scaling

-18-

argument within the statistical mechanical theory [74]. However, simulations show that a smectic phase can be formed by a system of hard spherocylinders [75, 76]. The critical volume fractions for stability of a smectic A phase depend on whether the model is that of parallel spherocylinders [75], or, more realistically, freely rotating spherocylinders [74].

C2.2.3.3 CONTINUUM THEORY FOR ELASTIC PROPERTIES

An aligned monodomain of a nematic liquid crystal is characterized by a single director $\hat{\mathbf{n}}$. However, in imperfectly aligned or unaligned samples the director varies through space. The appropriate tensor order parameter to describe the director field is then

$$Q_{\alpha\beta}(\mathbf{r}) = Q(T)[\hat{n}_\alpha(\mathbf{r})\hat{n}_\beta(\mathbf{r}) - \frac{1}{3}\delta_{\alpha\beta}] \quad (\text{C2.2.8})$$

where $\alpha, \beta = 1, 2, 3$ and $\delta_{\alpha\beta}$ is the Kronecker delta function. In the continuum theory, it is assumed that $\hat{\mathbf{n}}$ varies slowly and smoothly with spatial position \mathbf{r} , so that details on a molecular scale can be neglected. This model is an extension of the elastic theory for solid bodies and was first applied to liquid crystals by Oseen [77]. The modern version of the theory is due to Frank [39] and its relationship to hydrodynamic theory has been considered [78]. Details can be found elsewhere [20, 39 and 79]. The result is that the elastic energy per unit volume has the form

$$F_{el} = \frac{1}{2}K_1[\nabla \cdot \hat{\mathbf{n}}]^2 + \frac{1}{2}K_2[\hat{\mathbf{n}} \cdot (\nabla \times \hat{\mathbf{n}})]^2 + \frac{1}{2}K_3[\hat{\mathbf{n}} \times (\nabla \times \hat{\mathbf{n}})]^2. \quad (\text{C2.2.9})$$

Here K_1, K_2 and K_3 are elastic constants. The first, K_1 is associated with a splay deformation, K_2 is associated with a twist deformation and K_3 with bend (figure C2.2.11). These three elastic constants are termed the Frank elastic constants of a nematic phase. Since they control the variation of the director orientation, they influence the scattering of light by a nematic and so can be determined from light-scattering experiments. Other techniques exploit electric or magnetic field-induced transitions in well-defined geometries (Fréedericksz transitions, see section (C2.2.4.1) [20, 80].

Figure C2.2.11. (a) Splay, (b) twist and (c) bend deformations in a nematic liquid crystal. The director is indicated by a dot, when normal to the page. The corresponding Frank elastic constants are indicated (equation(C2.2.9)).

Continuum theory has also been applied to analyse the dynamics of flow of nematics [77, 80, 81 and 82]. The equations provide the time-dependent velocity, director and pressure fields. These can be determined from equations for the fluid acceleration (in terms of the total stress tensor split into reversible and viscous parts), the rate of change of director in terms of the velocity gradients and the molecular field and the incompressibility condition [20].

-19-

Further details can be found elsewhere [20, 78, 82 and 84]. An approach to the dynamics of nematics based on analysis of microscopic correlation functions has also been presented [85]. Various combinations of elements of the viscosity tensor of a nematic define the so-called Leslie coefficients [20, 84].

As for crystals, the elasticity of smectic and columnar phases is analysed in terms of displacements of the lattice with respect to the undistorted state, described by the field $\mathbf{u}(\mathbf{r})$. This represents the distortion of the layers in a smectic phase and, thus, $u(\mathbf{r})$ is a one-dimensional vector (conventionally defined along z), whereas the columnar phase is two dimensional, so that $\mathbf{u}(\mathbf{r})$ is also. The symmetry of a smectic A phase leads to an elastic free energy density of the form [86]

$$F = F_0 + \frac{B}{2} \left(\frac{\partial u}{\partial z} \right)^2 + \frac{K_1}{2} \left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} \right)^2. \quad (\text{C2.2.10})$$

Here F_0 is the free energy of the isotropic phase. As usual, the z direction is normal to the layers. Thus, two elastic constants, B (compression) and K_1 (splay), are necessary to describe the elasticity of a smectic phase [20, 79, 86]. A simple derivation of this equation based on the lowest-order derivative (curvature) of the layer displacement field $u(\mathbf{r})$ has been provided [87]. A similar expression can be obtained for a uniaxial columnar phase [20] (with the columns lying in the z direction):

$$F = F_0 + \frac{B}{2} \left(\frac{\partial u_x}{\partial x} + \frac{\partial u_y}{\partial y} \right)^2 + \frac{C}{2} \left[\left(\frac{\partial u_x}{\partial x} - \frac{\partial u_y}{\partial y} \right)^2 + \left(\frac{\partial u_x}{\partial y} + \frac{\partial u_y}{\partial x} \right)^2 \right] + \frac{K_3}{2} \left[\left(\frac{\partial^2 u_x}{\partial z^2} \right)^2 - \left(\frac{\partial^2 u_y}{\partial z^2} \right)^2 \right]. \quad (\text{C2.2.11})$$

Here B is again a compressional elastic constant, K_3 is a bend elastic constant and the elastic constant C results from an elliptical deformation of the rods (this term is absent if the column is liquid).

C2.2.3.4 THEORIES FOR PHASE TRANSITIONS

(A) NEMATIC–SMECTIC A TRANSITION

The nematic to smectic A phase transition has attracted a great deal of theoretical and experimental interest because it is the simplest example of a phase transition characterized by the development of translational order [88]. Experiments indicate that the transition can be first order or, more usually, continuous, depending on the range of stability of the nematic phase. In addition, the critical behaviour that results from a continuous transition is fascinating and allows a test of predictions of the renormalization group theory in an accessible experimental system. In fact, this transition is analogous to the transition from a normal conductor to a superconductor [89], but is more readily studied in the liquid crystal system.

When a nematic phase is cooled towards a smectic A phase, fluctuations of smectic order build up. These fluctuations were called ‘cybotactic clusters’ in the early literature. Regardless of the physical picture of such fluctuations,

it has been observed that the cluster size grows as the transition is approached [20, 90]. Furthermore, these clusters are anisotropic, being elongated along the director. They also grow faster along this direction as the transition is approached from above [20, 90].

Undoubtedly the most successful model of the nematic–smectic A phase transition is the Landau–de Gennes model [20]. It is applied in the case of a second-order phase transition by combining a Landau expansion for the free energy in terms of an order parameter for smectic layering with the elastic energy of the nematic phase [20]. It is first convenient to introduce an order parameter for the smectic structure, which allows both for the layer periodicity (at the first harmonic level, cf. equation (C2.2.1)) and the fluctuations of layer position $u\mathbf{r}$ [20]:

$$\psi(\mathbf{r}) = \rho_1(\mathbf{r}) e^{i\Phi(\mathbf{r})} \quad (\text{C2.2.12})$$

where $\Phi(\mathbf{r}) = -q_s u(\mathbf{r})$ is a phase factor.

Using this order parameter, the free energy in the nematic phase close to a transition to the smectic phase can be shown to be given by [20, 88, 89, 91]

$$F = F_0 + \frac{1}{2}A|\psi|^2 + \frac{1}{4}C|\psi|^4 + \frac{1}{6}E|\psi|^6 + C_{\parallel}|\nabla_{\parallel}|^2 + C_{\perp}|(\nabla_{\perp} - iq_s\delta\hat{\mathbf{n}})|^2 + F_N. \quad (\text{C2.2.13})$$

Here A , C and E are phenomenological coefficients in the Landau expansion in terms of the smectic ordering; C_{\parallel} and C_{\perp} account for gradients of the smectic order parameter; the fifth term also allows for director fluctuations, $\delta\hat{\mathbf{n}}$. The term F_N is the elastic free-energy density of the nematic phase, given by equation (C2.2.9). In the smectic A phase itself, the amplitude of the density modulation is constant and twist and splay distortions are forbidden, thus the expression for the free energy density simplifies to equation (C2.2.10).

High-resolution heat capacity measurements showed that the exponent for the temperature dependence of the heat capacity followed the predictions of the 3D XY model [92, 93] in systems where the nematic phase was large [94]. High-resolution x-ray scattering experiments in the nematic phase close to the continuous transition to a smectic A phase provided definitive evidence that the transition belongs to the 3D XY universality class [90]. The critical exponents obtained for the growth of correlation lengths were in excellent agreement with the renormalization group theory predictions, and provide strong support for the 3D XY model [92, 93].

(B) SMECTIC A–SMECTIC C TRANSITION

This transition is usually second order [18, 19 and 20]. The SmC phase differs from the SmA phase by a tilt of the director with respect to the layers. Thus, an appropriate order parameter contains the polar (θ) and azimuthal (ϕ) angles of the director:

$$\psi(\mathbf{r}) = \theta(\mathbf{r})e^{i\phi(\mathbf{r})}. \quad (\text{C2.2.14})$$

Obviously $\theta = 0$ corresponds to the SmA phase. This transition is analogous to the normal–superfluid transition in liquid helium and the critical behaviour is described by the XY model. Further details can be found elsewhere [18, 19 and 20].

(C) NAC POINT

A point at which nematic, SmA and SmC phases meet was demonstrated experimentally in the 1970s [95, 96]. The NAC point is an interesting example of a multicritical point because lines of continuous transition between N and

SmA phases, and SmA and SmC phases, meet the line of discontinuous transitions between the N and SmC phase. The latter transition is first order due to fluctuations of SmC order, which are continuously degenerate, being concentrated on two rings in reciprocal space rather than two points in the case of the N–SmA transition [18, 19 and 20]. Because the NAC point corresponds to the meeting of lines of continuous and discontinuous transitions it is an example of a Lifshitz point (a precise definition of this critical point is provided in [18, 19 and 20]). The NAC point and associated transitions between the three phases are described by the Chen–Lubensky model [97], which is able to account for the topology of the experimental phase diagram. In the vicinity of the NAC point, universal behaviour is predicted and observed experimentally [20].

(D) FRUSTRATED SMECTICS

Prost [21, 25, 98] showed that the properties and structure of frustrated smectic phases, as sketched in [figure C2.2.5](#) can be described by two order parameters. These are the mass density order parameter $\rho(\mathbf{r})$ ([equation \(C2.2.1\)](#)) and the polarization order parameter $P(\mathbf{r})$, which describes long-range correlations of dipoles. He then constructed a phenomenological Landau mean-field theory in which the free energy contains terms up to the quartic in these order parameters, their gradients and coupling terms. The number of terms in the free energy reflects the symmetry of the particular frustrated SmA and SmC phase under consideration. The theory has been comprehensively reviewed [18, 19, 20 and 21, 25].

(E) PHASE TRANSITIONS INVOLVING SMECTIC B PHASES

The transition from smectic A to smectic B phase is characterized by the development of a sixfold modulation of density within the smectic layers ('hexatic' ordering), which can be seen from x-ray diffraction experiments where a sixfold symmetry of diffuse scattering appears. This sixfold symmetry reflects the bond orientational order. An appropriate order parameter to describe the SmA–SmB phase transition is then [18, 19 and 20]

$$\psi_6 = \rho_6 e^{6i\phi} \quad (\text{C2.2.15})$$

where ϕ is the angle about the C_6 axis, and ρ_6 denotes a constant density. That such hexatic order could be created by dislocations was predicted by Halperin and Nelson and by Young [28, 99]. Again, high-resolution heat capacity measurements have also been useful in elucidating critical behaviour close to the transition in bulk samples [100, 101]. Calorimetry experiments on thin, freely suspended liquid crystal films have provided a great deal of information on the crossover between two- and three-dimensional behaviour at the SmA–HexB transition and they have confirmed that the transition is continuous [101, 102].

(F) PHASE TRANSITIONS IN DISCOTICS

McMillan's model [71] for transitions to and from the SmA phase ([section C2.2.3.2](#)) has been extended to columnar liquid crystal phases formed by discotic molecules [36, 103]. An order parameter that couples translational order to orientational order is again added into a modified Maier–Saupe theory, that provides the orientational order parameter. The coupling order parameter allows for the two-dimensional symmetry of the columnar phase. This theory is able to account for stable isotropic, discotic nematic and hexagonal columnar phases.

Monte Carlo computer simulations of spheres sectioned into a 'disc' [104, 105] show that steric interactions alone can produce a nematic phase of discotic molecules. Columnar phases are also observed [104, 105].

C2.2.4 APPLICATIONS OF LIQUID CRYSTALS

C2.2.4.1 NEMATIC LIQUID CRYSTAL DISPLAYS (LCDS)

The anisotropy of liquid crystal molecules leads to a susceptibility to electric and magnetic fields. Such fields can be used to change the average orientation of molecules and this is the basis for liquid crystal displays. In fact, the basic physics underlying nematic LCDs was worked out by Fréedericksz (a.k.a. Frederiks) in the 1930s [106]. It relies on the strong interactions of liquid crystal molecules with surfaces as well as their susceptibility to electromagnetic fields. Consider a nematic liquid crystal sandwiched in a thin film (about 10 μm thick) between two pieces of glass that have been treated to produce preferential orientation at the surface. In nematic liquid crystal displays, molecules are oriented parallel to the glass using a thin layer of rubbed polyimide polymer. Rubbing produces microscopic grooves in the polymer and, hence, alignment of the mesogens. To remain in an undeformed state, the bulk of the sample also adopts this orientation, which is termed homogeneous (figure C2.2.12) left). Now an electric or magnetic field is applied normal to the surface. In the bulk of the sample where the molecules are not pinned by the surface, the director tends to reorient in the direction of the field, as shown in figure C2.2.12 (right). If we compare with figure C2.2.11, we can see that this deformation involves bend and splay of the director field. This field-induced transition in director orientation is called a Fréedericksz transition [9, 106, 107]. We can also define Fréedericksz transitions when the director and field are both parallel to the surface, but mutually orthogonal or when the director is normal to the surface and the field is parallel to it. It turns out there is a threshold voltage for attaining orientation in the middle of the liquid crystal cell, i.e. a deviation of the angle of the director [9, 107]. For all three possible geometries, the threshold voltage takes the form [9, 107]

$$V_{th} = \pi \sqrt{\frac{K}{\epsilon_0 \Delta\epsilon}}. \quad (C2.2.16)$$

Here d is the thickness of the cell, K is either K_1 , K_2 or K_3 depending on the geometry (e.g. K_1 in the case of figure C2.2.12) and $\Delta\epsilon$ is the anisotropy in permittivity in the nematic liquid crystal. Note that in equation (C2.2.16) the threshold voltage, that is the relevant quantity for display operation, is independent of cell thickness.

-23-

Figure C2.2.12. A Fréedericksz transition involving splay and bend. This is sometimes called a splay deformation, but only becomes purely splay in the limit of infinitesimal displacements of the director from its initial position [106]. The other two Fréedericksz geometries (‘bend’ and ‘twist’) are described in the text.

This equation is derived by accounting for the energies of the electric field and of the distorted director fields. Further details are provided in [9] and [107]. It is also possible to obtain expressions for the switching time [107], using the appropriate expressions for the hydrodynamics of nematic liquid crystals in an external field [108, 109]. Clearly, both threshold voltage and switching times are critical factors in the application of Fréedericksz transitions in LCDs. Both can be tuned by varying the cell thickness and elastic constants. The latter can be varied by appropriate choice of molecule or, in commercial devices, mixtures of molecules. It should also be noted that equation (C2.2.16) provides a means of measuring the Frank elastic constant in each of the three Fréedericksz geometries.

C2.2.4.2 TWISTED NEMATIC (TN) AND SUPERTWISTED NEMATIC (STN) LCDS

The first stable commercial liquid crystal display (LCD) device was the twisted nematic (TN) [110], still widely

used in watches and calculators. A TN display is sketched in [figure C2.2.13](#) [9, 110, 111 and 112]. It relies on the Fréedericksz transition described in the preceding section. The cell consists of two glass plates coated with rubbed polyimide to induce orientation of the director parallel to the surface. In addition, there is a thin layer of the transparent conducting material, indium tin oxide. This is used to apply an electric field across the liquid crystal sandwich, which is about 10 μm thick (controlled by spacers). The display also needs polarizers on the top and bottom plates (actually these are the most expensive part of TN displays) with their polarization axes parallel to the rubbing direction. The bottom plate is twisted with respect to the top one, so that the surface-aligned director is rotated through 90° and the polarizers are crossed. This induces a twist to the nematic phase, hence the name for the device. In this state, as light passes through the cell, its polarization axis is guided through 90° so it is transmitted through the bottom plate. In a normal device, the light is then reflected from the back plate and passes through the device again. This produces a silver or grey state. However, when an electric field is applied across the cell, the director switches to orient parallel to the field in the middle of the cell. Then light passing through the cell does not have its polarization axis rotated and so cannot be transmitted through the bottom polarizer. The cell then looks dark in the ‘on’ state. This can be used to create dark characters against a light background, as in most LCDs.

The reverse contrast, i.e. bright characters on dark, can be achieved by orientating one polarizer parallel to the rubbing direction and the other one perpendicular to it, so that the device is dark in the ‘off’ state. Backlit versions of this device are used in car dashboard displays [111].

Figure C2.2.13. Principle of operation of a twisted nematic display. In the ‘off state’ the liquid crystal is in a homogeneous orientation throughout the cell. The director is oriented by rubbing the glass plates, which are placed such that the rubbing directions are parallel to the polarization direction in the adjacent polarizer. These polarizers are crossed. Light entering in the cell is rotated by the director and can pass through the cell. With a backlight or reflector, the cell appears ‘white’ (actually usually grey). However, upon application of an electric field via the indium tin oxide (ITO)-coated glass plates, the cell is switched ‘on’. The director undergoes a Fréedericksz transition to reorient parallel to the field and, thus, light entering the cell does not undergo rotation. With crossed polars the cell appears dark. This geometry describes displays with black pixels on a light background.

Important considerations for construction of a liquid crystal display include the following [111]:

- [1] *Operating conditions.* The nematic phase must be stable over the temperature range for which the device is to function, usually -20 to 80°C . At the same time, the mesogens must be rugged, i.e. chemically stable and capable of being switched many times. The development of LCDs in the 1970s was driven by the discovery of the alkylcyanobiphenyl ([figure C2.2.1](#)) class of mesogens that satisfy these requirements. No single compound, however, is able to provide the full desired operating temperature range, and in devices eutectic

mixtures are usually used.

- [2] *Threshold voltage.* Batteries can only supply low voltages, so for portable appliances the switching voltage or threshold voltage must be sufficiently small.
 - [3] *Current drawn.* LCDs usually draw small currents, which is one of their main advantages.
 - [4] *Sharpness.* This describes the steepness of the electro-optical switching as a function of voltage. This is defined in terms of the ratio of voltages required to achieve 90% compared to 10% transmission of light. This ratio should be as close to unity as possible.
-

-25-

- [5] *Contrast.* This can be quantified as the ratio of transmitted light intensity in the bright state compared to the dark state.
- [6] *Viewing angle.* The optical activity of the liquid crystal cell and polarizers depends strongly on viewing angle, leading to degradation in image quality if not viewed straight on (as confirmed by viewing a calculator display at different angles).
- [7] *Switching speed.* Typical switching times for TN devices are 20 to 50ms, which is quite slow and has limited their use in television displays.

Parameters (ii)–(vii) depend on the dielectric, mechanical and optical properties of the mesogens. To optimize a display, a compromise between different molecular characteristics is often required and mixtures of liquid crystals are usually used in commercial displays.

The desire to improve sharpness and viewing angle range led to the development of supertwisted nematic displays. As the name suggests, STN displays have higher twist angles than the TN display, typically 220–270°. They are widely used in laptop computers.

Often a seven-segment array is sufficient for TN devices where numbers are displayed [113]. The limited number of segments means that each can be addressed directly. However, dot matrix or VGA displays with large numbers of pixels are required to create alphabetical characters (not just in the Roman alphabet, but also more complex symbols such as those in C

C2.2.4.3 THIN-FILM TRANSISTOR (TFT) LCDS

Compared to STN displays, active matrix addressing in TFTs allows enhanced sharpness and greater multiplexing. In each liquid crystal pixel is addressed by a transistor, which thus primarily governs the response of the device. TFTs allow a greater number of pixels (higher resolution) and number of colour levels than STN devices. They are widely used in laptop computers, although they are more expensive than STN displays. Further details can be found elsewhere [115].

C2.2.4.4 FERROELECTRIC LCDS

Ferroelectric LCDs have potential as very fast displays and also do not require active matrix addressing technology. However, due to fabrication technology problems, they have yet to find extensive commercial application [112, 116, 117]. Thus, only the principles of operation is included here. The method relies on orientating the mesogens in a ferroelectric SmC* phase on the surfaces of the cell, but with no preferred in-plane orientation. This produces a so-called surface-stabilized ferroelectric liquid crystal (SSFLC) [112, 116, 117, 118, and 119] if the cell is sufficiently thin. In this so-called ‘bookshelf’ geometry the director vector lies perpendicular to the plane of the cell in either the ‘up’ or ‘down’ states and can be reoriented in response to an applied voltage. The reorientation of the polarization is coupled to molecular tilt and, hence, the optical axis, which can be used as an optical switch if the change in tilt angle is sufficient. Each of the two orientation states has the

same energy and so the device is bistable indefinitely. Further, bistable switching of spontaneous polarization occurs much faster than the polarization changes induced by reorientation of the director required in TN and STN display cells. However, there are a number of technical constraints that have to be overcome before SSFLC technology can be reliably used in displays: specifically, the cell has to be very thin (1 μm or less) and the director alignment and smectic layer orientation have to be controlled very carefully over large areas. Furthermore, the alignment in the optimal ‘bookshelf’ geometry can be destroyed by mechanical effects, e.g. simply by pressure of a finger, due to the high viscosity of the smectic phases, which are ‘soft solids’. In addition, there are problems with achieving a surface stabilized state, since other configurations are possible, particularly the so-called ‘chevron’ structure [120]. Further details are provided by Lagerwall [116]. Many of these problems can be solved and, indeed, prototype FLC displays have been demonstrated by several manufacturers [116].

C2.2.4.5 POLYMER DISPERSED LIQUID CRYSTAL (PDLC) DISPLAYS

A display which does not need polarizers can be made by dispersing a nematic liquid crystal in a polymer—a so-called polymer-dispersed liquid crystal (PDLC). The liquid crystals form microdroplets which scatter light in the ‘off’ state, but allow it to pass in the ‘on’ state, switched by an electric field. An example of the application of PDLCs is thus as switchable windows for privacy since the display can be switched between opaque and transparent states. For the device to function in this way, it is necessary for the director in the liquid crystal droplet to be oriented in a tangential orientation, which leads to two poles (bipolar droplet [121]). In addition, the refractive index of the polymer must be equal to the index of refraction for light polarized perpendicular to the director. In the off state, the two poles are oriented at random, but in an electric field they orient along the direction of the field (figure C2.2.14). In the off state, there is on average a difference in the refractive index of the liquid crystal droplets compared to the polymer, which leads to light scattering, whereas in the on state, the refractive indices are matched for light incident along the field direction and the display appears clear [9, 114, 121]. Thus, PDLCs are useful as switchable windows, e.g. for privacy or sunlight shading.

There are two basic methods of preparing PDLCs [121]. In the first, the liquid crystal is dispersed as an emulsion in an aqueous solution of a film-forming polymer (often polyvinyl alcohol) [121]. This emulsion is then coated onto a conductive substrate and the emulsion is dried to form the dispersed liquid crystal-in-polymer film. In the second method, the phase separation of a polymer is exploited to disperse the liquid crystal [123]. In the method of polymerization-induced phase separation [121], polymerization is induced through the application of heat, light or radiation e.g. through cross-linking of a network. A commonly used example exploits the cross-linking of epoxy adhesives to form a solid structure containing phase-separated liquid crystal droplets. In thermally induced phase separation, the liquid crystal is mixed with a thermoplastic polymer at high temperatures. When the system is cooled, the liquid crystal phase separates from the solidifying polymer. In solvent-induced phase separation, a polymer and a liquid crystal are mixed to form a single-phase mixture in an organic solvent. Evaporation of the solvent then drives the phase separation of polymer and liquid crystal [121].

Figure C2.2.14. Principle of operation of a polymer-dispersed liquid crystal display. The contours of the liquid

crystal droplets in the polymer matrix correspond to the director orientation, which here is dipolar. In the off state, the cell scatters light and appears opaque, due to refractive index variations between the liquid crystal and the polymer. However, when an electric field is applied and the liquid crystal directors reorient, the refractive index along the field is matched to that of the matrix, and the cell becomes clear.

Further details of PDLCs can be found in the excellent monograph by Drzaic [121]. A review of the non-linear optical properties of PDLCs has also been presented [124].

C2.2.4.6 OTHER APPLICATIONS

The main non-display applications of liquid crystals can be subdivided into two classes. The first exploits their anisotropic optical properties in spatial light modulators [125] or their non-linear optical properties (optical wave mixing etc) [48, 124, 125]. Spatial light modulators are usually based on the ferroelectric SmC* phase aligned in a thin film. Liquid crystal spatial light modulators find advanced applications such as the storage of computer-generated holograms [125]. The second class of non-display applications exploits temperature-dependent colour (thermochromic) changes in the chiral nematic phase [9, 126]. Chiral nematic phases can appear coloured due to scattering of light by the helical structure, which can have a pitch as small as 100 nm. The pitch 'unwinds' as temperature is decreased, usually as a smectic A phase is approached, leading to observable colour changes. These have been exploited in medical thermography, where heat variations across the body surface are mapped [126, 127]. This is especially important in oncology. The technique has also found applications in engineering and aerodynamic research. Models of aircraft, for example, in wind tunnels can be coated with a chiral nematic liquid crystal. The flow of air over the model leads to heat variations (turbulent flow leading to 'cold spots') which can be visualized directly [126]. Gimmick applications of thermochromic liquid crystals include colour-changing clothes or beer mats.

ACKNOWLEDGMENTS

This review is dedicated to Professor G R Luckhurst (University of Southampton) on the occasion of his 60th birthday. He is also thanked for comments on a draft version of this chapter.

C2.3 Micelles

John Texter

C2.3.1 INTRODUCTION

Surfactants are the primary molecular constituents of micelles. They are also called *amphiphiles*, and certain classes of surfactants are detergents. Surfactants are amphiphilic molecules having separate lyophilic or solvophilic (solvent-loving) groups and lyophobic or solvophobic (solvent-hating) groups (see [section C2.3.3](#)). Having both types of group makes a molecule *amphiphilic* and *amphipathic*. Micelles are the most prevalent aggregate structure in surfactant solutions and form over a narrow range in surfactant concentration centred around the critical micelle concentration, *cmc* (see [section C2.3.4](#)). This process of micellization is taken, in the so-called pseudophase approximation, as the formation of a two-phase system comprising the continuous solvent phase and a pseudophase consisting of the oily micellar cores. This approximation is convenient for many purposes, but it must not be taken literally, as micellar solutions are generally single-phase isotropic solutions and micelles are thermodynamically reversible aggregates, in dynamic equilibrium with surfactant ‘monomers’ in solution.

Idealized structures of some normal and reverse (inverse) micelles are illustrated in figure C2.3.1. Suctants self-assemble (aggregate) in order to lower the solution free energy. This process involves the creation of an interface separating the solvent (aqueous) phase from the solvophobic (hydrophobic) portions of the surfactant. When a solvophilic headgroup interacts attractively with a solvent, the solvophobic portions aggregate to form an oily nanodroplet of interpenetrating tail portions that is separated from the solvent by the headgroups. The headgroups serve to define a boundary between the solvent and solvophobic portion. Whether headgroups are charged or not,

their packing is influenced by repulsion forces between headgroups and solvation interactions with the solvent. Such aggregates define 'normal' micelles. When the surfactant headgroup is not solvated by the solvent, the headgroups tend to aggregate together, forming an internal structure separated from the solvent by an interface defined by the tailgroups. Such micelles are called inverse micelles or reverse micelles.

Figure C2.3.1. Idealized cross-sections of normal spherical micelles (left) and of reverse micelles (right).

-2-

C2.3.2 HISTORICAL OVERVIEW

Aqueous surfactant aggregation to form micelles appears to have first been suggested by McBain in 1913 [1]. A spherical model for micelle structure was put forward by Hartley [2, 3] where the hydrophilic headgroups were pictured to lie upon a roughly spherical surface, the internal volume was filled with the tailgroups and an electrical double layer developed radially out from the headgroups. The tailgroups form an oily nanodroplet that is covered with a polar shell. This early, and admittedly, idealized model was criticized on various grounds [4], although Hartley pointedly noted that the assumption of perfectly spherical symmetry was done for 'mathematical simplicity'. Menger proposed [4] taking more detailed account of the filling of the internal volume by the tailgroups and he explicitly introduced the use of *gauche* kinks in the hydrocarbon chains to help fill the requisite space.

This more careful attention to space filling was also addressed by Fromherz [5] and by Dill and Flory [6]. Fromherz showed that it was possible to produce space filling and nominally spherical micellar structures, with rough headgroup regions, while still allowing straight chain surfactants to aggregate with extended tailgroups, but allowing *gauche* defects to modify the orientation of headgroups. This model, along with that of Menger and with that of Dill and Flory, resulted in rough headgroup regions and significant contacts between the solvent and regions of the tailgroups. These approaches were put on a statistical dynamical basis by Dill and Flory using a lattice model illustrated in figure C2.3.2. In this lattice model the surfactant is imagined to be composed of a headgroup and tailgroup chain segments. Each of the headgroup and segments occupies a single lattice site, as illustrated in figure C2.3.2. The lattice comprises constant radial interlayer spacing and sites of equal volume. This approach set the stage for advances in structural modelling using the modern computational tools of statistical mechanics (see [section C2.3.7](#)).

Figure C2.3.2. Two-dimensional radial lattice representation of micelle structure using the approach of Dill and Flory [6]. Each lattice site is considered to be equal in volume to the others. Reproduced by permission from [6].

C2.3.3 SURFACTANTS

Surfactants are generally pictured as having a lyophilic (hydrophilic) headgroup of some type and a hydrocarbon tailgroup. The word surfactant derives as a contraction of the phrase *surface active agent*. They can also be exemplified by simple species such as short chain alcohols and amides that are usually surface active, but do not necessarily lower interfacial tensions significantly. It is difficult to draw clear boundaries with respect to molecular structure for defining what constitutes a surfactant, so we adopt an operational definition. A surfactant is a surface active amphiphile that aggregates in water or other solvent to form microstructures such as micelles and bilayers or segregates at interfaces to form monolayer assemblies. This definition is inclusive of many important polymeric dispersants, such as moderate molecular weight block copolymeric surfactants.

C2.3.3.1 CLASSIFICATION OF SURFACTANTS

Schemes for classifying surfactants are based upon physical properties or upon functionality. Charge is the most prevalent physical property used in classifying surfactants. Surfactants are charged or uncharged, ionic or nonionic. Charged surfactants are further classified as to whether the amphipathic portion is anionic, cationic or zwitterionic. Another physical classification scheme is based upon overall size and molecular weight. Copolymeric nonionic surfactants may reach sizes corresponding to 10 000–20 000 Daltons. Physical state is another important physical property, as surfactants may be obtained as crystalline solids, amorphous pastes or liquids under standard conditions. The number of tailgroups in a surfactant has recently become an important parameter. Many surfactants have either one or two hydrocarbon tailgroups, and recent advances in surfactant science include even more complex assemblies [7, 8 and 9].

Surfactants derive their general classification from their surface activity and tendency to preferentially segregate at liquid–gas, liquid–liquid and liquid–solid interfaces. They always contain at least two functional parts, a lyophilic or solvophilic part that preferentially solvates in the solvent and a lyophobic or solvophobic part that is poorly solvated in the same solvent. Solvophilicity (hydrophilicity in the case of water) is imparted by functional groups that have high solvent affinity. Carboxylates, sulphates and sulphonates are examples of charged functional groups that have relatively high affinity for water as a solvent. Uncharged hydrophilic groups may include almost any uncharged polar group. Hydroxyl and ethylene oxide groups are the most prevalent.

Solvophobicity (hydrophobicity with respect to water) is most often exemplified as a linear or branched hydrocarbon chain. Fluorocarbon chains and siloxane chains are also hydrophobic. Many commercially important

surfactants have more complex solvophobic groups such as substituted phenyl and naphthyl ring systems. The number of solvophobic tailgroups (single tail, double tail) in a surfactant is an important parameter because it dramatically affects solubility and surfactant packing in micellar aggregates (see [section C2.3.6](#)).

The majority of practical micellar systems of 'normal' micelles use water as the main solvent. Reverse micelles use water immiscible organic solvents, although the cores of reverse micelles are usually hydrated and may contain considerable quantities of water. Polar solvents such as glycerol, ethylene glycol, formamide and hydrazine are now being used instead of water to support 'regular' micelles [10]. Critical fluids such as critical carbon dioxide are

-4-

also being exploited for various micellar applications. Copolymeric surfactants of polystyrene and poly(1,1-dihydroperfluorooctyl acrylate) have been developed [11] to form polydisperse micelles in critical carbon dioxide and to solubilize polystyrene oligomers in such micellar solutions.

Charged surfactants impart electrostatic forces and ion-pairing interactions when they are aggregated as micelles. Charged surfactant solubility is greatly affected by counter-ions and the binding affinity of counter-ions. For example, lithium surfactant salts are much more hygroscopic than sodium salts and tend to have greater aqueous solubility. In such cases counter-ion *charge density* has a dramatic effect on binding affinity and, hence, on solubility. This ion-ion association also affects the formation and structure of micelles, since headgroup repulsion interactions are dramatically affected by counter-ion binding and the screening of repulsive electrostatic forces by counter-ions. An extensive practical listing of surfactants, as well as a key to their synthesis, may be found in an exhaustive review [12].

(A) ANIONIC

A selection of important anionic surfactants is displayed in [table C2.3.1](#). Carboxylic acid salts or the soaps are the best known anionic surfactants. These materials were originally derived from animal fats by saponification. The ionized carboxyl group provides the anionic charge. Examples with hydrocarbon chains of fewer than ten carbon atoms are too soluble and those with chains longer than 20 carbon atoms are too insoluble to be useful in aqueous applications. They may be prepared with cations other than sodium.

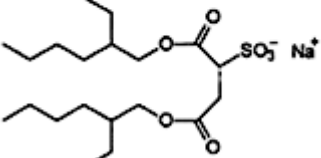

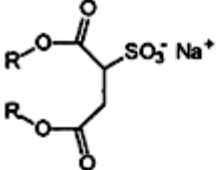

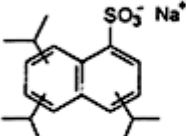

The blocking and elimination of the carboxyl group and replacement of anionic charge by sulphate and sulphonate substitution provided a revolution in detergency. Detergents such as sodium dodecylbenzene sulphonate (SDBS) have replaced soaps as laundry cleansing agents because of their efficacy and low cost. Such sulpho compounds may be readily derived from many natural products and synthetic precursors. Alkyl sulphates, such as sodium dodecylsulphate (SDS), alkyl ether sulphates, alkyl sulphonates, secondary alkyl sulphonates, aryl sulphonates such as alkylbenzene sulphonates, methylester sulphonates, α -olefinsulphonates and sulphonates of alkylsuccinates are important classes of anionic surfactants. Fatty acids and sulpho compounds illustrate three important anionic groups, carboxylate ($-\text{CO}_2^-$), sulphate ($-\text{OSO}_3^-$) and sulfonate ($-\text{SO}_3^-$). Phosphates such as mono- ($-\text{P}(\text{OH})\text{O}_2^-$) and dianions ($-\text{PO}_3^{2-}$) are also important. These dianions are basic and initially protonate in the neutral to slightly alkaline range, but they remain negatively charged to relatively low pH. Various data [13] have led to the following rank ordering of these groups with respect to their relative hydrophilicity:

The negative charge density is greatly affected by the group size. The carboxylate group is the smallest, attains the highest charge density and is the most hydrophilic in this series. However, it generally protonates in the pH 4–5 range, so its range of usefulness is very sensitive to pH. This follows also for the phosphates, but the sulphates and sulphonates generally remain charged, even to pH as low as 1.

Table C2.3.1 Structures of key anionic surfactants.

$\text{CH}_3(\text{CH}_2)_{10}\text{CH}_2\text{OSO}_3^- \text{Na}^+$	Sodium dodecylsulphate, SDS
$\text{R}-\text{CH}_2\text{OSO}_3^- \text{Na}^+$	Sodium alkylsulphates
$\text{CH}_3(\text{CH}_2)_{10}\text{CH}_2-\text{C}_6\text{H}_4-\text{SO}_3^- \text{Na}^+$	Sodium dodecylbenzene sulphonate, SDBS
$\text{R}-\text{C}_6\text{H}_4-\text{SO}_3^- \text{Na}^+$	Sodium alkylbenzenesulphonates
	Sodium bis(2-ethylhexyl) sulphosuccinate, AOT
	Sodium succinate esters
	Sodium di-, tri-isopropyl-naphthalene sulphonate, DTINS
$\text{R}-\text{CH}(\text{SO}_3^- \text{Na}^+)-\text{C}(=\text{O})-\text{OCH}_3$	α -sulpho fatty acid methyl esters
$\text{R}-\text{O}-\text{P}(=\text{O})(\text{O}^- \text{Na}^+)-\text{O}-\text{R}$	Dialkylphosphates

(B) CATIONIC

Most cationic surfactants derive from the quaternarization of nitrogen and most of the key cationic surfactant classes are illustrated in [table C2.3.2](#). Alkylammonium halides such as dodecylammonium bromide, for example, are good hydrogen bond donors and interact strongly with water. They also often can give up a proton and are then transformed into a nonionic surfactant. Chemical blocking of this hydrogen bond donating capability by full alkylation to yield the tetra-alkylammonium group results in cations that interact relatively weakly with halide counterions but strongly with organic anions.

Table C2.3.2 Structures of key anionic surfactants.

Alkylammonium halides
Hexadecyltrimethylammonium bromide, CTAB

A wide class of aryl-based quaternary surfactants derives from heterocycles such as pyridine and quinoline. The *N*-alkyl pyridinium halides are easily synthesized from alkyl halides, and the paraquat family, based upon the 4, 4'-bipyridine species, provides many interesting surface active species widely studied in electron donor-acceptor processes. Cationic surfactants are not particularly useful as cleansing agents, but they play a widespread role as charge control (antistatic) agents in detergency and in many coating and thin film related products.

(C) ZWITTERIONIC AND AMPHOTERIC

α -amino acids in the isoelectric pH range are true zwitterions and result from apparent intramolecular proton transfer. This class and other related surfactants are depicted in [table C2.3.3](#). The term zwitterionic surfactant is now taken to mean just about any combination of an anionic and a cationic group in a single amphiphilic molecule, whether or not either or both of these groups may be neutralized at some pH. In this sense zwitterionic is taken as synonymous with amphoteric. Often such species contain only one readily ionizable (or neutralizable) group. When such a group is the carboxyl group, the expected changes in charge and physical properties with pH must be borne in mind. Examples include tri-alkylammonioalkanoates, where the quaternary nitrogen and carboxylate are separated by the alkanolate carbon chain and wherein the nitrogen quaternerizes with the ω -carbon of the alkanolate. The relative hydrophilicities of carboxy, sulphonate and sulphate ammonio zwitterionics decrease in the following order:

This ordering is the same as discussed above for anionic surfactants and follows from the charge density of the particular acid group.

Table C2.3.3 Structures of key zwitterionic and amphipathic surfactants.

	Alkylamino acids
	Alkylbetaines
	Amidoalkylbetaines
	Alkylsulphobetaines
	Imidazolium betaines
	2,3-dimethyl-3-dodecyl-1,2,4-triazolium-5-thiolate
	Dialkanoyl lecithins

The various forms of betaines are very important for their charge control functions in diverse applications and include alkylbetaines, amidoalkylbetaines and heterocyclic betaines such as imidazolium betaines. Some surfactants can only be represented as resonance forms having formal charge separation, although the actual atoms bearing the formal charge are not functionally ionizable. Such species are *mesoionic* and an example of a triazolium thiolate is illustrated in table C2.3.3.

-8-

(D) NONIONIC

A selection of nonionic surfactant structures is listed in table C2.3.4. Many of these are analogous to some of the anionic and cationic surfactants, with the exception that the headgroup is uncharged. Steric and osmotic forces rather than electrostatic forces control interactions between nonionic surfactant headgroups. Oligomers of ethylene oxide have become the most important class of headgroup in nonionic surfactants and the alkanol polyethyleneglycol ethers, C_mE_n , have become the mostly widely studied class of nonionics. The ethylene oxide groups are generally believed to hydrate with about three water molecules. A related class is that of the alkylphenol ethoxylates. Triton X-100 (TX100) is the best known member of this class.

Table C2.3.4 Structures of key nonionic surfactants.

Alkanol polyethyleneglycol ethers,
 C_mE_n

-9-

The fastest growing class of block copolymeric nonionic surfactants derive from oligomeric ethyleneoxide (EO) and from oligomeric propyleneoxide (PO). They are obtained as diblocks, AB, as triblocks, ABA and as triblocks, BAB, where A denotes a hydrophilic block (such as EO) and B denotes a hydrophobic block (such as PO). Poly (butylene oxide) and polystyrene oligomers are also available for the more hydrophobic B blocks. These surfactants are now widely available commercially. An excellent review of their properties in aqueous solution is given by Alexandridis and Hatton [14]. Other nonionics include alkanol amides such as ethanolamides and diethanolamides, alkylamides and amine ethoxylates. Lecithin and other glycerol-based nonionics are physiologically important and are finding widespread pharmaceutical applications.

C2.3.3.2 PHYSICAL STATE OF SURFACTANTS

The physical state of surfactants affects how easily micellar solutions may be prepared. At room temperature surfactants are usually obtained as amorphous or crystalline solids, but increasing numbers of liquid surfactants are being derived, particularly as nonionics. The amorphous solid physical state is often obtained as a waxy paste. The surfactants in such pastes are usually in a liquid crystalline packing mode. Pure ionic surfactants of moderate formula weight (<500) are often obtained as crystalline powders. Published crystal structures suggest factors important to understanding how surfactants pack in micelles and in planar assemblies such as monolayers and bilayers. These factors include chain tilting and layering.

Molecular packing of surfactants in crystals has been reviewed at some length [15]. An almost universal factor

observed, at least for surfactants having long alkyl tailgroups, is that surfactants intrinsically pack in tail-to-tail or head-to-head bilayers in the absence of excess solvent. This factor makes it easy to understand the genesis of bilayer structures encountered in various surfactant mesophases, such as lamellar mesophases. Such bilayer packing typically allows for the compartmentalized separation of hydrophobic and hydrophilic domains in the crystal, wherein the hydrophobic tailgroups pack among themselves and the headgroups, often with solvent or water of crystallization, define a distinct hydrophilic or polar region. The tailgroups may pack end to end, as observed in a monohydrate of SDS [16], or they may pack in an interdigitated array such as in dodecylammonium bromide [17].

The extent of headgroup hydration provides relative control of the effective headgroup size and the tilt angles of hydrocarbon chains, relative to the normal, defined by the plane of the headgroups. As the effective headgroup size increases with increasing hydration this size must be accommodated by a concomitant amount of chain tilting. If the headgroup is small, little chain tilting is required in order to accommodate close packing of all of the molecules. As the headgroup size increases, the chains tilt to more densely fill space.

This headgroup size--chain tilting phenomenon can be illustrated for the case of SDS. The crystal structure of SDS monohydrate is illustrated in [figure C2.3.3](#) [18]. The packing is of a bilayer type and there is distinct chain tilting of about 40° relative to the ab plane of the headgroups. This tilting results in a bilayer thickness of about 28.9 \AA and a headgroup (projected) area of 29.5 \AA^2 . In a more anhydrous SDS polymorph [16] containing only four water molecules per 32 SDS, distinctly less tilting appears. A tilt angle of about 21° relative to the plane of the headgroups results from the much lower solvation, smaller headgroup projected area, 20.9 \AA^2 , and a much increased bilayer thickness, 38.9 \AA . Such dramatic variations in molecular packing with changing headgroup hydration and effective headgroup size underscores the importance of factors that control headgroup repulsion, such as counterion binding affinity and solvation, on packing in micelles.

-10-

Figure C2.3.3. Molecular packing of SDS monohydrate viewed as projected on the ac plane. This polymorph crystallizes in a triclinic cell with unit cell constants a , b and c of 10.423 \AA , 5.662 \AA and 28.913 \AA , respectively, and with $\alpha = 86.70^\circ$, $\beta = 93.44^\circ$, $\gamma = 89.55^\circ$. There are four molecules per unit cell. Adapted from figure 2 of [18].

C2.3.4 EXPERIMENTAL METHODS FOR EXAMINING MICELLES AND MICELLIZATION

The concentration at which micellization commences is called the critical micelle concentration, cmc. Any experimental technique sensitive to a solution property modified by micellization or sensitive to some probe (molecule or ion) property modified by micellization is generally adequate to quantitatively estimate the onset of micellization. The determination of cmc is usually done by plotting the experimentally measured property or response as a function of the logarithm of the surfactant concentration. The intersection of asymptotes fitted to the experimental data or as a breakpoint in the experimental data denotes the cmc. A partial listing of experimental

techniques used to determine cmc is given in [table C2.3.5](#). Foremost among these methods is surface tension measurement, typically at the air–water interface. An example of such a measurement is illustrated in [figure C2.3.4](#) for the case of an equal weight mixture of sodium diisopropyl naphthalene sulphonate and sodium triisopropyl naphthalene sulphonate. The measurements illustrated were obtained [[19](#)] by the Wilhelmy plate technique. There are numerous other methods for measuring surface tensions, such as capillary rise, maximum bubble pressure, drop weight and pendant drop techniques [[20](#)]. Mention should be made of the largest compendium of cmc data, assembled by Mukerjee and Mysels [[21](#)], and of an excellent updating compendium of van Os *et al* [[22](#)].

-11-

Table C2.3.5 Survey of techniques and observables for determining cmc.

Density	Refractive index
Diffusion coefficient	Solubilization
Dye decomposition kinetics	Solubilization rate
Electromotive force	Specific heat
Conductance	Streaming current
ESR probe	Surface tensions
Flocculation rate	Taylor diffusion
Foaming power	Turbidometry
Freezing point	Turbidometric solubilization
Heat of dilution	Ultracentrifugation
Light scattering	Ultrafiltration
NMR	Vapour pressure lowering
Neutron scattering	Velocity of sound
Optical probe	Viscosity
Partial volume	Voltammetry of electroactive probe
Polarographic maximum	Wein effect
Potentiometry	X-ray scattering

Micellization is a second-order or continuous type phase transition. Therefore, one observes continuous changes over the course of micelle formation. Many experimental techniques are particularly well suited for examining properties of micelles and micellar solutions. Important micellar properties include micelle size and aggregation number, self-diffusion coefficient, molecular packing of surfactant in the micelle, extent of surfactant ionization and counterion binding affinity, micelle collision rates, and many others.

-12-

Figure C2.3.4. Relative surface tension of DTINS at 25 °C. The intersection of the dotted lines indicates a cmc of 3.0 mM. Reproduced by permission from figure 1 of [20].

C2.3.4.1 CRITICAL MICELLE CONCENTRATION

Measured cmcs range from large concentrations, such as approximately 0.6 M for sodium octanoate, to concentrations lower than 10^{-6} M for amphiphiles of very low solubility. The cmcs are significantly affected by a variety of physical properties associated with the hydrophilic headgroup, the hydrophobic portion (tailgroup) and the means by which these two groups are connected. Various aspects have already been discussed as affecting surfactant classification. The number of headgroups, the number of tailgroups and the connectivity of these groups can vary widely. Several linear free energy relationships between cmc and these molecular properties are discussed below and more rigorous thermodynamic modelling of micellization is presented in [section C2.3.5](#). These linear free energy relationships are based upon the thermodynamics of hydrophobic chain transfer from oil to water, solvent–hydrocarbon chain contacts, hydrocarbon chain packing and interactions between headgroups.

(A) CMC OF HOMOLOGOUS SERIES

Such linear free energy relationships are available for alkyl sulphates and for the C4 to C9 homologues of the dialkanoyl lecithins (see [table C2.3.3](#) for structure). Most of the naturally occurring phospholipids are too insoluble to form micelles, but the lower alkanoyl lecithins, also known as phosphatidylcholines, do form micelles. The cmcs for these homologues are listed in [table C2.3.6](#). The approximately linear free energy relationship between the alkyl chain length and log cmc is given by:

-13-

$$\log \text{ cmc} = a - bn. \quad (\text{C2.3.3})$$

The alkyl chain length is n , and a and b are fitting constants. The constant a usually varies with headgroup type and typically is 3.5 to 10. The b parameter is usually fairly uniform among different homologous alkyl chain surfactants. Values for b of about 0.5 are often obtained for single-chain nonionic surfactants and values of about 0.3 are obtained for single-chain ionic surfactants. For this series of alkyl sulphates, parameters $a = 4.39$ and $b = 0.29$ were obtained, and for this lecithin series, $a = 5.77$ and $b = 0.85$. Studies suggest that this b parameter is

proportional to the hydrophobic interaction energy of micelle formation.

Table C2.3.6 Cmc of homologous alkyl sulphates and dialkanoyl lecithins.

Homologue	cmc (mM)
Sodium hexylsulphate	420
Sodium heptylsulphate	220
Sodium octylsulphate	130
Sodium nonylsulphate	60
Sodium undecylsulphate	16
Sodium dodecylsulphate	8.2
Sodium tetradecylsulphate	2.05
Dibutanoyl lecithin	80
Dihexanoyl lecithin	14.6
Diheptanoyl lecithin	1.42
Diocetanoyl lecithin	0.265
Dinonanoyl lecithin	0.002 87

-14-

(B) SALT EFFECTS

The cmcs of ionic surfactants are usually depressed by the addition of inert salts. Electrostatic repulsion between headgroups is screened by the added electrolyte. This screening effectively makes the surfactants more hydrophobic and this increased hydrophobicity induces micellization at lower concentrations. A linear free energy relationship expressing such a salt effect is given by:

$$\log \text{cmc} = (\log \text{cmc})_0 - k_c c_i. \quad (\text{C2.3.4})$$

Here $(\log \text{cmc})_0$ is the log cmc in the absence of added electrolyte, k_c is related to the degree of counterion binding and electrostatic screening and c_i is the ionic strength (concentration) of inert electrolyte. Effects of added salt on cmc are illustrated in table C2.3.7.

Table C2.3.7 Salt effects on cmc.

Surfactant/salt	[salt] (M)	cmc (mM)
Sodium dodecylsulphate/NaCl	0	8.2
	0.1	1.4

	0.2	0.83
	0.4	0.52
Dodecylpyridinium bromide/KBr	0	12
	0.02	7.25
	0.05	4.70
	0.1	2.74
Dodecyltrimethylammonium bromide/NaBr	0	14.8
	0.0175	10.4
	0.05	7.0
	0.1	4.65

-15-

(C) SOLUBILITY

Headgroups and tailgroups have a big effect on solubility. Important surfactants, such as the phospholipids that make up significant fractions of cellular membranes, are nearly insoluble in water. Such insoluble and double-tail surfactants typically do not form micelles and generally prefer to pack as bilayers. A very important double-tail surfactant, AOT (see [table C2.3.1](#) for structure), is soluble in water, but is much more soluble in very many organic solvents. Such surfactants having high solubility in oils form the basis of reverse micellar (see [section C2.3.8](#)) and reverse microemulsion (see [section C2.3.11](#)) technology.

A quantitative treatment of surfactant solubility has been successfully made empirically using linear free energy relationships. An important relation is that for the linear free energy of transfer of alkanes to water [[23](#)]:

$$RT \ln S = aA. \quad (\text{C2.3.5})$$

In this relationship S is alkane solubility, A is the cavity surface area and a is the hydrophobic free energy per unit area. Extensive fitting of this equation [[24](#)] yields a value of $88 \text{ kJ mol}^{-1} \text{ \AA}^{-2}$ for the proportionality constant a . This value corresponds to an unfavourable free energy of about 3.6 kJ mol^{-1} for the transfer of a CH_2 group to aqueous solution.

(D) KRAFT POINT

The Kraft point (T_K) is the temperature at which the cmc of a surfactant equals the solubility. This is an important point in a temperature–solubility phase diagram. Below T_K the surfactant cannot form micelles. Above T_K the solubility increases with increasing temperature due to micelle formation. T_K has been shown to follow linear empirical relationships for ionic and nonionic surfactants. One found [[25](#)] to apply for various ionic surfactants is:

$$T_K = an + b \quad (\text{C2.3.6})$$

where n is hydrocarbon chain length and a and b are fitting parameters. The parameter b typically varies for

different types of headgroup. Various values (a , b) have been obtained such as (5.5, 11) for sodium alkylsulphates, (5.5, 29) for sodium alkylsulphonates (odd number of carbons), (5.5, 34) for sodium alkylsulphonates with an even number of carbon, and (5.5, 44) for sodium alkyloxyethylenesulphates.

(E) CLOUD POINT

The temperature at which a clear solution of surfactant just becomes turbid with heating is called the cloud point. This turbidity comes from light scattering by assemblies of micelles. These assemblies arise as a result of attractive interactions between micelles and may be thought of as clusters of micelles that in some cases become ordered mesophases of micelles. Such a phenomenon has been identified as a thermodynamic critical point and is most often exhibited by nonionic surfactants. As a practical matter it is known that cloud points can be raised by adding ionic groups to a surfactant (such as by adding a sulphate group to an oligomeric poly(propylene oxide)–poly(ethylene oxide) surfactant. At higher temperatures a phase separation into a water-rich phase and a surfactant-rich phase is generally obtained.

C2.3.5 THERMODYNAMICS OF MICELLIZATION

The free energy driving micellar aggregation primarily derives from intermolecular attractive and repulsive forces between the hydrophobic tailgroups and the decrease in free energy obtained when these tailgroups are no longer solvated by water or other polar solvent. Typically 10–100 monomers self-assemble to form a micelle. The spheroidal object formed by such aggregation allows one to put forward the pseudophase approximation, wherein the oily micellar interior constitutes a disperse oil phase (pseudophase) and the continuous aqueous phase represents the other pseudophase. Micellar solutions are, however, single-phase solutions, but this pseudophase approximation is very useful for keeping track of solute binding and partitioning into micelles, and phenomena related to such pseudophase concepts. A very important alternative approach to modelling micellization is the stepwise aggregation or chemical equilibrium approach. In this approach the detailed molecular or ionic growth of micelles is modelled in terms of sequential chemical equilibria, as surfactant merges with clusters to form slightly larger aggregates. Both of these approaches lead to thermodynamically equivalent results.

C2.3.5.1 CHEMICAL POTENTIAL

Assume that the chemical potential, μ , of surfactant in aggregates of size N in equilibrium with one another is uniform. One may therefore write

$$\mu = \mu_N \quad (\text{C2.3.7})$$

where μ is a constant and μ_N is the chemical potential of an aggregate of size N . We may also write

$$\mu_N = \mu_N^0 + \frac{kT}{N} \ln \left(\frac{X_N}{N} \right) \quad (\text{C2.3.8})$$

where (μ_N^0) is the standard part of the chemical potential and X_N is the mole fraction of surfactant aggregates of size N . After rearranging terms, X_N may be written:

$$X_N = N X_1^N e^{\frac{N(\mu_1^0 - \mu_N^0)}{kT}}. \quad (\text{C2.3.9})$$

The standard chemical potentials (μ_N^0) are approximately the same if the surfactant in each aggregate sees nearly the same interaction with the solvent. This simplifying assumption then gives

$$X_1 < 1 \quad (\text{C2.3.10})$$

$$X_N \ll X_1 \quad (\text{C2.3.11})$$

-17-

and yields the conclusion that the surfactant is in a monomeric state (aggregate of size 1). However, (μ_N^0) actually often decreases with increasing N . When this is the case, we see from [equation \(C2.3.9\)](#) that the mole fraction of surfactant in large aggregates may be relatively large. A necessary condition for the formation of large aggregates is this decrease of (μ_N^0) with increasing N .

C2.3.5.2 SHAPE EFFECTS

The variation of this standard chemical potential (μ_N^0) with aggregate size is important in determining whether micelles or aggregates will form. This reference potential also determines polydispersity and aggregate shape. For the sake of discussion we consider the formation of (one-dimensional aggregates) linear chains of surfactants. We approximate the pairwise binding energy (relative to separated species) as αkT . The standard reference potential is then written:

$$\mu_N^0 = - \left(1 - \frac{1}{N} \right) \alpha kT. \quad (\text{C2.3.12})$$

It appears that (μ_N^0) approaches (μ_∞^0) as $N \rightarrow \infty$. We therefore have in one dimension:

$$\mu_N^0 = \mu_\infty^0 + \frac{\alpha kT}{N}. \quad (\text{C2.3.13})$$

This expression can be generalized to two-dimensional aggregates (dislike micelles) and to spherical micelles, where

$$\mu_N^0 = \mu_\infty^0 + \frac{\alpha kT}{N^v} \quad (\text{C2.3.14})$$

and the exponent v takes values that depend on the aggregate shape. For dislike micelles, $v = 1/2$, and for spherical micelles, $v = 1/3$. The parameter α reflects the energy of intermolecular binding in units of the thermal energy.

C2.3.6 MORPHOLOGY AND STRUCTURE

The early Hartley model [2, 3] of a spherical micellar structure resulted, in later years, in some considerable debate. The self-consistency (inconsistency) of spherical symmetry with molecular packing constraints was subsequently noted [4, 5 and 6]. There is now no serious question of the tenet that unswollen micelles may readily deviate from spherical geometry, and ellipsoidal geometries are now commonly reported. Many micelles are essentially spherical, however, as deduced from many light and neutron scattering studies. Even ellipsoidal objects will appear

spherical when the time scale of the experimental probe is longer than the rotational period of the micelle. Cylindrical micelles presumably originate as spherical or ellipsoidal objects, and grow cylindrically as a consequence of competing energetics, wherein cylindrical extension is favoured over (hemispherical) end cap completion.

-18-

Deviations from spherical geometry are more prevalent in reverse micelles of low hydration, because spherical symmetry is more difficult to construct when concentrically arranging headgroups that may only interact repulsively. That these headgroups must fill space at the reverse micellar core necessarily introduces packing defects that mitigates against spherical symmetry. Normal and reverse micelles become more spherical when they are swollen with solvent, and thereby form microemulsion droplets ([section C2.3.11](#)). Regular spheroidal micelles, cylindrical micelles and branched cylindrical micelles have been imaged by cryo transmission electron microscopy, so that such approximate shapes have been fairly directly visualized [[26](#), [27](#)].

Resolution at the atomic level of surfactant packing in micelles is difficult to obtain experimentally. This difficulty is based on the fundamentally amorphous packing that is obtained as a result of the surfactants being driven into a spheroidal assembly in order to minimize surface or interfacial free energy. It is also based upon the dynamical nature of micelles and the fact that they have relatively short lifetimes, often of the order of microseconds to milliseconds, and that individual surfactant monomers are coming and going at relatively rapid rates.

In addition to these long contested arguments over the sphericity of micelles are arguments over the accessibility of solvent to the core of normal micelles. The morphological models such as that of Dill and Flory in [figure C2.3.2](#) portray micellar cores as composed of alkyl chains, and it has generally been believed that such an environment is a place where water may be expected to bind. Various experimental methods have, however, suggested the existence of water accessibility to these hydrocarbon chains and have caused some considerable disagreement in the literature. The simple packing models put forward by Fromherz showed, in a particularly clear way, that it is feasible to picture most parts of tailgroups as having a reasonable probability of accessing the surface of micelles. In other words, the micelle surface is not densely packed with headgroups, but also comprises intermediate and end of chain segments of the tailgroups. Such segments reasonably interact with water, consistent with dynamical measurements. Given that the lifetime of individual surfactants in micelles is of the order of microseconds and that of micelles is of the order of milliseconds, it is clear that the dynamical equilibria associated with micellar structures is one that brings most segments of surfactant into contact with water. The core of normal micelles probably remains fairly ‘dry’, however.

C2.3.6.1 PACKING PARAMETER

The surfactant number or surfactant parameter [[28](#), [29](#) and [30](#)], N_s , is defined as a dimensionless group:

$$N_s = v/la_h \quad (\text{c2.3.15})$$

where v is the volume of the surfactant tailgroup, l is the tailgroup length and a_h is the area of the head group. These volume and length parameters may be estimated from partial molecular structural studies of various homologous series of surfactants, from single-crystal x-ray diffraction studies and from molecular models. The key result is that this dimensionless group, based upon surfactant molecular properties, allows for the prediction of mesoscale packing morphology. A summary of the predictions obtained is given in [figure C2.3.5](#). See [table C2.3.1](#), [table C2.3.2](#), [table C2.3.3](#) and [table C2.3.4](#) for examples of the structures of some of the surfactants mentioned below.

Figure C2.3.5. Mesoscale structures deriving from surfactants nominally exhibiting shapes corresponding to various packing parameter ranges.

(A) $N_s \leq 1/3$

This inequality indicates the amphiphile adopts a shape essentially equivalent to that of a cone with basal area a_h . Such cones self-assemble to form spheroidal micelles in solution or spheroidal hemimicelles on surfaces (see [section C2.3.15](#)). Single-chain surfactants with bulky headgroups, such as SDS, typify surfactants in this category.

(B) $1/3 < N_s < 1/2$

In this range the packing parameter yields a molecular shape similar to that of a truncated cone. Such cones may assemble to form rodlike structures and cylindrical micelles. Single-chain surfactants such as SDS and CTAB can fall within this range when the ionic strength is high enough to shield electrostatic repulsion between headgroups. This shielding is a *de facto* means for making the headgroups sterically smaller.

(C) $1/2 < N_s < 1$

This range yields more highly truncated cones. The main mesophase structure obtained from these units is a flexible bilayer such as that formed in vesicles and liposomes. These arrangements are often obtained from double-chain surfactants such as lecithin, double tailed cationic surfactants and AOT.

(D) $N_s \approx 1$

This parameter corresponds to cylindrical packing shapes. Surfactants and amphiphiles falling in this range often produce planar bilayers and lamellar mesophases. Such cylindrical building blocks also contribute to many

important liquid crystalline applications. Double-tailed surfactants with smaller headgroups, such as phosphatidyl ethanolamine, tend to form planar bilayers.

(E) $N_S > 1$

Surfactants having an inverted truncated cone shape yield inverted spheroidal micelles. Many double-chain surfactants such as AOT form such inverted micellar structures. These kinds of surfactant also form inverted anisotropic liquid crystalline phases.

C2.3.6.2 WORMLIKE MICELLES

Lengthy cylindrical micelles have become known as wormlike micelles, threadlike micelles and giant micelles. While the thickness of such micelles is typically of the order of two surfactant lengths (3–6 nm), the length of such micelles can approach 1000 nm or more [31]. These lengths are also known as persistence lengths, and usually are of the order of 30–200 nm. They are often studied in direct analogy to polymers, and much effort has been expended in applying the tenets of the statistical mechanics of polymer chains to wormlike micelles [32, 33]. Magid [34] gives an excellent review of the analogy of wormlike micelles to polymers. She presents a compelling picture of such giant micelles as living polymers.

C2.3.7 STATISTICAL MECHANICAL SIMULATIONS

In the absence of anisotropy introduced by specific surfactant–surfactant interactions, a spherical droplet model is reasonable because it tends to minimize the surface energy. Deviations from spherical symmetry occur because of the finite size and anisotropy of surfactant molecules and the anisotropy of interactions. Many early experimental data were interpreted on the assumption of spherical structures. In seminal Monte Carlo studies by Haan and Pratt [35], micelles simulating those of sodium octanoate were examined. They found that the chains adopted a spheroidal structure that was never close to perfectly spherical. An example packing configuration of the type observed is illustrated in [figure C2.3.6](#) for the case of an assembly involving 30 monomers. The shaded headgroups are mostly situated at the micellar surface, but it is obvious that much of the surface is also composed of methylene and methyl groups. This structure also obviously departs significantly from spherical symmetry. Spherical packing just is not energetically feasible when surfactant tailgroups must fill space. The situation changes dramatically when another solvent is permitted to fill the core region, as in microemulsions, and the surfactants can then pack in a more or less ‘planar’ manner at the oil–water interface. Similar conclusions have been upheld by much more time-consuming molecular dynamics simulations, such as those of Jönsoon *et al* [36]. A molecular dynamics snapshot of a sodium octanoate micelle is illustrated in [figure C2.3.7](#). This structure also shows that the micelle at a given instant is far from spherically symmetric. Of course, this structure is undergoing shape fluctuations as part of its dynamical equilibrium and it is constantly rotating in space. Such fluctuations and rotations tend to give an apparent spherical structure when averaged over time. This is why many structural studies based on neutron scattering,

for example, need to invoke spherical models. This molecular dynamics simulation also confirms the earlier Monte Carlo illustration of the accessibility of hydrocarbon chains to the micellar surface and the ensuing solvent contacts.

Figure C2.3.6. Illustration of micelle structure obtained by Monte Carlo simulations of model octanoate amphiphiles. There are 30 molecules simulated in this cluster. The shaded spheres represent headgroups. Reproduced by permission from figure 2 of [35].

Figure C2.3.7. Snapshot of micelle of sodium octanoate obtained during molecular dynamics simulation. The darkest shading is for sodium counter-ions, the lightest shading is for oxygens and the medium shading is for carbon atoms. Reproduced by permission from figure 2 of [36].

Since these early simulations the art and science of simulating micellar structures has advanced significantly [37, 38 and 39]. Ionic micelles are being simulated with specific inclusion of solvent water. Micellization processes are being simulated dynamically using model united atom techniques [40, 41 and 42]; such methods are proving useful for understanding micelle and bilayer [43] structural evolution in solutions of small surfactants and for understanding micellization of polymeric surfactants (block copolymers) [44].

C2.3.8 REVERSE MICELLES

The idealized reverse micelle sketched in [figure C2.3.1](#) is an aggregate of a double-tail surfactant. In such systems the solvent is more compatible with the lyophobic part of the surfactant than with the headgroup. This preference

leads to the inverted structure illustrated. There is much less known in terms of conclusive physical data (e.g., cmc, aggregation number) on reverse micelles than on normal micelles. This, in part, is due to the hydrophilic nature of surfactant headgroups, and the fact that it is experimentally challenging to prepare and study reverse micelles in water immiscible solvents while keeping all water out of the system. The cartoon in [figure C2.3.1](#) is actually much more appropriate for a reverse *microemulsion* droplet, where the mole ratio of water to surfactant is of the order of ten or greater.

Such reverse droplets generally have tiny water pools in the core that exhibit many of the bulk properties of water. In such cases it is more sensible to imagine the surfactant headgroups aligned as a monolayer at a water–oil interface. However, in the absence of more than a few water molecules per surfactant, such idealized packing cannot be obtained without generating energetically unfavourable vacuum cores. Another point of controversy has been the question of whether core water is a necessary condition for the formation of reverse micelles [45]. There is no fundamental reason why dipolar headgroups of even ionizable surfactants cannot associate to form a reverse micellar core. The presence of some waters of hydration will tend to ameliorate such association, and provide hydrogen bonding as a means of forming such associations. However, data showing that water facilitates reverse micelle (microemulsion) formation are incontrovertible. NMR self-diffusion data [46] for reverse micelles of AOT in decane are illustrated in [figure C2.3.8](#) where the ratio of decane to decane plus water (0.6 % brine) is varied. In the limit of no added water, the self-diffusion of the surfactant is almost equal to that of water, and indicates that the reverse micelles formed have only a very few monomers in them. As water is added, both the self-diffusion of water and the self-diffusion of AOT decrease. This decrease indicates that the reverse micelles are controlling the diffusion rate of the water and AOT composing these micelles and are growing in size as more water is added. Reverse micelles of some surfactants will not form without added water, but many surfactants have been demonstrated to form them without added water [47].

Figure C2.3.8. Self-diffusion coefficients at 45°C for AOT (●), water (■) and decane (▲) in ternary AOT, brine (0.6% aqueous NaCl) and decane microemulsion system as a function of composition, α . This compositional parameter, α , is the weight fraction of decane relative to decane and brine. Reproduced by permission from figure 3 of [46].

The issue of water in reverse micellar cores is important because water swollen reverse micelles (reverse microemulsions) provide means for carrying almost any water-soluble component into a predominantly oil-continuous solution (see discussions of microemulsions and micellar catalysis below). In the absence of water it appears that pre-micellar aggregates (pairs, trimers etc.) are commonly found in surfactant-in-oil solutions [47]. Critical micelle concentrations do exist (with some exceptions).

C2.3.9 SOLUBILIZATION AND PARTITIONING

Micelles are mainly important because they solubilize immiscible solvents in their cores. Normal micelles solubilize relatively large quantities of oil or hydrocarbon and reverse micelles solubilize large quantities of water. This is because the headgroups are water loving and the tailgroups are oil loving. These simple solubilization trends produce microemulsions (see [section C2.3.11](#)).

Other solubilization and partitioning phenomena are important, both within the context of microemulsions and in the absence of added immiscible solvent. In regular micellar solutions, micelles promote the solubility of many compounds otherwise insoluble in water. The amount of chemical component solubilized in a micellar solution will, typically, be much smaller than can be accommodated in microemulsion formation, such as when only a few molecules per micelle are solubilized. Such limited solubilization is nevertheless quite useful. The incorporation of minor quantities of pyrene and related optical probes into micelles are a key to the use of fluorescence depolarization in quantifying micellar aggregation numbers and micellar microviscosities [48]. Micellar solubilization makes it possible to measure acid–base or electrochemical properties of compounds otherwise insoluble in aqueous solution. Micellar solubilization facilitates micellar catalysis (see [section C2.3.10](#)) and emulsion polymerization (see [section C2.3.12](#)). On the other hand, there are untoward effects of micellar solubilization in practical applications of surfactants. When one has a multiphase

-24-

system as often encountered in cosmetic formulations or in photographic emulsion technology, one or more chemical components may be present as nanoparticulates (for example, an organic coupler that reacts to form image dye in a colour photographic element). If surfactant is present in excess, so as to form micelles, solubilization of such a component in the micelles often may lead to unwanted growth of such particulates via Ostwald ripening. Since micellar solubilization raises the effective solubility of the component, the ripening rates will increase and be exacerbated.

Micelles can solubilize gases. It has been demonstrated [49] that the Laplace model gives a good description of such solubilization for the case of ionic micelles:

$$\ln X_m = \ln X_b - \frac{2\sigma v}{\alpha n RT} \quad (\text{C2.3.16})$$

where X_m is the mole fraction of gas in the micelle and X_b is the mole fraction of gas in a bulk solvent equivalent to that of the surfactant tail, σ is the interfacial tension at the water–micelle interface, v is the partial molar volume of the gas in the micelle, n is the number of carbon atoms in the surfactant tail group, α is the segment length, T is temperature and R is the gas constant. This equation derives from the existence of a Laplace pressure differential across the micelle–water interface. Typical interfacial tensions applicable to micelles of hydrocarbon surfactants are in the neighbourhood of 30 dyn cm^{-1}

The solubilization of diverse solutes in micelles is most often examined in terms of partitioning equilibria, where an equilibrium constant K defines the ratio of the mole fraction of solute in the micelle (X_m) and the mole fraction of solute in the aqueous pseudophase. This ratio serves to define the free energy of solubilization ($-RT \ln K$). Recent monographs provide access to tabulations of such thermodynamic quantities [50, 51].

It is of particular interest to be able to correlate solubility and partitioning with the molecular structure of the surfactant and solute. ‘Likes dissolve like’ is a well-worn phrase that appears applicable, as we see in microemulsion formation where reverse micelles solubilize water and normal micelles solubilize hydrocarbons. Surfactant interactions, geometrical factors and solute loading produce limitations, however. There appear to be no universal models for solubilization that are readily available and that rest on molecular structure. Correlations of homologous solutes in various micellar solutions have been reviewed by Nagarajan [52]. Some examples of solubilization, such as for polycyclic aromatics in dodecyl sulphonate micelles, are driven by hydrophobic

interactions, while a variety of other types of micelle exhibit entropy driven solubilization. Other solutes and micelles involve solubilization in the headgroup region, and some of these cases are best modelled as specific binding phenomena (rather than partitioning). In cases where loading is fostered to the point of micellar swelling, where a core of neat solute is formed, we have the evolution of a microemulsion ‘droplet’.

C2.3.10 MICELLAR CATALYSIS

Reversibly formed micelles have long been of interest as models for enzymes, since they provide an amphipathic environment attractive to many substrates. Substrate binding (non-covalent), saturation kinetics and competitive inhibition are kinetic factors common to both enzyme reaction mechanism analysis and micellar binding kinetics.

-25-

Micellar catalysis has two important components. The first is the partitioning (localization, binding) of the reagent into or onto the micelle. Such localization provides increased interactions among the reagents, particularly with respect to the collision frequency in the case of bimolecular reactions. The second is a field or ‘solvent’ effect wherein the micellar environment provides catalysis by modifying the reaction transition state. The first of these components is the best understood and the most often encountered. Micellar catalysis differs from enzyme catalysis in some significant ways. Substrate specificity is usually much less significant in micellar catalysis. Also, the enhancement of reaction rates is much, much smaller in micellar catalysis than in enzyme catalysis. In addition, the substrate concentration in enzyme catalysis is usually much lower than the concentration of enzyme, but in micellar catalysis the concentration of micelles is usually of the same order as that of at least one of the reagents.

This localization phenomenon has also been shown to be important in a case of catalysis by *premicellar aggregates*. In such a case [53] premicellar aggregates of cetylpyridinium chloride (CPC) were shown to enhance the rate of the Fe(III) catalysed oxidation of sulphanic acid by potassium periodate in the presence of 1,10-phenanthroline as activator. This chemistry provides a lowering of the detection limit for Fe(III) by seven orders of magnitude. It must also be appreciated, however, that such premicellar aggregates of CPC actually constitute mixed micelles of CPC and 1,10-phenanthroline that are smaller than conventional CPC micelles.

The oily interiors of micelle cores often provide a driving force for substrate binding to micelles. Those interiors are not the only physical aspect that affect the chemistry. Studies have shown that both electrostatic and geometric factors may be important in micellar catalysis. In particular, the surfactant headgroup (its charge, its volume and its hydration) affects the catalytic power of the micelle. The role of surfactant headgroups in modifying transition states can be contrasted with the role of oily interiors in providing substrate binding. Micellar solubilization has also been shown to inhibit alkaline decomposition when the reactive site is buried *within* the micellar interior. However, many micellar catalysed reactions occur near the charged double layer in proximity to the ionic headgroups [54]. Nucleophilic aromatic substitutions, such as the attack by azide ion on 2,4-dinitrochloronaphthalene catalysed by CTAB micelles [55], are examples of micellar catalysis by field or solvent effects. Such substitutions typically involve charged transition states that can be significantly modified by micelle ionic structures.

C2.3.10.1 REACTION PATHWAYS

Alteration of reaction pathways by micellar catalysis often can yield modified product distributions. Such modification is most easily obtained when one pathway is catalysed and another is inhibited by the micellar environment. An excellent tabulation of product distribution variations obtained by micellar catalysis is given by Fendler [56]. An example is illustrated in [figure C2.3.9](#) for the CTAC (cetyltrimethylammonium chloride) catalysed photodecarbonylation of dissymmetrical ketones [57], A(CO)B. The CTAC micelles provide a cage effect that greatly enhances the joining of the A and B radicals produced by the photolysis. Although the localization effects and field effects provided in micellar catalysis can provide significant rate enhancements and

these environmental effects can provide dramatically altered product distributions, there has been little effective development of micellar catalysis in modifying stereoselectivities. The dynamical equilibria exhibited by micelles mitigates against easily developing stereoselective binding equilibria.

-26-

Figure C2.3.9. Product distribution of dissymmetrical ketone photolysis as influenced by cetyltrimethylammonium chloride (CTAC) micelles. The initial ketone, A(CO)B is photolysed to lose the carbonyl group and to produce three products, AA, AB and BB. These data are for benzyl (A) 4-methylbenzyl (B) ketone. Product AA is 1,2-diphenylethane, product BB is 1,2-ditolylethane and product AB is 1-phenyl-2-tolyl-ethane. At low CTAC concentration, in the absence of micelles, a random distribution of products is obtained. In the presence of micelles, however, the AB product is heavily favoured. Adapted with permission from [57].

C2.3.10.2 SELF-REPLICATION

A particularly interesting type of micellar catalysis is the autocatalytic self-replication of micelles [58]. Various examples have been described, but a particularly interesting case is the biphasic self-reproduction of aqueous caprylate micelles [59]. In this system ethyl caprylate undergoes hydroxyl catalysed hydrolysis to produce the free carboxylate anion, caprylate. Caprylate micelles then form. As these micelles form, they solubilize ethylcaprylate and catalyse further production of caprylate anion and caprylate micelles.

C2.3.10.3 REVERSE MICELLAR CATALYSIS

An even greater diversity of catalytic processes has been obtained in reverse micellar systems. Reverse micelles, as pictured in [figure C2.3.1](#) usually contain hydrating water molecules around the surfactant headgroups. Additional water solubilized in the core of reverse micelles produces reverse microemulsions ([section C2.3.11](#)), where the size of the water nanoreactor core can be simply adjusted by the amount of water added to the system. The same kinds of partitioning, field effects and headgroup charge effects encountered in normal micellar catalysis are also obtained in reverse micellar catalysis. However, the direct incorporation of varied catalysts, such as enzymes and cofactors, into the water pools provides a plethora of additional chemistries. Many of these chemistries are described in monographs [56, 60, 61], and include electron transfer reactions, donor-acceptor interactions, ester hydrolysis, carbohydrate hydrolysis, polymerization of olefinic monomers such as acrylates, methacrylates, acrylamides, acid dissociation,

Schiff base formation, photochemistry, protein partitioning, catalysis by chymotrypsin, lipase, peroxidase, phosphatase, catalase and alcohol dehydrogenase.

C2.3.11 MICROEMULSIONS

Microemulsions can be simply defined as solvent-swollen micellar solutions, wherein the swelling solvent is immiscible with the solvent of the pseudocontinuous phase. For example, in the case of normal micelles in aqueous solution, the swelling solvent typically is a water-immiscible organic solvent. This definition is not sufficient, however, because it only covers an important topological subset of microemulsions. This subset is one wherein the swelling solvent is present in objects readily identified as spheroidal or cylindrical ‘particles’ or ‘droplets’. Microemulsions also contain a distinct topological entity known as irregular, bicontinuous microemulsions, wherein interdigitated domains of immiscible solvents are separated by a monolayer of surfactant. These structures will be elaborated further in the discussion below.

All microemulsions have at least three chemical components, surfactant and two immiscible solvents; micellar solutions need only have two chemical components, surfactant and solvent. Microemulsions and micellar solutions are thermodynamically stable isotropic solutions. In this context the phrase ‘thermodynamically stable’ means that only moderate mixing is required to transform a mixture of the three main components into a transparent isotropic solution. There, of course, can be diverse kinetic barriers in such dissolution processing, and it often is convenient to dissolve the surfactant in one of the solvents before mixing in the other solvent, but, once formed, an isotropic microemulsion solution will not phase separate unless there is molecular decomposition or some field variable, temperature for example, is changed. Our use of the adjective isotropic in these contexts means that microemulsions are optically isotropic. That is to say the microstructures that exist in the aggregates in microemulsions are almost always significantly smaller than the wavelengths of visible light.

The composition of microemulsions is usefully considered in the context of ternary phase diagrams such as that illustrated in [figure C2.3.10](#). The region marked L_1 is the normal single-phase microemulsion domain wherein the solution microstructure is essentially that of micelles swollen with oil. Similarly, the L_2 domain essentially has water-swollen reverse micelles. At certain field variables these domains may be simply connected to one another. When such is the case, the microstructure in the ‘connecting’ region is predominantly that of an irregular, bicontinuous microemulsion. The physical, chemical and practical aspects of microemulsions fill many, many volumes, so no further attempt will be made to elucidate them here. Excellent monographs are available [[62](#), [63](#), [64](#), [65](#) and [66](#)].

Figure C2.3.10. Ternary phase diagram of surfactant, oil and water illustrating the (regular) L₁ and (reverse) L₂ microemulsion domains.

C2.3.12 EMULSION POLYMERIZATION

The production of organic polymeric particles in the size range of 30–300 nm by emulsion polymerization has become an important technological application of surfactants and micelles. Emulsion polymerization is very well and extensively reviewed in many monographs and texts [67, 68], but we want to briefly illustrate the role of micelles in this important process.

Surfactants provide temporary emulsion droplet stabilization of monomer droplets in the two-phase reaction mixture obtained in emulsion polymerization. A cartoon of this process is given in [figure C2.3.11](#). There we see that a reservoir of polymerizable monomer exists in a relatively large droplet (of the order of the size of the wavelength of light or larger) kinetically stabilized by surfactant.

The role of micelles comes into play in nucleating the formation of the polymerized organic particles. The initial stages of polymerization, in the case of some monomers, may occur in the aqueous phase, but at some point of growth the aqueous solubility is no longer sufficient. The micelles provide a place, through solubilization, for small oligomers to continue growing thereafter. The micellar environment provides a region of intermediate solubility, more favourable for these oligomers than the aqueous phase or the reservoir phase. Transport between the monomer reservoirs (emulsion droplets) and the reacting, polymerizing polymer particle is also facilitated by micellar solubilization of monomer.

Three phases, initiation, growth and termination, are typically encountered in emulsion polymerization. The initiation stage involves the creation of monomeric radicals and ensuing oligomeric radicals. These oligomers become temporarily engulfed in a micelle. The initiation stage is followed by the growth stage, wherein monomer in the reservoir (emulsion) particles is depleted. Finally, the radical chemistry and polymerization is shut down in the termination stage, and the radical polymerization ceases.

Figure C2.3.11 Key surfactant structures (not to scale) in emulsion polymerization: micelles containing monomer and oligomer, growing polymer particle stabilized by surfactant and an emulsion droplet of monomer (reservoir) also coated with surfactant. Adapted from figure 4-1 in [67].

C2.3.13 MICELLAR AND MICROEMULSION POLYMERIZATION

The polymerization of micelles composed of polymerizable surfactants while maintaining micellar morphology and size is a continuing challenge in colloid and polymer science. No significant case of polymerizing a micelle, while maintaining morphological integrity, has yet been convincingly reported. This situation will no doubt change in the near future, as the steric constraints of polymerization in related systems are being overcome [69, 70]. Since micelles and microemulsions are in dynamic equilibrium, it is difficult to polymerize surfactant monomers fast enough while maintaining the morphological integrity of the micelle. Also, steric constraints come into play once a monomer has been joined to another, so that it is difficult to carry on the polymerization while maintaining the nominal packing that existed before polymerization. It is noteworthy that Cussler and co-workers [71, 72] report what they believe to be polymerization in a bicontinuous microemulsion that preserves interfacial structure. However, it must be noted that the main evidence is that correlation lengths appear preserved, before and after polymerization, and that this preservation may be coincidental was not ruled out.

Irrespective of whether microemulsion and micellar interfaces can be polymerized using polymerizable surfactants, it is now very well established that monomers in microemulsions, whether part of or entirely composing the oil phase, whether solubilized in the aqueous phase or whether part of both pseudophases can be polymerized to form very small particles or interesting bulk materials. When oily monomers are polymerized inside conventional microemulsions or when aqueously soluble monomers (acrylamides, acrylates) are polymerized in reverse microemulsions, one usually obtains latexes similar to those obtained by emulsion polymerization (30–100 nm in diameter). The mechanism of microemulsion polymerization is essentially identical to that for emulsion polymerization, except that the initiation and termination intervals are often not connected by a very lengthy growth interval. This is because there are no large monomeric reservoirs and monomer transport is facile and essentially diffusion controlled. Excellent reviews on microemulsion polymerization are readily available [73, 74 and 75]. Very recent success has been obtained in obtaining very small particles in reverse microemulsion polymerization [76]. The key in the studies of Pileni and co-workers is

to use surfactants that have polymerizable counter-ions. Double-tail cationic surfactants with acrylate-type counter-ions yield ultrasmall particles (2–4 nm). Additional polymerizable monomer can be included in the water core, but having such species as part of the surfactant (headgroup) without covalently induced strain on the cationic surfactant packing appears to play a major factor in preserving the morphology through the polymerization interval.

C2.3.14 MICELLE-BASED MESOPHASES

Two-dimensional maps of single- and multiple-phase domains as a function of temperature and of surfactant/solvent mole fraction (or, alternatively, weight fraction) provide a useful means for characterizing ionic and nonionic surfactants. The variety of physical states discussed earlier, and more, are routinely exhibited in binary phase diagrams of surfactants. The formation of micellar and other aggregates is driven by hydrophobic interactions. As such aggregates become more concentrated and interact more strongly, supramolecular ordering of such aggregates occurs and the shape of such micelles and aggregates can change. These transitions yield a rich array of mesophases, such as lamellar phases where surfactant packs in infinite bilayers that can be swollen in the headgroup region by water or in the tailgroup region by organic solvent [77]. Some of these mesophases have building blocks identifiable as micelles.

Spherical and ellipsoidal micelles and rodlike micelles can form supramolecular assemblies having cubic symmetry. Ellipsoidal micelles at sufficiently high concentration may pack at cubic lattice sites to produce viscous cubic phases. For example, certain triblock copolymeric micelles form cubic mesophases [78], wherein the micelles aggregate in a cubic array. Such arrays are often thermoreversible gels that ‘melt’ on cooling, as isotropic and low viscosity micellar solutions form (as the number density of micelles decreases with concomitant increases in the cmc). Both fcc and bcc arrays have been reported for such cubic mesophases [79, 80, 81, 82, and 83]. Furthermore, such ordering is often induced by shear. Two-dimensional scattering from a shear-induced cubic mesophase of $\text{EO}_{96}\text{PO}_{39}\text{EO}_{96}$ (see table C2.3.4) is illustrated in figure C2.3.12 [84]. This is the type of scattering pattern expected for a bcc lattice.

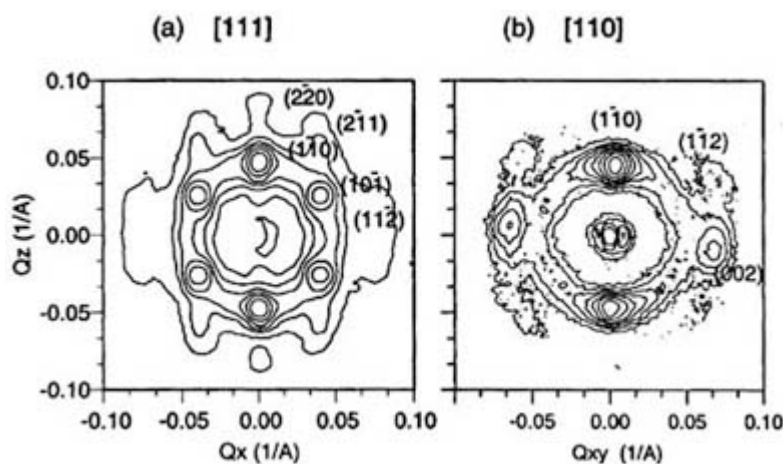

Figure C2.3.12. Two-dimensional neutron scattering by $\text{EO}_{96}\text{PO}_{39}\text{EO}_{96}$ (Pluronic F88) micellar solution under shear with (a) the sample shear axis parallel to the beam, and (b) the sample rotated 35° around the vertical axis. Reflections for several of the Miller indices expected for a bcc lattice are annotated. Reproduced by permission from figure 4 of [84].

Normal and reverse cylindrical micelles or rodlike micelles can pack hexagonally to form a variety of mesophases. When cylindrical rods (micelles) pack hexagonally in two dimensions to form the normal hexagonal (H_I) mesophase, one obtains what was known as the middle phase in soap technology. Similar arrays may form from reverse rodlike micelles, and such mesophases are called inverse hexagonal (H_{II}) phases. Such mesophases are liquid crystalline and highly viscous and are often formed by phospholipids. These hexagonal mesophases are illustrated in figure C2.3.13 [85]. A thorough theoretical analysis of nematic mesophase formation by rodlike micelles, in the framework of micellar growth coupling with micellar alignment, has been given by vander Schoot and Cates [86]. A summary of work done on trying to understand the formation of hexagonal mesophases has been

detailed by Odijk [87].

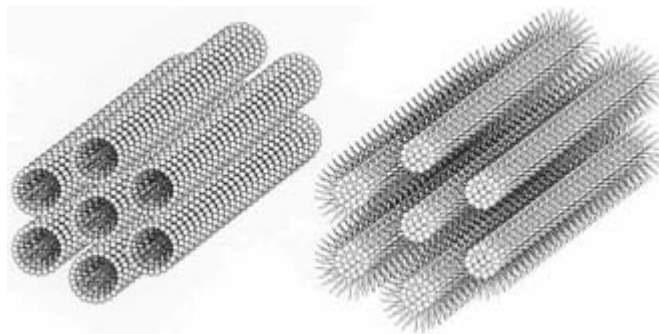

Figure C2.3.13. Normal (H_p , left) and inverse (H_{II} , right) hexagonal mesophases composed of rodlike micelles.

C2.3.15 ADSORBED MICELLES

The formation of surface aggregates of surfactants and adsorbed micelles is a challenging area of experimental research. A relatively recent summary has been edited by Sharma [51]. The details of how surfactants pack when aggregated on surfaces, with respect to the atomic level and with respect to mesoscale structure (geometry, shape etc.), are less well understood than for micelles free in solution. Various models have been considered for surface surfactant aggregates, but most of these models have been adopted without firm experimental support.

C2.3.15.1 ISOLATED SURFACTANT ADSORPTION

Individual and isolated surfactant adsorption onto a surface can be imagined to occur in various ways, such as those depicted in [figure C2.3.14](#). The headgroup end-on adsorption shown in [figure C2.3.14\(a\)](#) is the most commonly *assumed* mode of adsorption. It is generally invoked for charged surfactant adsorption, when it is assumed that the prevalent surface charge is opposite to that of the surfactant headgroup. This assumption has most often been applied to the adsorption of straight-chain cationic surfactants onto negatively charged surfaces (silica, metals etc.). The mode exhibited in [figure C2.3.14\(b\)](#) is one that requires interaction of the headgroup and a part of the surfactant chain. Modes depending on hydrophobic interactions with the surface are shown in parts (c) and (d). When both the headgroup and the tail interact with the surface, the structures in [figure C2.3.14\(e\)](#) and [figure C2.3.14\(f\)](#) would be expected. Recent Raman evidence for CTAB adsorption onto negatively charged silver according to modes such as those of (e) and (f) appears unequivocal [88]. Modes (c)–(f) appear to be the most often overlooked in the literature.

Figure C2.3.14. Isolated surfactant modes of adsorption at liquid–solid interfaces for a surfactant having a distinct headgroup and hydrophobic portion (dodecyltrimethylammonium cation): (a), (b) headgroup specific interaction; (c), (d) hydrophobic tail interaction, (e),(f) headgroup and tail interactions.

C2.3.15.2 HEMIMICELLE FORMATION

It is easy to see how extrapolation of isolated adsorption depicted in figure C2.3.14(a) can lead to a picture of hemimicelle structure as illustrated in figure C2.3.15(a). Combinations of the modes illustrated in figure C2.3.14 can be used to construct the alternative hemimicelle model of figure C2.3.15(b). This alternative model was much more popular in the 1960s and 1970s, but was supplanted by the evolution of dogma in favour of figure C2.3.15 (a) . It should be stressed that the structure for the hemispherical hemimicellar model takes simultaneous account of surfactant packing parameters and basic interfacial free energy, whilst the model of figure C2.3.15(a) ignores the highly unfavourable tail–solvent interactions that remain about the periphery after aggregation.

Figure C2.3.15. Hemimicelle structures: (a) monolayer type hemimicelle; (b) spheroidal, globular hemimicelle.

Adsorbed micelles, also called *admicelles*, are illustrated in cross-section in figure C2.3.16(a) and figure C2.3.16 (b) . The bilayer structure in (a), when capped at the ends, mitigates against the unfavourable solvent interactions maintained in the hemimicellar model of figure C2.3.15(a) . When suitable end caps are added, these two admicelle models in figure C2.3.16 become somewhat indistinguishable. It is possible for the bilayer admicelle, however, to propagate over large areas so that the detailed molecular packing remains fairly ordered and distinguishable from the more random short range packing exhibited in the model of figure C2.3.16(b) .

Figure C2.3.16. Adsorbed micelle structures: (a) bilayer admicelle; (b) spheroidal, globular adsorbed micelle.

Below the onset of surface aggregation through the adsorption of micelles, there are up to four regimes of adsorption observed. The first regime is that of isolated surfactant adsorption, such as depicted in [figure C2.3.14](#). The second regime is that in which hemimicelles form and/or admicelles adsorb. In log–log plots of adsorbed surfactant *versus* solution-phase surfactant concentration, the breakpoint between these first two regimes denotes the ‘surface cmc’ for hemimicelle formation. Additional surfactant uptake with increasing concentration in a subsequent regime has been interpreted as corresponding to completion of a surface bilayer. Asymptotic adsorption corresponds to a fourth regime, wherein solution micelles are believed to be in dynamical equilibrium with a surface bilayer-type admicelle, such as depicted in [figure C2.3.16\(a\)](#).

C2.3.15.3 DIRECT STRUCTURAL DATA

The qualitative resolution of the morphology and structure of surfactant aggregates on surfaces is experimentally formidable. Until only recently all such structural assignments were made on quite indirect bases. In the case of interpreting neutron scattering data, for example, generally only unbounded structures of the type illustrated in [figure C2.3.15\(a\)](#) and [figure C2.3.16\(a\)](#) were considered in the modelling and data fitting processes. Fortunately, recent AFM (atomic force microscopy) studies by Manne [89] and collaborators have provided direct morphological data for a variety of surfactants interacting with several different surfaces. The overall results are exciting because they illustrate a diversity of structure.

All of these results were obtained for solutions that were above the respective cmc in aqueous solution. Structural results [90] for tetradecyltrimethylammonium bromide are illustrated in [figure C2.3.17](#) where the surfactant is adsorbed onto a hydrophobic cleavage plane of MoS₂. The cartoon illustrated shows the structure deduced fairly directly from the atomic force micrographs. Other results are summarized in [table C2.3.8](#). The dodecyl- to hexadecyltrimethylammonium bromides, hexadecyltrimethylammonium chloride and SDS all yield similar parallel half-cylinders on a hydrophobic cleavage plane of graphite. These results contrast with earlier assignments of vertical monolayers (such as illustrated in [figure C2.3.15](#) for the cationic surfactants [93] and for SDS [94] and hemispheres for SDS [95]). A strikingly different result, parallel flexible cylinders [90], was obtained for the dodecyl- to hexadecyltrimethylammonium bromides and chlorides on an anionic cleavage plane of mica. These flexible cylinders remain parallel but undergo s-shaped shifts as the underlying lattice is covered. Earlier assignments [92, 96, 97 and 98] deduced uniform bilayer structures such as illustrated in [figure C2.3.16\(a\)](#). This AFM approach did yield an assignment of a uniform bilayer for the adsorption of the double-tail cationic bromide on mica in agreement with an earlier study [99]. The results obtained by AFM for adsorption of the cationic tetradecyltrimethylammonium bromide onto the anionic surface of SDS are particularly interesting, as spheres and spheroids, such as depicted in [figure C2.3.15\(b\)](#) and [figure C2.3.16\(b\)](#), were deduced in agreement with earlier assignments [100, 101] of spheres, but contrasted with other assignments inferring bilayer patches [102, 103, 104 and 105]. Much work remains in developing a firmer comprehension of hemimicellar structure at concentrations lower than those that produce micelles in bulk solution.

Table C2.3.8 Hemimicelle morphology by AFM.

Surface	Surfactant	Morphology
Graphite	$\text{CH}_3(\text{CH}_2)_{10}\text{CH}_2\text{N}^+(\text{CH}_3)_3 \text{Br}^-$	Parallel half-cylinders [90, 91]
	$\text{CH}_3(\text{CH}_2)_{12}\text{CH}_2\text{N}^+(\text{CH}_3)_3 \text{Br}^-$	
	$\text{CH}_3(\text{CH}_2)_{14}\text{CH}_2\text{N}^+(\text{CH}_3)_3 \text{Br}^-$ (CTAB)	Parallel half-cylinders [92]
Mica	$\text{CH}_3(\text{CH}_2)_{10}\text{CH}_2\text{OSO}_3^- \text{Na}^+$ (SDS)	Parallel flexible cylinders [91]
	$\text{CH}_3(\text{CH}_2)_{10}\text{CH}_2\text{N}^+(\text{CH}_3)_3 \text{Br}^-$	
	$\text{CH}_3(\text{CH}_2)_{12}\text{CH}_2\text{N}^+(\text{CH}_3)_3 \text{Br}^-$	Uniform bilayer [91]
	$\text{CH}_3(\text{CH}_2)_{14}\text{CH}_2\text{N}^+(\text{CH}_3)_3 \text{Br}^-$ (CTAB)	
MoS ₂	$\text{CH}_3(\text{CH}_2)_{10}\text{CH}_2 > \text{N}^+(\text{CH}_3)_2 \text{Br}^-$	Parallel half-cylinders [91]
	$\text{CH}_3(\text{CH}_2)_{10}\text{CH}_2$	Spheres and spheroids [91]
SiO ₂	$\text{CH}_3(\text{CH}_2)_{12}\text{CH}_2\text{N}^+(\text{CH}_3)_3 \text{Br}^-$ (CTAB)	
	$\text{CH}_3(\text{CH}_2)_{12}\text{CH}_2\text{N}^+(\text{CH}_3)_3 \text{Br}^-$ (CTAB)

C2.3.16 MICELLE–POLYMER INTERACTIONS

Many practical applications of surfactants and polymers utilize both types of component in the same single- or multi-phase formulation. For example, in the photographic industry, anionic surfactants are used as charge stabilizers for a myriad of organic and inorganic nanoparticulates and polymers (such as gelatin and other polyelectrolytes) are used as steric stabilizers for the same particulates. There are significant synergistic interactions between surfactants and polymers, and most of these interactions are based on how these polymers interact with micelles of these surfactants [106, 107, 108 and 109].

C2.3.16.1 EFFECTS ON CMC

An important mechanistic feature of such interactions is in the molecular detail of the interaction. Two general

types of interaction may be articulated: (1) nucleation of a micelle by some pendant group of the polymer, wherein a micelle grows about some part of the polymer; (2) polymeric adsorption onto the micellar surface, where one can picture a nonintegral type of binding between the micelle and polymer involving only the micellar headgroup region and active sites of the polymer [110]. These two limiting cases define boundaries between which mixtures of the two effects can be observed.

Additives, whether hydrophobic solutes, other surfactants or polymers, tend to nucleate micelles at concentrations lower than in the absence of additive. Due to this ‘nucleating’ effect of polymers on micellization there is often a measurable cmc, usually called a critical aggregation concentration or cac, below the regular cmc observed in the absence of added polymer. This cac is usually independent of polymer concentration. The size of these aggregates is usually smaller than that of free micelles, and this size tends to be small even in the presence of added salt (conditions where free micelles tend to grow in size).

These effects are illustrated in [figure C2.3.18](#) for the case of SDS micellization as influenced by poly(ethylene oxide), PEO, and salt [111]. The breakpoints in the figure denote the cmc or cac. From [table C2.3.6](#) and [table C2.3.7](#) we see that the cmc of SDS is 8.2 mM in the absence of salt and polymer and is 1.4 mM in 0.1 M NaCl. The open symbols in [figure C2.3.18](#) show that in the absence of salt, 35 000 Dalton PEO (at 0.1 % w/w) depresses the cac to about 3.5 mM and 60 000 Dalton PEO (also at 0.1 % w/w) depresses the cac even further to about 2.3 mM. In 0.1 M NaCl both molecular weight samples of PEO depress the cac, to about 1 mM (relative to 1.4 mM in the absence of polymer), but the relative depression is much less than in the absence of salt.

Figure C2.3.18. Vibronic peak fluorescence intensity ratio (III/I) as a function of SDS concentration for 0.1 % PEO solutions \circ , \bullet —35 000 Daltons; \square , \blacksquare —600 000 Daltons. Open symbols are for aqueous solution without added salt, and filled symbols are for 100 mM aqueous NaCl. Reproduced with permission from figure 2 of [111].

C2.3.16.2 EFFECTS ON RHEOLOGY

Solution viscosity in systems with strong polymer–micelle interactions generally increases with polymer–micelle binding. If one imagines the necklace model of Cabane and co-workers [112, 113 and 114], where micelles (beads) are bound to polymeric strands, two contributing features to viscosity may be identified. First, there exists an inertial effect due to the adsorbed micelles. These micelles serve to simply increase the effective molecular weight of the polymer and the effective friction coefficient of the polymer. In the neighbourhood of an adsorbed micelle, translation of the polymer strand in a reptation mode, for example, also requires translation of the attached micelle having considerably greater macromolecular cross-section. Second, occasional micelles may interact or bind to two different polymer strands. This kind of network formation also dramatically increases the effective molecular weight and friction coefficient of the polymer, as it introduces *de facto* cross-linking. This kind of cross-linking can also lead to the formation of gels at concentrations far below where the polymer would gel on its own.

A particularly interesting kind of sol–gel–sol sequence has been reported by Bloor *et al* [115] for SDS interactions

with ethyl-(hydroxyethyl)cellulose (EHEC). Below the cac the polymer and SDS are in solution and significant interactions among themselves or with each other are absent. As the cac is passed the SDS nucleates in micelles around the pendent ethyl groups. A fraction of these micelles attach to two or more pendent groups connecting different polymeric strands and thereby generating a gel network. This network grows with increasing SDS until a maximum number of cross-links are established. Further SDS additions displace some of these micelle–EHEC connections, and gradually dissolve the cross-links to produce another sol state comprising individual EHEC strands containing attached micelles.

C2.4 Organics films (Langmuir-Blodgett films and self-assembled monolayers)

Georg Hähner

C2.4.0 INTRODUCTION

The goal of constructing stable organic molecular architectures with desired properties that modify surfaces independent from their bulk characteristics is of fundamental interest in many areas. Organic chemists have made significant progress over recent years in designing and constructing molecules that have certain desired physical and chemical properties. Assembling such molecules onto surfaces, as well as characterizing and studying the resulting layers, lies at the centre of interest in many laboratories, and a variety of techniques have been employed in order to reach this goal. Ultrathin and especially monomolecular organic films with a high degree of order are of special interest since they open up new fields of research and could establish an organic counterpart to inorganic crystals. Such films play an important role not only in fundamental science, where they often serve as model systems (e.g. for polymers) but also in applied sciences, where they are employed as corrosion inhibitors, lubricants, adhesion promoters and in biosensors, as well as in many other applications.

Inorganic surfaces can be covered with organic molecules by different methods. The Langmuir–Blodgett (LB) and the self-assembly (SA) techniques that are described here both offer the possibility of tailoring the properties of ultrathin organic films to a certain degree. The LB technique is suitable only for a limited number of molecules and substrates and requires special equipment for preparation. It was the first technique that gave chemists a practical method by which to prepare ordered molecular structures on surfaces.

Adsorption from solution, which is most often employed in connection with the SA technique, provides the easiest

route for studying the behaviour of organic molecules. Organic films can be prepared by immersing the inorganic substrates in dilute solutions of the surfactant. However, not all molecules and substrates are appropriate for establishing self-assembled monolayers (SAMs).

Apart from the techniques described in this chapter other methods of organic film formation are vacuum deposition or film formation by allowing a melt or a solution of the material to spread on the substrate and subsequently to solidify. Vacuum deposition is limited to molecules with a sufficiently high vapour pressure while a prerequisite for the latter is an even spreading of the solution or melt over the substrate, which depends on the nature of the intermolecular forces. This subject is of general relevance to the formation of organic films.

Excellent books and review articles covering LB and SA films have appeared recently. The following covers the basics and some selected topics are presented as examples. For a more comprehensive overview and more details on specific topics the reader is referred to the cited literature.

-2-

C2.4.1 LANGMUIR–BLODGETT FILMS

The systematic study of ultrathin and, in particular, monomolecular organic films that are ordered originates from the end of the nineteenth century, and it was at that time when the first truly quantitative studies of amphiphilic (i.e. one end of the molecule is polar and hydrophilic, the other end is hydrophobic) monolayers were made by Pockels [1]. She demonstrated that in the case of amphiphilic molecules such as stearic acid ($C_{17}H_{35}CO_2H$) there exists a unique form of layer at the air–water interface, having a definite ratio of mass of stearic acid to surface area of water on which it resides [2, 3 and 4]. Using these results and the known density of stearic acid, one can deduce a thickness of these layers of about 2.3 nm, which compares well with the modern value of 2.5 nm for the length of such a molecule. Lord Rayleigh suggested that these films were monolayers and thus gave a direct measure of molecular dimensions [5]. Subsequent work showed that only amphiphilic molecules form good monolayers whereas simple aliphatic ones do not [6].

In 1917, Langmuir published his systematic study of amphiphilic compounds at the air–water interface [7]. In 1920, he mentioned the transfer of films from this interface to a solid substrate [8]. In 1935 K Blodgett published an extensive report on the deposition of mono- and multilayers of fatty acids on a solid substrate from films existing at the air–water interface [9]. In the following 30 years a number of publications appeared dealing with the properties of such films. The term *Langmuir–Blodgett* films (LB films) is usually employed to denote mono- or multilayers transferred from a liquid–gas interface onto a solid substrate. The molecular film at the (liquid–gas) interface itself is denoted a *Langmuir* film.

C2.4.1.1 PREPARATION OF LB FILMS

(A) LB MOLECULES (AMPHIPHILES)

It is well known from everyday life that there are substances that dissolve in water and others that are insoluble. Many salts, for example, are soluble in water, while lipids are not. However, the latter are soluble in nonpolar solvents, such as CCl_4 . This is due to the different interactions between the solvent and the solute. Materials that ‘like’ water (i.e. polar ones) are called hydrophilic, while those which do not like water are called hydrophobic. An amphiphile is a molecule that is not soluble in water, but has a hydrophilic and a hydrophobic end group (figure C2.4.1). Therefore one end goes into water while the other points out, resulting in a spreading of the material on the water surface. A typical example is stearic acid ($C_{17}H_{35}CO_2H$), where the long hydrocarbon chain is hydrophobic while the carboxyl group ($-COOH$), which can dissociate in water and become negatively charged, is hydrophilic.

-3-

Figure C2.4.1. Schematic diagram of a fatty acid with a hydrophilic (COO^-) and a hydrophobic end group (CH_3) (left) and of an amphiphile in general (right).

(B) TROUGH

The basic equipment for the preparation of LB films is a trough containing the subphase on which the compound is spread and which is equipped with barriers in order to manipulate the film at the liquid–gas interface ([figure C2.4.2](#)). Both the trough and the barrier are frequently made out of Teflon. This material is very inert and can be cleaned with strong oxidizing materials without any damage. The movable barrier allows the pressure exerted on the film to be controlled. All movements are performed by a motor. The substrate can be lowered and raised by means of another motor with a gearbox in order to transfer the film from the interface onto the substrate (see *(e)* below). The balance used to measure the pressure in the film is most often a so-called Wilhelmy plate. Discussion of methods for surface pressure measurements can for example be found in [10]. The full automatization and computerization for the preparation of monomolecular and multilayer films started in the early 1970s [11].

Figure C2.4.2. Schematic sideview of the trough. The movable barrier is used to push the molecules on the subphase together in the Langmuir film which is subsequently transferred to a solid substrate.

Demand for temperature controlled troughs came from the material scientists who worked with large molecules and polymers that establish viscous films. Such troughs allow a deeper understanding of the distinct phases and the transitions in LB films and give more complete pressure–area isotherms (see (d) below).

In general, extreme care has to be taken when LB films are prepared, since the quality of the resulting films depends crucially on the preparation conditions. The best place for an LB trough is a laboratory where the surroundings, i.e. temperature, humidity and atmosphere, are completely controlled. Often it is placed in a laminar flow box. Also, the trough should be installed in a shock-free environment.

(C) SUBPHASE

The most often used subphase is water. Mercury and other liquids [12], such as glycerol, have also occasionally been used [13, 14]. The water has to be of ultrapure quality. The pH value of the subphase has to be adjusted and must be controlled, as well as the ion concentration. Different amphiphiles are differently sensitive to these parameters. In general it takes some time until the whole system is in equilibrium and the final values of pressure and other variables are reached. Organic contaminants cannot always be removed completely. Such contaminants, as well as ions, can have a harmful influence on the film preparation. In general, all chemicals and materials used in the film preparation have to be extremely pure and clean.

(D) PRESSURE–AREA (Π –A) ISOTHERM

A drop of a dilute solution (1%) of an amphiphile in a solvent is typically placed on the water surface. The solvent evaporates, leaving behind a monolayer of molecules, which can be described as a two-dimensional gas, due to the large separation between the molecules (figure C2.4.3). The movable barrier pushes the molecules at the surface closer together, while pressure and area per molecule are recorded. The pressure–area isotherm yields information about the stability of monolayers at the water surface, a possible reorientation of the molecules in the two-dimensional system, phase transitions and changes in the conformation. While being pushed together, the layer at

the water surface goes through different states: gaseous, liquid and solid. If the pressure is increased further, the layer collapses due to mechanical instabilities. This collapse is detected as a sharp decrease in the pressure. This break-down pressure is a function of temperature, pH, the subphase and the velocity with which the barrier moves.

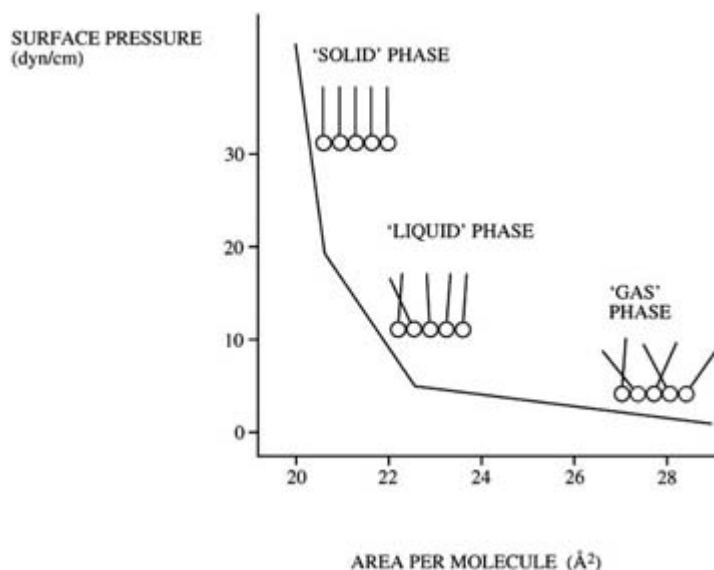

Figure C2.4.3. Pressure–area isotherm for a fatty acid. The molecules are in a gaseous, liquid or solid state, depending on the area per molecule available. If the pressure is further increased, a mechanical instability occurs and the film breaks down.

(E) FILM TRANSFER

Vertical deposition. The conventional method of transferring films from the air–water interphase onto a solid substrate is vertical deposition, which was demonstrated by Langmuir and Blodgett ([figure C2.4.4](#)). They showed that a monolayer of an amphiphile can be transferred to a substrate by moving a vertical plate through the film at the water–air interface. During transfer the Langmuir monolayer is held at constant surface pressure. The transfer process itself has not yet been fully understood, although it is known that there is a critical velocity above which it does not work. The effects of various parameters, such as viscosity, on the critical velocity have been investigated [[15](#)].

Figure C2.4.4. Schematic diagram of the transfer process of LB films onto a hydrophilic substrate. Vertical upward and downward strokes result in hydrophobic and hydrophilic surfaces, respectively.

If a substrate is moved through a monolayer at the water–air interface, a film can be deposited by both dipping the substrate into the water and retracting it. Usually the film is transferred while retracting, if the substrate is hydrophilic and the hydrophilic headgroups are interacting with the surface. On the other hand, if the substrate is hydrophobic, the film is transferred while dipping, as the hydrophobic alkyl chains interact with the surface. Thus, multilayers can be prepared by several subsequent transfer processes. If the transfer process starts with a hydrophilic substrate the surface will be hydrophobic after the first film transfer, hydrophilic after the second one and so on. This transfer mode is called Y-type deposition, resulting in multilayers with ‘head to head’ and ‘tail to tail’ configurations of the layers. Films can, however, also be transferred only in downstroke mode resulting in so-called X-type layers (‘head to tail’ configuration) or in upstroke mode only resulting in Z-type layers (‘tail to head’ configuration). The different transfer modes have specific advantages and disadvantages—in general, the Y-type (multi)layers are the most stable ones for very hydrophilic headgroups [16].

Horizontal transfer (Schaefer’s method). Another technique to prepare structures with LB (multi)layers is named after Schaefer [17]. This method is useful for depositing rigid films which can be described as two-dimensional solids. First, a compressed monolayer is established at the water–air interface. Subsequently a flat substrate is brought horizontally into contact with the film (figure C2.4.5). When the substrate is lifted and separated from the water surface a monolayer is transferred to the substrate while (theoretically) maintaining the molecular order.

Figure C2.4.5. Horizontal transfer on a hydrophobic substrate. This method is useful for very rigid films that are in the 'solid state' in the π -A-diagram.

(F) SUBSTRATES

Monolayers can be transferred onto many different substrates. Most LB depositions have been performed onto hydrophilic substrates, where monolayers are transferred when pulling the substrate out from the subphase. Transparent hydrophilic substrates such as glass [18, 19] or quartz [20] allow spectra to be recorded in transmission mode. Examples of other hydrophilic substrates are aluminium [21, 22, 23 and 24], chromium [9, 25] or tin [26], all in their oxidized state. The substrate most often used today is silicon wafer. Gold does not establish an oxide layer and is therefore used chiefly for reflection studies. Also used are silver [27], gallium arsenide [27, 28] or cadmium telluride wafer [28] following special treatment.

C2.4.2 EXAMPLES OF LB FILMS

(A) FATTY ACIDS

LB films of fatty acids are still studied today, particularly by those researchers who are interested in the basic physics of the subject. The literature on this topic is very extensive. The study of such films by means of x-ray diffraction revealed that the order of LB films in the direction normal to the substrate and of the lattice planes is extremely good. This fact was initially responsible for the widespread enthusiasm for the study of LB films. Structural aspects of such films are discussed in detail in the review article by Schwartz [29]. A number of authors have found that long-chain fatty acid (and fatty acid salt) LB monolayers deposited on a variety of hydrophilic substrates and under a variety of conditions adopt a hexagonal packing with the chain normal to the surface (untilted) on average [29] and short-range translational order. However, there are exceptions, such as calcium arachidate (CaA_2), which is tilted by 20–30° from the normal on Si oxide [29, 30 and 31]. Also LB monolayers of phospholipids often display hexagonal packing of the chains [29]. However, in most cases multilayers display different packing from that of monolayers [29]. They are typically packed in a crystalline rectangular or triclinic lattice and in most cases the transition from monolayer to

bulk structure is abrupt [29]. Techniques that can give direct information on in-plane order in LB films are electron diffraction and polarized-light optical microscopy [28, 29].

In most cases, once a two-dimensional structure has been established, it will propagate through the film as further layers are deposited [32]. It has been suggested that disclination structures that can be found in the resulting films exist already at the water–air interface [33] and are transferred to the substrate in the initial layer. It has also been proposed that annealing of the film at the water–air interface can greatly reduce the density of disclinations so that subsequent multilayers will also contain a low disclination density [34]. It is supposed that the regions immediately associated with the disclinations are responsible for electron conduction through the film.

Electron tunnelling through monolayers of long-chain carboxylic acids is one aspect of interest since it was assumed that such films could be used as gate electrodes in field-effect transistors or even in devices depending on electron tunnelling [24, 26, 35, 36, 37 and 38]. It was found, however, that the whole subject depends critically on

the materials involved, especially on the metal used as substrate and electrode. It seems that conduction through monolayers can be best understood by conduction through defects [39, 40, 41 and 42]. In addition to the defects due to disclinations on a small scale, there will be fluctuations in the distances between molecules on a somewhat larger scale.

Apart from fatty acids, straight-chain molecules containing other hydrophilic end groups have been employed in numerous studies. In order to stabilize LB films chemical entities such as the alcohol group and the methyl ester group have been introduced, both of which are less hydrophilic than carboxylic acids and are largely unaffected by the pH of the subphase.

New factors for the establishment of multilayer structures are, for example, the replacement of the hydrocarbon chain by a perfluorinated chain and the use of a subphase containing multivalent ions [29]. The latter can become incorporated into an LB film during deposition. The amount depends on the pH of the subphase and the individual ion. The replacement of the hydrocarbon by a rodlike fluorocarbon chain is one way to increase van der Waals' interaction and therefore enhance order and stability in molecular assemblies [43].

Remarkably, such fluorocarbon monolayers show higher friction than their hydrocarbon counterparts [44], although fluorocarbons are known to have the lowest surface free energy of all organic materials.

Mechanical stability. The LB technique can be used to force the ordering of long-chain molecules. They are forced to order on a liquid subphase and are subsequently transferred to a solid substrate. Although order in these materials can be high, achieving this is a potentially non-equilibrium and difficult procedure. The monolayer-substrate bond is often weak (either van der Waals or hydrogen-bond interactions); as a result, the assemblies are not very mechanically or thermally stable [45, 46]. Stable and high-surface-free-energy monolayers are difficult to prepare with this technique. The mechanical stability of a variety of systems, mainly arachidic ones, has been investigated with the atomic force microscope. Details and references can be found in the review article by Schwartz [29].

Thermal stability. For applications of LB films, temperature stability is an important parameter. Different techniques have been employed to study this property for mono- and multilayers of arachidate LB films. In general, an increase in temperature is connected with a conformational disorder in the films and above 390 K the order present in the films seems to vanish completely [45, 46 and 47]. However, a comprehensive picture for order-disorder transitions in mono- and multilayer systems cannot be given. Nevertheless, some general properties are found in all systems [47]. *Gauche* conformations mostly reside at the ends of the chains at room temperature, but are also present inside the

films at higher temperatures. The energy connected with a *gauche* conformation in a densely packed film of calcium arachidate (CaA_2) was found to be more than an order of magnitude higher compared to the liquid state [48].

(B) RODLIKE STRUCTURES WITH CYCLIC GROUPS

In addition to the rodlike molecules described above, amphiphiles, which consist of a rodlike structure containing a cyclic group near its centre, have also been studied. Of great interest here are materials containing both the azobenzene and the stilbene structure (figure C2.4.6) [49]. Interestingly, these are extended conjugated structures involving two rings and are thus constrained to remain approximately in the same plane (*trans* configuration). There are, however, *cis* conformations for both molecules. The reversible change between the two conformations by an irradiation are connected with different absorption spectra. This so-called photo-chromic effect is interesting because of potential applications, for example, in recording media. Materials containing modifications of these groups have been employed in devices intended to generate optical second harmonics. Studies of amphiphilic materials containing these groups are for example described in [50, 51, 52, 53 and 54].

Figure C2.4.6. Azobenzene structure modified with hydrocarbon chains [53, 54].

-10-

Success of depositing compounds where an 18-carbon chain was attached to one end of an azobenzene group and various different hydrophilic groups attached to the other end has been reported in X and Z mode [52] and piezo- and pyroelectric effects were demonstrated.

Many workers have used the *cis-to-trans* structural change referred to above and brought about by UV irradiation to change some physical parameter of the LB films formed from azobenzene derivatives [55, 56, 57, 58, 59 and 60].

(C) PORPHYRINS AND PHTHALOCYANINES

The porphyrin is one of the most important among biomolecules. It is involved in the fundamental processes of life, such as oxygen transfer and storage, electron transfer, and synthesis of amino acids [61]. Phthalocyanine is a very stable, planar, synthetic aromatic macrocycle. The basic porphyrin and phthalocyanine structures are shown in [figure C2.4.7](#). In the case of porphyrins the positions bearing numbers are capable of having various groups attached to them, though many of these positions are usually occupied by hydrogen. In the case of phthalocyanine, groups can be attached to the periphery of the benzene rings. Both molecules have a planar structure and a number of relatively low-lying excited states. Due to the latter property, it seems likely that interesting devices could be made from films in which derivatives of these materials are incorporated, which has led to great interest in these compounds. In addition the structures are extremely stable. Porphyrins, for example, can survive the fractioning process applied to petroleum and the phthalocyanine group is stable to 400°C [62]. Both materials can be complexed with divalent metals, which reside at the centre of the ring.

LB films of porphyrin and phthalocyanine derivatives can be made in different ways.

Molecules that have been rendered amphiphilic are deposited in the Y mode so that the planes of the molecules are nearly vertical with respect to the film plane. In the mid-1980s it was shown that certain derivatives of porphyrin can be used to obtain good Y layers [63, 64 and 65]. On another derivative electron diffraction studies led to the conclusion that films consist of crystallites formed from tilted molecules [66]. It seems likely that all these materials rearrange after deposition to form many small crystallites, which do not have crystal planes corresponding to the original LB planar structure.

In some cases it has been possible to prepare LB films from porphyrin and phthalocyanine containing fourfold symmetry. However, it is not entirely clear how such materials can be deposited by the LB technique. A number of studies deals with LB films made of non-amphiphilic phthalocyanines. However, it is very difficult to form LB films from symmetric porphyrins [67]. True LB deposition of such compounds leads to an edge-on structure, whereas related techniques can lead to a structure in which the molecular planes lie parallel to the substrate [68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78 and 79].

Another possibility is that the ring structure may have long hydrocarbon chains attached at the corners so that they stand up at one side. These chains provide the hydrophobic component and the polarizable ring structure provides the hydrophilic moiety. There are studies with porphyrins bearing four long hydrocarbon chains and whose hydrophilic moieties are associated with the ring structure [80, 81]. However, these materials did not lead to the formation of ordered multilayers. The same general principle applied to phthalocyanines led to stable films at the water–air interface and could produce multilayers by the LB technique [82, 83].

-11-

Figure C2.4.7. Porphyrin (a) and phthalocyanine (b) structures.

In summary, a vast number of materials has been used to form LB films. However, in the majority of cases an effort to characterize the film structure or even to show that a regular layer structure has been achieved is lacking. Work on the structure of films of disc-like molecules such as porphyrins and phthalocyanines is especially limited. Some references can be found in [29].

(D) MORE COMPLEX STRUCTURES (POLYMERS)

The generally low chemical, mechanical and thermal stability of LB films hinders their use in a wide range of applications. Two approaches have been studied to solve this problem. One is to spread a polymerizable monomer on the substrate and to polymerize it either before or following transfer to the substrate. The second is to employ preformed polymers containing hydrophilic and hydrophobic groups.

LB films made of more complex structures such as polymers can be divided into different classes [84].

-12-

(E) POST-FORMED POLYMERS FROM MONOMERS CONTAINING ONE OR MORE DOUBLE BONDS

These are systems in which multilayer structures are formed from molecules containing one or more double bonds and in which polymerization is subsequently initiated by appropriate means such as electron beam or UV light exposure.

A study of polymerization after deposition is of interest to polymer chemists since it is possible to arrange the monomers so that the polymerizable groups are adjacent to one another and to monitor changes in film structure arising from polymerization. The system under investigation is thus under control to a large degree. The first work published on this was upon multilayers of vinyl stearate and subsequent polymerization by γ -rays [85]. Under appropriate conditions a high level of polymerization was observed.

Polymerization of compounds performed with UV light was first reported in the 1970s [86] and was followed by further studies [87, 88 and 89]. Another study was concerned with the deposition and polymerization of multilayers of alcohols and acids incorporating the diene group, $-\text{CH}=\text{CH}-\text{CH}=\text{CH}-$, at the hydrophilic end of the molecule [90].

Other investigations dealt with straight-chain molecules (ω -tricosenoic acid) in which the penultimate and final carbon atoms at the hydrophobic end are connected by a double bond [91, 92]. The material does not polymerize as rapidly as those described before when irradiated by UV light, however, but it is readily polymerized when bombarded with an electron beam. It was thus thought to be an optimal material for the fabrication of electron beam resists.

The deposition and photo-polymerization of relatively complex amphiphilic compounds having two hydrophobic chains attached to a single hydrophilic headgroup have also been studied [93, 94]. This work is in the direction of materials for forming stable bio-compatible coatings for artificial organs, the most important outcome being the formation of stable multilayers having a hydrophilic outer surface.

(F) DIACETYLENES

Similar systems to those mentioned above exist where the constituent monomer contains the diacetylene group.

A summary of the studies performed on symmetrical compounds having a diacetylene group at the centre is given in [94]. Most of the materials studied in the context of LB films have been diyonic acids (figure C2.4.8).

Figure C2.4.8 Diacetylene structure employed to prepare polymeric LB films (a) and principle in diacetylene polymerization (b).

If these materials are deposited as LB multilayers, polymerization can be induced either by thermal or optical means. This subject has been intensively studied [95, 96, 97, 98 and 99]. Since parameters such as m , subphase components, pH and polymerization before and after dipping, as well as temperature and wavelength employed for polymerization can be varied, the literature on diacetylenes is extensive and the reader is referred for example to the book of Tredgold [100].

(G) PREFORMED POLYMERS

Mono- and multilayers may be formed by the LB technique from polymers bearing both hydrophilic and hydrophobic side groups that are already spread as a polymer at the water–air interface.

Unwanted structures in the film plane—often found within LB films formed from simple rodlike molecules or from molecules polymerized after deposition—can be problematic, since many possible applications of such films require a uniform structure within the plane. On the other hand, however, the production of a system in which the structure within the plane is so disordered that there exist no structural features large enough to cause problems would also render applications possible. In three-dimensional materials, for example, both inorganic glasses and many polymers are capable of transmitting light without any appreciable scattering for substantial distances.

Studies of the waveguiding of light in multilayers of certain polymers showed that it is possible to propagate light with an attenuation that is still large compared to many other materials but small compared to other LB materials [101].

Another approach to the fabrication of LB films from preformed polymers is to form a hydrophobic main chain by reacting monomers terminated by a vinyl group [102, 103, 104, 105 and 106]. The side groups studied also included perfluorinated hydrocarbon chains, which tilt with respect to the normal to the plane of the film, whereas the analogous ordinary hydrocarbon chains do not [105].

Other polymers, such as polymethacrylates, have been studied, as well as esters of naturally occurring polysaccharides. References can be found in the literature cited in the list of further reading.

(H) RIGID-ROD POLYMERS

Finally, rigid-rod polymers can be deposited on a solid substrate by the LB technique. These materials have both

hydrophilic and hydrophobic characteristics, and are capable of residing with the rod axis horizontal at the water–air interface.

The polymers described so far have relatively flexible main chains which can result in complex conformations. In some cases, they can double back and cross over themselves. There are also investigations on polymers which are constrained to remain in a conformation corresponding, at least approximately, to a straight line, but which have amphiphilic properties that ensure that this line is parallel to the water surface. Chiral molecules are one example and many polypeptides fall into this class [107]. Another example is cofacial phthalocyanine polymers (figure C2.4.9).

Figure C2.4.9. Part of a bridge-stacked polyphthalocyanine.

The species at the centre of the rings is usually Si or Ge and the bridging atom is oxygen. In one study the peripheral hydrogens on the phthalocyanine molecules were replaced by alkyl groups and the resulting polymers could be rendered soluble in ordinary organic solvents [108, 109 and 110]. Successful deposition of several of these materials has been achieved and different techniques were employed to study their structural properties [109, 111, 112, 113 and 114].

The variety of molecules used to prepare LB films is enormous, and only a small selection of examples can be presented here. Liquid crystals and biomolecules such as phospholipids, for example, can also be used to prepare LB films. The reader is referred to the literature for information about individual species.

C2.4.2 SELF-ASSEMBLED MONOLAYERS (SAMS)

Self-assembled monolayers (SAMs) are molecular layers that form spontaneously upon adsorption by immersing a substrate into a dilute solution of the surface-active material in an organic solvent [115]. This is probably the most comprehensive definition and includes compounds that adsorb spontaneously but are neither specifically bonded to the substrate nor have intermolecular interactions which force the molecules to organize themselves in the sense that a defined orientation is adopted. Some polymers, for example, belong to this class. They might be attached to the substrate via weak van der Waals' interactions only.

Most often the term SA is used in connection with compounds that attach strongly to the substrate and/or have significant intermolecular interactions. Order, orientation and stability in SA systems depend crucially on the compound involved. For establishing a lateral translational order the anchoring to the substrate and/or the intermolecular interactions are important. A highly ordered substrate, for example, may induce a high translational order if there is strong coupling between headgroups and substrate. This is, for example, the case for the alkyl thiol–gold system (see below).

The so-called self-assembly technique has its origin in 1946, when a paper was published by Bigelow *et al* [116] and thus is slightly younger than the LB technique. The authors noted that a hydrophilic surface exposed to an amphiphilic compound dissolved in a non-polar solvent induces the amphiphilic material to form a monolayer on it.

This idea was later extended to form multilayers by synthesizing a material with a hydrophilic group at one end and a further hydrophilic group, masked by a hydrophobic blocking group, at the other. After deposition on a hydrophilic surface by the technique introduced by Bigelow *et al*, the blocking groups are removed by a chemical reaction, revealing a further hydrophilic surface. Then the whole process can be repeated, which, in principle, should be capable of providing a simple way to produce ordered multilayers. In practice, however, there are many difficulties.

In the 1980s the study of SAMs was sparked by the use of octadecyltrichlorosilane (OTS) for film formation on silica surfaces [117] and by the investigation of dialkyldisulphide layers on gold [118], prepared by immersion of the substrates in diluted solutions of the surfactants. Higher-quality films on gold were obtained by the adsorption of structurally analogous alkyl thiols [119, 120]. These experiments initiated an avalanche of investigations with a plethora of SA systems, among which thiols on gold is the most intensively investigated combination to date.

C2.4.2.1 SA MOLECULES

Not all molecules are suited for establishing SAMs. The majority of cases studied have involved assembly of alkyl-chain-based entities. The molecules of self-organizing chemical compounds all have a similar structure. The spontaneous nature of film formation is due to the interaction energies of the monolayers. These can be considered in terms of three main components (figure C2.4.10) [121], which cooperatively establish stability, order and orientation in the monolayer.

-16-

Figure C2.4.10. Schematic diagram of a self-assembling molecule.

The first part is the headgroup, which is responsible for the bonding to the substrate surface, which may be by chemisorption or physisorption.

In the case of chemisorption this is the most exothermic process and the strong molecule substrate interaction results in an anchoring of the headgroup at a certain surface site via a chemical bond. This bond can be covalent, covalent with a polar part or purely ionic. As a result of the exothermic interaction between the headgroup and the substrate, the molecules try to occupy each available surface site. Molecules that are already at the surface are pushed together during this process. Therefore, even for chemisorbed species, a certain surface mobility has to be anticipated before the molecules finally anchor. Otherwise the evolution of ordered structures could not be explained.

The spontaneous adsorption brings the molecules close enough together that intermolecular interactions become important; these—in the case of alkyl-chain-based molecules—consist of the short-range van der Waals’

interaction. The chains constitute the second part of alkane-based self-organizing molecules. If the molecules are densely packed in the final layer they are forced to stretch and are in a nearly all *trans*-configuration for sufficiently long chains at room temperature [122].

The self-organizing process of the amphiphilic alkane chains would not be possible solely due either to the interaction between the chains or the bonding of the molecules to the substrate. In fact it is a cooperative process of both factors and there are limiting cases where one or the other dominates. In the case of alkanethiols the first and, as mentioned earlier, the most important process, is chemisorption. The establishment of a well ordered and densely packed layer is only possible following the anchoring of molecules at the surface sites. Van der Waals' forces are the most important *intermolecular* interactions in the case of simple alkane chains. By substitution of the methylene groups in the chain by larger polar groups, long-range electrostatic interactions can also play a significant role and can become energetically more important than the short-range van der Waals' interactions.

-17-

If the coupling to the substrate is weak (physisorption), as is the case for alkylsiloxanes on a SiO_x surface in the presence of a water layer, for example, the packing may also be mainly driven by intermolecular forces. Stability in this system is provided by crosslinking between the molecules (see below).

The third part is the interaction between the terminal functionality, which in the case of simple alkane chains is a methyl group ($-\text{CH}_3$), and the ambient. These surface groups are disordered at room temperature as was experimentally shown by helium atom diffraction and infrared studies in the case of methyl-terminated monolayers [122]. The energy connected with this conformational disorder is of the order of some kT .

This third part can be substituted by a functional group, a small fragment or even a polymer, where alkanethiols are only used to attach the whole compound to the surface. This potential makes compounds modified with SA molecules attractive in a whole variety of areas and technologies.

C2.4.2.2 PREPARATION OF SAMs

In contrast to the preparation of LB films, that of SAMs is fairly simple and no special equipment is required. The inorganic substrate is simply immersed into a dilute solution of the surface active material in an organic solvent (typically in the mM range) and removed after an extended period (~24 h). Subsequently, the sample is rinsed extensively with the solvent to remove any excess material (wet chemical preparation).

Preparation of films for sufficiently volatile molecules can also be performed by evaporating the molecules in vacuum (gas-phase deposition) or by the use of a desiccator which contains the substrate and the dilute solution in a vessel separately and which is evacuated to 0.1 mbar and kept under vacuum for several hours (~24 h). This also results in a vapour-phase-like deposition of the molecules onto the substrates.

C2.4.2.3 EXAMPLES OF SAMs

A plethora of different SA systems have been reported in the literature. Examples include organosilanes on hydroxylated surfaces, alkanethiols on gold, silver, copper and platinum, dialkyl disulphides on gold, alcohols and amines on platinum and carboxyl acids on aluminium oxide and silver. Some examples and references can be found in [123]. More recently also phosphonic and phosphoric esters on aluminium oxides have been reported [124, 125]. Only a small selection out of this number of SA systems can be presented here and properties such as kinetics, thermal, chemical and mechanical stability are briefly presented for alkanethiols on gold as an example.

The molecules for SA monolayers are chosen or synthesized according to the substrate that should be coated. Thiol-terminated entities have been mostly used in connection with metal surfaces, but also on GaAs [126]. Chloro- and acid-terminated molecules are most often employed on oxide surfaces of metals or semiconductors. However, they have also occasionally been used with metal surfaces [127].

(A) MONOLAYERS FORMED FROM ACIDS

The first work published in this area was that of Bigelow mentioned above [116]. In 1957, monolayers of long-chain fatty acids were formed on thin films of silver, copper, iron and cadmium deposited on glass microscope slides [43].

-18-

Finally, in 1985, the results of an extensive investigation in which adsorption took place onto an aluminium oxide layer formed on a film of aluminium deposited *in vacuo* onto a silicon wafer was published by Allara and Nuzzo [127, 128]. Various carboxylic acids were dissolved in high-purity hexadecane and allowed to adsorb from this solution onto the prepared aluminium oxide surface. It was found that for chains with more than 12 carbon atoms, chains are nearly in a vertical orientation and are tightly packed. For shorter chains, however, no stable monolayers were found. The kinetic processes involved in layer formation can take up to several days.

More recently, alternative chemistries have been employed to coat oxide surfaces with SAMs. These have included carboxylic [129, 130], hydroxamic [131], phosphonic [124, 132] and phosphoric acids [133]. Potential applications of SAMs on oxide surfaces range from protective coatings and adhesive layers to biosensors.

(B) SILANES

Organosilanes, such as trichlorosilanes or trimethylsilanes, can establish SA monolayers on hydroxylated surfaces. Apart from their (covalent) binding to the surface these molecules can also establish a covalent intermolecular network, resulting in an enhanced mechanical stability of the films (figure C2.4.11). In 1980, work was published on the formation of SAMs of octadecyltrichlorosilane (OTS) [117]. Subsequently, the use of this material was extended to the formation of multilayers [134].

Figure C2.4.11. The formation of SAMs from OTS on a silicon oxide substrate.

Although it has been claimed in the literature that well defined and organized films have been achieved, there is still some debate about the quality of these systems. It has been suggested that the assembly mechanism of chlorosilanes on oxidized surfaces depends very crucially on the processing conditions involved. The assembling process shows an interesting dependence on pre-hydration and temperature [135], suggesting that water plays a central role. The stability in the films seems to be mostly due to the intermolecular network and not to the bonding to the substrate. This is supported by the observation that organized films are established on amorphous substrates.

-19-

Apart from these simple silanes, derivatives with aromatic groups at different places in the chain have also been investigated [136, 137]. It was found that the average tilt angle of these molecules depends on the specific functional entities contained in the chains. It is likely that apart from packing considerations—important for bulky groups, for example—other factors also influence the resulting tilt.

(C) THIOLS

In 1983, it was shown that certain sulphur compounds have a strong affinity to gold and bind strongly to a gold surface [118]. This led to considerable interest and activity in the study of SAMs of sulphur compounds on gold and today alkyl thiols on gold are the most extensively studied SA system. Although ethanol has been most frequently used as a solvent, however, other liquids have also been employed [122]. Polycrystalline gold substrates prepared by thermal evaporation predominantly display the (111) face [138, 139, 140, 141 and 142], which has the lowest surface energy [138]. Most of the work cited in the following has been performed on such surfaces.

Monolayers of alkanethiols adsorbed on gold, prepared by immersing the substrate into solution, have been characterized by a large number of different surface analytical techniques. The lateral order in such layers has been investigated using electron [143], helium [144, 145] and x-ray [146, 147] diffraction, as well as with scanning probe microscopies [122, 148]. Information about the orientation of the alkyl chains has been obtained by ellipsometry [149], infrared (IR) spectroscopy [150, 151] and NEXAFS [152].

The systematic study of alkanethiols ($\text{CH}_3(\text{CH}_2)_n\text{-SH}$) with different chain lengths revealed that for $n = 11$ or greater closely packed layers are obtained with a tilt angle of the alkyl chains between 30 and 35° from the surface normal and with an area per molecule of approximately 21.4 \AA^2 [122]. For $n < 11$, there is a gradual deterioration in order with decreasing length. It is generally accepted that adsorption takes place by elimination of the terminal hydrogen and that the thiol is bound to the gold by a true valence bond [122]. In contrast to chlorosilanes on oxidized substrates, alkanethiols establish a superlattice on gold and much of their stability is due to the anchoring of the molecules to the substrate.

There is a controversy about the bonding state of the sulphur. Most evidence suggests that it is bound in the form of a thiolate [122], while x-ray diffraction suggests that the sulphur atoms may dimerize [147]. However, not all of the observed overstructures can be explained with this latter assumption.

The growth and the structure of fully developed alkanethiol films on gold have been extensively investigated with STM [153, 154, 155, 156 and 157]. This work has confirmed that four phases exist in the final layer. There is a basic hexagonal lattice corresponding to the superlattice established by the sulphur atoms and three variants of a rectangular lattice, which was experimentally observed in the organization of the chains in long-chain ($>\text{C}_{12}$) thiolate monolayers on Au(111). The rectangular lattices are due to different twist angles of the chains around their axis [148].

The domain size in alkanethiol films on gold depends on the concentration used during preparation and is typically between 10 and 50 nm [158]. Thiol monolayers on gold have long-range angular order but quite short-range radial order. This can be explained in terms of tightly packed tilted molecules.

Order and dense packing are relative in the context of these systems and depend on the point of view. Usually the term order is used in connection with translational symmetry in molecular structures, i.e. in a two-dimensional monolayer with a crystal structure. Dense packing in organic layers is connected with the density of crystalline polyethylene.

Self-organizing monolayers are highly disordered compared to inorganic crystals, due to the defects that are always present. On the other hand, when compared to polymeric glasses or liquid paraffin, they are highly ordered systems. Hence, the terms order and densely packed in this context do not imply the absence of defects. The degree of order is comparable to that of Langmuir–Blodgett layers.

Apart from domain boundaries, some of the defects in alkanethiol monolayers (pitholes) are created by the thiol itself [159] by 'etching' processes. It was found that the solvent used for preparation also has some effect on the resulting defect density.

In contrast to the gold surface, on silver the chains adopt a lower tilt angle of 12° from the surface normal [160, 161]. This is attributed to the different nature of the bonding of sulphur to silver as compared to gold and the slightly different packing density. The coherence length determined with He atom diffraction was found to be 12 nm [162].

GaAs has been coated with thiols with a view to modifying devices [123]. For these films, S–As bonds are presumed to be present. An ordering of the chains for $n = 18$ has been reported. However, this system has generally been much less investigated than those involving metal substrates.

The lubricant properties of alkanethiols and fluorinated alkanes have been studied extensively by scanning probe techniques [163]. In agreement with experiments on LB monolayers it was found that the fluorocarbon monolayers show considerably higher friction than the corresponding hydrocarbon monolayers [164, 165 and 166] even though the fluorocarbons are known to have the lowest surface free energy of all organic materials.

Kinetics of film formation. The kinetics of film formation of SAMs is important, in order to establish a recipe that allows films of reproducible quality to be prepared, i.e. densely packed, well ordered monolayers. Ellipsometry and contact-angle measurements can give information about coverage and orientation present in the films. In general it has been reported that film formation is a two-step process, at least for dilute solutions (~ 1 mM). A fast first step where the contact angles and film thickness are already close to their limiting values (minutes) is followed by a second slower step, after which the final values are reached [120]. It was also shown that the order is established during this second step, where the last 5–10% of molecules are incorporated into the film and force the molecules on the surface to stretch [167]. For different chain lengths and solvents it was found that only Langmuir kinetics can explain the experimental data of thiolate films on polycrystalline gold, irrespective of the experimental conditions [168].

Lateral structuring of SAMs—microcontact printing. Of great interest is the application-specific chemical structuring of ultrathin organic films, for example for use in biomedical devices. Such structuring can be accomplished by lithographic means, including the so-called microcontact printing technique (μ CP) [169, 170 and 171]. This is a relatively simple technique and allows lateral patterning down to submicrometre scale. It is also known as soft-lithographic patterning. In short, a structured stamp made of poly(dimethylsiloxane) (PDMS) is inked with the diluted solution and brought into contact with the substrate (figure C2.4.12). Patterns with dimensions in the (sub) micrometre range can routinely be produced by this technique [172]. Although the contact time between stamp and surface is of the order of only 10–20 s, the resulting films of alkanethiols on gold are chemically not distinguishable from those prepared by immersion. Remarkably, even the order in areas that are prepared by μ CP is comparable to that in films prepared by immersion [173]. However, with lateral force microscopy, regions prepared by immersion can be distinguished from those prepared by μ CP [173, 174]. This is probably due to slightly different domain size distributions and thus different mechanical stabilities of the films on a nanometre scale [173].

Figure C2.4.12. Principle of the microcontact printing process. Chemically patterned organic films with differently functionalized regions can be prepared by a combination of μCP and subsequent immersion.

Other lithographical means include micromachining [175], photopatterning [176] or electron beam patterning [177], which have been demonstrated on alkanethiolate/Au SAMs, alkanethiolate and organo-siloxane on Si and Ti and alkanethiolates on GaAs.

Chemical stability. The chemical stability of SA films is of interest in many areas. However, there is no general rule for it. The chemical stability of silane films is remarkable, due to their intermolecular crosslinking. Therefore, they are found to be more stable than LB films. Alkyltrichlorosilane monolayers provide structures that are stable to chemical conditions that most LB films could not stand. However, photopolymerized LB films also show considerable stability in organic solvents.

SAMs of thiolates on gold are generally resistant to strong acids or bases [175, 178 and 179], are not destroyed by solvents [180] and can withstand physiological environments [181, 182 and 183]. However, they also show some degradation if exposed to the ambient atmosphere for sufficiently extended periods [184].

Thermal stability. The thermal stability of SAMs is, similarly to LB films, an important parameter for potential applications. It was found that SA films containing alkyl chains show some stability before an increase in the number of *gauche* conformations occurs, resulting in melting and irreversible changes in the film. The disordering of the

chain structure as temperature is increased has been studied for both LB films and SAMs. In general, an all-*trans* structure dominates at room temperature for most of the systems. When the melting point is approached, however, the number of *gauche* defects increases. For thiols with more than 16 carbon atoms it was shown experimentally that *gauche* defects are mainly concentrated near the free ends of the chains [151, 185]. Unlike bulk hydrocarbons, these films do not show a sharp phase transition in the temperature range between 80 and 420 K but rather a gradual change to a progressively more ordered state as the temperature is lowered.

Similarly to LB films, the order of alkanethiols on gold depending on temperature has been studied with NEXAFS. It was observed that the barrier for a *gauche* conformation in a densely packed film is an order of magnitude higher than that of a free chain [48].

SAMs that are made out of structures capable of forming strong intermolecular hydrogen bonds have been studied especially in view of their expected high thermal and chemical stability [186, 187].

A good survey of the chemical and physical film characteristics of highly organized SAMs is given in [123].

Mechanical stability. Chemisorption to the surface, intermolecular interactions and crosslinking between adjacent compounds—if possible—all contribute to the resulting stability of the monolayer film. Lateral force microscopy investigations revealed that the mechanical stability towards lateral forces on the nanometre scale is likely to be determined by the defect density and the domain size on a nano- to micrometre scale [163, 173].

Experiments with chemically grafted SAMs displayed much larger wear resistance than films produced by the LB technique [188]. Also it was found that wear properties of SAMs can be further improved by chemically grafting C₆₀ molecules onto SAM surfaces [189].

(D) ALKANETHIOLS WITH FUNCTIONAL ENTITIES ATTACHED

The strong bond formed between the thiol endgroups and gold and silver surfaces allows the possibility of forming molecules that have a wide variety of different functional groups at the opposite end and thus of coating a noble metal surface with a variety of differently functionalized molecules and mixtures.

A large number of studies concerned with thiol-terminated molecules has been directed at the preparation of tailored organic surfaces, since their importance has been steadily increasing in various applications. Films of ω -functionalized alkanethiols have facilitated fundamental studies of interfacial phenomena, such as adhesion [190, 191], corrosion protection [192], electrochemistry [193], wetting [194], protein adsorption [195, 196] or molecular recognition [197, 198, 199, 200 and 201] to mention only a few.

Biological applications are attracting increasing attention and examples from this area are given below. An understanding of the mechanism of protein adsorption, the interaction of proteins with ‘artificial’ substrates and the way in which these interactions determine the biological activity of these substrates are of immense biomedical significance [202, 203, 204, 205 and 206]. SAMs play a particularly important role here, since they can serve as models of polymer surfaces, allowing surface chemical properties to be investigated independent from the effects of surface morphology. In this way, macroscopic concepts such as hydrophobicity, hydrophilicity, wettability and water

content, which are crucial to understanding cell adhesion and anchorage-dependent cell behaviour [207, 208, 209, 210 and 211], can be substituted by more fundamental, molecular-level concepts of surface organization, reactivity and structure. Efforts have been undertaken to engineer gradients of surface hydrophobicity/hydrophilicity on polymeric surfaces [212, 213, 214 and 215] and, more recently, on SAMs prepared from thiols [216].

Hydroxylated surfaces are of particular interest, due to the possibility of derivatizing the –OH groups with biologically active moieties. The spatial arrangement and density of –OH groups within a monolayer matrix are relevant, since they may regulate the accessibility of a specific functional group to biomolecules. One approach to controlling these properties uses mixed chain length CH₃- and OH-terminated alkanethiolate SAMs [216, 217, 218, 219 and 220]. Another approach is a thiol-terminated hexasaccharide with acetyloxy groups that can be replaced by hydroxyl groups, and which was also adsorbed on gold [221] (figure C2.4.13). It was found that deprotection and thus the degree of hydrophilicity can be tailored before as well as following adsorption on the surface. This allows the OH-group density to be adjusted to a high degree and might have advantages over the mixed monolayers, since it can be better controlled.

Figure C2.4.13. Thiol-terminated hexasaccharide, where acetoxy groups can be replaced by hydroxyl groups, both before and following adsorption [221].

In another study, coadsorption of simple *n*-alkanethiols, which acted as a scaffolding, and a synthetic receptor was studied on gold [222]. The design of the system mimics those of receptors bound to lipid membranes.

Poly(ethylene glycol) is often employed to render surfaces protein resistant. Oligo(ethylene glycol)- (OEG-) terminated alkanethiols were adsorbed on Ag and Au and were studied concerning their properties towards protein adsorption [223, 224]. Interestingly, the slight difference in the packing density and chain tilt of the alkane chains on gold and silver leads to a completely different behaviour of the OEG-terminated thiols concerning protein adsorption [223]. While the SAMs on gold are protein resistant, those on silver adsorb a certain amount of fibrinogen.

Regarding protein adsorption properties, differently terminated SAMs on gold have also been investigated [225]. It was found that the nature of the adsorbate chain structure was the most important parameter for the observed behaviour towards protein and cell adsorption.

Covalent immobilization of proteins on microstructured gold surfaces was studied in [226]. On these substrates, which were prepared by μ CP and etching, the immobilization sites of proteins could be spatially controlled using an amino-reactive SAM. The whole process, i.e. production of the micropatterned substrate including SAM exchange and protein immobilization, took a reasonably small amount of time (~24 h), providing some flexibility in the experimental work.

(E) THIOL-MODIFIED POLYMERS

In addition to simple alkanethiols or those functionalized with small groups or compounds, thiols can also be used to attach polymers to metal surfaces. However, there are specific problems, since the accessibility of the surface for the thiol groups of the modified polymers, for example, is often strongly restricted and a significant entropy change may be connected with the adsorption, depending on the polymer, the surface and the solvent.

The study of ultrathin polymer layers on metals is relevant in understanding the behaviour of polymers on surfaces, as well as in the areas of adhesion and corrosion. Gold and copper surfaces can be covered with monolayers of polymers by adsorption from solution [227, 228, 229, 230, 231, 232, 233, 234 and 235].

One example of a polymer layer on gold consists of adsorbed thiol-terminated poly(styrene)s of different molecular weights [234]. Poly(styrene) itself does not adsorb significantly on gold from tetrahydrofuran (THF) [232] or toluene [236]. As the average molecular weight (M_n) increases up to ~100 000, an increasing amount of the thiol-terminated polymer adsorbs on the surface [234]. The adsorbed mass remains constant up to M_n of ~200 000 or more, corresponding to a layer thickness of ~3 nm [234]. However, thiol-terminated poly(styrene) with $M_n = 500$ 000 does not adsorb at all [234]. It seems that the sulphur–gold interaction is no longer sufficient to overcome the entropy loss and loss of polymer–solvent interactions, which would accompany adsorption of very high-molecular-weight chains [234].

Structure, morphology and friction of thiol-terminated poly(styrene) have also been studied with atomic force microscopy [237, 238 and 239].

No adsorption of a block copolymer with a styrene/propylene sulphide molar ratio of 3:1 from THF was found when the propylene sulphide blocks were capped with ethyl groups [227]. Thiol-capped styrene-propylene sulphide block copolymers ($M_n = 60\ 000$), in contrast, adsorb on gold from THF [234]. The layer thickness of styrene-propylene sulphide block copolymers decreases with increasing propylene sulphide block size, since the propylene sulphide block interacts with and, as a result, adheres to the surface [234]. A strong interaction of the thiol endgroup seems, however, to be necessary for any further segmental adsorption of the polymer chain [227]. The styrene block most likely escapes from the gold surface, at least partially, and this could explain the observed changes in layer thickness. Analogously, poly(styrene) that is terminated with six or seven ethylene sulphide units with a thiol end group also adsorbs from toluene onto gold [235].

Poly(methyl methacrylate) (PMMA) with sulphide-modified side chains adsorbs onto gold from methyl ethyl ketone and dichloromethane (there is little influence of the solvents on the layer formation) [229]. Two polymers with one sulphide group per 10 and 100 monomer units were examined [229]. The thickness of the adsorbed layers was ~1.5–3 nm, depending on the concentration of the polymer in the solution and, to a degree, on the sulphur content [229]. Angle-dependent XPS measurements indicate that the sulphide groups are not concentrated at the interface but dispersed relatively uniformly throughout the film [229]. Unmodified poly(methyl methacrylate) also adsorbs under the same conditions, but the thickness of the corresponding layer is below 1 nm [229]. Also, a poly(benzylglutamate) with a disulphide endgroup yields thicker layers on gold than the corresponding non-modified poly(benzylglutamate) [228]. Moreover, poly(acrylate)s with disulphide moieties in the side chains have been studied. In this case it was found that the disulphide groups promote the adsorption [230, 232].

-25-

The examples described above are only a small selection out of a tremendous number of investigations of LB films and SAMs. This number is still increasing and it is expected that ultrathin organic films will play a central role in both fundamental and applied sciences in the future.

C2.5 Introducing protein folding using simple models

D Thirumalai and D K Klimov

C2.5.1 INTRODUCTION

Most reactions in cells are carried out by enzymes [1]. In many instances the rates of enzyme-catalysed reactions are enhanced by a factor of a million. A significantly large fraction of all known enzymes are proteins which are made from twenty naturally occurring amino acids. The amino acids are linked by peptide bonds to form polypeptide chains. The primary sequence of a protein specifies the linear order in which the amino acids are linked. To carry out the catalytic activity the linear sequence has to fold to a well defined three-dimensional (3D) structure. In cells only a relatively small fraction of proteins require assistance from chaperones (helper proteins) [2]. Even in the complicated cellular environment most proteins fold spontaneously upon synthesis. The determination of the 3D folded structure from the one-dimensional primary sequence is the most popular protein folding problem.

For a number of years the protein folding problem remained only of academic interest. The synthesis of proteins in cells was described by Crick in [1]. Schematically this process can be represented as DNA → RNA → Proteins. This proposal and Anfinsen's [3] demonstration that a denatured protein would fold to the native conformation under suitable conditions was sufficient to understand the role of protein folding in cells. However, in the last couple of decades many diseases have been directly linked to protein folding (especially misfolding) [4]. Thus, there is an urgency to understand the mechanisms in the formation of folded structures. The biotechnology industry is also interested in the problem because of the hope that by understanding the way polypeptide chains fold one can design molecules (using natural or synthetic constituents) of use in medicine. Finally, the full potential of the human genome project involves understanding what the genes encode. For all these profoundly important reasons the protein folding problem has taken centre stage in molecular biology.

Because this problem is complex several avenues of attack have been devised in the last fifteen years. A combination of experimental developments (protein engineering, advances in x-ray and nuclear magnetic resonance (NMR), various time-resolved spectroscopies, single molecule manipulation methods) and theoretical approaches (use of statistical mechanics, different computational strategies, use of simple models) [5, 6 and 7] has led to a greater understanding of how polypeptide chains reach the native conformation.

From our perspective there are four major problems that comprise the protein folding enterprise. They are:

- (a) Prediction of the 3D fold of a protein given only the amino acid sequence. This is referred to as the structure prediction problem. In [figure C2.5.1](#) we show the 3D structure of haemoglobin. The structure prediction problem involves determining this fold using the primary sequence which is given in the lower part of [figure C2.5.1](#).
-

Given that a sequence folds to a known native structure, what are the mechanisms in the transition from the unfolded conformation to the folded state? This is a kinetics problem, the solution of which requires elucidation of the pathways and transition states in the folding process.

- (d)

How to design sequences that adopt a specified fold [9]? This is the inverse protein folding problem that is vital to the biotechnology industry. There are some proteins that do not spontaneously reach the native conformation. In the cells these proteins fold with the assistance of helper molecules referred to as chaperonins. The chaperonin-mediated folding problem involves an understanding of the interactions between proteins.

It is not the aim of this section to introduce the reader to all the areas listed above. Our goal is modest. We describe some of the theoretical developments which arose from studies of caricatures of proteins. Such models were designed in order to understand certain general features about protein structures and how these are kinetically reached. To keep the bibliography compact we mostly cite review articles. The interested reader can find the original papers in these cited works. We hope that this short introduction will entice the reader to delve into the ever surprising world of biological macromolecules.

C2.5.2 RANDOM HETEROPOLYMER AS A CARICATURE OF PROTEINS

In homopolymers all the constituents (monomers) are identical, and hence the interactions between the monomers and between the monomers and the solvent have the same functional form. To describe the shapes of a homopolymer (in the limit of large molecular weight) it is sufficient to model the chain as a sequence of connected beads. Such a model can be used to describe the shapes that a chain can adopt in various solvent conditions. A measure of shape is the dimension of the chain as a function of the degree of polymerization, N . If N is large then the precise chemical details do not affect the way the size scales with N [10]. In such a description a homopolymer is characterized in terms of a single parameter that essentially characterizes the effective interaction between the beads, which is obtained by integrating over the solvent coordinates.

Proteins are clearly not homopolymers because many energy scales are required to characterize the polypeptide chain. Besides the excluded volume interactions and hydrogen bonds the potential between the side chain depends on the nature of the residues [1]. Therefore, as a caricature of proteins the heteropolymer model is a better approximation. A convenient limit is the random heteropolymer for which approximate analytic treatments are possible [11]. In a random heteropolymer the interactions between the beads are assumed to be randomly distributed. Some of the interactions are attractive (which are responsible for conferring globularity to the chain) while others are repulsive and these residues are better accommodated in an extended conformation. In proteins water is a good solvent for polar residues while it is a poor solvent for hydrophobic residues. (In a good solvent contacts between the monomer and solvent are favoured whereas in a poor solvent the monomers are attracted to each other.) Because only 55% of the residues in proteins are hydrophobic it is clear that in a typical protein energetic frustration plays a role. In addition because of chain connectivity there is also topological frustration. This arises because residues that are proximal tend to form structures on short-length scales. The assembly of such short-length scale structures would typically be incompatible with the global fold giving rise to topological frustration. Even if energetic frustrations are eliminated a polypeptide chain (in fact any biomolecule) is topologically frustrated [7].

In the field of spin glasses and structural glasses such frustration effects are well known [12]. Thus, it was natural to suggest that random heteropolymers could serve as a simple representation of polypeptide chains. In appendix C2.5.A we sketch computational details for one model of random heteropolymers. Bryngelson and Wolynes [13] proposed, using phenomenological arguments, that the random energy model (REM) would be an appropriate description of some aspects of proteins. The rationale for this is the following: consider the exponentially large number of conformations. Because of the presence of several conflicting energies in a polypeptide chain it is natural to assume that these energies are randomly distributed. If there are no correlations between these energies and if the distribution is Gaussian one gets the REM. Of course, in the REM model the chain connectivity is ignored and there is no manifest for a spatial dependence of the chain coordinates. We show in appendix C2.5.B that in the compact phase the random heteropolymer is equivalent to REM.

The random heteropolymer models of proteins are interesting from a statistical mechanics perspective. However, they do not explain the key characteristics of proteins, such as reversible and cooperative folding to a unique native conformation. Moreover, the theories for heteropolymers suggest that, typically, the energy landscapes for these systems are extremely rugged consisting of many minima that are separated by barriers of varying heights [11]. This would mean that kinetically it would be impossible for chain with a typical realization of interactions to reach

the ground state in finite time scales. Thus, the dynamics of such random heteropolymer models typically exhibits glassy behaviour. Natural proteins do not exhibit any hallmarks of glassy dynamics at most temperatures of interest. It follows that a certain refinement of the random heteropolymers is required to capture protein-like properties. One of the important theoretical advances is the observation that very simple minimal models [14] can be constructed that capture many (not all) of the salient features observed in proteins [14]. The simplest manifestation of such models are the lattice representation of polypeptide chains. In the next section we introduce the models and describe a few results that have been obtained by numerically exploring their behaviour.

C2.5.3 LATTICE MODELS OF PROTEINS

The computational protocol for describing protein folding mechanisms is straightforward in principle. The dynamics is well described by the classical equations of motion. Simulations of a monomeric protein involves equilibrating the polypeptide chain in a box of water molecules at the desired temperature and density. If an appropriately long trajectory is generated then the dynamics of the protein can be directly monitored. There are two crucial limitations that prevent a straightforward application of this approach to a study of the folding of proteins. First, the interaction potentials or the force fields for such a complex system are not precisely known. Molecular dynamics simulations in the standard packages use potentials that rely on the transferability hypothesis, i.e. that interactions designed in one context can be used in aqueous medium and for larger systems. The need to compute potentials that can be used reliably in simulations of protein dynamics remains acute.

The second problem is related to the limitations in generating really long duration trajectories that can sample all the relevant conformational spaces of proteins. To observe reversible folding of even a moderate sized protein requires simulations that span the millisecond time scale. More importantly, making comparisons with experiments involves generating many (greater than perhaps 100) folding trajectories so that a reliable ensemble average is obtained. Thus, we need to make progress on both fronts (force fields and enhanced sampling techniques in long duration simulations) before straightforward all-atom simulations become routine.

In the light of the previously mentioned difficulties various simplified models of proteins have been suggested [14]. The main rationale for using such drastic simplifications is that a detailed study of such models can enable us to decipher certain general principles that govern the folding of proteins [5, 6 and 7]. For this class of model detailed computations without sacrificing accuracy is possible. Such an approach has yielded considerable insights into the mechanisms, time scales and pathways in the folding of polypeptide chains. In this section we will outline some of the results that have been obtained (largely from our group) with the aid of simple lattice models of proteins.

In the simple version of the lattice representation of proteins the polypeptide chain is modelled as a sequence of connected beads. The beads are confined to the sites of a suitable lattice. Most of the studies have used the cubic lattice. To satisfy the excluded volume condition only one bead is allowed to occupy a lattice site. If all the beads are identical we have a homopolymer model the characteristics of which on lattices have been extensively studied.

-5-

To introduce protein-like character the interactions between beads (those separated by at least three bonds) that are nearest neighbours on a lattice are assumed to depend on the nature of the beads. The energy of a conformation, specified by $\{r_i, i = 1, 2, \dots, N\}$, is

$$E(\{r_i\}) = \sum_{i < j} \Delta(|r_i - r_j| - a) B_{ij} \quad (\text{C2.5.1})$$

where N is the number of beads in the chain, a is the lattice spacing, and B_{ij} is the value of the contact interaction between beads i and j . We will consider different forms of B_{ij} . Since this model can be viewed as a coarse-grained representation of the α -carbons of the polypeptide chain the value of a is typically taken to be about 3.8 Å.

Lattice models have been used for a long time in polymer physics [15]. They were instrumental in computing many properties (scaling of the size of the polymer with N , distribution of end-to-end distance, etc.) of real homopolymer chains. In the context of proteins lattice models were first introduced by Taketomi *et al* [16]. The currently popular Go model [16] only considers interactions between residues (beads on the lattice) that occur in the native (ground) state. Thus, in this ‘strong specificity limit’ only native contacts are taken into account. It follows that in this version of the Go model the chain is forced to adopt the lowest energy conformation at low temperatures. Go also considered a variant of this model in which certain nonnative contacts are allowed. Although these models were insightful, Go and co-workers did not use them to obtain plausible general principles of protein folding. This was partly due to the fact that in their studies they typically used long chains, and hence exact enumeration was not possible.

Simple lattice models, with the express purpose of obtaining minimal representations of polypeptide chains, were first suggested by Chan and Dill [17]. To account for the major interactions in proteins these authors argued that the twenty naturally occurring amino acids can be roughly divided into two categories, namely, hydrophobic (H) and polar (P). Chan and Dill have suggested that this simple HP model can capture many salient features of proteins. They also suggested that many of the conceptual puzzles (the Levinthal paradox in particular) could be addressed by systematically studying short chains. This simple exactly enumerable HP model and their variants have been used to understand cooperativity, folding kinetics, and the designability of protein structures [14]. Thus, it is instructive to describe the calculations that have been done using lattice models. A study of such models indeed provides a good introduction to the computational aspects of protein folding.

C2.5.3.1 EMERGENCE OF STRUCTURES

The sequence space of proteins is extremely dense. The number of possible protein sequences is 20^N . It is clear that even by the fastest combinatorial procedure only a very small fraction of such sequences could have been synthesized. Of course, not all of these sequences will encode protein structures which for functional purposes are constrained to have certain characteristics. A natural question that arises is how do viable protein structures emerge from the vast sea of sequence space? The two physical features of folded structures are: (1) in general native proteins are compact but not maximally so. (2) The dense interior of proteins is largely made up of hydrophobic residues and the hydrophilic residues are better accommodated on the surface. These characteristics give the folded structures a lower free energy in comparison to all other conformations.

Lattice models are particularly suited for answering the questions posed. We will show that the two physical restrictions are sufficient to rationalize the emergence of very limited (believed to be only of the order of a thousand

-6-

or so) protein -like structures. To provide a plausible answer to this question using lattice models we need to specify the form of the interaction matrix elements B_{ij} . For purposes of illustration we consider the random bond (RB) model in which the elements B_{ij} are distributed as

$$P(B_{ij}) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{(B_{ij} - B_0)^2}{2\sigma^2}\right). \quad (\text{C2.5.2})$$

Here σ ($=1$) is the variance in B_{ij} , and the hydrophobicity parameter B_0 is the mean value. We chose $B_0 = 0$ (half the beads are hydrophobic) and $B_0 = -0.1$. The latter is motivated by the observation that in natural proteins roughly 55% of the residues are hydrophobic [18].

Protein-like structures are not only compact but also have low energy. With this in mind we have calculated the number of compact structures (CS) as CS with low energy for a given N . The number of CS in its most general form may be written as

$$C_N(\text{CS}) \simeq \bar{Z}^N Z_1^{N(d-1)/d} N^{\gamma_c-1} \quad (\text{C2.5.3})$$

where $\ln \bar{Z}$ is the conformational free energy (in units of $k_B T$), Z_1 is the surface fugacity, d is the spatial dimension, and γ_c represents the possible logarithmic corrections to the free energy. It is clear that natural proteins are relatively unique and hence their number on an average has to grow at rates that are much smaller than that given in (C2.5.3). To explore this we have calculated by exact enumeration the number of compact structures, $C_N(\text{CS})$ and the number of minimum energy structures $C_N(\text{MES})$ as a function of N (MES are compact, but not necessarily maximally compact).

We performed exhaustive enumeration of all self-avoiding conformations to explore the conformational space of the polypeptide chain of a given length. In order to reduce the sixfold symmetry on the cubic lattice we fixed the direction of the first monomeric bond in all conformations. The remaining conformations are related by eightfold symmetry on the cubic lattice (excluding the cases when conformations are completely confined to a plane or straight line). To decrease further the number of conformations to be analysed the Martin algorithm [19] was modified to reject all conformations related by symmetry.

We define MES as those conformations, the energies of which lie within the energy interval Δ above the lowest energy E_0 . Several values for Δ were used to ensure that no qualitative changes in the results are observed. We set Δ to be constant and equal to 1.2 (or 0.6) (definition (i)). We have also tested another definition for Δ , according to which $\Delta = 1.3|E_0 - t B_0|/N$, where t is the number of nearest-neighbour contacts in the ground state (definition (ii)). It is worth noting that in the latter case Δ increases with N . Both definitions yield equivalent results. Using these definitions for Δ , we computed $C(\text{MES})$ as a function of the number of residues N .

The computational technique involves exhaustive enumeration of all self-avoiding conformations for $N \leq 15$ on a cubic lattice. In doing so we calculated the energies of all conformations according to (C2.5.1) and then determined the number of MES. Each quantity, such as the number of MES, $C(\text{MES})$, the lowest energy E_0 , the number of nearest-neighbour contacts t in the lowest energy structures, is averaged over 30 sequences. Therefore, when referring to these quantities, we will imply their average values. To test the reliability of the computational results an additional

-7-

sample of 30 random sequences was generated. Note that in the case of $C(\text{MES})$ we computed the quenched averages, i.e., $C(\text{MES}) = \exp[\ln\langle c(\text{MES}) \rangle]$, where c is the number of MES for a given sequence.

The number of MES $C(\text{MES})$ is plotted as a function of the number of residues N in figure C2.5.2 for $B_0 = -0.1$ and $\Delta = 0.6$. A pair of squares at given N represents $C(\text{MES})$ computed for two independent runs of 30 sequences each. For comparison, the number of self-avoiding walks $C(\text{SAW})$ and the number of CS $C(\text{CS})$ are also plotted in this figure (diamonds and triangles, respectively). The most striking and important result of this graph is the following. As expected on general theoretical grounds, $C(\text{SAW})$ and $C(\text{CS})$ grow exponentially with N , whereas $C(\text{MES})$ exhibits drastically different scaling behaviour. There is no variation in $C(\text{MES})$ and its value remains practically constant within the entire interval of N starting with $N = 7$. We find (see figure C2.5.2) that $C(\text{MES}) \approx 10^1$. These results suggest that $C(\text{MES})$ grows (in all likelihood) only as $\ln N$ with N . Thus the restriction of compactness and low energy of the native states may impose an upper bound on the number of distinct protein folds.

Figure C2.5.2. Scaling of the number of MES $C(\text{MES})$ (squares) is shown for the hydrophobic parameter $B_0 = -0.1$ and $\Delta = 0.6$. Data were obtained for the cubic lattice. The pairs of squares for each N represent the quenched averages for different samples of 30 sequences. The number of compact structures $C(\text{CS})$ and self-avoiding conformations $C(\text{SAW})$ are also displayed to underscore the dramatic difference of scaling behaviour of $C(\text{MES})$ and $C(\text{CS})$ (or $C(\text{SAW})$). It is clear that $C(\text{MES})$ remains practically flat, i.e. it grows no faster than $\ln N$.

C2.5.3.2 3D HP MODEL

The calculations described above suggest that upon imposing minimal restrictions on the structures (compactness and low energies) the structure space becomes sparse. As suggested before this must imply that each basin of attraction (corresponding to a given MES) in the structure space must contain numerous sequences. The way these sequences are distributed among the very slowly growing number (with respect to N) of MES, i.e. the density of sequences in structure space, is an important question. This was beautifully addressed in the paper by Li *et al* [20]. They considered a 3D ($N = 27$) cubic lattice. By using the HP model and restricting themselves to only maximally compact structures as putative native basins of attractions (NBAs) they showed that certain basins have a much larger number of sequences. In particular, they discovered that one of the NBAs serves as a ground state for 3794 (total number is 2^{27}) sequences

and hence was considered most designable (figure C2.5.3). The precise density of sequences among the NBAs is clearly a function of the interaction scheme. These calculations and the arguments presented in the previous subsection using the random bond model point out that since the number of NBA for the entire sequence space is small it is likely that proteins could have evolved randomly. Naturally occurring folds must correspond to one of the basins of attraction in the structure space so that many sequences have these folds as the native conformations, i.e. these are highly designable structures in the language of Li *et al* [20]. These ideas were further substantiated by Lindgard and Bohr [21], who showed that among maximally compact structures there are only very few folds that have protein-like characteristics. These authors also estimated, using geometrical characteristics and stability arguments, that the number of distinct folds is of the order of a thousand. All of these studies confirm that the density of the structure space is sparse. Thus, each fold can be designed by many sequences. From the purely structural point of view nature does have several options in the sense that many sequences can be ‘candidate proteins’. However, there is also evolutionary pressure to fold rapidly (i.e. a kinetic component to folding). This requirement further restricts the possible sequences that can be considered as proteins, because they must satisfy the dual criterion of reaching a definite fold on a biologically relevant time scale. These observations are schematically sketched in [figure C2.5.4](#).

Figure C2.5.3. Histogram of the number of structures with a given number of associated sequences N_s for the $3D\ 3 \times 3$ case, in a log–log plot.

C2.5.3.3 SYMMETRY AND DESIGNABILITY

In the study by Li *et al* [20] it was noted that highly designable structures appear to be symmetric. Independently, in a thought provoking article Wolynes [22] has made a series of compelling arguments as to why nature might use symmetry (at least in an inexact manner) to generate symmetrical tertiary folds of proteins. Many enzymes are oligomers. Wolynes makes a number of observations about the symmetry aspects of protein structures: (a) the tetrameric haemoglobin (α -helical protein) molecule has an approximate two-fold symmetry.

-9-

(b) A striking example of approximate symmetry in β -proteins is found in the structure of a monomeric γ crystallin in which the shapes adopted by residues 1–88 and 89–174 are nearly the same. However, the two individual sequences do not bear much similarity. This, of course, is consistent with the notion that the structure space is so sparse that many sequences are forced to adopt similar shapes. The interesting conclusion from examining the γ crystallin structure is that the underlying symmetries in the shape are only inexact. (c) The obvious example of nearly symmetrical structures are helical proteins, with the four helix bundle being one the most prominent examples (see [figure C2.5.5](#)). (d) Various proteins with mixed topology (like triose phosphate isomerase (TIM) barrels and jelly rolls) appear to have the kind of inexact but apparently symmetrical arrangement discussed by Wolynes [23]. (e) He also conjectured that it is likely that the underlying approximate symmetry is reflected in the free energy landscape being funnel like. This would facilitate rapid folding which for many proteins may be a result of evolutionary pressure. The precise connections between the symmetries and the folding mechanisms and functional competence of biological molecules have not been worked out. Nevertheless, it appears that employing such ideas might be useful in the *de novo* design of proteins.

We note that equally striking are the kind of symmetrical arrangements found in RNA molecules [24]. The crystal structure of the P4–P6 domain of *Tetrahymena* self-splicing RNA clearly is highly symmetric with helices packed in a nearly regular arrangement. Since in an evolutionary sense the RNA world preceded the protein world it is interesting to speculate that the emergence of inexact symmetries may have been a biological necessity. The observation of inexact symmetries in a protein structure might be a consequence of the fact that they are present in the ‘parent’ molecules. In fact this evolutionary conservation may have been imprinted when evolution from the RNA world to the current scheme for protein synthesis took place. The most compelling reason for observing near regular patterns in biomolecular structures is because synthesis of symmetrical folds might be energetically

economical.

C2.5.3.4 EXPLORING THE PROTEIN FOLDING MECHANISM USING THE LATTICE MODEL

It is well known that proteins reach the biologically active native states in a relatively short time, which is of the order of a second for most single domain proteins [1]. Based on folding and refolding experiments on ribonuclease A, Anfinsen concluded that under appropriate conditions natural sequences of proteins spontaneously fold to their native conformation [3]. This implies that protein folding is a self-assembly process, i.e. the information needed for specifying the topology of the native state is contained in the primary sequence itself. This thermodynamic hypothesis does not, however, address the question of how the native state is accessed in a short time scale. This issue was raised by Levinthal who wondered how a polypeptide chain of reasonable length can navigate the astronomically large conformational space so rapidly. Levinthal posited that certain preferred pathways must guide the chain to the native state. The Levinthal paradox, simplistic as it is, has served as an intellectual impetus to gain an understanding of the ease with which a polypeptide chain reaches the native conformation [5, 6]. We use lattice models to describe the foldability of biological sequences of proteins. A sequence is foldable if it reaches the native state in a reasonable time and remains stable over some range of external conditions (pH, temperature).

C2.5.3.5 CHARACTERISTIC TEMPERATURES

The basic features of folding can be understood in terms of two fundamental equilibrium temperatures that determine the ‘phases’ of the system [7]. At sufficiently high temperatures (kT greater than all the attractive interactions) the shape of the polypeptide chain can be described as a random coil and hence its behaviour is the same as a self-avoiding walk. As the temperature is lowered one expects a transition at $T = T_\theta$ to a compact phase. This transition is very much in the spirit of the collapse transition familiar in the theory of homopolymers [10]. The number of compact

-10-

conformations at T_θ is still exponentially large. Because the polypeptide chains have additional energy scales that discriminate between the various compact conformations we expect a transition to the ground (native) state at a lower temperature T_F . Generally the transition at T_θ is second order, while the transition at T_F is similar to first order. Since we are considering finite systems, the notion of ‘phases’ should be used with care. These expectations, based on fairly general arguments, have been confirmed in various lattice simulations of protein-like heteropolymers. For the lattice models the collapse temperature T_θ is determined from the peak of the specific heat and the folding transition temperature is obtained from the fluctuations in the overlap function given by

$$\Delta\chi = \langle \chi^2 \rangle - \langle \chi \rangle^2 \quad (C2.5.4)$$

where

$$\chi = 1 - \frac{1}{N^2 - 3N + 2} \sum_{i < j+2} \delta(r_{ij} - r_{ij}^N) \quad (C2.5.5)$$

with r_{ij}^N referring to the native state. In [figure C2.5.6 a](#)) (for the structure displayed in [figure C2.5.7](#)) we plot the temperature dependence of C_v , which has a peak at $T_\theta = 0.83$. This figure also shows the variation of $d\langle R_g \rangle / dT$ with temperature. The peak of this curve (at 0.86) almost coincides with that of the specific heat indicating that this transition is associated with compaction of the chain. Hence, the maximum in C_v legitimately indicates the collapse temperature. X-ray scattering experiments have been used to obtain T_θ for a few proteins. In [figure C2.5.6 \(a\)](#) we also show the temperature dependence of $\Delta\chi$ from which the folding temperature T_F is determined to be 0.79.

(A) FOLDING RATES

The key question we want to answer is what are the intrinsic sequence dependent factors that not only determine the folding rates but also the stability of the native state? It turns out that many of the global aspects of the folding kinetics of proteins can be understood in terms of the equilibrium transition temperatures. In particular, we will show that the key factor that governs the foldability of sequences is the single parameter

$$\sigma_T = \frac{T_\theta - T_F}{T_\theta} \quad (\text{C2.5.6})$$

which indicates how far T_F is from T_θ . To establish a direct correlation between the folding time τ_F and σ_T we generated a number of sequences for $N = 27$. The folding time was taken to be equal to the mean first passage time. The first passage time for a given initial trajectory was calculated by determining the total number of Monte Carlo steps (MCS) needed to reach the native conformation for the first time. By averaging over an ensemble of initial trajectories (typically this number varies between 400–800 in our examples) the mean first passage time is obtained. The precise moves that are utilized in the simulations are described elsewhere [18]. The dependence of τ_F on σ_T (for the random bond model and for the other interaction schemes) is given in [figure C2.5.8](#). This figure shows a remarkable correlation between the folding time and σ_T . A small change in σ_T results in a dramatic effect (a few orders of magnitude) on the folding times. It is clear that both T_θ and T_F are dependent on the sequence. As a result mutations that preserve the native state can alter the folding rates due to the change in the σ_T values.

Using lattice models we have also established that folding rates correlate well with $Z = (E_N - E_{MS}) / \delta$, where E_N is the native state energy, E_{MS} is the average energy of the ensemble of misfolded structures, and δ is the dispersion in the contact energies. The relationship between σ and Z also suggests that, in general, the correlation between τ_F and σ should be superior. More importantly, experimental measurements of Z are difficult. On the other hand, both T_θ and T_F can be measured in scattering, CD, or fluorescence experiments. Other measures, such as energy gap (however it is defined), do not correlate with τ_F .

In the previous section we showed that because the structure space is very sparse there have to be many sequences that map onto the countable number of basins in the structure space. The kinetics here shows that not all the sequences, even for highly designable structures, are kinetically competent. Consequently, the biological requirements of stability and speed of folding severely restrict the number of evolved sequences for a given fold. This very important result is schematically shown in [figure C2.5.4](#).

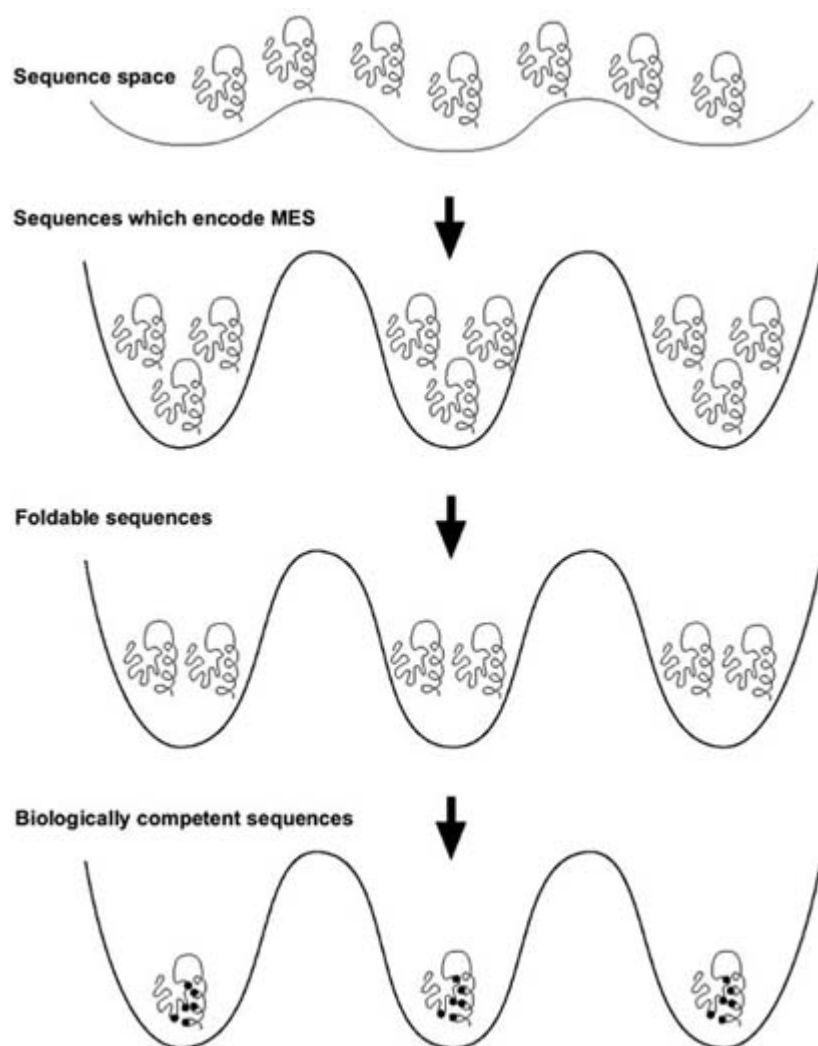

Figure C2.5.4. Schematic illustration of the stages in the drastic reduction of sequence space in the process of evolution to functionally competent protein structures.

It is important to point out that the simulations reported in [figure C2.5.8](#) were done at sequence-dependent temperatures using the condition $\langle \chi(T_s) \rangle = 0.21$. At these temperatures, all of which are below their respective folding transition temperatures, the native conformation has the highest occupation probability. In lattice models the native state is a single conformation (a microstate) which is, of course, physically unrealistic. In real systems there is a volume associated with the native basin of attraction and there are many conformations that map onto the NBA. The probability of being in the NBA at the various simulation temperatures is in excess of 0.5 so that under the conditions of our simulations the *stability criterion is automatically satisfied*. The results in [figure C2.5.8](#) therefore, shows that the *dual requirement of stability and the kinetic accessibility* of NBA is most easily satisfied by those sequences that have small values of σ_T . Thus rapid folding occurs when $\sigma_T \approx 0$, i.e. near a multicritical-like point. In this case there are no detectable intermediate ‘phases’. The sequence, whose native state is shown in [figure C2.5.7](#) has $\sigma_T = 0.05$. We found that this sequence folds rapidly.

Figure C2.5.5. Native structure of acyl-coenzyme A binding protein (first NMR structure out of 29 deposited to PDB). The figure was created using RasMol 2.6 [8].

-13-

Figure C2.5.6. Thermodynamic functions computed for the sequence whose native state is shown in [figure C2.5.7](#). (a) Specific heat C_v (dotted curve) and derivative of the radius of gyration with respect to temperature $d\langle R_g \rangle/dT$ (broken curve) as a function of temperature. The collapse temperature T_θ is determined from the peak of C_v and found to be 0.83. T_θ is very close to the temperature at which $d\langle R_g \rangle/dT$ becomes maximum (0.86). This illustrates

that T_θ is indeed associated with the compaction of the chain. The temperature dependence of fluctuations of overlap function $\Delta\chi$ is given by the full curve. The folding transition temperature T_F is obtained from the peak of $\Delta\chi$ and for this sequence $T_F = 0.79$. The curves are scaled to fit one plot. (b) Time dependence of the fraction of unfolded molecules $P_u(t)$ for the sequence shown in [figure C2.5.7](#) calculated at folding conditions $T_s \lesssim T_F$. The function $P_u(t)$ is computed from a distribution of first passage times τ_{li} . The first passage time for a given initial condition is the first time the trajectory reaches the native conformation. Typically an adequately converged distribution is obtained by averaging over several hundred initial conditions. For the conditions used in this simulation folding is two state, therefore, $P_u(t)$ is adequately fitted with the single exponential (thick full curve). The folding time τ_F obtained from the fit is 1.4×10^6 MCS.

-14-

Figure C2.5.7. The native conformation of fast folding sequence ($N = 27$) with random bond potentials is shown. This structure has $c = 22$ non-bonded contacts, therefore it is not a maximally compact conformation for which $c = 28$. The figure was created using RasMol 2.6 [8].

-15-

Figure C2.5.8. Plot of the folding times τ_F as a function of σ_T for the 22 sequences. This figure shows that under the external conditions when the NBA is the most populated there is a remarkable correlation between τ_F and σ_T . The correlation coefficient is 0.94. It is clear that over a four orders of magnitude of folding times $\tau_F \approx \exp(-\sigma_T/\sigma_0)$ where σ_0 is a constant. The filled and open circles correspond to different contact interactions used in [C2.5.1](#). The open squares are for $N = 36$.

(B) TOPOLOGICAL FRUSTRATION AND KINETIC PARTITIONING MECHANISM

Lattice models can also be used to obtain the outlines of the mechanisms for the folding of proteins. The qualitative aspects of the folding kinetics of biomolecules can be understood in terms of the concept of topological frustration. The primary sequence of proteins has about 55% hydrophobic residues. The linear density of hydrophobic residues along the polypeptide chain is roughly constant, implying that the hydrophobic residues are spread throughout the chain. As a result on any length scale l there is a propensity for the hydrophobic residues to form tertiary contacts under folding conditions. The resulting structures which are formed by contacts between residues that are in proximity would be in conflict with the global fold corresponding to the native state. The incompatibility of structures on local scales with the near unique native state on the global scale leads to topological frustration. It is important to realize that topological frustration is inherent to all foldable sequences, and is a direct consequence of the polymeric nature of proteins as well as competing interactions (hydrophobic residues which prefer the formation of compact structures and hydrophilic residues which are better accommodated by extended conformations). A consequence of topological frustration is that the underlying energy landscape is rugged, consisting of many minima that are separated by barriers of varying heights.

-16-

It is important to understand the nature of the low-lying minima in the rugged energy landscape. On the length scale l there are many ways of forming structures that are in conflict with the global fold. It is expected that most of these structures have high free energies and are unstable to thermal fluctuations. We expect a certain number of these structures to have low free energies and represent relatively deep minima. The similarity between these structures and the native fold could be considerable and hence these structures could be viewed as being native like. These competing basins of attraction (CBA) in which the polypeptide chain adopts native-like structures can act as kinetic traps that will slow down the folding process.

The basic consequences of topological frustration for mechanisms of folding can be understood in terms of the kinetic partitioning mechanism (KPM) [7]. Imagine an ensemble of denatured molecules in search of the native conformation. This is the experimental situation that arises when the concentration of denaturant molecules is decreased. It is clear that a fraction of molecules Φ would reach the NBA rapidly without being trapped in the low lying energy minima. The remaining fraction would be trapped in the minima and only on longer time scales do

fluctuations enable the chain to reach the NBA. The value of the partition factor Φ depends on the sequence and is explicitly determined by the σ_T value. Thus because of topological frustration the initial pool of denatured molecules partitions into fast folders and slow folders that reach the native state by indirect off-pathway processes.

From the description of the kinetic partitioning mechanism (KPM) given above it follows that generically the time dependence of the fraction of molecules that have not folded at time t , $P_u(t)$, is given by

$$P_u(t) = \Phi \exp\left(-\frac{t}{\tau_{\text{NC}}}\right) + \sum_k a_k \exp\left(-\frac{t}{\tau_k}\right) \quad (\text{C2.5.7})$$

where τ_{NC} is the time constant for reaching the native state by the fast process, τ_k is the time for escape from the CBA labelled k , and a_k is the ‘volume’ associated with the k th CBA. From this consideration we expect that for a given sequence, trajectories can be grouped into those that reach the native conformation rapidly (Φ being their fraction), and those that remain in one of the CBA for a discernible length of time. In [figure C2.5.9 a](#)) we show an example of a trajectory that reaches the native state directly from the random coil conformation. In contrast in [figure C2.5.9 \(b\)](#) we show an example of a trajectory for the same sequence at the same simulation temperature. This figure shows that on a very short time scale the chain gets trapped in conformations other than the NBA and only on a long time scale does it reach the native state. This figure illustrates the basic principle of KPM. If we perform an average over an ensemble of such trajectories the kinetic result given in (C2.5.7) ensues.

-17-

Figure C2.5.9. Examples of folding trajectories at $T = T_s$ derived from the condition $\langle \chi(T_s) \rangle = 0.21$. (a) Fast folding trajectory as monitored by $\chi(t)$. It can be seen that sequence reaches the native state very rapidly in a two-state manner without being trapped in intermediates. The first passage time for this trajectory is 277 912 MCS. (b) Slow folding trajectory for the same sequence. The sequence becomes trapped in several intermediate states with large χ *en route* to the native state. The first passage time is 11 442 793 MCS. Notice that the time scales in both panels are dramatically different.

(C) CLASSIFYING FOLDING MECHANISMS IN TERMS OF Σ_T

The various folding mechanisms expected in foldable sequences may be classified in terms of the σ_T . We have already shown that sequences that fold extremely rapidly have very small values of σ_T . Based on our study of several model proteins as well as analysis of real proteins we classify the folding kinetics of proteins in the following [7].

-18-

(D) FAST FOLDERS

For these sequences the value of σ_T is less than a certain small value σ_f . For such sequences the folding occurs directly from the ensemble of unfolded states to the NBA. The free energy surface is dominated by the NBA (or a funnel) and the volume associated with NBA is very large. The partition factor Φ is near unity so that these sequences reach the native state by two-state kinetics. The amplitudes a_k in (C2.5.7) are nearly zero. There are no intermediates in the pathways from the denatured state to the native state. Fast folders reach the native state by a nucleation–collapse mechanism which means that once a certain number of contacts (folding nuclei) are formed then the native state is reached very rapidly [25, 26]. The time scale for reaching the native state for fast folders (which are normally associated with those sequences for which topological frustration is minimal) is found to be

$$\tau_{\text{NCNC}} = \frac{\eta a}{\gamma} f(\sigma_T) N^\omega \quad (\text{C2.5.8})$$

where η is the solvent viscosity, a is the typical size of a residue, γ is the average surface tension between the residue and water, $f(\sigma_T)$ is typically an exponential function of σ_T , and the exponent ω is between 3.8 and 4.2. In general, only small proteins (N less than about 100) are fast folders.

(E) MODERATE FOLDERS

Sequences for which $\sigma_f \leq \sigma_T \leq \sigma_h$ (where σ_h is the upper boundary for moderate filters) can be classified as moderate folders. Unlike fast folding sequences the Φ values are fractional which means that a substantial fraction of molecules is essentially trapped in one of the CBAs for some length of time. For these sequences there are detectable intermediates and, for all but very small proteins, the rate determining step is the activated transition from one of the CBAs to the native state. The average time scale for transition from these misfolded structures to the native conformation is given by

$$\tau_F \approx \tau_0 \exp(\sqrt{N}) \quad (\text{C2.5.9})$$

at $T \approx T_F$. This shows that typical barriers for moderate folders are quite small. As a result the folding times even for long proteins ($N \approx 200$) are only of the order of a second. It is these small barriers that enable typical proteins to fold in a biologically relevant time scale without encountering the Levinthal paradox.

(F) SLOW FOLDERS AND CHAPERONES

For sequences with $\sigma_T \geq \sigma_h$, folding is extremely slow and these sequences may not reach the native state in a

biologically relevant time scale. The volume corresponding to NBA is very small in this case and as a result Φ is nearly zero. The free energy surface is dominated by CBAs. Under these circumstances spontaneous folding does not become viable. In cells such proteins are rescued by chaperones. Typically this happens when N is so large that $\tau_0 \exp(\sqrt{N})$ exceeds reasonable folding time scales. Thus in cells we expect that only those proteins which are large or whose biological functioning state has to be oligomers require chaperones.

-19-

C2.5.3.6 MINIMUM NUMBER OF RESIDUES FOR OBTAINING FOLDABLE PROTEIN STRUCTURES

Natural proteins are made up of twenty amino acid residues. An important question, from the perspective of protein design, is how many distinct types of residues are required for protein-like behaviour? Such a selection cannot be made arbitrarily because in natural proteins one should have polar, hydrophobic, and charged residues. In addition, for optimal packing of the core, hydrophobic residues with different van der Waals radii may be required. To explore the potential simplification of the number of residues Wang and Wang [27] have carried out a highly significant study using lattice models and standard statistical potentials for the contact interaction elements B_{ij} (C2.5.1). They discovered that a grouping of amino acid residues into five categories mimics the folding behaviour found using the standard twenty residues. To demonstrate this they used a cubic lattice with $N = 27$ and mostly focused on the maximally compact structures as ground states. Thus, structures such as ones given in [figure C2.5.6](#) are not explicitly considered. Nevertheless, the demonstration that a suitable set of five amino acid residue types is sufficient is an important result which should have implications for the protein design problem—the generation of primary sequences that can fold to a chosen target folded structure.

In their original article they mostly focused on various thermodynamic properties (nature and degeneracy of the ground states). They also carried out kinetic simulations to assess if the kinetic properties are altered by using a reduced number of residues. To test this idea Wang and Wang used the foldability index σ (which correlates well with folding rates) as a discriminator of sequence properties. The precise question addressed by Wang and Wang is the following: what is the minimum number of residues that are required to obtain foldable (characterized by having relatively small values of σ) sequences? We found that fast folding sequences have σ less than about a quarter. They carried out two sets of computations. In one set they initially optimized the stability gap [5] of various sequences using the twenty residues. They substituted the residues in these optimized sequences by the representative residue for each group. Four subgroups were considered with each containing five and a variant, three and two amino acids. The foldability index for the standard sample and their substitutes is shown in [figure C2.5.10](#) as full circles. In another set of computations they examined the foldability index (open diamonds in [figure C2.5.10](#)) for sequences that were optimized using the reduced sets of amino acids. Both these curves show that as long as the number of amino acid types exceeds five one can generate sequences with relatively small values of σ . [figure C2.5.10](#) also shows that smaller values of σ can be obtained if optimization is carried out with reduced sets of amino acids. Such sequences are foldable, i.e. the dual requirements of stability over a wide temperature range and the kinetic accessibility of their native states are simultaneously satisfied.

-20-

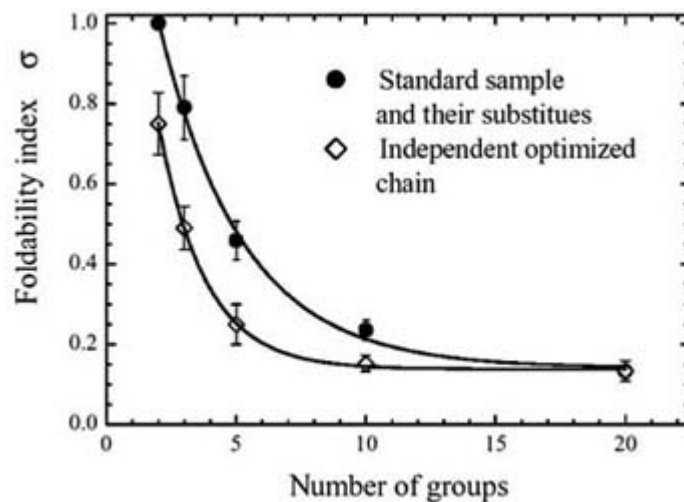

Figure C2.5.10. The figure gives the foldability index σ of 27-mer lattice chains with sets containing different number of amino acids. The sets are generated according to scheme described in [27]. The set of 20 amino acids is taken as a standard sample. Each sequence with 20 amino acids is optimized to fulfil the stability gap [5]. The residues in the standard samples are substituted with four different sets containing a smaller number of amino acids [27]. The foldability of these substitutions is indicated by the full circles. The open diamonds correspond to the sequences with same composition. However, the amino acids are chosen from the reduced representation and the resultant sequence is optimized using the stability gap [5].

C2.5.4 CONCLUSIONS

The examples of modelling discussed in [section C2.5.2](#) and [section C2.5.3](#) are meant to illustrate the ideas behind the theoretical and computational approaches to protein folding. It should be borne in mind that we have discussed only a very limited aspect of the rich field of protein folding. The computations described in [section C2.5.3](#) can be carried out easily on a desktop computer. Such an exercise is, perhaps, the best of way of appreciating the simple approach to get at the principles that govern the folding of proteins.

In this section we have not discussed experimental advances that are offering extraordinary insights into the way the denatured molecules reach the native state. Two remarkable experimental approaches hold the promise that in short order we will be able to watch the folding process from submicrosecond time scale until the native state is reached. A brief summary of these follow.

- (1) Eaton *et al* [28] have shown that optical triggers of folding can offer a window into the folding process from the microsecond time scale. Since this many laboratories have probed the plausible structure formations that occur on a short time scale. Fast folding experimental techniques have been used to obtain the detailed kinetics for the building blocks of proteins, namely, β -hairpin, α -helices, and loops. Very recent experiments have given compelling evidence that there are populated native-like intermediates even in proteins that were thought to follow two-state kinetics.

- (2) Perhaps the most exciting development in the last few years is the ability to nanomanipulate single biomolecules using atomic force microscopy and optical tweezer techniques [29]. So far such experiments have been used to provide a microscopic basis of elasticity in muscle proteins. If these stretching experiments can be combined with fluorescent resonance energy transfer experiments then it is possible to follow the folding of individual molecules as it passes through the transition state to the native conformation. It has been suggested on theoretical grounds that such two-dimensional single-molecule experiments can measure directly the distribution of folding rates (and the barrier distribution) in much the same way that mean first passage times are computed in minimal protein models (see [section C2.5.3](#)).

The challenges posed by these high precision experiments demand more refined models and further developments in computational techniques. For the theoretically inclined it will no longer be sufficient to describe kinetics only in terms of energy landscapes. The wealth of data that are being generated by experiments such as those mentioned above, requires a quantitative understanding of the various factors that govern the pathways, mechanisms, and the transition states in the folding process. These challenging issues will make the area of biomolecular folding an engaging one for many years to come.

ACKNOWLEDGMENTS

APPENDIX C2.5.A

There are several versions of the random heteropolymer models. To keep the discussions technically simple we will consider one case—the so-called random hydrophilic–hydrophobic chain whose phases were studied by Garel *et al* (GLO) [11]. The GLO model consists of a polymer chain with N monomers. The GLO model can be viewed as a generalization of the popular Edwards model which was introduced in order to understand the swelling of real homopolymer chains in good solvents [10]. In the GLO model the chain is made up of hydrophobic (hydrophilic) residues that tend to collapse (swell) the chain when dispersed in a solvent. The solvent mediated interactions at each site are assumed to be random. The random interactions depend only on a given site i and the strength depends on the degree of hydrophilicity λ_i . Besides the term accounting for chain connectivity there are two- and higher-body interactions that determine the shape of the chain. In the GLO model the two-body interaction is given by

$$v_{ij} = v_0 + \beta(\lambda_i + \lambda_j)\delta[r_i - r_j] \quad (\text{C2.5.A1})$$

where v_0 is repulsive short-range interaction, λ_i is a quenched random variable which is distributed as

$$P(\lambda_i) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{(\lambda_i - \lambda_0)^2}{2\sigma^2}\right). \quad (\text{C2.5.A2})$$

-22-

If the mean λ_0 is positive then the majority of the residues are hydrophilic. A description of the collapsed phase of the chain requires introducing three- and four-body interaction terms. Thus, the total Hamiltonian is

$$\begin{aligned} \beta H = & \frac{1}{2} \sum_{i \neq j} v_{ij} + \frac{1}{6} \sum_{i \neq j \neq k} \omega_3 \delta(r_i - r_j) \delta(r_i - r_k) \\ & + \frac{1}{24} \sum_{i \neq j \neq k \neq l} \omega_4 \delta(r_i - r_j) \delta(r_j - r_k) \delta(r_k - r_l). \end{aligned} \quad (\text{C2.5.A3})$$

Since the charge variables λ_i are quenched the thermodynamics of the system requires averaging the free energy using the distribution $P(\lambda_i)$, i.e.

$$F = -k_B T \int \prod P(\lambda_i) \ln Z(\lambda_i) d\{\lambda_i\}. \quad (\text{C2.5.A4})$$

The average of $\ln Z(\lambda_i)$ is most conveniently done using the replicas through the relation

$$\ln Z = \lim_{n \rightarrow 0} \frac{Z^n - 1}{n}. \quad (\text{C2.5.A5})$$

Using (C2.5.A2)–(C2.5.A4) the required average can be carried out. This leads to a complicated expression for $\overline{Z^n}$ where the bar indicates the average over the quenched random variables λ_i . In terms of the order parameters

$$q_{ab}(r, r') = \int ds \delta(r_a(s) - r) \delta(r_b(s) - r') \quad (\text{C2.5.A6})$$

and

$$\rho_a(r) = \int ds \delta(r_a(s) - r) \quad (\text{C2.5.A7})$$

(a and b are replica indices) the expression for $\overline{Z^n}$ becomes

$$\overline{Z^n} = \int Dq_{ab}(r, r') D\hat{q}_{ab}(r, r') D\rho_a(r) D\phi_a(r) \exp[H_{\text{eff}}] \quad (\text{C2.5.A8})$$

where

$$H_{\text{eff}} = G(q_{ab}, \hat{q}_{ab}, \rho_a, \phi_a) + \ln \zeta(\hat{q}_{ab}, \phi_a) \quad (\text{C2.5.A9})$$

-23-

with

$$G = \int dr \sum \left(i\rho_a \phi_a - (v_0 + 2\beta\lambda_0) \frac{\rho_a^2}{2} - \frac{\omega'_3}{6} \rho_a^3 - \frac{\omega_4}{24} \rho_a^4 \right) + \int dr \int dr' \sum_{a < b} (i q_{ab}(r, r') \hat{q}_{ab}(r, r') + \beta^2 \lambda^2 q_{ab}(r, r') \rho_a(r) \rho_b(r'))$$

and

$$\zeta(\hat{q}_{ab}, \phi_a) = \int \prod_a D r_a(s) \exp(-H_T\{r_a(s)\}). \quad (\text{C2.5.A10})$$

In (C2.5.A10) $H_T\{r_a(s)\}$ is

$$H_T\{r_a(s)\} = \exp \left(-\frac{d}{2a^2} \int_0^N ds \sum_a \left(\frac{dr}{ds} \right)^2 - i \int_0^N ds \sum_a \phi_a(r_a(s)) - i \int_0^N ds \sum_{a < b} \hat{q}_{ab}(r_a, r_b) \right) \quad (\text{C2.5.A11})$$

and

$$\omega'_3 = \omega_3 - 3\beta^2 \lambda^2. \quad (\text{C2.5.A12})$$

The path integrals in (C2.5.A10) may be evaluated using the spectrum of the effective n -body Hamiltonian

$$H_n = -\frac{d}{2a^2} \sum_a \nabla_a^2 + \sum_a i\phi(r_a) + \sum_{a<b} i\hat{q}_{ab}(r_a, r_b) \quad (\text{C2.5.A13})$$

in the limit of $n \rightarrow 0$. If N is very large then we can use ground state dominance to evaluate the spectrum of H_n . This gives

and

$$\xi(\hat{q}_{ab}, \phi_a) \simeq \exp[-N \min_{\{\Psi(r)\}} \{(\Psi | H_n | \Psi) - E_0(\Psi | \Psi) - 1\}] \quad (\text{C2.5.A14})$$

where E_0 is the ground state energy of H_n . GLO evaluated the integral over q_{ab} (C2.5.A6) by a saddle point approximation which leads to

$$i\hat{q}_{ab}(r, r') = -\beta^2 \lambda^2 \rho_a(r) \rho_b(r'). \quad (\text{C2.5.A15})$$

-24-

From the above equation it follows that in the mean-field limit replica symmetry is not broken. This makes the GLO model conceptually simpler to interpret than the random bond heteropolymer model discussed in the appendix.

The total wavefunction $\Psi\{r_1, r_2, \dots, r_n\}$ is written as a product of single-particle functions (Hartree approximation). The various integrals are evaluated in the saddle point approximation. A simple Gaussian form for the trial one-particle wavefunction

$$\phi(r) = \left(\frac{1}{2\pi R^2}\right)^{d/4} \exp\left(-\frac{r^2}{2R^2}\right) \quad (\text{C2.5.A16})$$

is chosen with R being the single variational parameter. Upon performing the Gaussian integrals the free energy per monomer f becomes

$$\beta f = \frac{a^2}{8R^2} + \frac{1}{(2\sqrt{\pi})^d} \frac{(v_0 + 2\beta\lambda_0) N}{2} \frac{N}{R^d} + \Omega \quad (\text{C2.5.A17})$$

where

$$\Omega = \left(\frac{1}{(2\pi\sqrt{3})^d} \frac{\omega_3}{6} - \left(\frac{1}{2\pi}\right)^d (3^{-d/2} - 2^{-d})\right) \left(\frac{N}{R^d}\right)^2 + \left(\frac{1}{(32\pi^3)^d}\right)^{d/2} \frac{\omega_4}{24} \left(\frac{N}{R^d}\right)^3. \quad (\text{C2.5.A18})$$

At low temperatures the shape of the chain is determined by the sign of first term in (C2.5.A18). If the sign is negative then the positive four-body term is required for a stable theory.

The phase of the random hydrophobic–hydrophilic model is complicated and depends on the value of λ_n [11]. We

only describe the hydrophilic case when λ_0 is positive. In this case there is a first-order transition to a collapsed state ($R \sim N^{-1/d}$) induced by the negative three-body term. GLO have pointed out that this transition is neither the usual θ -point nor is it a freezing temperature because there is no replica symmetry breaking. In fact, this collapse transition resembles that seen in proteins where it is suspected that it is a first-order transition. The microscopic origin of the first-order transition upon collapse of polypeptide chains is not fully understood. Recent arguments suggest that it could arise because the burial of hydrophobic residues and the accommodation of the hydrophilic ones at the surface of proteins in water requires some work and perhaps this assembly happens in a discontinuous manner.

APPENDIX C2.5.B

In [section C2.5.2](#) we considered a variational-type theory to treat the thermodynamics of the random hydrophobic-hydrophilic heteropolymer. Here we describe a limiting behaviour of the random bond model [\[30\]](#).

-25-

In this appendix we show that the random bond model in the compact phase is identical to the random energy model (REM). Historically, REM was proposed as a caricature for proteins on phenomenological grounds [\[13\]](#). The heteropolymer with random bond interactions was treated using a variational theory which suggested that when the disorder increases beyond a limiting value the chain undergoes a thermodynamic glass transition. The nature of this transition is closely related to Potts glasses.

The random-bond heteropolymer is described by a Hamiltonian similar to (C2.5.A3) except that the short-range two-body term v_{ij} is taken to be random with a Gaussian distribution. In this case a three-body term with a positive value of ω_3 is needed to describe the collapsed phase. The Hamiltonian is

$$H = \sum_{i < j} (v_0 + v_{ij}) \delta(r_i - r_j) + \sum_{i \neq j \neq k} \delta(r_i - r_j) \delta(r_j - r_k) \quad (\text{C2.5.B1})$$

The distribution of the random couplings is given by

$$P(v_{ij}) = \frac{1}{\sqrt{2\pi v^2}} \exp\left(-\frac{v_{ij}^2}{2v^2}\right). \quad (\text{C2.5.B2})$$

In the collapse phase the monomer density $\rho = N/R^3$ is constant (for large N). Thus, the only conformation dependent term in (C2.5.A1) comes from the random two-body term. Because this term is a linear combination of Gaussian variables we expect that its distribution is also Gaussian and, hence, can be specified by the two moments. Let us calculate the correlation $\overline{E_1 E_2}$ between the energies E_1 and E_2 of two conformations $\{r_i^{(1)}\}$ and $\{r_i^{(2)}\}$ of the chain in the collapsed state. The mean square of E_1 is

$$\overline{E_1^2} = \frac{v^2}{2} \sum_{i,j} \delta(r_i^{(1)} - r_j^{(1)}) = \frac{v^2}{2} N\rho \quad (\text{C2.5.B3})$$

which is independent of the collapsed conformation. Similarly, we have

$$\begin{aligned}\overline{E_1 E_2} &= \frac{v^2}{2} \sum_{i,j} \delta(r_i^{(1)} - r_j^{(1)}) \delta(r_i^{(2)} - r_j^{(2)}) \\ &= \frac{v^2}{2} \sum_{r,r'} q_{12}^2(r, r')\end{aligned}$$

-26-

where $q_{12}(r, r')$ is the overlap between the two conformations. Because

$$\sum_{r,r'} q_{12}(r, r') = N \quad (\text{C2.5.B4})$$

and since the monomer density is constant we have $q_{12}(r, r') = \rho^2/N$. This implies

$$\overline{E_1 E_2} = \frac{v^2}{2} \rho^2. \quad (\text{C2.5.B5})$$

Thus the joint probability is

$$\lim_{N \rightarrow \infty} \sim \exp\left(-\frac{E_1^2 + E_2^2}{N\rho v^2}\right) \quad (\text{C2.5.B6})$$

which is equivalent to the behaviour in uncorrelated REM. Thus, it is not a surprise that in large dimensions (which are captured by variational type treatments) the random bond heteropolymer model yields exactly the same result as the REM.

C2.6 Colloids

Jeroen S van Duijneveldt

C2.6.1 INTRODUCTION

C2.6.1.1 CLASSIFICATION OF COLLOIDS

The term colloid refers to systems where one phase is finely divided in another phase—with at least one of the dimensions in the range of about 1 nm to 1 μm . This encompasses a wide variety of systems, some of which will be mentioned below. In a narrower sense, the word colloid is often used to denote systems consisting of solid particles (or liquid droplets) suspended in a liquid. This contribution will mainly focus on such systems. On the one hand, these particles are (significantly) larger than the solvent molecules. On the other hand, they are sufficiently small to remain suspended and undergo vivid Brownian motion (after the British botanist Robert Brown, who published his observations on aqueous pollen suspensions in 1827). The term colloid (after the Greek word for ‘glue’) was coined by Thomas Graham in the 1860s, to denote substances such as gelatin, albumin and gums. In a solution, these would not pass a dialysis membrane.

First of all, a general classification can be made depending on the nature of the continuous and suspended phases: gas, liquid, or solid. The names of the corresponding colloidal systems are summarized in table C2.6.1. Traditionally, following Kruyt [1], colloids are further classified as either reversible or irreversible, depending on whether they redisperse spontaneously when they are added to a solvent. Polymer and micellar solutions would be reversible, for instance, whereas suspensions and emulsions would usually be irreversible. These terms are more or less equivalent to the terms lyophilic (solvent-loving) and lyophobic (solvent-hating), respectively, which are also used widely. Many systems encountered in technology or in nature are colloids. Some examples are given in [table C2.6.2](#).

Table C2.6.1 Classification of colloidal systems.

Disperse phase	Dispersion medium		
	Gas	Liquid	Solid
Gas	—	Foam	Solid foam
Liquid	Aerosol	Emulsion	Solid emulsion
Solid	Aerosol	Suspension	Solid dispersion

C2.6.1.2 SCOPE

In practice, e.g., in nature or in formulated products, colloidal suspensions (also denoted sols or dispersions) tend to be complex systems, consisting of many components that are often not very well defined, in terms of particle size for instance. Much progress has been made in the understanding of colloidal suspensions by studying well defined model systems, which allow for a quantitative modelling of their behaviour. Such systems will be discussed here.

Although the remainder of this contribution will discuss suspensions only, much of the theory and experimental approaches are applicable to emulsions as well (see [2] for a review). Some other colloidal systems are treated elsewhere in this volume. Polymer solutions are an important class—see [section C2.1](#). For surfactant micelles, see [section C2.3](#). The special properties of certain particles at the lower end of the colloidal size range are discussed in [section C2.17](#).

C2.6.1.3 COLLOIDS AS ATOMS

In addition to their practical importance, colloidal suspensions have received much attention from chemists and physicists alike. This is an interesting research area in its own right, and it is an important aspect of what is referred to as soft condensed matter physics. This contribution is written from such a perspective, and although a balanced account is aimed for, it is inevitably biased by the author's research interests. References to the original literature are included, but within the scope of this contribution only a fraction of the vast amount of literature on colloidal suspensions can be mentioned.

Colloidal particles can be seen as large, model 'atoms'. In what follows we assume that particles with a typical radius $a = 100$ nm are studied, about 10^3 times as large as atoms. Usually, the solvent is considered to be a homogeneous medium, characterized by bulk properties such as the density ρ and dielectric constant ϵ . A full statistical mechanical description of the system would involve all colloid and solvent degrees of freedom, which tend to be intractable. Instead, the potential of mean force, V , is used, in which the interactions between colloidal particles are averaged over

all solvent degrees of freedom [3, 4]. Usually, V is written as a sum of pair potentials. Its equivalent for an atomic system is the potential energy. Analogously, the osmotic pressure Π replaces the pressure p . As a consequence of

this colloid–atom analogy, for instance, colloidal suspensions at low concentrations obey van 't Hoff's law, $\Pi = nkT$, the equivalent of the ideal gas law. At higher concentrations, colloids can display a similar phase behaviour as simple liquids, including colloidal gas, liquid, and crystal phases, that differ in the arrangement of the particles within the solvent.

Model colloids have a number of properties that make them experimentally convenient and interesting systems to study. For instance, the timescale for 'structural relaxation' of a colloidal fluid can be estimated as the time for a particle to diffuse a distance equal to its radius,

$$t_R \approx \frac{a^2}{D}$$

where the Stokes diffusion coefficient of a sphere in a liquid of viscosity η is given by

$$D = \frac{kT}{6\pi\eta a}. \quad (\text{C2.6.1})$$

This typically yields t_R of order 0.01 s.

Due to the particle size, a colloidal crystal is much weaker than a normal solid material—the elastic moduli are proportional to the number density n , and therefore a colloidal solid would be about 10^9 times weaker than its atomic equivalent. The weakness of a colloidal solid means that a crystal can be broken up easily, by shaking the sample, for instance. The slow structural relaxation means that non-equilibrium behaviour is experimentally accessible, such as crystallization kinetics and glass or gel formation. Indeed, many colloidal systems probably never reach thermodynamic equilibrium on the timescale of experiments. Furthermore, as shown below, the interaction potential between colloidal particles can be tuned by varying the surface chemistry of the particles and the solvent conditions.

In the theory of the liquid state, the hard-sphere model plays an important role. For hard spheres, the pair interaction potential $V(r) = \infty$ for $r < d$, where d is the particle diameter, whereas $V(r) = 0$ for $r > d$. The structure of a simple fluid, such as argon, is very similar to that of a hard-sphere fluid. Hard-sphere atoms do, of course, not exist. Certain model colloids, however, come very close to hard-sphere behaviour. These systems have been studied in much detail and some results will be quoted below.

C2.6.1.4 OUTLINE

The remainder of this contribution is organized as follows. In [section C2.6.2](#), some well studied colloidal model systems are introduced. Methods for characterizing colloidal suspensions are presented in [section C2.6.3](#). An essential starting point for understanding the behaviour of colloids is a description of the interactions between particles. Various factors contributing to these are discussed in [section C2.6.4](#). Following on from this, theories of colloid stability and of the kinetics of aggregation are presented in [section C2.6.5](#). Finally, [section C2.6.6](#) is devoted to the phase behaviour of concentrated suspensions.

Encyclopedia of Chemical Physics and Physical Chemistry

C2.6.2 MODEL COLLOIDS

A huge variety of model colloids have been studied. In this section we will highlight a few of these, of particular interest to the discussion of concentrated suspensions in [section C2.6.6](#).

C2.6.2.1 POLYDISPERSITY

Even when carefully prepared, model colloids are almost never perfectly monodisperse. The spread in particle sizes, or polydispersity, is usually expressed as the relative width of the size distribution,

$$\sigma = \frac{s_a}{\bar{a}}$$

where s_a denotes the standard deviation of a . So-called monodisperse model systems tend to have polydispersities ranging from about $\sigma = 0.01$ to about 0.2. Suspensions encountered in practice tend to be much more polydisperse than that. When performing accurate quantitative experiments, the polydispersity needs to be taken into account. In some cases, such as in the formation of colloidal crystals (see [section C2.6.6](#)), the qualitative behaviour may also depend sensitively on the polydispersity.

C2.6.2.2 INORGANIC PARTICLES

Traditionally, most model studies were carried out using inorganic colloids, for instance gold and sulphur sols. A variety of particle types and shapes are provided by hydrous metal oxides [5] and silica [6]. Inorganic model suspensions are usually made using a nucleation and growth process. By controlling the nucleation step, monodisperse suspensions can be obtained. For instance, monodisperse silica spheres can be obtained by hydrolyzing alkoxysilanes in alcoholic solution [7]. Alternatively, seed particles can be prepared using microemulsions and then grown to the required size, resulting in very monodisperse suspensions (see [figure C2.6.1](#)). Near hard-sphere silica suspensions can then be obtained by coating the particles with a chemically grafted polymer layer and suspending them in organic solvents [8].

Encyclopedia of Chemical Physics and Physical Chemistry

C2.6.2.3 POLYMER LATTICES

An important step in the progress of colloid science was the development of monodisperse polymer latex suspensions in the 1950s. These are prepared by emulsion polymerization, which is nowadays also carried out industrially on a large scale for many different polymers. Perhaps the best-studied colloidal model system is that of polystyrene (PS) latex [9]. This is prepared with a hydrophilic group (such as sulphate) at the end of each molecule. In water this produces well defined spheres with a number of end groups at the surface, which (partly) ionize to

produce charged particles. In aqueous suspensions, near hard-sphere behaviour can be obtained by adding sufficient salt to screen the electrostatic repulsions (see [section C2.6.4](#)).

Another model system consists of polymethylmethacrylate (PMMA) latex, stabilized in organic solvents by a 'comb' polymer, consisting of a PMMA backbone with poly-12-hydroxystearic acid (PHSA) chains attached to it [10]. The PHSA chains form a steric stabilization layer at the surface (see [section C2.6.4](#)). Such particles can approach the hard-sphere model very well [11].

C2.6.2.4 PARTICLES WITH UNUSUAL PROPERTIES

In addition to the 'standard' model systems described above, more exotic particles have been prepared with certain unusual properties, of which we will mention a few. For instance, using seeded growth techniques, particles have been developed with a silica shell which surrounds a core of a different composition, such as particles with magnetic [12], fluorescent [13] or gold cores [14]. Another example is that of spheres of polytetrafluoroethylene (PTFE), which are optically anisotropic because the core is crystalline [15].

A different class, in between polymer lattices and polymer solutions, is that of microgels, consisting of weakly crosslinked polymer networks. Just as for polymer solutions, small changes in the solvency conditions may have large

Encyclopedia of Chemical Physics and Physical Chemistry

-6-

effects on their behaviour. They tend to undergo a swelling–deswelling transition, which for sufficiently weakly crosslinked particles may result in a particle size change by a factor of 5 [16].

C2.6.2.5 NON-SPHERICAL COLLOIDS

Although the majority of studies on model colloids involve (quasi-) spherical particles, there is a growing interest in the properties of non-spherical colloids. These tend to be either rod-like or plate-like.

One model for rod-like colloids is the tobacco mosaic virus (TMV), which consists of rods of diameter D about 18 nm and length L of 300 nm [17, 18]. These colloids have the advantage of being quite monodisperse, but are hard to obtain in large amounts. The *fd* virus gives longer, semi-flexible rods ($L = 880$ nm, $D = 9$ nm) [18, 19]. Inorganic boehmite rods have also been prepared successfully [20].

The major class of plate-like colloids is that of clay suspensions [21]. Many of these swell in water to give a stack of parallel, thin sheets, stabilized by electrical charges. Natural clays tend to be quite polydisperse. The synthetic clay laponite is comparatively well defined, consisting of discs of about 1 nm in thickness and 25 nm in diameter. It has been used in a number of studies (e.g. [22]).

C2.6.2.6 PURIFICATION

After preparation, colloidal suspensions usually need to undergo purification procedures before detailed studies can be carried out. A common technique for charged particles (typically in aqueous suspension) is dialysis, to deal with ionic impurities and small solutes. More extensive deionization can be achieved using ion exchange resins.

Another standard method is to use a (high-speed) centrifuge to sediment the colloids, replace the supernatant and redisperse the particles. Provided the particles are well stabilized in the solvent, this allows for a rigorous purification. Larger objects, such as particle aggregates, can be fractionated off because they settle first. A third method is (ultra)filtration, whereby larger impurities can be retained, particularly using membrane filters with accurately defined pore sizes.

C2.6.3 PROPERTIES AND CHARACTERIZATION METHODS

Even when well defined model systems are used, colloids are rather complex, when compared with pure molecular compounds, for instance. As a result, one often has to resort to a wide range of characterization techniques to obtain a sufficiently comprehensive description of a sample being studied. This section lists some of the most common techniques used for studying colloidal suspensions. Some of these techniques are discussed in detail elsewhere in this volume and will only be mentioned in passing. A few techniques that are relevant more specifically for colloids are introduced very briefly here, and a few advanced techniques are highlighted.

Although the behaviour of colloidal suspensions does in general depend on temperature, a more important control parameter in practice tends to be the particle concentration, often expressed as the volume fraction ϕ . In fact, for hard-sphere suspensions the phase behaviour is determined by ϕ only. For spherical particles $\phi = \frac{4}{3}\pi a^3 n$.

Encyclopedia of Chemical Physics and Physical Chemistry

-7-

In practice, there are various ways by which ϕ can be determined for a given sample, and the results may be (slightly) different. In particular, for sterically stabilized particles, the effective hard-sphere volume fraction will be different from the value obtained from the total solid content.

C2.6.3.1 OBSERVATION

Straightforward, direct observation is generally very useful to assess suspension stability, phase separations, etc. Light microscopy (see [section B1.19](#)) can, under some conditions, image particles directly. Often, however, this is prevented by sample turbidity or insufficient resolution. An enhanced resolution can be obtained by preparing core-shell particles with a fluorescent core. Even when the particles are touching, the cores can still be resolved using confocal scanning laser microscopy (CSLM), allowing for the determination of three-dimensional structures in dense suspensions [23] (see [figure C2.6.2](#)).

Electron microscopy (see [section B1.18](#)) is very valuable in characterizing particles (see, for instance, [figure C2.6.1](#)). The suspension structure is, of course, not represented well because of the vacuum conditions in the microscope. This can be overcome using environmental SEM [24].

Figure C2.6.2. CSLM image of near hard-sphere silica particles of diameter $d = 1050$ nm with a fluorescent core of diameter 400 nm, showing fcc stacking (top), hcp stacking (bottom middle) and amorphous areas (image size $16.3 \mu\text{m} \times 16.3 \mu\text{m}$, courtesy of Professor A van Blaaderen)

C2.6.3.2 GENERAL PROPERTIES

Because model colloids tend to have a rather well defined chemical composition, elemental analysis can be used to obtain detailed information, such as the grafted amount of polymer in the case of sterically stabilized particles. More details about the chemical structure can be obtained using NMR techniques ([section B1.13](#)). In addition, NMR

Encyclopedia of Chemical Physics and Physical Chemistry

-8-

relaxation techniques can be used to quantify properties such as polymer adsorption to the particle surface (see [section B1.13](#)). Often further details, such as particle density and refractive index, need to be determined as well.

C2.6.3.3 SCATTERING TECHNIQUES

Because colloidal particles typically have a size similar to that of the wavelength of light, light scattering and diffraction are very useful in characterizing their suspensions. In particular, for small particles, x-ray and neutron scattering are employed as well (see [section B1.9](#)). Photon correlation spectroscopy (PCS) is a standard technique for particle size determination. Static light scattering is also used for this, and to characterize the structure of suspensions. Although, in an indirect way, both techniques can yield information on particle interactions as well.

C2.6.3.4 PARTICLE INTERACTIONS

The interactions between colloidal particles (see [section C2.6.4](#)) are central to the understanding of suspension behaviour. Although most work has had to rely on rather indirect ways to characterize these interactions, novel techniques are emerging that access these interactions more directly.

Particles can be manipulated in suspension using strongly focused laser beams ('optical tweezers') [[25](#)] or magnetic fields [[26](#)] and by collecting statistics on the particle movements using video microscopy, information on the particle interactions can be obtained.

Surfaces can be characterized using scanning probe microscopies (see [section B1.19](#)). In addition, by attaching a colloidal particle to the tip of an atomic force microscope, colloidal interactions can be probed as well [[27](#)]. Interactions between surfaces can be studied using the surface force apparatus (see [section B1.20](#)). This also helps one to understand the interactions between colloidal particles.

C2.6.3.5 RHEOLOGY

The study of the rheology, or flow behaviour, of suspensions is an important method for characterizing particle interactions. Controlling the rheological properties of suspensions is also crucial in practice, where during processing and in the final application the flow behaviour usually has to be within fairly narrow specifications. This field is only touched upon here; for more details consult [[28](#), [29](#), [30](#) and [31](#)], or the general colloid science texts [[32](#), [33](#) and [34](#)]. For Newtonian fluids, the shear stress (force/area) τ is proportional to the shear rate (velocity gradient), $\dot{\gamma}$,

$$\tau = \eta \dot{\gamma}. \quad (\text{C2.6.2})$$

For dilute dispersions of hard spheres, Einstein's viscosity equation predicts

$$\frac{\eta}{\eta_0} = 1 + 2.5\phi + \dots$$

where η_0 denotes the solvent viscosity. For concentrated hard-sphere suspensions, experimental data can be

using the Krieger–Dougherty equation,

$$\frac{\eta}{\eta_0} = [1 - (\phi/\phi_{\max})]^{-[\eta]\phi_{\max}}$$

where $[\eta]$ is called the intrinsic viscosity and the viscosity diverges at a concentration ϕ_{\max} . At low shear rate, $\phi_{\max} = 0.63$ (similar to the random close packing density; see [section C2.6.6.2](#)) and $[\eta] = 3.13$. The Krieger–Dougherty equation is also widely used to correlate data for other types of suspensions.

Colloidal dispersions often display non-Newtonian behaviour, where the proportionality in [equation \(C2.6.2\)](#) does not hold. This is particularly important for concentrated dispersions, which tend to be used in practice. [Equation \(C2.6.2\)](#) can be used to define an apparent viscosity, η_{app} , at a given shear rate. If η_{app} decreases with increasing shear rate, the dispersion is called shear thinning (pseudoplastic); if it increases, this is known as shear thickening (dilatant). The latter behaviour is typical of concentrated suspensions. If a finite shear stress has to be applied before the suspension begins to flow, this is known as the yield stress. The apparent viscosity may also change as a function of time, upon application of a fixed shear rate, related to the formation or breakup of particle networks. Thixotropic dispersions show a decrease in η_{app} with time, whereas an increase with time is called rheopexy.

C2.6.3.6 SEDIMENTATION AND DIFFUSION

In most colloidal suspensions the particles have a tendency to sediment. At infinite dilution, spherical particles with a density difference $\Delta\rho$ with the solvent will move at the Stokes velocity

$$U_0 = \frac{2a^2\Delta\rho g}{9\eta}.$$

At finite concentration, the settling rate is influenced by hydrodynamic interactions between the particles. For purely repulsive particle interactions, settling is hindered. Attractive interactions encourage particles to settle as a group, which increases the settling rate. For hard spheres, the first-order correction to the Stokes settling rate is given by [\[33\]](#)

$$\frac{U}{U_0} = 1 - 6.55\phi.$$

The tendency for particles to settle is opposed by their Brownian diffusion. The number density distribution of particles as a function of height z will tend to an equilibrium distribution. At low concentration, where van 't Hoff's law applies, the barometric height distribution is given by

$$n(z) \propto \exp\left(-\frac{mgz}{kT}\right)$$

where m is the buoyant mass of the particles and g the gravitational acceleration. Perrin has already used this to determine Avogadro's number [\[35\]](#).

Given the a^2 size dependence of the settling rate, sedimentation can be used for particle size analysis. Indeed, a quick

impression of particle size (or degree of aggregation of primary particles) is often obtained from the settling behaviour of dilute suspensions. A quantitative analysis of particle sizes can be carried out using the analytic ultracentrifuge (see, for instance, [34]).

In practice, sedimentation is an important property of colloidal suspensions. In formulated products, sedimentation tends to be a problem and some products are shipped in the form of weak gels, to prevent settling. On the other hand, in applications such as water clarification, a rapid sedimentation of impurities is desirable.

C2.6.3.7 ELECTROKINETIC PHENOMENA

In particular, in polar solvents, the surface of a colloidal particle tends to be charged. As will be discussed in [section C2.6.4.2](#), this has a large influence on particle interactions. A few key concepts are introduced here. For more details, see [32] (ch 13), [33] (ch 7), [36] (ch 4) and [34] (ch 12). The presence of these surface charges gives rise to a number of electrokinetic phenomena, in particular electrophoresis.

In electrophoresis, the motion of charged colloidal particles under the influence of an electric field is studied. For spherical particles, we can write

$$v = \mu_E E$$

where v is the particle velocity, E the electric field and μ_E is called the electrophoretic mobility. For low surface electrostatic potentials, it is given by Henry's equation,

$$\mu_E = 2 \frac{\epsilon \epsilon_0}{3\eta} \zeta f(\kappa a)$$

where κ is the inverse screening length (see [section C2.6.2](#)). $f(\kappa a)$ increases from 1 at $\kappa a = 0$ to 1.5 at $\kappa a \rightarrow \infty$. The zeta-potential ζ represents the electrostatic potential near the point where the diffuse double layer ([section C2.6.4.2](#)) starts.

Related phenomena are electro-osmosis, where a liquid flows past a surface under the influence of an electric field and the reverse effect, the streaming potential due to the flow of a liquid past a charged surface.

C2.6.4 PARTICLE INTERACTIONS

Many properties of colloidal suspensions, such as their stability, rheology, and phase behaviour, are closely related to the interactions between the suspended particles. The background of the most important contributing factors to these interactions is discussed in this section.

C2.6.4.1 VAN DER WAALS INTERACTIONS

Between any two atoms or molecules, van der Waals (or dispersion) forces act because of interactions between the fluctuating electromagnetic fields resulting from their polarizabilities (see [section A1.5](#), and, for instance,

Encyclopedia of Chemical Physics and Physical Chemistry

[37]). Similarly, van der Waals forces operate between any two colloidal particles in suspension. In the 1930s, predictions for these interactions were obtained from the pairwise addition of molecular interactions between two particles [38]. The interaction between two identical spheres is given by

$$V_{\text{vdW}}(r) = -\frac{A}{6} \left[\frac{2a^2}{r^2 - 4a^2} + \frac{2a^2}{r^2} + \ln \left(1 - \frac{4a^2}{r^2} \right) \right] \quad (\text{C2.6.3})$$

where A is the Hamaker constant, which typically is of order 10^{-20} J. Similar equations are obtained for other geometries [37, 39].

At large separation r , equation (C2.6.3) decays as $V_{\text{vdW}}(r) \propto r^{-6}$, just as the van der Waals interactions between molecules do. However, at large separation, say $r > 100$ nm, relativistic effects have to be taken into account and the so-called retarded van der Waals interactions decay as r^{-7} .

At short separations, equation (C2.6.3) tends to

$$V_{\text{vdW}}(r) \approx \frac{A a}{12 H} \quad (\text{C2.6.4})$$

where $H = r - 2a$ is the surface separation. At contact, equation (C2.6.4) would predict an infinitely strong attraction. In reality, this is prevented by steep Born repulsions at short distances. Nevertheless, the van der Waals interactions tend to create a deep interaction minimum near $r = 2a$, strong enough to result in aggregation of suspended particles, unless a stabilizing mechanism such as electrostatic interactions or steric stabilization is provided (see section C2.6.2 and section C2.6.3).

The Hamaker constant can be evaluated accurately using the continuum theory, developed by Lifshitz and coworkers [40]. A key property in this theory is the frequency dependence of the dielectric permittivity, $\epsilon(\omega)$. If this spectrum were the same for particles and solvent, then $A = 0$. Since the refractive index n is also related to $\epsilon(\omega)$, the van der Waals forces tend to be very weak when the particles and solvent have similar refractive indices. A few examples of values for A for interactions across vacuum and across water, obtained using the continuum theory, are given in table C2.6.3.

Encyclopedia of Chemical Physics and Physical Chemistry

-12-

Table C2.6.3 Hamaker constants A (10^{-20} J) (from [120]).

Material	Medium	
	Vacuum	Water
Water	3.7	—
Pentane	3.8	0.34
PS	6.6	0.95
PMMA	7.1	1.05
Fused silica	6.6	0.85

More generally, approximate relations can be used to estimate the Hamaker constant for particles 1 and 2, suspended in a medium 3, such as

$$A_{132} \approx (\sqrt{A_{11}} - \sqrt{A_{33}})(\sqrt{A_{22}} - \sqrt{A_{33}}) \quad (\text{C2.6.5})$$

where A_{ii} is the Hamaker constant for interaction of material i across a vacuum. Although the validity of such equations is limited, one interesting aspect of [equation C2.6.5](#) is that van der Waals interactions between two suspended particles can be repulsive, when the suspending medium has a Hamaker constant intermediate between that of the two particles.

C2.6.4.2 ELECTROSTATIC INTERACTIONS

Particularly in polar solvents, electrostatic charges usually have an important contribution to the particle interactions. We will first discuss the ion distribution near a single surface, and then the effect on interactions between two colloidal particles.

THE ELECTRICAL DOUBLE LAYER

Here a few core equations are presented from the simplest theory for the electric double layer: the Gouy–Chapman theory [41]. We consider a solution of ions of valency z_+ and z_- in a medium with dielectric constant ϵ . The ions are represented by point charges (they have no size) and it is assumed that the ions undergo rapid Brownian motion, and their average spatial distribution may be obtained through Boltzmann's distribution from the electrostatic potential. For simplicity, we restrict ourselves to symmetric electrolytes, $z = z_+ = z_-$. We write the electrostatic potential ϕ in dimensionless form as

$$\Phi = \frac{ze\phi}{kT}$$

Encyclopedia of Chemical Physics and Physical Chemistry

-13-

where e is the elementary charge. A combination of Poisson's law and the Boltzmann distribution gives the Poisson–Boltzmann equation, which here takes the form

$$\nabla^2 \Phi = \kappa^2 \sinh \Phi \quad (\text{C2.6.6})$$

and κ is given as a function of the bulk electrolyte concentration c_0 by

$$\kappa = \sqrt{\frac{2e^2 N_A c_0 z^2}{\epsilon \epsilon_0 kT}}. \quad (\text{C2.6.7})$$

This is an inverse length; κ^{-1} is known as the Debye screening length (or double layer thickness). As demonstrated below, it gives the length scale on which the ion distribution near a surface decays to the bulk value. [Table C2.6.4](#) gives a few numerical examples.

Table C2.6.4 Debye screening length κ^{-1} for aqueous solutions of a 1-1 electrolyte at 298 K (equation (C2.6.7)).

c_0 (mol dm⁻³) κ^{-1} (nm)

10⁻⁵ 97

10^{-3}	9.7
0.1	0.97

Surfaces in polar solvents and particularly in water tend to be charged, through dissociation of surface groups or by adsorption of ions, resulting in a charge density σ . Near a flat surface, ϕ only depends on the distance x from the surface. The solution of equation (C2.6.6) then is

$$\Phi = 2 \ln \left(\frac{1 + \gamma e^{-\kappa x}}{1 - \gamma e^{-\kappa x}} \right) \quad (\text{C2.6.8})$$

where $\gamma = \tanh(\frac{1}{4}\Phi_s)$ and the subscript s denotes values at the surface. The corresponding surface charge density is given by

$$\sigma = 2\sqrt{2\epsilon\epsilon_0 kT N_A c_0} \sinh \frac{1}{2} \Phi_s. \quad (\text{C2.6.9})$$

From Φ , the charge distribution can then be calculated using Boltzmann's distribution. An example of this is shown in

Encyclopedia of Chemical Physics and Physical Chemistry

-14-

figure C2.6.3, which plots the distribution of counterions (of opposite sign to the charged surface) and co-ions (of the same sign as the surface). More detailed descriptions of the ionic distribution take into account the non-uniform packing of ions and molecules close to the surface. A significant potential drop may occur across this so-called Stern layer adjacent to the surface. The potential ϕ_d outside the Stern layer then enters the description of the diffuse double layer. In practice, ϕ_d is usually equated to the ζ -potential, discussed in [section C2.6.3.7](#).

Figure C2.6.3. Distribution of positive and negative ions (c_+ , c_-) near a flat surface in water at 298 K ([equation \(C2.6.8\)](#)). Parameters: $z = 1$, $\phi_s = 70$ mV, $c_0 = 0.1$ mol dm⁻³, corresponding to $\sigma = -0.068$ C m⁻² ([equation \(C2.6.9\)](#)). The double layer thickness $\kappa^{-1} = 0.96$ nm is indicated.

DOUBLE LAYER INTERACTIONS

When describing the interactions between two charged flat plates in an electrolyte solution, [equation \(C2.6.6\)](#) cannot be solved analytically, so in the general case a numerical solution will have to be used. Several equations are available, however, to describe the behaviour in a number of limiting cases (see [41] for a detailed discussion). Here we present two limiting cases for the interactions between two charged spheres, surrounded by their counterions and added electrolyte, which will be referred to in further sections. This pair interaction V_R is always repulsive in the theory discussed here.

The first case is relevant in the discussion of colloid stability of [section C2.6.5](#). It uses the potential around a single sphere in the case of a double layer that is thin compared to the particle, $\kappa a \gg 1$. Furthermore, it is assumed that the surface separation is fairly large, such that $\exp(-\kappa H) \ll 1$, so the potential between two spheres can be calculated from the sum of single-sphere potentials. Under these conditions, V_R is approximated by [42]:

Encyclopedia of Chemical Physics and Physical Chemistry

-15-

$$V_R = \frac{32\pi\epsilon\epsilon_0ak^2T^2\gamma^2}{z^2e^2}e^{-\kappa H}. \quad (\text{C2.6.10})$$

Again, κ^{-1} is the length scale on which the interaction decays.

In the second case, a thick double layer, $\kappa a \ll 1$ (low ionic strength), is assumed. When the surface potential is low, $\Phi_s \ll 1$, a reasonable approximation is given by

$$V_R = 4\pi\epsilon\epsilon_0a^2\phi_s^2e^{2\kappa a}\frac{e^{-\kappa r}}{r}. \quad (\text{C2.6.11})$$

This r dependence is also known as a Yukawa potential. This type of potential has been used to describe the behaviour of latex suspensions at low ionic strength.

More sophisticated approaches to describe double layer interactions have been developed more recently. Using cell models, the full Poisson-Boltzmann equation can be solved for ordered structures. The approach by Alexander *et al* shows how the effective colloidal particle charge saturates when the 'bare' particle charge is increased [43]. Using integral equation methods, the behaviour of the 'primitive model' has been studied, in which all the interactions between the colloidal macro-ions and the small ions are addressed (see, for instance, [44, 45]).

C2.6.4.3 INTERACTIONS DUE TO SOLUBLE POLYMERS

In many colloidal systems, both in practice and in model studies, soluble polymers are used to control the particle interactions and the suspension stability. Here we distinguish three scenarios: interactions between particles bearing a grafted polymer layer, forces due to the presence of non-adsorbing polymers in solution, and finally the interactions due to adsorbing polymer chains. Although these cases are discussed separately here, in practice more than one mechanism may be in operation for a given sample.

STERIC STABILIZATION

The first case concerns particles with polymer chains attached to their surfaces. This can be done using chemically (end-)grafted chains, as is often done in the study of model colloids. Alternatively, a block copolymer can be used, of which one of the blocks (the anchor group) adsorbs strongly to the particles. The polymer chains may vary from short alkane chains to high molecular weight polymers (see also [section C2.6.2](#)). The interactions between such

'hairy' colloidal particles depend on many parameters, such as the nature of the polymer and the solvent, the molecular weight and grafting density. For theoretical approaches to describe the resulting behaviour, see [33, 46, 47]. Here a few general observations are made.

For so-called steric stabilization to be effective, the polymer needs to be attached to the particles at a sufficiently high surface coverage and a good solvent for the polymer needs to be used. Under such conditions, a fairly dense polymer brush with thickness L will be present around the particles. When two particles approach, such that $r < d + 2L$, the polymer layers may be compressed from their equilibrium configuration, thus causing a repulsive interaction.

Encyclopedia of Chemical Physics and Physical Chemistry

-16-

Alternatively, the polymer layers may overlap, which increases the local polymer segment density, also resulting in a repulsive interaction. Particularly on close approach, $r < d + L$, a steep repulsion is predicted to occur. When a relatively low molecular weight polymer is used, the repulsive interactions are rather short-ranged (compared to the particle size) and the particles display near hard-sphere behaviour (e.g., [11]).

When the solvent quality is reduced, by changing the solvent composition or temperature, for instance, steric stabilization may not occur. On close approach, a repulsive interaction will still result, but for partial overlap of the polymer layers an attractive interaction may arise. For a number of systems, steric stabilization was found to fail, resulting in particle aggregation, at the θ temperature of the polymer [46] (at the θ temperature, the second osmotic virial coefficient of the polymer solution is zero; see also section C2.1). The attractions tend to be of short range compared to the particles themselves. The behaviour of such systems has been modelled using a narrow square well potential [48]. In the limit of a very narrow attraction range, Baxter's adhesive sphere ('sticky' sphere) potential [49] is obtained. Many authors have interpreted their observations by modelling the particle interactions using this potential.

NON-ADSORBING POLYMER

The second case involves non-adsorbing polymer chains in solution. It was realized by Asakura and Oosawa (AO) [50] and separately by Vrij [51] that these chains will give rise to an effective attraction between colloidal particles. This is known as depletion attraction (see figure C2.6.4). We will summarize the AO theory to explain this.

Figure C2.6.4. Graphical representation of the AO model. A depletion shell of thickness δ surrounds each particle.

The colloidal particles are represented by hard spheres with diameter d , and the polymer coils by spheres with radius δ . As a guide, δ is often taken to be equal to R_g , the radius of gyration of the polymer. Polymer molecules are considered not to have any interaction. A polymer 'sphere', however, cannot overlap with a colloidal particle (the colloidal particles and polymer molecules behave as hard spheres towards each other). This means that a polymer coil cannot enter a sphere with radius $a + \delta$, centred on a colloidal particle. In other words, there is a depletion shell of thickness δ around each particle. If two particles approach each other, their depletion zones will overlap when $r < d + 2\delta$. This gives rise to an osmotic pressure imbalance, which results in an effective attraction between the particles, given by

$$V_{\text{dep}} = -\Pi_p V_{\text{overlap}} \quad (d < r < d + 2\delta) \quad (\text{C2.6.12})$$

where Π_p is the polymer osmotic pressure and V_{overlap} is the overlap volume of the excluded spheres of the two particles. It is given by

Encyclopedia of Chemical Physics and Physical Chemistry

-17-

$$V_{\text{overlap}} = \left(1 - \frac{3r}{2d(1+\xi)} + \frac{1}{2} \left[\frac{r}{d(1+\xi)} \right]^3\right) \frac{\pi}{6} d^3 (1+\xi)^3$$

where

$$\xi = \delta/a$$

is the polymer/colloid size ratio. Figure C2.6.5 shows examples of the shape of this potential. A few points are worth noting about this potential. First, although the net effect is an attraction between the colloids, this is the result of purely repulsive interactions. Second, this interaction can easily be tuned experimentally: the range (2δ) is set by the polymer size (molecular weight), whereas the strength can be adjusted by the polymer concentration (at low concentration, van 't Hoff's law can again be applied: $\Pi_p = n_{\text{pol}}kT$). Some results obtained in this way will be discussed in section C2.6.6.4. For a more advanced discussion of depletion interactions, see [33, 46, 47 and 52]. The depletion picture also applies to other systems, such as mixtures of colloidal particles. However, whereas neglecting the interactions between polymer molecules may be reasonable, this cannot be done in the general case.

ADSORBING POLYMER

Finally, we briefly mention interactions due to adsorbing polymers. Block copolymers, with one block strongly adsorbing to the particles, have already been mentioned above. Here, we focus on homopolymers that adsorb moderately strongly to the particles. If this can be done such that a high surface coverage is achieved, the adsorbed polymer layer may again produce a steric stabilization between the particles.

Figure C2.6.5. Examples of the AO potential, equation (C2.6.12). The values of ξ are indicated next to the curves. The hard-sphere repulsion at $r = d$ has not been drawn.

At lower surface coverage, however, the possibility exists that one polymer chain may attach itself to two particles. If the adsorption is strong enough, this results in an aggregation of the particles, known as bridging flocculation [33, 46, and 47].

C2.6.5 COLLOID STABILITY AND AGGREGATION

In this section we focus on the theory of stability of charged colloids. In section C2.6.5.1 it is shown how particles can be made to aggregate by adding sufficient electrolyte. The associated aggregation kinetics are discussed in [section C2.6.5.2](#), and the structure of the aggregates in [section C2.6.5.3](#). For more details, see the recent reviews [53, 54 and 55], or the colloid science textbooks [33, 39].

C2.6.5.1 CHARGED PARTICLES

In suspensions containing no soluble polymer, the van der Waals forces and electrostatic interactions are the main factors in controlling the particle interactions. The van der Waals interactions are often strong enough to cause an irreversible aggregation of the particles, unless a stabilizing mechanism is present. In polar solvents, particularly in water, the particle surfaces tend to be charged. At low salt concentration, the resulting double layer repulsions can be strong enough to prevent aggregation.

Here we consider the total interaction between two charged particles in suspension, surrounded by their counterions and added electrolyte. This is the celebrated DLVO theory, derived independently by Derjaguin and Landau and by Verwey and Overbeek [41]. By combining the van der Waals interaction ([equation \(C2.6.4\)](#)) with the repulsion due to the electric double layers ([equation \(C2.6.10\)](#)), we obtain

$$V_{DLVO} = V_{vdW} + V_R. \quad (C2.6.13)$$

For the repulsions, the approximate result of [equation \(C2.6.10\)](#) is appropriate for the typical conditions relevant for investigating the particle stability ($\kappa a \gg 1$, $\kappa H \approx 1$) [33, 41]. Examples of the shape of this potential are shown in [figure C2.6.6](#). At short range, a deep attractive minimum (called the primary minimum) is found, due to the van der Waals attractions. At slightly larger separation, a repulsive maximum is present at low salt concentration. Once two particles have reached the primary minimum this tends to be irreversible. They may, however, be kinetically stabilized against reaching this minimum when the repulsive maximum is sufficiently high, $V_{\max} \gg kT$.

Figure C2.6.6. DLVO potential for gold spheres with $A/kT=25$, $a=100$ nm and $\Phi_s = 1$ in water, at a range of concentrations of 1-1 electrolyte (equations (C2.6.3), (C2.6.10) and (C2.6.13)).

As can be seen in figure C2.6.6 the repulsive maximum is reduced at high ionic strength. A rapid and irreversible aggregation into the primary minimum (also referred to as coagulation) is expected to occur when the maximum has become sufficiently small. Over a narrow range of electrolyte concentrations, a transition occurs from kinetic stabilization to rapid aggregation, when the maximum is about zero. By solving equation (C2.6.13) for $V_{DLVO} = 0$ and $dV_{DLVO}/dH = 0$, we obtain $\kappa H = 1$, and the corresponding electrolyte concentration, known as the critical coagulation concentration (c.c.c.), is given by

$$c_{ccc} = \frac{49.6\gamma^4}{N_A z^6 l_b^3} \left(\frac{kT}{A} \right)^2 \quad (\text{C2.6.14})$$

where $l_b = e^2/4\pi\epsilon\epsilon_0 kT$ is the Bjerrum length. For the conditions used in figure C2.6.6 c_{ccc} is calculated to be 1.3 mmol dm⁻³.

In equation (C2.6.14) it can be seen that the required salt concentration depends strongly on the valency of the ions z . At high surface potential $\gamma \rightarrow 1$, and $c_{ccc} \propto z^{-6}$. This had been observed experimentally and is known as the Schulze–Hardy rule. This result was one of the early successes of DLVO theory. At low surface potential, however, the valency dependence is less pronounced, $c_{ccc} \propto z^{-6}$. In reality, the behaviour of higher valency ions can be rather complicated, for instance, they may adsorb to the particle surface and even change the sign of the surface charge.

Encyclopedia of Chemical Physics and Physical Chemistry

At larger particle separation, a second minimum may occur in the potential energy. In many cases, this minimum is too shallow to be of much significance. For larger particles, however, the minimum may become of order kT . Aggregation in this minimum is referred to as secondary minimum flocculation.

For a more complete understanding of colloid stability, we need to address the kinetics of aggregation. The theory discussed here was developed to describe coagulation of charged colloids, but it does apply to other cases as well. First, we consider the case of so-called rapid coagulation, which means that two particles will aggregate as soon as they meet (at high salt concentration, for instance). This was considered by von Smoluchowski [56]; here we follow [39, 57].

It is assumed that irreversible aggregation occurs on contact. The rate of coagulation is expressed as the aggregation flux J of particles towards a central particle. Using a steady-state approximation, the diffusive flux is derived to be

$$J = 16\pi D a n$$

where D is again the diffusion coefficient of a single particle (equation (C2.6.1)) and n is the initial monomer concentration. As aggregation proceeds, a distribution of aggregate sizes (monomers, dimers, trimers, etc) is established, which evolves in time. This is described by

$$n_i = \frac{n(t/t_p)^{i-1}}{(1+t/t_p)^{i+1}} \quad (\text{C2.6.15})$$

where n_i denotes the number density of i -mers at time t . The half-life time of aggregation t_p , after which the total number of aggregates has halved, is given as a function of the volume fraction ϕ by

$$t_p = \frac{\pi \eta a^3}{kT \phi} \quad (\text{C2.6.16})$$

In table C2.6.5, a few numerical examples for t_p are shown. Smaller colloids are found to aggregate much faster and stabilizing them is therefore more difficult. The validity of equation (C2.6.15) has been confirmed experimentally (e.g. [58]).

Table C2.6.5 Rapid coagulation half-life time for particles in water at $T=300$ K (equation (C2.6.16)).

a	$\phi = 10^{-5}$	$\phi = 0.1$
100 nm	76 s	8 ms
1 μm	21 h	8 s

Encyclopedia of Chemical Physics and Physical Chemistry

The second case concerns situations where not all particle encounters result in aggregation. This is known as slow coagulation. This was addressed first by Fuchs [59]; again we follow [39, 57].

In slow coagulation, particles have to diffuse over an energy barrier (see the previous section) in order to aggregate. As a result, not all Brownian particle encounters result in aggregation. This is expressed using the stability ratio W , defined as

$$W = \frac{J_0}{J} \quad (\text{C2.6.17})$$

where J_0 denotes the rapid coagulation rate. By solving the diffusion equations under steady-state conditions, it was found that

$$W = 2a \int_{2a}^{\infty} \frac{\exp(V_{\text{DLVO}}/kT)}{r^2} dr. \quad (\text{C2.6.18})$$

Because of the exponential term, W is mainly determined by the potential energy maximum V_{max} , and it can be approximated as [57]

$$W \approx \frac{1}{2\kappa a} \exp(V_{\text{max}}/kT). \quad (\text{C2.6.19})$$

A combination of equation (C2.6.13), equation (C2.6.14), equation (C2.6.15), equation (C2.6.16), equation (C2.6.17), equation (C2.6.18) and equation (C2.6.19) then allows us to estimate how low the electrolyte concentration needs to be to provide kinetic stability for a desired length of time. This theory successfully accounts for a number of observations on slowly aggregating systems, but two discrepancies are found (see, for instance, [33]). First, the observed dependence of stability ratio on salt concentration tends to be much weaker than predicted. Second, the variation of the stability ratio with particle size is not reproduced experimentally. Recently, however, it was reported that for model particles with a low surface charge, where the DLVO theory is expected to hold, the aggregation kinetics do agree with the theoretical predictions (see [60], and references therein).

C2.6.5.3 AGGREGATE STRUCTURE

Although the theories of colloid stability and aggregation kinetics were developed several decades ago, the actual structure of aggregates has only been studied more recently. To describe the structure, we start with the relationship between the size of an aggregate (linear dimension), expressed as its radius of gyration R_g and its mass m :

$$m \propto R_g^{d_f}.$$

For compact, homogeneous objects in three dimensions, $d_f = 3$. Colloidal aggregates, however, tend to be rather open, fractal structures, with $d_f < 3$. For a general introduction to fractals, see [section C3.6](#) and [61].

Encyclopedia of Chemical Physics and Physical Chemistry

-22-

First, we consider the case of rapid, irreversible aggregation. In the literature on fractal aggregates, this is known as diffusion limited cluster aggregation (DLCA), where particles (monomers) and also the aggregates diffuse and aggregate when any two of them meet. Computer simulations predicted rather open structures with $d_f \approx 1.8$ under these conditions [62, 63 and 64], and experiments have confirmed this (figure C2.6.7) [65]. Various methods exist for measuring d_f . For instance, scattering (light, x-ray) experiments yield d_f from the variation of the scattered intensity I with wavevector Q , as

$$I \propto Q^{-d_f}.$$

This relationship holds for wavevectors that probe the appropriate size range, $1/R_g < Q < 1/a$ (see [section B1.10](#)).

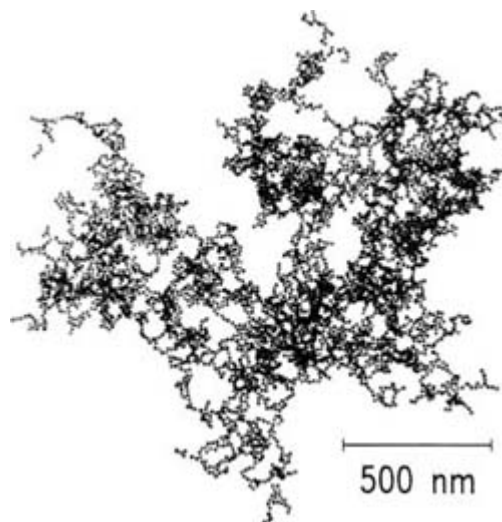

Figure C2.6.7. Fractal aggregate of gold particles with $a = 7.2 \pm 0.7$ nm, obtained under DLCA conditions, with $d_f = 1.74$ (reproduced with permission from [65]. Copyright 1984 Elsevier Science Publishers B.V).

More compact structures are obtained in the slow coagulation regime. Here aggregation is still irreversible but not every collision results in aggregation, and the clusters have more time to explore the available space. This is known as reaction limited cluster aggregation (RLCA). Here computer simulations predicted $d_f \approx 2.1$ [66], which was again confirmed experimentally [67]. The DLCA and RLCA regimes have been observed for a range of colloidal systems [64]. Only when the particle bonds are sufficiently weak that restructuring of a cluster can occur, are more dense clusters with $d_f \approx 3$ obtained (see, for instance, [54]).

Although this section has focused on the behaviour of charged particles, similar phenomena may be observed using sterically stabilized particles. As discussed in [section C2.6.4](#), these can also be given strong, short-ranged attractions, by changing the solvent quality or by adding non-adsorbing polymers. A similar aggregation behaviour to the charged spheres may then be observed [68].

Encyclopedia of Chemical Physics and Physical Chemistry

C2.6.6 BEHAVIOUR OF CONCENTRATED SUSPENSIONS

In the previous section, non-equilibrium behaviour was discussed, which is observed for particles with a deep minimum in the particle interactions at contact. In this final section, some examples of equilibrium phase behaviour in concentrated colloidal suspensions will be presented. Here we are concerned with purely repulsive particles (hard or soft spheres), or with particles with attractions of moderate strength and range (colloid–polymer and colloid–colloid mixtures). Although we shall focus mainly on equilibrium aspects, a few comments will be made about the associated kinetics as well [69, 70].

C2.6.6.1 COLLOIDAL CRYSTALS

One of the intriguing and beautiful properties of suspensions of well defined colloidal particles is their ability to order into a regular crystal lattice, called a colloidal crystal. The lattice spacing in colloidal crystals is set by the particle size and tends to be similar to the wavelength of light. Therefore, Bragg scattering (iridescence) can be observed using light (see [section B1.9](#)). Examples of this were found first in nature. For instance, tipula iridescent virus (TIV) particles were observed to assume face centred cubic (fcc) stackings [71], and opals are fossilized colloidal crystals consisting of silica [72]. For further background, see [69, 73, 74]. Colloidal crystals are used as model systems to study the freezing transition. Because of their optical properties, they are also being investigated for potential applications such as optical rejection filters (for instance, [75]).

C2.6.6.2 HARD SPHERES

Hard spheres are perhaps the simplest system to undergo a freezing transition. Freezing of hard spheres was observed using computer simulations [76]. The freezing and melting densities were found to be $\phi_F = 0.49$ and $\phi_M = 0.55$ [77]. The stable crystal structure is fcc (see [78] and references therein). So, although this may seem counter intuitive, no particle attractions are needed for a freezing transition to occur—at sufficiently high density (pressure), this will also occur for particles with purely repulsive interactions. The phase behaviour of hard spheres is summarized in figure C2.6.8.

Encyclopedia of Chemical Physics and Physical Chemistry

-24-

Figure C2.6.8. Phase diagram of hard spheres (see text for details)

Experimentally, the hard-sphere phase transition was observed using non-aqueous polymer lattices [79, 80]. Samples are prepared, brought into the fluid state by tumbling and then left to stand. Depending on particle size and concentration, colloidal crystals then form on a time scale from minutes to days. Experimentally, there is always some uncertainty in the actual volume fraction. Often the concentrations are therefore rescaled so freezing occurs at $\phi_F = 0.49$. The width of the coexistence region agrees well with simulations [11, 80].

On further increasing the concentration, the glass transition at $\phi_G \approx 0.58$ is reached [81]. At this concentration, the overall structure is arrested and particles can only undergo local diffusive motion. In other words, the sample is not ergodic anymore, as can be shown using dynamic light scattering, where the intermediate scattering function does not relax to zero (see section B1.10). The hard-sphere glass serves as a model to understand the glass transition in simple liquids (see also section C2.15 *Disordered Systems*).

Samples can be concentrated beyond the glass transition. If this is done quickly enough to prevent crystallization, this ultimately leads to a random close-packed structure, with a volume fraction $\phi_{rcp} \approx 0.64$. Close-packed structures, such as fcc, have a maximum packing density of $\phi_{cp} = 0.74$. The crystallization kinetics are strongly concentration dependent. The nucleation rate is fastest near the melting concentration. On increasing concentration, the nucleation process is arrested. This has been found to occur at the glass transition [82].

The formation of colloidal crystals requires particles that are fairly monodisperse—experimentally, hard sphere crystals are only observed to form in samples with a polydispersity below about 0.08 [69]. Using computer

simulations, a maximum polydispersity for the solid phase of 0.06 was predicted [83].

C2.6.6.3 SOFT SPHERES

Charged particles in polar solvents have soft-repulsive interactions (see section C2.6.4). Just as hard spheres, such particles also undergo an ordering transition. Important differences, however, are that the transition takes place at (much) lower particle volume fractions, and at low ionic strength (low κ) the solid phase may be body centred cubic (bcc), rather than the more compact fcc structure (see [69, 73, 84]). For the interactions, a Yukawa potential (equation (C2.6.11)) is often used. The phase diagram for the Yukawa potential was calculated using computer simulations by Robbins *et al* [85].

We will focus on one experimental study here. Monovoukas and Gast studied polystyrene particles with $a = 67$ nm in potassium chloride solutions [86]. They obtained a very good agreement between their observations and the predicted Yukawa phase diagram (see figure C2.6.9). In order to make the comparison they rescaled the particle charges according to Alexander *et al* [43] (see also [87]). At high electrolyte concentrations, the particle interactions tend to hard-sphere behaviour (see section C2.6.4) and the phase transition shifts to volume fractions around 0.5 [88].

Figure C2.6.9. Phase diagram of charged colloidal particles. The solid lines are predictions by Robbins *et al* [85]. Fluid phase (open circles), fcc crystal (solid circles) and bcc crystal (triangles). U_a is the interaction energy at the mean particle separation $x = n^{-1/3}$, and $\lambda = \kappa x$ (reproduced with permission from [86]. Copyright 1989 Academic Press).

In extensively deionized suspensions, there are experimental indications for effective attractions between particles, such as long-lived void structures [89] and attractions between particles confined between charged walls [90]. Nevertheless, under these conditions the DLVO theory does seem to describe interactions of isolated particles at the pair level correctly [90]. It may be possible to explain the experimental observations by taking into account explicitly the degrees of freedom of both the colloidal particles and the small ions [91, 92].

C2.6.6.4 COLLOID–POLYMER MIXTURES

In section C2.6.4.3 it was shown how the addition of non-adsorbing polymer chains induces a depletion attraction between colloidal particles. If sufficient polymer is added, these attractions can be strong enough to induce a phase separation of the colloidal particles. An early application of this was the creaming of rubber latex [93].

Much later, experiments on model colloids revealed that the addition of polymer may either induce a gas–liquid type phase separation or a fluid–solid transition [94, 95, 96 and 97]. Using perturbation theories, these observations could be accounted for quite well [97, 98].

At equilibrium, in order to achieve equality of chemical potentials, not only the colloid but also the polymer concentrations in the different phases are different. We focus here on a theory that allows for this polymer partitioning [99]. Predictions for two polymer/colloid size ratios are shown in figure C2.6.10. A liquid phase is predicted to occur only when the range of attractions is not too small compared to the particle size, $\delta/a > 0.3$. Under these conditions a phase behaviour is obtained that is similar to that of simple liquids, such as argon. Because of the polymer partitioning, however, there is a three-phase triangle (rather than a triple point). For smaller polymer (narrower attractions), the gas–liquid transition becomes metastable with respect to the fluid–crystal transition. These predictions were confirmed experimentally [100]. The phase boundaries were predicted semi-quantitatively.

Figure C2.6.10. Phase diagram of colloid–polymer mixtures: polymer coil volume fraction $\frac{4}{3}\pi\delta^3 n$ vs particle volume fraction ϕ . (a) Narrow attractions, $\delta/a = 0.1$. Only a fluid–crystal transition is present. Tie lines indicate coexisting phases. (b) Longer range attractions, $\delta/a = 0.4$. Gas, liquid and crystal phases (G, L and C) are present, as well as a critical point (CP). The three-phase triangle is shaded (reproduced with permission from [99]. Copyright 1992 EDP Sciences).

In practice, colloidal systems do not always reach the predicted equilibrium state, which is observed here for the case of narrow attractions. On increasing the polymer concentration, a fluid–crystal phase separation may be induced, but at higher concentration crystallization is arrested and amorphous gels have been found to form instead [101, 102]. Close to the phase boundary, transient gels were observed, in which phase separation proceeded after a lag time.

The behaviour of these systems is similar to that of suspensions in which short-range attractions are induced by changing solvent quality for sterically stabilized particles (e.g. [103]). Another case in which narrow attractions arise is that of solutions of globular proteins. These crystallize only in a narrow range of concentrations [104].

C2.6.6.5 MIXTURES OF HARD SPHERES

As shown in [section C2.6.6.2](#), hard-sphere suspensions already show a rich phase behaviour. This is even more the case when binary mixtures of hard spheres are considered. First, we will mention the case of moderate size ratios, around 0.6. At low concentrations these form a mixed fluid phase. On increasing the overall concentration of mixtures, however, binary crystals of type AB_2 and AB_{13} were observed (where A represents the larger spheres), in addition to pure A or B crystals [[105](#), [106](#)]. An example of an AB_2 structure is shown in figure C2.6.11. Computer simulations confirmed the thermodynamic stability of the structures that were observed [[107](#), [108](#)].

Figure C2.6.11. SEM of AB_2 structure, formed in aqueous mixtures of PS latex spheres with $a = 68$ nm and $a = 264$ nm (courtesy of Prof R H Ottewill).

A second case to be considered is that of mixtures with a small size ratio, <0.2 . For a long time it was believed that such mixtures would not show any instability in the fluid phase, but such an instability was predicted by Biben and Hansen [[109](#)]. This can be understood to be as a result of depletion interactions, exerted on the large spheres by the small spheres (see [section C2.6.4.3](#)). Experimentally, such mixtures were indeed found to display an instability [[110](#)]. The gas–liquid transition does, however, seem to be metastable with respect to the fluid–crystal transition [[111](#), [112](#)]. This was confirmed by computer simulations [[113](#)].

C2.6.6.6 NON-SPHERICAL COLLOIDS

Other possibilities for observing phase transitions are offered by suspensions of non-spherical particles. Such systems can display liquid crystalline phases, in addition to the isotropic liquid and crystalline phases (see also [section C2.2](#)). First, we consider rod-like particles (see [[114](#), [115](#)], and references therein). As shown by Onsager [[116](#), [117](#)], sufficiently elongated particles will display a nematic phase, in which the particles have a tendency to align parallel to

each other. Several experimental systems display this Onsager transition [[114](#)].

Hard spherocylinders (cylinders with hemispherical end caps) were studied using computer simulations [[118](#)]. In addition to a nematic phase, such particles also display a smectic-A phase, in which the particles are arranged in liquid-like layers. To observe this transition, rather monodisperse particles are needed. The smectic-A phase was indeed observed in suspensions of TMV particles [[17](#)].

Disc-like particles can also undergo an Onsager transition—here the particles form a discotic nematic, where the short particle axes tend to be oriented parallel to each other. In practice, clay suspensions tend to display sol–gel transitions, without a clear tendency towards nematic ordering (for instance, [[22](#)]). Using sterically stabilized platelets, an isotropic–nematic transition could be observed [[119](#)].

C2.7 Catalysis

Bruce C Gates

C2.7.1 INTRODUCTION

The idea of a *catalyst* is one of the most fascinating and significant in science and the word is one of the few that have carried over broadly from scientific into nonscientific language. A *catalyst* speeds up a chemical reaction without being consumed substantially—the occurrence of a reaction accelerated by a catalyst is called *catalysis*. At first, one might think that catalysis seems too good to be true, but the principles are well understood; a catalyst works by forming chemical bonds with reactants, generating intermediates that react more readily to give products than the reactants would alone—and giving back the catalyst. A catalyst affects the rate of approach to equilibrium of a reaction but not the position of the equilibrium. Catalysts provide subtle control of chemical conversions; a good catalyst increases the rate of a desired reaction but not the rates of undesired side reactions. Catalysis is ubiquitous in biology and technology and is the key to the efficiency of most chemical conversions. Only temperature provides a comparable means for increasing reaction rates, but high temperatures are often unacceptable—for example, because they harm biological organisms; high temperatures in chemical technology often mean high costs, e.g., because reaction in a liquid at high temperature requires a high pressure to maintain the liquid state, and high-pressure equipment is expensive.

The *activity* of a catalyst is a measure (e.g., a rate or a rate constant) of how fast a catalytic reaction occurs under some standard conditions. Activities vary from catalyst to catalyst and depend on the variables that influence reaction rates (temperature, reactant concentrations etc). The *selectivity* of a catalyst is a measure of how fast it causes one reaction to proceed relative to others; selectivity might be defined, e.g., as the rate of formation of a desired product divided by the rate of formation of all products under some standard conditions. The *stability* of a catalyst accounts for how fast it loses activity during operation; the ideal catalyst is infinitely stable, but real catalysts undergo changes causing loss of activity and selectivity, and they must be replaced or regenerated (at intervals ranging from seconds to years). The *regenerability* of a technological catalyst is a measure of how well it responds to treatments to bring back its activity and selectivity after deactivation; many solid catalysts are regenerated by burning off carbonaceous deposits formed during operation with organic reactants.

Biology and chemical technology as we know them are hardly imaginable without catalysis. Almost all biological reactions are catalytic and the number of biological catalysts is huge. Most large-scale technological reactions are also catalytic, generating products valued in trillions of dollars annually—roughly two orders of magnitude more than the annual cost of the catalyst purchase and replacement. Products of catalytic technology (with examples) include fuels (gasoline), polymeric materials (polypropylene), clothing (nylon), pharmaceuticals (pain relievers), foods (hydrogenated fats), solvents (methanol) and chemicals (sulphuric acid). Catalysis is also essential to the

minimization of environmental pollutants, e.g., by conversion of automobile and power-plant emissions (e.g., CO and NO_x). By converting these harmful emissions into benign gases (e.g., CO₂ and N₂) and by reducing the production of harmful byproducts of chemical processes that had earlier been dumped, catalysis has dramatically improved the quality of the earth's air and water.

-2-

Catalysis spans chemistry, chemical engineering, materials science and biology. The goal here is to enliven the subject with diverse examples showing the microscopic details of catalysis.

C2.7.2 CLASSIFICATION OF CATALYSTS AND CATALYSIS

Catalysis in a single fluid phase (liquid, gas or supercritical fluid) is called *homogeneous catalysis* because the phase in which it occurs is relatively uniform or homogeneous. The catalyst may be molecular or ionic. Catalysis at an interface (usually a solid surface) is called *heterogeneous catalysis*; an implication of this term is that more than one phase is present in the reactor, and the reactants are usually concentrated in a fluid phase in contact with the catalyst, e.g., a gas in contact with a solid. Most catalysts used in the largest technological processes are solids. The term *catalytic site* (or *active site*) describes the groups on the surface to which reactants bond for catalysis to occur; the identities of the catalytic sites are often unknown because most solid surfaces are nonuniform in structure and composition and difficult to characterize well, and the active sites often constitute a small minority of the surface sites.

Most biological catalysts are enzymes, i.e., proteins, which are macromolecules (polypeptides) formed by biopolymerization of amino acids (with elimination of water); some enzymes are huge, with hundreds of monomer units. The 20 amino acid monomers occurring in nature,

have R groups including, e.g. H (in glycine), CH₂OH (in serine), CH₂COOH (in aspartic acid), CH₂CH₂COOH (in glutamic acid) and CH₂(CH₂)₃NH₂ (in lysine). Some of the R groups are ligands for metal ions (e.g., Zn, Fe, Cu, Mo and Co) that play catalytic roles. Acidic, basic and metal groups typically constitute the active sites of enzymes. The structures of a number of enzymes are known from x-ray crystallography. The polymer chains are usually folded to give a precise juxtaposition of the active sites on the interior surface of a clamlike structure. It is not a straightforward matter to classify enzyme catalysis as simple homogeneous or heterogeneous catalysis, because, in biological cells, enzymes exist both in solution (e.g., in cytoplasm) and within membranes—some enzymes are even arranged in assembly-line fashion so that the product molecules from one pass directly to the next.

The subject of catalysis has evolved with little integration of homogeneous, heterogeneous, and biological catalysis, as is reflected in the general references cited in the further reading section.

-3-

C2.7.3 A BIT OF HISTORY—THE AMMONIA SYNTHESIS REACTION

A definition of catalysis similar to that given above was stated first in about 1895 by Wilhelm Ostwald, whose work on catalysis was recognized with a Nobel prize. Sixty years before, Jakob Berzelius had coined the term

‘catalysis’, recognizing that a single concept could account for changes in compositions of numerous substances resulting from their mere contact with liquids, solids or ‘ferments’. Berzelius’s insight bears on phenomena that had earlier vexed the alchemists, who, aware of the then mysterious actions of these ‘ferments’ and other substances (‘contacts’), sought vainly for a philosopher’s stone to change base metals into gold.

Ostwald’s definition of catalysis rests on reaction kinetics and, indeed, at about the time he stated it, the beginnings of physical chemistry were emerging in the quantitative representation of the thermodynamics and kinetics of chemical reactions. The first concepts of reaction thermodynamics and kinetics came into focus in the early 1900s in work by Nernst and by Fritz Haber and coworkers; Haber carried out research motivated by the goal of synthesizing ammonia on a large scale from nitrogen and hydrogen, to produce fertilizers—and also explosives. The ammonia synthesis reaction,

which is still of great technological importance, takes place at almost negligibly low rates, except in the presence of a catalyst, and the reaction is strongly equilibrium limited. As the reaction is exothermic, the equilibrium conversion decreases with increasing temperature, so that the advantage of increasing the rate by increasing temperature is offset by a decrease in the attainable (equilibrium) conversion. Thus, an advantage of a highly active catalyst such as iron or ruthenium is that by increasing the reaction rate, the catalyst lowers the temperature at which the reaction can practically be carried out, thereby increasing the attainable conversion. Haber’s understanding of the interplay of thermodynamics and kinetics was pivotal to the development of the early concepts of physical chemistry; Haber’s Nobel prize is one of several that recognize research in catalysis.

Figure C2.7.1 is a potential energy diagram for the ammonia synthesis reaction taking place on the surface of an iron catalyst [1]. The reaction proceeds via chemisorbed intermediates (i.e., those chemically bonded to the iron surface) N, H, NH and NH₂, and the energy barriers shown in figure C2.7.1 are much lower than those that would pertain if the intermediates were N, H, NH and NH₂ in the gas phase; thus, figure C2.7.1 shows why iron is a good ammonia synthesis catalyst (and a good ammonia decomposition catalyst). Notice that by causing the reaction to proceed via steps whereby chemisorbed H combines with N, NH and then NH₂, the catalyst provides a sequence with each elementary step characterized by only a moderately high activation energy barrier; notice also that iron’s ability to cause dissociation of H₂ and N₂, leading to the formation of the chemisorbed atomic species, allows the formation of intermediates that are not too stable (not too low in energy)—if they were much more stable, then the barriers would be higher, the overall reaction not so fast and the catalyst not so active. Good catalysts generally provide efficient pathways for both the formation and conversion of highly reactive intermediates.

Figure C2.7.1. Schematic potential energy diagram for the catalytic synthesis and decomposition of ammonia on iron. The energies are in kJ mol^{-1} ; the subscript 'ads' refers to species adsorbed on iron [1].

The ammonia synthesis reaction provides another important lesson; it illustrates how fundamental science developed from research that was motivated by a technological need. Catalysis is one of the most essential and enduring enabling technologies, and it has been pulling researchers into unexplored territory from the beginning, with no end in sight. For example, much of ultrahigh-vacuum surface science (section A1.7) has emerged from work directed toward understanding of catalysis by solids and much of organometallic chemistry has emerged from work directed toward understanding of catalysis by transition metal compounds in solution.

C2.7.4 CATALYTIC CYCLES

Because a good catalyst is not consumed to a significant degree as it functions, catalysis is a cyclic process, and compact representations of catalysis are cycles that show the various intermediate species, illustrated by the following simple example, where C is the catalyst, R the reactant, P the product and RC the intermediate:

(using figure C2.7.1 can you write a cycle for the ammonia synthesis reaction?).

A well-understood catalytic cycle is that of the Wilkinson alkene hydrogenation (figure C2.7.2) [2]. Like most catalytic cycles, that shown in figure C2.7.2 is complex, involving intermediate species in the cycle (inside the dashed line) and other species outside the cycle and in dead-end paths. Knowledge of all but a small number of catalytic cycles is only fragmentary because of the complexity and because, if the catalyst is active, the cycle turns over rapidly and the concentrations of the intermediates are minute; thus, these intermediates are often not even

identified. Typically, as understanding develops, a more complex model emerges—i.e., a cycle with more intermediates. Determination of the important intermediates and quantitative representation of the kinetics and thermodynamics of the separate elementary reactions (e.g., figure C2.7.2) are often daunting tasks requiring the concerted application of various physical/chemical techniques. The challenges have helped to motivate the development of more and more sensitive spectroscopic methods, transient kinetics methods and so forth, some of which are mentioned below and described elsewhere in this encyclopedia.

Figure C2.7.2. Catalytic cycle (within dashed lines) for the Wilkinson hydrogenation of alkene [2]. Values of rate and equilibrium constants are given in [2]

An important point about kinetics of cyclic reactions is that if an overall reaction proceeds via a sequence of elementary steps in a cycle (e.g., figure C2.7.2), some of these steps may be equilibrium limited so that they can proceed at most to only minute conversions. Nevertheless, if a step subsequent to one that is so limited is characterized by a large enough rate constant, then the equilibrium-limited step may still be fast enough for the overall cycle to proceed rapidly. Thus, the step following an equilibrium-limited step in the cycle pulls the cycle along—it drains the intermediate that can form in only a low concentration because of an equilibrium limitation and allows the overall reaction (the cycle) to proceed rapidly. A good catalyst accelerates the steps that most need a boost.

C2.7.5 MACROSCOPIC PHYSICAL PROPERTIES OF CATALYSTS

C2.7.5.1 SOLUBLE CATALYSTS

If a catalyst is to work well in solution, it (and the reactants) must be sufficiently soluble and stable. Most polar catalysts (e.g., acids and bases) are used in water and most organometallic catalysts (compounds of metals with organic ligands bonded to them) are used in organic solvents. Some enzymes function in aqueous biological solutions, with their solubilities determined by the polar functional groups (R groups) on their outer surfaces.

A solution containing both reactants and a catalyst may be mixed mechanically to bring the constituents into efficient contact—otherwise, the rate of the catalytic reaction would be affected by mass transport (e.g., diffusion)

and thus the reaction would proceed more slowly than in the absence of significant concentration gradients.

In technology, an economic separation of the products of a reaction from the solution containing the catalyst is necessary. Distillation is a commonly used method and, for it to work successfully, the products and catalyst must be stable at the temperatures of the distillation, which are often relatively high; some organometallic compounds, for example, may not meet this criterion.

As the separation is often an expensive part of a process, simplifications may be valuable. For example, in a process for hydroformylation of propene,

the reaction is carried out in a mixed reactor with a gas and two separate liquid phases, one organic, containing most of the product, and the other aqueous, containing almost all the catalyst, which is an organometallic compound of rhodium with phosphine ligands that are sulphonated to make them water soluble. The separation of the product from the catalyst is simple and economical [3] (figure C2.7.3): product liquid flows continuously to a tank (comparable to a separatory funnel) where it settles into two layers: one organic, containing the product; the other aqueous, containing the catalyst. The aqueous stream is recycled to the reactor so that the catalyst is continuously reused; thus, the process as well as the reaction is cyclic.

-7-

Figure C2.7.3. Process flow diagram for hydroformylation of propene; 1, reactor; 2, separator; 3, phase separator; 4, stripping column; 5, heat exchanger.

C2.7.5.2 SOLID CATALYSTS

Macroscopic properties often influence the performance of solid catalysts, which are used in reactors that may simply be tubes packed with catalyst in the form of particles—chosen because gases or liquids flow through a bed of them (usually continuously) with little resistance (little pressure drop). Catalysts in the form of honeycombs (monoliths) are used in automobile exhaust systems so that a stream of reactant gases flows with little resistance through the channels and heat from the exothermic reactions (e.g., CO oxidation to CO₂) is rapidly removed.

Efficient use of a catalyst requires high rates of reaction per unit volume and, since reaction takes place on the surface of a solid, catalysts have high surface areas per unit volume. Therefore, the typical catalyst is porous, with an internal surface area often exceeding 100 m² g⁻¹. Porous materials often consist of aggregates of nonporous (crystalline) microparticles, with the void spaces between them constituting a labyrinth of internal pores with

diameters roughly equal to those of the microparticles; reaction takes place on the microparticle surfaces. The pores may have average diameters <2.0 nm (micropores) because these imply high surface areas per unit volume, but larger pores are also common.

Because catalysts lose activity and need to be regenerated and replaced periodically, they must be robust enough to withstand these processes. Catalyst particles used in large reactors must be strong enough to resist crushing under the weight of the particles above them. Some catalyst particles are used in entrained and fluidized bed reactors, where they are in constant motion (for rapid heat transfer), and they must be resistant to abrasion. Many catalysts must withstand use at high temperatures (~ 800 K).

Physical properties affecting catalyst performance include the surface area, pore volume and pore size distribution ([section B1.26](#)). These properties regulate the tradeoff between the rate of the catalytic reaction on the internal surface and the rate of transport (e.g., by diffusion) of the reactant molecules into the pores and the product molecules out of the pores: the higher the internal area of the catalytic material per unit volume, the higher the rate of the reaction

-8-

per unit volume—up to a limit; beyond the limit, an increase in internal surface area requires such small microparticles (and hence such small pores) that the restrictions of the pores limit the rate of transport through them and lead to the existence of significant concentration gradients within the catalyst particles. Thus, the reactant concentration becomes less at the particle interior than at the edge, and the overall reaction rate is reduced and no longer proportional to the internal surface area. If internal area is gained at the expense of increases in pore volume, a limit is reached at which the material no longer meets the crush strength requirement.

Catalyst particles are usually cylindrical in shape because it is convenient and economical to form them by extrusion—like spaghetti. Other shapes may be dictated by the need to minimize the resistance to transport of reactants and products in the pores; thus, the goal may be to have a high ratio of external (peripheral) surface area to particle volume and to minimize the average distance from the outside surface to the particle centre, without having particles that are so small that the pressure drop of reactants flowing through the reactor will be excessive.

C2.7.5.3 CONSTITUENTS OF SOLID CATALYSTS

A solid catalyst is usually a composite, consisting of a material called a support or carrier (which often lacks catalytic activity) and other components, including those with catalytic activity, and perhaps still others, called promoters. The support is usually the principal component, sometimes being 99% or more of the catalyst mass. Thus, the physical properties are largely determined by the support. Supports are usually ceramic materials ([section C2.12](#)), the most common being transition aluminas such as γ - Al_2O_3 . Others include silica (SiO_2), carbon and zeolites. Transition aluminas offer the advantages of being inexpensive, robust, stable and formable into particles with wide ranges of shapes, internal surface areas and pore size distributions. The typical catalyst incorporates small amounts (e.g., 1 wt%) of catalytically active components (e.g., metals, metal oxides or metal sulphides) on the internal surface of the support. Since these components are often expensive, they are dispersed as small particles on the support surface; for example, particles of Pt on Al_2O_3 may be less than 1 nm in diameter, so small that almost all the Pt atoms are exposed at a surface where reactant molecules can bond to them and catalysis can occur. Supported metal catalysts have been applied for decades and are among the first *nanomaterials* ([section C1.2](#)) to find industrial applications.

The components in catalysts called promoters lack significant catalytic activity themselves, but they improve a catalyst by making it more active, selective, or stable. A *chemical promoter* is used in minute amounts (e.g., parts per million) and affects the chemistry of the catalysis by influencing or being part of the catalytic sites. A *textural (structural) promoter*, on the other hand, is used in massive amounts and usually plays a role such as stabilization of the catalyst, for instance, by reducing the tendency of the porous material to collapse or sinter and lose internal surface area, which is a mechanism of deactivation.

C2.7.6 EXAMPLES OF CATALYSIS

C2.7.6.1 WILKINSON HYDROGENATION OF ALKENES CATALYSED BY A RHODIUM COMPLEX

The hydrogenation of alkenes catalysed by organometallic compounds is exemplified by the Wilkinson catalyst of [figure C2.7.2](#) invented by the Nobel-prize-winning chemist Geoffrey Wilkinson. The cycle of [figure C2.7.2](#) elucidated by the group of Halpern [[4](#), [5](#) and [6](#)], has a number of characteristics that are so common that it can be regarded as

-9-

a prototype. The rhodium compounds (complexes) that react with the H_2 and alkene are coordinatively unsaturated and their reactions with these reactants lead to dissociation of the reactants (which become ligands bonded to the metal). The ligands that are formed, H and alkyl, combine with each other while bonded to the Rh, leading to the formation of the alkane product and regeneration of the catalyst (closure of the cycle). Thus, the role of the Rh centres in the Wilkinson catalyst is similar to that of the iron sites on the surface of the ammonia synthesis catalyst in that they both cause dissociation of the reactants and position the resultant ligands so that they combine with each other to give the product. This generalization is often valid for metals in catalysts, whether they are in compounds in solution, on metal surfaces or on surfaces of metal oxides or sulphides, for example.

There is more to the Wilkinson hydrogenation mechanism than the cycle itself; a number of species in the cycle are drained away by reaction to form species outside the cycle. Thus, for example, PPh_3 (Ph is phenyl) drains rhodium from the cycle and thus it inhibits the catalytic reaction (slows it down). However, PPh_3 plays another, essential role—it is part of the catalytically active species and, as an electron-donor ligand, it affects the reactivities of the intermediates in the cycle in such a way that they react rapidly and lead to catalysis. Thus, there is a tradeoff that implies an optimum ratio of PPh_3 to Rh.

When a strong electron-donor ligand such as pyridine is added to the reaction mixture, it can bond so strongly to the Rh that it essentially drains off all the Rh and shuts down the cycle; it is called a catalyst *poison*. A poison for many catalysts is CO; it works as a physiological poison in essentially the same way as it works as a catalyst poison: it bonds to the iron sites of haemoglobin in competition with O_2 .

The reactivities of the species within the Wilkinson cycle are so great that they are not observed directly during the catalytic reaction; rather, they are present in a delicate dynamic balance during the catalysis in concentrations too low to observe easily, and only the more stable species outside the cycle (outside the dashed line in [figure C2.7.2](#) are the ones observed. Obviously it was no simple matter to elucidate this cycle; the research required piecing it together from observations of kinetics and equilibria under conditions chosen so that sometimes the cycle proceeded slowly or not at all.

Techniques such as NMR spectroscopy ([section B1.12](#)) and IR spectroscopy ([section B1.2](#)) are useful in such experiments. Furthermore, theory ([section B3.1](#)) has proceeded to the point of being successful in predicting some simple catalytic cycles.

C2.7.6.2 CHIRAL HYDROGENATION OF ALKENES CATALYSED BY A RHODIUM COMPLEX

A hydrogenation reaction closely related to that referred to in the preceding paragraphs is that represented in [figure C2.7.4](#) [[7](#), [8](#)]. The catalyst incorporates a bidentate (two-toothed) phosphine ligand that affects the stereochemistry (chirality) of the reaction. There are two pathways for reaction ([figure C2.7.5](#)) giving products of different stereochemistries: the pathway shown on the left shows the preferred (more stable) mode of binding of the reactant with the catalyst; the pathway on the right involves a minor isomer of the reactant–catalyst complex. The chirality of the product is determined predominantly by the latter pathway, which gives the major product because the reactant–catalyst complex on the right is much more reactive than that on the left, even though it is formed in lower concentrations than that on the left.

Figure C2.7.4. Catalytic cycle for hydrogenation of methyl-(*Z*)- α -acetamidocinnamate; the rate constants were measured at 298 K; S' is solvent [8].

This example illustrates a subtle control of a chemical reaction by a delicate manipulation of the stereochemical environment around a metal centre dictated by the selection of the ligands. This example hints at the subtlety of nature's catalysts, the enzymes, which are also typically stereochemically selective. Chiral catalysis is important in biology and in the manufacture of chemicals to regulate biological functions, i.e., pharmaceuticals.

C2.7.6.3 NO DECOMPOSITION CATALYSED BY A RUTHENIUM SURFACE

Scanning tunnelling microscopy (STM, [section B1.19](#)) has made it possible to observe microscopic details of catalyst surfaces, as shown by an investigation of one of the simplest solid catalysts, a single crystal of a pure metal (see [section A1.7](#)), Ru, which is active and selective for the decomposition of NO, which proceeds via dissociative chemisorption to give N and O atoms [9]. A clean Ru(0001) sample was prepared under ultrahigh vacuum and exposed to NO at 300 K, which dissociated completely on the surface. The distribution of N and O atoms on the surface was investigated by STM at 300 K, allowing the researchers to distinguish isolated N atoms (dark spots), islands of O atoms, and individual O atoms ([figure C2.7.6](#)); adsorbed NO molecules were not observed, as they move very rapidly on the surface [9]. Data were obtained at various times after the exposure of the crystal to NO.

Figure C2.7.5. Pathways for the hydrogenation of methyl-(Z)- α -acetamidocinnamate catalysed by a rhodium complex with a chiral diphosphine ligand: S' is solvent [8].

Figure C2.7.6. STM images of an Ru(0001) surface after dissociative adsorption of NO at 315 K. (A) Image (38 nm×33 nm) showing two terraces separated by a monatomic step (black stripe). (B) Close-up (6 nm×4 nm) showing an O island and individual N atoms. Individual O atoms are imaged as dashes (arrow) [9]

The Ru surface is one of the simplest known, but, like virtually all surfaces, it includes defects, evident as a step in figure C2.7.6. The observations show that the sites where the NO dissociates (active sites) are such steps. The evidence for this conclusion is the locations of the N and O atoms; there are gradients in the surface concentrations of these elements, indicating that the transport (diffusion) of the O atoms is more rapid than that of the N atoms; thus, the slow-moving N atoms are markers for the sites where the dissociation reaction must have occurred, where their surface concentrations are highest.

It has long been inferred that surface sites of low coordination (comparable to the metals in coordinatively unsaturated rhodium complexes in figure C2.7.2 are catalytically more active than those with larger numbers of neighbours and lower degrees of coordinative unsaturation, e.g., those on terraces on the Ru surface. Even more highly unsaturated are those sites at corners. The sites for one catalytic reaction may be different from those for another and, furthermore, the reactants may change the surface and create active sites. Active sites on surfaces more complex than those of single metal crystals are difficult to determine.

C2.7.6.4 PROPANE METATHESIS CATALYSED BY TANTALUM COMPLEXES ANCHORED TO SILICA

An alternative to elucidating the active sites on a surface is to synthesize them. For example, a new catalyst for metathesis of alkanes,

was synthesized on the surface of silica by the reaction of surface oxygen atoms with a reactive organometallic precursor, Ta(-CH₂CMe₃)₃(=CHCMe₃) (Me is methyl); two surface species were formed and identified by techniques including IR, NMR and EXAFS spectroscopies (section B1.6) [10]: (SiO-)Ta(-CH₂CMe₃)₂(=CHCMe₃) (~65%) and (SiO-)₂Ta(-CH₂CMe₃)₂(=CHCMe₃) (~35%). The authors suggested a catalytic cycle (although they lack the strongest evidence of the intermediates) (figure C2.7.7) in which the surface-bound Ta group is denoted with a subscript s. Thus, the catalysis is molecular and the silica just an enormous, rigid ligand. This anchoring helps to stabilize the tantalum complex in states of coordinative unsaturation that probably do not exist in solution—analogue complexes in solution could react with each other (leading to self-inhibition of catalysis).

Figure C2.7.7. Catalytic cycle for the metathesis of propane [10]

C2.7.6.5 CATALYTIC ACTION OF THE ENZYME HALOALKANE DEHALOGENASE

An organism investigated for conversion of environmentally harmful halogenated compounds (e.g., dry-cleaning solvents) degrades them by dehalogenation catalysed by the enzyme haloalkane dehalogenase; 1-haloalkane and water react to give a primary alcohol and halide ion. The reaction mechanism was investigated by x-ray crystallography; enzyme crystals were soaked in dichloroethane to give a reactant–catalyst complex at 277 K and pH 5.0 (values less than those corresponding to the maximum reaction rate) and the complex was stable enough to allow an accurate structure determination [11]. Similar measurements were made with the sample warmed to room temperature and after standing long enough for the catalytic reaction to take place and the enzyme to become complexed with Cl^- product (but not 2-chloroethanol product).

The data led to the cycle shown in [figure C2.7.8](#). Here, only the active site on the interior enzyme surface ([section C2.6](#)) is depicted, consisting of R groups including aspartic acid, glutamic acid and others, represented with the shorthand Asp_{260} , Glu_{56} etc; the subscripts represent the positions on the polypeptide chain.

Figure C2.7.8. Catalytic cycle indicating the working of the enzyme haloalkane dehalogenase [11].

C2.7.6.6 CO OXIDATION CATALYSIS ON A PLATINUM SURFACE

In the preceding example, the structure of the catalyst combined with reactants and products was determined and the data were used to infer a cycle. Structures of the highly reactive intermediates in catalysis are generally elusive and information about them based only on inference. In prospect, the most incisive information about the workings of a catalyst can be obtained by observations of the catalyst in action. The following example illustrates this

strategy.

The CO oxidation occurring in automobile exhaust converters is one of the best understood catalytic reactions, taking place on Pt surfaces by dissociative chemisorption of O₂ to give O atoms and chemisorption of CO, which reacts with chemisorbed O to give CO₂, which is immediately released into the gas phase. Details are evident from STM observations focused on the reaction between adsorbed O and adsorbed CO [12].

Experiments were carried out with a Pt(111) single-crystal surface cleaned in an ultrahigh-vacuum system. To monitor the progress of the reaction as a function of time, the researchers brought O₂ into contact with the Pt to give a surface partially covered with O atoms, which aggregate into islands with a distinct periodic structure; the O atoms show up as dark dots in islands in the image of [figure C2.7.9](#) at time 0. At time 0, CO was introduced into the reactor and bonded with the surface, thereupon reacting with the chemisorbed O and reducing the sizes of the islands, as shown by the STM images at increasing times after the introduction of CO ([figure C2.7.9](#)). The CO molecules that must have been present on the surface at short times were not visible because of their high mobilities. But after 290 s, and more clearly after 600 s, the O islands had markedly shrunk because of reaction, and the CO had become evident as an additional ordered, streaky structure ([figure C2.7.9](#)); at these times the CO had formed into closely packed immobilized structures. After longer times, the O islands became smaller, indicating the progress of the catalytic reaction; by 2020 s, the O had been completely converted ([figure C2.7.9](#)). Note the contrast with the NO decomposition reaction; the CO oxidation takes place on the flat metal surface, not just on minority sites such as steps.

A striking feature of the images is the nonuniformity of the distribution of the adsorbed species. The reaction between O and CO takes place at the boundaries between the surface domains and it was possible to determine reaction rates by measuring the change in length L of the boundaries of the O islands. The kinetics is represented by the rate equation

$$r = -dn_{\text{O}}/dt = kL \quad (\text{C2.7.4})$$

where r is rate, n_{O} the number of surface O atoms, t time and k the rate constant. Data determined from the images are shown in [figure C2.7.10](#). Similarly, the rate was determined in the conventional way by macroscopic measurements of the surface coverages, assuming a random distribution of chemisorbed O and CO:

$$r = k'\theta_{\text{O}}\theta_{\text{CO}} \quad (\text{C2.7.5})$$

where k' is a rate constant. Data determined in this way are also shown in [figure C2.7.10](#). The agreement between the microscopic and macroscopic kinetics data provides a verification of the simplified representation of the conventional macroscopic kinetics, which works rather well, although the distribution of surface species is far from random.

Figure C2.7.9. STM images recorded during reaction of adsorbed O atoms with adsorbed CO molecules on a Pt(111) crystal at 274 K; image size, 18 nm×17 nm. Times are those after addition of CO to the surface; see text for details [12].

Figure C2.7.10. Rates of reaction of CO with O on Pt(111), determined from microscopic (■) and macroscopic (+) data; see text for details [12].

C2.7.6.7 SHAPE-SELECTIVE HYDROCARBON REACTIONS CATALYSED BY ZEOLITES

Zeolites (section C2.13) are unique because they have regular pores as part of their crystalline structures. The pores are so small (about 1 nm in diameter) that zeolites are *molecular sieves*, allowing small molecules to enter the pores, whereas larger ones are sieved out. The structures are built up of linked SiO₄ and AlO₄ tetrahedra that share O ions. The faujasites (zeolite X and zeolite Y) and ZSM-5 are important industrial catalysts. The structure of faujasite is represented in figure C2.7.11 and that of ZSM-5 in figure C2.7.12. The points of intersection of the lines represent Si or Al ions; oxygen is present at the centre of each line. This depiction emphasizes the zeolite framework structure and shows the presence of the intracrystalline pore structure. In the centre of the faujasite structure is an open space (supercage) with a diameter of about 1.2 nm. The pore structure is three dimensional,

with the supercages connected by apertures with diameters of about 0.74 nm. Molecules large enough to fit through the apertures can undergo catalytic reaction in the cages. ZSM-5 also has a three-dimensional structure, with straight parallel pores intersected by zig-zag pores.

Figure C2.7.11. Framework structure of zeolites X and Y.

Figure C2.7.12. Structure of zeolite ZSM-5; (a) framework, (b) schematic representation of pores.

The zeolite frameworks are built up of SiO_4 tetrahedra, which are neutral, and AlO_4 tetrahedra, which have a charge of -1 . The charge of the AlO_4 tetrahedra is balanced by the charges of cations located at various crystallographically defined positions in the zeolite, many of them exposed at the internal surface. The cations are typically catalytically active sites. When the cations are H^+ (in OH groups), the zeolites are acidic. Acidic zeolite Y (HY) and HZSM-5 are applied as components of petroleum cracking catalysts to make gasoline. The OH groups located near AlO_4 tetrahedra are strong Brønsted acids and the catalytic sites for many reactions, including those mentioned below.

Zeolites are unique as shape-selective catalysts. *Mass transport shape selectivity* is a consequence of transport restrictions allowing some species to diffuse more rapidly than others in zeolite pores. Small molecules enter the pores and are catalytically converted, but larger molecules may pass through a flow reactor unconverted because they do not fit into the pores, where almost all the catalytic sites are located. Similarly, product molecules formed inside a zeolite may be so large that their diffusion out of the pores may be so slow that they are largely converted into other products before escaping into the product stream. Mass transport selectivity is illustrated by toluene disproportionation catalysed by HZSM-5 [13](#) (figure C2.7.13). The desired product is industrially valuable *p*-xylene.

The *ortho*- and *meta*-isomers are bulkier than the *para*-isomer and diffuse less readily in the zeolite pores. The transport restriction favours their conversion into the *para*-isomer, which is formed in excess of the equilibrium concentration. Because the selectivity is transport influenced, it is dependent on the path length for transport, which is the length of the zeolite crystallites.

Figure C2.7.13. Schematic representation of diffusion and reaction in pores of HZSM-5 zeolite-catalysed toluene disproportionation; the numbers are approximate relative diffusion coefficients in the pores [13].

-19-

A different kind of shape selectivity is *restricted transition state shape selectivity*. It is related not to transport restrictions but instead to size restrictions of the catalyst pores, which hinder the formation of transition states that are too large to fit; thus reactions proceeding through smaller transition states are favoured. The catalytic activities for the cracking of hexanes to give smaller hydrocarbons, measured as first-order rate constants at 811 K and atmospheric pressure, were found to be the following for the reactions catalysed by crystallites of HZSM-5 14: *n*-hexane, 29; 3-methylpentane, 19; 2,2-dimethylbutane, 12 s^{-1} . The reaction rates were independent of the zeolite crystallite size, which rules out a transport effect. Instead, the selectivity is determined by the geometry of the transition states, which become bulkier with increasing branching of the molecules and are believed to be C_{12} carbenium ions resulting from the carbon-carbon bond formation reaction of the alkane with a carbenium ion formed from the alkane by abstraction of a hydride ion by another carbenium ion. These C_{12} carbenium ions easily fit in the zeolite pores when the reactant has no branches and barely fit when it has two branches; the crowding in the pores hinders the reaction.

C2.8 Corrosion

P Schmuki and M J Graham

C2.8.1 INTRODUCTION

Corrosion is the ‘gnawing away’ of materials due to exposure to different environments. Basically, a material is trying to return to its natural state, e.g., metallic iron oxidizes to form the ore from whence it came.

The most common form of corrosion (in terms of tons of materials lost) is electrochemical corrosion, which can occur for example in aqueous solutions, in the atmosphere and in the ground. Here, the actual corrosion reaction is invariably the anodic or oxidation reaction, whereby a metal dissolves while releasing electrons and ions. Thus one might say that ‘corrosion’ is a negative way of looking at an electrochemical dissolution or oxidation reaction. The reason for separating this topic from other dissolution or oxidation reactions which are of economic benefit, e.g. oxidation of silicon to form semiconductor devices, is based on the historic roots of corrosion science and the tremendous economic significance of material destruction. In industrialized countries, the cost of corrosion is estimated to be about 3.5% of the GNP. Areas such as construction materials, electronics and transportation are affected and thus an extensive number of reference books is available [[1](#), [2](#), [4](#), [5](#), [6](#), [7](#), [8](#), [9](#), [10](#), [11](#), [12](#), [13](#), [14](#), [15](#), [16](#), [17](#), [18](#), [19](#), [20](#), [21](#), [22](#), [23](#), [24](#), [25](#), [26](#), [27](#), [28](#), [29](#), [30](#), [31](#), [32](#) and [33](#)]. Frequently, modes of corrosion are described according to the type of attack (e.g. uniform corrosion, localized corrosion) or the topic is categorized according to the specific material involved.

In the following, however, classification of corrosion processes is made according to the reaction mechanism rather than the phenomenology. Emphasis is placed on electrochemical reactions, including high temperature oxidation. Other types of corrosion such as purely physical processes (e.g. erosion, fretting) or mixed type (e.g. stress corrosion cracking) are only briefly mentioned, with reference to further reading, in [section C2.8.5](#).

C2.8.2 ELECTROCHEMICAL FUNDAMENTALS [34, 35, 36, 37 AND 38]

One can distinguish between a thermodynamic and kinetic stability to corrosion.

C2.8.2.1 THERMODYNAMIC CONSIDERATIONS

Thermodynamic stability is generally provided for noble metals in most media as their oxidation potential is more anodic than the reduction potential of species commonly occurring in the surrounding phase. However, for many materials of technological and industrial importance this is not the case.

For example, for iron in aqueous electrolytes, the thermodynamic warning of the likelihood of corrosion is given by comparing the standard electrode potential of the metal oxidation, with the potential of possible reduction reactions. The metal anodic oxidation reaction, $\text{Fe} \rightarrow \text{Fe}^{2+} + 2\text{e}^-$, can be written in the standard (reduction) notation as:

-2-

where E^0 denotes the standard redox potential of the reaction versus the normal hydrogen electrode (NHE).

Depending on the electrolyte pH, one of the following reduction (cathodic) reactions will dominate:

(a) in acidic solutions:

(b) in neutral and in alkaline solutions:

Both cathodic reactions can drive the metal oxidation. Of course, the potentials given above are only *standard* Gibbs values (E^0), and the effective electrode potential follows the Nernst equation (see [section C2.11](#)). For the oxidation (anodic) reaction, the potential (E_a) of the Nernst equation can be written as:

$$E_a = E_{\text{Fe}^{2+}/\text{Fe}}^0 + \frac{RT}{zF} \ln[\text{Fe}^{2+}]. \quad (\text{C2.8.5})$$

For the reduction reaction potential (E_c), the Nernst equations are:

(a)

$$E_c = E_{H^+/H}^0 + \frac{RT}{zF} \ln[H^+] \approx -0.059 \text{ pH} \quad (\text{C2.8.6})$$

(b)

$$E_c = E_{H^+/H}^0 + \frac{RT}{zF} \ln[H^+] \approx 1.23 \text{ V} - 0.059 \text{ pH}. \quad (\text{C2.8.7})$$

The right-hand term in both equations indicates the direct dependence of E_c on the pH of the medium (assuming otherwise standard conditions).

-3-

For the coupled redox cell, the e.m.f. (E) results as:

$$E = E_c - E_a \quad (\text{C2.8.8})$$

and the Gibbs free energy (ΔG) of the reaction as:

$$\Delta G = -zFE. \quad (\text{C2.8.9})$$

Thus, it can basically be predicted under what conditions (pH, concentration of redox species) the metal dissolution reaction ($\text{Fe} \rightarrow \text{Fe}^{2+}$) proceeds thermodynamically. From a practical point of view, the rate of the reaction and therefore the fate of the oxidized species (Fe^{2+}) is extremely important: they can either be solvated, i.e., to form $\text{Fe}(\text{H}_2\text{O})_6^{2+}$ complexes, and therefore be efficiently dissolved in the solution, or they can react with oxygen species of the solution to form a surface oxide layer (FeO , Fe_3O_4 , Fe_2O_3). Such oxide layers can represent effective kinetic barriers against corrosion (see [section C2.8.3](#) on passive films).

Thus it is important to take into account the thermodynamics of oxide formation and any additional electrochemical reactions such as the oxidation of the Fe^{2+} to Fe^{3+} . The results of the calculations are frequently represented as pH-potential diagrams (so-called Pourbaix diagrams [39]). The Pourbaix diagram for iron in an aqueous environment is shown in figure C2.8.1.

Figure C2.8.1. Simplified E/pH diagram (Pourbaix diagram) for the iron–water system at 25°C. The diagram is drawn for a concentration of dissolved Fe species of $10^{-6} \text{ mol l}^{-1}$. The potentials are given versus the normal hydrogen electrode (NHE) scale.

-4-

The diagram gives regions of existence, i.e. for a particular combination of pH and redox potential it can be predicted whether it is thermodynamically favourable for iron to be inert (stable) (region A), to actively dissolve (region B) or to form an oxide layer (region C).

The dotted lines represent the cases when the above cathodic reactions, (a) or (b), drive the reaction. The solid lines indicate the stability ranges for Fe and its corrosion products (Fe^{2+} , Fe^{3+} , Fe_3O_4 , Fe_2O_3 , HFeO_2^-).

Consider, for example, an acidic solution at pH 1: iron dissolves (formation of $\text{Fe}(\text{H}_2\text{O})_6^{2+}$); as E_c of reaction (a) is at -0.06 V NHE we are in region B (existence of Fe^{2+}). Additionally, it can be seen that the Fe^{2+} species can be further oxidized to Fe^{3+} if O_2 is present in the electrolyte (line (b) lies in the region of existence of Fe^{3+}).

Considering the case of $\text{pH} > 9$, the formation of an oxide film is favoured compared with Fe dissolution.

In the case of a neutral solution (e.g. $\text{pH} = 7$), depending on the corrosion potential all these three ranges (stability, dissolution or oxide formation) may be involved.

pH –potential diagrams are available for many elements in aqueous environments and are often a valuable tool in the preliminary assessment of the (thermodynamic) stability of a system. However, it should be pointed out that these calculations are based purely on thermodynamic considerations and, hence, this approach gives no information on the rate (kinetics) of the possible corrosion reactions.

C2.8.2.2 KINETIC CONSIDERATIONS

For many practically relevant material/environment combinations, thermodynamic stability is not provided, since $E_a > E_c$. Hence, a key consideration is how fast the corrosion reaction proceeds. As for other electrochemical reactions, a variety of factors can influence the rate determining step. In the most straightforward case the reaction is activation energy controlled; i.e. the ion transfer through the surface Helmholtz double layer involving migration and the adjustment of the hydration sphere to electron uptake or donation is rate determining. The transition state is

called an ‘activated surface complex’.

Alternatively, the mass transport properties in the solution can become rate determining—the reaction is then said to be diffusion controlled.

(A) ACTIVATION CONTROL (SEE ALSO SECTION C2.11 OF THIS BOOK)

Let us consider the oxidation of Fe(s) to Fe²⁺ (solvated), which can be described by the following reaction sequence [36, 40]:

-5-

The intermediate species Fe(OH) and FeOH⁺ can be regarded as constituting the activated surface complex.

The rate constant for formation and decay of this complex, *k*, can be written as

$$k = B e^{-\Delta G^\ddagger / RT} \quad (\text{C2.8.11})$$

As the reaction leading to the complex involves electron transfer it is clear that the activation energy ΔG^\ddagger for complex formation can be lowered or raised by an applied potential ($\Delta\Phi$). Of course, both the forward (oxidation) and well as the reverse (reduction) reaction are influenced by $\Delta\Phi$. If one expresses the reaction rate as a current flow (*j*), the above equation C2.8.11 can be expressed in terms of the Butler–Volmer equation (for a more detailed treatment see [section C2.11](#)). For the anodic reaction (Fe → Fe²⁺), the resulting anodic current density, *j_a*, upon applying externally an anodic voltage $\Delta\Phi$ has the form

$$j_a = j_0 e^{b\Delta\Phi} \quad (\text{C2.8.12})$$

For the cathodic reaction (Fe²⁺ → Fe), the cathodic current density *j_c* can analogously be written as

$$j_c = -j_0 e^{-b'\Delta\Phi} \quad (\text{C2.8.13})$$

where *j₀*, *b* and *b'* are constants. (*j₀* is the so-called exchange current density, i.e., the reaction current density in the absence of an external applied potential.)

Since any current resulting from the anodic reaction must be consumed by the cathodic reaction, the cathodic current, *j_c*, must be equal to the anodic current *j_a*. As a consequence, the equilibrium potential Φ_0 of a metal (e.g. Fe) that is immersed into an aqueous electrolyte will be adjusted by the condition that $j_a = |j_c| (=j_0)$. This is illustrated in [figure C2.8.2\(a\)](#). Under ideal conditions, $\Delta\Phi_0$ is the Nernst potential (E_{Fe}) of the Fe²⁺/Fe couple. For iron immersed in an aqueous electrolyte, the dominant reduction reaction is, however, one of the reactions involving the electrolyte (equations (C2.8.2), (C2.8.3) and (C2.8.4)). For this reaction equilibrium the same principle applies as outlined above for the Fe²⁺/Fe case (e.g. for H ↔ H₂ the concept of $j_a = j_c$ applies at E_H (an analogous diagram as for Fe in [figure C2.8.2 \(a\)](#) could be drawn for the H⁺/H couple).

Figure C2.8.2. (a) Schematic polarization curves for the anodic and cathodic reaction of an Fe/Fe²⁺ electrode. The anodic and cathodic branches of the curve correspond to equations (C2.8.12) and (C2.8.13) respectively. The equilibrium potential of this electrode will adjust so that $|j_a| = |j_c|$; the corresponding potential is E_{redox} of Fe. (b) Schematic polarization curves for a mixed electrode (Fe in an aqueous solution in the presence of hydrogen ions), i.e. the redox system of Fe (figure 2(a)) is coupled with a second redox system: H⁺/H₂. Also in this mixed case the absolute values of the two partial current densities are equal ($|j_a^*| = |j_c^*|$) at equilibrium. The corresponding potential is the corrosion potential (E_{corr}); the corrosion current density is equal to the anodic current density at E_{corr} ($j_{corr}^* = j_a^*$). Experimentally, only the sum of the anodic and cathodic branch is accessible—the dotted line represents this sum of current density (j_s^*). (c) Determination of the corrosion current from a so-called Tafel plot ($\log(j_s^*)$ against U). The corrosion current density (j_{corr}^*) is obtained from the extrapolation of linear parts of the cathodic and anodic branches of j_s^* to the corrosion potential.

The coupled situation of both redox equilibria is described by the so-called ‘mixed potential theory’. The mixed oxidation (Fe → Fe²⁺) and reduction (H⁺ → H₂) systems will equilibrate to zero net current; the resulting potential, which lies between $E_{Fe^{2+}/Fe}$ and E_{H^+/H_2} , is called the corrosion potential (E_{corr}). This is illustrated in figure C2.8.2 (b) (which is obtained by ‘adding’ figure C2.8.2(a) and the analogous curves for the H⁺/H couple). The rate of corrosion is given by the current of metal ions leaving the metal surface in the anodic region. Thus, the corrosion current density, j_{corr} , can be identified with the anodic current of the coupled system, j_a^* .

As both processes, reduction and oxidation, take place on the same electrode surface (a short-circuited system), it is not possible to directly measure the corrosion current. Experimentally, only the sum of the anodic

current densities (j_s^*) is accessible (the dotted line in figures C2.8.2(b) and (c)). To obtain the corrosion rate, j_s^* can be measured as a function of an externally applied voltage. To acquire the polarization curves as in figure C2.8.2 (c), a traditional three-electrode set-up (figure C2.8.3) is mainly used where the system is compared with a reference electrode. The potential (voltage) between the metal and the reference electrode is varied using a counter-electrode and the current is registered (figure C2.8.3). From figure C2.8.2 (b) it is clear that, for potentials which are sufficiently far from the equilibrium value, $j_a^* \approx j_c^*$. Thus, in a plot of $\log(j_s)$ versus ΔU a linear portion is obtained which can be extrapolated back to E_{corr} as shown in figure C2.8.2(c). The corresponding current density value is j_{corr} . The semilog representation of figure C2.8.2 (c) is often referred to as a Tafel plot; the slope of the linear portions, which depends on the exact mechanism of the charge transfer reaction, is accordingly called the Tafel slope.

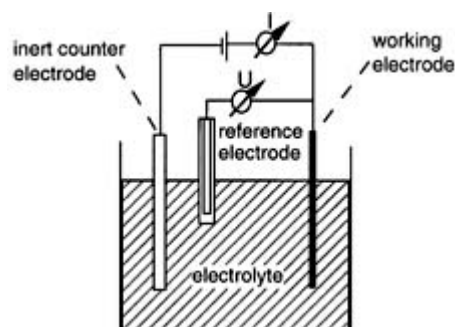

Figure C2.8.3. A three-electrode electrochemical set-up used for the measurement of polarization curves. A potentiostat is used to control the potential between the working electrode and a standard reference electrode. The current is measured and adjusted between an inert counter-electrode (typically Pt) and the working electrode.

The corrosion current can be converted into material loss (m_{corr}) using Faraday's law according to equation C2.8.14):

$$m_{corr} = (M/zF) j_{corr} t \quad (C2.8.14)$$

where M is the molar mass of the metal, z is the charge number of the ion, F is the Faraday constant and t is the time.

This, of course, assumes a 100% current efficiency regarding metal dissolution, i.e. no other competitive electrochemical reactions occur.

It should be pointed out that external polarization differs from the unbiased (open circuit) case in that after application of, say, an anodic voltage only the oxidation reaction takes place on the metal, whereas the cathodic reaction ($H \rightarrow H_2$) occurs at the external counter-electrode.

Other techniques to determine the corrosion rate use instead of DC biasing, an AC approach (electrochemical impedance spectroscopy). From the impedance spectra, the polarization resistance (R_p) of the system can be determined. The polarization resistance is indirectly proportional to j_{corr} . An advantage of an AC method is given by the fact that a small AC amplitude applied to a sample at the corrosion potential essentially does not remove the system from equilibrium.

(B) DIFFUSION CONTROL (SEE ALSO SECTION C2.11 OF THIS BOOK)

Electrochemical processes can become diffusion controlled if the formation of the activated complex is fast compared with the diffusion of the reacting anion to the surface or dissolving cations from the surface. In aqueous

solutions diffusion control of uniform corrosion is frequently encountered when the cathodic reaction depends on the supply of $O_2(g)$ —which is only sparingly soluble in water and therefore is present only in small concentrations.

Under diffusion controlled conditions the reaction rate depends, then, only on the supply of $O_2(g)$ to the surface which is determined by Fick's law:

$$\text{flux} = D(\partial N/\partial x) \tag{C2.8.15}$$

where D is the diffusion coefficient and $\partial N/\partial x$ is the particle (e.g. O_2) concentration gradient within the Nerstian diffusion layer.

Therefore, in the limiting case—the surface concentration of the reacting species is zero as all the arriving ions immediately react—the current density becomes voltage independent and depends only on diffusion, specifically, on the width of the Nerstian diffusion layer δ , and of course the diffusion coefficient and the bulk concentration of anions (c). The limiting current density (j_L) is then given by

$$j_L = (zFD/\delta)c. \tag{C2.8.16}$$

The diffusion layer width is very much dependent on the degree of agitation of the electrolyte. Thus, via the parameter δ , the hydrodynamics of the solution can be considered. Experimentally, defined hydrodynamic conditions are achieved by a rotating cylinder, disc or ring-disc electrodes, for which analytical solutions for the diffusion equation are available [37, 41, 42 and 43].

In the polarization curve of [figure C2.8.4](#) (solid line), the two regimes, activation control and diffusion control, are schematically shown. The anodic and cathodic plateau regions at high anodic and cathodic voltages, respectively, indicate diffusion control; the current is independent of the applied voltage and j_L is reached.

-9-

Figure C2.8.4. The solid line shows a typical semilogarithmic polarization curve ($\log j$ against U) for an active electrode. Different stages of reaction control are shown in the anodic and cathodic regimes: the linear slope according to an exponential law indicates activation control; at high anodic and cathodic potentials the current becomes independent of applied voltage, indicating diffusion control.

It is worth noting that under activation control the reaction rate depends on crystal orientation as the strength of the

bonds to the rest of the lattice, as well as the number of available bonds, directly influences the activation energy needed to create the activated complex. For instance, the kinetics of the dissolution of a Si(111) plane is much slower than for Si(100) due to stronger backbonding of an Si(111) surface atom. (An Si(111) surface is ‘attached’ by three backbonds to the lattice and has only one available (dangling) bond sticking out into the electrolyte, whereas an Si(100) surface has two backbonds and two of the bonds are dangling).

Under diffusion-controlled dissolution conditions (in the anodic direction) the crystal orientation has no influence on the reaction rate as only the mass transport conditions in the solution determine the process. In other words, the material is removed uniformly and electropolishing of the surface takes place.

C2.8.3 OXIDE FORMATION AND PASSIVITY [44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54 AND 55]

C2.8.3.1 PASSIVITY

(A) PASSIVE FILM FORMATION

In terms of an electrochemical treatment, passivation of a surface represents a significant deviation from ideal electrode behaviour. As mentioned above, for a metal immersed in an electrolyte, the conditions can be such as predicted by the Pourbaix diagram that formation of a second-phase film—usually an insoluble surface oxide film—is favoured compared with dissolution (solvation) of the oxidized anion. Depending on the quality of the oxide film, the formation of a surface layer can retard further dissolution and virtually stop it after some time. Such surface layers are called passive films. This type of film provides the comparably high chemical stability of many important construction materials such as aluminium or stainless steels.

Highly protective layers can also form in gaseous environments at ambient temperatures by a redox reaction similar to that in an aqueous electrolyte, i.e. by oxygen reduction combined with metal oxidation. The thickness of spontaneously formed oxide films is typically in the range of 1–3 nm, i.e., of similar thickness to electrochemical passive films. Substantially thicker anodic films can be formed on so-called valve metals (Ti, Ta, Zr, ...), which allow the application of anodizing potentials (high electric fields) without dielectric breakdown.

Passivation is manifested in a polarization curve ([figure C2.8.4](#) dashed line) by a dramatic decrease in current at a particular onset potential (the passivation potential, U_p). The corrosion reaction rate kinetics, i.e. the anodic current density, is lowered by several orders of magnitude.

The value and existence of a passivation potential U_p is based on the thermodynamics of oxide formation. Accordingly, passivation potentials and conditions for oxide formation can be predicted from a Pourbaix diagram ([figure C2.8.1](#)). A polarization curve as in [figure C2.8.4](#) can be perceived as reflecting a cross section through the Pourbaix diagram at a fixed pH. For example, at pH 7 one crosses, moving from cathodic to anodic potentials, first the active metal dissolution line (I), then the passivation line (II) at U_p .

It is generally believed that in the first stage of a passivation reaction—just below U_p —a precursor film is formed (e.g. a thin hydroxide layer), which then facilitates subsequent oxide formation.

The actual chemical mechanism of oxide formation has to address several factors, as schematically shown in [figure C2.8.5](#). Although in essence very similar, two slightly different mechanisms are distinguished: [figure C2.8.5 \(a\)](#) represents the growth of an oxide under open-circuit conditions, i.e. a piece of iron immersed in a passivating solution or exposed to an oxygen-containing environment. [Figure C2.8.5 \(b\)](#) shows the situation under an externally applied voltage in an electrolyte.

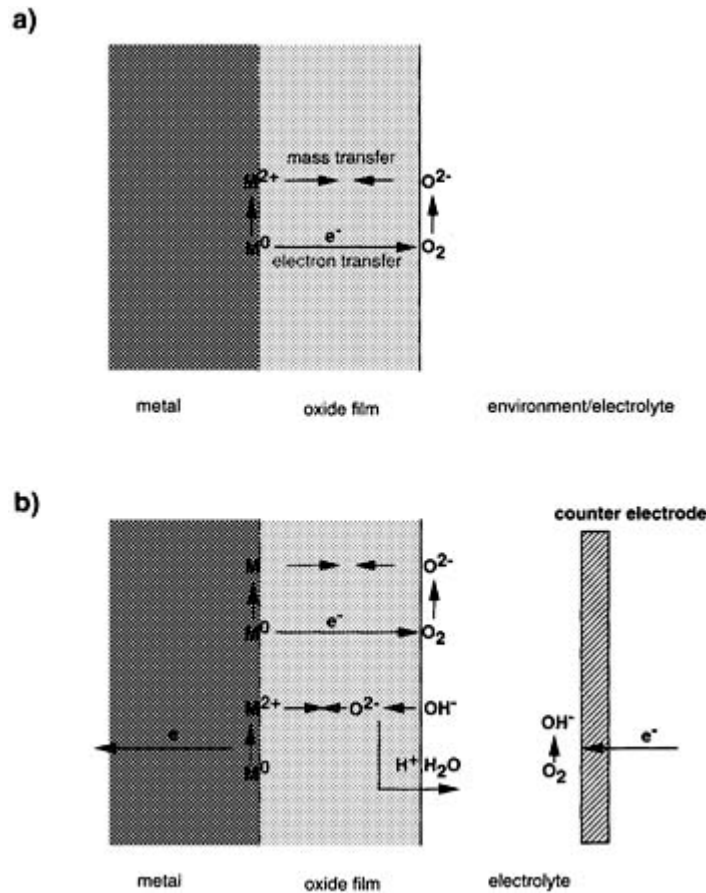

Figure C2.8.5. Growth of an oxide film on a metal surface. (a) In the absence of an externally applied potential: metal oxidation ($M \rightarrow M^{2+}$) occurring at the inner interface is coupled with oxygen reduction ($O_2 \rightarrow O^{2-}$) at the outer interface. For film growth one of the ionic species migrates predominantly—mass transfer is coupled with electron transfer through the layer. (This situation also corresponds to high-temperature corrosion.) (b) In the presence of an externally applied anodic potential (potentiostat): in addition to the mechanism of (a) film growth can also take place without electron transfer through the film as oxygen reduction happens at the counter-electrode. Mass transfer is not coupled with electron transfer.

In both cases, the anodic reaction occurs by oxidation at the metal/oxide interface:

For the situation in figure C2.8.5 a), the cathodic reaction is the reduction of O₂ at the oxide/gas or oxide/electrolyte interface:

At least one of the ionic species has to diffuse or migrate through the oxide and accordingly the layer grows usually either at the inner or outer interface. (Alternatively, the transport of ions through the film can be formulated as cation and anion vacancies moving through the lattice of the oxide film [44,56, 57].) As the cathodic and anodic

reactions are spatially separated by the oxide, electrons have also to be transferred through the layer and, thus, the conductance of the layer is essential to the process. Most oxides are semiconductors due to a non-equilibrated stoichiometry and, thus, either a negatively or positively charged species has the freedom to migrate through the lattice.

The driving force for migration is established by the different electrochemical potentials (ΔU) that exist at the two interfaces of the oxide. In other words, the electrochemical potential at the outer interface is controlled by the dominant redox species present in the electrolyte (e.g. O_2).

The situation in [figure C2.8.5\(b\)](#) is different in that, in addition to the mechanism in [figure C2.8.5\(a\)](#), reduction of the redox species can occur at the counter-electrode. Thus, electron transfer through the layer may not be needed, as film growth can occur with OH^- species present in the electrolyte involving a (field-aided) deprotonation of the film. The driving force is provided by the applied voltage, ΔU .

Quantitative approaches to describe the kinetics of film formation i.e. the mechanistic extraction of growth laws for film formation date back to the work of Cabrera and Mott [[58](#)] and Vetter [[59](#)]. It is essential that at low to moderate temperatures pure diffusion of ionic species is very small. Thus, film growth is controlled by the electric field across the layer and the lowering of the activation energy for ion or vacancy hopping (so-called high-field mechanism). This results in the so-called inverse logarithmic growth law.

$$1/x = A - B \log(t) \quad (C2.8.19)$$

where x is the film thickness and t is the time.

The growth according to this equation is self-limiting as the field strength F is lowered (at constant voltage) with an increasing film thickness x .

$$F(t) = \Delta U/x(t). \quad (C2.8.20)$$

In most practical cases (and at moderate voltages) the high-field growth law can control film growth, say up to only a maximum of 10 nm, as at this thickness the field strength effects become even less important than film growth due to diffusion of vacancies or ions.

The above rate law has been observed for many metals and alloys either anodically oxidized or exposed to oxidizing atmospheres at low to moderate temperatures—see e.g. [[60](#)]. It should be noted that a variety of different mechanisms of growth have been proposed (see e.g. [[61](#), [62](#)]) but they have in common that they result in either the inverse logarithmic or the direct logarithmic growth law. For many systems, the experimental data obtained up to now fit both growth laws equally well, and, hence, it is difficult to distinguish between them.

It should be mentioned that as well as for metals the passivation of semiconductors (particularly on Si, GaAs, InP) is also a subject of intense investigation. However, the goal is mostly not the suppression of corrosion but either the formation of a dielectric layer that can be exploited for devices (MIS structures) or the minimization of interface states (dangling bonds) on the semiconductor surface [[63](#), [64](#)].

(B) PROPERTIES OF PASSIVE FILMS

The protective quality of the passive film is determined by the ion transfer through the film as well as the stability of the film with respect to dissolution. The dissolution of passive oxide films can occur either chemically or electrochemically. The latter case takes place if an oxidized or reduced component of the passive film is more soluble in the electrolyte than the original component. An example of this is the oxidative dissolution of Cr_2O_3

films as CrO_4^{2-} [39, 65, 66].

From polarization curves the ‘protectiveness’ of a passive film in a certain environment can be estimated from the passive current density in [figure C2.8.4](#) which reflects the layer’s resistance to ion transport through the film, and chemical dissolution of the film. It is clear that a variety of factors can influence ion transport through the film, such as the film’s chemical composition, structure, number of grain boundaries and the extent of flaws and pores. The protectiveness and stability of passive films has, for instance, been based on percolation arguments [67, 68], structural arguments [69], ion/defect mobility [56, 57] and charge distribution [70, 71].

To illustrate some of the different approaches, let us consider passive films grown on Fe–Cr alloys. It has been established since 1911 [72] that an increase of Cr in the alloy increases the stability of the oxide film against dissolution.

The percolation argument is based on the idea that with an increasing Cr content an insoluble interlinked chromium oxide network can form which is also protective by embedding the otherwise soluble iron oxide species. As the threshold composition for a high stability of the oxide film is strongly influenced by solution chemistry and is different for different dissolution reactions [73], a comprehensive model, however, cannot be based solely on geometrical considerations but has in addition to consider the dissolution chemistry in a concrete way.

Other authors have attributed the improved corrosion resistance with increasing Cr content with the increasing tendency of the oxide to become more disordered [69]. This would then suggest that an amorphous oxide film is more protective than a crystalline one, due to a bond and structural flexibility in amorphous films.

This example illustrates that exact information on the chemistry and structure of the passive film is necessary to clarify the mechanisms relevant to stability and protectiveness of passive films.

The nature of passive oxide films on many technologically important metals and alloys has been the subject of investigation for many years. *Ex situ* surface analytical techniques such as x-ray photoelectron spectroscopy (XPS), Auger electron spectroscopy (AES) and secondary ion mass spectrometry (SIMS) provide useful information on the chemical composition and thickness of the films. Good agreement exists regarding a qualitative description of the chemistry of passive films on many metals. However, due to either different experimental approaches or data analysis, slightly different views can be found on the more detailed nature of the different films. Generally, it is important to note that the passive film, once formed should not be considered as a rigid layer, but instead as a system in dynamic equilibrium between film dissolution and growth. In other words, the passive film can adjust its composition and thickness to changing environmental factors. Principally, the chemical composition and the thickness of electrochemically formed passive films depend (apart from the base metal) on the passivation potential, time, electrolyte composition and temperature, i.e., on all passivation parameters and, hence, a detailed treatment is beyond the scope of this chapter. For further relevant literature the reader is referred to e.g. [74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88 and 89] and references therein.

The question of the structure of the passive film has been tackled by many research groups. Methods used to investigate the structure include x-ray scattering, diffraction and Mössbauer spectroscopy. For thick anodic oxide films or thick oxide films grown at elevated temperatures, the structure can be assessed by x-ray diffraction techniques. However, for thin passive films formed at low to moderate temperatures, the thickness of the films is usually less than 10 nm and, hence, it is experimentally difficult to investigate the structure by traditional x-ray diffraction. Another question often asked is whether the structure of a thin, mostly hydrated passive film formed under electrochemical conditions may change as it is removed from the conditions under which it was formed. Therefore, lately, new *in situ* techniques (STM, x-ray scattering using synchrotron radiation, EXAFS) to study the structure of thin oxide films have attracted considerable interest. In the case of the passive film on Fe, for instance, it could be shown with *in situ* STM [90] as well as with *in situ* x-ray scattering [91] that the passive film has a crystalline structure. Up to now, however, these investigations have been extended to only a few metals and, hence, the question of the structure of passive films remains to be investigated further.

As outlined above, electron transfer through the passive film can also be crucial for passivation and thus for the corrosion behaviour of a metal. Therefore, interest has grown in studies of the electronic properties of passive films. Many passive films are of a semiconductive nature [92, 93, 94, 95, 96, 97, 98, 99, 100, 101, 102 and 103] and therefore can be investigated with techniques borrowed from semiconductor electrochemistry—most typically photoelectrochemistry and capacitance measurements of the Mott–Schottky type [104]. Generally it is found that many passive films cannot be described as ideal but rather as amorphous or highly defective semiconductors which often exhibit doping levels close to degeneracy [105].

(C) PASSIVITY BREAKDOWN AND LOCALIZED CORROSION

The passive state of a metal can, under certain circumstances, be prone to localized instabilities. Most investigated is the case of localized dissolution events on oxide-passivated surfaces [51, 106, 107, 108, 109, 110, 111, 112, 113, 114, 115, 116, 117 and 118]. The essence of localized corrosion is that distinct anodic sites on the surface can be identified where the metal oxidation reaction (e.g. $\text{Fe} \rightarrow \text{Fe}^{2+} + 2\text{e}^-$) dominates, surrounded by a cathodic zone where the reduction reaction takes place (e.g. $2\text{H}^+ + 2\text{e}^- \rightarrow \text{H}_2$). The result is the formation of an active pit in the metal, an example of which is illustrated in figure C2.8.6(a) and (b).

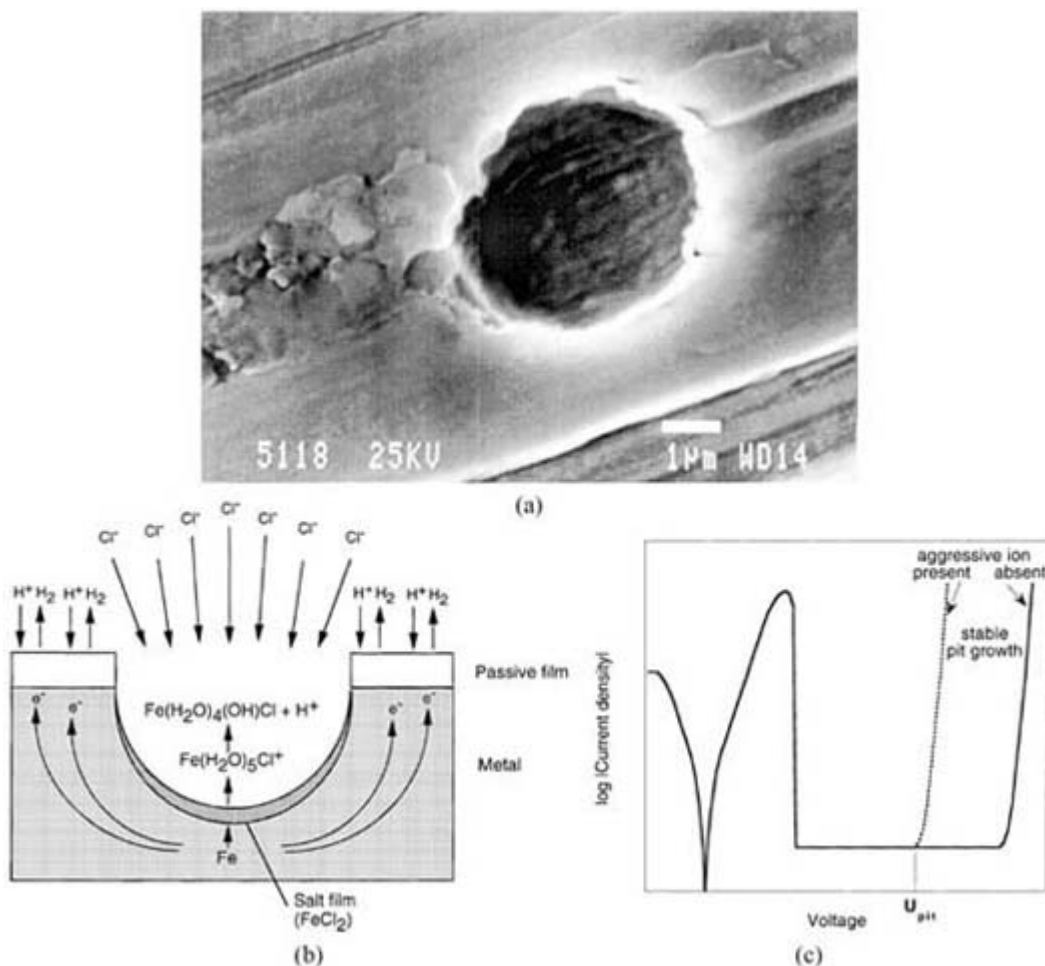

Figure C2.8.6. (a) SEM image of an early stage of pit formation on AISI304 steel in chloride containing solution. (b) Schematic cross section through an actively growing pit. Metal oxidation occurs at the pit base and the corresponding reduction on the passive film surrounding the pit. Acidification and an increase of the halogen ion concentration (due to migration) within the pit additionally accelerate dissolution. (c) Polarization curve of a passive metal showing localized breakdown of passivity and pit growth at U_{pit} (dashed line). The solid line represents a polarization curve of the same material in the absence of aggressive (pit-triggering) anions. In this case the current increase at higher anodic voltages indicates either transpassive oxide film dissolution or the onset of

oxygen evolution at the anodically polarized electrode.

Pitting occurs with many metals in halide containing solutions. Typical examples of metallic materials prone to pitting corrosion are Fe, stainless steels and Al. The process is autocatalytic, i.e., by initial dissolution, conditions are established which further stimulate dissolution: inside the pit the metal (Fe in the example of figure C2.8.6 dissolves.

-16-

The M^{2+} species form an aquo-complex:

To maintain charge neutrality, additional halide ions (Cl^- in our example) have to migrate inside the pit thus increasing the local chloride concentration and a chloro-complex is formed.

The chloro-complex is in equilibrium with its hydroxo-chlorocomplex and H^+ .

For many metals the equilibrium lies strongly to the right hand side. Thus, within the pit the chloride concentration and the H^+ concentration both increase, further accelerating metal dissolution.

Generally, the following two stages of pitting are distinguished: pit initiation and pit growth. The reasons for the initiation of pits at distinct surface locations are manifold and can either be deterministic or stochastic in nature. They can be ascribed to bulk metal inhomogeneities (inclusions, precipitates, grain boundaries, dislocations etc.) or to properties of the passive film (thermally induced stochastic film rupture, electrostriction, local composition or structure variations). Initiation mechanisms assigning the key role to the passive film involve Cl^- penetration, local film thinning, or vacancy condensation; mechanisms focusing on the bulk metal ascribe the key role to preferential dissolution at inhomogeneities.

In an electrochemical polarization experiment on a passive system the onset of localized dissolution can be detected by a steep current increase at a very distinct anodic potential (the pitting potential, U_{pit})—see [figure C2.8.6\(c\)](#). This increase occurs far below either transpassive dissolution (oxide film dissolution due to the formation of soluble higher oxidation states (e.g. $Cr_2O_3 \rightarrow Cr^{6+} aq$) or the occurrence of oxygen evolution ($OH^- \rightarrow O_2$)).

In the potential range anodic to U_{pit} , stable pit growth occurs. The value of U_{pit} is shifted to lower anodic potentials with increasing temperature, increasing Cl^- concentration and decreasing pH, and is dependent on the presence of other anions in the electrolyte.

From an electrochemical viewpoint, stable pit growth is maintained as long as the local environment within the pit keeps the pit under active conditions. Thus, the effective potential at the pit base must be less anodic than the passivation potential (U_p) of the metal in the pit electrolyte. This may require the presence of voltage-drop (IR -drop) elements. In this respect the most important factor appears to be the formation of a salt film at the pit base. (The salt film forms because the solubility limit of e.g. $FeCl_2$ is exceeded in the vicinity of the dissolving surface in the highly Cl^- -concentrated electrolyte.)

In the potential range cathodic to U_{pit} , one frequently observes so-called metastable pitting. A number of pit growth events are initiated, but the pits immediately repassivate (an oxide film is formed in the pit) because the conditions within the pit are such that no stable pit growth can be maintained. This results in a polarization curve with strong current oscillations at $U < U_{pit}$.

Another type of localized corrosion closely related to pitting corrosion is crevice corrosion. This type of attack occurs preferentially in regions on the metal surface where mass transfer is limited (e.g., in narrow crevices or under deposits) and, hence, an increase in concentration of aggressive species (halides), combined with a pH decrease as discussed above and depletion of oxygen, can rapidly lead to activation of the surface in the crevice area. Metals which are susceptible to pitting corrosion also suffer from crevice corrosion. The presence of crevices on the surface often triggers localized corrosion already under conditions where stable pitting would not take place (e.g., with lower concentration of aggressive halides).

In all cases of localized corrosion, the ratio of the cathodic to the anodic area plays a major role in the localized dissolution rate. A large cathodic area provides high cathodic currents and, due to electroneutrality requirements, the small anodic area must provide a high anodic current. Hence, the local current density, i.e., local corrosion rate, becomes higher with a larger cathode/anode-ratio.

Localized corrosion is far more treacherous in nature and far less readily predictable and controllable than uniform corrosion and it is, moreover, capable of leading to unexpected damage with disastrous consequences, especially since inspection of corrosion damage is in many cases difficult.

Recently, the phenomenon of localized dissolution has attracted a great deal of interest in the field of semiconductor technology. This is due to the discovery of visible light emission from porous Si [119] which is formed by an electrochemical treatment of a Si surface in an HF-containing electrolyte [120]. It is interesting to note that the formation process is in many respects similar to pitting of metals [118] and that preferential triggering of the formation process at defects can be exploited to form highly defined localized dissolution [121].

C2.8.3.2 HIGH-TEMPERATURE OXIDATION AND CORROSION [122, 123, 124, 125, 126 AND 127]

So far, discussions have been limited to oxide film growth at low temperatures, where the model of Cabrera and Mott [58] usually applies. Oxide growth, controlled by the electric field across the film, follows an inverse logarithmic growth law (equation (C2.8.19)). At elevated temperature, scales can grow much thicker in water, air or oxygen, for example, or other more aggressive gases containing sulphur or chlorine. Mechanistically, the processes are similar to the passivation discussed earlier in terms of oxidation, reduction, ion transport and electron transfer, as outlined in figure C2.8.5(a). The main difference is that elevated temperatures promote ionic diffusion and, thus, oxide formation can proceed to a much greater extent than at low temperatures where only thin layers are formed by the high-field mechanism. The most common growth law observed at higher temperatures is the so-called parabolic rate law [128]:

$$x^2 = k_p t + C \quad (\text{C2.8.24})$$

where the rate of oxidation dx/dt is inversely proportional to the oxide thickness, x , and k_p is the parabolic rate constant. This indicates that a thermal diffusion process is rate controlling, with oxygen or cations or both diffusing

through a compact layer (figure C2.8.5(a)). Protective oxides are formed in this manner, the most important in practice being Cr_2O_3 , Al_2O_3 and SiO_2 . SiO_2 layers are particularly protective, but it is difficult to form continuous silica layers on silicon-containing steels. It is, however, straightforward to produce SiO_2 on silicon single crystals,

and the ability for silicon to form high-quality (amorphous) thermal oxide is to a large extent responsible for its successful application in MOS (metal/oxide/semiconductor) technologies [129].

The rate of diffusion through an oxide film depends on a number of factors, such as the temperature, oxygen partial pressure and structure of the oxide. At high temperatures (>0.7 of the melting point of the metal) lattice diffusion dominates through the crystalline oxide formed on a metal. However, at moderate temperatures diffusion via oxide grain boundaries is predominant. In this case, the rate of oxidation of a metal or alloy depends on the oxide grain size, which is often dictated by substrate grain orientation, surface pretreatment etc [130]. Deviation from parabolic oxidation behaviour is often observed and can be the result of the oxide grain size changing with time at a particular temperature. In this case, the number of oxide grain boundary 'easy diffusion paths' decreases with time, causing an apparent decrease in oxidation rate. If true parabolic behaviour is observed, then the change in oxidation rate with temperature will follow an Arrhenius equation; $k_p = Ae^{-\Delta E/PT}$. The log of the parabolic rate constant $\ln k_p$ is proportional to $1/T$, where T is the absolute temperature. The slope of such a plot yields the activation energy, ΔE , for oxidation.

If a compact film growing at a parabolic rate breaks down in some way, which results in a non-protective oxide layer, then the rate of reaction dramatically increases to one which is linear. This combination of parabolic and linear oxidation can be termed parilinear oxidation. If a non-protective, e.g. porous oxide, is formed from the start of oxidation, then the rate of oxidation will again be linear, as rapid transport of oxygen through the porous oxide layer to the metal surface occurs. Figure C2.8.7 shows the various growth laws. Parabolic behaviour is desirable whereas linear or 'breakaway' oxidation is often catastrophic for high-temperature materials.

Figure C2.8.7. Principal oxide growth rate laws for low- and high-temperature oxidation: inverse logarithmic, linear, parilinear and parabolic.

High-temperature protective oxides often fail as the result of the development of stress during growth, which causes cracking and rupture of the scales leading to much faster metal degradation. Mechanisms for intrinsic growth stresses include the epitaxial relationship between the metal and scale [131], the volume change that occurs when a metal is converted into oxide by oxidation (the Pilling–Bedworth ratio) [132], compositional changes in either the metal or oxide and the influence of vacancies generated during oxidation [133]. Many discussions of the mechanisms of growth stresses have been published, e.g. [134, 135].

C2.8.4 SUPPRESSION OF CORROSION

C2.8.4.1 ELECTROCHEMICAL PROTECTION

Based on the polarization curves of [figure C2.8.4](#) there are several possibilities for reducing or suppressing the corrosion reaction. The main idea behind every case is to shift the corroding anode potential away from E_{corr} . This can be done in the following ways.

(i) *Cathodic protection* [[136](#), [137](#) and [138](#)]. By imposing a negative external voltage, the potential can be shifted cathodic to the corrosion potential (or better negative to the oxidation potential $E_{Fe/Fe^{2+}}$, to achieve thermodynamic stability).

Cathodic protection can also be achieved without the application of an external voltage by coupling with a less noble metal. The coupled metal has an E_{redox} that is negative to the material to be protected and thus becomes the anode which corrodes. The anode is therefore termed sacrificial.

(ii) *Anodic protection* [[139](#)]. If the material exhibits a passive behaviour (dotted line in [figure C2.8.4](#)), the potential of the corroding material can be anodically shifted into the passive range. This can be achieved by imposing a positive external voltage. The remaining corrosion current then depends on the quality of the passive film.

For practical applicability, several aspects have to be considered such as the anode material (sacrificial (e.g. zinc) or inert (e.g. Pt/Ti or graphite)), the conductivity of the medium and the current distribution. Cathodic protection is typically used for buried constructions (e.g. pipelines), off-shore structures or ship hulls.

C2.8.4.2 CHEMICAL INHIBITION [[140](#), [141](#), [142](#), [143](#), [144](#) AND [145](#)]

Corrosion suppression by inhibitors can be achieved by adding chemical species to the environment, which lead to a strong reduction of the dissolution rate. Depending on their specific action, corrosion inhibitors can be divided into the following groups.

(i) *Oxidizing inhibitors*. The idea is essentially the same as with anodic protection. If the material shows a passive range, the corrosion potential can be shifted into the passivity region by adding an additional redox couple to the electrolyte that possesses an E_{red} at potentials in the passive regime (oxidative inhibition).

-20-

The effectiveness of anodic methods can vary considerably and is mainly determined by the protective nature of the passive layer formed.

(ii) *pH modifiers*. The primary effect of pH modification can be deduced from the Pourbaix diagram ([figure C2.8.1](#)). The goal is to shift the pH into a region where thermodynamically, the formation of a passive layer is favoured as opposed to active dissolution. Often pH buffers are used, which keep the pH stable and thus hamper acidification, as discussed in the localized corrosion section.

(iii) *Surface blockers*. Type 1: the inhibiting molecules set up a geometrical barrier on the surface (mostly by adsorption) such as a variety of ionic organic molecules. The effectiveness is directly related to the surface coverage. The effect is a lowering of the anodic part of the polarization curve without changing the Tafel slope.

Type 2: the inhibiting species takes part in the redox reaction, i.e. it is able to react at either cathodic or anodic surface sites to electroplate, precipitate or electropolymerize. Depending on its 'activation' potential, the inhibitor affects the polarization curve by lowering the anodic or cathodic Tafel slope.

C2.8.4.3 SURFACE TREATMENTS [[137](#), [146](#), [147](#)]

For corrosion protection a large number of different types of surface treatment and coating have been developed, ranging from inorganic enamel coatings to organic coatings. In the following, the main two types of coating are

briefly discussed.

(i) *Paint and insulating coatings.* Coating the surface with some impermeable layer, such as paint, is frequently used due to the ease of application. The protection mechanism is simply to provide a physical barrier against metal dissolution. Unfortunately, this protection can fail disastrously if the coating is defective. Therefore, in many practical applications, a combination of an insulating coating and cathodic protection is employed.

(ii) *Deposition of a less noble metal (mostly by galvanizing).* The principle is again identical to cathodic protection. The coating has an E_{redox} that is negative to the material to be protected and the layer serves as a sacrificial anode. Therefore, this type of coating is not sensitive to defects, pinholes or mechanical damage during service. A typical example is galvanized steel (Zn layer on steel).

C2.8.4.4 PROTECTION AGAINST HIGH-TEMPERATURE CORROSION

Increasing operating temperatures result in increasing rates of corrosion and protective coatings are used to enhance component performance. These coatings serve as effective diffusion barriers between the oxidizing environment and the base alloy. In practice, corrosion-resistant coatings usually produce protective oxide scales consisting of thermally formed Cr_2O_3 , Al_2O_3 or SiO_2 films. The coating and the substrate should preferably have closely matched thermal expansion coefficients to prevent cracking during thermal cycling; the coating should also be able to withstand damage from impacts, erosion and abrasion.

-21-

C2.8.5 BRIEF OVERVIEW OF OTHER SPECIFIC CASES OF CORROSION

In the following, the most typical modes of corrosion—other than the above discussed uniform dissolution (active corrosion) and localized pitting and crevice corrosion (local active dissolution)—are briefly presented.

The paragraphs below are arranged in alphabetical order and are intended only as a short reference. For readers interested in a particular topic a few references are given which serve as a link for further reading. Generally, it should be noted that the separation of the categories below is to a large extent based on historic evolution rather than physicochemical mechanisms.

C2.8.5.1 ATMOSPHERIC CORROSION [148, 149, 150]

Atmospheric corrosion results from a metal's ambient-temperature reaction, with the earth's atmosphere as the corrosive environment. Atmospheric corrosion is electrochemical in nature, but differs from corrosion in aqueous solutions in that the electrochemical reactions occur under very thin layers of electrolyte on the metal surface. This influences the amount of oxygen present on the metal surface, since diffusion of oxygen from the atmosphere/electrolyte solution interface to the solution/metal interface is rapid. Atmospheric corrosion rates of metals are strongly influenced by moisture, temperature and presence of contaminants (e.g., NaCl, SO_2 , ...). Hence, significantly different resistances to atmospheric corrosion are observed depending on the geographical location, whether rural, urban or marine.

C2.8.5.2 CONTACT CORROSION = GALVANIC CORROSION [151, 152, 153, 154, 155 AND 156]

This type of corrosive attack occurs when dissimilar metals (i.e., with a different E_{redox}) are in direct electrical contact in corrosive solutions or atmospheres. Under such conditions, enhanced corrosion of the less noble part of the bimetallic couple takes place, whereas the corrosion rate of the more noble part of the couple is reduced or even completely suppressed (as in the case of corrosion suppression by cathodic protection). The difference in corrosion potential of the components of the couple provides the driving force for the corrosion reaction. However, to determine the kinetics of galvanic corrosion, knowledge of the nature and kinetics of the cathodic reaction at the

surface of the more noble metal as well as the nature and kinetics of the anodic reaction on the surface of the less noble metal are required. The nature and conductivity of the electrolyte solution determines the current and potential distribution: the larger the conductivity, the farther from the contact site the coupling action is experienced. A major factor in determining the danger of galvanic corrosion is the ratio of the area of the cathode and the anode. The higher the cathode area compared with the anode area, the larger the enhancement of dissolution of the less noble metal due to coupling.

C2.8.5.3 CAVITATION (CORROSION) [157, 158, 159 AND 160]

Cavitation damage is a form of deterioration associated with materials in rapidly moving liquid environments, due to collapse of cavities (or vapour bubbles) in the liquid at a solid–liquid interface, in the high-pressure regions of high flow. If the liquid in movement is corrosive towards the metal, the damage of the metal may be greatly increased (cavitation corrosion).

-22-

C2.8.5.4 CORROSION FATIGUE [161, 162 AND 163]

Corrosion fatigue is a type of failure (cracking) which occurs when a metal component is subjected to cyclic stress in a corrosive medium. In many cases, relatively mild environments (e.g., atmospheric moisture) can greatly enhance fatigue cracking without producing visible corrosion.

C2.8.5.5 DEALLOYING, SELECTIVE CORROSION

In certain alloys and under certain environmental conditions, selective removal of one metal (the most electrochemically active) can occur that results in a weakening of the strength of the component. The most common example is dezincification of brass [164, 165]. The residual copper lacks mechanical strength.

Another case of selective corrosion is the graphitization of grey cast iron, resulting in preferential removal of the metallic constituent, leaving graphite. Here again the physical form of the casting is maintained, but it is devoid of any mechanical strength.

C2.8.5.6 EROSION (CORROSION) [166, 167]

Erosion is the deterioration of a surface by the abrasive action of solid particles in a liquid or gas, gas bubbles in a liquid, liquid droplets in a gas or due to (local) high-flow velocities. This type of attack is often accompanied by corrosion (erosion–corrosion). The most significant effect of a joint action of erosion and corrosion is the constant removal of protective films from a metal's surface. This can also be caused by liquid movement at high velocities, and will be particularly prone to occur if the solution contains solid particles that have an abrasive action.

C2.8.5.7 FRETTING CORROSION [168]

Fretting corrosion is a form of damage which occurs at the interface of two closely fitting surfaces when they are subject to slight oscillatory slip and joint corrosion action. Almost all materials are subject to fretting and, hence, its incidence in vibrating machinery is high. The damage is mostly of a localized form and any debris which is generated (mostly oxide) has some difficulty escaping from the rubbing zone, and this can lead to an increase in stress.

C2.8.5.8 HYDROGEN EMBRITTLEMENT [169]

A process resulting in a decrease in toughness or ductility of a metal due to absorption of hydrogen. This atomic hydrogen can result, for instance, in the cathodic corrosion reaction or from cathodic protection.

C2.8.5.9 IMPINGEMENT ATTACK [158]

Localized erosion–corrosion caused by turbulence or impinging flow at certain points of the surface. In the majority of cases of impingement attack, a geometrical feature of the system results in turbulence at one or more parts of the surface.

-23-

C2.8.5.10 INTERGRANULAR CORROSION [170]

Corrosion damage due to enhanced dissolution in or adjacent to the grain boundaries of a metal, due to composition gradients between the grain boundary area and the bulk metal. An example is the intergranular attack of stainless steels, which can be explained by a chromium depletion. In a specific temperature region, carbon diffuses to the grain boundaries and reacts with chromium to form chromium carbides, thereby depleting the adjacent areas of chromium. Since stainless steels depend on chromium for corrosion resistance, the grain boundary areas become less resistant to corrosion and more susceptible to localized attack.

C2.8.5.11 MICROBIOLOGICALLY INDUCED CORROSION (MIC) [171, 172 AND 173]

Corrosion associated with the action of micro-organisms present in the corrosion system. The biological action of organisms which is responsible for the enhancement of corrosion can be, for instance, to produce aggressive metabolites to render the environment corrosive, or they may be able to participate directly in the electrochemical reactions. In many cases microbial corrosion is closely associated with biofouling, which is caused by the activity of organisms that produce deposits on the metal surface.

C2.8.5.12 STRAY-CURRENT CORROSION [138]

Corrosion due to stray current—the metal is attacked at the point where the current leaves. Typically, this kind of damage can be observed in buried structures in the vicinity of cathodic protection systems or the DC stray current can stem from railway traction sources.

C2.8.5.13 STRESS CORROSION CRACKING (SCC) [174, 175, 176, 177, 178 AND 179]

A process involving combined corrosion and straining of the metal due to residual or applied stresses. The occurrence of stress corrosion cracking is highly specific; only particular metal/environment systems will crack. The appearance of stress corrosion cracking may be either intergranular or transgranular in nature.

C2.9 Tribology

Andrew J Gellman

C2.9.1 INTRODUCTION

The term tribology translates literally into ‘the study of rubbing’. In modern parlance this field is held to include four phenomena: adhesion, friction, lubrication and wear. For the most part these are phenomena that occur between pairs of solid surfaces in contact with one another or separated by a thin fluid film. *Adhesion* describes the resistance to separation of two surfaces in contact while *friction* describes their tendency to resist shearing. *Lubrication* is the phenomenon of friction reduction by the presence of a fluid (or solid) film between two surfaces. Finally, *wear* describes the irreversible damage or deformation that occurs as a result of shearing or separation.

Tribological phenomena have been known to mankind since prehistorical times when friction between wooden sticks was used to produce fire. The first historical record of tribology described the use of lubrication in the

construction of Egyptian temples as far back as 2400 BC. The earliest scientific studies of tribological phenomena are attributed to da Vinci in the 15th century, Amontons in the 17th and Coulomb in the 18th. More recently, the application of modern methods of physics and chemistry to tribology is usually credited to Bowden and Tabor for work done in the post World War II era [1, 2]. In the past decade there has been a great deal of progress in the understanding of tribological phenomena. This progress has been catalysed by the development and application of a number of experimental and theoretical methods that allow study of tribological phenomena at an unprecedented level of detail [3, 4]. This effort has been further motivated by the development of several ‘high tech’ devices that have pushed the need for tribology into extreme conditions and environments. Examples include: the lubrication of ceramics for high temperature applications, lubrication of the surfaces of hard disks for data storage [5] and microelectromechanical systems (MEMS) [6]. These applications place unprecedented demands on the performance of tribological systems. Furthermore, there is increasing interest in solving tribological problems that arise in such diverse environments such as the human body (joints), vacuum (satellite components) and the Earth’s mantle (tectonic motion and earthquakes).

The scope of this entry includes a description of tribological phenomena and the modern tools that are spurring developments in our understanding of tribology. The goal is to provide the reader with a basic understanding of the concepts, an understanding of their limitations and a perspective on the breadth and scope of phenomena that are included under the umbrella of tribology.

C2.9.2 PHYSICAL DESCRIPTION OF TRIBOLOGICAL PHENOMENA

A typical physical process involving friction occurs in three steps: the formation of a contact between two solid surfaces, the shearing of those surfaces and the separation of those surfaces ([figure C2.9.1](#)). A device used to measure friction includes the elements shown in [figure C2.9.1](#) and measures friction forces (F) and normal forces (N) as extension (or compression) of springs during sliding. The phenomenological measure of friction is in terms of a friction coefficient given by

-2-

$$\mu = \frac{F}{N}.$$

The proportionality between normal and friction forces is observed for many systems but is not founded in any basic physics. Much work in the field of tribology has been devoted to rationalizing the implication that the friction coefficient does not depend upon the apparent contact area between the two solid surfaces. For this reason the field of contact mechanics has always been intimately linked to tribology.

Figure C2.9.1 Schematic representation of the steps involved in a tribological process: (a) contact between surfaces, (b) shearing under a constant normal force and (c) separation against adhesive forces. In the absence of gravity the normal (N) and friction (F) forces are measured by the extension or compression of the springs.

C2.9.2.1 CONTACT OF SOLID SURFACES

With very few exceptions it is possible to produce surfaces of materials that are atomically smooth across macroscopic length scales. The protrusions that exist on the surfaces of all common materials are called asperities. As two surfaces are brought together, the peaks of asperities come into contact first. If the two solids were nondeformable there would be at most three contact points spanning the entire apparent contact area and supporting the normal force. In reality, the normal forces between two solids cause both elastic and plastic deformation of the regions around the initial contact points such that the two solids come into contact across a finite area.

Modelling of the true contact area between surfaces requires consideration of the deformation that occurs at the peaks of asperities as they come into contact with mating surfaces. Purely elastic contact between two solids was first described by H Hertz [7]. The Hertzian contact area (A_H) between a sphere of radius r and a flat surface compressed under normal force N is given by

$$A_H = \pi(r\kappa N)^{2/3}$$
$$\kappa = \frac{3}{4} \left(\frac{1 - \nu_1^2}{E_1} + \frac{1 - \nu_2^2}{E_2} \right)$$

where E_1, E_2 are the elastic moduli, and ν_1, ν_2 are the Poisson numbers for the sphere and the surface. The friction force during shearing is proportional to the contact area; however, under conditions of purely elastic Hertzian contact it cannot be proportional to the normal force. This is inconsistent with the empirical observation of a coefficient of friction. The most important correction to the Hertz expression is due to Johnson, Kendall and Roberts (JKR) who included the fact that the surface tensions of two solids will contribute to the contact area [8]. The JKR expression for the contact area between a sphere and a flat surface is

$$A_{JKR} = \pi(r\kappa)^{2/3} (N + 3\pi r\gamma + \sqrt{6\pi r\gamma N + 9\pi^2 r^2 \gamma^2})^{2/3}.$$

In this expression $\gamma = \gamma_1 + \gamma_2 - \gamma_{12}$ where γ_1 and γ_2 are the surface tensions of the sphere and flat, respectively, and γ_{12} is the surface tension of the interface between them. The JKR expression recognizes the fact that even in the absence of a normal force ($N = 0$) surface tension will cause some elastic deformation of the surfaces producing a finite contact area. This fact alone renders the concept of a coefficient of friction meaningless since it implies that there is some finite friction force between solids even under zero normal force.

In reality most solids in contact under macroscopic loads undergo irreversible plastic deformation. This is caused by the fact that at high normal forces the stresses in the bulk of the solid below the contact points exceed the yield stress. Under these conditions the contact area expands until the integrated pressure across the contact area is equal to the normal force. Since the pressure is equal to the yield strength of the material σ , the plastic contact area is given by

$$A_p = \frac{N}{\sigma}.$$

Thus, under conditions of plastic deformation the real area of contact is proportional to the normal force. If the shear force during sliding is proportional to that area, one has the condition that the shear force is proportional to the normal force, thus leading to the definition of a coefficient of friction.

Determining the contact area between two rough surfaces is much more difficult than the sphere-on-flat problem and depends upon the morphology of the surfaces [9]. One can show, for instance, that for certain distributions of asperity heights the contact can be completely elastic. However, for realistic morphologies and macroscopic normal forces, the contact region includes areas of both plastic and elastic contact with plastic contact dominating.

Sliding of two solid surfaces in contact is induced by the application of a shear force. As the shear force spring in [figure C2.9.1](#) is stretched at a constant velocity, the shear force on the interface increases until sliding begins. This process is illustrated in [figure C2.9.2\(a\)](#) in which the shear force increases until a critical shear stress is reached. At that point sliding begins and the shear stress at the interface often drops to some constant value. The critical shear force (F_c) needed to induce sliding is often used to define a static coefficient of friction

$$\mu_s = \frac{F_c}{N}$$

while the shear force during sliding defines a dynamic coefficient of friction

$$\mu_d = \frac{F}{N}.$$

A second type of dynamics is commonly observed during sliding: stick–slip motion. This is responsible for the generation of acoustic emission, e.g., the squealing of chalk on a blackboard or brakes in a car. The dynamics of stick–slip motion are illustrated in [figure C2.9.2 b](#)) which shows the shear stress at the interface going through periodic oscillations. It is important to point out that the origins of stick–slip behaviour lie in the dynamics of the entire system and not simply the properties of the interface. In the device of [figure C2.9.1](#) stick–slip motion will always occur at low sliding speeds or for shear springs with low spring constants [10].

The role of solid and liquid lubricants at solid–solid interfaces is to reduce friction forces during sliding. Liquid lubrication is commonly described as occurring in three regimes that depend upon the normal forces and sliding speeds of two surfaces in contact. At low normal force and high sliding speeds liquid films can completely separate two surfaces, preventing solid–solid contact. Under these conditions, usually referred to as *hydrodynamic* lubrication, the frictional forces between two surfaces are determined by the rheological properties of the thin fluid film that separates them. As the normal force is increased and the sliding speed decreased the interface enters the *boundary* regime of lubrication. The surfaces have deformed under the high normal forces and are thought to be separated by monomolecular films of adsorbed molecules. These are typically surfactant-like species that are added to lubricant fluids for just this purpose. Under even higher normal forces the interface enters the *extreme pressure* regime during which direct solid–solid contact occurs. The surfaces are deformed even further and high rates of wear are observed exposing clean solid surfaces. Lubricant fluids usually contain extreme pressure additives which can react with clean exposed surfaces under high pressure and high temperature conditions to form thin solid films with low shear yield strengths. It is these thin solid films that provide lubrication. As implied by the discussion above, lubricant fluids are often very complicated mixtures containing as many as ten or 20 additives, each of which serves a specific purpose in reducing friction and wear of solid surfaces in sliding contact [2].

Figure C2.9.2 Shear force *versus* time during (a) sliding and (b) stick–slip motion. The motion of the surface beneath the sliding block of [figure C2.9.1](#) is at constant velocity.

C2.9.2.3 SEPARATION OF SOLID SURFACES

The separation of two surfaces in contact is resisted by adhesive forces. As the normal force is decreased, the contact regions pass from conditions of compressive to tensile stress. As revealed by JKR theory, surface tension alone is sufficient to ensure that there is a finite contact area between the two at zero normal force. One contribution to adhesion is the work that must be done to increase surface area during separation. If the surfaces have undergone plastic deformation, the contact area will be even greater at zero normal force than predicted by JKR theory. In reality, continued plastic deformation can occur during separation and also contributes to adhesive work.

C2.9.2.4 ENERGY DISSIPATION MECHANISMS

The friction between two surfaces in sliding contact often manifests itself experimentally as a force. At a fundamental level, however, it is more relevant to think of friction in terms of energy dissipation [11]. In a completely conservative world the lateral translation of one object over another does not require work. Nonetheless, in the presence of friction, work is done. If one considers two solids in contact as a thermodynamic system, then sliding is an adiabatic process in which work is done to the system through the shear spring in [figure C2.9.1](#) increasing its internal energy. The increase in internal energy can be considered to take two forms: thermal energy and potential energy. The thermal energy manifests itself as an increase in temperature. The potential energy increase is in the form of structural or even chemical changes to the system resulting from sliding. Examples include changes in the surface area due to

deformation, the creation of bulk defects in solids and changes in the composition of the system due to chemical reactions occurring during sliding or separation.

One of the primary goals of current research in the area of tribology is to understand how it is that the kinetic energy of a sliding object is converted into internal energy. These dissipation mechanisms determine the rate of energy flow from macroscopic motion into the microscopic modes of the system. Numerous mechanisms can be

and have been suggested: sliding causes excitation of atomic motions at the interface; bulk deformation along slip planes which leads to excitation of atomic motions and formation of defects; excitation of long wavelength motions of the solids can lead to acoustic emission; excitation of electronic motion in the solids can lead to friction due to electronic resistance. Understanding the relative importance of such energy dissipation mechanisms is one of the goals of tribological research. This is an extremely difficult challenge, since their relative importance depends upon the properties of the materials and the characteristics of the motions of the system.

C2.9.3 MODERN METHODS OF TRIBOLOGY

Progress in the understanding of tribology fundamentals has been accelerated over the past decade by the development of both experimental and theoretical tools for its study. While there have been many ideas put forward to describe the sources of friction, one of the primary impediments to progress has been a lack of reproducible measurements of friction under well defined conditions. It is possible to find tabulated lists of the coefficients of friction between various materials sometimes reported to three significant figures of accuracy. However, friction forces are sensitive to so many variables that it is not at all clear that these numbers are useful or even reproducible. As a simple example, friction between metals is influenced by adsorbed molecular films of a few monolayers thickness [12]. Without going to extraordinary lengths it is not possible to create perfectly clean metal surfaces and, as a result, the vast majority of friction measurements between metal surfaces are influenced by contaminant films. Even in the scientific literature it is difficult to find consistency among reported absolute values of friction between solids, undoubtedly because of lack of control over various characteristics of the sliding interface or the measurement mechanism itself.

C2.9.3.1 ATOMIC FORCE MICROSCOPY

The atomic force microscope (AFM) provides one approach to the measurement of friction in well defined systems. The AFM allows measurement of friction between a surface and a tip with a radius of the order of 5–10 nm (figure C2.9.3 a)). It is the true realization of a single asperity contact with a flat surface which, in its ultimate form, would measure friction between a single atom and a surface. The AFM allows friction measurements on surfaces that are well defined in terms of both composition and structure. It is limited by the fact that the characteristics of the tip itself are often poorly understood. It is very difficult to determine the radius, structure and composition of the tip; however, these limitations are being resolved. The AFM has already allowed the spatial resolution of friction forces that exhibit atomic periodicity and chemical specificity [3, 10, 13].

Figure C2.9.3 Schematic diagrams of the interfaces realized by (a) the atomic force microscope, (b) the surface forces apparatus and (c) the quartz crystal microbalance for achieving fundamental measurements of friction in well defined systems.

C2.9.3.2 SURFACE FORCES APPARATUS

The surface forces apparatus (SFA) measures forces between atomically flat surfaces of mica. Mica is the only material that can be prepared with surfaces that are atomically flat across square-millimetre areas. The SFA confines liquid films of a few molecular layers' thickness between two mica surfaces and then measures shear and normal forces between them (figure C2.9.3b)). In essence, it measures the rheological properties of confined, ultra-thin fluid films. The SFA is limited to the use of mica or modified mica surfaces but can be used to study the properties of a wide range of fluids. It has provided experimental evidence for the formation of layered structures in fluids confined between surfaces and evidence for shear-induced freezing of confined liquids at temperatures far higher than their bulk freezing temperatures [14, 15].

C2.9.3.3 MOLECULAR DYNAMICS

Molecular dynamics (MD) methods can be used to simulate tribological phenomena at a molecular level. These have been used primarily to simulate behaviour observed in AFM and SFA measurements. Such simulations are limited to short-timescale events, but provide a wealth of information and insight into tribological phenomena at a level of detail that cannot be realized by any experimental method. One of the most interesting contributions of molecular dynamics

is the demonstration that many of the predictions of continuum mechanics, such as those of Hertz, hold true down to length scales of the order of 10 nm, in spite of the obvious atomic coarseness on these length scales.

Investigations of confined fluids have revealed the layered structures observed experimentally by the SFA and shear-induced freezing/melting transitions that can occur during stick–slip motion [16, 17].

C2.9.3.4 QUARTZ CRYSTAL MICROBALANCE

Quartz crystal microbalances (QCMs) have been used to measure friction between thin films of adsorbed gases and gold surfaces. These measure both the resonant frequency and Q -factor of a quartz crystal oscillator coated with metal (figure C2.9.3(c)). The frequency is determined by the total mass of the system and is sensitive to the presence of fractions of a monolayer of adsorbates. The Q of the resonance serves to measure energy dissipation at the interface between the metal film and weakly adsorbed gases such as Ar, Xe and N_2 . One of the most important contributions of this measurement has been the observation of electronic effects in the friction between adsorbed N_2 and a Pb surface. These electronic effects manifested themselves as discontinuities in the energy dissipation as the Pb was heated and cooled through its superconducting phase transition [4].

C2.9.3.5 UHV SURFACE SCIENCE METHODS

Ultra-high vacuum (UHV) surface science methods allow preparation and characterization of perfectly clean, well ordered surfaces of single crystalline materials. By preparing pairs of such surfaces it is possible to form interfaces under highly controlled conditions. Furthermore, thin films of adsorbed species can be produced and characterized using a wide variety of methods. Surface science methods have been coupled with UHV measurements of macroscopic friction forces. Such measurements have demonstrated that adsorbate film thicknesses of a few monolayers are sufficient to lubricate metal surfaces [12, 18].

C2.9.4 OUTLOOK

Tribological problems will continue to plague society and will become more problematic as technology forces the development of mechanical systems that operate in increasingly extreme environments. These problems cannot be solved indefinitely using empiricism and adaptation of existing methods. This is spurring development of experimental methods for study of tribological phenomena in highly defined systems and at the atomic level. As a result, there is a very encouraging outlook for increased understanding of the mechanisms of adhesion, friction, lubrication and wear. Furthermore, this will have long term impact on the understanding of many other areas in which tribology plays an important but often unnoticed role. These include biological problems such as the adhesion of cells or the lubrication of joints and geological problems such as plate tectonics and earthquakes.

C2.10 Surface electrochemistry

Hans-Henning Strehblow and Dirk Lützenkirchen-Hecht

C2.10.1 INTRODUCTION

The structure and the composition of the electrode/electrolyte interface is of great scientific and technological interest. It is generally accepted that the adsorption of anions and cations from the solution is the initial step for many important electrochemical processes such as oxide formation, pitting corrosion, electrocatalysis and metal or semiconductor deposition. Classical electrochemical techniques, which are in principle based on potential and current measurements, are able to reveal a detailed description of the electrochemical interface. For example, the kinetics of oxide or chloride film formation on several different metals have been investigated with a high accuracy, and different growth modes can easily be identified [1, 2 and 3]. In some cases, also a microscopically detailed picture of the electrode surface can be derived. For example, each single crystal metal surface in a well defined electrolyte shows a typical cyclic voltammogram which can be used for a simple control of the single crystal surface preparation (as an example see [4, 5 and 6]); in contrast to the large experimental expenditures which are necessary for a conventional surface structure analysis e.g. with low energy electron diffraction (LEED) or grazing incidence x-ray diffraction. For the underpotential deposition (upd) of copper on stepped platinum surfaces, a clear influence of the copper coverage on the hydrogen adsorption reaction was found; even small amounts of adsorbed Cu on the Pt surface are able to block the hydrogen adsorption reaction [7, 8]. Due to the fact that this reaction preferentially takes place at Pt step sites, one can directly deduce that the blocking of hydrogen

adsorption is a consequence of the selective adsorption of Cu at step sites [8].

In general, however, the electrochemical methods cannot provide structural details of the electrode surface such as the binding geometry or the valency of adsorbates. In addition, they can hardly address the question of surface water, the charge distribution in the electrochemical double layer and the structure of the electrode and their changes with potential. Although in principle possible, it is often very difficult to calculate precise values for the coverage of adsorbates from electrochemical measurements, for example in the presence of coadsorbed species (see, e.g., [9]) or if a partial charge transfer from the adsorbate to the electrode occurs (see, e.g., [10]). Therefore, a large variety of different techniques have been introduced to the investigation of electrochemical interfaces in the past. *In situ* techniques, such as ultraviolet (UV) and visible reflectance, infrared (IR) and Raman spectroscopy, scanning tunnelling and atomic force microscopy (STM and AFM), surface x-ray scattering (SXS) and x-ray absorption spectroscopy (XAS), as well as *ex situ* techniques, among them electron diffraction methods (LEED and RHEED), x-ray and UV photoelectron spectroscopy (XPS and UPS), Auger electron spectroscopy (AES) and ion scattering spectroscopy (ISS), revealed a comprehensive picture—detailed on an atomic level—of the electrode surface in contact with the electrolyte and have furthered our understanding of electrochemical processes in many ways. In this contribution, we will report on recent results obtained with *in situ* and *ex situ* techniques with the focus of the present article on adsorption phenomena and underpotential deposition.

C2.10.2 ADSORPTION

During the past decades, anionic and cationic adsorption on metal electrodes have been intensively investigated. Especially the electrosorption of halides (Cl^- , Br^- , I^-) on noble metals (Au, Ag, Pt) were in the focus of interest. Several different techniques such as electrochemical methods including the electrochemical quartz microbalance technique and capacity measurements [3, 11], radiochemistry and radiotracer experiments [12, 13], SXS [14, 15], electroreflectance spectroscopy [16, 17 and 18], second harmonic generation (SHG) [19, 20], LEED and electron spectroscopies (XPS, UPS and AES) [21, 22, 23, 24 and 25], electrode resistivity measurements [26, 27] and STM [6, 28, 29] have been successfully applied. Well ordered phases which can be commensurate or incommensurate with the underlying noble metal surface were found (e.g. [6, 29, 30, 31 and 32]); in some cases several different adsorbate structures can be observed simultaneously (see, e.g., [29, 33]). As an example, results obtained recently for the adsorption of bromine on Ag (100) with *in situ* SXS are presented in figure C2.10.1 [15]. The absence of translational invariance perpendicular to a single crystal surface causes scattering rods between the three dimensional bulk reflections [34, 35]. SXS comprises the measurement of the intensity distribution of the scattered x-rays in reciprocal space; the comparison of the measured diffraction patterns with atomic models enables the accurate determination of adsorbate structures such as the adsorbate coverage, nearest neighbour bond distances and numbers. Although each element has a characteristic backscattering power, the type of adsorbate can also be identified; this has been successfully used for the investigation of the structures of surface water on silver [36].

Figure C2.10.1. Potential dependence of the scattering intensity of the (1,0) reflection measured *in situ* from Ag (100)/0.05 M NaBr after a background correction (dots). The solid line represents the fit of the experimental data with a two dimensional Ising model with a critical exponent of 1/8. Model structures derived from the experiments are depicted in the insets for potentials below (left) and above (right) the critical potential (from [15]).

-3-

The Ag (100) surface is of special scientific interest, since it reveals an order–disorder phase transition which is predicted to be second order, similar to the two dimensional Ising model in magnetism [37]. In fact, the steep intensity increase observed for potentials positive to ~ -0.76 V against Ag/AgCl for the (1,0) reflection, which is forbidden by symmetry for the clean Ag(100) surface, can be associated with the development of an ordered $(\sqrt{2} \times \sqrt{2})R45^\circ$ -Br lattice, where the bromine is located in the fourfold hollow sites of the underlying fcc (100) surface; this structure is depicted in the lower right inset in figure C2.10.1 [15].

Below the critical potential, the scattered intensity is zero. Obviously, the experimental data are in good agreement with the curve calculated using a critical exponent of 1/8 as predicted by the Ising model. The measurement of further scattering peaks gives additional information about the position of the adsorbed bromine ions for potentials cathodic to the critical potential. The determined positions are consistent with the assumption of a lattice gas adsorption at the fourfold sites, however with a large lateral displacement, especially for low coverages. The observations can be explained by unbalanced Br–Br interactions and filling of the unoccupied area with surface water [15]. While similar results were obtained for Cl^- on Ag(100) [15], no order-disorder transition, but several different commensurate and incommensurate surface structures were found for bromine adsorption on Au (100) [38] although both surfaces are in the same universality class [37].

Besides adsorption on noble metal surfaces, however, also less noble metals like copper have been investigated in halide containing electrolytes during recent years. In figure C2.10.2 the cyclic voltammogram of a (111)-oriented Cu single crystal in 10 mM HCl is given together with two STM micrographs; the latter were recorded at potentials below and above the distinct oxidation and reduction peaks, respectively [39].

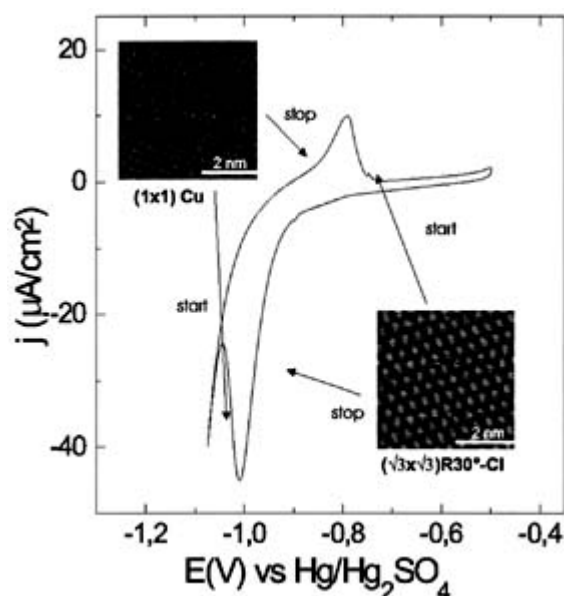

Figure C2.10.2. Cyclic voltammogram of Cu(111)/10 mM HCl and *in situ* measured STM micrographs revealing the bare Cu(111) surface (-1.05 V, left) and the $(\sqrt{3} \times \sqrt{3})R30^\circ\text{-Cl}$ adsorbate superstructure (-0.6 V, right) (from [39]).

-4-

Two clearly different surface structures are visible. Due to the lack of chemical information, however, the relation of these structures to the Cu(111) substrate or the presence of an ordered array of adsorbate molecules is very difficult for the following reasons. Firstly, it is well known from the literature that a surface reconstruction—i.e. a rearrangement or relaxation of the outer atomic layers—can be induced by a change of the electrode potential and charge; the reconstruction and its lifting are in general accompanied by small oxidation and reduction current densities (see, e.g., [40]). For example, the reconstruction observed during negative charging of Au(111) electrodes has been explained by an increasing compressive stress induced by an increasing density of s-p electrons (see [10] and references therein). Secondly, if the presence of an adsorbate is likely or expected, its nature cannot be clarified by STM experiments alone. For example, the first ordered adsorbate structures found for Au(111) in sulfate solutions were interpreted as a hydrogen bonded bisulfate layer [41], while later on, additional FTIR and radiochemical studies proved the presence of adsorbed sulfate rather than bisulfate [42, 43]. In addition, the long range ordered structure observed during the underpotential deposition of copper on gold was imaged by STM long before its composition was known: though anions were believed to be invisible to STM, these structures were ascribed to the metal deposit [44, 45 and 46] while later on it was shown by XAS [47] and SXS [48] that they are related to coadsorbed anions (see below). Furthermore, a surface reconstruction can also be affected by ionic adsorption [14, 20, 28, 40, 49], which can additionally complicate the interpretation of STM micrographs. In the presented study, *ex situ* XPS and ion scattering experiments were performed after the controlled emersion of the electrodes from the solution and their transfer to a UHV system in order to clarify the situation [39]. It has to be mentioned that UHV techniques such as LEED, XPS, UPS and ISS have been successfully applied for the *ex situ* investigation of electrode surfaces since the construction of well suited transfer cells in the 1980s [50, 51, 52, 53 and 54]; a review about this topic was given by Kolb [24]. For Cu(111) in dilute HCl solutions, only very low Cl^- surface concentrations were found for potentials negative to -0.9 V against $\text{Hg}/\text{Hg}_2\text{SO}_4$ in the anodic direction and below -1.0 V in the cathodic scan direction, while positive to the mentioned potentials strong Cl signals were found with XPS and ISS [39]. Therefore, the STM investigations reveal the unreconstructed (1×1) Cu(111) structure and the $(\sqrt{3} \times \sqrt{3})R30^\circ\text{-Cl}$ adsorbate structure, respectively [39].

As a further example for the meaning of *ex situ* investigations of emersed electrodes with surface analytical techniques, results obtained for the double layer on polycrystalline silver in alkaline solutions are presented in figure C2.10.3. This system is of scientific interest, since thin silver oxide overlayers (thickness up to about 5 nm) are formed for sufficiently anodic potentials, which implies that the adsorption of anions, cations and water can be studied on the clean metal as well as on an oxide covered surface [55, 56]. For the latter situation, a changed

adsorption behaviour can be expected due to the semiconducting properties of Ag oxides; this effect is responsible e.g. for a significant enhancement of the catalytic activity for ethene epoxidation [57]. In addition, the oxide layer can be doped with anions or cations as found for copper in alkaline chloride solutions [58]. One great advantage of XPS in this case is the possibility to determine surface concentrations of all double layer constituents; in particular the contributions of surface water, adsorbed hydroxyl ions and possible oxide signals can be fully separated as shown in figure C2.10.3(a) for an Ag electrode emersed from an alkaline perchlorate solution. The surface concentrations of the adsorbed hydroxyl ions, surface water as well as the oxide layer thickness calculated from the corresponding O^{2-} signals are presented in figure C2.10.3(b) and figure C2.10.3(c). It should be mentioned that an oxide formation was found for potentials significantly lower than the Nernst potential of Ag_2O formation [56].

-5-

Figure C2.10.3. *Ex situ* investigation of the electrochemical double layer on Ag after hydrophobic emersion from 1 M NaClO₄ + 0.1 M NaOH. (a) Peak deconvolution of the XPS O1s signals after emersion at +0.2 V: A surface oxide as well as OH⁻ and water/perchlorate contributions can be identified. (b) Potential dependence of the OH⁻ surface concentration. The inset depicts the oxide thickness t determined from the O²⁻ signals. The hatched area visualizes the potential region where an underpotential Ag(I) oxide formation occurs. (c) Amount of adsorbed water calculated from the H₂O/ClO₄⁻ XPS signals; the perchlorate contributions were determined from the Cl 2p signals and subtracted accordingly [56]. The dashed horizontal line represents a monolayer coverage of H₂O.

In addition, the OH⁻ coadsorption significantly influences the adsorption of all other double layer components [55, 56]. For example, in chloride containing media, a significant reduction of the Cl⁻ surface concentration was found, while the concentration of cations and surface water was significantly increased compared to the emersion from acidic solutions [55]. Even the adsorption of the strongly binding iodine on silver is pH dependent [31]. The results can be explained by a specific adsorption of OH⁻ on silver [55, 56, 59]; this interpretation is consistent with the fact that appreciable amounts of adsorbed OH⁻ were also found for copper electrodes in alkaline solutions [60]. Due to the high bond strength between the OH⁻ ion and the Ag metal surface, OH⁻ is able to expel Cl⁻ from the inner Helmholtz plane [55], while it is not able to displace Br⁻ [59]. Br⁻ adsorption itself, however, suppresses Ag oxide formation [59].

The last example presented in this section deals with the pitting corrosion of Fe in ClO₄⁻ solutions. Perchlorate is less known as an aggressive ion but reveals some unique and remarkable characteristics with regard to pitting corrosion. For example, the critical pitting potential (1.46 V against a standard hydrogen electrode (SHE) for Fe/1 M NaClO₄) can be measured with an accuracy of less than 4 mV [61] which is very unexpected if compared to other aggressive ions such as Cl⁻ or Br⁻. In concentrated HClO₄, a slightly lower value of 1.37 V was found [62]. In figure C2.10.4 two Cl 2p XPS spectra obtained from an Fe electrode emersed from 1 M HClO₄ for a potential cathodic and anodic to the pitting potential E_p are compared. Obviously, only ClO₄⁻ species can be detected at a binding energy of ~208 eV (Cl 2p_{3/2} peak) for the passive iron ($E < E_n$), while clear and intense Cl⁻ contributions

were found at about 198 eV binding energy for $E > E_p$ [62]. The anionic fraction of Cl^- , i.e. the ratio of the Cl^- intensity and the sum of the chlorine and the perchlorate intensity ($I_{\text{Cl}^-} / (I_{\text{Cl}^-} + I_{\text{ClO}_4^-})$) is less than 5% for the passive Fe sample while a value of about 30% is

-6-

found for the corroded sample [62]. The experiments clearly suggest that perchlorate is decomposed at the oxide covered Fe surface for sufficiently anodic potentials, resulting in Cl^- ions which cause breakdown of passivity and finally lead to the localized corrosion phenomena. This observation is very special as a reduction of ClO_4^- is expected at more negative potentials for thermodynamic reasons. Presumably its decomposition is caused in the high field of the electrical double layer [62].

Figure C2.10.4. XPS Cl 2p signals of an iron specimen emersed from 1 M HClO_4 : (a) after passivation at 1 V (SHE); (b) after 2 minutes pitting corrosion at 1.5 V (SHE). Contributions of ClO_4^- at ~ 208 eV and Cl^- at ~ 198 eV are visible in different amounts.

C2.10.3 METAL MONOLAYER DEPOSITION

At potentials positive to the bulk metal deposition, a metal monolayer-or in some cases a bilayer-of one metal can be electrodeposited on another metal surface; this phenomenon is referred to as underpotential deposition (upd) in the literature. Many investigations of several different metal adsorbate/substrate systems have been published to date. In general, two different classes of surface structures can be classified: (a) simple superstructures with small packing densities and (b) close-packed (bulklike) or even compressed structures, which are observed for deposition of the heavy metal ions Tl, Hg and Pb on Ag, Au, Cu or Pt (see, e.g., [63, 64, 65, 66, 67, 68, 69 and 70]). In case (a), the metal adsorbate is very often stabilized by coadsorbed anions; typical representatives of this type are Cu/Au (111) (e.g. [44, 45, 71, 72 and 73]) or Cu/Pt(111) (e.g. [46, 74, 75, and 76]). It has to be mentioned that the two dimensional ordering of the Cu adatoms is significantly affected by the presence of coadsorbed anions, for example, for the upd of Cu on Au(111), the onset of underpotential deposition shifts to more positive potentials from SO_4^{2-} to Br^- and Cl^- [72].

-7-

STM measurements suggested for the bilayer formed by Cu and coadsorbed Cl^- either a (5×5) long range order similar to that of the (111) plane of CuCl or a (4×4) -based structure [46, 77, 78], while the bilayer formed with Cu and BR^- has always a (4×4) -based structure [78, 79]. Therefore, x-ray absorption spectroscopy (XAS) is a well suited technique for the investigation of these mixed overlayers since it probes the local atomic structure around an absorbing atom with a high precision [47, 80, 81]. Similar to SXS, different neighbouring atoms can easily be separated due to their different backscattering amplitudes. In addition, by the choice of the absorption edge, the central atom can also be selected. Usually, XAS spectra were recorded using photons polarized parallel to the surface in the past. However, the application of polarization resolved XAS is very promising for the investigation of highly anisotropic samples such as upd layers with coadsorbed anions [47, 82]: if the polarization of the x-rays and an investigated bond are aligned parallel to each other, the corresponding atom is visible in the XAS signal. However, with increasing bond angle, the respective contributions to the XAS decrease continuously until the atom is invisible for an angle of 90° . In [figure C2.10.5](#). Fourier transforms (FTs) of x-ray absorption spectra measured in the vicinity of the Cu K edge are displayed for several different anions using a polarization parallel to the sample surface ($E_{||}$) or parallel to the surface normal (E_{\perp}) [82]. Although the peaks in the FTs are generally shifted towards lower distances, these FTs can be interpreted as an approximation of the corresponding radial distribution functions. Due to the fact that neighbouring Cu atoms as well as the Au substrate, water and Cl, Br or S (from the sulfate) contribute to these FTs, the interpretation of the Ft data is not straightforward in the present situation, although one might expect stronger Cu–Cu peaks for $E_{||}$, while stronger Cu–Au and Cu–anion peaks are likely for E_{\perp} . Therefore, XAS multiple scattering calculations (FEFF 6.01 code [83, 84]) were performed for several different model structures of the bilayer structure: besides the Cu adatoms, up to 200 Au and anion atoms were included in these model clusters [47, 82]. For coadsorbed Cl^- , the best fit was obtained for a structural model which is very similar to the (111) plane of a CuCl crystal, in which the Cu adatoms are placed in registry with the top layer of Cl^- , while they are out of registry with the gold(111) substrate. However, the copper adatoms have to be moved out of the high symmetry positions in order to obtain better agreement between experiment and simulation [84], indicating that the bilayer is characterized by a large static disorder with a broad distribution of Cu–Cl, Cu–Au and Cu–Cu distances rather than by a single set of bond length and bond angles [47, 82].

For coadsorbed sulfate, the well ordered overlayer consists of a honeycomb ($\sqrt{3} \times \sqrt{3}$) $R30^\circ$ lattice of Cu adatoms, which corresponds to a coverage of $2/3$ [80, 81]. The sulfate anions occupy the empty centres of the honeycomb [81] and the fit of the polarization dependent XAS data is best if three oxygen ions from the sulfate are directed towards the the empty centres of the honeycomb [82]. These results are in accordance with those of an SXS study [85] and a quantum statistical model [86] and imply that STM and AFM images obtained from this system are rather images of sulfate than of upd Cu. For Cu upd on Pt(100), an ordered Br layer on top of a pseudomorphic Cu (1×1) layer was found [87]; the Cu monolayer grows with enhanced kinetics compared to the halide free solutions [48, 76, 87, 88]. At this point it should be mentioned briefly that only a few efforts have been made to deposit metal monolayers on semiconducting substrates to date (for references, see, e.g., [89, 90, 91 and 92]), despite the technological importance of the electrochemical metallization and the contamination of semiconductors with metal ions.

Figure C2.10.5. Magnitude of the Fourier transform of the k -weighted absorption fine structure $k\chi(k)$ measured at the Cu K edge for the underpotential deposition of Cu/Au(111) from 0.1 M $\text{KClO}_4 + 10^{-3}$ M $\text{HClO}_4 + 5 \times 10^{-5}$ M Cu $(\text{ClO}_4)_2 + 10^{-3}$ M potassium salt of sulfate, chloride, bromide and a mixture of sulfate and chloride, for polarization of the x-rays parallel to the sample surface (E_{\parallel}) or parallel to the surface normal (E_{\perp}) (from [81]).

C2.10.4 CONCLUSIONS

The presented examples clearly demonstrate that a combination of several different techniques is urgently recommended for a complete characterization of the chemical composition and the atomic structure of electrode surfaces and a reliable interpretation of the related results. Structure sensitive methods should be combined with spectroscopic and electrochemical techniques. Besides *in situ* techniques such as SXS, XAS and STM or AFM, *ex situ* vacuum techniques have proven their significance for the investigation of the electrode/electrolyte interface.

C2.11 Ceramic processing

Kevin G Ewsuk

C2.11.1 INTRODUCTION

Ceramics represent a unique class of materials that are distinguished from common metals and plastics by their: (1) high hardness, stiffness, and good wear properties (i.e. abrasion resistance); (2) ability to withstand high temperatures (i.e. refractoriness); (3) chemical durability; and (4) electrical properties that allow them to be electrical insulators, semiconductors, or ionic conductors. Ceramics can be broken down into two general categories, traditional and advanced ceramics. Traditional ceramics include common household products such as clay pots, tiles, pipe, and bricks; porcelain china, sinks, and electrical insulators; and thermally insulating refractory bricks for ovens and fireplaces. Advanced ceramics, also referred to as ‘high-tech’ ceramics, include products such as spark-plug bodies, piston rings, catalyst supports, and water-pump seals for automobiles; thermally insulating tiles for the space shuttle; sodium vapour lamp tubes in street lights; and the capacitors, resistors, transducers, and varistors in the solid-state electronics we use daily.

The major differences between traditional and advanced ceramics are in the processing tolerances and cost. Traditional ceramics are manufactured with inexpensive raw materials, are relatively tolerant of minor process deviations, and are relatively inexpensive. Advanced ceramics are typically made with more refined raw materials and processing to optimize a given property or combination of properties (e.g. mechanical, electrical, dielectric, optical, thermal, physical, and/or magnetic) for a given application. Advanced ceramics generally have improved performance and reliability over traditional ceramics, but are typically more expensive. Additionally, advanced ceramics are typically more sensitive to the chemical and physical defects present in the starting raw materials, or those that are introduced during manufacturing.

In general, ceramic manufacturing involves creating fine particle size powders, forming powders into a particulate compact, and heat treating (i.e. sintering) that compact to produce a cohesive body with the desired microstructure and properties for a given application. Because powder systems have a relatively large total surface area for their mass, surfaces and interfaces are very important in ceramic processing. From the perspective of a physical chemist, ceramic processing involves understanding and controlling the physical chemistry of surfaces and interfaces [1, 2].

Initially in ceramic powder processing, particle surfaces are created that increase the surface energy of the system. During shape forming, surface/interface energy and interparticle forces are controlled with surface active additives.

Ultimately, the surface energy is used to produce a cohesive body during sintering. As such, surface energy, which is also referred to as surface tension, γ , is obviously very important in ceramic powder processing. Surface tension causes liquids to form spherical drops, and allows solids to preferentially adsorb atoms to lower the free energy of the system. Also, surface tension creates pressure differences and chemical potential differences across curved surfaces that cause matter to move.

The Laplace equation, which defines the pressure difference, ΔP , across a curved surface of radius, r ,

-2-

$$\Delta P = \gamma(1/r_1 + 1/r_2) \quad (C2.11.1)$$

has been characterized as the fundamental equation of capillarity [1]. In ceramic processing, the pressure associated with surface tension and capillary forces contribute to, among other things, particle clustering (i.e. agglomeration) and rearrangement, to the migration of liquids through pores during mixing, shape forming, and drying, and to pore shrinkage during sintering.

The equilibrium vapour pressure, P , over a curved surface is defined by the Kelvin equation

$$\ln P/P_0 = 2\gamma\Omega/rkT \quad (C2.11.2)$$

where P_0 is the equilibrium vapour pressure over a planar surface, Ω is the molecular volume of the condensed phase, k is Boltzmann's constant, and T is the absolute temperature. Because the chemical potential difference, $\Delta\mu$, between a curved and flat surface is related to the vapour pressures over those respective surfaces,

$$\Delta\mu = kT \ln P/P_0 \quad (C2.11.3)$$

chemical potential is also related to surface curvature:

$$\Delta\mu = \mu - \mu_0 = 2\gamma\Omega/r. \quad (C2.11.4)$$

The chemical potential of a curved surface is extremely critical in ceramic processing. It determines reactivity, the solubility of a solid in a liquid, the rate of liquid evaporation from solid surfaces, and material transport during sintering.

This chapter will describe some of the basic unit processes in ceramic manufacturing, and will touch on the pertinence of the physical chemistry of surfaces in selected unit processes. For a more comprehensive review of ceramics and ceramic processing, the reader is referred to other sources [3, 4 and 5].

C2.11.2 POWDER PROCESSING

Ceramic manufacturing involves multiple unit process steps ranging from raw materials beneficiation to finish machining (figure C2.11.1). Ceramics are fabricated using raw materials, typically in powder form, that are generally beneficiated to improve their handling and processability. The desired size and shape ceramic component is produced by consolidating powder in a process that generally involves a forming pressure. Ultimately, this powder compact is heat-treated (i.e. sintered) to form a cohesive body.

-3-

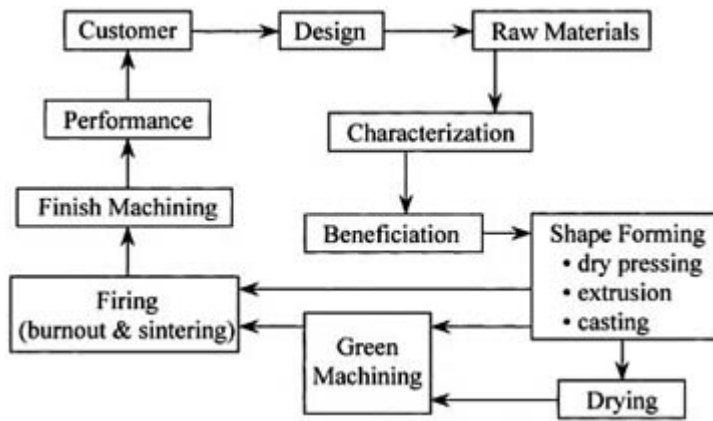

Figure C2.11.1. A flow chart summarizing the ceramic design and manufacturing process.

The fabrication of an alumina spark-plug body is a good example of ceramic manufacturing. The manufacturing process begins with an alumina powder (figure C2.11.2) comprised of individual alumina particles of the desired size distribution. To enhance densification, precursors of CaO , MgO , and SiO_2 are typically mixed with the alumina powder to produce several weight per cent of a glass phase during sintering. This mixture is then transformed into a slurry of ceramic particles dispersed in water, which is subsequently granulated with an organic binder by spray drying. Spray drying produces larger clusters of particles called agglomerates or granules that have improved powder flow, packing, and formability (figure C2.11.3). These granules are then pressed and machined to produce a powder compact of the desired size and shape that is held together by the organic additives. Finally, this powder compact is sintered to produce a dense ceramic spark-plug body (figure C2.11.4). The mechanical and electrical properties of this body are determined by the microstructure of the polycrystalline alumina ceramic produced on sintering (figure C2.11.5).

Figure C2.11.2. A scanning electron micrograph showing individual particles in a polycrystalline alumina powder.

Figure C2.11.3. A scanning electron micrograph of the spherical alumina granules produced by spray drying a ceramic slurry. The granules are comprised of individual alumina particles, sintering additives, and an organic binder.

Figure C2.11.4. A commercial spark plug with its electrically insulating ceramic body comprised of alumina and glass (white portion).

Figure C2.11.5. Scanning electron micrographs showing the microstructure of an alumina ceramic spark-plug body (a) fracture surface and (b) polished and thermally etched cross section.

There is unquestionably a substantial engineering component in manufacturing ceramics. There is also a very critical scientific component that involves understanding and controlling the physical chemistry of surfaces. Not only are a number of different unit process steps required to manufacture a ceramic, but each unit process has its own set of requirements for optimization. Often, the requirements to optimize one step are diametrically opposed to those for another unit process. This necessitates compromise in order to optimize the complete manufacturing process. For example, while a fine-particle-size powder provides a high surface area and driving force for sintering, electrostatic attraction and van der Waals forces promote agglomeration of fine particles and make them difficult to mix, pack, and compact. As a compromise, a practical lower limit of $\sim 0.1 \mu\text{m}$ diameter particles, is typical in advanced ceramic powder processing.

C2.11.2.1 RAW MATERIALS

Ceramic processing generally starts with ceramic powders that range from relatively impure, naturally occurring clays, to ultra-high-purity, controlled morphology powders. Inexpensive, mined raw materials are typically used to manufacture traditional, high-volume production, ceramics [6, 7, 8, 9, 10, 11 and 12]. Chemically synthesized ceramic powders, which are often considerably more expensive, are used to manufacture high-cost, lower-volume,

advanced ceramics [13, 14, 15, 16, 17, 18, 19 and 20].

Naturally occurring ceramic raw materials such as silica (SiO_2 , or quartz), silicates (e.g. talc) and aluminosilicates (e.g. clays) are generally mined from the Earth's surface. In contrast, nanometre size, controlled chemistry ceramic powders are produced from high-purity, specialty chemicals: the precipitation of solids from liquid solutions is one example. Precipitation occurs by a combination of nucleation and growth, both of which occur to lower the free energy of the system. The system's desire to minimize its surface energy per unit volume determines the shape of the precipitate. Most powders used in the manufacture of advanced ceramics fall somewhere between these two extremes. For example, reasonably pure ceramic powders can be formed by reacting constituent oxide powders and/or salts at an elevated temperature (i.e. calcining). Barium titanate, BaTiO_3 , which is used to make capacitors in solid-state electronics, can be produced by mixing BaCO_3 with TiO_2 and calcining. High-surface-area fine powders promote rapid and complete reaction of the constituent powders to produce the desired compound.

C2.11.2.2 BENEFICIATION

Beneficiation is the process or processes whereby the chemical and/or physical properties and characteristics of a raw material are modified to make it more processable. Particle-size reduction (i.e. comminution) using mechanical energy may be the most common process [21, 22, 23, 24, 25, 26, 27 and 28]. Crushing, grinding, and/or milling create new surfaces by breaking down aggregates (i.e. clusters of tightly bound particles) and by fracturing particles. Comminution produces the desired size distribution powder for subsequent processing.

After comminution, soluble impurities either inherent to the raw materials or introduced during processing can be extracted by washing (e.g. with water), followed by filtration [6, 23]. Chemical leaching and magnetic separation are also used to purify raw materials. In a more specialized process, a frothing agent can be used to promote differential adsorption of impurity particles onto gas bubbles to separate out the desired product [23].

C2.11.2.3 GRANULATION

In dry powder processing, after the desired particle size and chemistry are obtained, the powder is generally granulated. Powders comprised of micrometre-size particles are difficult to handle due to interparticle forces. Granulation transforms individual particles into agglomerates with controlled size, shape, and strength, to improve the flow, packing, and compaction behaviour of powders in ceramic processing [29, 30 and 31]. Granules are formed by spraying a liquid or a binder solution directly into a tumbling powder, or by spray drying a slurry in a heated chamber. In the former, granules form under the influence of the capillary forces between the liquid–solid (particle) interfaces. In spray drying, a combination of (liquid) surface tension and interparticle forces produce ~50–300 μm diameter granules. Due to liquid surface tension, the atomization of a slurry produces spherical droplets that subsequently dry to form spherical granules. Capillary forces hold the individual particles together within the granule during the drying, while van der Waals forces and bonds from the organic additives adsorbed onto particle surfaces hold the dry granule together.

C2.11.2.4 FORMING ADDITIVES

Immediately prior to, during, and/or immediately following granulation, forming additives or processing aids are commonly added to a ceramic powder to enhance processing [32, 33, 34, 35, 36 and 37]. Organic additives adsorb onto the surfaces of ceramic particles to modify surface energy and particle–particle interactions. Two common additives used in ceramic processing are binders and lubricants. Organic binders, which are also referred to as coagulants and flocculants, are polymer molecules or colloids that adsorb onto particle surfaces and promote interparticle bridging (i.e. flocculation). The main purpose of a binder is to provide strength to the powder compact after shape forming, which may be necessary for subsequent handling and/or green machining. Binders are used extensively in dry powder pressing operations, and are also added to extrusion bodies and to pastes.

Lubricants are added to lower interfacial frictional forces between individual particles and/or between particles and forming die surfaces to improve compaction and ejection (i.e. extraction of the pressed compact from the forming die). Individual particle surfaces can be lubricated by an adsorbed film that produces a smoother surface and/or decreases interparticle attraction. Forming (die) surfaces can be lubricated by coating with a film of low-viscosity liquid such as water or oil.

B1.20.3 SHAPE FORMING

Ceramic forming typically involves using pressure to compact and mould particles to the desired size and shape. Ceramics can be formed from slurries, pastes, plastic bodies (i.e. such as a stiff mud), and from wet and dry powders.

C2.11.3.1 SLURRIES

In preparation for the shape forming process, ceramic particles can be dispersed in a liquid. The dispersion of solid particles in a liquid is known as a slurry, and is often referred to as a suspension or a dispersion. Forming a slurry involves (1) wetting the solid particle surface with the liquid (i.e. replacing the solid–vapour interfacial area with solid–liquid interfaces), (2) breaking down agglomerates, and (3) controlling particle surface charge to prevent flocculation or reagglomeration [38, 39, 40, 41 and 42]. To optimize dispersion and stability, dispersants (also known as deflocculants or anticoagulants) are often added to slurries [33, 36]. Deflocculants prevent dispersed particles from reagglomerating in a slurry by keeping particle–particle separation distances sufficiently large such that the short range van der Waals attractive forces that will hold particles together are negligible. Particle separation is maintained by the steric effect of the preferential adsorption of large deflocculant molecules on the particle surfaces. Electrostatic stabilization is achieved through the use of the electrical double layer that forms around particles such that neighbouring particles are repelled from one another by like (negative or positive) surface charges. Deflocculation by electrostatic stabilization is common in clay slurries as well as with ceramic particles dispersed in polar liquids (e.g. water).

The use of acids and bases to control interparticle forces in oxide (ceramic)–water suspensions is an example of electrostatic stabilization. Hydroxylated oxide surfaces react with H^+ (acid) or OH^- (base) by surface ionization to become positively charged (low pH) or negatively charged (high pH), respectively. The like-charged particle surface layers repel neighbouring particles and stabilize the solution. A stable dispersion is produced by progressively adding

acid or base to a system to increase the particle surface charge such that the long-range electrostatic repulsive forces dominate over the short-range van der Waals attractive forces. Conversely, an oxide slurry can be induced to flocculate by adjusting the system pH to the point where there is no net charge on a particle's surface. The pH at which this occurs is defined as the point of zero charge (PZC) for the oxide. At the PZC, the electrostatic repulsive forces are eliminated and the van der Waals attractive forces take over, causing flocculation. Surfactants or wetting agents offer another means to improve dispersion in a slurry. By reducing the surface tension of a liquid, a wetting agent decreases the solid–liquid interfacial energy, making it more favourable for the liquid to coat the solid particles. A low-surface-tension surfactant also makes a good antifoam agent.

C2.11.3.2 CASTING

Slurry or slip casting provides a relatively inexpensive way to fabricate uniform-thickness, thin-wall, or large cross section shapes [43, 44, 45, 46, 47 and 48]. For slip casting, a slurry is first poured into a porous mould. Capillary suction then draws the liquid from the slurry to form a higher solids content, close-packed, leather-hard cast on the inner surface of the mould. In a fixed time, a given wall thickness is formed, after which the excess slurry is drained.

Electrophoretic deposition (EPD) is another method of casting slurries. EPD is accomplished through the controlled migration of charged particles under an applied electric field. During EPD, ceramic particles typically deposit on a mandrel to form coatings of limited thickness, or thin tubular shapes such as solid $\beta'''' - \text{Al}_2\text{O}_3$ electrolytes for sodium–sulfur batteries.

C2.11.3.3 DRYING

After casting, the residual liquid in the ceramic part must be removed by drying [49, 50, 51, 52, 53 AND 54]. It is important to achieve relatively uniform drying throughout the body in order to avoid the excessive differential (capillary) stresses and stress gradients that can result in drying cracks (i.e. like those formed in a mud puddle) and warping (i.e. like that seen in lumber on drying). Air drying by convection and conduction is the most common means of drying ceramic ware, whereby drying occurs by liquid evaporation at the drying front. Initially, the drying front starts at the ware surface and then moves into the part. During drying, liquid migrates to the drying front by capillary flow, chemical diffusion, and/or thermal diffusion at a rate determined by the permeability of the ware. The size of the porosity in the ceramic body, the viscosity and surface tension of the liquid, and the moisture gradient from inside the body to the drying front determine the permeability. When liquid migration cannot keep pace with the evaporation process, the drying front moves from the surface into the body, where drying continues by evaporation from the menisci of the liquid within the pores. Large pores and interstices are emptied in preference to smaller pores, and the large capillary stresses produced as the menisci recede into fine pores can result in cracking. The finer the particles, the greater the drying shrinkage, and the greater the capillary stresses during drying.

Stresses during drying can be minimized by controlled humidity drying, by supercritical drying, or by freeze drying. Controlled humidity drying utilizes a high-humidity atmosphere during the critical, initial stage of drying to maintain a liquid film on the (solid) surface of the ware (i.e. a solid–liquid interface). Supercritical drying is accomplished by heating ware under pressure in an autoclave until the liquid becomes a supercritical fluid (i.e. both a liquid and a vapour simultaneously), after which drying can be accomplished by isothermal depressurization to remove the vapour. Supercritical drying is often used to avoid generating catastrophic capillary stresses during the drying of fine-pore materials such as gels. Freeze drying makes use of freezing and sublimation to minimize drying stresses due to capillarity. In freeze drying, the temperature of the ware is initially decreased to below the freezing point of the liquid.

-9-

Then the pressure is reduced to transform the frozen liquid to a vapour and to remove it. Freeze drying is commonly used to make powders that are not agglomerated.

C2.11.3.4 POWDER PRESSING

Powder pressing may be the most common method of forming ceramic components [55, 56, 57, 58 and 59]. Dry pressing, also referred to as mechanical pressing, is an economical, yet versatile technique for fabricating small, relatively simple-shape powder compacts. Automated dry pressing, which is used extensively in the production of pharmaceutical tablets, is capable of producing 5000 ceramic parts per minute. Dry pressing involves compacting a, typically granulated, ceramic powder between two plungers in a die cavity. Friction between the powder and the die walls must be controlled during forming to minimize pressing pressure gradients that can create defects in the form of density gradients and/or cracking in a pressed powder compact. Friction can be controlled using lubricants during forming or through the design of the die (i.e. materials and geometry).

C1.11.4 THERMAL PROCESSING

Generally, the last step in ceramic component manufacturing is thermal processing [60, 61, 62 and 63]. This is the stage where the weakly-bound particulate body produced during shape forming is heat treated to produce a

cohesive body with the desired properties for its end-use application. Thermal consolidation, which is more commonly referred to as ‘firing’, typically involves two steps, burnout and sintering. Generally, both are accomplished in a single firing process with burnout preceding sintering.

C2.11.4.1 BURNOUT

The burnout stage involves eliminating the organic processing aids and any residual organic impurities or water prior to sintering [60, 61, 62 and 63]. Minor concentrations of residual liquid used in forming, and physically adsorbed moisture on particle surfaces can be eliminated on heating to ~200 °C. Most organic binders used in ceramic forming are physically adsorbed onto particle surfaces, and can be burned out by heating to ~500 °C. Clays such as kaolin must be heated to 700 °C to liberate the water of crystallization and produce the desired dehydrated aluminosilicate phase for subsequent processing. The decomposition of constituents such as sintering aids, which may be added in the form of a salt precursor, may require temperatures up to ~900 °C. Temperatures in excess of 1000°C may be required to completely eliminate chemically adsorbed water on fine-particle surfaces.

C2.11.4.2 RAW MATERIALS

Sintering involves the densification and microstructure development that transforms the loosely bound particles in a powder compact into a dense, cohesive body [60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72 and 73]. The end-use properties of a finished ceramic are largely dependent on the degree of densification achieved during sintering, and on the microstructure produced; consequently, sintering is one of the most critical steps in ceramic processing. Sintering, which is often considered to be synonymous with densification, is usually accomplished by heating a powder compact to approximately two-thirds of its melting temperature for a given time. Sintering can also occur by subjecting a powder compact to externally applied pressure, or heat and pressure simultaneously (e.g. hot pressing and hot isostatic

pressing). A ceramic densifies during sintering as the porosity (i.e. void space) between the solid particles is reduced in size with time. Concurrently, the cohesiveness of the body increases as interparticle contact (i.e. grain boundary) area increases during sintering.

(a) Driving force for sintering. Ceramic powder compacts sinter as a result of the thermodynamic driving force to minimize the Gibbs’ free energy, G , of a system [61, 62, 63 and 64, 74]. This includes minimizing the volume, interfacial, and surface energy in the system. In a powder compact, excess free energy is present primarily in the form of surface or interfacial energy (i.e. liquid–vapour and/or solid–vapour interfaces) associated with porosity. Under the influence of elevated temperature and/or pressure during sintering, atoms migrate to thermodynamically more stable positions within a powder compact. Material transport is driven by the chemical potential difference that exists between surfaces of dissimilar curvature within the system. Physically, in a particulate system, atoms or ions move from higher energy convex (i.e. as viewed from the particle centre out) particle surfaces to lower energy concave particle surfaces to decrease the curvature and chemical potential gradients in the system.

Material transport can occur by solid-state, liquid-phase, and/or vapour-phase mechanisms. For polycrystalline ceramics, material transport commonly occurs as ions diffuse through the volume, along grain boundaries (i.e. particle–particle intersections) and on particle surfaces (figure C2.11.6.). Additionally, ions can vaporize from, and subsequently recondense onto, particle surfaces (i.e. evaporation–condensation). A powder compact will densify (i.e. undergo volume contraction) when material transport occurs in a manner that allows particle centres to approach during sintering. Material transport by volume and grain boundary diffusion can result in densification. Material transport that changes the geometry of the system without densification is termed coarsening. Grain growth is perhaps the most prevalent form of coarsening during sintering. Coarsening can occur when material is transported by volume diffusion, surface diffusion, or evaporation–condensation.

Figure C2.11.6. The classic two-particle sintering model illustrating material transport and neck growth at the particle contacts resulting in coarsening (left) and densification (right) during sintering. Surface diffusion (a), evaporation~condensation (b), and volume diffusion (c) contribute to coarsening, while volume diffusion (d), grain boundary diffusion (e), solution~precipitation (f), and dislocation motion (g) contribute to densification.

-11-

(b) *Densification and microstructure development.* Microstructurally, material transport during sintering manifests itself as interparticle pore shrinkage, grain boundary formation, a decrease in the total volume of the system (i.e. densification), and an increase in the average size of the particles that make up the compact (i.e. grain growth) [61, 62, 63 and 64]. Interparticle contacts flatten, the curvature within the system decreases, and the surface area and free energy of the system decrease during sintering

The ideal sintering process can be divided into three basic stages [74]. Initially, material is transported from convex particle surfaces to the pore~grain boundary intersection to form necks between adjacent particles. As this occurs, grain boundaries grow to create a three-dimensional array of approximately cylindrical, interconnected (i.e. continuous) pore channels at three grain junctions throughout the compact. These pore channels shrink in diameter during intermediate-stage sintering. Ultimately, because of Rayleigh instability (i.e. the critical ‘cylinder’ length to diameter ratio), the channels pinch off to form approximately spherical, isolated (i.e. closed) pores at four grain junctions within the ceramic matrix. The radial shrinkage of closed pores and the growth of larger grains at the expense of smaller ones constitute final-stage sintering.

Sintering phenomena are generally similar in real powder compacts; however, factors including surface energy anisotropy and packing heterogeneities in real systems can contribute to heterogeneous (i.e. non-uniform) densification and microstructure development. To circumvent this problem, minor concentrations of select chemicals, referred to as sintering aids or dopants, are commonly added prior to sintering. These chemical impurities preferentially segregate to high-energy crystallographic planes to decrease the crystalline anisotropy in the system to provide improved control over microstructure development during sintering. MgO-doped Al₂O₃ is the classic example in ceramics [71]. Impurity segregation to high-energy grain boundaries will also produce lower-energy interfaces that reduce the overall driving force for material transport during sintering.

(c) *Solid-state sintering.* Ceramics can be densified by solid-state [71, 72, 73, 75], liquid-phase [76], and viscous [77] sintering. Solid-state sintering refers to the process whereby densification occurs by solid-state, diffusion-controlled material transport. Densification occurs as higher-energy, solid~vapour (i.e. pore) interfaces are replaced by lower energy, solid~solid (i.e. grain boundary) interfaces. The change in free energy associated with the elimination of porosity, which drives densification, can be approximated by

$$dG = \gamma_{ss} dA_{ss} - \gamma_{sv} dA_{sv}. \quad (C2.11.5)$$

After the pore surfaces are eliminated and densification is complete, grain growth can further reduce the free energy of the system by reducing the amount of high-energy, solid–solid interfacial area. The change in free energy associated with the elimination of particle–particle interfaces, which drives grain growth, can be approximated by

$$dG = -\gamma_{ss} dA_{ss}. \quad (\text{C2.11.6})$$

Because densification occurs via the shrinkage of thermodynamically unstable pores, densification and microstructure development can be assessed on the basis of the dihedral angle, θ , formed as a result of the surface energy balance between the two solid–vapour and one solid–solid interface at the pore–grain boundary intersection [61, 78, 79 and 80],

$$\theta = 2 \cos^{-1} \left(\frac{\gamma_{ss}}{2\gamma_{sv}} \right) \quad (\text{C2.11.7})$$

-12-

where γ_{ss} and γ_{sv} are the solid–solid and solid–vapour interfacial energies, respectively (figure C2.11.7). Pore shrinkage and densification are favoured by a dihedral angle that is greater than the geometric dihedral angle, Ψ , of the regular polyhedron whose number of sides equals the coordination number of the pore. Theoretically, for the ideal four-sided pore present during final-stage sintering, θ must be greater than 70.4° (i.e. the geometric dihedral angle for a tetrahedron) to achieve 100% theoretical density during sintering. A larger dihedral angle will be required to eliminate larger pores (i.e. surrounded by more grains) formed as a result of packing defects. The larger the dihedral angle, the larger the intergranular pores that can be eliminated during sintering and the greater the surface tension driving force for pore shrinkage. Thermodynamics and/or kinetics limit the shrinkage of pores trapped within grains (i.e. intragranular porosity) and pores above a critical size [78, 79 and 80].

Figure C2.11.7. An illustration of the equilibrium dihedral angle, θ , formed by the balance of interfacial energies at a pore–grain boundary intersection during solid-state sintering.

(d) *Liquid-phase sintering.* To promote faster densification at lower temperatures, relatively small concentrations of chemical additives, referred to as sintering aids, are commonly used to create a liquid phase during sintering. Traditional liquid-phase sintering involves heating and melting crystalline solids to form a eutectic liquid during sintering [63, 76]. The requirements for liquid-phase sintering are that the liquid wets the solid particles, there is sufficient liquid present, and that the solid is soluble in the liquid. The concentration of the liquid and the solubility of the solid in the liquid (i.e. reactivity) increase dramatically with increasing temperature above the eutectic temperature.

Liquid-phase sintering is significantly more complex than solid-state sintering in that there are more phases, interfaces, and material transport mechanisms to consider. In general, densification will occur as long as it is

energetically favourable to replace liquid–vapour (subscript lv), solid–solid (subscript ss), and solid–vapour (subscript sv) interfaces with solid–liquid (subscript sl) interfaces during sintering:

$$dG = \gamma_{sl} dA_{sl} - (\gamma_{lv} dA_{lv} + \gamma_{ss} dA_{ss} + \gamma_{sv} dA_{sv}). \quad (C2.11.8)$$

Densification during liquid-phase sintering occurs in three stages. Initially, liquid forms at particle intersections and redistributes throughout the particulate mass under the influence of the capillary action. Shear stresses due to the

-13-

capillary pressure imbalance on different particles (e.g. different size particles) result in particle rearrangement to improve packing, and contribute to initial-stage densification. Solution–precipitation controls densification during intermediate-stage sintering. Material dissolves from higher energy, convex particle surfaces and migrates to lower energy, pore surfaces where it precipitates. This process is sometimes referred to as grain accommodation, because individual grains will actually change shape to fill void space. Densification by solution–precipitation continues until a rigid, three-dimensional skeletal structure is formed. The transition to final-stage liquid-phase sintering occurs when closed pores are formed at a compact relative density of ~90%. Final-stage liquid-phase sintering, as with solid-state sintering, is characterized by the shrinkage of isolated pores and by grain growth.

In liquid-phase sintering, densification and microstructure development can be assessed on the basis of the liquid contact or wetting angle, ϕ , formed as a result of the interfacial energy balance at the solid–liquid–vapour intersection as defined by the Young equation:

$$\phi = \cos^{-1} \left(\frac{\gamma_{sv} - \gamma_{sl}}{\gamma_{lv}} \right) \quad (C2.11.9)$$

where γ_{sl} and γ_{lv} are the solid–liquid and liquid–vapour interfacial energies, respectively (figure C2.11.8). A low contact angle favours liquid wetting of particle surfaces and densification during liquid-phase sintering. Theoretically, ϕ must be less than 60° to achieve 100% of the theoretical density.

Figure C2.11.8. An illustration of the equilibrium contact (i.e. wetting) angle, ϕ , formed by the balance of interfacial energies for a liquid (sessile) drop on a flat solid surface.

(e) *Pressure sintering.* Pressure sintering employs the simultaneous use of both pressure and temperature during sintering to effect densification. Externally applied pressure on a powder compact increases the compressive stress at particle contacts, increasing the chemical potential gradient and the driving force for material transport relative to conventional sintering [63, 79, 80]. During conventional solid-state sintering, the driving force (DF) for final-stage pore closure at any given time, t , is determined by the surface energy, γ_{sv} of the sintering material and the radius, r , of the pore:

$$DF(\gamma)_t = 2\gamma_{sv}/r_t. \quad (C2.11.10)$$

During pressure sintering, interparticle compressive stress, approximated by the externally applied stress σ_a and normalized by the relative density of the compact ρ , supplements the surface tension driving force for pore shrinkage:

$$DF_t = DF(\gamma)_t + \sigma_a/\rho_t. \quad (C2.11.11)$$

-14-

As such, under an externally applied pressure a powder compact can densify faster and/or at a lower temperature during sintering. Pressure sintering is generally used to densify materials that are difficult or impossible to densify conventionally, and to produce dense fine-grain-size ceramics without the use of sintering aids. Additionally, the increased driving force for material transport and densification makes it possible to eliminate larger pores during pressure sintering, which can contribute to improved performance and reliability.

(f) *Sintering atmosphere.* The sintering atmosphere plays an important role in determining how a material densifies, the ultimate density achieved, and the end-use properties of the finished ceramic [63]. In particular, in complex electronic ceramics like lead zirconate titanate, where the phases present during and after sintering are strongly dependent on oxygen stoichiometry, the sintering atmosphere can determine if the system densifies by solid-state or liquid-phase sintering, and what the resultant electrical properties are [61]. In addition, if gas from the sintering atmosphere becomes trapped in closed pores during final-stage sintering and cannot readily diffuse through the system, it will impede and ultimately limit densification [81]. The pressure, P , of the gas trapped within a closed pore will counteract the surface tension driving force to shrink the pore during sintering:

$$DF_t = DF(\gamma)_t - P_t. \quad (C2.11.12)$$

Trapped gas in closed pores often limits densification when sintering with a liquid or viscous (glass) phase because rapid material transport through the liquid often results in pore closure early in the sintering process.

C2.11.5 SUMMARY

The manufacture of ceramics starts with the constituent raw materials and carries through to thermal consolidation. Intermediate processing steps include raw material beneficiation, shape forming, and pre-sinter thermal processing. Surfaces are created, modified, and eliminated during ceramic powder processing. Optimizing ceramic manufacturing requires understanding and controlling the physical chemistry of surfaces and interfaces during the various unit process steps. The control and utilization of surface energy and surface curvature are critical. Surface tension creates pressure gradients that contribute to the agglomeration and rearrangement of particles in powders, to the migration of liquids during mixing, shape forming, and drying, and to pore shrinkage during sintering. Chemical potential gradients associated with surface curvature determine the solubility of any particles in liquids, control the rate of evaporation from solid surfaces, and drive material transport during sintering. In combination with a strong engineering component, robust ceramic processing requires understanding and controlling the physical chemistry of surfaces.

C2.12 Zeolites

Andreas Kogelbauer and Roel Prins

C2.12.1 INTRODUCTION AND HISTORY

Compared to other crystalline inorganic oxides, zeolites represent a special class of materials. Their crystalline, microporous nature with well-defined pore dimensions in combination with high thermal stability, ion exchange and sorption capacity, as well as the ability to generate acidity has made them unique materials for practical applications. In recent decades, zeolites have gained tremendous importance both from an academic and an economic point of view. On the one hand, it is the versatility of zeolites that makes them such outstanding materials. They are well suited for a broad range of applications such as use as drying agents, use in gas separation processes, use as detergent additives and as catalysts (see [section C2.12.7](#)). On the other hand, the variety of structure types, the broad range of chemical modifications of the zeolite matrix, and the derived physico-chemical properties all carry a distinct fascination for the scientist which is much reflected in the ever growing number of

zeolite-related publications and people involved in zeolite research [1].

The term *zeolite* was coined by the Swedish mineralogist A F Cronstedt who in 1756 observed that certain minerals exhibited intumescence upon heating. Since they seemed to boil he referred to them as ‘boiling stones’ (Greek: *zein* = to boil, *lithos* = stone) [2]. Mineralogical studies that followed in the nineteenth century comprised mainly the determination of morphological, physical, and chemical properties of zeolitic minerals. The first systematic studies regarding the reversible hydration behaviour of zeolites and their chemical composition date back to the mid-1800s [3] and were followed by investigations regarding their adsorption properties around the beginning of this century. To explain the selective adsorption of small molecules in chabazite, McBain coined the term *molecular sieve* [4]. With the availability of x-ray diffraction around the 1920s, structure determination of zeolites became possible. Analcime was the first zeolite structure to be determined in 1930 [5]. At the same time, the hydrated aluminosilicate framework with loosely bonded alkali and earth alkali cations was established as the common criterion to distinguish zeolites chemically from other materials. About 1938, Barrer started the systematic investigation of the properties of natural zeolites: in particular, he applied physico-chemical principles and thereby put the study of zeolites on a firm scientific base. His investigations regarding zeolite synthesis led to the first reproducible and substantiated synthesis of zeolites in a laboratory environment [6]. The industrial use of zeolites followed shortly afterwards. Researchers at Union Carbide Corporation discovered the commercially important zeolite types A, X, and Y which were commercialized in 1954. Most prominent among those was the use of synthetic zeolite X as cracking catalyst by Mobil Oil in 1962. The use of template molecules for zeolite synthesis during the 1960s led to a variety of new synthetic structures with interesting properties. Ongoing synthesis efforts have led to more than 100 different synthetic structures known today. Zeolite nomenclature is based on a three-letter code assigned to the different structure types by the International Zeolite Association (IZA) [7] and compiled in the *Atlas of Zeolite Structure Types* [8]. It is, however, still common practice to use traditional designations as for instance in the case of X and Y zeolites which belong to the FAU structure type. Many of these traditional designations originate from the laboratory in which the materials were synthesized (e.g. ZSM for Zeolite Socony Mobil). For those materials whose framework topology has been confirmed, cross-references exist in the *Atlas of Zeolite Structure Types* enabling the assignment of traditional designations to the IZA structure type.

C2.12.2 COMPOSITION AND STRUCTURE OF ZEOLITES

The traditional definition of a zeolite refers to microporous, crystalline, hydrated aluminosilicates with a three-dimensional framework consisting of corner-linked SiO_4 or AlO_4 tetrahedra, although today the definition is used in a much broader sense, comprising microporous crystalline solids containing a variety of elements as tetrahedral building units. The aluminosilicate-based zeolites are represented by the empirical formula

in which M represents a cation of valence n , and $x \geq 1$ since no Al–O–Al bonds are permitted in a zeolite according to Loewenstein’s rule [9]. The latter states that the ratio of silicon-to-aluminium must be equal to or greater than one due to local charge restrictions. The SiO_4 tetrahedra are charge balanced but each AlO_4 tetrahedron carries a formal charge of -1 due to the $+3$ charge of the aluminium atom (see figure C2.12.1). Cations M are therefore required for balancing the lattice charge. These cations are rather mobile if the zeolite is in a hydrated state and, therefore, they can be easily exchanged. Typically sodium, potassium or organic tetralkyl ammonium is present as a monovalent charge-compensating cation in synthetic zeolites. Besides cations from the alkaline and alkaline earth series, transition metal cations are also frequently found in zeolites from natural sources. One of the outstanding properties of zeolites derives from the exchange of the charge-balancing cations by protons which can be attained by treatment in dilute mineral acids or by the exchange of ammonium cations that are subsequently thermally decomposed to yield ammonia and surface bonded protons (see figure C2.12.2). These protons are acidic which makes zeolites solid Brønsted acids with an acid strength comparable to that of 70% sulphuric acid [10]. The concentration of these acid sites increases with the aluminium concentration in the zeolite lattice and is in the range of 10^{-3} – 10^{-4} mol per gram zeolite.

Figure C2.12.1. Origin of ion exchange capacity in zeolites. Since every oxygen atom contributes one negative charge to the tetrahedron incorporated in the framework, the silicon tetrahedron carries no net charge while the aluminium tetrahedron carries a net charge of -1 which is compensated by cations M.

-3-

Figure C2.12.2. Formation of Brønsted acid sites in zeolites. Aqueous exchange of cation M with an ammonium salt yields the ammonium form of the zeolite. Upon thermal decomposition ammonia is released and the proton remains as charge-balancing species. Direct ion-exchange of M with acidic solutions is feasible for high-silica zeolites.

The connection of the primary building unit, the tetrahedron, through oxygen bridges leads to the secondary building units (SBU), some of which are illustrated in [figure C2.12.3](#) [11]. The way of depicting SBUs and whole zeolite structures, as in [figure C2.12.3](#), is common practice in zeolite science; only the central atoms of the tetrahedra (T-atoms) are drawn and lines represent oxygen bridges between tetrahedra. The pore openings that result from the arrangement of the primary building units are only referred to by the number of T-atoms; that is, a four-membered ring actually consists of four T-atoms and four bridging oxygen atoms in alternating arrangement. The prevalence of certain SBUs is used to classify zeolites but other ways of classifying framework topologies have also been developed [12](#).

Figure C2.12.3. Secondary building units in zeolites. Each corner represents a T-atom (Si, Al) while the connecting lines represent oxygen bridges with the oxygen atom in the middle.

Many zeolite structures can be envisaged as being constructed from polyhedra that are obtained by appropriate arrangement of the SBUs. Some of the more common polyhedra are depicted in [figure C2.12.4](#). The formation of different zeolite structures from the same polyhedron, the sodalite cage, is demonstrated in [figure C2.12.5](#). By connection of two sodalite cages through one shared 4-ring, sodalite is obtained (IZA structure code SOD) whose largest pores are formed by 6-rings. The effective dimension of these pores is about 2.5 Å which is too small for any molecule of interest to penetrate into the zeolite micropores. Sodalite is therefore unimportant for technical applications. By connecting two sodalite cages with a double 4-ring prism zeolite A is obtained (IZA structure code LTA). The larger void that is formed by the specific arrangement of eight sodalite cages in zeolite A is called α -cage. It is accessible through 8-membered rings with a pore opening of 4.1 Å. The α -cage is therefore accessible to small molecules such as water which makes zeolite A an excellent drying agent. The pore diameter of zeolite A can further be varied between 3 and 5 Å by substituting different cations such as K, Na or Ca. These materials are commercially available as molecular sieve 3A, 4A and 5A. An even larger internal void space is obtained when sodalite cages are connected through double 6-ring prisms such as in the cubic faujasite (IZA structure code FAU). Zeolites X or Y are the synthetic equivalents and vary only in their Si/Al ratio. The pore opening of these zeolites is formed by 12-membered rings with diameters of 7.4 Å which are big enough even for larger organic molecules such as substituted aromatics. Reversing the stacking order results in hexagonal faujasite (IZA structure code EMT). This zeolite has distorted 12-membered rings as pore openings.

Figure C2.12.4. Typical polyhedra found in zeolites: (a) sodalite cage found in sodalite, zeolite A or faujasite; (b) cancrinite or ϵ -cage found in cancrinite, erionite, offretite or gmelinite; (c) the 5-ring polyhedron found in ZSM-5 and ZSM-11; (d) the large cavity of the faujasite structure; and (e) the α -cage forming the large cavity in zeolite A.

Figure C2.12.5. Different framework topologies based on the sodalite cage obtained through different connection patterns.

Another technically relevant class of zeolites is the pentasil group [13]. Their dominating structural building units are 5-membered rings and they contain less aluminium than the sodalite cage-based zeolites. The polyhedron shown in figure C2.12.4 can be arranged to form chains, as shown in figure C2.12.6, which build the basis for the ZSM-5 (IZA structure code MFI) and ZSM-11 (IZA structure code MEL) topologies. The pores of these zeolites, which are classified as medium pore zeolites, are formed by 10-membered rings. Small pore zeolites are in analogy those having 8-membered ring pores and large pore zeolites those with 12-membered rings and above. The micropores in ZSM-5 form a two-dimensional channel system in which straight channels are intersected by sinusoidal channels as depicted

in figure C2.12.7. In ZSM-11, perpendicular straight channels intersect each other. Transport of molecules, however, is possible in all three main crystallographic directions by moving from one channel system to the other. There are also zeolite structures with only mono- or two-dimensional channel systems such as L, ZSM-12, ferrierite and mordenite. Some zeolite structures exhibit small pore openings but larger internal voids (supercages) such as erionite or faujasite. A compilation of the structural and chemical characteristics of technically important

zeolite types is given in table C2.12.1.

Table C2.12.1. Characteristics of technically important zeolites.

Zeolite	IZA structure code	Typical unit cell composition	SiO ₂ /Al ₂ O ₃ range by synthesis	Dimensionality of channel system	Pore apertures (nm)
A	LTA	Na ₁₂ [(AlO ₂) ₁₂ (SiO ₂) ₁₂]27 H ₂ O	2.0–6.8	3	0.41
L	LTL	K ₉ [(AlO ₂) ₉ (SiO ₂) ₂₇]22 H ₂ O	6.0–10.0	1	0.71
X	FAU	Na ₈₆ [(AlO ₂) ₈₆ (SiO ₂) ₁₀₆]264 H ₂ O	2.0–3.0	3	0.74
Y	FAU	Na ₅₆ [(AlO ₂) ₅₆ (SiO ₂) ₁₃₆]250 H ₂ O	3.0–9.0	3	0.74
Mordenite	MOR	Na ₈ [(AlO ₂) ₈ (SiO ₂) ₄₀]24 H ₂ O	9.0–32	2 ^a	0.65×0.70 0.26×0.57
ZSM-5	MFI	(Na,TPA) ₃ [(AlO ₂) ₃ (SiO ₂) ₉₃]16 H ₂ O	30–∞	3	0.53×0.56 0.51×0.55;
Beta	BEA	(Na,TEA) ₅ [(AlO ₂) ₅ (SiO ₂) ₅₉]	20–∞	3	0.76×0.64 0.55×0.55

^a Free apertures in second channel system are too small for organic molecules to diffuse readily, making the channel system of mordenite essentially monodimensional.

Figure C2.12.6. Framework topology of ZSM-5. The 5-ring polyhedron is connected into chains which form the ZSM-5 structure with the 10-membered openings of the linear channels.

Figure C2.12.7. Channel system of MFI (top) and MEL (bottom). The linear channels are interconnected by zigzag channels in ZSM-5 while exclusively straight running channels are present in ZSM-11 – larger internal openings are present at the channel intersections – the arrows indicate the pathways for molecular transport through the channel system.

Progress in zeolite synthesis throughout the last decade has led to ultra-large pore zeolites, that is, zeolitic materials with pore sizes larger than those of 12-membered rings. These are very attractive and sought after materials because they can admit very bulky organic molecules typical of fine chemicals into the interior of the zeolite matrix where adsorption and catalysis can be carried out [14]. Very few structures have been synthesized so far which were initially based on aluminophosphates (AlPO_4 -8, 14-membered ring, $7.9 \times 8.7 \text{ \AA}$ pore dimension; VPI-5, 18-membered ring, 12.1 \AA pore diameter, see also below), or gallophosphates (cloverite, 20-membered ring with clover shape). Only recently true silicon-based zeolites with 14-membered rings have been synthesized (UTD-1 [15], CIT-5 [16]) that exhibit high thermal stability, especially when compared with the aluminium or gallium phosphates, and have comparable Brønsted acidity to other zeolites. Their synthesis, however, is based on the use of expensive or commercially unavailable template molecules.

-8-

The search for zeolitic materials with pore sizes larger than 10 \AA recently resulted in a new class of materials termed mesoporous molecular sieves (known by the designation M41S), which are prepared using surfactant micelles as templating agents [17]. The pore diameter of these materials is tunable in a wide range of about 30 to 100 \AA but the matrix consists of amorphous rather than crystalline silica walls. Incorporation of hetero-atoms (Al, Ti, B, Ni, Cr, Fe, Co, Mn) has been described, as was the synthesis of nonsiliceous materials such as oxides of W, Fe, Pb, Mo, and Sb [18]. Although these materials do not represent true zeolites, they are highly interesting materials which are commonly covered in the zeolite literature with great potential for shape-selective catalysis of bulky molecules.

Besides structural variety, chemical diversity has also increased. Pure silicon forms of zeolite ZSM-5 and ZSM-11, designated silicalite-1 [19] and silicalite-2 [20], have been synthesised. A number of other pure silicon analogues of zeolites, called porosils, are known [21]. Various chemical elements other than silicon or aluminium have been incorporated into zeolite lattice structures [22, 23]. Most important among those from an applications point of view are the incorporation of titanium, cobalt, and iron for oxidation catalysts, boron for acid strength variation, and gallium for dehydrogenation/aromatization reactions. In some cases it remains questionable, however, whether incorporation into the zeolite lattice structure has really occurred.

Compositional variety can also be achieved by ion exchange [24]. The cations are then located at the ion-exchange

positions rather than being incorporated in the zeolite lattice as oxygen tetrahedra. Ion exchange methods are used for the preparation of a number of commercially important zeolitic materials. Most important is the exchange for ammonium as discussed above because it represents the least damaging route for the preparation of the proton form of zeolites used in acid catalysis. Cs-exchange leads to zeolites that act as solid base catalysts. Using reducible metal salts for the ion exchange (e.g. $\text{Pt}(\text{NH}_3)_4^{2+}$) with subsequent reduction in hydrogen, metal-loaded zeolites with a high dispersion can be prepared which find applications in refinery processes as bifunctional catalysts (acidic and reducing functionality). Alternatively, the metal can be introduced using uncharged carbonyl complexes such as $\text{Ni}(\text{CO})_4$.

Additional to the aluminosilicate-based zeolites, a number of other crystalline microporous three-dimensional oxides have been synthesized [25]. Most prominent among these are the aluminophosphates (ALPO₄ series) [26, 27] whose framework is composed of strictly alternating $(\text{AlO}_4)^-$ and $(\text{PO}_4)^+$ tetrahedra. Since the pure ALPO₄ framework does not require charge-balancing cations, further compositional modifications are required to make use of these materials as catalysts. This is achieved by the partial or complete isomorphic substitution of framework phosphorus or aluminium by other elements during the synthesis. A variety of aluminophosphate derivatives have been synthesized in this way such as the SAPO (silicoaluminophosphate), MeAPO (metal aluminophosphate, Me=Mg, V, Cr, Mn, Fe, Co, Ni), ZnPO (zincphosphate), BePO (berylliumphosphate), GaPO₄ (galliumphosphate), and MeAPSO (metal silicoaluminophosphate) families. Although most elements substitute either for Al or P, in the case of silicon substitution of P and Al is possible. In SAPO-5 materials (IZA structure code AFI) silicon rich domains are simultaneously present besides SiAlP domains, the former being generated by substitution of Al-P pairs for silicon, the latter, which essentially carries all the Brønsted acidity, arising from substitution of phosphorus by silicon.

C2.12.3 SYNTHESIS OF ZEOLITES

Zeolites are the product of a hydrothermal conversion process [28]. As such they can be found in sedimentary deposits especially in areas that show signs of former volcanic activity. There are about 40 naturally occurring zeolite types. Types such as chabazite, clinoptilolite, mordenite and phillipsite occur with up to 80% phase purity in quite large

sedimentary deposits all over the world which makes mining economical. Due to the lack of purity and consistency in composition, the application of natural zeolites is rather limited and mainly adsorbent and ion exchange applications have been realized. Natural zeolites are, for instance, used as soil amendment, as cement additives or for the purification of municipal and nuclear wastewater [29].

For more demanding applications such as catalysis or the meaningful characterization of zeolitic phases by physico-chemical methods, only synthetic zeolites provide the required phase purity and compositional consistency. For their synthesis, hydrothermal conditions are commonly applied similar to those occurring during the formation of zeolitic phases in nature [23, 30]. The crystallization occurs from a gel formed from an aqueous silicate and aluminate solution at temperatures between 60 and 100 °C and atmospheric pressure, with higher temperatures and elevated pressures being occasionally required (e.g. for the synthesis of mordenite). Syntheses from clear solutions have been described but they are mainly of academic interest due to the low zeolite yields. More recently, new strategies toward zeolite synthesis have been developed which aim mainly at the formation of zeolite films and zeolitic membranes [31]. They are based on solid-state transformation, vapour-phase synthesis, secondary growth and casting of nanoparticles [32]. Synthesis routes that lead to binder-free materials are interesting from an applications point of view [33].

Since zeolites are metastable crystallization products they are subject to Ostwald's rule which states that metastable phases are initially formed and gradually transform into the thermodynamically most stable product. The least stable zeolitic phase (that with the lowest framework density) is therefore formed first and consumed with further synthesis time at the expense of a more stable phase due to a continuous crystallization/redissolution equilibrium.

The synthesis time is therefore of great importance. The primary condition for the crystallization of a zeolitic structure is a certain degree of supersaturation in the synthesis mixture leading to nucleation. If the degree of supersaturation is too high, rapid polycondensation occurs that does not permit the formation of highly organized crystals. The gel that is formed during this initial process, however, is sufficiently soluble to provide the right degree of supersaturation and zeolites can nucleate if other requirements such as the correct Si/Al ratio of the synthesis mixture or the presence of a specific template are fulfilled.

On a laboratory scale, hydrothermal synthesis is usually carried out in Teflon-coated, stainless-steel autoclaves under autogenous pressure. A typical synthesis mixture consists of up to four major constituents, a T-atom source (silicon and aluminium, other elements may also be incorporated as indicated above), a solvent (almost exclusively water), a mineralizer (OH^- , F^-), and a template. The T elements are usually provided as amorphous hydroxides, oxides or aluminosilicates, but alkoxy silicates may be used when high reactivity is required. Various solids such as precipitated gels, fumed silicas or clays may also be used as T-atom sources and the choice depends mainly on the desired reactivity. The mineralizer can be present in the T-atom source itself such as in aqueous silicate solutions. The primary function of the mineralizer is the dissolution of the T-atom source and the formation of the gel but it also assists in the quick equilibration of monomeric and polycondensated silicate species in the solution. Optimum concentration ranges exist for the mineralizing agent in dependence of the desired zeolite structure (e.g. aluminium rich zeolites crystallize preferentially at higher pH). Distinct differences in the resulting zeolites also result from the different pH ranges in which OH^- (strongly alkaline) and F^- (alkaline to slightly acidic) operate, the lower concentration of crystal defects in fluoride synthesis being one. The template generally assists in the formation of the solid by forming additional bonds with the zeolite (ionic, dipole, hydrogen bond or van der Waals interaction) and additionally exerts a structure directing effect. The most commonly encountered templates are either the hydrated alkaline or alkaline earth cations present in solution (e.g. Na^+ in the synthesis of zeolite X), or quaternary organic ammonium cations such as tetrapropyl ammonium (TPA) for ZSM-5 synthesis. Substituting TPA with tetrabutyl or tetraethyl ammonium reveals the structure

-10-

directing effect since ZSM-11 and zeolite beta are obtained instead of ZSM-5. Ongoing research has meanwhile identified a vast array of suitable templates and synthesis routes free of organic templates have been developed for zeolites that were formerly only attainable through template synthesis such as ZSM-5. As well as the factors discussed above, other variables such as the concentration and ratio of the constituents of the synthesis mixture, the preparation of the synthesis mixture, ageing, seeding, agitation during the synthesis, and crystallization time and temperature have a distinct influence upon the synthesis and need to be considered. The IZA maintains a collection of verified recipes [34] that are available through their web page [7].

C2.12.4 POST-SYNTHETIC MODIFICATION OF ZEOLITES

Only in very rare cases can zeolites be used directly in the form in which they were originally synthesized. For many larger-scale industrial applications, for instance, the synthetically obtained zeolite powders must be formed into larger attrition and crush-resistant particles using inorganic binder materials [33]. In most cases a thermal treatment in air (calcination) is at least required to decompose the organic template, to dehydrate the zeolite and to desorb impurities [35]. This holds particularly true if the proton form of a zeolite is desired from the ammonium form for acid catalysis.

The simplest and most commonly applied modification method is ion exchange [24]. By far the vast majority of studies regarding ion exchange of zeolites were carried out in aqueous solutions. Ion exchange processes are described by equilibrium ion-exchange isotherms; these relate the equivalent fraction of the ion in the zeolite to that in solution. Zeolites exhibit different selectivities for ion exchange depending upon factors such as the silicon-to-aluminium ratio of the zeolite, the size, charge and polarizability of the cation, the solvation medium and the size and stability of the solvation sphere. For example, the selectivity series for exchange of monovalent cations into NaY is $\text{Ag} \gg \text{Tl} > \text{Cs} > \text{Rb} > \text{K} > \text{Na} > \text{Li}$, lithium being the smallest cation but with the largest hydration sphere. The presence of ion exchange positions in small cages such as the sodalite cage, which is accessible through a 6-ring window with an effective pore diameter of about 2.5\AA , may hinder or exclude the exchange of certain cations

that are too bulky to penetrate it. As a consequence, the maximum theoretical exchange capacity, which is determined by the number of lattice aluminium atoms, is not attainable and only 63–65% ion exchange is observed (e.g. for Rb and Cs exchange of NaY). Another undesired effect that is frequently observed is the simultaneous exchange of protons, particularly in the case of transition metals which tend to hydrolyse in aqueous solution. Additionally, when di- and trivalent cations are exchanged they tend to hydrolyse and exchange as lower-valency hydroxylated ions; subsequent migration from the ion exchange positions and clustering upon calcination is frequently observed. More recently, solid-state ion exchange using fused salts has been successfully applied, a procedure in which the zeolite and the salt are ground and subsequently heated to elevated temperatures either under aerobic or anaerobic conditions [36]. For exchange processes that are difficult in aqueous solution, vapour phase exchange using salts that are volatile at elevated temperatures such as FeCl_3 and GaCl_3 has yielded a high degree of ion exchange [37].

Dealumination, the removal of aluminium from the zeolite framework, is generally applied for stabilizing zeolites and for the formation of mesopores which help in overcoming diffusional problems in the zeolite micropores. For instance ultrastable Y zeolite (USY), a major component of fluid-catalytic cracking (FCC) catalysts, is obtained by a twofold ammonium exchange with intermediate steam calcination leading to a dealuminated material that retains its structure upon heating up to 900 °C [38]. Due to the susceptibility of the Al–O bond to hydrolysis, one of the issues associated with the use of zeolites is their stability in acidic and basic media or under hydrothermal conditions as commonly experienced in speciality chemical manufacture or hydrocarbon conversion. During such treatment, Si–O–Al bonds are

broken and the aluminium is removed from its tetrahedral lattice position, leaving silanol nests as lattice defects (see figure C2.12.8). The extensive and uncontrolled removal of aluminium from the zeolite framework leads to the destabilization of the remaining framework and ultimately to complete structural collapse. A controlled dealumination treatment is the most successfully applied postsynthetic modification for stabilizing zeolites. The most commonly used dealumination methods are acid leaching, steaming, chemical treatment with silicon fluorides, and direct replacement of framework aluminium by means of gaseous SiCl_4 [24]. Combinations of these techniques have proven useful for the subsequent extraction of extra-framework species for example, steaming followed by acid leaching or extraction with complexing agents such as EDTA or oxalic acid. Inadvertent and thus undesired dealumination may occur during regular calcination of zeolites and during ion exchange in acidic medium, particularly in the case of zeolites with low lattice Si/Al ratio or a high concentration of lattice defects.

Figure C2.12.8. Schematics of the dealumination of zeolites. Water adsorbed on a Brønsted site hydrolyses the Al–O bond and forms the first silanol group. The remaining Al–O bonds are successively hydrolysed leaving a silanol nest and extra-framework aluminium. Aluminium is cationic at low pH.

-12-

Another important modification method is the passivation of the external crystallite surface, which may improve performance in shape selective catalysis (see C2.12.7). Treatment of zeolites with alkoxy silanes, SiCl_4 or silane, and subsequent hydrolysis or poisoning with bulky bases, organophosphorus compounds and arylsilanes have been used for this purpose [39]. In some cases, the improved performance was, however, not related to the masking of unselective active sites on the outer surface but rather to a narrowing of the pore diameters due to silica deposits.

C2.12.5 PHYSICAL AND CHEMICAL PROPERTIES OF ZEOLITES

Zeolites form small crystallites with an average size of about 1–2 μm . Specially modified synthesis methods have yielded crystals as small as 10 nm [40] and ranging up to millimetre size [41]. Crystal agglomeration and intergrowth are commonly observed. The density range of zeolites is from 1.9 to 2.3 g cm^{-3} . Due to the high porosity, specific surface areas are in the range of several 100 $\text{m}^2 \text{g}^{-1}$ with a micropore volume of the dehydrated zeolites in the range from 0.1 to 0.3 $\text{cm}^3 \text{g}^{-1}$. Due to the mobility of the hydrated cations, zeolites exhibit electrical conductivity. The sodium form of zeolites leads to a pH value between 9 and 12 in aqueous solution while the proton form reacts in an acidic manner. The lattice Si/Al ratio is the governing factor determining the overall physico-chemical properties. A schematic representation of the effect of the aluminium concentration on ion-exchange capacity, acid strength of the protons, resistance to acidic media, thermal stability and hydrophilicity is given in figure C2.12.9. Since every aluminium atom in the framework requires a charge balancing cation, the ion-

exchange capacity is proportional to the aluminium concentration. This also holds true if the cations are protons. The acid strength of each of these protons, however, increases with decreasing aluminium concentration and levels off at a constant value at a Si/Al ratio characteristic for each zeolite type. This effect is related to the mutual influence of aluminium atoms in close proximity to one another, referred to as next nearest neighbour (NNN) aluminium that are separated only by one SiO₄ tetrahedron [42]. For instance, in zeolite A with a Si/Al ratio of 1 only NNN aluminium is present. With decreasing aluminium concentration, aluminium atoms become more and more isolated in the silica matrix and only Si can be found in the NNN coordination shell. The overall acidity, the product of acid site concentration and acid strength, therefore goes through a maximum dependent on the Si/Al ratio. Since the Al–O bond is susceptible to hydrolysis in acidic medium, the acid and thermal stability are also higher when less aluminium is present in the zeolite lattice. The higher the aluminium concentration, the higher is the overall lattice charge leading to hydrophilic materials. The adsorption capacity of zeolite A decreases with decreasing polarity and polarizability of adsorbates. On the other hand, zeolites with a low aluminium concentration are increasingly more hydrophobic and selectively adsorb hydrocarbons over water.

-13-

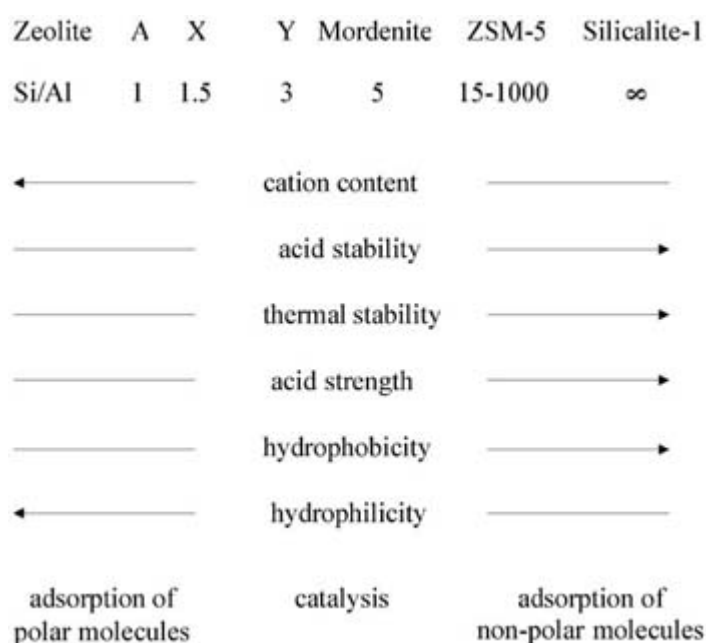

Figure C2.7.9. Effect of the Si/Al ratio of zeolites on their properties.

Factors other than the Si/Al ratio are also important. The alkali-form of zeolites, for instance, is *per se* not susceptible to hydrolysis of the Al–O bond by steam or acid attack. The concurrent ion exchange for protons, however, creates Brønsted acid sites whose AlO₄ tetrahedron can be hydrolysed (e.g. leading to complete dissolution of NaA zeolite in acidic aqueous solutions).

C2.12.6 CHARACTERIZATION OF ZEOLITES

Characterization of zeolites is primarily carried out to assess the quality of materials obtained from synthesis and postsynthetic modifications. Secondly, it facilitates the understanding of the relation between physical and chemical properties of zeolites and their behaviour in certain applications. For this task, especially, *in situ* characterization methods have become increasingly more important, that is, techniques which probe the zeolite under actual process conditions.

The first analytical tool to assess the quality of a zeolite is powder x-ray diffraction. A collection of simulated powder XRD patterns of zeolites and some disordered intergrowths together with crystallographic data is available from the IZA [43]. Phase purity and x-ray crystallinity, which is arbitrarily defined as the ratio of the intensity of

selected reflections in the diffractogram with respect to a standard material are determined in this way. Additional routine characterization techniques comprise elemental analysis for the determination of the chemical composition, N₂ and Ar adsorption for the determination of textural properties and scanning electron microscopy for the determination of the crystal size and morphology.

-14-

Solid-state nuclear magnetic resonance (NMR) spectroscopy applying magic angle spinning (MAS) and infrared (IR) spectroscopy have been traditionally used to characterize the zeolite itself. The widespread availability of modern Fourier transform spectrometers means that these instruments are becoming increasingly important in the study of dynamic processes occurring during adsorption and catalytic reactions [44]. *In situ* measurements of adsorbate interactions with precise control of temperature and partial pressure is considered state-of-the-art regarding IR spectroscopic measurements. The interesting spectral region is between 3800 and 1200 cm⁻¹ covering the stretching and deformation vibrations of the zeolite hydroxyl groups and most organic functional groups. Of particular importance is the differentiation of Lewis and Brønsted acid sites by means of pyridine adsorption. IR spectroscopy has meanwhile matured so far that *in situ* monitoring of the zeolite surface during catalytic reactions is possible. In MAS-NMR it is mainly ²⁷Al and ²⁹Si NMR that provides useful information about the local environment of aluminium and silicon in the zeolite matrix. For aluminium, differentiation between tetrahedral aluminium in the zeolite lattice and octahedral extra-framework aluminium is, in principle, possible. The number of AlO₄ tetrahedra directly linked to an SiO₄ tetrahedron can be determined from ²⁹Si NMR since different chemical shifts are observed for the corresponding Si nuclei. In the absence of large concentrations of silanol defects, which can be ascertained by ¹H cross-polarization measurements, the lattice Si/Al ratio can be determined from such data. Using *in situ* dehydration techniques, ¹H-NMR is also turning into a more commonly applied method providing quantitative information about the nature of zeolite hydroxyl groups. Recent developments have even led to the possibility of studying catalytic reactions on zeolites in continuous flow by means of NMR spectroscopy [45].

Alongside these techniques, microbalance measurements of adsorption capacities and kinetics, microcalorimetric measurements of adsorption processes and temperature-programmed desorption of base molecules have provided useful information about the thermochemistry of adsorption processes and the acidity characteristics of zeolites [46].

C2.12.7 APPLICATIONS OF ZEOLITES

The applications of zeolites can be divided into three major categories: ion exchange, adsorption and catalysis. The largest amount of zeolites is used in ion exchange applications while the largest value is derived from catalytic applications [1, 33].

The most important example for ion exchange applications is the use of zeolites as detergent additives for the removal of mainly Ca and partly Mg from washing waters. As an environmentally acceptable alternative, zeolites have taken over the traditional role of sodium polyphosphate which was a major contributor to the eutrophication of waters. Zeolite A is mainly used for this purpose and commercial syntheses have been optimized for the efficient preparation of large quantities from cheap, natural resources giving products with a homogeneous crystal size below 5 μm. The annual global production for this application has reached several hundred thousand tons [33]. Important natural zeolite-based ion exchange applications comprise the selective removal of ammonium from industrial and municipal wastewater and the removal of ¹³⁷Cs and ⁹⁰Sr from radioactive wastewater [29].

The excellent suitability of zeolites as adsorbents derives from three main characteristics: namely, a high intracrystalline void volume, a high electrostatic field and the molecular sieving effect. The high adsorption capacity of zeolites for water has already been mentioned, which is exploited when zeolites are used as static drying agents for refrigerants, in double glazing, or as additives in the manufacture of solvent-free polyurethanes. Industrial processes based on temperature-swing or pressure-swing adsorbents are applied for the desiccation of natural gas and cracking gas and the

purification of natural gas prior to liquefaction [33]. It is mainly the various ion-exchanged forms of zeolite A that are used for these applications.

Impurities such as hydrocarbons, carbon dioxide and water that are present in ppm levels can be successfully removed using molecular sieves. In particular, the presence of hydrocarbons is hazardous in cryogenic air separation plants since they form explosive mixtures with liquefied oxygen. Furthermore, the low degree of interaction of hydrogen with zeolites is exploited in the production of ultrahigh purity hydrogen where trace amounts of CO, CO₂, N₂, O₂, Ar, CH₄ and water are removed to ppm levels. Zeolites are also an excellent means of gas separation. The higher degree of interaction of N₂ with the cations in Ca-exchanged zeolite A or Li-exchanged zeolite X as compared to O₂ can be used to enrich oxygen up to 95 wt%. Another application, the selective removal of volatile organic compounds (VOC) from humid exhaust vents such as in commercially-used frying pans, derives from the selective adsorption of hydrocarbons on hydrophobic high-silica zeolites [47]. Molecular sieving effects, that is, selective adsorption due to size exclusion effects, are exploited in the separation of *n*-paraffins from iso-paraffins. Along the same lines ethylbenzene, *para*-ethyltoluene or *para*-xylene can be separated from their isomers.

Catalysis with zeolites has traditionally been located in the petroleum refining industry where zeolites have replaced the traditional amorphous silica–alumina as catalysts [48]. The zeolite catalysts (zeolite X at first and USY later) provided higher activity by orders of magnitude and also improved yields of motor gasoline. Their success as FCC catalysts led to the application in many refinery processes soon after. Over recent decades zeolites have moved increasingly into the manufacture of petrochemicals and base chemicals. The most recent trends are in an augmented use of zeolites for the production of fine and speciality chemicals [49, 50]. Additionally zeolites have shown remarkable potential in environmental catalysis, namely for exhaust purification (transition metal-exchanged zeolites) [51] or as replacements for traditionally used liquid catalysts such as sulphuric and hydrofluoric acid [50]. Alkylation, acylation, nitration or Beckmann rearrangement are some examples that are presently being studied.

The reasons for their excellent suitability as catalysts are multifaceted. Depending on their chemical state, zeolites can be used for acid catalysis, base catalysis, bifunctional catalysis (hydrogenation–dehydrogenation reactions coupled with acid catalysis), or redox reactions. As solid acids they provide a high acidity, both in terms of acid strength and acid site concentration, which is imperative for achieving high reaction rates in acid-catalysed reactions; corrosion is less of a concern compared to liquid acids. In this respect, theoretical work based on quantum chemical calculations has significantly contributed to the understanding of zeolite acidity in relation to carbenium ion chemistry [52, 53]. As inorganic solids, zeolites are easily separable by filtration facilitating product separation and permit fixed-bed flow-through operation. Further advantages arise from their excellent thermal stability and regenerability, properties sought for in heterogeneous catalysts. Some structures, like ZSM-5, show an exceptionally high intrinsic resistance to coke formation, which permits long reaction times between regeneration cycles. Of the utmost importance, however, is their ability to discriminate molecules based upon their size and shape, coined shape selectivity, which makes them attractive materials for intermediates and fine-chemicals synthesis. Following the original definition, shape selectivity can become apparent in three different ways (see figure [figure C2.12.10](#) [54]). It refers to the exclusion of molecules (reactant selectivity), the retardation of molecular transport within the zeolite pores depending on the molecular dimensions (product selectivity), or the confinement of the transition state for a certain reaction (transition state selectivity). A comprehensive discussion of the implications of shape selectivity was given recently [55].

Figure C2.12.10. Different manifestations of shape-selectivity in zeolite catalysis. Reactant selectivity (top), product selectivity (middle) and transition state selectivity (bottom).

A typical example for reactant selectivity is the selectoforming process, the selective cracking of *n*-paraffins from reformates and naphthas using small-pore zeolites such as erionite. Only linear paraffins can penetrate into the zeolite micropore system and are converted while the desired branched and cyclic hydrocarbons remain unaffected. The same effect is being exploited in dewaxing processes and in the above mentioned *n*-paraffin/iso-paraffin separation by adsorption. The alkylation of toluene over ZSM-5 is an example of product selectivity. Due to its higher diffusivity, *para*-xylene can leave the pore system much more rapidly than the bulkier *ortho* and *meta* isomers which are continuously reequilibrated in the zeolite pores. Thereby, a higher yield of the *para*-isomer is obtained. During xylene isomerization, transition-state selectivity is manifested through the absence of trimethylbenzenes in the product which would originate from transalkylation reactions. The confined space in the zeolite pore prohibits the formation of the sterically demanding transition state for the bimolecular transalkylation.

Only a very few selected examples have been discussed. The number of processes based on shape-selective catalysis by zeolites is ever increasing, particularly in the field of speciality and fine chemicals and quite a few have been

commercialized. For a more comprehensive picture the reader is advised to consult the further reading suggestions.

C2.13 Plasma chemistry

Martin Schmidt and Kurt Becker

C2.13.1 INTRODUCTION

The plasma state is often referred to as the fourth state of matter [1]. It is characterized by the presence of free positive (and sometimes also negative) ions and negatively charged electrons in a neutral background gas. The charge carrier concentration can vary from 10^5 m^{-3} in a dilute interstellar plasma to 10^{28} m^{-3} in a dense stellar plasma. Most matter in the universe is found in the plasma state. Examples include the sun and other stars, interstellar matter and the terrestrial ionosphere. Naturally occurring plasmas on Earth are rare and include lightning and flames. Plasmas generated for technological applications include, among others, welding arcs, plasma torches, high-pressure lamps and the ignition spark in an internal combustion engine. In the efforts to solve the energy problem on Earth, magnetically confined plasmas in nuclear fusion reactors are one of several choices to achieve the extreme conditions under which nuclear fusion might occur [1]. This chapter focuses primarily on gaseous plasmas at pressures ranging from a fraction of an atmosphere to at most atmospheric pressure. Plasmas are generally created by supplying a sufficient amount of energy to a volume containing a neutral gas, so that free electrons and ions are generated from the atoms and molecules in the gas. The energy may be supplied in the form of electrical energy, heat, ultra violet radiation or particle beams. In technical plasma devices, the input energy is

generally supplied as electrical energy that causes the ignition of a gas discharge. Chemical reactions among the different neutral and ionic atomic and molecular species occur in this gaseous atmosphere (volume processes) and also at the surfaces that surround the plasma (surface or wall processes). The study and the technical utilization of these chemical reactions is referred to as plasma chemistry [2, 3, 4, 5, 6 and 7].

A brief description of a low-density non-equilibrium plasma is given followed by a review of its characteristic features and of the relevant collision processes in the plasma. Principles for the generation of plasmas in technical devices are discussed and examples of important plasma chemical processes and their technical applications are presented.

C2.13.2 THE CHARACTERIZATION OF PLASMAS

A plasma is a globally quasi-neutral system of free electrons and positive and negative ions in a neutral background gas consisting of atoms, molecules and free radicals (some of which may be in electronically and/or rotationally-vibrationally excited states) [8, 9]. Global quasi-neutrality means that the plasma contains overall an equal number of positive and negative charges. The electrons in the plasma have a mean kinetic energy that can range from less than 0.01 eV in an interstellar plasma to more than 10 keV in fusion plasmas. In most laboratory plasmas, the mean kinetic energy of the electrons is higher than the thermal energy corresponding to room temperature (0.025 eV) (figure C2.13.1). In some cases, the positive ions and the neutrals in the plasma also have temperatures significantly above room temperature. An additional criterion for the existence of a plasma (as opposed to a mere mixture of electrons, ions and neutrals) is that the charge carriers and their mutual electromagnetic interaction determine the properties of the system.

-2-

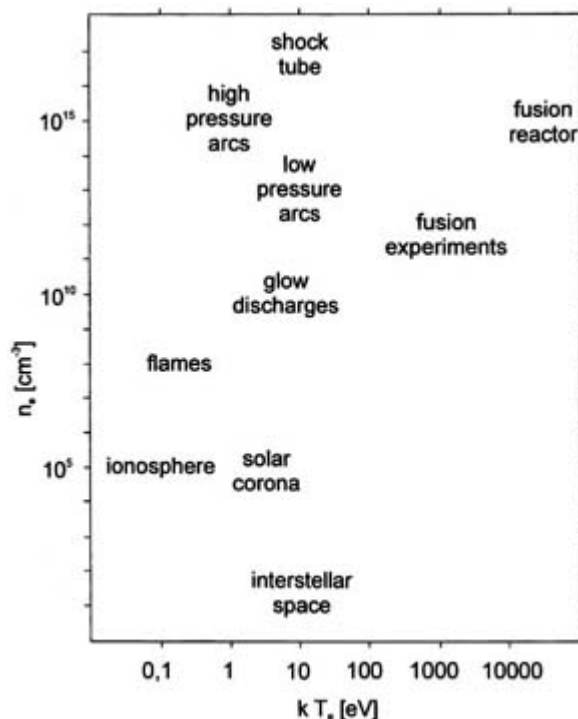

Figure C2.13.1. Electron energies and electron densities for different plasmas.

Any charge imbalance in a plasma (i.e. any local deviation from charge neutrality) results in a motion of the electrons that, in turn, leads to oscillations of the electrons with the electron plasma frequency ω_{pe} (Langmuir frequency)

$$\omega_{pl} = \sqrt{\frac{e_0^2 n_e}{\epsilon_0 m_e}}$$

where e_0 is the elementary charge, n_e is the electron density, ϵ_0 is the permittivity of free space, and m_e denotes the electron mass. Deviations from the global quasi-neutrality of the plasma are possible only locally in a small volume referred to as the Debye sphere whose radius is characterized by r_D , the Debye length:

$$r_D = \sqrt{\frac{\epsilon_0 k T_e}{e_0^2 n_e}}$$

where k is the Boltzmann constant and T_e refers to the temperature of the electrons. A plasma, as opposed to a mixture of electrons and ions, exists if the linear dimensions of the plasma (diameter, length) are large compared to the Debye length. The number of charge carriers in the Debye sphere amounts to 10^4 for an electron temperature of 10 000 K and an electron density of 10^{15} cm^{-3} . Electromagnetic forces in such systems are important if the plasma frequency is higher than the collision frequency of the charge carriers with the neutral particles in the plasma.

-3-

A non-thermal, non-equilibrium plasma is characterized by an electron temperature T_e much larger than the ion temperature T_i and the neutral gas temperature T_g ($T_e \gg T_i, T_g$). Typical non-thermal, non-equilibrium plasmas used in technological applications have electron temperatures of 10^4 to 10^5 K (corresponding to mean electron energies of about 0.5–5 eV). In plasmas that are in or near thermal equilibrium ('thermal' plasmas), the electron, ion and neutral temperatures are roughly equal. The degree of ionization α in a plasma is given by

$$\alpha = \frac{n_e}{n_e + n_0}$$

to denote the fraction of charge carriers (e.g. positive ions) in the plasma. In the above relation n_0 is the neutral gas density. Weakly ionized ('thin') plasmas have a degree of ionization in the range of 10^{-6} , whereas α approaches unity in fully ionized plasmas.

The generation of non-thermal plasmas by externally supplied electrical energy is possible because of the efficient interaction of the light electrons in the plasma with the external electric field. This results in a plasma with a high mean electron energy compared to the low energy of the near-thermal ions and neutrals. Energy transfer from the light electrons to the heavy particles in elastic collisions is negligible due to the difference in their masses. A selective energy transfer from the electrons to the heavy particles occurs *via* the various inelastic electron collision processes. In a molecular plasma, electron collisions will also lead to the formation of new species *via* dissociative processes. On the other hand, the energy gained by the ions in the external electric field is transferred efficiently to the gas molecules *via* elastic collisions. But this energy is generally small, so that the plasma will consist of a 'hot' electron gas and a 'cold' ionic and neutral gas.

The velocity distribution of the electrons in a plasma is generally a complicated function whose exact shape is determined by many factors. It is often assumed for reasons of convenience in calculations that such velocity distributions are Maxwellian and that the electrons are in thermodynamical equilibrium. The Maxwell distribution is given by

$$f(v) dv = 4\pi \left(\frac{m_e}{2\pi k T_e} \right)^{3/2} v^2 e^{-m_e v^2 / 2k T_e} dv$$

and the energy distribution with $kT_e = eU_e$ and $\frac{1}{2}mv^2 = eU$ is given by

$$h(U) dU = U^{1/2} \frac{2}{\sqrt{\pi} U_e^{3/2}} e^{-U/U_e} dU = U^{1/2} f(U) dU.$$

In plasmas, Maxwellian distributions are generally found only in cases where the energy exchange between the electrons is an important process. In most plasmas generated by external electrical fields, the observed velocity distributions deviate significantly from a Maxwellian distribution. The energy distribution function of the electrons is determined by their energy gain in the electric field and by their losses in elastic and inelastic collisions. The distribution function can be calculated using the Boltzmann equation [10, 11]. The shape of realistic electron energy distributions is often characterized by a lack of electrons with higher energies (figure C2.13.2), [12].

-4-

Figure C2.13.2. Electron energy distributions $f(U)$ for a mean electron energy of 4.2 eV, Maxwell distribution (M), Druyvesteyn distribution (D) and a calculated distribution (Ar) for an Ar plasma [12].

The transport of particles in the plasma is diffusive or convective for the neutrals, whereas the charge carriers move under the influence of the external and internal electric and magnetic fields. The drift velocity v of the charged particles is proportional to the electric field E :

$$v = \mu E$$

where μ denotes the mobility. The mobility is related to the diffusion coefficient D by the Einstein relation

$$\mu = e_0 D / kT.$$

The movement of the fast electrons leads to the formation of a space-charge field that impedes the motion of the electrons and increases the velocity of the ions (ambipolar diffusion). The ambipolar diffusion of positive ions and negative electrons is described by the ambipolar diffusion coefficient D_a :

$$D_a = \frac{D_i \mu_e + D_e \mu_i}{\mu_e + \mu_i}.$$

Non-thermal plasmas in contact with insulating walls (substrate) have an important property. The plasma with the hot electrons is positively charged relative to the wall (self-bias). A sheath with a positive space charge and an electric field is formed between the wall and the plasma. The hot electrons travel faster to the wall than the heavy

ions, but the two currents must be equal. This is achieved by the negative potential (10–20 V) of the wall which reflects the slow electrons and accelerates the ions towards the wall. The sheath potential V_S is determined for a planar surface by

-5-

$$V_S = \frac{kT_e}{2e} \ln \left(\frac{m_e}{2.3m_i} \right)$$

where m_i denotes the ion mass.

C2.13.3 COLLISION PROCESSES IN PLASMAS

Collision processes involving the different plasma components play an important role in non-thermal plasmas (table C2.13.1) [13, 14 and 15]. Electron collision processes are of particular importance because of the high temperature or high mean energy of the plasma electrons. Stepwise excitation and ionization, that is the excitation/ionization of an atom or molecule which is already in an excited or, in particular, in a metastable state, can occur with appreciable probability even though the concentration of excited/metastable species in a non-thermal plasma is generally low. The energy spacing between excited states is typically much smaller than the energy gap between the ground state and the first excited state. The number of low-energy electrons is typically much higher than the number of electrons with energies above about 10 eV and the excitation/ionization cross section out of an excited state is much larger than the cross section for excitation/ionization of ground-state species. This may result in rate coefficients (see below) for stepwise excitation/ionization that are quite large. Metastable species cannot decay *via* radiative dipole transitions to lower states. This results in a comparatively long lifetime of microseconds or even milliseconds for these species (compared to nanoseconds for excited states which can decay radiatively *via* dipole transitions). As a consequence, metastables can accumulate in the plasma and can be an efficient source of species for stepwise excitation/ionization processes or for super-elastic collisions in which the scattered electron gains energy. Ionization due to binary collisions involving metastable atoms or molecules is an efficient mechanism for charge carrier production. The generation of free radicals by electron collisions in molecular plasmas is an important precursor for plasma chemical reactions. Electron impact ionization is the fundamental process for sustaining a non-thermal plasma. Electron-impact-induced dissociation leading to the formation of free radicals is the most important reaction channel in plasma chemistry. In conventional chemistry, the formation of radicals is determined by the temperature of the entire system offering a different spectrum of secondary reactions from that resulting from radical production by electron collision in the cold neutral gas environment of a non-thermal plasma.

-6-

Table C2.13.1 Collision processes of electrons and heavy particles in non-thermal plasmas. The asterisk * denotes short-lived excited particles, the superscript m denotes long-lived metastable excited atoms or molecules.

Collisions of electrons

$e^- + A \rightarrow A^+ + 2e^-$	ionization of atoms
$e^- + AB \rightarrow AB^{*/m} + e^-$	excitation of molecules
$AB^* \rightarrow AB + h\nu$	spontaneous de-excitation
$e^- + AB^* \rightarrow AB + h\nu + e^-$	collisional-induced de-excitation
$e^- + AB^* \rightarrow A^{(*)} + B + e^-$	dissociation of molecules
$e^- + AB \rightarrow A + B^+ + 2e^-$	dissociative ionization
$e^- + A^{*/m} \rightarrow A + e^- + E_{kin}$	super-elastic collisions

Table C2.13.1 Continued.

Collisions of heavy particles

$A^+ + B \rightarrow A + B^+$	charge transfer
$A^m + B \rightarrow A + B^+ + e$	Penning ionization
$A^m + A^m \rightarrow A + A^+ + e$	pair collision
$A^* + A \rightarrow A_2^+ + e$	Hornbeck-Molnar ionization
$A^+ + BC \rightarrow AC^+ + B$	ion-molecule reaction

The probability for a particular electron collision process to occur is expressed in terms of the corresponding electron-impact cross section σ which is a function of the energy of the colliding electron. All inelastic electron collision processes have a minimum energy (threshold) below which the process cannot occur for reasons of energy conservation. In plasmas, the electrons are not mono-energetic, but have an energy or velocity distribution, $f(v)$. In those cases, it is often convenient to define a rate coefficient k for each two-body collision process:

$$k = \int \sigma(v) v f(v) dv$$

where $\sigma(v)$ denotes the cross section (here written as a function of velocity rather than energy) and $f(v)$ represents the velocity distribution function of the electrons. Realistic plasmas typically exhibit complicated velocity distribution functions for the plasma electrons (see above). For the simple case of a Maxwellian velocity distribution of the electrons and a collision cross section, whose low-energy behaviour (in a limited range of impact energies E above the threshold energy E_{thr}) can be described by the expression

$$\sigma(E) = \pi r^2 (1 - E_{\text{thr}}/E)$$

the resulting rate coefficient has the form

$$k(T) = \pi r^2 (8kT_e/\pi m_e)^{1/2} \exp(-E_{\text{thr}}/kT_e).$$

This expression corresponds to the Arrhenius equation with an exponential dependence on the threshold energy and the temperature T_e . The factor in front of the exponential function contains the collision cross section and implicitly also the mean velocity of the electrons.

C2.13.4 PLASMA GENERATION

The usual means for the generation of technological plasmas is by supplying electrical energy to the gas in the plasma reactor (figure C2.13.3) and [figure C2.13.4](#). The electrons are accelerated in the external electric field and transfer energy by collisions with the other particles to the plasma. Depending on the time dependence of the sustaining external electric field, discharges are classified as direct current (DC) or alternate current (AC) discharges. The DC low-pressure normal glow discharge between two plane electrodes in a cylindrical glass tube is the prototypical DC discharge and has been studied extensively for about 100 years [16]. Such discharges exhibit characteristic luminous structures. The brightest part of the discharge is the negative glow, which is separated from the cathode by the cathode dark space (Crookes or Hittorf dark space). The large drop of the electrical potential in this cathode dark space is called the cathode fall. The positive column and the negative glow are separated by the

Faraday dark space. The positive column extends to the anode, which may be covered by the anode glow.

Figure C2.13.3. Schematic illustrations of various electric discharges: (a) DC-glow discharge, R denotes a resistor; (b) capacitively coupled RF discharge, MN denotes a matching network; (c), (d) inductively coupled RF discharge, MN denotes matching network; (e) dielectric barrier discharge.

Figure C2.13.4. Schematic illustrations of selected microwave discharges: (a) the discharge tube DT is inserted through a rectangular wave guide RW parallel to the electric field, M denotes the magnetron; (b) plasma reactor with slots, CP denotes the coupling probe, RC refers to the ring circulator CS to the coupling slots and Q denotes the quartz tube [22]; (c) planar microwave plasma source: MW, microwave and MWW, microwave window [21]; (d) electron cyclotron plasma reactor, MC denotes the magnetic coils.

The microscopic processes in the DC glow discharge are fairly well understood [17]. Positive ions are accelerated by the high electric field in the cathode fall towards the cathode surface. The collisions of the energetic ions with the surface sputter neutral atoms and, most importantly, produce secondary electrons which are accelerated in the cathode fall. The energetic electrons transfer most of their energy in the cathode dark space and the negative glow to heavy particles in inelastic collisions by excitation and dissociation and create charge carriers by impact ionization. The discharge regions close to the cathode (cathode fall and negative glow) are necessary for establishing a self-sustaining glow discharge. A positive column is formed only under conditions where there is a long narrow separation between cathode and anode so that significant charge carrier losses to the surrounding discharge wall occur. The electrons, which have lost most of their energy in the negative glow, gain energy in the longitudinal electrical field of the positive

column. A steady-state electron energy distribution is formed that produces ions and electrons in sufficient numbers to balance the charge carrier losses at the wall.

Discharges sustained by time-varying electric fields are referred to as pulsed or AC discharges. High-frequency electromagnetic fields in the radio-frequency (RF) [8] or microwave [18] range are of particular interest for generating discharge plasmas for various plasma chemical applications.

In a capacitively coupled RF discharge, the electrodes are covered by sheath regions similar to the cathode dark space in the DC glow discharge. The bulk plasma occupies the region between the electrodes. The coupling capacitor between the RF generator and the powered electrode and the appropriate choice of different areas for the (smaller) powered electrode and (larger) grounded electrode leads to a negative DC potential between the plasma and the powered electrode, the so-called self-bias potential. The self-bias accelerates the ions near the powered electrode to energies of up to a few hundred electron volts. In contrast to the DC discharge, the electrodes of RF discharges must not be in conductive contact with the plasma. The most commonly used RF frequency is 13.56 MHz; the pressure range is between 0.1-100 Pa. Such discharges are successfully used for the plasma-assisted deposition of thin films, for plasma etching and for the sputtering of insulating materials.

The inductively coupled plasma [19] is excited by an electric field which is generated by an RF current in an inductor. The changing magnetic field of this inductor induces an electric field in which the plasma electrons are accelerated. The helicon discharge [20] is a special type of inductively coupled RF discharge.

Gas discharge plasmas have also been successfully excited by microwaves. Two characteristic features of the microwaves are (i) the fact that the wavelength is of the order of the dimensions of the plasma apparatus (the standard frequency of 2.45 GHz corresponds to a wavelength of 12.2 cm) and (ii) the short period of the exciting microwave field. Only electromagnetic waves with a frequency higher than the electron plasma frequency f_0 can penetrate into the plasma. Waves with lower frequencies than f_0 are reflected. The electron density which corresponds to the frequency f_0 is called the cut-off density; however, electromagnetic fields can penetrate through a skin depth into the plasma. This skin sheath permits a partial absorption of electromagnetic power even above the cut-off density. These facts limit the electron density for a 2.45 GHz excitation to $10^{11} - 10^{12} \text{ cm}^{-3}$.

Plasmas excited by microwaves may be produced in closed structures, in open structures and in resonance with a magnetic field. In closed structures, the plasma vessel is surrounded by metallic walls. Depending on the resonance conditions either multi-mode or single-mode cavities are used. Discharges in open structures include microwave torches, slow-wave structures and surfatrons in which the plasma is generated by the excitation of surface waves. Various types of slotted waveguides are applied successfully for the excitation of specially shaped microwave plasmas for technical applications [21, 22]. Such configurations produce plasmas with electron concentrations up to 10^{12} cm^{-3} in a broad pressure range.

Microwave discharges at pressures below 1 Pa with low collision frequencies can be generated in the presence of a magnetic field B where the electrons rotate with the electron cyclotron frequency. In a magnetic field of 875 G the rotational motion of the electrons is in resonance with the microwaves of 2.45 GHz. In such low-pressure electron cyclotron resonance plasma sources collisions between the atoms, molecules and ions are reduced and the formation of unwanted particles in the plasma volume ('dusty plasma') is largely avoided.

A special type of the RF discharge is the silent or dielectric barrier discharge [23] which can be operated at pressures

from 0.1 – 10 bar. Such a discharge was already used in 1857 by Siemens [24] for the production of ozone from air or oxygen. The silent discharge is generated between two electrodes with a dielectric barrier covering at least one electrode. The gas-filled gap is small, rarely exceeding a few millimetres. Voltages of 5 – 100 kV with frequencies from 50 Hz up to 1 MHz are necessary to sustain these discharges. The breakdown is connected with the formation of a large number of statistically distributed filaments (filament diameter 0.1 mm). The charge carriers from the plasma remain on the dielectric barrier and compensate the external electric field. Therefore, the lifetime of the filaments is very short (1 – 10 ns). The current density in one filament can be as high as $100 - 1000 \text{ A cm}^{-2}$ with electron densities in the range $10^{14} - 10^{15} \text{ cm}^{-3}$, and electron energies in the range 1 – 10 eV. Homogeneous dielectric barrier discharges are also observed. This type is called atmospheric pressure glow discharge [23].

Plasmas are used for the processing of solid surfaces such as in etching, cleaning and oxidizing and for the deposition of various thin films. In these applications chemical processes occur in the plasma volume as well as on the surfaces. The substrate may be positioned within the active plasma region or outside (remote plasma processing). Plasma chemistry is used for the treatment of gases to create and to change gaseous compounds in homogeneous gaseous reactions or heterogeneous surface processes. Several examples are discussed below.

C2.13.5.1 PLASMA SURFACE PROCESSES

(A) PLASMA ETCHING

Plasma etching is an important process in the manufacture of microelectronic devices [25]. It is used for pattern transfer during the fabrication of integrated circuits. Structured masks of photoresist determine where the etching should occur and where not. For structures that are small in comparison with the thickness of the mask, anisotropic etching using a non-thermal plasma is the only feasible technique. The removal (sputtering) of atoms or molecules from a solid surface is possible by momentum transfer from the heavy particles impinging on the surface and *via* collision cascades. Chemical surface reactions initiated by reactive particles from the plasma can lead to the formation of volatile reaction products. The nature of a gaseous reaction product formed in the surface reactions often determines the choice of etching gas used in a particular application (table C2.13.2, [3, 9]). For instance, fluorine-containing molecules are used in the etching of silicon because SiF₂, the main reaction product, is highly volatile. Hydrocarbons are etched using O₂ because of the benign by-products H₂O and CO₂. The etching of Al uses Cl-containing gases because of the high vapour pressure of AlCl₃. Ion impact leads to non-isotropic etching owing to the directed flow of the ions through the plasma sheath to the surface. Ion impact can also influence the formation of inhibitors, e.g. sidewall passivation (figure C2.13.5). Characteristic parameters to describe the etching process are the etch rate, the selectivity, the anisotropy, the uniformity of the process across the wafer surface and the possible material damage. Chemical reactions are isotropic and have a high etch rate and a high selectivity. Material damage is usually negligible. Physical sputtering processes are characterized by high anisotropy, low selectivity and low etch rates. The impact of energetic ions can damage the substrate. In these processes, the plasma serves two purposes. Firstly, it activates the often inert feed gases of the plasma gas mixtures through the formation of reactive radicals and, secondly, the ions are accelerated in the plasma sheath and impact on the substrate nearly perpendicularly to the surface and influence the surface processes.

Table C2.13.2 Gases for etching of various materials [3, 4].

Silicon	CF ₄ /O ₂ , CF ₂ Cl ₂ , CF ₃ Cl, SF ₆ /O ₂ /Cl ₂ , Cl ₂ /H ₂ /Cl ₂ F ₂ /CCl ₄ , C ₂ ClF ₅ /O ₂ , SiF ₄ /O ₂ , NF ₃ , CCl ₄ , C ₂ ClF ₅ /SF ₆ , C ₂ F ₆ /CF ₃ Cl, Br ₂ , CF ₃ Cl/Br ₂
SiO ₂	CF ₄ /H ₂ , C ₂ F ₆ , C ₃ F ₈ , CHF ₃ /O ₂
Si ₃ N ₄	CF ₄ /O ₂ /H ₂ , C ₂ F ₆ , C ₃ F ₈ , CHF ₃ , NF ₃ , CHF ₃ /O ₂
Organics, polymers	O ₂ , CF ₄ /O ₂ , SF ₆ /O ₂
Silicides	CF ₄ /O ₂ , NF ₃ , SF ₆ /Cl ₂ , CF ₄ /Cl ₂
Al	BCl ₃ , BCl ₃ /Cl ₂ , CCl ₄ /Cl ₂ /BCl ₃ , SiCl ₄ /Cl ₂
Cr	Cl ₂ , CCl ₄ /Cl ₂
Mo, Nb, Ta, Ti, W	CF ₄ /O ₂ , SF ₆ /O ₂ , NF ₃ /H ₂
Au	C ₂ Cl ₂ F ₄ , Cl ₂ , CClF ₃
GaAs	BCl ₃ /Ar, Cl ₂ /O ₂ /H ₂ , CCl ₂ F ₂ /O ₂ /Ar/He, CCl ₄ , PCl ₃ , HCl, Br ₂ , COCl ₂

Figure C2.13.5. Schematic illustrations of isotropic etching by a neutral gas and anisotropic plasma etching.

-13-

As an example, we look at the etching of silicon in a CF₄ plasma in more detail. Flat Si wafers are typically etched using quasi-one-dimensional homogeneous capacitively or inductively coupled RF-plasmas. The important process in the bulk plasma is the formation of fluorine atoms in collisions of CF₄ molecules with the plasma electrons

The subsequent reaction of the F atoms with the silicon surface leads to the formation of the volatile product SiF₄:

The flux of F radicals to the wafer is nearly isotropic. Anisotropic etching is due to ions that are incident on the wafer essentially perpendicular to the surface (see above).

The sidewall protection by a thin polymeric film is an additional important process that occurs. The formation of F atoms in the gas phase leads to the formation of CF₃ radicals among other species. These radicals are the precursors for the deposition of a polymeric C_xF_y film on the substrate surface. The growth of this film is governed by a balance between the ion-induced fragmentation and the desorption of CF_x particles. The thickness of this film is typically 1–6 nm [26]. The F atoms do not react directly with the silicon surface. They diffuse through this film and then react. The volatile SiF₄ reaction products diffuse back into the gas phase after penetrating the thin film. The ion bombardment generates additional F atoms in the fragmentation of the C_xF_y film and increases the diffusion velocity of the F atoms and the SiF₄ molecules due to the energy deposited into the film. It is obvious that the ion current density at the sidewall of the trench is much smaller than the density at the bottom of the trench. This sidewall passivation mechanism is crucial for the success of anisotropic etching. The formation of sidewall layers also results in characteristic angular distributions of the ions at the wall. CF₃⁺ ions which have a high etch potential have a narrow angular distribution, whereas CF₂⁺ and CF⁺ ions, which are responsible for fluorocarbon layers, have a broad angular distribution [27]. The addition of oxygen to the CF₄ plasma leads to an increase of the etch rate, but decreases the anisotropy. This is understandable on the basis of the gas phase chemistry. CO₂ is formed, the CF_x concentration is reduced, and the formation of fluorine is enhanced. The decrease of the CF_x concentration impedes the formation of the protective sidewall layers.

A special case of plasma etching is the etching of hydrocarbons in an oxygen discharge. The removal of photoresist in oxygen-containing plasmas is a frequently employed process in the semiconductor industry. The cleaning of metallic work pieces covered with organic surface layers is another widely applied technique in industry. The oxygen plasma generates oxygen atoms that react with the surface contaminant to form volatile CO_2 and H_2O . Plasma cleaning causes low thermal stress of the surface. Ecologically and environmentally harmful solvents are largely avoided.

(B) SURFACE TREATMENT

Plasmas are successfully applied in surface oxidation at low substrate temperatures. In the plasma oxidation process the substrate is held at a floating potential in an oxygen plasma [9]. Plasma anodization is usually carried out with a positively biased substrate. The high oxidation rates of plasma anodization are a result of the high currents of electrons and negative ions to the substrate. High-quality oxide layers with excellent electrical properties, which cannot be achieved by standard thermal oxidation methods [28], are produced by a remote oxygen plasma and keeping the substrate surface at room temperature.

-14-

The surface properties of solids are controlled by the chemical structure of the surface layer: e.g., CH_3 and CF_3 groups at the surface produce a high-degree hydrophoby. Oxygen- and nitrogen-containing groups (e.g., $-\text{OH}$, $-\text{NH}_2$) produce a hydrophilic surface with high adhesion and unique properties for printing, painting, glueing and cell growth. Treatment of polymers in 'mild' (low ion energy) remote plasmas in selected gases provides highly selective surface properties. Biomaterials prepared by plasma chemical methods are sterile [29].

(C) THIN-FILM DEPOSITION

Thin films with a broad spectrum of properties can be deposited in plasma chemical processes [30, 31]. Hard coatings such as diamond films and TiN films, soft plasma polymer films, insulating SiO_x films, highly conducting Si films, anti-reflection coatings, semi-permeable membranes and very effective diffusion barriers can be deposited. Important parameters for the film deposition are (i) the nature of the precursor, (ii) the gas mixture and (iii) the selected plasma parameters. The advantage of plasma-assisted processes is the possibility to work with lower substrate temperatures than in pure chemical vapour deposition techniques, since the important reactions are initiated by energetic electrons. Plasma-deposited films have a high substrate adhesion because the substrate surface at the beginning of the deposition is activated by the plasma-surface interaction.

The deposition of amorphous hydrogenated silicon (a-Si:H) from a silane plasma doped with diborane (B_2H_6) or phosphine (PH_3) to produce p-type or n-type silicon is important in the semiconductor industry. The plasma process produces films with a much lower defect density in comparison with deposition by sputtering or evaporation.

The SiH_3 radical is the dominant growth precursor for the formation of the a-Si:H films in a low-temperature silane plasma [32]. Silane molecules are dissociated by energetic plasma electrons:

followed by the reactions

The SiH_3 radical physisorbs on the a-Si:H surface and recombines there with another SiH_3 radical to form disilane Si_2H_6 , or abstracts H from the surface to form a dangling bond and SiH_4 . The film growth is determined by the chemisorption of the SiH_3 radical on a free dangling bond site by formation of a Si-Si bond. The cross-linking of

neighbouring Si-H bonds leads to the elimination of H₂.

Admixtures of oxygen or oxidizing agents such as N₂O to the silane plasma enable the deposition of SiO₂ films. Other Si-containing compounds such as SiCl₄ or tetraethoxysilane (Si(OCH₂CH₃)₄) are used for plasma-enhanced SiO₂ deposition at lower temperatures [33].

The deposition of organic films by plasma polymerization is an important application of non-thermal plasmas [30]. Plasma polymers are formed at the electrodes and the walls of electrical discharges containing organic vapours. Oily products, soft soluble films as well as hard brittle deposits and powders are formed. The properties of plasma

-15-

polymers are similar to those of conventional polymers, but their structure is different. The often highly cross-linked material is not characterized by a mere repetition of the basic units. The properties of the polymers are essentially determined by the deposition conditions as well as by the plasma and by the gas flow rather than by the particular monomer. All organic compounds can be used as monomers or precursors for plasma polymerization. Functional groups such as double bonds are not necessary. Thus methane can be used as a precursor for plasma polymerization. Plasma polymer films have numerous advantages over conventional films: good adhesion on very different substrates, freedom from pinholes, good conformation to various substrate surfaces, a high degree of cross-linkage, chemical inertness and low levels of leachables [29].

The reaction mechanisms of plasma polymerization processes are not understood in detail. Poll *et al* [34] (figure C2.13.6) proposed a possible generic reaction sequence. Plasma-initiated polymerization can lead to the polymerization of a suitable monomer directly at the surface. The reaction is probably triggered by collisions of energetic ions or electrons, energetic photons or interactions of metastables or free radicals produced in the plasma with the surface. Activation processes in the plasma and the film formation at the surface may also result in the formation of non-reactive products.

Figure C2.13.6. Schematic illustrations of plasma - assisted thin - film deposition.

An important and well studied example is the deposition of plasma-polymerized fluorinated monomer films [35]. Monomers are fluoroalkyls, fluorohydroalkyls, cyclo-fluoroalkyls, as well as unsaturated species. The actual

-16-

monomers are the CF_x radicals from which the polymer deposit is built. Electron impact produces the active species: ions, F atoms and F_2 molecules, and CF_x radicals. CF^+ and CF_2^+ ions are more effective for the polymer deposition than CF_3^+ ions (see above) [27]. The film growth occurs by the addition of CF_x radicals to previously activated sites. The activation of surface sites occurs *via* collisions of charged particles, *via* ion collisions on negatively charged substrates and *via* electron collisions on positively charged substrates. The fluorine-to-carbon ratio influences the fluorine content in the plasma which, in turn, determines whether polymerization or etching is the dominant process (figure C2.13.7, [36]). The admixture of oxygen enhances the fluorine concentration and thus the etching properties by reducing the recombination probability of F atoms by formation of CO, CO_2 , COF_2 . The addition of H_2 reduces the fluorine concentration *via* the formation of HF, thus enhancing the polymerization. The competition between etching and deposition is also influenced by other conditions such as the substrate bias.

Figure C2.13.7. Change between polymerizing and etching conditions in a fluorocarbon plasma as determined by the fluorine-to-carbon ratio of chemically reactive species and the bias voltage applied to the substrate surface [36].

C2.13.5.2 PLASMA VOLUME PROCESSES

The chemical reactions in plasmas find applications in the generation or conversion of gaseous products, primarily *via* homogeneous reactions or in surface treatment and modification processes *via* heterogeneous reactions. A classical example for the production of a gaseous product is the ozone synthesis in dielectric barrier discharges. The electrons are the most important species for ozone formation [23]. A non-thermal plasma generated in a dielectric barrier discharge reactor at atmospheric pressure in pure oxygen causes a significant fraction of the oxygen molecules to be dissociated as the result of electron collisions.

-17-

Nitrogen molecules, a major constituent of air, are excited by electron collisions and the excitation energy is transferred to the O₂ molecules, or the N₂ molecules may be dissociated and O atoms formed *via* the reactions

The ozone formation occurs in a three-body collision of O atoms with O₂ molecules:

The probability for three-body collisions increases with increasing pressure making the use of an atmospheric pressure plasma desirable. The above process is used worldwide for ozone production for water purification.

Pollution control such as the reduction of nitrogen oxides, halocarbons and hydrocarbons from flue gases [37] is another important field of plasma-assisted chemistry using non-thermal plasmas. The efficiency of plasma chemical reactions can be enhanced by introducing catalysts into the plasma [38, 39].

C2.13.5.3 PLASMA CHEMISTRY IN NATURE

Naturally occurring plasma induced processes on Earth are not common. One example is the formation of nitrogen oxides in lightning. Another area of naturally occurring plasmas is the ionosphere [40]. The charge carriers are mainly produced by UV radiation from the Sun. The neutral gas composition in the ionosphere is determined by oxygen and nitrogen with smaller admixtures of water molecules, CO₂ and inert gases such as He and Ar. The most effective ionization process is the photoionization of O₂ and N₂ leading to the formation of atomic and molecular ions.

Mass spectrometric investigations of the ionosphere show an abundance of molecular ions such as NO⁺ and watercluster ions [41]. This is an indication of the result of ion-molecule reactions which change the chemical state of the ions in this plasma:

-18-

In addition, charge transfer processes such as

are efficient

Molecular ions have an important role in charge carrier losses in the ionosphere. The probability of electron-atom-

ion recombination processes is very small, because the frequency of the necessary three-body collisions (momentum conservation) at this low pressure is very low. Dissociative electron-molecular ion recombination processes are more effective. Here the two atoms that are formed ensure momentum conservation:

Negative ions [42] are the result of electron attachment processes such as

Loss processes for O_2^{-} ions are

The ozone formation in the atmosphere is induced by radiation and a result of three-body collisions of the oxygen atoms with O_2 molecules. This process requires a higher gas density and is, therefore, not efficient in the ionosphere.

C2.13.6 PLASMA MODELLING

C2.13.6.1 MICROSCOPIC KINETICS

Modelling plasma chemical systems is a complex task, because these systems are far from thermodynamical equilibrium. A complete model includes the external electric circuit, the various physical volume and surface reactions, the space charges and the internal electric fields, the electron kinetics, the homogeneous chemical reactions in the plasma volume as well as the heterogeneous reactions at the walls or electrodes. These reactions are initiated primarily by the electrons. In most cases, plasma chemical reactors work with a flowing gas so that the flow conditions, laminar or turbulent, must be taken into account. As discussed before, the electron gas is not in thermodynamic equilibrium

-19-

with the heavy particles. The velocity distribution function of the electrons is determined by the energy and momentum exchange in collisions with the heavy particles, in electron-electron collisions and by the energy gain in the electric field. It can be determined from the Boltzmann equation or by particle simulation methods (e.g., Monte Carlo, particle in cell). The concentrations of the various kinds of particles can be calculated by systems of balance equations including the generation and loss mechanisms of particles by electron impact, heavy-particle collisions and the interaction with surfaces. The reaction probabilities of molecules also depend on their electronic, vibrational and rotational states. Aside from the mathematical problems in solving a coupled system of balance equations, the collision cross sections, the natural life times of excited states, sticking and recombination coefficients at the wall etc must be known. Their knowledge, however, is limited in the case of most, if not all, realistic plasmas. Only a few very special cases can be solved, provided further simplifying assumptions are made [43, 44].

C2.13.6.2 MACROSCOPIC KINETICS

The concept of macroscopic kinetics avoids the difficulties of microscopic kinetics [46, 47]. This method allows a very compact description of different non-thermal plasma chemical reactors working with continuous gas flows or closed reactor systems. The state of the plasma chemical reaction is investigated, not in the active plasma zone, but

in the final state after all unstable reaction products have been converted into stable products. The investigation is restricted to the gross reaction; intermediate reaction steps are not considered. Chemical quasi-equilibrium states play an important role in this method. Quasi-equilibrium is reached in plasmas with high electron concentration (high-power plasma) after a comparatively short time, whereas this state is reached after a much longer time in a low-power plasma (low electron concentration). Experimentally determined reaction rates of the net reaction allow the computational treatment of the system. The specific energy $P/V\tau$ (where P is the power, V is the plasma volume and τ is the residence time of the gas in the plasma) is a particularly crucial parameter. Up until now, only simple systems have been successfully modelled.

C2.13.7 CONCLUSIONS

Non-thermal plasmas with their hot electron gas extend the realm of conventional chemistry in many interesting directions. New technical applications have emerged such as surface treatment of materials in plasma etching and thin-film deposition in the microelectronics industry, plasma chemical surface modifications to achieve a variety of desired properties (increased wettability, biocompatibility) and the deposition of various coatings to improve the hardness and the tribological and optical properties of materials. As successfully and widely used as plasma chemistry has been in surface processing applications, the applications of plasma chemical methods for producing gaseous products are limited. The ozone synthesis is a unique process in that category and has been well known for more than a century. The development of new processes for the synthesis or decomposition of gaseous compounds will require a broader as well as a more detailed knowledge of the processes in non-thermal plasma, particularly at higher gas densities, and will necessitate the study of the effect of catalysts on the plasma.

C2.14 Biophysical chemistry

J J Ramsden

C2.14.1 INTRODUCTION

Biophysical chemistry may be defined as the application of physical chemistry to biological systems. The underlying question (e.g.[1]) is whether the laws of physics and chemistry suffice to understand biology. This question, whose origins go back a long way and which encompasses notions of vitalism and so on, has still not been definitively answered. Nowadays it is formulated somewhat differently, typically as ‘What emergent properties are needed to characterize biological systems?’ Half a century ago the prevailing view was encapsulated

in a rather well-known statement of P A M Dirac: ‘The underlying physical laws necessary for the mathematical theory of a large part of physics and the whole of chemistry are thus completely known, and the difficulty is only that the exact application of these laws leads to equations much too complicated to be soluble.’ Biology being even more complicated than chemistry, the difficulty was expected to be correspondingly greater. Nevertheless, as P W Anderson [2] has pointed out, biology is not applied chemistry, any more than chemistry is applied physics. Emergent properties are expected to arise through increases in scale and complexity, and there is no need to endow them with mystical attributes: one hopes to formulate them in mathematical terms just like the descriptions of simpler systems.

Biological systems are bewilderingly complex; the task of biophysical chemistry is to render this complexity intelligible. It is, challengingly, complexity of the most difficult kind, falling between the tractable extremes of elements few enough to be enumerated and analysed exactly, and huge crowds of similar or identical elements whose statistical properties are sufficient for understanding the behaviour of the whole. The molecules of biology are astonishingly diverse and even apparently very minor changes—the single amino acid substitution in haemoglobin causing sickle cell anaemia is a paradigmatic example—has consequences at the levels of the structure of the molecules, the shape of the erythrocytes containing haemoglobin, the health of the individual human being, and the biology of the population.

Most biochemists and molecular biologists make use of chemistry and physics in their investigations. Every time they run a ‘gel’—a kind of chromatography used to separate protein (or DNA) mixtures, and appearing in almost every molecular biological lecture or publication—certain assumptions are made relating the position of a protein on the gel to its molecular mass, and a few ‘standard’ proteins are used to calibrate the positions. Is the procedure reliable? Certainly, many factors other than mass intervene. For example, the protein MARCKS, $M_r \approx 30\,000$, appears near proteins almost three times heavier [3]. Why? Biophysical chemistry can provide the answer, and a correct apprehension of the reasons enhances the domain of application of the technique. Another example is the use of biosensors to investigate protein–protein association. Many investigators first coat the sensing platform with a thick dextran hydrogel, and covalently attach one of the pair of proteins whose association is to be investigated to the matrix. The hydrodynamics of the aqueous phase containing the binding partner are thereby greatly distorted compared with the free solution, and the measured binding rates tend to reflect highly retarded transport rather than affinity [1]. Even greater caution is required when using gene chips, two dimensional arrays of $\sim 10^4$ to 10^5 single stranded DNA fragments whose nucleic acid constitution and coordinates are, in principle, known. If it is desired to ascertain whether certain mutations are present in the gene of a patient, his or her DNA is isolated, separated into single-stranded molecules, labelled with a fluorescent marker, and brought into contact with a gene chip including sequences complementary to those sought. If they are present in the isolate, they will be bound specifically to the chip,

-2-

and after dissociating nonspecifically bound material, the remaining fluorescence is scanned and the corresponding sequences identified from their spatial coordinates. If it is desired to ascertain which genes in a given cell are expressed at a given moment, the messenger RNA (selected copies of the gene corresponding to those amino acid sequences, proteins, which will subsequently be synthesized—see also [section C2.14.8](#) is isolated from the cell, labelled and exposed to the gene chip. The pattern of residual fluorescence should bear some relation to the messenger RNA population in the cell. Potential sources of misinterpretation include: variable degrees of labelling; complementary binding hindered by the presence of the label, or by the immobilization of the DNA strand to the chip surface; insufficient time allowed for specific association, or for dissociation of nonspecifically bound material; binding of the same sequence to multiple sites, or of different sequences to the same site. Clearly the specificity of binding to a given site increases with increasing length of the immobilized DNA sequence, but then so does the likelihood of mistakes in the synthesis of the sequences on the chip. The pattern of fluorescent spots—their positions and intensities—may depend as much on biophysico-chemical details of the binding processes taking place at the molecular level as on the actual nucleic acid sequences themselves. Since the information potentially available from the pattern is huge, it must necessarily be analysed largely automatically, by algorithms which fix certain choices regarding the interpretation of the data, and hence it is important for their alternatives to be thoroughly investigated.

Classical biophysical chemistry has concentrated heavily on the elucidation of the structures of biomolecules and

biomolecular assemblies. Since there are already several excellent texts and reviews dealing with techniques such as x-ray diffraction, electron microscopy, scanning probe microscopies and so on, and since they are all dealt with elsewhere in this encyclopaedia, it is superfluous to discuss them here. A few structural methods whose domain of application has been so exclusively concerned with biological material that they have not warranted individual entries elsewhere will be discussed in [section C2.14.2](#).

Apart from the sheer complexity of the static structures of biomolecules, they are also rather labile. On the one hand this means that especial consideration must be given to the fact (for example in electron microscopy) that samples have to be dried, possibly stained, and then measured in high vacuum, which may introduce artifacts into the observed images [5]. On the other, apart from the vexing question of whether a protein in a crystal has the same structure as one freely diffusing in solution, the static structure resulting from an x-ray diffraction experiment gives few clues to the molecular motions on which operation of an enzyme depends [6].

Biology has been defined as the organization of parts and processes, their reciprocal interactions and directedness. Given instantaneous and perfect mixing, could not metabolic duties be accomplished via specific intermolecular interactions, at least on the level of an individual cell? The description and understanding of specificity is another great area of classical biophysical chemistry. Compared with the rather high level of development of structural elucidation, the field of biomolecular interactions has progressed less; they are often described using oversimplified models, e.g. exponential decay for the dissociation of two molecules, or of a molecule from a surface, despite the fact that empirically this law has been found to be an exception to the more general occurrence of time-dependent dissociation rate 'constants' ([section C2.14.4.3](#)). Specificity is dealt with in [section C2.14.6](#); one should keep in mind that mixing is neither instantaneous nor perfect, and the relative importance of directed transport over random diffusion within a cell is a major current preoccupation in biophysical chemistry.

Biological reactions *in vivo* rarely operate under conditions even remotely approaching those of reversibility. For a living organism, the *rate* of a process is usually more important than the attainment of equilibrium, and large driving

-3-

forces are employed to achieve a rapid rate, leading to profligate waste of free energy from the classical chemical thermodynamical viewpoint. The law of mass action has universal validity, but emphasis on the 'biochemical standard state' (in which all components are fully hydrated and dissolved at a concentration of 1 M in water, which itself has a concentration of 55.6 M), far removed from reality, is to the detriment of discussion of the actual concentrations of the molecules participating in biochemical pathways. Moreover, since biology is a realm of almost universally broken ergodicity, the premises of statistical mechanics approaches need to be carefully scrutinized; more emphasis on pathways would be appropriate.

The degree of coarse graining appropriate to solve a biological problem is an ever-present preoccupation [7]. When attempting to predict the three-dimensional structure of a protein, is it enough to consider the amino acids as structureless blobs, or do their individual atoms need to be included? The structure of large, elongated extracellular matrix proteins such as fibronectin can be successfully modelled even more coarsely as a string of beads [8], each bead comprising tens of amino acids. Coarse graining seems to be carried too far, however, when human brain activity is investigated *in vivo* using nuclear magnetic resonance (NMR) imaging. 'High spatial resolution' in the context of this technique means averaging over a volume of $\sim 10\text{mm}^3$, containing hundreds of thousands of neurons, each of which may be connected to thousands of other neurons elsewhere. It might be recalled that currently we are not even capable of giving a comprehensive description of the brain of the leech, with only a couple of dozen ganglions, each containing about 400 nerve cells. Moreover, although the NMR imaging technique is considered to be noninvasive, one may legitimately enquire whether a human being will, indeed can, behave naturally and normally when constrained to lie still in a narrow tube with his head tightly fixed.

A further problem confronting the biophysical chemist is that biological systems are usually highly compartmentalized, and the actual numbers of each active species taking part in a reaction within a given compartment may be very small. Hence there can be no question of passing to the thermodynamic limit. Fluctuations are expected to play a dominant, sometimes enabling, sometimes destructive role in biology, and the

way that living beings have evolved sufficient autonomy to deal with fluctuations is itself a fascinating area.

Compartmentalization not only leads to a greatly amplified role for the incoherent fluctuations of groups of molecules, but inevitably implies the possibility of interaction between those molecules and the compartment walls (often a bilayer lipid membrane), i.e. interfacial phenomena, added to which is the fact that the properties of the solvent (usually water) may be modified in the vicinity of the wall. In experiments now considered as classic, Kempner and Miller [9, 10] centrifuged *intact* cells and showed that virtually no enzymes were present in the soluble phase; the term cytosol refers to the solution, containing a wide variety of enzymes and other macromolecules, obtained from cell fractionation *after disruption*. Despite these and other observations, experiments to elucidate *in vitro* reactions between biomolecules under homogeneous conditions greatly preponderate over those in which the equivalent reaction is studied heterogeneously. Perhaps the recent introduction of some excellent new techniques for investigating biomolecular interactions at the solid–liquid interface [11] will start to shift this balance, complementing and ultimately replacing molecular biological techniques such as the two-hybrid system.

Once pairwise biomolecular interactions have been correctly characterized, the next step is to understand how they mesh together in a network. During the past couple of decades, molecular biology has been rather successful at identifying individual genes and their protein products, and obtaining valuable mechanistic insights through site-directed mutagenesis. A cell is not a mosaic of individual reactions, however, any more than a protein is a (linear) mosaic of amino acids. To establish that process X is catalysed by Xase, which may then be cloned, sequenced and

-4-

expressed, is only the beginning of understanding how the reactions are linked together in an elaborate network of control in which some gene products regulate the activity of others, and which is not merely hierarchical, but heterarchical. Moreover, it is essential to recognize that the intramolecular bonds which determine the structures of biological molecules are usually comparable in strength to the intermolecular interactions as well as interactions with the solvent (water). Hence the structures will in many cases be modified upon association, changing the affinity of the complex for a third and subsequent molecules, and hence a comprehensive catalogue of all the pairwise interactions in a cell will be a very incomplete representation of the network.

In order to meet the challenge of understanding how hundreds or even thousands of partly interrelated reactions fit together to form a coherent functioning whole, *systems theory* was developed in the 1960s. It was supposed to lead to general principles governing complex organizations such as the living cell. A considerable *œuvre* was achieved (e.g. [12]), but it must be conceded that it has had rather little influence on biological research. Perhaps it was too ambitious for the level of phenomenological knowledge extant when it was first developed, and since therefore no immediate application of its predictive power was possible, it fell into neglect. Moreover the theory quickly becomes intractable when nonlinear systems involving more than two elements are considered. After three decades of immensely diligent data-gathering, the situation may now be more propitious for the application of systems theory to biology, but to begin with a more modest programme may be in order, such as an investigation of the scaling laws of biological reactions, which are far more strongly nonlinear than those encountered in most nonbiological systems.

Acknowledgement of the existence of biological *systems* refocuses attention on the old question of whether new physico-chemical concepts are required in order to understand their working. Is regulation and control theory, as developed mainly in departments of engineering and electronics, adequate to describe biological systems, or is their complexity—multilevelled and on multiple time scales—sufficiently great to make them qualitatively different in some way? This question is still open. The old dream was to predict protein structure (and possibly even some dynamical properties) from gene sequence, and then function from structure. The first part looks close to being achieved, although many proteins are post-translationally modified (glycosylated, lipidated, etc) and these modifications, carried out by other proteins, are crucial for regulating the specific molecular interactions which play such an essential role in metabolism. But the notion of the ‘function’ of a particular molecule embodies all its interactions with others, and it is not clear that studying the genome alone will enable one to understand them. Put even more starkly, could one predict the existence of a central nervous system merely from studying the genome? The reductionist view is to seek a molecular explanation, but a list of all the molecules in a cell, even if their spatially varying concentrations are given, is not sufficient to understand how the whole cell works, let alone

multicellular organisms.

It is of course futile to attempt to cover all of biophysical chemistry within one short chapter. The emphasis will be on necessary concepts, especially where these diverge from the mainstream of physical chemistry; inevitably there will be gaps. Material which is well known and readily found in standard texts (e.g. [13]), or in other chapters of this encyclopaedia, will be dealt with cursorily, if at all, but new material, and topics less well known than they should be, are accorded a more detailed treatment. Given the central role of macromolecular interactions in biological systems, they are covered extensively ([section C2.14.6](#) and [section C2.14.7](#) and part of [section C2.14.3](#)), except for protein folding ([section C2.14.2](#)) since it is also the topic of chapter 2.5. Biological membranes and associated topics such as the conduction of the nervous impulse [14, 15] will not be discussed. Another omission is the interaction of light with biological molecules, because it does not seem that in essence they diverge significantly from photochemical processes in general, without excluding the possibility that photons may be involved in intercellular signalling. For the same reason, intra- and intermolecular electron transfer phenomena have also been omitted.

-5-

To some extent, the division into sections is arbitrary: for example, aspects of biological structure prediction ([section C2.14.2.2](#)) hinge on kinetic considerations ([section C2.14.3.5](#) and [section C2.14.4](#)). Most obviously in a developing organism, but actually throughout life, morphogenesis and regulation depend on proteins which are being synthesized at definite rates. The essence of enzyme function lies in the dynamical aspect of structure (conformational relaxation). Indeed, if one had to name a single principle characterizing biophysical chemistry and how it differs from the rest of physical chemistry, it would be the emphasis on kinetics, and an alternative definition of biophysical chemistry might be the science of kinetics and pattern. The reason for including pattern, i.e. spatial inhomogeneity, will become clear in [section C2.14.4.4](#).

C2.14.2 BIOLOGICAL STRUCTURE

Ever since it became apparent that many proteins can refold from a denatured random coil into a fully functional enzyme, implying that the amino acid sequence alone encodes the necessary information, this field has been divided into two: the experimental determination and the prediction of structure from sequence. It may be that one day it will be much easier and quicker to compute structures from sequences ([section C2.14.2.2](#)), but at present the experimental determination is more reliable. The choice is between classical methods capable of yielding three-dimensional coordinates of many or all the atoms in the molecule, which is however not under *in vivo* conditions; and a panoply of diverse methods capable of lower resolution, or of elucidating only one particular aspect of structure, but under physiological conditions. Nowadays it is realized that the determination of structure is a problem of inference using data from diverse sources which must be combined, and no one method is universally applicable. It is furthermore as well to remember that biological structure is set in a dynamical context, and that the characteristic patterns of biopolymer structural fluctuations are probably essential to understanding functional mechanisms; Ageno [16] gives an excellent example of the consequences of rapid transitions between different conformational states of DNA.

C2.14.2.1 STRUCTURE DETERMINATION

The classical methods of determining three-dimensional native structures of biopolymers, i.e. the spatial coordinates of all their atoms, are well documented by Cantor and Schimmel [13] and will not be reiterated in any detail here. The most comprehensively useful technique is x-ray diffraction (see chapter B1.9), for which the material must be prepared in crystalline form. The attainable resolution is strongly dependent on the size and quality of the crystal. Crystallization is still a highly empirical art. Intense x-ray sources (synchrotron radiation) enable smaller crystals to be used, although the rate of radiation damage is correspondingly faster. Until recently, membrane proteins, which may comprise about a third of the expressed protein repertoire of a typical cell, could not be crystallized in their native environment and their structure determination using x-rays was problematical; the use of cubic phase lipids offers a promising new route [17].

The main problem with x-ray (and neutron) diffraction is that the information it is made to yield is essentially

static. X-ray diffraction generates data on the millisecond time scale, whereas amino acid residues in a protein can rotate about 10^{11} times per second, and even proton exchange takes place on a submicrosecond scale. Hence an enormous amount of information is averaged out. Some attempts to quantify molecular motility have been made by analysing the temperature dependence of the broadening of the Debye–Waller factors [18], but large infrequent motions do not perceptibly contribute to the broadening. Since it is precisely these motions which may constitute the key part of enzyme action, their invisibility vitiates the structure → function path of inference. An equally serious problem is that many, or possibly most, proteins can exist in several stable conformational states and therefore possess the ability to

-6-

remember. This polymorphism, proper characterization of which may be essential to understand the functional mechanism of a protein, usually remains undetected by the classical methods, for the simple reason that in the final stage of numerically refining the atomic coordinates derived from the diffraction data a computer is programmed to find a single optimal structure, not the optimal mix of (unknown) structures, which is probably anyway indeterminate from the available information.

A further problem is the influence of the rather unusual—from the physiological viewpoint—salt conditions necessary for crystallization. It should not be presumed that proteins embedded in a crystal are in their most common native structure. It is well known that, with the exception of sodium or potassium chloride, which are not very useful for inducing crystallization, salts change key protein parameters such as the melting temperature [19].

A weakness with x-ray, but not neutron diffraction (although the latter is experimentally more difficult, mainly because neutrons are far harder to produce and focus than x-rays) is that the hydrogen atoms are invisible, and their positions must be inferred during numerical structure refinement. Given the primordial role of hydrogen bonding in determining biological structure, this omission is unfortunate.

The spatial arrangement of atoms in two-dimensional protein arrays can be determined using high-resolution transmission electron microscopy [20]. The measurements have to be carried out in high vacuum, but since the method is used above all for investigating membrane proteins, it may be supposed that the presence of the lipid bilayer ensures that the protein remains essentially in its native configuration.

Nuclear magnetic resonance spectroscopy (chapters B1.11, B1.12, B1.13 and B1.14) can provide cross-relaxation rates between two proton spins, from which a set of short range (up to ~ 5 Å) distance constraints can be generated [21], from which in turn a three dimensional conformation can be computed [22, 23]. The number of constraints is much larger than the number of degrees of freedom in the protein, which partly compensates for the limited accuracy of the constraints (uncertainties can be as much as ~ 1 Å, but renders the computational problem exceedingly difficult, comparable to the protein folding problem (section 2.5). The upper limit of protein molecular weight is about 200 000. Since the intrinsic time scale of NMR is about 1 ms, as in the case of x-ray diffraction, many conformations are averaged out. An attraction of the method is that the protein is not constrained in a crystal, but is presumably present in its native structure, although in order to measure signals of adequate intensity, rather high protein concentrations have to be used and there is a risk of aggregating the protein.

Apart from these mainstream methods enabling one to gain a comprehensive and detailed structural picture of proteins, which may or may not be in their native state, there is a wide variety of other methods capable of yielding detailed information on one particular structural aspect, or comprehensive but lower resolution information while keeping the protein in its native environment. One of the earliest of such methods, which has recently undergone a notable renaissance, is analytical ultracentrifugation [24], which can yield information on molecular mass and hence subunit composition and their association/dissociation equilibria (via sedimentation equilibrium experiments), and on molecular shape (via sedimentation velocity experiments), albeit only at solution concentrations of at least a few tenths of a gram per litre.

The new scanning probe microscopies (chapter B1.19) have been used enthusiastically by biologists almost since their invention, because biomolecules can be investigated in aqueous, physiological *milieux* at room temperature. Early hopes of using atomic force microscopy to sequence DNA, or scanning tunnelling microscopy to characterize

individual ion channels, have not been realized, however. While a degree of resolution close to that achievable with good electron microscopy has been reported for fairly rigid protein arrays, notably bacteriorhodopsin, biological samples are on the whole too sticky and labile to be successfully imaged at submolecular resolution. Even the smallest achievable probe–sample interaction forces deform the sample, assuming that it does not slide about the surface, and the use of specially fine tips (radius < 1 nm) is vitiated by the rapid accumulation of biological debris at the tip. A brighter future lies in the more easily attainable realm of imaging the two-dimensional arrangement of proteins at a surface, from which the radial distribution function, a rich source of information on short and long range intermolecular interactions, can be obtained. For this application, it is sufficient to image each protein as a featureless blob.

Circular dichroism has been a useful servant to the biophysical chemist since it allows the non-invasive determination of secondary structure (α -helices and β -sheets) in dissolved biopolymers. Due to the dissymmetry of these structures (containing chiral centres) they are biaxial and show circular birefringence. Circular dichroism is the Kramers–Kronig transformation of the resulting optical rotatory dispersion. The spectral window useful for distinguishing between α -helices and so on lies in the region 200–250 nm and hence is masked by certain salts. The method as usually applied is only semi-quantitative, since the measured optical rotations also depend on the exact amino acid sequence.

Another technique used for structural inference is dielectric dispersion in the frequency [25] or time [26] domains. The biopolymer under investigation must have a permanent dipole moment μ_0 . It is first dissolved in a dielectrically inert solvent, e.g. octanol, which may be considered to bear some resemblance to a biological lipid membrane, and then the complex impedance $\hat{\epsilon} = \epsilon' + i\epsilon''$ is measured over a range of frequencies f typically from a few kHz up to several tens of MHz. The dielectric dispersion arises through the rotational relaxation of the molecules. One or more Debye relaxation functions:

$$\epsilon' = \epsilon_{\infty} + \Delta\epsilon_0 / (1 + [f/f_0]^2) \quad (\text{C2.14.1})$$

and

$$\epsilon'' = \Delta\epsilon_0 [f/f_0] / (1 + [f/f_0]^2) \quad (\text{C2.14.2})$$

where $\Delta\epsilon_0$ is the dielectric relaxation amplitude (related to the square of the permanent dipole moment μ_0 [25]), are fitted to the data in order to determine the relaxation frequency f_0 , which is related to the rotational friction coefficient and hence to the shape of the molecule. Water contributes significantly to the impedance spectrum and its contribution must be carefully assessed and eliminated.

Careful measurement of the kinetics of association of a molecule with a surface can also yield structural information at this level of resolution [27], and lateral clustering and crystallization can also be deduced. This is described in more detail in [section C2.14.7.2](#).

Another method applicable to interfaces is the determination of the partial molecular area \bar{a} of a biopolymer partitioning into a lipid monolayer at the water–air interface using the Langmuir trough [28]. The first step is to record a series of pressure π –area (A) isotherms with different amounts n of an amphiphilic biopolymer spread at the interface.

A particular surface pressure is then chosen, and n plotted against the values of A at that pressure. From the

conservation of mass, we must have

$$n = \Gamma A + c_b V \quad (\text{C2.14.3})$$

where Γ is the surface concentration and c_b the concentration in the subphase bulk of volume V . Such plots yield straight lines from which Γ and c_b can be determined using equation (C2.14.3). A plot of Γ (from which \bar{a} can be deduced) versus π can then be constructed; typically such a plot has several features which can be assigned to conformational transitions.

A little known structural method for investigating protein motions is to measure the Rayleigh scattering of Mössbauer radiation (RSMR) [29]. A Mössbauer source moving with velocity $\pm v$ irradiates the sample, and both elastically and inelastically scattered radiation are measured as a function of the scattering angle θ . The energy spectrum (resonant peak position and linewidth) and the fraction of elastic scattering embody information on the dynamics of the protein. These measurements are especially valuable for characterizing the main types of movements in a protein, namely:

1. solid state motions (amplitudes $A_1 \sim 0.1\text{--}0.2 \text{ \AA}$ and correlation times $\tau_0 \sim 10^{-13} - 10^{-12} \text{ s}$);
2. large scale individual motions of small groups of atoms (amplitudes A_2 up to 0.5 \AA and correlation times $\tau_2 \sim 10^{-11} - 10^{-9} \text{ s}$);
3. complex cooperative motions of larger domains (amplitudes A_3 up to 1 \AA and correlation times $\tau_3 \sim 10^{-8} - 10^{-7} \text{ s}$);

C2.14.2.2 THE PREDICTION OF STRUCTURE

A native protein is folded from a linear chain comprising anything from about 30 to 2000 amino acids, mainly chosen (with differing probabilities) from a set of twenty or so different ones. The prediction of the stable, three-dimensional structure (or structures) of a biopolymer is an horrendously difficult problem. It is not even known if the stable structure corresponds to the global energy minimum; even if it does, the calculation of this minimum, of a rough energy surface with countless local minima, is an extremely difficult optimization problem. In any case, realistic estimates of the time needed to search through all possible conformations would exceed the lifetime of the universe, whereas proteins are known to fold spontaneously within typically a few seconds. This is sometimes referred to as the ‘Levinthal paradox’.

An excellent account of the statistical physics of polymer chains, with some consideration of biological macromolecules, is given by Lifschitz *et al* [30]. Much recent work on the protein folding problem seems to have been inspired by the concept of frustration in spin glasses [31]—whether the analogy is deep or superficial remains to be seen—and hence it has been proposed that proteins fold on a rough energy landscape [32], which implies certain generic features of the folding pathway, but whether these are sufficient to solve the folding problem is unclear. Perhaps the most delicate issue is the relative importance of local versus nonlocal (i.e. between residues distant from each other along the polypeptide chain) interactions [33]. From a practical viewpoint this approach has not led to a

successful algorithm for predicting structure. It is a mark of the lack of progress that much attention is now being devoted to expert algorithms based on the (now quite large) data bases of known structures and the sequences specifying them; they merely compare a new sequence of unknown structure with extant sequences whose structures are known. Of course a causal basis is lacking and no fundamental insight into the underlying mechanisms governing folding is gained.

A different approach is based on the realization that equilibrium thermodynamics cannot dictate a sequence of

events under time constraints unless the contributions to the thermodynamic potential themselves represent kinetic parameters [34]. Life as a whole is well characterized as a thermodynamic system operating under kinetic constraints; individual life is essentially transient, and metastable structures are nearly always good enough. This naturally leads to viewing expedience rather than equilibrium as the driving principle of folding, and the preeminence of the Lagrangian $\mathcal{L} (=T - V$ for conservative systems, where T and V are respectively the kinetic and potential energies), rather than the Hamiltonian $\mathcal{H} = T + V$. Minimization of the action (the integral of \mathcal{L}) is an inerrant principle for finding the correct solution of a dynamical problem [35]; the difficulty resides in the fact that there is no general recipe for constructing \mathcal{L} .

A solution leading to a successful algorithm was recently found for the folding of ribonucleic acid (RNA) [36]. Natural RNA polymers (figure C2.14.1) are mainly made up from four different ‘bases’, A, C, G and U. As with DNA, multiple hydrogen bonding favours the formation of G–C and A–U pairs [16, 37, 38] which leads to the appearance of certain characteristic structures. Loop closure is considered to be the most important folding event.

Figure C2.14.1. Diagram of a fragment of a folded RNA polymer, the Q β replicase MDV-1 [176]. Note the various structural features: stems closed with a loop (‘hairpins’), bows, and single strands.

V (the potential) is identified with the enthalpy, i.e. the number n of base pairings (contacts), and T corresponds to the entropy. At each stage in the folding process, as many as possible new favourable intramolecular interactions are formed, while minimizing the loss of conformational freedom (the principle of sequential minimization of entropy loss, SMEL). The entropy loss associated with loop closure is ΔS_{loop} (and the rate of loop closure $\sim \exp(\Delta S_{\text{loop}})$); the function to be minimized is $\exp(-\Delta S_{\text{loop}}/R)/n$ [36]. A quantitative expression for ΔS_{loop} can be found by noting that the N monomers in an unstrained loop ($N \geq 4$) have essentially two possible conformations, pointing either inwards or outwards. For loops smaller than a critical size N_0 , the inward ones are in an apolar environment, since the enclosed water no longer has bulk properties, and the outward ones are in polar bulk water; hence the electrostatic charges on

the ionized phosphate moieties of the bases will tend to point outwards. For $N < N_0$, $\Delta S_{\text{loop}} = -RN \ln 2$, and for $N > N_0$, the Jacobson–Stockmayer approximation based on excluded volume yields $\Delta S_{\text{loop}} \sim R \ln N$.

In the case of proteins, it is advantageous to make use of the fact that not all combinations of the two dihedral angles (the only degrees of freedom of the polypeptide chain) specifying the orientations of the $C_\alpha - C$ and $C_\alpha - N$ bonds are permitted [39]. Essentially there are just three basins of attraction, corresponding to left- and right-handed α -helices (compact conformations) and the β -sheet (extended conformation). Consensus sequences (runs of amino acid residues whose local conformations fall in the same basin) result in persistent, ultimately global structure being built up (the folding problem can be viewed as fixing the relation between local and global structures). As with RNA, the barriers are entropic, determined solely by loop closure (except where contacts have to be disassembled), and the SMEL principle applies. This approach has been successfully used to fold bovine pancreatic trypsin inhibitor [40].

C2.14.2.3 BIOMOLECULAR ASSEMBLIES

The modern era of biochemistry and molecular biology has been shaped not least by the isolation and characterization of individual molecules. Recently, however, more and more polyfunctional macromolecular complexes are being discovered, including nonrandomly codistributed membrane-bound proteins [41]. These are made up of several individual proteins, which can assemble spontaneously, possibly in the presence of a lipid membrane or an element of the cytoskeleton [42] which are themselves supramolecular complexes. Some of these complexes, e.g. snail haemocyanin [43], are merely assembled from a very large number of identical subunits; viruses are much larger and more elaborate; and we are still some way from understanding the processes controlling the assembly of the wonderfully intricate and beautiful structures responsible for the iridescent colours of butterflies and moths [44].

Specific intramolecular interactions (section C2.14.6) can be expected to play a role in the spontaneous assembly of the constituent elements, so that simply mixing the constituents will result in a correctly assembled structure provided the environment is right. One wonders whether stigmergic building algorithms [45] are involved, in which individual elements communicate only through the local environment. If one observes a nest of ants after a disturbance, the impression is one of haphazard movement as the ants drag exposed eggs hither and thither, but within a very short time they have all been moved to safety, without any hierarchical command system in operation.

C2.14.3 BIOLOGICAL EQUILIBRIUM

Ergodicity is generally broken in biological systems, and hence the standard notion of equilibrium is not very useful for solving biological problems; as already mentioned in section C2.14.2.2, most living systems operate under time constraints. Processes are therefore not infinitesimally slow and perfectly reversible: an organism is willing to sacrifice free energy in order to ensure that events take place rapidly and are consequently irreversible.

C2.14.3.1 TRANSFER AND STORAGE OF CHEMICAL POTENTIAL

Many biochemical reactions are involved in converting and storing energy, and the primary consideration is the chemical potential at which the product is recovered, rather than the yield. Consider the simple reaction

-11-

The rate of storage of chemical potential (in other words, the power P carried by the chemical reaction) is $j\mu_B$, where $j = db/dt = J_f - J_b$, the net flux per unit volume (here, as elsewhere, lower case letters denote concentrations, and subscripts f and b refer to the forward and backward reactions). If A and B are at equilibrium, $j = 0$; if the forward reaction proceeds at a finite rate, then $\mu_B < \mu_A$, but if j goes to its maximum value, $j = J_f$ (i.e. $J_b = 0$), $\mu_B = 0$ and no chemical potential is stored. At what intermediate flux is P optimal [46]? The change in chemical potential is given by the van't Hoff isotherm

$$\Delta\mu = \mu_B - \mu_A = -RT[\ln K - \ln(b^*/a^*)] \quad (C2.14.5)$$

where the stars serve as a reminder that the concentrations should be multiplied by activity coefficients, assumed to equal unity in the following discussion. Provided one is allowed to assume that the equilibrium constant $K = k_f/k_b$, a valid assumption if Boltzmann equilibrium is maintained in the steady state and hence a single rate coefficient correctly characterizes the reaction, then

$$\Delta\mu = RT \ln \frac{bk_b}{ak_f} = RT \ln \left[1 - \frac{j}{J_f} \right] \quad (\text{C2.14.6})$$

and the efficiency of free energy transfer is $(\mu_A + \Delta\mu)/\mu_A$. Writing P as $j(\mu_A + \Delta\mu)$, it is a simple matter to substitute in expression (C2.14.6) for $\Delta\mu$, differentiate with respect to j and set the derivative to zero, obtaining:

$$\frac{j_{\max}/J_f}{1 - j_{\max}/J_f} - \ln \left[1 - \frac{j_{\max}}{J_f} \right] = \frac{\mu_A}{RT}. \quad (\text{C2.14.7})$$

Once the reaction is accomplished, it is usually desirable to store the product, i.e. a further reaction

must follow (C2.14.4). Since all the reactions are reversible, at first sight it would appear impossible to store B indefinitely: the back reaction out of the store could only be prevented by an infinitely high energy barrier. To avoid this, the store is fitted with a door; only when this door is closed is the barrier infinitely high. Furthermore, the store has a variable volume such that the chemical potential is constant and independent of the amount of material contained.

When the door is open, the optimal net flux into the store is j_{\max} , given by equation (C2.14.7). It may be that the stochastically gated diffusion treated by Szabó *et al* [47], see also [48] is a good representation of typical biological storage reactions (C2.14.8).

C2.14.3.2 'MISSING ENTROPY'

The calorimetrically measured ΔH is usually assigned to the formation and breaking of chemical bonds. The equation

$$-RT \ln K = \Delta H - T \Delta S \quad (\text{C2.14.9})$$

linking enthalpy and entropy is, as has been aptly pointed out [49], 'as infallible as the laws of thermodynamics'; equally infallible statements can be generated by adding, *pace* Hall and Knight, some arbitrary quantity ξ to both terms on the right-hand side, which becomes $\Delta H + \xi - (T \Delta S + \xi)$. As Weber has pointed out [50], the separation of ΔH and ΔS depends upon specific hypotheses relating them, among which there is no *prima facie* unique choice, and one may legitimately enquire whether a proposed choice of ξ is appropriate. As hinted at by Planck [51], ΔH is a composite quantity comprising (a) the chemical bonding energy, and (b) the integral of the specific heat increments ΔC_p (defined as dQ/dT in a reversible change, where Q is the heat), i.e. $\int_0^T \Delta C_p dT$, obtainable by painstaking measurements of ΔC_p from 0 K to T . For ideal gases and other small entities, this integral is practically zero and can be neglected, but for biological macromolecules it could well be more significant than the chemical bonding energy. Since $C_p = (\partial H/\partial T)_p$, this assertion can easily be verified by enquiring whether ΔH varies with temperature for the reaction under consideration [52, 53]. Since $dQ = T dS$ in a reversible change, equation (C2.14.9) can be rewritten as [49]

$$-RT \ln K = \Delta H_0 - \Delta W \quad (\text{C2.14.10})$$

where the subscript 0 stands as a reminder that this is the (defined) heat of reaction at 0 K, and

$$\Delta W = T \int_0^T \frac{\Delta C_P}{T} dT - \int_0^T \Delta C_P dT \quad (\text{C2.14.11})$$

represents the work obtainable by conversion of ‘thermal’ heat expendable in the separation of chemically bonded atoms [49]. At all temperatures above absolute zero, the integral $\int_0^T \Delta C_P dT$ must be subtracted from the measured enthalpy in order to obtain the true heat of reaction.

This argument was pointed out almost 30 years ago by Benzinger [49], in a paper which referred to some still earlier work of his, and yet its implications, even more pertinent today given the wider use of calorimetry in molecular biology, still appear to be largely ignored, an exception being Weber’s work on the association enthalpy of protein subunits [50].

The ‘missing entropy’ $-\int_0^T (\Delta C_P/T) dT$ is proportional to the number of possible states. In typical biological macromolecules and also other nonergodic materials such as glasses and spin glasses, disorder is quenched: only one of the very large number of possible realizations occurs, and Nernst’s third law is violated [54].

The entropy of a solution is itself a composite quantity comprising: (i) a part depending only on the amount of solvent and solute species, and independent from what they are, and (ii) a part characteristic of the actual species (A, B, ...) involved (equal to zero for ideal solutions). These two parts have been denoted respectively cratic and unitary by Gurney [55]. At extreme dilution, (ii) becomes more or less negligible, and only the cratic term remains, whose contribution to the free energy of mixing is

-13-

$$-kT \ln W_{\text{config}} = kT (n_A \ln x_A + n_B \ln x_B + \dots) \quad (\text{C2.14.12})$$

where the n_A, x_A etc represent the numbers and mole fractions of A, B,....

C2.14.3.3 COOPERATIVE EFFECTS IN BINDING

Switching and control (‘signal transduction’) in biological systems as elsewhere usually strives to achieve a highly nonlinear response, which *inter alia* confers a certain immunity from noise onto the system. Cooperative binding is an easy way to achieve this end. Most signalling in biology is based on the binding of a ligand L to an unoccupied site S on a receptor B:

The ligand-receptor complex C has changed properties which typically allow it to undergo further, previously inaccessible reactions (e.g. binding to a DNA promoter sequence). The role of L is to switch B from one of its stable conformational states to another. The approximate equality of the intramolecular, molecule–solvent and L–B binding energies is an essential feature of such biological switching reactions. An equilibrium binding constant K_0 is defined according to the law of mass action:

$$K_0 = \frac{c}{s\ell}. \quad (\text{C2.14.14})$$

If there are n independent binding sites per receptor, conservation of mass dictates that $s = nb_0 - c$, where b_0 is the

total concentration of B, and the binding ratio $r = c/b_0$ (number of bound ligands per biopolymer) becomes

$$r = \frac{nK_0\ell}{1 + K_0\ell}. \quad (\text{C2.14.15})$$

Suppose now that the sites are not independent, but that addition of a second (and subsequent) ligand next to a previously bound one (characterized by an equilibrium constant K_1) is easier than the addition of the first ligand. In the case of a linear receptor B, the problem is formally equivalent to the one-dimensional Ising model of ferromagnetism, and neglecting end effects, one has [56]:

$$r = \frac{n}{2} \left(1 - \frac{1 - K_0\ell}{[(1 - K_0\ell)^2 + 4K_0\ell/q]^{1/2}} \right) \quad (\text{C2.14.16})$$

where the degree of cooperativity q is determined by the ratio of the equilibrium constants, $q = K_1 / K_0$. For $q > 1$ this yields a sigmoidal binding isotherm. Another interesting case, also yielding a sigmoidal relation between r and ℓ , is represented by the uncharged oligopeptide alamethicin which partitions as a monomer into bilayer lipid membranes and aggregates within the membrane [57].

-14-

If $q < 1$, then binding is anticooperative, for example when an electrically charged particle adsorbs at an initially neutral surface; the accumulated charge repels subsequent arrivals and makes their incorporation more difficult [58].

Another important noise-reduction mechanism is to incorporate a threshold into the responsive apparatus. Essentially this is why antibodies are multidentate, why serial triggering of antigen-presenting cells [59] is necessary, and so on. The benefits of a response threshold T in have been thoroughly investigated in the context of radiation detectors [60], and the argument can be adapted to biological detectors. Suppose that L ligands are incident on an area containing R receptors. The number arriving at any particular receptor will fluctuate around $\lambda = L/R$, the mean number of ligands per receptor, and assuming a Poisson distribution for these fluctuations, the expected number \bar{f} of activated receptors (i.e. those receiving T or more ligands) is fR , where

$$f = 1 - e^{-\lambda} \left(1 + \lambda + \frac{\lambda^2}{2!} + \dots + \frac{\lambda^{T-1}}{(T-1)!} \right). \quad (\text{C2.14.17})$$

\bar{f} is binomially distributed and its standard deviation σ is $[N\bar{f}(1 - \bar{f})]^{1/2}$. The least detectable signal L' must exceed L by a certain amount—let us suppose that the least detectable increment is σ (the argument remains unchanged if some other multiple of σ is taken) and it is given by the solution of

$$Rf' = Rf + \sigma \quad (\text{C2.14.18})$$

where f' is given by equation C2.14.17 with $\lambda = L' / R$. As an example, suppose that $R = 200$ and background $L = 400$. If $T = 1$, then 79 additional ligands are needed to engender a response; but if $T = 2$, only 53 are required. The optimal threshold depends on the expected background level. Note that the most perfect possible detector is still subject to a basic limitation due to the inherently fluctuating nature of the input; in the case of a Poisson process $\sigma = \sqrt{L} = 20$ ligands would be the smallest detectable increment.

C2.14.3.4 THE EXPERIMENTAL DETERMINATION OF ASSOCIATION (BINDING) CONSTANTS

The two main difficulties facing the experimenter are (i) how to detect binding, and (ii) how to ensure that the system under investigation is truly in an equilibrium state.

(i) Typically an atom or group of atoms is selected as a reporter whose measured property (e.g. intensity of a particular Raman line) is characteristic of the state of binding. One of the most popular reporters is the photoluminescence intensity at a certain wavelength, since it can be very easily measured using a commercial fluorimeter. Sometimes the intrinsic photoluminescence of an amino acid (tryptophan, tyrosine) can be used, but quantum yields are low and the sample has to be excited in the far ultraviolet. Hence a fluorescent group is often covalently bound to one of the reaction partners, although this may drastically change its binding properties, an obvious caveat all too often overlooked. Such assays have to be calibrated, typically by measuring the photoluminescence (or other property) at binding saturation [57], although since true saturation requires one partner to be in infinite excess more or less ingenious extrapolation procedures are required. Once this is done, the relationship linking photoluminescence intensity with intermediate degrees of binding must be established. These steps are not trivial and usually end up relying on assumptions (e.g. of linearity) which are far from incontrovertible.

-15-

The easiest way to accomplish (ii) is to dilute the supposedly equilibrium bound state and check that the predicted degree of dissociation takes place on the time scale of the experiment. This is often inconvenient in homogeneous assays, however. Another check is to incubate the ligand and receptor for different times τ : invariance of c with τ would be evidence of equilibrium having been reached, provided that the range of τ has been chosen judiciously. One may also compare the amount bound after adding successive small increments of ligand L to receptor B with the amount bound after having added L to B in a single large increment: if the system is in thermodynamic equilibrium, c should be path-independent.

The development of extremely sensitive microcalorimeters has popularized the ‘direct’ determination of reaction enthalpy ΔH simply by measuring the heat evolved upon mixing L and B. The free energy is determined from the equilibrium constant K deduced from fitting a plot of r versus μ to an appropriate isotherm, such as [equation \(C2.14.15\)](#). No labelling is required, but it is often awkward to properly establish the reversibility of the reaction, and the validity of the evaluation of K depends on the binding model assumed. A graver deficiency is the neglect of specific heat effects ([section C2.14.3.2](#)), manifested by temperature-dependent ‘standard’ reaction enthalpies. Here, as elsewhere, the very ease of experimentation can lead the investigator into error, and microcalorimetry is no exception.

Great interest has recently been developed in heterogeneous systems in which B is immobilized to a solid surface and ligand binding measured directly, e.g. using a quartz crystal microbalance (QCM) or an optical method such as optical waveguide lightmode spectroscopy (OWLS), ellipsometry or surface plasmon resonance (SPR) [61], i.e. the solid surface plays a dual role as both receptor and sensing platform. When carried out properly neither labelling of the participating molecules nor calibration of the response are required, and direct measurement of the reverse reaction can be accomplished with ease. These heterogeneous methods are discussed in more detail in [section C2.14.7.2](#).

Attempts have been made to combine the sensitive detection possibilities of heterogeneous systems with the more familiar (to non-electrochemists) homogeneous ones by recreating a quasihomogeneous environment between the solid–liquid interface proper (the sensing platform) and the bulk liquid phase by interposing a hydrogel (e.g. carboxydextran) fixed to the solid phase. The receptors are covalently attached to the hydrogel scaffold. A drawback to this procedure is that it has been found empirically that association kinetics measured with such hydrogels do not correspond to those expected from truly homogeneous systems, the reason being that mass transport within the hydrogel is sufficiently drastically retarded that binding becomes diffusion limited for all but the slowest reactions [4]. Furthermore, upon dissociation the ligand has an extremely high probability of rebinding before it can diffuse away from the receptor (see also [section C2.14.6.3](#)). Hence binding parameters derived from the kinetics do not reflect the true chemical affinity of the receptor for its ligand. This is apart from the fact that covalent immobilization to the hydrogel may inactivate the receptors, e.g. by involving amino acids on an epitope or at the active site. A good way to avoid these difficulties is to anchor B to a lipid bilayer [62].

C2.14.3.5 CONFORMATIONAL RELAXATION

Agno [63], Blumenfeld [64] and possibly others have emphasized that biological systems are constructions: a living cell is much closer to a mechanical clock than to a bowl of consommé. To characterize the latter, a statistical approach is adequate, in which the motions of an immense number of individual particles are subsumed into a few macroscopic parameters such as temperature and pressure. But one does not usually need to know the pressure when analysing the working of a clock. The energy contained in a given system can be divided into two categories: (a) the multitude of microscopic or thermal motions sufficiently characterized by the temperature and (b) the (usually small number of) macroscopic, highly correlated motions, whose existence turns the construction into a machine. The total energy

-16-

contained in the microscopic degrees of freedom may be far larger than those in the macroscopic ones, but nevertheless the microscopic energy can usually be successfully neglected in the analysis of a construction. In informational terms, the macrostates are remembered, but the microstates are not [65].

The question then is, to what degree can the microscopic motions influence the macroscopic ones: is there a flow of information between them [66]? Biological systems appear to be nonconservative *par excellence* and present at least the possibility that random thermal motions are continuously injecting new information into the macroscales. There is certainly no shortage of biological molecular machines for turning heat into correlated motion (e.g. [67] and section C2.14.5; note also [16]).

A construction makes use of only an insignificant fraction of the Gibbs canonical ensemble and hence is essentially out of equilibrium. This is different from thermodynamic nonequilibrium—it arises because the system is being investigated at time scales much shorter than those required for true statistical equilibrium. Such systems exhibit ‘broken ergodicity’ [68], as epitomized by a cup of coffee in a closed room to which cream is added and then stirred. The cream and coffee equilibrate within a few seconds (during which vast amounts of microinformation are generated within the whorled patterns); the cup attains room temperature within tens of minutes; and days may be required for the water in the cup to saturate the air in the room.

Broken ergodicity may be regarded as a generalization of broken symmetry, a concept introduced by Landau (see [69]) in the context of phase transitions, and which leads to a new thermodynamic quantity, the order parameter ξ whose value is zero in the symmetrical phase. ξ may be thought of as conferring a kind of generalized rigidity on a system [70], allowing an external force applied at one point to be transferred to another. Some protein molecules demonstrate this very clearly: flash photolysis of oxygenated haemoglobin causes motion of the iron core of the haem which results in (much larger) movement at the distant intersubunit contacts, leading ultimately to an overall change in the protein conformation involving hundreds of atoms.

In the case of enzymatic catalysis, it has been proposed that when substrate binds to the active site, local fast vibrational relaxation takes place on the picosecond time scale, but the active site is no longer in equilibrium with the rest of the molecule and the resulting strain modifies the energy surface on which the enzymatic reaction takes place [71, 72]. Subsequent conformational relaxation involves making and breaking a multiplicity of weak bonds, but at a slower rate than the reaction being catalysed. This description implies a definite and striking prediction: the reaction rate should exhibit an inverse Arrhenius temperature dependence, because increasing the temperature accelerates conformational relaxation, and hence shortens the time during which the strained molecule is able to accelerate the enzymatic reaction. Evidence for this mechanism is provided by the pulsed photolysis of carbonmonoxy (relaxed, R) haemoglobin at 532 nm. Time-resolved resonance Raman spectroscopy of aromatic amino acid residues associated with the intersubunit contact show that a strained tense (T) conformation (characterized by the tyr α_{42} – asp β_{99} intersubunit hydrogen bond and a close trp β_{37} – tyr α_{140} contact, indicated by an increased tyr 830/850 cm^{-1} Fermi doublet intensity ratio and a decreased trp 880 cm^{-1} band intensity respectively [73]) is produced within the 7 ns duration of the photolysis pulse. Strain is also inferred from the enhanced optical adsorption difference (compared with the difference between equilibrium T and R forms) at 315 nm (due to the trp β_{37} – tyr α_{140} contact) which appears on the nanosecond time scale. The enhancement then

relaxes with the same (microsecond) time constants [74] characteristic of tertiary structural changes in the vicinity of the haem iron which can be probed by the Soret band adsorption (R A Copeland, S Dasgupta, J J Ramsden, R H Austin and T G Spiro, unpublished observations). Another intriguing piece of evidence comes from direct observation of the adenosine triphosphate (ATP)-induced generation of mechanical force by immobilized myosin interacting with actin tethered to beads held in optical traps. Upon hydrolysis

-17-

of ATP, adenosine diphosphate (ADP) is released. Individual hydrolysis events could be monitored by microscopic observation of fluorescently labelled adenosine. The simultaneous monitoring of bead displacements due to the mechanical force exerted on the actin clearly showed that force is generated several hundred milliseconds after release of ADP [75].

C2.14.4 Kinetics It has already been emphasized (section C2.14.1, section C2.14.2.2 and section C2.14.3.1) that kinetics are of paramount importance in describing living systems [76]. The root of this may ultimately lie in the fact that whereas inanimate matter has endless time in which to undergo its transformations, mortal, animate matter is constantly racing against the clock.

C2.14.4.1 TRANSPORT IN BIOLOGICAL SYSTEMS

The determination of biological affinity by mixing two species and measuring their rates of association and dissociation presupposes that the contribution of transport to the association dynamics is precisely known. Well-defined hydrodynamic conditions are therefore a prerequisite for the experimental determination of affinities via rates.

In a homogeneous system, the rate of mixing is governed by Smoluchowski's equations [77], according to which the diffusion-limited association rate of S and L (equation (C2.14.13)), supposed uncharged, equals that of the flux and is

$$(C2.14.19)$$

where d and D are the molecular radii and diffusivities respectively. In the presence of an energy barrier characterized by an association (forward) rate coefficient k_f , one introduces a vicinal concentration (subscript v) and writes the rate as $dc/dt = k_{fv}$ per S, and the flux from the bulk to the vicinity of L as $4\pi(d_S + d_L)(D_S + D_L)(c - c_v)$, giving the familiar expression:

$$(C2.14.20)$$

The equivalent equations for heterogeneous and quasi-heterogeneous systems (the latter are small vesicles which can practically be handled as homogeneous systems, but which are nevertheless large enough to possess a macroscopic solid-liquid interface) are dealt with in section C2.14.7.

At first sight it seems that biochemical reactions taking place in the cytoplasm can be modelled homogeneously, but in fact the cytoplasm is a complex, highly viscous medium belonging to the class of soft matter or complex fluids, which bears little relation to the cytosol [78], and in which diffusion may be anomalous. It is a current experimental challenge to reconstruct the cytoplasm *in vitro* and systematically investigate biomolecular reaction kinetics in such media, although since the majority of intracellular reactions actually seem to take place at the solid-liquid interface [78], it is even more important to correctly apply the methods of heterogeneous kinetics to biochemical reactions.

-18-

An important aspect of biological transport is that nature makes extensive use of the reduction of dimensionality to speed up search and discovery (SD) (see also [section C2.14.6.2](#)). SD is enormously enhanced upon moving from three to two or one dimensions, because the spatial extent to be explored is drastically reduced. Affinity follows kinetics in being enhanced upon moving from three dimensions to two dimensions [79].

C2.14.4.2 SMALL SYSTEMS

Consider again the prototypical homogeneous reaction (C2.14.13), which Rényi has analysed in detail [80]. Taking the forward reaction only (other cases are also dealt with in [80]), and supposing that $k_f \ll 4 \pi (d_s + d_L)(D_S + D_L)$ (cf equation (C2.14.20)), then

$$\frac{dc}{dt} = k_f[\langle s \rangle \langle \ell \rangle + \Delta^2(\gamma_t)] = k_f \langle s \ell \rangle \quad (\text{C2.14.21})$$

where the angular brackets denote expected numbers, and γ_t is the number of C molecules created up to time t . The term $\Delta^2(\gamma_t)$ expresses the fluctuations in γ_t : $\langle \gamma_t^2 \rangle = \langle \gamma_t \rangle^2 + \Delta^2(\gamma_t)$: supposing that γ_t approximates to a Poisson distribution, then $\Delta^2(\gamma_t)$ will be of the same order of magnitude as $\langle \gamma_t \rangle$. The so-called kinetic mass action law (KMAL) putting $\langle s \rangle = s_0 - c(t)$ and so on, the subscript 0 denoting initial concentration at $t = 0$, is a first approximation in which $\Delta^2(\gamma_t)$ is supposed negligibly small compared to $\langle s \rangle$ and $\langle \ell \rangle$, implying that $\langle s \rangle \langle \ell \rangle = \langle s \ell \rangle$, whereas strictly speaking it is not since s and ℓ are not independent. The neglect of $\Delta^2(\gamma_t)$ is justified for molar quantities of starting reagents (except near the end of the process, when $\langle s \rangle$ and $\langle \ell \rangle$ become very small), but inconceivably so for reactions in minute subcellular compartments.

These number fluctuations, i.e. the $\Delta^2(\gamma_t)$ term, will constantly tend to be eliminated by diffusion. On the other hand, because of the correlation between s and ℓ , initial inhomogeneities in their spatial densities lead to the development of zones enriched in either one or the other faster than the enrichment can be eliminated by diffusion. Hence instead of L disappearing as t^{-1} (when $\ell_0 = s_0$), it is consumed as $t^{-3/4}$ [82], and in the case of a reversible reaction, equilibrium is approached as $t^{-3/4}$ [82] (charged particles are dealt with in [83]). Deviations from perfect mixing are more pronounced in dimensions lower than three.

C2.14.4.3 NONEXPONENTIAL DECAY AND ITS ORIGINS

The paradigmatical binding reaction (equation (C2.14.22)) is generally analysed as a second order forward reaction and a first order backward reaction, leading to the following rate law:

$$\frac{dc}{dt} = k_f s \ell - k_b c \quad (\text{C2.14.22})$$

supposing $\ell \approx \ell_v$. Despite its beguiling simplicity, this equation cannot, in general, be solved analytically, but a numerical solution is straightforward and can be fitted to experimental data to determine the forward and backward rate coefficients k_f and k_b . Ideally, the data collected should comprise both an association phase, during which S and L

are brought into contact, and a dissociation phase, in which C is diluted into a large volume of pure solvent, and the fitting carried out globally over both phases. It is unfortunate that many of the traditional binding assays used in biochemistry are awkward or impossible to apply to dissociation. This has led to an underappreciation of the fact

that simple Poisson dissociation (rate proportional to the amount remaining undissociated) giving familiar exponential decay is the exception rather than the rule in biomolecular interactions. This is very easy to demonstrate with a heterogeneous reaction such as the adsorption of serum albumin onto silica (e.g. [84, 85]): the dissociation rate coefficient is clearly time dependent. The amount of protein bound, $v(t)$, can be represented by the integral [86]

$$v(t) = k_f \ell \int_0^t \phi(t_1) Q(t, t_1) dt_1 \quad (\text{C2.14.23})$$

where ϕ is the fraction of unoccupied receptors. The memory kernel Q denotes the fraction of L bound at epoch t_1 which remain adsorbed at epoch t (if dissociation is indeed a first order (Poisson) process $Q(t) = \exp(-k_b t)$). A necessary condition for the system to reach equilibrium is

$$\lim_{t \rightarrow \infty} Q(t) = 0. \quad (\text{C2.14.24})$$

Processes of this type have been analysed [84, 85] by adding an irreversible step, either in parallel:

$$\frac{dc_{\text{irr}}}{dt} = k_{\text{irr}} s \ell \quad (\text{C2.14.25})$$

for which the memory function is [87]:

$$Q = \frac{k_{\text{irr}}}{k_f} + e^{-k_b t} \quad (\text{C2.14.26})$$

or in series

$$\frac{dc_{\text{irr}}}{dt} = k_{\text{irr}} c \quad (\text{C2.14.27})$$

for which the memory function is [86]

$$Q = \frac{k_{\text{irr}} + k_b e^{-(k_{\text{irr}} + k_b)t}}{k_{\text{irr}} + k_b} \quad (\text{C2.14.28})$$

to equation (C2.14.22), which is modified accordingly. Note that in neither of these cases does $\lim_{t \rightarrow \infty} Q(t) = 0$; the

systems do not reach equilibrium and the usual KMAL assumption that the equilibrium constant K can be equated to the quotient of the forward and backward rate coefficients does not apply; the backward reaction (dissociation) coefficient is time dependent and can be obtained from the quotient [86]

$$k_b(t) = \frac{\int_0^t \phi(t_1) Q'(t, t_1) dt_1}{\int_0^t \phi(t_1) Q(t, t_1) dt_1}. \quad (\text{C2.14.29})$$

The existence of multiple stable conformations with different affinities implies time-dependent dissociation: a molecule initially associated in a low-affinity conformation has the chance to switch to a high affinity one before dissociating. Even a single conformation may actually comprise many slightly different subconformations ('conformational substates', CS, possibly rotamers) separated by finite barriers [7, 40]. At some finite temperature the molecule will exist in several different CS (i.e. ergodicity is broken), each of which may be presumed to make a slightly different contribution to the rate of any process in which that conformation of the biopolymer participates. In biological (and inanimate glassy) systems relaxation is empirically often found to follow 'stretched exponential' (Kohlrausch) decay:

$$c(t)/c_0 = \exp[-(k_b t)^\beta], \quad 0 < \beta < 1. \quad (\text{C2.14.30})$$

If the contributions from the different CS are additive and relax in parallel,

$$\frac{c(t)}{c_0} = \int_0^\infty w(k_b) e^{-k_b t} dk_b \quad (\text{C2.14.31})$$

with which equation (C2.14.30) can be simulated, but unless there is some independent way of determining the weight distribution $w(k_b)$, its choice is arbitrary. Series relaxation avoids this difficulty [88]: relaxation on the n th level is only possible if certain elements in the $(n-1)$ th level satisfy some condition. For example, in the case of biopolymer relaxation (cf section C2.14.3.5) the condition might be that μ_{n-1} monomer units in level $n-1$ attain one particular state of their $2^{\mu_{n-1}}$ possible ones, giving an average relaxation time $\tau_n = 2^{\mu_{n-1}} \tau_{n-1}$.

C2.14.4.4 PATTERN FORMATION

Relative to the multicellular organism into which it develops, the fertilized egg is rather homogeneous, but within a few generations of cell division, an embryonic animal already shows remarkable spatial variation, which ultimately develops into the differentiated limbs and organs of the adult organism. The realization that diffusion and chemical reaction provides an adequate basis for the formulation of a mathematical model of morphogenesis dates back to a seminal paper published by Turing in 1952 [89]. The essential idea is that the initially homogeneous, stable state moves out of stability due to some random disturbance (not necessarily diffusive; wetting and percolation may also play a role [90]). The unstable state generates waves of morphogens, molecules capable of leading to the generation of differentiated forms.

The great complexity of morphogenesis makes it rather difficult to formulate a theory of the process beyond stating

the equations; particular cases have to be investigated with the help of numerical simulation. In this respect, cellular automata [91] seem to show great promise. An example is the model of neurogenesis in *Drosophila* recently described by Luthi *et al* [92]. The system is divided up into cells corresponding to the actual cellular divisions of the organism, each of which is initially assigned concentrations of a substance which promotes neuralization within the cell and inhibits it in the neighbours to which it is transmitted. Subsequent evolution is governed by plausible rules inspired by recent advances in the molecular biology of the developing embryo.

C2.14.5 BIOLOGICAL MACHINES

One of the most fascinating recent developments in biology has been the discovery of numerous highly complex biopolymer assemblies (see also section C2.14.2.3) such as the ribosome or the bacterial flagellum [93, 94 and 95], the envy of nanotechnologists seeking to miniaturize man-made mechanical devices (note that the word 'machinery' is also sometimes used to refer to multienzyme complexes such as the proteasome [96]), and an entire

organism might indeed be considered as a machine [63]. Even very complex processes such as mitosis can now be analysed in considerable biophysicochemical detail [97]. Mitosis serves as an exemplar of the process design which seems to epitomize much of life, the so-called S^3 architecture [97]: stochastic (influenced by noise and showing strong fluctuations); self-correcting (working by trial and error, with checkpoints and feedbacks to ensure efficient regulation); and synchronized (which may itself be self-correcting).

Mitosis is characterized [99] by steady elongation (at a velocity v_g , depending *inter alia* on the concentration of monomeric tubulin) of the microtubule (polymerized tubulin) filaments which search for, and ultimately mechanically separate freshly replicated DNA prior to cell division, punctuated by their abrupt shrinkage (with velocity v_s). This dynamic instability is characterized by length fluctuations of the order of the mean microtubule length, hinting at a phase transition. Let f_{gs} denote the frequency of switching from growth to shrinkage ('catastrophe'), and the reverse switching back to growth (in a different direction) by f_{sg} ('rescue'). When $v_g f_{sg} = v_s f_{gs}$, at which point the average tubule length $\bar{l} = v_g v_s / (v_s f_{gs} - v_g f_{sg})$ diverges, growth switches from unbounded (during the so-called interphase, between cell division) to bounded (during mitosis, when the microtubules have to find and grab chromosomes) [97]. The molecular origin of catastrophe and rescue lies in the fact that tubulin monomers can bind to guanosine triphosphate (GTP), and the complex can spontaneously assemble to form filaments. But the GTP slowly hydrolyses to guanosine diphosphate (GDP), thereby somewhat changing the tubulin conformation such that it prefers to be monomeric. The microtubule can only be disassembled from the end, however: a catastrophe occurs if the rate of GTP hydrolysis exceeds that of tubulin addition for a while. After a catastrophe, growth occurs in a new direction. This dynamic instability-based mechanism is an extremely efficient way to search a volume [100].

C2.14.5.1 THE GENERATION OF TRANSLATION AND ROTATION

The forces involved in muscle contraction [101] can now be directly scrutinized by attaching an actin filament to a small dielectric sphere which can be nanomanipulated using optical tweezers [102, 103] and bringing the filament into contact with myosin. Using similar techniques it has become possible to directly observe kinesin molecules moving along microtubules [104]: the kinesin is labelled with a fluorescent molecule and imaged with low background total internal reflexion fluorescence microscopy, sensitive enough to detect single molecules.

Apart from the development of imaging and force measurement devices, an important biophysico-chemical problem is

-22-

understanding how motion occurs within the framework of molecular interactions. The general concept is based on Brownian particles moving along a periodic but asymmetric ('sawtooth') potential, resulting in directed ('processive') motion [67] (see [95] and [105] for examples of rotatory motors). Either the potential or the force acting on the particle fluctuate. Beautiful experiments based on direct imaging of these molecular motions, and direct measurements of the fluctuating forces, have enabled this generic concept to be refined into realistic models whose parameters are closely bounded by the experimental observations [67]. Kinesin has two heads connected by a flexible hinge. At the start of a cycle, both heads are sitting in a potential well. ATP hydrolysis (see below; and cf the effect of GTP hydrolysis on tubulin, above, and the general mechanism of enzyme catalysis described in [section C2.14.3.5](#)) results in a conformational change of one head which consequently advances to the next well. The hinge is now strained, and during relaxation bringing the two heads together again it is more probable (because of the asymmetric shape of the wells) that the laggard head is dragged to the advanced one, rather than vice versa. This relaxation together with the release of hydrolysed ATP completes the cycle [67].

A vital biophysico-chemical problem is to understand how chemical energy (released by ATP or GTP hydrolysis [105], or by protons falling down an electrochemical potential gradient [95]) is converted into mechanical energy. The thermodynamic constraints on the energy requirements of biological machines have been set out by Gray [106]. The force F which has to be applied to a molecular lever requires accurate knowledge of its position x if reversible work is to be performed. Specifying the positional accuracy as Δx , the uncertainty principle gives the energy requirement as

$$\Delta E \geq hc/(4\Delta x) \quad (\text{C2.14.32})$$

and the uncertainty in the force generated at x is then

$$\Delta F = F(x) \pm \Delta x(dF/dx). \quad (\text{C2.14.33})$$

To compute the work W done by the system, equation (C2.14.33) is integrated over the appropriate x interval. The first term on the right-hand side yields the reversible work W_{rev} , and the second term yields $-\Delta x \sum_j |F_j - F_{j+1}|$ for any cycle involving j steps. The energy conversion factor ϵ is

$$\epsilon = W/(Q + \Delta E) \quad (\text{C2.14.34})$$

where Q is the net energy input during the cycle. With the help of inequality (C2.14.32) and defining two dimensionless quantities:

$$\alpha = hc \sum_j |F_j - F_{j+1}|/(4QW_{\text{rev}}) \quad (\text{C2.14.35})$$

and

-23-

$$z = \Delta E/Q \quad (\text{C2.14.36})$$

(the relative energy cost of control), one can write

$$\epsilon/\epsilon_{\text{rev}} \leq (1 - \alpha/z)/(1 + z) \quad (\text{C2.14.37})$$

where $\epsilon_{\text{rev}} = W_{\text{rev}}/Q$, the classical conversion factor. The maximum possible value of this ratio is obtained by substituting z by its optimal value z_{opt} , obtained from the turning point of equation (C2.14.33) and given by

$$z_{\text{opt}} = \alpha(1 + \sqrt{1 + 1/\alpha}) \quad (\text{C2.14.38})$$

which is

$$\left(\frac{\epsilon}{\epsilon_{\text{rev}}}\right)_{\text{max}} = \frac{1 - 1/(1 + \sqrt{1 + 1/\alpha})}{1 + \alpha(1 + \sqrt{1 + 1/\alpha})}. \quad (\text{C2.14.39})$$

If more energy than z_{opt} is used, then α decreases because of the energy cost of information; if less, then ϵ decreases because of the irreversibility (dissipation etc). For a macroscopic system these quantities are insignificant. But consider the myosin motor: taking $F_j \approx 2$ pN [102, 103], the displacement $x \approx 10$ nm [102], and $Q \approx 0.067$ aJ (the energy released by hydrolysing a single ATP molecule), then the energy cost of optimum control, Qz_{opt} , is equivalent to hydrolysing almost 150 ATP molecules (cf [107]) and $(\epsilon/\epsilon_{\text{rev}})_{\text{opt}} = 0.0033$. As with the

storage reaction discussed earlier ([section C2.14.3.1](#)), reversible operation is far from efficient. Chemical to mechanical conversion occurs at a finite rate which may be essentially uncontrolled, i.e. determined intrinsically. The parallel to the storage reaction may be developed further by noting that the duty ratio of a molecular machine (the fraction of time the motor spends attached and working) corresponds to the fraction of time the store is open.

C2.14.6 THE SPECIFICITY OF BIOMOLECULAR INTERACTIONS

The marvellous intricacy of a living organism could not function without the multitude of highly specific interactions which pervade almost every aspect of physiology. The concept of molecular recognition can be traced at least as far back as Fischer's lock and key mechanism for the recognition of its substrate by an enzyme [108]. Given perfect mixing along with specificity, cell physiology could presumably function in a structureless medium on the basis of concentration gradients and diffusion; real cells are internally structured, but even the transport of molecules and organelles along cytoskeletal filaments requires specific binding of molecules to their carriers, and the assembly of large multimolecular, multifunctional complexes ([section C2.14.2.3](#)) also requires specific recognition between the constituents.

From the viewpoint of biophysical chemistry, the main problems to be solved are: (i) what is the submolecular basis of

-24-

recognition and (ii) what is the required degree of specificity? Beyond these two, the study of specific interactions inevitably leads to questions about the origin of specificity and how it evolved from more primitive and presumably less specific interactions, but these lie beyond the scope of this chapter.

C2.14.6.1 THE SUBMOLECULAR BASIS OF RECOGNITION

One of the earliest successes of biophysical chemistry in the postwar era, which helped to lay the foundations of modern molecular biology, was the discovery of the base pairing mechanism in nucleic acids [16, 37], based on the hydrogen bond [38, 109] ([figure C2.14.2](#)), which could be considered to be the most important bond in biology; as well as providing the basis for molecular recognition and all that implies, it also gives water its unusual and vital properties. As well as ensuring the fidelity of DNA replication and its transcription into RNA, nucleotide base pairing also allows RNA to adopt the unique structure ([figure C2.14.1](#) and [section C2.14.2.2](#)) needed for its subsequent translation into protein [110]. Furthermore, hydrogen bonding determines the folding of a denatured protein in water into its three-dimensional conformation via hydrogen bonds between donor and acceptor groups on polar amino acids, and the inability of water to form hydrogen bonds with apolar amino acid residues, which drives as many of them as possible into the protein interior.

Figure C2.14.2. The hydrogen bond in water. The oxygen lone pairs (shaded blobs) are the donors, and the hydrogen atoms the acceptors [177, 178].

Given that the hydrogen bond is rather weak, with bond energies $\Delta E \sim$ a few kT , biological recognition has to be based on multiple interactions (cf [section C2.14.3.3](#)). If dissociation requires the simultaneous, independent rupture of all the interactions, then k_b (cf [equation \(C2.14.13\)](#)) $\sim \exp(-\nu \Delta E/kT)$, where ν is the number of bonds, even a few of which, taken together, thereby become equivalent to a single strong covalent bond.

Hydrogen donor/acceptor complementarity, complemented by electrostatic complementarity, although this appears to play the minor role, is the basis for a vast effort in computational drug design based on putative receptor structures mostly derived from x-ray crystallography [111]. Calculations based on static structures without allowing for subtle structural modifications of the binding partners following initial association have produced less than spectacular results; attempts are now being made to incorporate flexibility into the simulated molecules. The simple idea of docking taking place much as two rigid spacecraft interact is further complicated by the ubiquitous presence of water, itself a strongly hydrogen bonding molecule. Some interactions may involve expulsion of solvent. The omission of water in numerical simulations of docking is likely to be fatal for the accuracy and relevance of the results.

-25-

C2.14.6.2 THE REQUIRED DEGREE OF SPECIFICITY

SEARCH AND DISCOVERY (SD)

A somewhat naïve view is that affinity should be maximal for the molecule to be recognized, and zero for all other molecules. This strategy may not overall be the most efficient for recognition. Given the essential similarity of many biomolecules, the complete absence of attraction or even the presence of repulsion between any given pair of dissimilar molecules is likely to be rather exceptional, but nature can make good use of weak, ‘nonspecific’ attractive interactions. Consider the recognition of a particular DNA base sequence, say 10 base pairs long, by a protein. This type of process is very common and is the basis of transcription regulation and DNA restriction (scission of foreign DNA). If out of all 4^{10} possible sequences only the correct sequence has any affinity, then it can only be found by a tedious process of trial and error in three-dimensional space. If the protein has weak affinity for all of the DNA however, it can quickly bind anywhere on the molecule, and then execute a fast one-dimensional walk along it until the recognition site is found [112]. Searching in one or two dimensions is much more efficient than in three [113], and it has been experimentally demonstrated that a dimerization reaction has a much higher affinity at the two-dimensional solid–liquid interface than in three-dimensional bulk liquid [79].

A conceptually related effect occurs in immune recognition, when a ligand (antigen) present at the surface of an antigen presenting cell (APC) is bound by a T lymphocyte (TL). Binding triggers a conformational change in the receptor protein to which the antigen is fixed, which initiates further processes within the APC, resulting in the synthesis of more receptors, and so on. Apparently, effective stimulation of these further processes depends on *sustained* activation at the surface (*pace* the noise-reduction effect of a response threshold discussed in [section C2.14.3.3](#), and cf [88]). This can be accomplished with a few, or even only one TL, provided the affinity is not too high: the TL binds, triggers one receptor, then dissociates and binds anew to a nearby untriggered receptor (successive binding attempts in solution are highly correlated [114, 115 and 116]). This ‘serial triggering’ [59] can formally be described by:

(with rate coefficient k_a) where the starred R denotes an activated receptor, and

with rate coefficient k_d for dissociation of the ligand from the activated receptor, and the same rate coefficient k_a for reassociation of the ligand with an already activated receptor. The rate of activation (triggering) is $-dr/dt = -k_a r$, solvable by noting that $d\ell/dt = -k_a(r + r^*) + k_d r_L^*$. One obtains

$$(C2.14.42)$$

$$\ell(t) = \frac{k_a \tau}{1 - Y e^{-t/\tau}} + \frac{k_a(\ell_0 - r_0) - k_d - 1/\tau}{2k_a}$$

-26-

where $\tau = \{4\ell_0 k_a k_d + [k_a(\ell_0 - r_0) - k_d]^2\}^{-1/2}$ and $Y = (k_d + k_a[\ell_0 + r_0] - 1/\tau)/(k_d + k_a[\ell_0 + r_0] + 1/\tau)$, and the sought-for solution is then

$$r(t) = r_0 \exp \left[\ln \left(\frac{1 - Y e^{-t/\tau}}{1 - Y} \right) - \frac{t}{\tau} \right]. \quad (\text{C2.14.43})$$

CELLULAR RECOGNITION

Yet another example of SD is provided by the leukocytes which are constantly circulating in the bloodstream but do not normally interact with tissue. Venules of inflamed and infected tissue are dilated, however, which changes the hydrodynamic regimen and allows some leukocytes to come into contact with the venule wall (endothelium) [117]. The leukocytes are coated with glycoproteins which can interact with selectins (proteins able to selectively bind oligosaccharides) present in the outer membranes of the venule wall tissue. The combination of weakened hydrodynamic flow and weak selectin-glycoprotein bonds induces the leukocytes to roll along the venule wall [117], until they encounter integrins, another class of membrane-embedded proteins, which are able to interact more strongly with complementary molecules embedded in the leukocyte outer membrane. The leukocyte then stops, spreads out over the endothelium and penetrates between its constituent cells in order to search for, and destroy, pathogens.

THE IMMUNE REPERTOIRE

Antibodies binding to an antigen interact with a relatively small portion of the molecule. The number N of foreign antigens which must be recognized by an organism is very large, perhaps greater than 10^{16} , and there is a smaller number N' ($\sim 10^6$) of self-antigens which must *not* be recognized. Yet the immunoglobulin and T-cell receptors may only contain $n \sim 10^7$ different motifs. Recognition is presumed to be accomplished by a generalized lock and key mechanism involving complementary amino acid sequences. How large should the complementary region be, supposing that the system has evolved to optimize the task [118]? (A similar problem is posed by the olfactory system [119].) If P_S is the probability that a random receptor recognizes a random antigen, the value of its complement $P_F = 1 - P_S$ maximizing the product of the probabilities that each antigen is recognized by at least one receptor, and that none of the self-antigens is recognized, i.e. $(1 - P_F)^N P_F^{nN'}$, is:

$$P_F = \left(1 + \frac{N}{N'} \right)^{-1/n}. \quad (\text{C2.14.44})$$

Using the above estimates for n , N and N' , one computes $P_S \approx 2 \times 10^{-6}$. Suppose that the complementary sequence is composed of m classes of amino acids and that at least c complementary pairs on a sequence of s amino acids are required for recognition. Since the probability of a long match is very small, to a good approximation the individual contributions to the match can be regarded as being independent. A pair is thus matched with probability $1/m$, and mismatched with probability $1 - 1/m$. Starting at one end of the sequence, runs of c matches occur with probability m^{-c} , and elsewhere they are preceded by a mismatch and can start at $s - c$ possible sites. Hence

$$P_S = [(s - c)(m - 1)/m + 1]/m^c. \quad (\text{C2.14.45})$$

If $s \gg c > 1$, one obtains

$$c = \log_m [s(m - 1)/m] - \log_m P_S. \quad (\text{C2.14.46})$$

Supposing s to be a few tens, $m = 3$ (positive, negative and neutral residues), and again using the numbers given above (since they all enter as logarithms the exact values are not critical) one estimates $c \sim 15$, which seems to be in good agreement with observation.

C2.14.6.3 MODELLING INTERACTIONS WITH BROWNIAN DYNAMICS

The first predictions of antibody–antigen binding rates were made on the basis of the Smoluchowski [equation \(C2.14.20\)](#). Experimental work suggested a rate about 1000 times slower, which was understood to reflect the rather precise rotational alignment required for two molecules to dock specifically, since the area of the docking zone (epitope) is only a tiny fraction of the total surface area of the antibody. Careful calculations taking this into account indicated that the actual rates should be about a million times slower than those predicted from [equation \(C2.14.20\)](#), and that the experimentally measured rates were therefore a thousand times faster than expected. Two interpretations for the discrepancy were proposed: long range attractive forces steering the antigen to the complementary sequence on the antibody [120]; and the Franck–Rabinowitsch (cage) effect [114, 116]. It was a notable early achievement of Brownian dynamics (BD) [120, 121 and 122] to elucidate the conditions under which either or both apply. In these simulations, a large number of Brownian trajectories of the ligand are started on the surface of a sphere of radius b centred on the receptor. A fraction β terminate with a successful encounter, and the remainder reach the surface of a ‘quitting sphere’ of radius $q > b$. The bimolecular association rate coefficient is $\beta k_a(b)/[1 - \Omega(1-\beta)]$, where

$$k_a(b) = \left[\int_b^\infty \frac{\exp(\Delta G^{\text{IF}}/RT)}{4\pi D z^2} dz \right]^{-1}. \quad (\text{C2.14.47})$$

$\Delta G^{\text{IF}}(z)$ is the ligand–receptor interfacial interaction potential ([section C2.14.7.1](#), [equation \(C2.14.52\)](#), [equation \(C2.14.53\)](#) and [equation \(C2.14.54\)](#)), and Ω is the probability that a particle at q will return to b , equal to the ratio $k_a(b)/k_a(q)$ [121].

In favourable contrast to molecular dynamics, BD allows molecular movements of realistically long duration to be simulated. Nevertheless, the practical number of protein molecules which can be simulated is only two; since collective phenomena are often of crucial importance in determining the course of interaction events, other simulation techniques, such as cellular automata [115], need to be used to capture the behaviour of large numbers of particles.

C2.14.7 INTERFACIAL PHENOMENA

Interfaces play a predominant role in metabolic processes [78], as well as in immune recognition (e.g. T lymphocytes recognizing antigens on the surface of antigen presenting cells, [section c2.14.6.2](#)). Historically, the bulk of experimental

work on the kinetics of biomolecular interactions has dealt with homogeneous systems, however. Heterogeneous systems are in principle very attractive for investigating molecular interactions experimentally because the

contribution of transport to the kinetics can be precisely controlled, allowing diffusion and chemical effects to be separated. Several excellent experimental techniques for investigating heterogeneous binding kinetics *in situ* have been developed during recent years. Compared with the methods available for homogeneous systems, they are generally more sensitive and less cumbersome, have better time resolution, and do not require the use of labelled molecules [61]. The *in situ* capability arises because the solid part of the interface can play an additional role as a transducer for converting the number of bound molecules into an electrical or optical signal. The various techniques may be classified as follows:

- i. *electrochemical*: typically the change of electrode impedance due to the adsorption of biomolecules is monitored. Another possibility is to monitor the collective oscillations (surface plasmons) of the electrons in a thin metallic film [123]. Since these oscillations are excited at optical frequencies the measured surface plasmon resonance (SPR) may be considered as a hybrid opto-electronic technique. The oscillations are retarded by interactions with biomolecules adsorbed at the metal surface;
- ii. *mechanical*: the oscillation frequency of a quartz crystal is inversely proportional to the mass of biomolecules (and their shape and viscoelasticity) attached to the crystal surface;
- iii. *optical*: the reflectance change of the solid–liquid interface due to the formation of a thin film of biomolecules is monitored. Since they are the most sensitive, the most versatile (especially regarding possible choices of solid materials) and the most informative, optical methods have become rather popular.

The simplest approach conceptually is to directly measure the reflectance at different angles and fit the Fresnel equations to the data (scanning angle reflectometry, SAR) [124]. A thin film of adsorbed biomolecules needs at least two parameters to characterize it, its refractive index n_A and geometrical thickness d_A . Even though an adlayer composed of randomly adsorbed particles is nonuniform (heterogeneous on the nanometer scale), the uniform thin film approximation appears to yield satisfactory results [125], although the optically determined geometrical thickness depends on the refractive index profile perpendicular to the interface and may be smaller than the largest dimension of the adsorbed molecule. The number ν of adsorbed molecules per unit area can be calculated from the relation [126]

$$\nu = \frac{(n_A - n_C)d_A}{dn/dc} \quad (\text{C2.14.48})$$

where n_C is the refractive index of the solvent and dn/dc is the refractive index increment of the biomolecules in solution [127].

The Fresnel equations predict that reflexion changes the polarization of light, measurement of which forms the basis of ellipsometry [128]. Although more sensitive than SAR, it is not possible to solve the equations linking the measured parameters with n_A and d_A in closed form, and hence they cannot be solved unambiguously, although their product yielding ν (equation C2.14.48) appears to be robust.

The most recently introduced optical technique is based on the retardation of light guided in an optical waveguide when biomolecules of a polarizability different from that of the solvent they displace are adsorbed at the waveguide surface (optical waveguide lightmode spectroscopy, OWLS) [11]. It is even more sensitive than ellipsometry, and the mode

equations characterizing the phase velocities of the guided light can be solved analytically to yield n_A and d_A . All work reported so far appears to have been restricted to the measurement of two modes, which are sufficient to completely characterize uniform isotropic films, but in principle higher modes can also be measured, enabling more complex films to be characterized. The integrated optical interferometer [129], in which two orthogonally polarized modes interfere with one another (since each polarization interacts differently with the adsorbed biomolecules, the interference pattern shifts according to ν) is a further development which offers even higher sensitivity,

proportional to the path length over which interference and adsorption take place.

C2.14.7.1 BIOCOMPATIBILITY

The reactions of biopolymers at interfaces form the basis of some extremely important industrial processes. The primary process in all cases is the adsorption of biomolecules, usually proteins. If ultimately living cells are adsorbed, this always takes place onto a preadsorbed protein layer (which may be secreted by the cells themselves [130]). These processes can be classified into three categories:

- i minimal adsorption, as in the preparation of materials for surgical implants in contact with the blood (stents, replacement tubing, heart valves, biosensors, etc), filtration (including renal dialysis), storage of pharmaceuticals in solution, and antifouling paint for ships' hulls;
- ii maximal adsorption, mainly for surgical implants in contact with tissue (e.g. replacement bones) which should be mechanically firmly integrated into the host;
- iii variable adsorption, as in coatings for chromatographic separation materials.

Current emphasis is on the behaviour of proteins at the solid–liquid interface, but liquid–air and liquid–liquid interfaces, which were actually investigated much earlier [131], are still important.

Much of the science of biocompatibility can be reduced to the principles of how to determine the interfacial energies between biopolymer and surface. The biopolymer is considered to be large enough to behave as bulk material with a surface; since (for example) a water cluster containing only 15 molecules and with a diameter of 0.5 nm already behaves as a bulk liquid [132] it appears that most biological macromolecules can be considered to have surfaces. The interfacial energy ΔG^{IF} can be decomposed into three components:

$$\Delta G_{123}^{IF} = \Delta G_{123}^{(LW)} + \Delta G_{123}^{(da)} + \Delta G_{123}^{(el)} \quad (C2.14.49)$$

corresponding to the Lifschitz–van der Waals (LW), electron donor-acceptor (da) and electrostatic (el) interactions; subscripts 1, 2 and 3 refer to solid, solvent and biopolymer respectively.

A salient feature of natural surfaces is that they are overwhelmingly electron donors [133]. This is the basis for the ubiquitous 'hydrophilic repulsion' which ensures that a cell can function, since massive protein–protein aggregation and protein–membrane adsorption is thereby prevented. In fact, for biomolecule interactions under typical physiological conditions, i.e. aqueous solutions of moderately high ionic strength, the donor–acceptor energy dominates.

-30-

Tables of single substance surface tensions γ can be built up through the measurement of contact angles [134]; a few examples are collected in [table C2.14.1](#). These can be combined pairwise according to:

$$\gamma_{12}^{(LW)} = (\sqrt{\gamma_1^{(LW)}} - \sqrt{\gamma_2^{(LW)}})^2 \quad (C2.14.50)$$

and

$$\gamma_{12}^{(da)} = 2(\sqrt{\gamma_1^{\oplus}} - \sqrt{\gamma_2^{\oplus}})(\sqrt{\gamma_1^{\ominus}} - \sqrt{\gamma_2^{\ominus}}). \quad (C2.14.51)$$

The interfacial free energies for infinite parallel surfaces at contact are given by the relation [134]:

$$\Delta G_{123}^{(\text{LW or da})\parallel} = \gamma_{13}^{(\text{LW or da})} - \gamma_{12}^{(\text{LW or da})} - \gamma_{23}^{(\text{LW or da})} \quad (\text{C2.14.52})$$

and these can already provide an indication whether a surface is suitable for promoting or hindering biopolymer adsorption.

A next step is to consider the surface–particle distance z and curvature (interfacial radius R) dependence of the interactions [134], for which approximate expressions are:

$$\Delta G^{(\text{LW})} = 2\pi \ell_0^2 \Delta G^{(\text{LW})\parallel} R/z \quad (\text{C2.14.53})$$

where ℓ_0 is the equilibrium contact distance (distance of closest approach);

$$\Delta G^{(\text{el})} = 4\pi \varepsilon_0 \varepsilon \psi_1 \psi_3 \ln[1 + \exp(-\kappa z)] R \quad (\text{C2.14.54})$$

where the ψ are the electrostatic surface potentials (see [135] for an up-to-date discussion), and $1/\kappa$ is the Debye length; and

$$\Delta G^{(\text{da})} = 2\pi \chi \Delta G^{(\text{da})\parallel} \exp[(\ell_0 - z)/\chi] r \quad (\text{C2.14.55})$$

where χ is the decay length for the da interaction. These equations (equation C2.14.53), (equation C2.14.54) and (equation C2.14.55) are for a sphere approaching an infinite plane; for two spheres approaching each other the perfect energies must be halved. Their sum (C2.14.49) can be integrated to compute the association distance δ_a [136]:

-31-

$$\delta_a = \int_{\ell_0}^{\infty} [\exp(\Delta G(z)/kT) - 1] dz \quad (\text{C2.14.56})$$

whence the adsorption rate constant (cf k_f in section C2.14.4 can be computed:

$$k_a = D/\delta_a. \quad (\text{C2.14.57})$$

Cases are known in which the use of the single substance surface tensions leads to predictions at variance with observation. For example, using equations (C2.14.49), (C2.14.50), (C2.14.51), (C2.14.52), (C2.14.53), (C2.14.54) and (C2.14.55) and the data in table C2.14.1 the interfacial free energy between serum albumin and silica is predicted to be positive, and the protein should therefore be repelled, whereas as is well known it is strongly adsorbed. There are several possible reasons for discrepancies. One is that the characteristic length scale of the (macroscopic) surface tension is different from (probably larger than) the characteristic length for protein adsorption; possibly it is more appropriate to use the microsurface tension [137] for these calculations. Another is that the use of average curvatures, surface potentials and so on is too crude for biomolecules with their intricate surface topography. Finally, equation C2.14.49, equation C2.14.50, equation C2.14.51, equation C2.14.52, equation C2.14.53, equation C2.14.54 and equation C2.14.55 assume that the protein remains unchanged upon interaction with the surface. While this is likely to be true up to the moment of initial contact, native folded proteins are only marginally stable and intramolecular contacts maintaining the native structure may be substituted by molecule–surface contacts with

concomitant unfolding. Since [equation C2.14.56](#) and [equation C2.14.57](#) apply to the approach of the protein up to its initial contact with the surface, [equation C2.14.49](#), [equation C2.14.50](#), [equation C2.14.51](#), [equation C2.14.52](#), [equation C2.14.53](#), [equation C2.14.54](#) and [equation C2.14.55](#) should be valid for computing k^a [equation C2.14.56](#) – [equation C2.14.57](#), but a complete description of the adsorption process must take subsequent events into account. Folding is entropically costly since compact configurations are restricted to fairly small regions of the Ramachandran map [39], but in the native conformation this cost is outweighed by the enthalpy-losing intramolecular contacts. At a surface, however, the possibility of losing enthalpy by protein–surface contacts enables the molecule to adopt an extended, less entropically costly (since the corresponding Ramachandran map regions are large) configuration. This view is corroborated by observed changes in the optical rotation (circular dichroism) of protein solutions to which minute colloidal particles onto which the proteins can adsorb are added; the changes are consistent with varying degrees of loss of α -helical secondary structure [138]. There are still some puzzles, however: some protein–surface combinations appear to lead to an increase of α -helical structure [139], and differential scanning calorimetry of proteins in the absence and presence of minute colloidal particles [140] have shown that the temperature of the denaturation transition can be significantly lower for adsorbed proteins compared with the native dissolved state. Clearly the nature of the protein–surface contacts need more careful scrutiny: a complicating feature is that if conformational rearrangement does take place, it will usually lead to a biopolymer surface chemically different from that of the native conformation. For example, essentially no polar amino acids are found in the interior of a globular protein, and therefore almost any conformational rearrangement must result in the dilution of polar residues on the surface. The diminished protein surface polarity should result in stronger adsorption to apolar surfaces. A plethora of non-native adsorptive contacts constraining the polypeptide chain could in principle cost even more entropy than the native folded structure. Desolvation of the protein–solvent and protein–surface interfaces will also contribute to the free energy [141]. A further complication at all but the lowest coverages is that lateral interactions between adsorbed proteins will also affect ΔG^{IF} [142]. Far too few different proteins and surfaces have been investigated experimentally sufficiently carefully for reliable general conclusions to be drawn on these matters at present.

Table C2.14.1 Single substance macroscopic surface tensions/(mJ m⁻²) of various materials (data mostly from [134]).

Material	$\gamma^{(LW)}$	γ^{\oplus}	γ^{\ominus}
Biomaterials			
Cellulose	44	1.6	17
Dextran T-150	42	0	55
Fibrinogen	37	0.1	38
Immunoglobulin	34	1.5	50
Lecithin	29	2.7	60
Serum albumin	27	6.3	51
Synthetic polymers			
Nylon 6,6	36	0.02	22
Polyethylene	33	0	0
Polyethylene oxide	43	0	64
Polystyrene	42	0	1.1
Polyvinyl chloride	43	0.04	3.5
Teflon	18	0	0

Metal oxides

Materials implanted in a living body should not engender an immune response. Even though the adsorption of a few pure proteins to interfaces under diverse conditions appears now to be reasonably well characterized, at least phenomenologically, adsorption from highly complex body fluids such as blood are only just beginning to be investigated quantitatively using the same methods applied successfully to pure materials [143]. Among the hundreds of different proteins in blood are enzymatic networks capable of triggering thrombus formation [144], or an immune response as soon as the adsorbed layer acquires certain, essentially still unknown, attributes. Furthermore, the implanted material must not corrode or disintegrate, releasing particles which could themselves engender an immune response. In fact, a truly biocompatible material needs to have an adaptive capability, and should thus qualify for the appellation ‘smart’, just as biological tissue itself does.

C2.14.7.2 KINETICS OF BIOPOLYMER ADSORPTION

The presence of the solid surface imposes new conditions onto the disposition of reactants, compared with the homogeneous case (section C2.14.4.1). Adsorption is often observed to approach a plateau, yet is irreversible with respect to dilution. The plateau must therefore arise because no more space is available for adsorption, rather than through a dynamic adsorption–desorption equilibrium and it can be inferred that the dissolved biopolymer does not adsorb to its preadsorbed congeners. This behaviour is by no means universal: it has been proposed that the plaques associated with spongiform encephalopathies arise through the native, normally soluble PrP^C protein being partially denatured upon contact with a surface to become the pathogenic PrP^{Sc} form, to which the PrP^C can adhere to form multilayers.

A common feature of biopolymer adsorption is that its rate is usually one to three orders of magnitude smaller than the diffusion-limited rate to a perfect sink:

$$(dv/dt)_{\max} = Dc_b/\delta \quad (\text{C2.14.58})$$

where C_b is the bulk dissolved concentration and δ the thickness of the diffusion boundary layer [145] (this can be quickly ascertained by drawing a tangent to a plot of v versus t at $t \rightarrow 0$ and comparing its slope with the right-hand side of equation C2.14.58. This implies the existence of an energy barrier characterized by a rate coefficient k_a (equations (C2.14.56) and (C2.14.57)). For adsorption to small particles (colloidal minerals, vesicles etc.) of radius R , the effective δ is given by [146]:

$$(\text{C2.14.59})$$

$$1/\delta_{\text{eff}} = 1/R + 1/\delta.$$

Even cursory inspection of typical (v,t) data shows that the evolution does not follow the single exponential approach to saturation implied by, for example, (equation C2.14.22) with initial concentrations $\lambda_0 \gg s_0$. Such data are sometimes described as ‘biphasic’, and one encounters attempts to fit and interpret them with two exponentials, even though there does not seem to be any theoretical justification for doing so. The basic kinetics of adsorption are described by:

$$dv/dt = k_a c_v \phi \tag{C2.14.60}$$

-34-

where c_v is the concentration in the vicinity of the surface and depends on c_b , k_a and hydrodynamic factors, i.e. D and δ [87], and ϕ is the fraction of the surface available for adsorption. The familiar Langmuir expression $\phi = 1 - \theta$, where θ is the fraction of surface occupied, introduced to describe the adsorption of gases onto metals, whose surface is assumed to consist of discrete, noninteracting sites larger than the ligand, indeed predicts an exponential approach to saturation. For most cases of practical interest in biocompatibility, however, the Langmuir assumptions are invalid: the surface is a continuum. The adsorption of one particle creates an *exclusion zone* around it, within which the centre of another particle may not adsorb, since particles cannot overlap. The exclusion zone has twice the diameter of the particle and its area is quadruple that of the particle, hence, for small θ , $\phi = 1 - 4\theta$. As coverage increases, exclusion zones begin to overlap and the factor -4θ overcompensates for the loss of available area; for the overlap of two exclusion zones, a factor proportional to θ^2 , and for the overlap of three exclusion zones, a factor proportional to θ^3 , must be added back [147], the proportionality constants depending on the shapes of the particles and whether lateral diffusion or desorption is allowed. This problem of random sequential adsorption (RSA) has been solved exactly in one dimension (useful for describing proteins adsorbing onto DNA) [148], and accurate interpolation formulae, for two dimensions are now available [149], which have been shown to describe experimental adsorption data very well [150]. The RSA process has infinite memory and the configurations generated are quite different in many respects from their equilibrium counterparts [151].

RSA has turned out to be an extremely useful formalism for making structural inferences from adsorption kinetics. Where pure random sequential adsorption is observed, the area a occupied per molecule can be determined (note that a is the constant of proportionality between θ and v). If this area depends on c_b , conformational rearrangement leading to spreading is inferred and its kinetics and magnitude can be determined [152]. Nucleation and growth of two dimensional islands also have a characteristic kinetic signature [153]. Occasionally, Langmuir adsorption is observed in protein adsorption onto a continuum [154], unambiguously implying that clustering or crystallization of the adsorbed biopolymer takes place, thereby annihilating the exclusion zones. Both kinetic parameters and the crystal unit cell dimensions can then be determined [154].

A simple mapping enables the RSA formalism to be applied to binding of a ligand L to receptors R embedded in a surface (the RSA-random site (RSA-RS) model) [149],

-35-

C2.14.8 BIOLOGICAL INFORMATION

Information, like energy, is an irreducible concept, but is surprisingly rarely mentioned in textbooks of biophysical chemistry (whereas bioenergetics has developed into a distinct field of its own). Yet information is maybe even more germane than energy to the very essence of life, starting with the DNA which, it is often stated, encodes our organism, initially via the amino acid sequence which encodes protein structure, and so on. The neologism ‘bioinformatics’ usually denotes the analysis of DNA sequences, in particular the comparison of sequences derived from different organisms but apparently encoding the same protein. That this is a very difficult task is well illustrated by the analysis of transcriptional promoter sequences (to which a protein must bind in order for transcription to be initiated), which have few discernible common features which could be used to identify them.

To get some flavour of the magnitude of the problem, consider that the familiar bacterium *E. coli* contains almost five million nucleic acid base pairs, which encode about 4000 genes and a comparable number of promoters. Eukaryotic organisms have much more DNA, of which only a small proportion appears to code for proteins. It is a puzzle that non-coding DNA (introns and intra-gene sequences) shows long range correlations whereas coding DNA does not [156].

Perhaps the central question in this field is whether the genome specifies the construction of the organism in a rather deterministic (and hierarchical, according to the homeotic gene concept [157]) fashion, or whether the genes merely specify rules with which the organism can be constructed, more in the spirit of the stigmergic building referred to previously [45], or the brain, in which it appears that connexions between specific cells are not preprogrammed, but grow according to an algorithm given genetically to select certain favourable system structures [158]; moving back a stage further, the genes could merely specify how to construct an algorithm for specifying the construction. It is actually difficult to establish the existence of a real command structure, and it is consequently legitimate to enquire whether so-called master genes are merely akin to the king who daily ordered the sun to set, and in the morning to rise again, and was considered by most of his subjects to be an omnipotent autocrat whose orders were infallibly obeyed. What is established is that genes are powerless in isolation: they specify protein, but the realization of the specifications (and indeed the synthesis of the genes themselves) itself involves (other) proteins. The scheme of organization thus appears to be heterarchical rather than hierarchical, rather like the brain [159].

Current views of metabolic regulation are largely inspired by the *lac* operon of *E. coli*, which was comprehensively described almost 40 years ago [160] and was for many years thereafter the sole exemplar discussed in textbooks. Much work has been dedicated to identifying and characterizing the molecules involved, but how all these elements fit together remains elusive [161], and the need to move beyond the treatment of individual elements in isolation, towards concepts such as distributive control and supramolecular organization has been stressed [162]. Systems theory [12, 163, 164] was originally developed to render tractable this jungle of complexity, but it no longer seems to be part of mainstream research in the field, possibly because of the insufficiently close collaboration of the different disciplines which would have been needed to ensure its successful application to biological problems [165]. More recently an approach based on analogies between genetic and electric circuits seems capable of yielding valuable insights [166, 167, 168].

Biological information is also concerned with the analysis of biological messages and their import. The fundamental premise of the protein-folding problem section C2.14.2.2 is that the full three-dimensional arrangement of the protein molecule can be predicted, given only the amino acid sequence, together with the solvent composition, temperature and pressure. One test of the validity of this premise is to compare the information content of the sequence with the information contained in the structure [169]. The former can be obtained from Shannon's formula:

-36-

$$H = - \sum_{r=1}^R p_r \log_2 p_r \quad (\text{C2.14.64})$$

where p_r is the probability of occurrence of the r th amino acid, and the latter can be quantified via the algorithmic complexity [169]; they are approximately 2 and 0.5 bits per amino acid respectively, i.e. the sequence contains somewhat more information than is required by the structure. This is a puzzle. Clearly discussion of information content needs to be complemented by an appraisal of the value of the information [65]. The discrepancy between the two measures hints at the protein indeed being an object whose structure in part reflects noise expressed macroscopically [66, 158].

Analysis of the global statistics of protein sequences has recently allowed light to be shed on another puzzle, that of the origin of extant sequences [170]. One proposition is that proteins evolved from random amino acid chains, which predict that their length distribution is a combination of the exponentially distributed random variable giving the intervals between start and stop codons, and the probability that a given sequence can fold up to form a compact

structure, which increases with sequence length. An alternative view is that modern proteins evolved from a small set of ‘starter’ sequences, but this does not provide a simple, natural explanation for the observed extant distribution in the way that the first proposition does [170].

Reference to gene chips as a tool for investigating the expression of messenger RNA (mRNA), the precursor to protein synthesis, has already been made [section C2.14.1](#). The alternative is to extract all the proteins in a cell and separate them (according to molecular weight and isoelectric point) using two-dimensional gel electrophoresis [171], after which their abundances may be quantified. This is a much more onerous procedure than the gene chip method, and has its own drawbacks, such as poor recovery of membrane proteins, but on the other hand the relationship between mRNA and protein abundance is complex, nor can the gene chip take account of the numerous post-translation modifications such as glycosylation.

The collection of proteins expressed in a cell is called its *proteome* (cf the genome, the collection of genes). Much effort has been expended on identifying the individual proteins separated by 2D gel electrophoresis, but this is rather like discussing an author’s use of particular words, for example when the authorship of a work is disputed: as Yule has pointed out in that context, such discussion gives not the slightest notion as to what the vocabulary is like *as a whole* [172]. It is therefore of great interest to examine the properties of the entire proteome, and such an investigation has yielded the curious result that the distribution of rates of protein synthesis p_r (or protein abundances) in prokaryotes follows the simple canonical law (scl):

$$p_r = P(r + \rho)^{-1/\theta} \tag{C2.14.65}$$

where r is the rank, and P , ρ and θ are parameters, remarkably well [173]. This might be regarded merely as a useful exercise in data reduction were it not for the fact that the simple canonical law is precisely the distribution expected for a communication system minimizing its energy expenditure, while constrained by the given amount of information which has to be conveyed, word by word.

The distribution also has a certain information content which can be calculated using equation (C2.14.64), and it turns

out that this is a rather low number: typically around 8 bits/protein [173], far less than the information contained in the sequence, let alone in the structure [169]. Does this mean that much of the sequence-structure information is actually irrelevant to the protein, which has ‘merely’ to fulfil a certain specified function? For an enzyme or a protein which has to recognize a substrate or a binding site, the conformation and side-chain chemistry of the catalytic or binding site may be far more crucial than the rest of the protein. But one should also bear in mind that proteins do not exist in isolation. Their expression (and folding, for about 10% of proteins) requires the presence of other proteins, and nearly all proteins interact with others, either to build up structures, or in subtle and complex signalling pathways. Hence the information content and value of an individual protein cannot be assessed in isolation, but must be evaluated in the context of the entire repertoire, just as the genome is not a mosaic of individual genes, each coding for a single protein or attribute, but a highly complex interconnected, possibly even heterarchical, network [174]; and just as a little ‘no’ in a long paragraph could be absolutely crucial to the import of the entire message.

C2.14.9 CONCLUDING REMARKS

The study of living organisms, although traditionally reserved for the biologist, is a field in which biology, chemistry and physics must work together in order to make real advances. Ageno [16] has further emphasized that to view this development as the ‘conquest’ of one discipline by another is quaintly outmoded: the classification of this or that field as part of a particular discipline is rather arbitrary and mainly of historical interest. The fusion of the work of the biologist, chemist and physicist is irremediable; one may call this fusion biological physics, or, more comprehensively, biophysical chemistry; a toolbox with the help of which a mathematical description of biological

phenomena can be given. Sometimes these descriptions will be caricatures of reality, but one hopes that they at least fulfil their purpose of capturing its essence.

It has become fashionable to prefix the names of disciplines with ‘bio’, as in biophysics, bioinformatics and so on, giving the impression that in order to deal with biological systems, a different kind of physics, or information science, is needed. But there is no imperative for this necessity. Biological systems are often very complex and compartmentalized, and their scaling laws may be different from those familiar in inanimate systems, but this merely means that different emphases from those useful in dealing with large uniform systems are required, not that a separate branch of knowledge should necessarily be developed.

Experimental work in the field is often burdened by tension between the small amounts of pure materials generally available for investigation (a problem compounded by their instability) and the complexity of biological systems and hence the large number of possible interpretations of data, which calls for more detailed investigation than otherwise. The frequently encountered, seemingly poor, reproducibility of experiments with biological materials and systems also calls for more experiments than would suffice for simpler systems. This ‘irreproducibility’ might well be a manifestation of the fact that the measured phenomena are the result of multiplicative rather than additive processes. For the latter, the sum and its distribution converge rapidly enough to their asymptotic values; for the former, a principle comparable to the central limit theorem is lacking; in fact the average value of the product diverges exponentially from the most probable value as the number of random variables contributing to it increases [175].

C2.15 Optoelectronics

William L Wilson

C2.15.1 INTRODUCTION

Optoelectronic technologies [1] encompass a wide variety of devices and structures used to generate, manipulate, detect and direct light signals. This interdisciplinary field, born at the intersection of microelectronics and optics, is poised to provide the primary building blocks of the communications and computing infrastructure of the 21st century. The development of high-bandwidth optical networks using wave division multiplexing [2], for example, requires a wide variety of components for network construction. The optical communications and optical networking revolution is being fought with fibre, optical routers, modulators and detectors. The development of these basic optoelectronic components will be key in determining the progression of communication technologies for years to come.

In this chapter we review the fundamental processes which allow us to define and control optical sources and signals. The basic mechanisms for generation, transmission and manipulation are described. A large number of detailed treatises have been published describing many of the phenomena covered here [3, 4, 5, 6 and 7]. Because of space limitations, we will offer rudimentary descriptions and insights of the subjects covered and will attempt to ensure that the references listed will allow exploration of the subject matter to whatever detail is desired. It is important to note that any description of optoelectronic technologies will have roots deep in optical physics, quantum mechanics and electromagnetic theory. Here only essential formulae are derived; detailed derivation of all the expressions can be found in the references cited. Our goal is to give the reader a flavour of the technology and hopefully to stir your imagination and interest in this exciting, evolving and rapidly expanding field.

C2.15.2 ELECTROMAGNETIC WAVES

In order to understand how light can be controlled, we must first review some of the basic properties of the electromagnetic field [8]. The electromagnetic theory of light is governed by the equations of James Clerk Maxwell. The field phenomena in free space with no sources are described by the basic set of relationships below:

$$\nabla \times \mathbf{H} = \epsilon_0 \frac{\partial \mathbf{E}}{\partial t} \quad (\text{C2.15.1})$$

$$\nabla \times \mathbf{E} = -\mu_0 \frac{\partial \mathbf{H}}{\partial t} \quad (\text{C2.15.2})$$

$$\nabla \cdot \mathbf{E} = 0 \quad (\text{C2.15.3})$$

$$\nabla \cdot \mathbf{H} = 0 \quad (\text{C2.15.4})$$

-2-

where \mathbf{E} and \mathbf{H} are the electric and magnetic fields respectively. Here the constants ϵ_0 and μ_0 are the electric permittivity and the magnetic permeability of free space.

The necessary boundary conditions required for \mathbf{E} and \mathbf{H} to satisfy Maxwell's equations give rise to the well known wave equation for the electromagnetic field:

$$\nabla^2 U - \frac{1}{c^2} \frac{\partial^2 U}{\partial t^2} = 0 \quad (\text{C2.15.5})$$

where $c = 1 / (\epsilon_0 \mu_0)^{1/2} = 3 \times 10^8 \text{ m s}^{-1}$, the speed of light in a vacuum.

This wave equation is the basis of all wave optics and defines the fundamental structure of electromagnetic theory with the scalar function U representing any of the components of the vector functions \mathbf{E} and \mathbf{H} . (Note that equation (C2.15.5) can be easily derived by taking the curl of equation (C2.15.1) and equation (C2.15.2) and substituting relations (C2.15.3) and (C2.15.4) into the results.)

Although a complete treatment of optical phenomena generally requires a full quantum mechanical description of the light field, many of the devices of interest throughout optoelectronics can be described using the wave properties of the optical field. Several excellent treatments on the quantum mechanical theory of the electromagnetic field are listed in [9].

In general, the wave equation describes the propagation characteristics of a disturbance through some transparent media, specifically the electromagnetic wave is just a subset of the physical phenomena which satisfy this relationship. The solutions of this equation with appropriate boundary conditions gives rise to all the behaviours we commonly associate with the wave properties of light. For monochromatic waves, all of the components of the electric field are harmonic functions of time and space. Electromagnetic waves are by definition *transverse*, i.e. the electric (\mathbf{E}) and magnetic (\mathbf{H}) field disturbances are orthogonal to the propagation direction (z), with the \mathbf{E} and \mathbf{H} fields orthogonal to each other (figure C2.15.1). The electric field is characterized by the amplitude (A), the wavelength (λ), the phase of the wave and the velocity of the wavefront. The plane wave is the most general and simplest example of a three-dimensional solution of the wave equation, in addition it provides a somewhat ideal input field for all optoelectronic applications. The wave has the form:

$$U(\mathbf{r}, t) = A e^{-i(\mathbf{k} \cdot \mathbf{r} - \omega t)} \quad (\text{C2.15.6})$$

where A is the amplitude of the field disturbance, \mathbf{k} is the propagation vector and has the magnitude $2\pi/\lambda$ and ω is the angular frequency, $\omega = 2\pi\nu$.

-3-

where A is the amplitude of the field disturbance, \mathbf{k} is the propagation vector and has the magnitude $2\pi/\lambda$ and ω is the angular frequency, $\omega = 2\pi\nu$.

Figure C2.15.1. The transverse electromagnetic wave.

This basic equation describes waves, whose properties are related as follows:

$$\nu = \frac{c}{\lambda} \tag{C2.15.7a}$$

$$\frac{\omega}{k} = v_p = \frac{1}{\sqrt{\mu_0 \epsilon_0}} \tag{C2.15.7b}$$

where ν is the frequency of the wave and v_p is the phase velocity.

For the electromagnetic fields \mathbf{E} and \mathbf{H} the form of the waves of interest is

$$\begin{aligned} \mathbf{E}(\mathbf{r}, t) &= \mathbf{E}_0 e^{-i(\omega t - \mathbf{k} \cdot \mathbf{r})} \\ \mathbf{H}(\mathbf{r}, t) &= \mathbf{H}_0 e^{-i(\omega t - \mathbf{k} \cdot \mathbf{r})} \end{aligned} \tag{C2.15.8}$$

for many of the applications described here.

Above we described the nature of Maxwell's equations in free space in a medium, two more vector fields need to be

-4-

$$\nabla \times \mathbf{H} = \frac{\partial \mathbf{D}}{\partial t} \tag{C2.15.9}$$

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \quad (\text{C2.15.10})$$

$$\nabla \cdot \mathbf{D} = 0 \quad (\text{C2.15.11})$$

$$\nabla \cdot \mathbf{B} = 0 \quad (\text{C2.15.12})$$

with

$$\mathbf{D} = \varepsilon_0 \mathbf{E} + \mathbf{P} \quad (\text{C2.15.13})$$

$$\mathbf{B} = \mu_0 \mathbf{H} + \mu_0 \mathbf{M}. \quad (\text{C2.15.14})$$

These new quantities allow us to directly relate properties of the *media* to \mathbf{E} and \mathbf{H} . In essence they afford us the opportunity to quantify the field–matter interaction. The media response to the fields is described generally in terms of the polarization, \mathbf{P} and the magnetization, \mathbf{M} . (We note that in free space \mathbf{P} and $\mathbf{M} = 0$ and we recover [equation \(C2.15.1\)](#), [equation \(C2.15.2\)](#), [equation \(C2.15.3\)](#) and [equation \(C2.15.4\)](#) above.)

For isotropic media we will assume that \mathbf{P} is parallel to \mathbf{E} with the coefficient of proportionality independent of direction:

$$\mathbf{P} = \chi_e \mathbf{E} \quad (\text{C2.15.15})$$

where the constant χ_e is the electric susceptibility of the medium. The electric displacement is therefore proportional to \mathbf{E} :

$$\mathbf{D} = \varepsilon \mathbf{E} \quad (\text{C2.15.16})$$

where $\varepsilon = 1 + 4\pi\chi_e$ is the dielectric constant. This parameter relates the material properties of the media to the polarization generated through its interaction with the external field. This polarization becomes a source term in Maxwell's equations giving rise to new fields mediated *via* the material–field interaction [9]. Absorption and dispersion processes can be attributed to ε with

$$\hat{n} = \sqrt{\varepsilon} = n + iK \quad (\text{C2.15.17})$$

being the complex refractive index, where the real part is related to dispersive properties of the media and K , the absorption coefficient, is determined by the imaginary part of the polarization [8].

The last attribute of the electromagnetic field we need to discuss is wave polarization. The nature of the transverse field is such that the oscillating field disturbance (which is perpendicular to the propagation direction) has a particular orientation in space. The polarization of light is determined by the time evolution of the direction of the electric field

-5-

vector $\mathbf{E}(r,t)$. In our description, \mathbf{E}_0 is modulated by a phase factor which maps out the field oscillation in space. If z is the axis of propagation, we can define the amplitude factor as

$$\mathbf{E}_0 = E_x \hat{x} + E_y \hat{y} \quad (\text{C2.15.18})$$

where the unit vectors \hat{x} and \hat{y} are orthogonal and

$$E_x = e_x \exp(i\phi_x) \quad (\text{C2.15.19})$$

the amplitudes e_x with their phase factors ϕ map out the polarization vector in the x – y plane. The resultant \mathbf{E}_i ranges from linear polarized light, for ϕ_x or $\phi_y = 0$, through all possible combinations resulting in elliptical fields. In figure

C2.15.2 a right circularly polarized wave is illustrated. As the wave propagates, E_0 sweeps out a circle in the x - y plane. It is clear that, given a well characterized light source, there are many attributes we can attempt to control (wavelength, polarization, etc.); the question is how to generate well-characterized light?

Figure C2.15.2. Right circularly polarized light. As the wave propagates the resultant E sweeps out a circle in the x - y plane.

C2.15.3 SOURCES: THE LASER

Given the general description of the electromagnetic field, let us explore the sources available for optoelectronics. The one primary light source for optoelectronic device and system architectures is the laser. The laser [10] is the source of choice simply because if we want to control light fields they need to be well defined at the start and the laser is the most

The acronym LASER (Light Amplification via the Stimulated Emission of Radiation) defines the process of amplification. For all intents and purposes this method was elegantly outlined by Einstein in 1917 [11] wherein he derived a treatment of the dynamic equilibrium of a material in a electromagnetic field absorbing and emitting photons. Key here is the insight that, in addition to absorption and spontaneous emission processes, in an excited system one can stimulate the emission of a photon by interaction with the electromagnetic field. It is this ‘stimulated’ emission process which lays the conceptual foundation of the laser.

The essential result of quantum theory [12] is that each physical system can be found upon measurement to be in one of a pre-determined set of energy states—the eigenstates of the system. These eigenstates [13] result from the solution of the Schrödinger equation for the system under study with the Hamiltonian [13] chosen to give the most complete characterization of the total energy of the system. Some classic analyses of generic systems [13] include the harmonic oscillator, the hydrogen atom and the hydrogen molecule ion problems. In each of these cases the solutions allow us to adequately predict the energetic processes for the complex systems mentioned. Let us assume we have a system described by Figure C2.15.3. Let us isolate two levels E_1 and E_2 . If the system is in E_2 , there is a finite probability per unit time that the system will decay to E_1 with the emission of a photon of energy $h\nu_{21}$. (The energy difference is $(E_n - E_{n-1}) = h\nu_{n,n-1}$.) This spontaneous emission is characterized by a lifetime for state E_2 . For an ensemble of the systems described above, we can represent the time rate of change of the population density as

$$-\frac{d\rho_2}{dt} = A_{21}\rho_2 = \rho_2/(\tau_{\text{spon}}) \quad (\text{C2.15.20})$$

Figure C2.15.3. Generalized energy level diagram.

-7-

In the presence of an electromagnetic field of energy of about $h\nu_{21}$, our systems can undergo absorptive transitions from E_1 to E_2 , extracting a photon from the electric field. In addition, as described by Einstein, the field can induce emission of photons from E_2 to E_1 (given E_2 is occupied). Let the energy density of the external field be $E(\nu)$ then,

$$W_{21} = B_{21}E(\nu) \quad (\text{C2.15.21})$$

$$W'_{12} = B_{12}E(\nu) \quad (\text{C2.15.22})$$

where the B_{ij} are the Einstein coefficients for absorption and stimulated emission. The W_{ij} are the associated transition probabilities. In this picture the total transition rate would be

$$W'_{21} = B_{21}E(\nu) + A_{21} \quad (\text{C2.15.23})$$

where we have simply added the spontaneous contribution. In thermal equilibrium it can be shown that [1]

$$W_{\text{eq}} = \frac{\lambda^2 I}{8\pi n^2 h \nu \tau} g(\nu) \quad (\text{C2.15.24})$$

where W_{eq} is the equilibrium transition probability and $g(\nu)$ is a spectral lineshape function.

Using equation (C2.15.24), we can derive a general expression for the absorption coefficient for this simple two-level system:

$$\alpha(\nu) = (N_2 - N_1) \frac{c^2}{8\pi n^2 \nu^2 \tau} g(\nu). \quad (\text{C2.15.25})$$

If we substitute equation (C2.15.25) into Beer's law

$$I(l) = I(0) e^{\alpha(\nu)l} \quad (\text{C2.15.26})$$

it is clear that when the upperstate population exceeds that of the lower state there will be an exponential increase in the field intensity as the photon flux propagates through the active media. This ‘population inversion’ is the primary condition required for laser action. Since this is a non-equilibrium condition energy must be introduced into the system to reach this state, the process of ‘pumping’ is the introduction of the energy required to reach inversion and depends on the system in which we are attempting to obtain laser action. The first optical lasers were developed nearly 50 years after the introduction of the Einstein equations—direct evidence of the difficulty of creating inverted conditions. The key to laser design has been to find systems that can be efficiently pumped to produce gain.

It has been said that anything will lase if pumped with enough energy, but the efficiency of the pumping process is important for practical, economical devices. In this regard two-level lasers are of little interest because, except under extraordinary pumping conditions, one can only equalize the populations of the upper and lower levels. A three-level laser is illustrated in [figure C2.15.4\(a\)](#). The first solid-state laser ($\text{Cr}^{3+}:\text{AlO}_3$) ruby was of the three-level variety (b). The scheme works as follows. Atoms are pumped optically from state 1 to state 3. Non-radiative relaxation moves the

-8-

population from state 3 to state 2, creating (at sufficient pumping levels) a population inversion between level 2 and level 1. Lasing occurs on the 2–1 transition with the linewidth of the emission determined by the kinetics of the system and the resonator design.

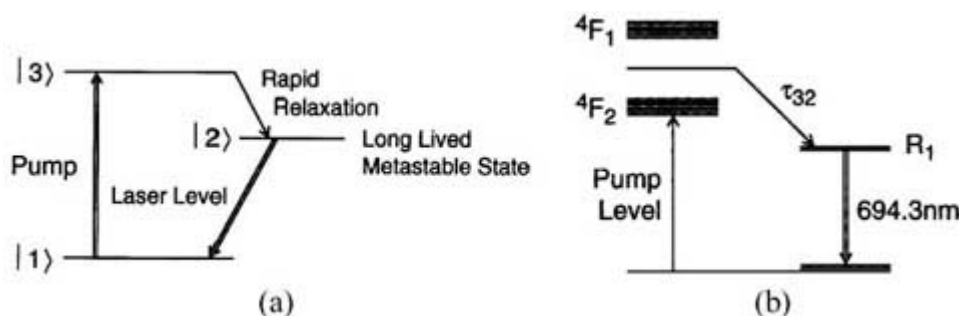

Figure C2.15.4. (a) A three-level laser energy level diagram and (b) the ruby system.

Four-level lasers offer a distinct advantage over their three-level counterparts, (figure C2.15.5). The $\text{Nd}^{3+}:\text{YAG}$ system is an excellent example of a four-level laser. Here the terminal level for the laser transition, |2>, is unoccupied thus resulting in an inverted state as soon as any atom is pumped to state 3. Solid-state systems based on this pumping geometry dominate the marketplace for high-power laser devices.

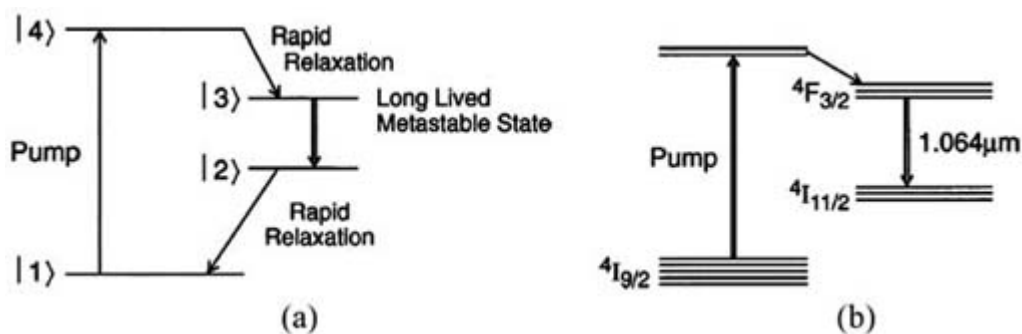

Figure C2.15.5. (a) A four-level laser energy level diagram and (b) the $\text{Nd}^{3+}:\text{YAG}$ system.

A wide variety of methods has been used to pump laser systems. Although optical pumping has been implied, there is an array of collisionally or electron impact pumped systems, as well as electrically pumped methods. The efficiency of the pumping cycle in many ways defines the utility and applications of each scheme. The first

material where optical laser action was observed was in the ruby system mentioned above. Here intense flashlamps were used to pump the system, which runs naturally in a pulsed mode. True continuous wave (CW) systems were first demonstrated in gaseous gain media.

The He-Ne laser system was the first efficient CW laser. It is still one of the most common systems in use today. Its level diagram is shown in [figure C2.15.6](#). Here a DC or RF discharge is used to excite the He⁺ ions, which in turn

collisionally excite Ne⁺ ions. Lasing occurs between several S and P bands with resonators designed to optimize the wavelength of interest.

Figure C2.15.6. The He-Ne system.

For primary optoelectronic device applications the most relevant laser source is the semiconductor laser. A detailed analysis of semiconductor laser theory can be found in several references [6, 14] and is treated elsewhere in this volume, the basic operation of the lasers will be described qualitatively here. Semiconductors [15] are in complex multi-atom crystalline systems which can be characterized by dense bands of energy levels (derived from atom-atom interactions) separated by 'forbidden' gaps. These gaps are regions of phase space which do not match the boundary conditions required for electronic states. The simplest view of a semiconductor is as an ensemble of interacting atoms characterized by loosely bound valence electrons, coupled to a strong periodic potential derived from the atomic nuclei. The periodicity gives rise to the boundary conditions mentioned above, with the details of the energy levels determined by the atoms in the array and the specifics of the crystal structure. [Figure C2.15.7](#) shows a generic energy level diagram for metals, semimetals, insulators, and semiconductors. Intrinsic semiconductors have full valence bands and generally have band gaps that range from 0.1 to 4 eV. Absorption and

emission occurs *via* promotion of excited electrons from occupied to unoccupied band states. The key property of these materials is that the number of these states can be modified thereby changing the electronic properties of these materials. It is the ability to change the

-10-

electronic properties of these materials easily that has led to their extensive use as materials for complex electronic device fabrication. The addition ('doping') of electron-deficient or electron-rich atoms to the lattice can greatly modify the populations of the electrons and holes. Clearly, one now has another degree of freedom to adjust when attempting to reach inversion. The ability to create 'unoccupied' (hole) and/or 'occupied' (electron) states allows for 'chemical' pumping in addition to any other scheme designed. The p-n junction laser is a perfect example of this exploitation, (figure C2.15.8). Here a p-type material, (excess 'holes') is joined with a n-type material, (excess electrons), figure C2.15.8(a). At the junction a 'depletion layer' is created by the internal electric fields in the material which results in potential barriers that spatially localize each of the carriers, figure C2.15.8(b). When the structure is positively biased these barriers are lowered, allowing charge injection into the depleted region resulting in radiative recombination (figure C2.15.8(c)). This electric pumping process is extremely efficient and results in the low-current, high-output devices that are common today.

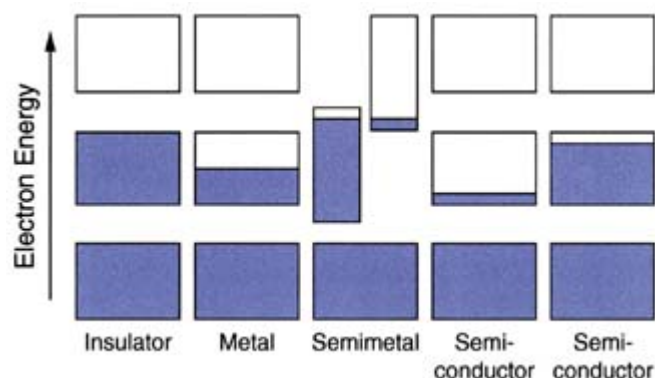

Figure C2.15.7. Generic band diagrams: insulator, metal, semimetal, and semiconductor.

We do not have space, nor is it appropriate to review all laser types and modes of operation, (the references included will afford the reader ample opportunity to survey the field). For reference we include a table giving an overview of the common laser types and their modes of operation (table C2.15.1). In general, pulsed laser output results from *Q*-switching or mode locking the devices. In both of these cases the kinetics of the optical system and the configuration of the optical resonator define the modulation frequency limits. In a *Q*-switched system a controllable loss is introduced into the resonator, allowing the steady-state population inversion to reach a level far above that achieved by conventional pumping. When this additional loss is removed the system begins oscillations at a point well above the threshold, lasing occurs with a rapid depletion of the gain, which eventually turns off the oscillation. The pulses generated have widths typically in the range of tens to hundreds of nanoseconds, with repetition rates of 10^4 – 10^5 pulses s^{-1} .

-11-

Figure C2.15.8. The p–n junction: (a) p-type and n-type materials, (b) depletion layer formation at the p–n interface or ‘junction’ and (c) p–n junction laser action.

Table C2.15.1 Common laser sources (s denotes solid-state lasers and g denotes gaseous lasers).

Laser type	Lasing wavelength λ	Efficiency η (%)	Mode of operation	Typical output power
ArF excimer (g)	193 nm	1	Pulsed	500 mJ
KrF excimer (g)	248 nm	1	Pulsed	500 mJ
He–Cd (g)	442 nm	0.1	CW	10 mW
Ar ⁺ (g)	514 nm	0.05	CW	10 W
He–Ne	633 nm	0.05	CW	1 mW

Kr ⁺ (g)	647 nm	0.01	CW	500 mW
Dye laser (R6G)	550–650 nm	0.005	CW or pulsed	100 mW
Ruby (Cr ³⁺) (s)	694 nm	0.1	Pulsed	5 J
Ti ³⁺ :Al ₂ O ₃ (s)	650–1180 nm	0.01	CW	1–10 W
Nd ³⁺ :glass (s)	1064 nm	1	Pulsed	10–50 J
Nd ³⁺ :YAG (s)	1064 nm	0.5	CW or pulsed	10–30 W
KF colour centre (s)	1.25–1.45 μm	0.005	CW	500 mW
CO ₂	10.6 μm	10–20	CW	100 W

Another method for producing pulsed laser output is longitudinal ‘mode locking’. Here, the natural longitudinal modes of a laser resonator are phase locked, resulting in wavepacket formation. This method takes advantage of the coupled gain characteristics of laser modes in optical resonators. It is the ability to dynamically control the phase relationships between the lasing modes in the cavity that makes this phenomenon possible. The width of this pulse is determined by the gain bandwidth, with the limits defined by the uncertainty principle. Mode locking is actually achieved by the intra-cavity modulation of the optical gain of the laser at the round trip frequency of the resonator. This frequency is $c/2l$, where c is the speed of light and l is the cavity length of the laser. This modulation induces sidebands which couple the gain of adjacent cavity modes.

The importance of laser light, in brief, is that its base characteristics, coherence, spectral and polarization purity, and high brilliance allow us to manipulate its properties. Gain switching [1, 10] and mode locking [16] are prime examples of our ability to very specifically control the laser output. It is easy to see why lasers are the ideal sources for optoelectronic applications.

C2.15.4 NONLINEAR OPTICS

The high-field output of laser devices allows for a wide variety of ‘nonlinear’ interactions [17] between the radiation field and the matter. Many of the initial relationships can be derived using engineering principles by simply expanding the media polarizability in a Taylor series in powers of the electric field:

$$P = \epsilon_0 \chi E + P_{NL} \quad (C2.15.27)$$

where

$$P_{NL} = 2\chi^{(2)} E^2 + 4\chi^{(3)} E^3 + \dots \quad (C2.15.28)$$

A wide variety of useful phenomena that allow the manipulation of the wavelength, amplitude and phase of the optical fields are mediated by χ , the first- and higher-order susceptibilities. In essence, the $\chi^{(n)}$ represent the complex interactions of the electric fields with the nonlinear media. They determine the explicit interaction of the quantum mechanical system (the propagation medium) with the quantized radiation field. Our engineering approach is a precursor to the well known semi-classical approach, where the radiation field is treated classically and the media quantum mechanically [18]. Assuming the electric dipole interaction represents the dominant contribution to the interaction Hamiltonian, the macroscopic polarization of the material of interest is the expectation value of the dipole matrix element scaled by the volume,

$$\mathbf{P}(r, t) = \frac{\langle E_a | \hat{d} | E_b \rangle}{\Delta V}$$

where the interaction Hamiltonian is

$$\hat{H}_i = -\hat{d}\mathbf{E}(r, t) \quad (\text{C2.15.30})$$

(here $\mathbf{E}(r, t)$ represents all external driving fields). This quantity incorporates all matter–field interactions. A perturbative expansion of this system allows correlation of the terms of equation (C2.15.29) to the n th order, with the terms generated from the simple Taylor series expansion described initially. This analysis gives an atomic/molecular basis for the susceptibilities, allowing greater insight to the nonlinear processes observed. An excellent treatment of this analysis is found in [18]. For our purposes the simple view that the intense fields drive a nonlinear oscillation of the polarizable electronic states of the materials is sufficient.

We will obtain a flavour of the nonlinear phenomena by exploring the processes generated via the matter–field

-14-

interactions to second order. The polarization to second order in the electric field is

$$\begin{aligned} \mathbf{P}^{(2)}(r, t) = \frac{\epsilon_0}{(2\pi)^2} \sum_{i,k} \int_{-\infty}^{+\infty} d\omega_1 \\ \int_{-\infty}^{+\infty} d\omega_2 \chi_{i,j,k}^{(2)}(\omega : \omega_1, \omega_2) \mathbf{E}_j(\omega_1) \mathbf{E}_k(\omega_2) e^{i(\omega_1 + \omega_2)t} \end{aligned} \quad (\text{C2.15.31})$$

where the various contributions arise through the permutation of the indices j and k . The most encountered spectral component of $\chi^{(2)}$ arises from a two-photon coupling of a single electric field, resulting in the generation of a second harmonic of the field. Second harmonic generation (SHG) [19], discovered soon after the laser, is an essential wavelength conversion tool utilized throughout laser physics and engineering. The relevant terms in the polarization are of the form

$$\mathbf{P}_i^{(2)}(\omega, z) = \epsilon_0 \sum_{i,j,k} \chi_{i,j,k}^{(2)}(\omega : 2\omega, -\omega) \mathbf{E}_j(2\omega, z) \mathbf{E}_k^*(\omega, z) \quad (\text{C2.15.32})$$

and

$$\mathbf{P}_i^{(2)}(2\omega, z) = \epsilon_0 \sum_{i,j,k} \chi_{i,j,k}^{(2)}(2\omega : \omega, \omega) \mathbf{E}_j(\omega, z) \mathbf{E}_k^*(\omega, z). \quad (\text{C2.15.33})$$

$\mathbf{P}_i^{(2)}$ will of course be the source term in the wave equation. It is clear that for SHG the generated polarization scales as $|\mathbf{E}(\omega)|^2$. In general, the intensity scales with the incident power per cross sectional area. To maximize the SHG output, the interaction length of the ω and 2ω fields needs to be as long as possible, or power begins to be converted back to ω . In most materials, dispersion and diffraction effects limit the conversion efficiency. A wide variety of techniques have been developed to solve this problem. The most widespread is the use of uniaxial nonlinear crystals for wavelength conversion. In these systems (which have orientation dependent indices of refraction) the crystals are cut such that the propagating second harmonic and fundamental wavelength traverse the media at the same speed, thus resulting in optimal conversion. This is commonly known as phase matching. (A detailed analysis of the phase matching arrangements can be found in [20].) In addition, several waveguide and fibre SHG devices have been developed [21]. Another second-order process of great utility is optical rectification [22] (the coupling and generation of DC fields using an optical field). An outgrowth of this process is the ‘electro-optic effect’, which allows the manipulation of optical radiation with strong DC fields in appropriate media. In

these materials, the change in index can be written as

$$\Delta n \approx \frac{\chi^{(2)}}{n} E(0) = -\frac{1}{2} n^3 \tilde{r} E(0) \quad (\text{C2.15.34})$$

where r is the Pockels coefficient. This effect allows for electric field induced phase shifting of the optical fields. The nonlinear process allows the direct, rapid, and efficient coupling of electrical RF signals to high-frequency optical fields, making the Pockels effect an essential tool for high-frequency modulation.

-15-

C2.15.5 OPTICAL LIGHT GUIDES

Traditionally, light signals are directed using lenses, mirrors, and optical prisms. This free-space guiding of light, although exceedingly useful, is not very robust for optical transmission over long distances. The push to transmit ‘information’ optically drove the development of optical conduits to transmit light signals from place to place. The development of guided-wave optics has been key to the advances of optical communication, leading to the optoelectronics revolution. In addition, the concentration of intense radiation afforded by these guides has impacted every area from laser design to nonlinear optical devices and has opened the door for the development of *integrated optical devices*. In this section we will outline the basics of guided-wave optics. As in [1], we will start with the planar-mirror waveguide as an introduction to the essential concepts, and then move on to dielectric structures.

Consider a light conduit constructed using two planes of parallel mirrored surfaces (figure C2.15.9). Assuming the mirrors are lossless, a light ray at an appropriate angle θ will propagate along the conduit axis, reflecting without loss of energy. (Note that waveguides of this type are not made in practice due to the difficulty of fabricating mirrors with low enough losses.) Consider launching a monochromatic wave into the guide with wavelength $\lambda = \lambda_0/n$ (where n is the refractive index between the plates). Given our basic assumption of lossless surfaces, the guide constrains the propagating modes to those that maintain the same transverse distribution at all distances along the waveguide axis. To fulfill this requirement *any launched wave must remain unchanged after two reflections*. In addition there are a limited number of angles which satisfy these conditions for this system, and they must satisfy the relationship

$$\sin \theta_m = m \frac{\lambda}{2d} \quad (\text{C2.15.35})$$

where $m = 1, 2, 3, \dots$. The guided-wave modes are composed of two distinct plane waves at $\pm\theta$. We define the propagation constant of the m th mode as

$$\beta_m^2 = k^2 - \frac{m^2 \pi^2}{d^2}. \quad (\text{C2.15.36})$$

There is a maximum number of modes possible, defined by the range of accessible angles. For $\sin \theta < 1$, the maximum allowed value of modes is the greatest integer smaller than $1/(\lambda/2d)$ or

$$M \cong \frac{2d}{\lambda}. \quad (\text{C2.15.37})$$

As shown, the number of modes increases with increasing mirror separation and decreasing wavelength. If $2d/\lambda$ is less than one, $M = 0$ and no self-consistent modes are supported. $2d$ represents the cut-off wavelength of the guide. It is the longest wavelength supported by the guide. It is clear that if the spacing is adjusted properly, M can be set to one and only a single mode will be supported. For completeness, we note TM (transverse magnetic) and TE (transverse electric) mode distributions define the direction of \mathbf{E} of the propagating field as shown in [figure](#)

Figure C2.15.9. The planar-mirror light guide.

Figure C2.15.10. Orientation of the TE and TM modes.

C2.15.6 THE DIELECTRIC WAVEGUIDE

Optical conduits as described above are generally not practical. The most common waveguide is the slab dielectric waveguide. In these devices, a high-transmission material is surrounded by a media of a lower refractive index. The light is guided into the device by total internal reflection. The basic structure is shown in [figure C2.15.11](#). As with our initial description, light rays making an angle θ with the z -axis experience multiple total internal reflections at the interfaces, provided that θ is *smaller than the complement of the critical angle*. The slab boundaries define all of the properties of the guide. As before, rays making angles larger than the complement of the critical angle refract, losing a fraction of their optical power at each reflection and eventually vanishing (the unguided waves of [figure C2.15.11](#)). The detailed analysis of the waveguide modes requires a full solution of Maxwell's equations both inside and outside the high-index core with the appropriate boundary conditions. Such an analysis, which is beyond the scope of this review, can be found in [1, 23]. We will summarize the results here. As with our first analysis, a twice-reflected wave undergoes a phase shift that must be zero or a multiple of 2π to be self-consistent. The number of TE modes allowed is

$$M \cong \frac{\sin \theta_c}{\lambda/2d} \tag{C2.15.38}$$

where M is increased to the nearest integer, More generally

$$M = 2 \frac{d}{\lambda_0} NA \quad (C2.15.39)$$

where the numerical aperture $NA = (n_1^2 - n_2^2)^{1/2}$. The NA is the sine of the angle of acceptance of rays from air into the core of the slab. When $\lambda/2d > \sin \theta_c$ or $(2d/\lambda_0)NA < 1$ the waveguide supports a single mode. The TE and TM modes in a dielectric planar waveguide are as shown in [figure C2.15.12](#). The possible modes can be characterized by a propagation constant, β where

$$\beta_m = nk_0 \cos \theta_m. \quad (C2.15.40)$$

One can of course fabricate two-dimensional waveguides. These devices confine light in two transverse directions (x and y). An important example of two-dimensional waveguides is the optical fibre, which we will treat directly. Generally, two-dimensional waveguides are of the channel variety. An array of two-dimensional waveguide geometries is shown in [figure C2.15.13](#). So far, we have not considered modal interactions in guides, that is, the coupling of light from one mode to another, or the energy transfer between modes. The mode coupling of light is an important tool in optoelectronics. Although a full treatment of this process is beyond the scope of this chapter, we will describe one relatively simple device as an example and leave it to the reader to survey the references for greater detail on a wide variety of structures. It should be stated that the design and fabrication of these devices is an exciting area of current research.

Figure C2.15.11. The dielectric waveguide.

-18-

Figure C2.15.12. (a) TE and (b) TM modes for the dielectric planar waveguide.

Figure C2.15.13. Two-dimensional waveguide configurations, the darker shading indicates the different indexes.

Our model device will be the directional coupler ([figure C2.15.14](#)). The basic function of the structure is to couple two optical inputs to two optical outputs. Consider two single-mode waveguides on the same substrate, as shown in the figure. Using a simple-coupled mode model, if the guides are non-interacting, the amplitudes of the input fields as a function of propagation distance are

$$\frac{dA_1}{dz} = -i\beta A_1(z) \quad (\text{C2.15.41a})$$

$$\frac{dA_2}{dz} = -i\beta A_2(z) \quad (\text{C2.15.41b})$$

with solutions

$$A_i(z) = A_i(0) e^{i\beta z} \quad (\text{C2.15.42})$$

where $i = 1$ and 2 respectively. (Note that the modes propagate unchanged.) If the two guides are brought close enough together, the evanescent fields of the two modes interact, allowing energy exchange. One can define a coupling constant κ that characterizes the perturbative interaction of the modes. Under these conditions equation (C2.15.41a) and equation (C2.15.41b) become

$$\frac{dA_1}{dz} = -i\beta A_1(z) - i\kappa A_2(z) \quad (\text{C2.15.43a})$$

$$\frac{dA_2}{dz} = -i\beta A_2(z) - i\kappa A_1(z). \quad (\text{C2.15.43b})$$

If the guides are lossless (here we ignore bending losses) and we only launch a field into guide 1 (i.e. $A_1 = 1, A_2 = 0$)

$$A_1(z) = \cos(\kappa z) \quad (\text{C2.15.44a})$$

$$A_2(z) = \sin(\kappa z). \quad (\text{C2.15.44b})$$

The optical power $|A_i|^2$ oscillates between the guides depending upon the propagation distance. Clearly, by controlling z , β and κ , a wide variety of passive devices (beam splitters, combiners, attenuators, and interferometers) can be readily constructed.

Figure C2.15.14. The directional coupler.

C2.15.7 THE OPTICAL FIBRE

The optical fibre [4, 24] is the most extensively used optical waveguide. The cylindrical step index structure is composed of an ultra-pure, extremely-low-loss, high-index core surrounded by a slightly lower index cladding. The fibre properties are characterized by the relative diameters of the cladding and the core, $2a/2b$ (where a and b are the core and cladding radii), and the delta of the two materials (figure C2.15.15). The delta, Δ , is defined as

$$\Delta = \frac{n_1 - n_2}{n_1} \quad (\text{C2.15.45})$$

where n_1 and n_2 are the core and cladding indexes of refraction, respectively. (Typical deltas range from 0.001 to 0.02.) An optical field is guided in the fibre core just as in the dielectric waveguide *via* the total internal reflection at the core-cladding boundary. Again, rays propagate if their angle of incidence is less than the complement of the critical angle. The fibre input is defined in terms of the numerical aperture NA , with

$$\theta_a = \sin^{-1} NA \quad (\text{C2.15.46})$$

where θ_a is the fibre acceptance angle. The NA can also be written in terms of the Δ of the fibre:

$$NA = (n_1^2 - n_2^2)^{1/2} \cong n_1(2\Delta)^{1/2}. \quad (\text{C2.15.47})$$

Another important characterization parameter for fibres is the normalized frequency V :

$$V = k_0 a (n_1^2 - n_2^2)^{1/2} = k_0 NA. \quad (\text{C2.15.48})$$

Note that here $k_0 = 2\pi/\lambda$ and a is the core radius. The parameter V determines the number of modes supported by

the fibre design, therefore defining the cut-off frequency of the fibre. For $V < 2.405$, only a single mode is supported. Although written here very simply, the V parameter is exactly derived from solution of the complex eigenvalue problem of the weakly guiding fibre [25]. A full solution of the Helmholtz equation representation of the Maxwell's equations in cylindrical coordinates must be obtained in the core and cladding, with the appropriate boundary conditions. The Bessel function solutions of this problem give rise to the characteristic equations for V . In practice, many of the solutions are obtained graphically. For large V there are a large number of roots to the characteristic equations, allowing for a large number of propagating modes. In this limit, the number of modes is

$$M \approx \frac{4}{\pi^2} V^2 \tag{C2.15.49}$$

for $V \gg 1$. Under these conditions the propagation constant can be found to be

$$\beta_{l,m} \cong n_1 k_0 \left[1 - \frac{(l+2m)^2}{M} \Delta \right] \tag{C2.15.50}$$

-21-

and the group velocity of the (l, m) mode is

$$v_{l,m} \cong c_1 \left[1 - \frac{(l+2m)^2}{M} \Delta \right]. \tag{C2.15.51}$$

This spread in velocity is called ‘modal dispersion’ and is the principle limit to the use of multimode fibres for long-distance transmissive applications.

Figure C2.15.15. The structural profile of a step index fibre.

As described above for small a and NA , a fibre is single mode if $V < 2.405$. Here only one mode, with one group velocity, is possible. This lack of ‘modal dispersion’ is why single-mode fibre dominates transport media in long-haul communication systems.

Graded index structures allow greater control over fibre characteristics. In these structures, the core has a variable

refractive index, highest in the centre and gradually decreasing until it reaches that of the cladding at the core–cladding interface. The result is that the phase velocity gradually increases with spatial position in the core. Properly designed structures can greatly minimize the differences in the group velocity of the fibre modes, limiting modal dispersion.

For optical transmission, the parameters of greatest importance are attenuation (i.e. loss) and ‘material’ dispersion. In effect they define the limits of the optical communication system. Loss, due to absorption and scattering, limits the lengths between the transmission nodes. In transmission quality fibre, the loss is in units of decibels per kilometre.

(Attenuation of less than 0.2 dB km^{-1} is common for telecom quality fibre.) Since modal dispersion can be greatly mitigated by fibre design, real material dispersion is of greatest consequence. Silica is a dispersive media. There is a wavelength dependence to the index of refraction, as a result an optical pulse of finite bandwidth, $\delta\lambda$, spreads as it propagates along the core axis. This spread limits the spacing of successive pulses and hence the maximum transmission frequency. Figure C2.15.16 shows a plot of the dispersion for silica as a function of wavelength within the transmission window. Because the zero dispersion point is at approximately $1.31 \mu\text{m}$, this wavelength has become one of the base telecom transmission bands. The other key telecom transmission wavelength, $1.54 \mu\text{m}$, is near the loss minimum of the fibre.

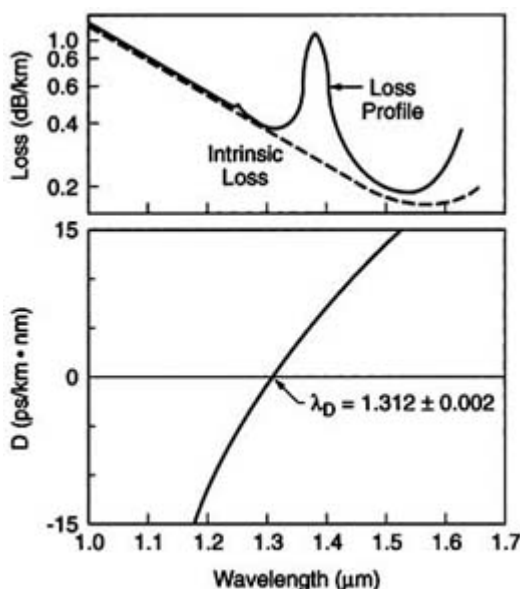

Figure C2.15.16. Wavelength dependent loss (upper) and dispersion (lower) in a silica fibre.

Nonlinear dispersion becomes relevant at sufficient pulse powers. In some fibre structures the interplay between the nonlinear dispersion and the group velocity dispersion can be used to produce non-dispersive waves called solitons. Solitons, although beyond the scope of this treatment, may revolutionize the communication systems of the future. A full treatment of soliton theory can be found in [4, 26].

C2.15.8 OPTICAL MODULATION AND DETECTION

We will complete our survey of optoelectronics with a brief discussion of optical modulation and optical detection. These two categories of devices are important because they define the speed of the optoelectric link. The ability to generate and detect high-frequency signals determines the ultimate limits on any optical circuit. Transmission modulation can be accomplished two ways: (a) direct modulation, switching of an optical source and (b) external ‘shuttering’ of a CW optical source. Although both are adequate, the latter allows for greater flexibility and

The most useful direct modulation technique is the current gain switching of semiconductor laser devices. This technique is unique to semiconductor sources, nearly all other lasers are modulated externally. In these devices the excitation current of the laser is modulated, resulting in modulated gain and therefore modulated output power. A detailed analysis of this process is found in [27]. Simply put, an oscillating current of the form

$$I = I_0 + i_m e^{i\omega_m t} \tag{C2.15.52}$$

is applied to the device. Since the laser output power is

$$P_0 \approx \frac{\eta(I - I_{th})}{\lambda} \tag{C2.15.53}$$

there will be a modulation in the output power. Careful laser design can result in modulation frequencies in the hundreds of megahertz to gigahertz range. In general, the limitation of the high-frequency response of these laser devices is due to the broadening of linewidth and spectral output due to a change of the material absorption, gain and index of refraction as a function of the carrier density. This ‘chirping’ of the laser output bounds the modulation frequencies possible. To surpass this limitation external modulation of CW lasers is employed, allowing modulation frequencies greater than 10 GHz.

A wide variety of external modulators are used in practice. Electro-optic modulators can produce amplitude, frequency, or phase modulation utilizing the Pockels effect (mentioned when we studied nonlinear optical phenomena above). By polarizing the input wave and setting the electro-optic device between crossed polarizers. A controllable bias on the modulator determines the optical phase shift induced on the optical beam and therefore the output. Waveguide electro-optic devices are also of great interest. Single-mode waveguide devices, such as couplers and interferometers, were mentioned earlier and are becoming of great importance in the communications industry. Waveguides fabricated using electro-optic materials such as LiNbO₃ can be made into active devices. The Pockels effect allows dynamic index switching, enabling the modulation of an optical input. A diagram of an optical Mach–Zender modulator is shown in figure C2.15.17. In addition, external electroabsorption has achieved wide success in communication links. Here the process that limits the direct modulation of a semiconductor laser, i.e. the change (shift) of the absorption spectrum with carrier density, is used for high-speed modulation. A beneficial side effect is that fully integrated laser/modulator packages can be fabricated.

Figure C2.15.17. The Mach–Zender modulator. A 3 dB coupler splits the input wave into the two arms of the device. The output 3 dB combiner recombines half the wave with its phase-shifted counterpart. By adjusting V_0 the output transmission can be rapidly modulated.

Optical detectors generally fall into two broad categories: thermal and photoelectric detectors. Thermal devices operate by converting the photon detected into heat with the heat evolution used to quantify the emissive output. Photoelectric devices convert the photons directly to electrons or other charge carriers, with the subsequent current proportional to the photon input. In general thermal devices are slow and not easily integrated into complex devices. The dominant detectors for optoelectronic applications are of the photoelectric variety. Again, two general categories of devices are prevalent: those that rely on the photoelectric effect and those that are based on photoconductivity. Photodetectors, based on the photoelectric effect, are known as phototubes. In these devices a photoemissive material is configured as a cathode. The input radiation induces the ejection of a photoelectron from the cathode, which is accelerated towards the anode (which is at a higher electric potential), generating a current. Often secondary emission devices (called dynodes) are used to produce a large amplification of the photocurrent. These dynodes are electron multipliers with successive stages, resulting in large current gains. Phototubes are commonly used as high-gain (10^7), high-sensitivity detectors for a wide variety of applications.

For optoelectronic applications photoconductive devices are more common. Semiconductor photoconductives tend to be inexpensive and can be easily integrated with other components. In these devices photo-illumination above the bandgap of the material generates charge carriers, increasing the conductivity of the semiconductor and resulting in a photocurrent. For example in a p–n junction device, photons absorbed in the depletion layer generate electrons and holes under the influence of an electric field, this directly generates the photocurrent described. If a large reversed bias is placed across the junction, the large field produced can accelerate photogenerated carriers with enough kinetic energy to excite additional carriers by impact ionization. This ‘avalanche’ effect results in a dramatic improvement in detector sensitivity. Avalanche photodiodes have become critical devices for many photonic applications.

C2.15.9 OPTICAL COMMUNICATIONS

The primary driver for the expansion of optoelectronic technologies is optical communications [2]. It was realized in the second-half of the 20th century that an increase of several orders of magnitude in bandwidth would be possible if optical waves were used as the carrier for telephone signals. The basic configuration of an optical communication

system is shown in figure C2.15.18. All the components described in this review are used, and, in many cases, were developed to complete the optical link. The primary application that drove optoelectronics research through the 1980s and early 1990s was long-distance business; the goal being to send gigabit data rate information efficiently over very long distances (thousands of kilometres). The need to go farther and faster led to the development of extremely-low-loss optical fibre, ultra-high-speed modulators and high-sensitivity avalanche photodetectors. This important innovation enabled all-optical transmission. The development of the optical fibre amplifier revolutionized optical communication, allowing digital optical signals to be transmitted vast distances before being converted back to electronic pulses, therefore greatly simplifying long-haul links. (These devices amplify the optical data signals via stimulated emission.)

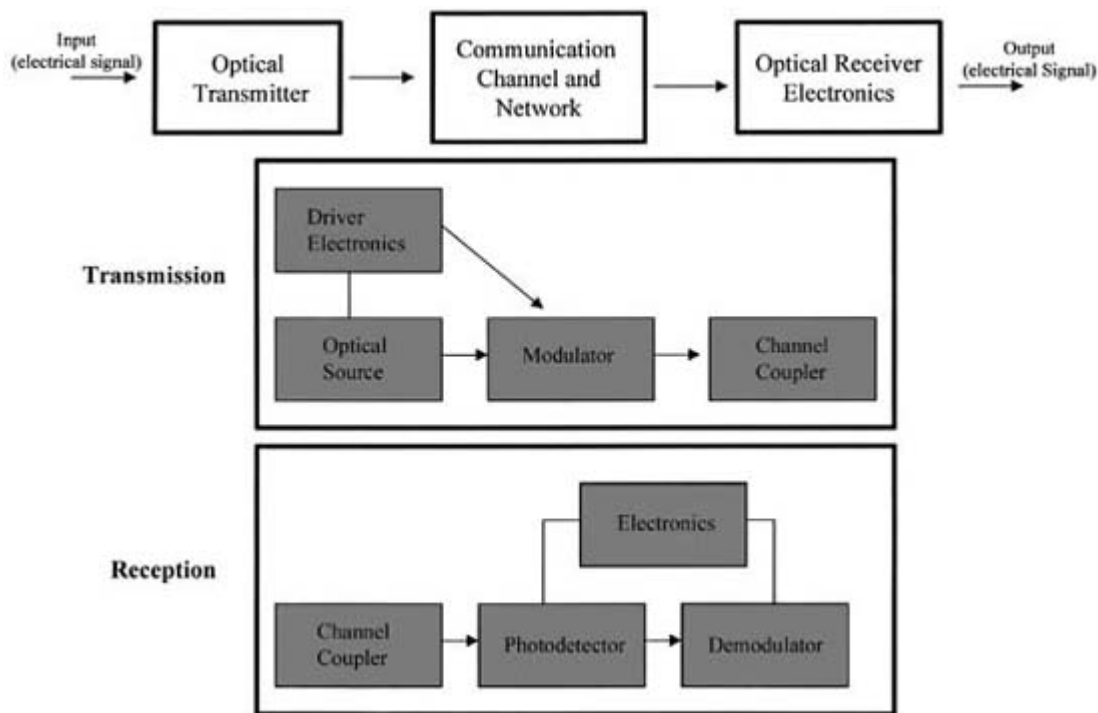

Figure C2.15.18. The basic components of an optical communications link.

During the last 5–10 years optical networks of all varieties have become a very important part of the World’s communications infrastructure for data transmission. The new focus has become the transmission of multi-gigabit information over moderate distances at *low cost*. These requirements are profoundly affecting the design criteria for optoelectronics devices and components. In addition, coarse and dense wavelength division multiplexed systems are being developed to increase bandwidth. The essence of wavelength division multiplexing is the simultaneous transmission of many optical data channels each at a different wavelength on a single optical fibre. Systems with as many as 40, 1–10 Gbit optical channels are becoming commercially available. Low-cost components will be the key factor in determining how rapidly this technology will be deployed throughout the communications infrastructure.

C2.15.10 CONCLUSION

In this chapter we have laid out much of the underlying basis for a wide variety of optoelectronic devices and structures. I hope that it is clear from the text that optoelectronics is optical physics in action. While optical technologies are beginning to mature, much new work is needed to provide new sources and devices for next-generation photonic applications. The introduction of organic electronic devices [28] and novel photonic bandgap materials [29] will no doubt add fuel to the fire. I expect these technologies to redefine computing and communication well into the 21st century.

C2.16 Semiconductors

Henryk Temkin and Stefan K Estreicher

I think there is a world market for maybe five computers.

Thomas Watson Sr, IBM Chairman, 1943

The history of semiconductor devices can be traced back to the paper of Braun, published in 1874, describing rectifying behavior of a contact [1]. However, for many years semiconductors were considered too difficult a subject and the science of semiconductors began only during World War II.

The physics of semiconductors was understood rather quickly but the materials were far too poor for practical applications. The first high-purity semiconductor grown in large quantities was Ge. Si emerged only in the mid 1950s as the semiconductor of choice. Compound semiconductors, such as GaAs, began to play a role in the mid-1970s. These developments are presented in a number of recent review articles [2, 3, 4 and 5].

Since the early days of this field, the scientific and technological advances have been chasing each other. Advances in technology enabled implementation of new ideas, which in turn suggested new applications. In the last 50 years this process has resulted in a series of unprecedented advances that have transformed our society. There is, as of yet, no sign of a slowdown.

The present article reviews basic concepts of semiconductor physics and devices with emphasis on current problems. Further details can be found in the references.

C2.16.1 INTRODUCTION

Semiconductors are a class of materials whose conductivity, while highly pure, varies with temperature as $\exp(-E_g/k_B T)$, where E_g is the size of a forbidden energy gap. The conductivity of semiconductors can be made to vary over orders of magnitude by *doping*, the intentional introduction of appropriate impurities. The range in which the conductivity of Si can be made to vary is compared to that of typical insulators and metals in [figure C2.16.1](#).

In an *intrinsic* semiconductor, the conductivity is limited by the thermal excitation of electrons from a filled *valence band* (VB) into an empty *conduction band* (CB), across a forbidden energy *gap* of width E_g . The process leaves *holes* (h^+) in the VB and *electrons* (e^-) in the CB, and both of these *charge carriers* participate in the conduction.

In an *extrinsic* semiconductor, the conductivity is dominated by the e^- (or h^+) in the CB (or VB) provided by shallow *donors* (or *acceptors*). If the dominant charge carriers are negative (electrons), the material is called n type. If the conduction is dominated by holes (positive charge carriers), the material is called p type.

-2-

Figure C2.16.1. A nomogram comparing electrical resistivity of pure (intrinsic) and doped Si with metals and insulators.

C2.16.2 MATERIALS

There are hundreds of semiconductor materials, but silicon alone accounts for the overwhelming majority of the applications world-wide today. The families of semiconductor materials include tetrahedrally coordinated and mostly covalent solids such as group IV elemental semiconductors and III–V, II–VI and I–VII compounds, and their ternary and quaternary alloys, as well as more exotic materials such as the adamantane, non-adamantane and organic semiconductors. Only the key features of some of these materials will be mentioned here. For a more complete description, the reader is referred to specialized publications [6, 7, 8 and 9].

C2.16.2.1 ELEMENTAL SEMICONDUCTORS

The ‘group IV’ semiconductor materials are fourfold coordinated covalent solids from elements in column IV of the periodic table. The elemental semiconductors are diamond, silicon and germanium. They crystallize in the diamond lattice.

Diamond may never be used to make devices because it is nearly impossible to make it sufficiently n type, that is to obtain high electron concentration. Substitutional B is a good shallow acceptor, and interstitial Li has been reported to produce some n type conductivity.

Silicon is used in many forms, from high-purity thin films to bulk material, which may be crystalline, multi- or polycrystalline and amorphous (usually hydrogenated). Silicon is the material discussed the most in this article. Substitutional B and P are the most common (of many) shallow acceptors and donors, respectively.

-3-

Germanium is very similar to Si, but its band gap is too small for many practical applications. Large crystals of ultra-high-purity Ge have been grown for use as gamma-ray detectors. In such crystals, the net concentration of electrically active centres is incredibly low, of the order of 10^{12} cm^{-3} . Isotopically pure Ge crystals have been grown as well [10].

C2.16.2.2 COMPOUND SEMICONDUCTORS

There is a great number of mostly covalent and tetrahedral binary IV–IV, III–V, II–VI and I–VII semiconductors. Most crystallize in the zincblende structure, but some prefer the wurtzite structure, notably GaN [11, 12]. While the bonding in all of these compounds (and their alloys) is mostly covalent, some ionic character is always present because of the difference in electron affinity of the constituent atoms.

C2.16.2.3 IV – IVS

The ionic character of compounds of C, Si, and Ge [13] ranges from a few percent (SiGe) to as much as 16% (SiC). In addition to compounds, many alloys can be grown, such as $\text{C}_x\text{SiGe}_{1-x}$, where x is of the order of 0.02 to 0.04. Compounds such as $\text{Si}_x\text{Ge}_{1-x}$ are used because their gap can be made to vary from the Ge to the Si value.

Compounds and alloys of group IV elements normally have the zincblende structure. A notable exception is SiC which can crystallize in hundreds of polytypes that differ in the way the Si–C units are stacked along the c -axis of the crystal. For example, the *zincblende* structure (3C) has the sequence ABC–ABC–... with cubic symmetry, and the *wurtzite* structure (2H) is hexagonal with the sequence AB–AB–... (figure C2.16.2). The lowest-energy structure of SiC is 6H, with sequence ABCACB–ABCACB–.... In all these polytypes, each atom is fourfold coordinated and makes (almost or exactly) tetrahedral angles with its neighbours. In addition to the cubic and hexagonal polytypes, many other structures of SiC exist with rhombohedral or trigonal symmetries.

Figure C2.16.2. The sequence of atoms in the two polytypes of SiC, zincblende and wurtzite, along the *c*-direction. The zincblende lattice has perfect tetrahedral angles.

-4-

C2.16.2.4 III – VS

III–V compound semiconductors with precisely controlled compositions and gaps can be prepared from several material systems. Representative III–V compounds are shown in the gap–lattice constant plots of figure C2.16.3. The points representing binary semiconductors such as GaAs or InP are joined by lines indicating ternary and quaternary alloys. The special nature of the binary compounds arises from their availability as the substrate material needed for epitaxial growth of device structures.

Figure C2.16.3. A plot of the energy gap and lattice constant for the most common III–V compound semiconductors. All the materials shown have cubic (zincblende) structure. Elemental semiconductors, Si and Ge, are included for comparison. The lines connecting binary semiconductors indicate possible ternary compounds with direct gaps. Dashed lines near GaP represent indirect gap regions. The line from InP to a point marked * represents the quaternary compound InGaAsP, lattice matched to InP.

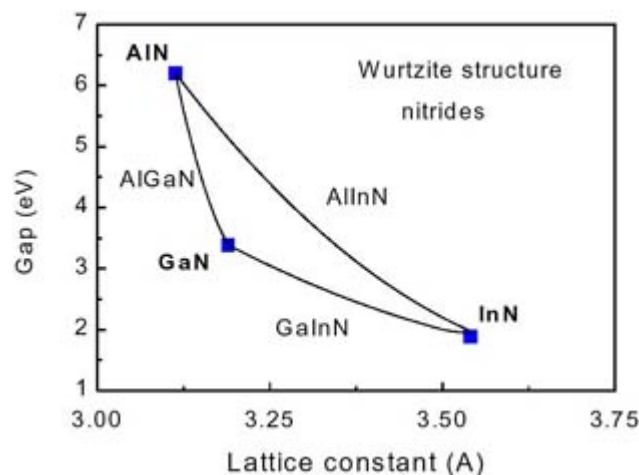

Figure C2.16.4. A plot of the energy gap and lattice constant for large-gap nitrides. These materials have wurtzite structure.

Ternary and quaternary semiconductors are theoretically described by the *virtual crystal approximation* (VCA) [7]. Within the VCA, ternary alloys with the composition $AB_{1-x}C_x$ are considered to contain two sublattices. One of them is occupied only by atoms A, the other is occupied by atoms B or C. The second sublattice consists of virtual atoms, represented by a weighted average of atoms B and C. Many physical properties of ternary alloys are then expressed as weighted linear combinations of the corresponding properties of the two binary compounds. For example, the lattice constant d dependence on composition is written as:

$$d = (1 - x)d_{AB} + xd_{AC}.$$

This approximation, known as *Vegard's law*, accurately describes the average lattice constant (but not the microscopic structure!) of most ternary compounds. However, the expression for the gap must be modified by the inclusion of a quadratic term

$$E_g(x) = (1 - x)E_g(AB) + xE_g(AC) - \Omega x(1 - x)$$

where the *bowing coefficient* Ω is positive. The term $-x(1 - x)$ is due to the random distribution of atoms B and C within their sublattice. It represents the probability of finding sequences of atoms B–A–C, or C–A–B, in the random alloy [14].

Some semiconductors with compositions close to $AB_{0.5}C_{0.5}$ are known to become ordered. This results in changes in the gap, and electrical and optical properties, compared to random alloys of the same composition.

Two of the material systems shown in [figure C2.16.3](#) are of particular importance. These are the ternary compounds formed from group III elements such as Al and Ga in combination with As and quaternary compounds formed from Ga and In in combination with As and P [8, 15]. Ternary $Al_xGa_{1-x}As$ grown on GaAs is the best known of the general class of compounds $A_x^{III}B_{1-x}^{III}C^V$. Quaternary $Ga_xIn_{1-x}As_{1-y}P_y$ grown on InP is representative of the general class $A_x^{III}B_{1-x}^{III}C_y^VD_{1-y}^V$. The lattice constants, gaps, indices of refraction and most other parameters of these materials depend on their composition x and y .

$Al_xGa_{1-x}As$ grown on GaAs is used for the preparation of *light-emitting diodes* (LEDs), *injection lasers* and bipolar *transistors*. The lattice constants of GaAs (0.565 nm) and AlAs (0.566 nm) are almost identical. Aluminum atoms can be substituted for Ga atoms in the GaAs lattice to form $Al_xGa_{1-x}As$ without significant change in the lattice constant. It is thus possible to vary the gap from $E_g(\text{GaAs}) = 1.43$ eV to $E_g(\text{AlAs}) = 2.16$ eV simply by adjusting the Al fraction x in the epitaxial layer. This feature of $Al_xGa_{1-x}As$ is quite unique among the compound semiconductors.

An even wider range of gaps can be reached with *lattice-mismatched* structures of $Ga_xIn_{1-x}As$ grown on GaAs. This ternary system is shown in [figure C2.16.3](#) by the line joining GaAs and InAs. The thickness of defect-free layers of $Ga_xIn_{1-x}As$ is limited by the biaxial compressive strain arising from the lattice mismatch with the substrate. Structures based on $Ga_xIn_{1-x}As$ are thus implemented in the form of *quantum wells*, typically less than 10 nm thick.

The usual acceptor and donor dopants for $Al_xGa_{1-x}As$ compounds are elements from groups II, IV and VI of the periodic table. Group II elements are acceptors and group VI elements are donors. Depending on the growth conditions, Si and Ge can be either donors or acceptor, i.e. *amphoteric*. This is of special interest in LEDs.

Quaternary $Ga_xIn_{1-x}As_{1-y}P_y$ grown on InP is of major importance to fibre-optic communications. In quaternary compounds, both the gap and the lattice constant can be tailored by changing the chemical composition. In thick layers, in order to avoid the generation of strain-induced defects, care must be taken in adjusting the ratio of x and y to maintain the lattice-matched composition $x = 2.2y$. The available gaps range from 1.34 eV in InP to ~0.75 eV in

lattice-matched $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$. A particularly interesting feature of this system is the high reliability of LEDs and diode lasers [16].

While quaternary layers and structures can be exactly lattice matched to the InP substrate, strain is often used to alter the gap or carrier transport properties. In $\text{Ga}_x\text{In}_{1-x}\text{As}$ or $\text{Ga}_x\text{In}_{1-x}\text{As}_{1-y}\text{P}_y$ grown on InP, strain can be introduced by moving away from the lattice-matched composition. In sufficiently thin layers, strain is accommodated elastically, without any change in the in-plane lattice constant. In this material, strain can be either compressive, with the lattice constant of the layer trying to be larger than that of the substrate, or tensile.

C2.16.2.5 III – V NITRIDES

Figure C2.16.2 shows the gap–lattice constant plots for the III–V nitrides. These compounds can have either the wurtzite or zincblende structures, with the wurtzite polytype having the most interesting device applications. The large gaps of these materials make them particularly useful in the preparation of LEDs and diode lasers emitting in the blue part of the visible spectrum. Unlike the smaller-gap III–V compounds illustrated in figure C2.16.3 single crystals of the nitride binaries of AlN, GaN and InN can be prepared only in very small sizes, too small for epitaxial growth of device structures. Substrate materials such as sapphire and SiC are used instead.

There is also a possibility of preparing mixed III–V nitride alloys, e.g. $\text{GaAs}_{1-y}\text{N}_y$, connecting the two sets of semiconductor materials. Their gap dependence on composition is the subject of active research.

C2.16.3 GENERAL PROPERTIES OF SEMICONDUCTORS

C2.16.3.1 ENERGY BANDS

The optical and electrical characteristics of semiconductors are conveniently described by energy level diagrams [17, 18, 19 and 20]. Electrons in atoms are restricted to sets of discrete energy states, separated by gaps in which electrons are not allowed. In solids, formed by bringing isolated atoms close together, the allowed energy levels of discrete atoms spread into essentially continuous energy *bands*. Two such bands are of particular importance in semiconductors: the highest-lying filled VB and the lowest-lying empty CB. The VB and CB are separated by the energy gap E_g .

In a defect-free, undoped, semiconductor, there are no energy states within the gap. At $T = 0$ K, all of the VB states are occupied by electrons and all of the CB states are empty, resulting in zero conductivity. The thermal excitation of electrons across the gap becomes possible at $T > 0$ and a net electron concentration in the CB is established. The electrons excited into the CB leave empty states in the VB. These holes behave like positively charged electrons. Both the electrons in the CB and holes in the VB participate in the electrical conductivity.

Calculated plots of energy bands as a function of wavevector k , known as band diagrams, are shown in figure C2.16.5 for Si and GaAs. Semiconductors can be divided into materials with *indirect* and *direct* gaps. In direct-gap

semiconductors (represented by GaAs) the minimum energy in the CB and the maximum in the VB occur for the same value of k , namely $k = 0$, the Γ point. This is not the case in indirect materials (represented by Si) in which the maximum of the VB occurs at $k = 0$ but the minimum of the CB at $k \neq 0$. This difference has profound consequences for the rates of electron–hole *recombination* across the gap.

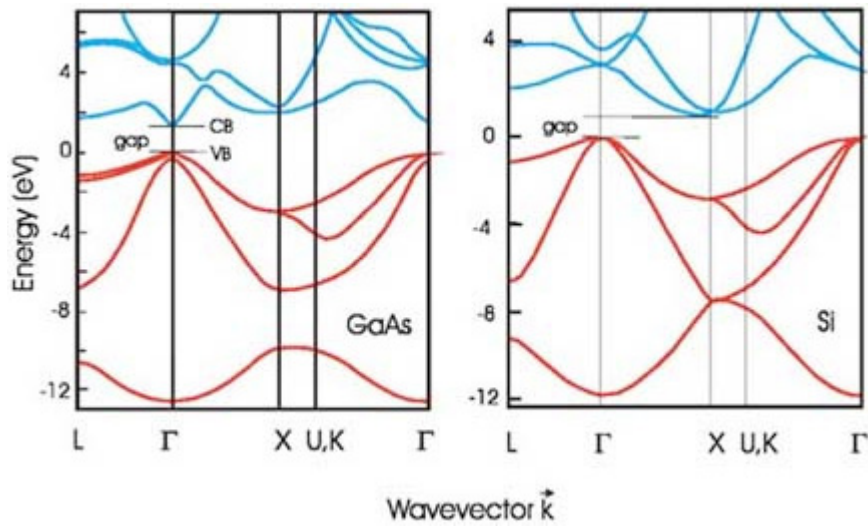

Figure C2.16.5. Calculated plots of energy bands as a function of wavevector k , known as band diagrams, for Si and GaAs. Indirect (Si) and direct (GaAs) gaps are indicated. High-symmetry points of the Brillouin zone are indicated on the wavevector axis.

All technologically important properties of semiconductors are determined by defect-associated energy levels in the gap. The conductivity of pure semiconductors varies as $\sigma \sim \exp(-E_g/k_B T)$, where E_g is the gap. In most semiconductors with practical applications, the size of the gap, $E_g \sim 1\text{--}2$ eV, makes the thermal excitation of electrons across the gap a relatively unimportant process. The introduction of shallow states into the gap through *doping*, with either donors or acceptors, allows for large changes in conductivity (figure C2.16.1). The donor and acceptor levels are typically a few meV below the CB and a few tens of meV above the VB, respectively. The depth of these levels usually scales with the size of the gap (see below).

C2.16.3.2 ELECTRICAL PROPERTIES

The application of a small external electric field E to a semiconductor results in a net average velocity component of the carriers (electrons or holes) called the *drift velocity*, v_d . The coefficient of proportionality between E and v_d is known as the carrier *mobility* μ . At higher fields, where the drift velocity becomes comparable to the thermal velocity of the carriers (which is about 10^7 cm s⁻¹ in Si at room temperature), the carriers decelerate by scattering with charged impurities and *lattice vibrations* (phonons and local vibrational modes). The simple linear relationship between E and v_d no longer applies. Thus the low-field mobility μ describes the mean free time between collisions. It depends strongly on the *effective mass* (see below) of the carriers, the purity of the semiconductor and the temperature. The effective mobility μ of carriers in a semiconductor reflects the contributions of various scattering mechanisms and is written as $1/\mu = 1/\mu_{\text{lattice}} + 1/\mu_{\text{impurity}}$. The temperature dependence of the mobility reflects these individual

contributions. For instance, since $\mu_{\text{lattice}} \sim T^{-3/2}$ and $\mu_{\text{impurity}} \sim T^{+3/2}$, most semiconductors show a peak in the mobility measured as a function of temperature [21]. In some of the modern semiconductor structures, it is possible to essentially eliminate μ_{impurity} and thus reach very high, metallic, mobilities at low temperatures [22].

In terms of the carrier mobility, the electrical conductivity σ of an n type semiconductor can be written as

$$\sigma = ne\mu$$

where n is the conduction electron density and e the electron charge. Since n is a strong (exponential) function of temperature, σ varies with temperature both through n and μ .

In thermal equilibrium at the temperature T , the distribution of electrons in the band is given by the Fermi–Dirac distribution function $f(E) = [1 + e^{(E-E_f)/kT}]^{-1}$, where k is the Boltzmann constant. The function $f(E)$ describes the probability that a state with an energy E is occupied at the temperature T . The quantity E_f , called the *Fermi level*, denotes the energy level with the occupation probability 1/2 at $T = 0$. At $T = 0$, all the available states below E_f are filled, $f(E < E_f) = 1$, all the states above E_f are empty, $f(E > E_f) = 0$. At $T = 0$, the Fermi level coincides with the chemical potential.

Instead of plotting the electron distribution function in the energy band diagram, it is convenient to indicate the position of the Fermi level. In a semiconductor of high purity, the Fermi level is close to mid-gap. In p type (n type) semiconductors, it lies near the VB (CB). In very heavily doped semiconductors the Fermi level can move into either the CB or VB, depending on the doping type.

The distributions of states in the CB and VB are described by the effective *density of states*. The concentration of electrons in the CB can be calculated as $n = \int_{E_c}^{\infty} f(E) N(E) d(E)$, where $f(E)$ is the Fermi distribution and $N(E) d(E)$ is the density of states between E and $E + dE$. A simpler way of calculating n is to represent all the electron states in the CB by an effective density of states N_c at the energy E_c (band edge). The electron density is then simply $n = N_c f(E_c)$.

Most of our ideas about carrier transport in semiconductors are based on the assumption of diffusive motion. When the electron concentration in a semiconductor is not uniform, the electrons move (*diffuse*) under the influence of concentration gradients, giving rise to an additional contribution to the current. In this motion, electrons also undergo collisions and their temporal and spatial distributions are described by the *diffusion equation*. The proportionality constant between the flux and the concentration gradient is called *diffusivity*, D ($\text{cm}^2 \text{s}^{-1}$). Diffusivity and mobility are related by Einstein's relationship $D = (kT/q)\mu$, where q is the carrier charge. In the context of diffusive motion, it is also straightforward to introduce the carrier lifetime τ as the average time between collisions and define a diffusion length $L = \sqrt{D\tau}$. This concept is particularly useful to describe *minority carriers*. The minority carrier diffusion length varies from the sub-micrometre in heavily doped semiconductors to tens of micrometres in high-purity materials.

C2.16.3.3 RECOMBINATION

In n type semiconductors, electrons are the *majority carriers*. Holes will also be present through accidental incorporation of acceptor impurities or, more importantly, through the intentional creation of electron-hole pairs. Holes in n type and electrons in p type semiconductors are *minority carriers*.

There are many ways of increasing the equilibrium carrier population of a semiconductor. Most often this is done by generating electron–hole pairs as, for instance, in the process of absorption of a photon with $h\omega \geq E_g$. Under reasonable levels of illumination and doping, the generation of electron–hole pairs affects primarily the minority carrier density. However, the excess population of minority carriers is not stable: it gradually disappears through a variety of *recombination* processes in which an electron in the CB fills a hole in a VB. The excess energy E_g is released as a photon or phonons. The former case corresponds to a *radiative* recombination process, the latter to a *non-radiative* one. The radiative processes only rarely involve direct recombination across the gap. Usually, this type of process is assisted by shallow defects (impurities). Non-radiative recombination involves a defect-related deep level at which a carrier is trapped first, and a second transition is needed to complete the process.

Radiative recombination of minority carriers is the most likely process in direct gap semiconductors. Since the carriers at the CB minimum and the VB maximum have the same momentum, very fast recombination can occur. The radiative recombination lifetimes in direct semiconductors are thus very short, of the order of the ns. The presence of deep-level defects opens up a non-radiative recombination path and further shortens the carrier lifetime.

The situation is very different in indirect gap materials where phonons must be involved to conserve momentum. Radiative recombination is inefficient, resulting in long lifetimes. The minority carrier lifetimes in Si reach many ns, again in the absence of defects. It should be noted that long minority carrier lifetimes imply long diffusion lengths. Minority carrier lifetime can be used as a convenient quality benchmark of a semiconductor.

C2.16.4 DEFECTS AND IMPURITIES

Intrinsic defects (or ‘native’ or simply ‘defects’) are imperfections in the crystal itself, such as a vacancy (a missing host atom), a self-interstitial (an extra host atom in an otherwise perfect crystalline environment), an anti-site defect (in an AB compound, this means an atom of type A at a B site or vice versa) or any combination of such defects. *Extrinsic* defects (or impurities) are atoms different from host atoms, trapped in the crystal. Some impurities are intentionally introduced because they provide charge carriers, reduce their lifetime, prevent the propagation of dislocations or are otherwise needed or useful, but most impurities and defects are not desired and must be eliminated or at least controlled.

The presence of defects and impurities is unavoidable. They are created during the growth or penetrate into the material during the processing. For example, in a crystal grown from the melt, impurities come from the crucible and the ambient, and are present in the source material. Depending on factors such as the pressure, the pull rate and temperature gradients, the crystal may be rich in vacancies or self-interstitials (and their precipitates).

After the growth, virtually all the processing steps create defects and/or add impurities. Ion implantation and electron irradiation create vacancy–self-interstitial pairs (*Frenkel pairs*). Wet or dry etching, the deposition of organic masks, metallic contacts, or other surface layers, furnace or rapid thermal anneals and other processes also result in defects or impurities penetrating into the material or diffusing through the bulk.

Experimentally, local vibrational modes associated with a defect or impurity may appear in infra-red absorption or Raman spectra. The defect centre may also give rise to new photoluminescence bands and other experimentally observable signature. Some defect-related energy levels may be visible by deep-level transient spectroscopy (DLTS) [23].

C2.16.4.1 NOMENCLATURE

Most electrical and optical properties of semiconductors are determined by the impurities and defects they contain. The underlying reason for this is that any kind of imperfection in the crystal means a different local potential and therefore new energy eigenvalues (*energy levels*) and eigenfunctions associated with the defect or impurity and its immediate environment. If the new levels are in the gap, as is often the case, they give rise to some electrical activity. The energy levels can be *shallow* (near a band edge) or *deep* (far from a band edge). ‘Hyper-deep’ refers to a localized level in the VB.

A gap level is called an *acceptor level* if the defect is neutral when the state is empty (no electron). It is called a *donor level* if the defect is neutral when the state is occupied (one electron). The former is often labelled (0 / –) and the latter (+ / 0), where the first (second) sign refers to the charge of the defect when no electron (one electron) is present. Double or triple acceptor and donor levels are similarly labelled.

Common terminology used to characterize impurities and defects in semiconductors includes point and line defects, complexes, precipitates and extended defects. These terms are somewhat loosely defined, and examples follow.

A *point defect* refers to a localized defect (such as a monovacancy) or impurity (such as interstitial O). This includes any relaxation and/or distortion of the crystal around it. Many point defects are now rather well understood, especially in Si, thanks to a combination of experiments providing information of microscopic nature

(such as electron paramagnetic resonance, local vibrational mode spectroscopy, or photoluminescence) and ‘*ab initio*’ or ‘first-principles’ theory (which means that no experimentally adjusted parameters are used). Tremendous progress has been achieved since the mid-1980s in the theory of defects in semiconductors, to the point where nearly quantitative predictions are common.

A combination of a small number of point defects is called a *complex*. Examples are the boron–hydrogen pair in Si, a small cluster of vacancies such as the hexavacancy, or a C–C pair. *Precipitates* refer to more complicated and larger aggregates of impurities or defects, such as the O-related thermal donors in Si, or metallic impurities trapped at some internal void. Such precipitates can be of substantial size, involving anywhere from a handful to thousands of atoms. They can be permanent sinks for specific impurities (such as SiO₂ precipitates in Si) or serve as sources of impurities or defects, such as the {311} platelets of self-interstitials in Si. Such defects are difficult to study. The number of degrees of freedom and local minima of a multi-dimensional potential energy surface render the theorist’s task very challenging. Experimentalists must deal with complicated spectra and often broad lines. As a result, only a few small complexes are well understood, and almost nothing microscopic is known about large complexes and precipitates. For example, despite almost 50 years of experimental studies and theoretical modelling, the structure and nature of O-related thermal donors in Si is still unknown [24, 25].

Extended defects range from well characterized dislocations to grain boundaries, interfaces, stacking faults, etch pits, D-defects, misfit dislocations (common in epitaxial growth), blisters induced by H or He implantation etc. Microscopic studies of such defects are very difficult, and crystal growers use years of experience and trial-and-error techniques to avoid or control them. Some extended defects can change in unpredictable ways upon heat treatments. Others become gettering centres for transition metals, a phenomenon which can be desirable or not, but is always difficult to control. Extended defects are sometimes cleverly used. For example, the ‘smart-cut’ process relies on the controlled implantation of H followed by heat treatments to create blisters. This allows a thin layer of clean material to be lifted from a bulk wafer [26].

Point defects and complexes exhibit *metastability* when more than one configuration can be realized in a given charge state. For example, neutral interstitial hydrogen is metastable in many semiconductors: one configuration has H at a relaxed bond-centred site, bound to the crystal, and the other has H atomic-like at the tetrahedral interstitial site.

Bistability refers to defects which have different configurations in different charge states. The transition to a bistable state can be induced by the exposure to band-gap light for example. One example is the EL2 centre in GaAs [27]. A defect or impurity is called *negative U* when the energy gained by pairing two electrons (or holes) at the defect is greater than the Coulomb repulsion between them. The best known example is the vacancy (V) in Si which is stable in the spin singlet ++, 0 and – – charge states but unstable in the spin doublet + and – states [28].

The energetics associated with a metastable and/or bistable defect are often described using a *configuration diagram*. It is a semi-quantitative plot of the energy against a global coordinate which combines the position of the impurity and all the relaxations and distortions of the crystal, which can be substantial. The configuration diagram in figure C2.16.6 was obtained from muon spin rotation (μ SR) data in Si [29], and relates to the states of muonium (Mu), a light isotope of hydrogen. This example illustrates configuration diagrams, acceptor and donor levels, metastability, bistability and negative-*U* behaviour.

Figure C2.16.6. The energy states of a metastable and bistable muonium in Si are illustrated in a *configuration diagram*. It plots the defect energy as a function of a coordinate which combines position and all the relaxations and distortions of the crystal. The specific example, discussed in the text, illustrates acceptor and donor levels, metastability, bistability and negative- U [50] behaviour.

The configuration diagram consists of three (potential) energy curves associated with the three charge states of hydrogen in Si. The two types of minima correspond to the impurity at the tetrahedral interstitial (T) and at the bond-centred (BC) sites, respectively. There is little relaxation of the host crystal when hydrogen is at the T site, but the BC site is a minimum of the energy only after an Si–Si bond relaxes substantially to become the bridged Si–H–Si bond. The H_T^- state exists only in n type Si and is stable only at the T site. The H_{BC}^+ state is observed predominantly in p type Si, and is only stable at the BC site. The neutral state is found in two configurations, at the BC site (stable) and the T site (metastable). The energy difference between these two sites is shown as Δ , the value of which is estimated at a few tenths of an eV. The μ SR data show that all three charge states coexist at the microsecond time scale above room

-12-

temperature and there is experimental evidence that this is the case for H as well. The energy differences marked in the figure were either measured directly (ionizations) or deduced from fitting the data.

The ionization energies and impurity levels are shown in the flat-band figure next to the configuration diagram. The donor level (+ / 0) corresponds to the ionization energy $H_{BC}^0 \rightarrow H_{BC}^+$ since the transition occurs between essentially identical configurations. The ionization energy measured by μ SR is very close to the donor level obtained for hydrogen by DLTS [30], 0.175 ± 0.005 eV.

The situation is more complicated for the acceptor level, as the measured ionization energy corresponds to a transition from the stable state H_T^- to the metastable state H_T^0 . However, the acceptor level corresponds to the energy difference between stable states $H_T^- \rightarrow H_{BC}^0$ that is the ionization energy corrected by Δ . The μ SR data therefore imply that muonium (or hydrogen) is negative U if $\Delta < 0.35$ eV, and positive U otherwise. The energy difference U between the acceptor and donor levels is in any case quite small, whether positive or negative. Note that quantum effects (such as the zero-point energy) do play a role in this case, as the impurity (a muon of hydrogen) is very light.

C2.16.4.2 SHALLOW LEVELS

Shallow impurities have energy levels in the gap but very close to a band. If an impurity has an empty level close to the VB maximum, an electron can be thermally promoted from the VB into this level, leaving a hole in the VB. Such an impurity is a *shallow acceptor*. On the other hand, if an impurity has an occupied level very close to the CB minimum, the electron in that level can be thermally promoted into the CB where it participates in the conductivity. Such an impurity is a *shallow donor*.

There are other, more exotic, possibilities. For example, if a defect has an empty level near the CB, an electron may become trapped in it. This localized electron may in turn bind a hole in a loose orbit, forming a *bound exciton*.

Shallow donors (or acceptors) add new electrons to the CB (or new holes to the VB), resulting in a net increase in the number of a particular type of charge carrier. The implantation of shallow donors or acceptors is performed for this purpose. But this process can also occur unintentionally. For example, the precipitation around 450°C of interstitial oxygen in Si generates a series of shallow double donors called thermal donors. As-grown GaN crystal are always heavily n type, because of some intrinsic shallow-level defect. The presence and type of new charge carriers can be detected by Hall effect measurements.

Since shallow-level impurities have energy eigenvalues very near those of the perfect crystal, they can be described using a perturbative approach first developed in the 1950s and known as *effective mass theory* (EMT). The idea is to approximate the band nearest to the shallow level by a parabola, the curvature of which is characterized by an effective mass parameter m^* .

The simplest example is that of the shallow P donor in Si. Four of its five valence electrons participate in the covalent bonding to its four Si nearest neighbours at the substitutional site. The energy of the fifth electron which, at ~0 K, is in an energy level just below the minimum of the CB, is approximated by $\hbar^2 k^2 / 2m^*$ plus the screened Coulomb attraction to the P^+ ion, $e^2 / \epsilon r$, where ϵ is the dielectric constant or the frequency-dependent dielectric function. The Schrödinger equation for this electron reduces to that of the hydrogen atom, but m^* replaces the electronic mass and ϵ screens the Coulomb attraction.

-13-

In Si, the binding energy is reduced to ~20–40 meV independently of the shallow donor. The solution further yields a hydrogenic series of levels analogous to the 1s, 2sp etc states of atomic hydrogen. This series bridges the shallow level of the donor and the CB minimum, facilitating the thermal ionization of the electron into the CB. This ionization, which begins below liquid nitrogen temperature, is what provides free electrons to the CB.

The Bohr radius is very large, 3–5 nm, and the shallow impurity wavefunction extends over a large portion of the crystal. Doping up to the ‘metallic limit’ consists in implanting a sufficiently high concentration of donors so that the shallow-donor wavefunctions overlap, creating a half-filled impurity band in which the electrons move freely.

C2.16.4.3 DEEP LEVELS

If the level(s) associated with the defect are deep, they become electron–hole recombination centres. The result is a (sometimes dramatic) reduction in carrier lifetimes. Such an effect is often associated with the presence of transition metal impurities or certain extended defects in the material. For example, substitutional Au is used to make fast switches in Si. Many point defects have deep levels in the gap, such as vacancies or transition metals. In addition, complexes, precipitates and extended defects are often associated with recombination centres. The presence of grain boundaries, dislocation tangles and metallic precipitates in poly-Si photovoltaic devices are major factors which reduce their efficiency.

Deep-level defects cannot be described by EMT or be viewed as simple perturbations to the perfect crystal. Instead, the full crystal-plus-defect problem must be solved and the geometries around the defect optimized to account for lattice relaxations and distortions. The study of deep levels is an area of active research.

In order to remove the unwanted electrical activity associated with deep-level impurities or defects, one can either physically displace the defect away from the active region of the device (*gettering*) or force it to react with another impurity to remove (or at least change) its energy eigenvalues and therefore its electrical activity (*passivation*).

Gettering is a black art. It consists in forcing selected impurities (typically, transition metals) to diffuse toward unimportant regions of the device. This is often done by creating precipitation sites and performing heat treatments. The precipitation sites range from small oxygen complexes to layers such as an Al silicide. The formation of such a

metallization injects vacancies into the bulk and they enhance the diffusivity of some transition metals. Phosphorus gettering occurs during the heat treatment that follows the implantation of a heavily doped n^+ layer in Si. However, boron-rich buried layers and H-induced platelets are efficient gettering sites as well, because transition metals are much more stable at such defective regions than dissolved in the bulk. Recent success in achieving copper contacts on Si involved creating a gettering layer (TiN) in the subsurface region to precipitate Cu and keep it out of the active region of the device.

Passivation involves mostly the use of hydrogen [31]. H is a rapid diffuser in most semiconductors and is unavoidable. It may be present in an ambient (water vapour for example) and in many processing steps such as the deposition of Schottky contacts or antireflection coatings, the use of organic masks etc. Hydrogen diffuses and traps at a range of impurities and defects. The trapping always involves some covalent interaction, a change in the configuration and electronic structure of the complex and a shift in its energy eigenvalues. Passivation results when an energy level shifts from the gap into a band. The thermal stability of most H–impurity pairs is normally rather low (a few hundred degrees Celsius at the most), but that of H–defect pairs tends to be higher. This is why H is used to passivate grain boundaries and other defects in poly-Si solar cells for example. In GaN, hydrogen passivates the shallow Mg acceptor with an

-14-

unusually high thermal stability. In order to obtain p type GaN, the material is often annealed at high temperatures to dissociate the {H, Mg} pairs and diffuse H out of the crystal.

C2.16.4.4 DIFFUSION

In addition to the configuration, electronic structure and thermal stability of point defects, it is essential to know how they diffuse. A variety of mechanisms have been identified. The simplest one involves the diffusion of an impurity through the interstitial sites. For example, copper in Si diffuses by hopping from one tetrahedral interstitial site to the next via a saddle point at the hexagonal interstitial site.

However, most impurities and defects are Jahn–Teller unstable at high-symmetry sites or/and react covalently with the host crystal much more strongly than interstitial copper. The latter is obviously the case for substitutional impurities, but also for interstitials such as O (which sits at a relaxed, puckered bond-centred site in Si), H (which bridges a host atom–host atom bond in many semiconductors) or the self-interstitial (which often forms more exotic structures such as the ‘split- $\langle 110 \rangle$ ’ configuration). Such point defects migrate by breaking and re-forming bonds with their host, and phonons play an important role in such processes.

The vacancy is very mobile in many semiconductors. In Si, its activation energy for diffusion ranges from 0.18 to 0.45 eV depending on its charge state, that is, on the position of the Fermi level. While the equilibrium concentration of vacancies is rather low, many processing steps inject vacancies into the bulk: ion implantation, electron irradiation, etching, the deposition of some thin films on the surface, such as Al contacts or nitride layers etc. Such non-equilibrium situations can greatly affect the mobility of impurities as vacancies flood the sample and trap interstitials.

Self-interstitials are also mobile. In Si, the activation energy for diffusion is believed to be of the order of the eV, but this drops to zero when minority charge carriers are present. This is probably due to *recombination-enhanced diffusion*, a process in which the defect itself is a recombination centre for electrons and holes. The recombination releases an energy about equal to size of the gap and this energy is used to propel the impurity above a diffusion barrier. Since many processing steps which inject self-interstitials also inject minority carriers, self-interstitials tend to diffuse excessively fast during the processing step and react with impurities and defects. They often kick out substitutional impurities, thus transforming a slow-diffusing impurity into a rapidly diffusing one. Important examples include boron in Si and the 3d transition metals which diffuse much faster as interstitial than substitutional impurities.

More exotic diffusion processes have been identified, although they may not be fully understood. One example is the substantial enhancement [25] of the diffusivity of interstitial O by H, resulting in the increased formation rate of

C2.16.5 STRUCTURES AND DEVICES

C2.16.5.1 P – N JUNCTION

In order to obtain appreciable conductivities, semiconductors must be doped with small amounts of selected impurities. It is possible to switch the doping type from n to p type, or vice versa, either during the growth of a crystal or by the selective introduction of impurities after the growth. The boundary region between the p type and n type regions is

-15-

called a *p-n junction* [17, 32, 33, and 34].

The detailed spatial distribution of carriers in the immediate vicinity of the p–n junction is very important. Some of the majority carriers at the junction neutralize each other. This results in a thin region depleted of free carriers, known as the *space-charge region*. In this region, negatively ionized acceptors on the p side repel the mobile electrons from the n side of the junction. Similarly, the mobile holes from the p side are repelled by the positively ionized donors on the n side. The result is a built-in electric field which inhibits carrier diffusion across the p–n junction. The electrostatic potential, or *contact potential*, associated with this field bends the conduction and valence bands in the space-charge region by an amount called the *barrier height*, as is illustrated in figure C2.16.7.

Figure C2.16.7. A schematic energy band diagram of a p–n junction without external bias (a) and under forward bias (b). Electrons and holes are indicated with – and + signs, respectively. It should be remembered that the energy of electrons increases by moving up, holes by moving down. Electrons injected into the p side of the junction become minority carriers. Approximate positions of donor and acceptor levels and the Fermi level, are indicated.

V_d is the built-in potential of the p–n junction.

A current flow across the p–n junction can be accomplished only by the application of an external voltage which opposes the contact potential and reduces the barrier height. This voltage, called a *forward bias*, supplies electrons at the n and holes at the p contact. Since the barrier height is similar in magnitude to the gap energy, the external bias needs to be fairly small, on the order of the gap energy divided by the electron charge.

-16-

Under a forward bias, the majority carriers cross the p–n junction and become minority carriers, e.g. holes on the n side of the junction. These holes rapidly come into thermal equilibrium with the crystal and reach the energy approximately equal to the energy of the valence band edge on the n side of the junction (it should be remembered that electrons moving up on the energy band increase their energy while holes increase their energy by moving down). Similarly, the minority electrons reach equilibrium at the p side of the junction. However, the minority carriers are not in thermodynamic equilibrium with the majority carriers and must give up their excess energy. A hole on the n side recombines with a majority electron, which then loses an energy about equal to E_g . The minority electron loses a similar energy by recombining with a majority hole.

The distributions of excess, or *injected*, carriers are indicated in band diagrams by so-called quasi-Fermi levels for electrons (E_{fn}) or holes (E_{fp}). These functions describe steady state concentrations of excess carriers in the same form as the equilibrium concentration. In equilibrium we have $E_{fn} = E_{fp} = E_f$.

C2.16.5.2 PHOTODETECTORS AND SOLAR CELLS

The current–voltage characteristic of an ideal p–n junction is $I = I_s[\exp(qV/mkT) - 1]$, where q is the electron (hole) charge, m is the ideality factor, $1 \leq m \leq 2$, and I_s the saturation current. Under applied reverse bias, the current through the junction is limited to I_s . Illuminating a reverse-biased diode with photons of energy greater than E_g results in the generation of photocarriers. The photocurrent is proportional to the intensity of the incident light. In low-doped diodes, I_s can be quite low and even small amounts of light can be detected. The diode is being operated as a *photodetector*. Very sophisticated detector structures have been designed, particularly those relying on high-field *avalanche multiplication* of photocarriers [35].

The p–n junction diode can also be used to convert optical energy directly to electrical power, without external power supplies. Absorption of a photon with $E > E_g$ produces an e^-h^+ pair. The internal electric field of the p–n junction separates the carriers; the e^- and h^+ move toward metallic contacts on opposite sides of the cell. The resulting photocurrent is sent to an external load. The maximum power delivered to a load is obtained under small forward bias. In Si cells, the largest voltage output produced in the open circuit mode (i.e. with $I = 0$) is about 0.7 V. Si solar cell power efficiencies as high as 24% have been reported, close to the theoretical limit of 32%. The power generated depends on the design of the diode itself and a match to the electrical load. The gap of the cell's semiconductor must match the solar spectrum as closely as possible and the structure of the gap should allow for efficient absorption of the solar photons. Perfection of the semiconductor material is also very important for high efficiency. Electrons and holes generated far from the electrodes must be extracted from the bulk of the cell and this requires long minority carrier diffusion lengths.

C2.16.5.3 LIGHT EMITTING DIODES

Light is generated in semiconductors in the process of radiative recombination. In a direct semiconductor, minority carrier population created by injection in a forward biased p–n junction can recombine radiatively, generating photons with energy about equal to E_g . The recombination process is *spontaneous*: individual electron–hole recombination events are random and not related to each other. This process is the basis of LEDs [36].

LEDs can be now fabricated in all primary colours and with efficiencies much higher than those of light bulbs. Red LEDs, based on InGaAlP, are sufficiently bright to be used in traffic lights and automobile brake lights. Blue LEDs, based on GaInN, have become commercially available in the last few years. White light can be produced by blue LEDs

pumping appropriate phosphor materials. Inexpensive and very reliable infrared LEDs are common in communication systems.

C2.16.5.4 BIPOLAR TRANSISTORS

The bipolar junction transistor (BJT) consists of three layers doped n–p–n or p–n–p that constitute the emitter, base and collector, respectively. This structure can be considered as two back-to-back p–n junctions. Under normal operation, the emitter–base junction is forward biased to inject minority carriers into the base region. For example, the n type emitter injects electrons into a p type base. The electrons in the base, now minority carriers, diffuse through the base layer. The base–collector junction is reverse biased and its electric field sweeps the carriers diffusing through the base into the collector. The BJT operates by transport of minority carriers, but both electrons and holes contribute to the overall current.

A band diagram of a biased n–p–n BJT is shown in figure C2.16.8. Under forward bias, electrons are injected from the n type emitter, giving rise to the current $I_{E,n}$ flowing into the p type base. Some of the carriers injected into the base recombine in the base or at the surface. This results in a reduction of the base current by I_r , the lost recombination current, and the base current becomes $I_B = I_{E,n} - I_r$. At the same time, holes are injected from the base into the emitter giving rise to the $I_{E,p}$ component of the current. The two components, I_r and $I_{E,p}$, must be minimized since they reduce the collector current $I_C = (I_{E,n} - I_{E,p}) - I_r$. The ‘current gain’ of the transistor is the ratio I_C/I_B . Since the base current is much smaller than the collector current, large gains are possible.

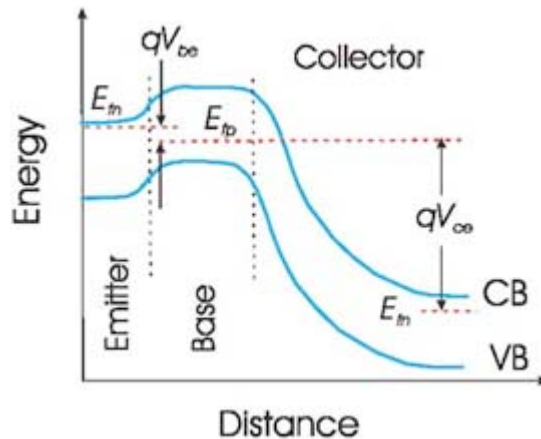

Figure C2.16.8. Schematic energy band diagram for an n–p–n bipolar junction transistor. Positions of quasi-Fermi levels and bias voltages are indicated.

In a BJT, the width of the base region must be smaller than the minority carrier diffusion length, and the two junctions strongly influence each other. Small increases in the current flowing through the first junction result in large increases in the collector current. The ratio of the current at the collector to the base current is the current gain. In Si-based BJTs, the gain is limited by the injection of the base majority carriers into the emitter. In order to maintain an adequate current gain, the doping level of the base must be lower than that of the emitter. Unfortunately, this results in higher base resistance and larger *RC* time constant of the transistor.

Some of these problems are avoided in *heterojunction* bipolar transistors (HBTs) [37, 38], the majority of which are based on III–V compounds such as GaAs/AlGaAs. In an HBT, the gap of the emitter is larger than that of the base. The conduction and valence band offsets that result from the matching up of the two different materials at the heterojunction prevent or reduce the injection of the base majority carriers into the emitter. This permits the use of

the highly doped, very thin bases needed to achieve high gain and high speed of operation at the same time. The conduction band offset at the emitter–base interface gives rise to the possibility of injecting carriers with high kinetic energy and *ballistic* transport in the base.

C2.16.5.5 METAL – OXIDE – SEMICONDUCTOR TRANSISTORS

Metal–oxide–semiconductor field-effect transistors (MOSFETs) are the basic devices of modern electronics [32, 33 and 34]. They can be produced in large numbers with very reproducible characteristics and their low power consumption makes large-scale integrated circuits possible. They are majority carrier devices and thus relatively insensitive to materials defects. A schematic cross section of a MOSFET is shown in [figure C2.16.9](#). The heart of the device is the metal–oxide–semiconductor (MOS) *gate* structure that controls the current flow in the channel. In normal operation of an *n-channel enhancement mode* device, the gate bias is used to produce a conducting channel between two contact regions known as the *source* and *drain*. A positive bias attracts electrons into the channel; a negative bias repels them. For low source–drain bias, the conductivity of the channel is proportional to the gate voltage, the channel width is uniform from source to drain and the transistor behaves as a voltage-controlled resistor. As the drain bias approaches a threshold value (V_p) the voltage drop across the oxide, in the vicinity of the drain, decreases. This results in a non-uniform channel width, lower at the drain, and overall higher resistance. For a drain bias greater than V_p , the channel is pinched off at the drain. Increased source–drain voltage does not produce any incremental source–drain current. At this point, the slope of the output current versus source–drain bias curve is zero. This bias region is known as the *saturation* region. In this region, small changes in the gate voltage produce large changes in the drain current and the device is said to have large *transconductance*.

The performance of MOSFETs depends critically on the gate dimension measured along the channel (the *gate length*), and the gate oxide thickness. Higher transconductance is obtained for shorter gate length and thinner oxides. State-of-the-art devices use gate length shorter than 200 nm and gate oxides thinner than 10 nm.

The carriers in the channel of an enhancement mode device exhibit unusually high mobility, particularly at low temperatures, a subject of considerable interest. The source–drain current is carried by electrons attracted to the interface. The ionized dopant atoms, which act as fixed charges and limit the carriers' mobility, are left behind, away from the interface. In a sense, the source–drain current is carried by the two-dimensional (2D) electron gas at the Si–gate oxide interface.

Electron effective masses are much smaller in compound semiconductors and quantum effects in 2D gas much more pronounced. It is also easier to engineer the 2D electron (or hole) gas by the use of *heterostructures* and *modulation doping*. The channel of a compound semiconductor FET can be formed by two layers with different gaps, for instance GaAs and InGaAs [39]. An undoped *spacer layer* may be introduced at the interface. The electrons associated with the donors in the wider-gap layer see lower-lying energy states in the adjacent narrower-gap material and transfer to it. The electrons and positively charged donors become spatially separated, effectively eliminating ionized impurity scattering in the narrower-gap channel. High-mobility electrons can be then maintained with high sheet charge densities down to very low temperatures.

Figure C2.16.9. Schematic cross-section and biasing of a metal–oxide–semiconductor transistor. A uniform conducting channel is induced between source (S) and drain (D) for $V_{gs} > V_t$. Voltage V_{gs} is applied between the gate (G) and the source. Part (A) shows the channel for $V_{ds} < V_{gs} - V_t$; the transistor acts as a triode. The source–drain voltage is increased in part (B) to $V_{ds} > V_{gs} - V_t$. The channel is now pinched off at the drain side and I_d is saturated. This is the proper regime of operation of the MOS transistor.

C2.16.5.6 HETEROSTRUCTURES

In the p–n junction illustrated in [figure C2.16.7](#) both sides are made of the same semiconductor, and therefore have the same energy gap. Such a junction is called a *homojunction*. In a homojunction, the minority carriers are free to move away from the junction by a few diffusion lengths. It is therefore very difficult to achieve high carrier densities. Significantly higher carrier densities can be obtained by introducing an energy barrier at, or very near, the p–n junction. The energy barrier arises when two different semiconductors (therefore with different gaps) are joined [[8](#), [40](#)]. Barriers in the CB and VB, called the *band-edge discontinuities* ΔE_c and ΔE_v , are formed by changing the composition of the semiconductor layers. The junction of a small- with a large-gap semiconductor is called a *single heterojunction*. It confines one type of minority carrier (electrons or holes) to the p–n junction region.

A more effective carrier confinement is offered by a *double heterostructure* in which a thin layer of a low-gap material is sandwiched between larger-gap layers. The physical junction between two materials of different gaps is called a *heterointerface*. A schematic representation of the band diagram of such a structure is shown in [figure C2.16.10](#). The electrons, injected under forward bias across the p–n junction into the lower-bandgap material, encounter a potential barrier ΔE_c at the p–p junction which inhibits their motion away from the junction. The holes see a potential barrier of

ΔE_v at the n–p heterointerface which prevents their injection into the n region. The result is that the injected minority carriers are confined to the thin narrow-bandgap region. If this region is thinner than the average *diffusion*

length, very high densities of injected carriers can be obtained in a forward-biased diode. Heterojunctions are the basic structures of LEDs, semiconductor lasers and HBTs.

Figure C2.16.10. Band diagram of a double p-p-n double heterostructure without the external bias. The gap E_{g1} is smaller than E_{g2} . Conduction and valence band discontinuities are indicated. Structures of this type are used in LEDs and diode lasers.

C2.16.5.7 QUANTUM WELL STRUCTURES

Advances in epitaxial crystal growth methods make it possible to prepare heterostructures with essentially arbitrary thickness of the small-gap layer. When the thickness of this layer is reduced to dimensions of the order of 10 nm (between 20 and 30 atomic planes) a quantum mechanical description of the confined carriers is needed. Such heterostructures are called *quantum wells* [41, 42].

In quantum wells, Heisenberg's uncertainty principle requires an increase in the carrier energy over the equilibrium energy of the bulk semiconductor. The confined carriers are allowed only a few discrete states, with energies inversely proportional to the carrier's effective mass and the square of the well width. The incorporation of quantum wells into the material has a number of subtle consequences. The VB in direct bulk semiconductors is degenerate at the Γ point (see figure C2.16.5, resulting in two types of holes with the same energy, the *heavy holes* and *light holes*. The effective mass of the light hole is similar to that of the electron, while that of the heavy hole is typically ten times larger than that of the electron. In quantum wells, the degeneracy of the two hole bands is lifted. The energy shift due to quantum well confinement is larger for the light holes. This has important consequences for quantum well lasers and modulation-doped FETs.

C2.16.5.8 DIODE LASERS

The light emitted in the spontaneous recombination process can leave the semiconductor, be absorbed or cause additional transitions by stimulating electrons in the CB to make a transition to the VB. In this *stimulated recombination* process another photon is emitted. The rate of stimulated emission is governed by a detailed balance between absorption, and spontaneous and stimulated emission rates. Stimulated emission occurs when the probability of a photon causing a transition of an electron from the CB to VB with the emission of another photon is greater than that for the upward transition of an electron from the VB to the CB upon absorption of the photon. These rates are commonly described in terms of Einstein's A and B coefficients [8, 43]. For semiconductors, there is a simple condition describing the carrier density necessary for stimulated emission, or lasing. This carrier density is known as

the *threshold density*. There is also a corresponding *threshold current density* that has to be supplied to the p-n junction. Lasing can start when the density of electrons injected into the CB exceeds the hole density in the VB, a condition of *population inversion*. It occurs when the separation of the quasi-Fermi levels for holes (E_p) and electrons (E_n) is greater than the energy of the emitted photon,

$$E_n - E_p > h\omega$$

and the photon energy $h\omega$ must be at least equal to E_g . Thus, in semiconductor lasers, stimulated emission occurs between distributions of states in the conduction and valence bands. In most other lasers, such as gas or glass lasers, this transition occurs between discrete energy levels.

The emission wavelength of the laser is directly related to the size of the gap. The early lasers were based on GaAs and emitted therefore in the near infrared. Lasers based on InGaAsP produce light between 1.3 and 1.55 μm , specifically tailored to optical fibre communications [44]. Ongoing advances in GaN-based materials are resulting in lasers emitting in the blue [11]. We thus have a very wide range of gaps and emission wavelengths at our disposal.

A diode laser requires the generation of spatially localized high concentrations of minority carriers, a medium to provide the gain and a way of providing feedback to the stimulated emission [43, 44 and 45]. The medium is the semiconductor heterostructure arranged to help to confine the carriers and the photons to the same region of space. Light is generated by a p–n junction which injects electrons from the valence to the conduction band and thus provides the population inversion. This is followed by electron–hole recombination and the emission of light. Further recombination can be stimulated by light already present in the medium. The optical feedback is arranged by forming a cavity with two mirrors parallel to each other. Light generated within the cavity is then partially reflected back into the crystal. Such mirrors can be formed in most compound semiconductors by simply cleaving both ends of the heterostructure wafer.

Figure C2.16.11 illustrates the evolution of the threshold current density of diode lasers with the structure of the recombination region within the p–n junction, known as the *active* region. The early diode lasers were based on GaAs homojunctions. Their large threshold current densities resulted from poor carrier confinement and large effective active region thickness. This is because the diffusion length of electrons is fairly long in most of the semiconductors discussed here, of the order of several micrometres. A very high threshold current density limits operation to short pulses and cryogenic temperatures.

-22-

Figure C2.16.11. Changes in the threshold current density of diode lasers resulting from new structure concepts. A homojunction diode laser was first demonstrated in 1962. SH and DH stand for single and double heterostructure, respectively. The best laser performance is now obtained in quantum well (QW) lasers.

In a heterostructure laser, the active region can be defined by epitaxial layers and made considerably thinner. In GaAs/Al_xGa_{1-x}As heterostructures, the active region can be made as thin as 100 nm, and the threshold current density drops to less than 0.5 kA cm⁻². Such lasers readily achieve continuous operation at room temperature and are capable of high power output.

A logical consequence of this trend is a *quantum well laser* in which the active region is reduced further, to less than 10 nm. The 2D carrier confinement in the wells (formed by the CB and VB discontinuities) changes many basic semiconductor parameters, in particular the density of states in the CB and VB, which is greatly reduced in quantum well lasers. This makes it easier to achieve population inversion and results in a significant reduction in the threshold carrier density. Indeed, quantum well lasers are characterized by threshold current densities lower than 100 A cm^{-2} .

The history of the diode laser illustrated in figure C2.16.11 shows the interplay of basic device physics ideas and technology. A new idea often does not produce a better device right away. It requires a certain leap of faith to see the improvement potential. However, once the belief exists, the technology can be developed to demonstrate its validity. In the case of diode lasers, the better technology was invariably associated with improved epitaxial growth.

C2.16.6 OUTLOOK

We are aware of the dangers inherent in predicting the future. It is much safer to summarize the present and to extrapolate to the near term only.

The speed and general performance of semiconductor electronics have been doubling and the cost halving every 18

-23-

months for the last 50 years, a phenomenon known as Moore's law [46]. It is remarkable that this rate of advances still holds today, even as the active volume of devices is becoming so small that quantum effects are critical. The semiconductor industry has listed the expected challenges and specific goals in a 'road-map' extending well into the next decade [47]. The gate length of MOS transistors will be measured in nanometres, not in micrometres. The thickness of gate dielectrics is expected to drop to less than 20 nm. This reduction in size demands a much better microscopic understanding of materials and processes.

Atomic-scale devices already projected pose design challenges at the quantum mechanical level. The framework of quantum computing is now being discussed in research laboratories [48, 49].

In additions to improvements in Si, a variety of devices based on compound semiconductors can be expected. Blue lasers with high brightness and long operating lifetimes already exist in the laboratory. LEDs are likely to be used for all lighting purposes. The bandwidth of optical communications will continue to increase with ever faster semiconductor lasers.

There appears to be a world market for an infinite number of computers and other electronic devices.

C2.17 Nanocrystals

Vicki L Colvin and Dan M Mittleman

C2.17.1 INTRODUCTION

Throughout most of the twentieth century, the size of a solid has been an uninteresting parameter in the developing areas of solid-state physics and chemistry. Millimetre-thick gold wires have the same colour, conductivity and melting point as gold coins; even in state-of-the-art microelectronics, where structural features with sub-micrometre sizes have become typical, semiconductors and metals have the same behaviour as measured in their macroscopic counterparts. These facts are not surprising, as most material properties, such as conduction and colour, emerge from interactions between, at most, hundreds of unit cells, each less than a nanometre in size. Thus size is not an important factor in understanding and controlling crystalline solids unless the length of solid shrinks to the nanometre length scale. Of course, this is the relevant size range for the next generation of microelectronics, and is evidently an important length scale for many biological systems. These factors have spurred the development of the field of nanoscience, which is the study of the influence of size on the properties of solids. Innumerable

studies of the properties of nanocrystalline materials have amply demonstrated that size really does matter; it can be a powerful parameter in the systematic study of bulk behaviour, as well as in the design of new materials with unique and special properties.

For the purposes of this review, a nanocrystal is defined as a crystalline solid, with feature sizes less than 50 nm, recovered as a purified powder from a chemical synthesis and subsequently dissolved as isolated particles in an appropriate solvent. In many ways, this definition shares many features with that of ‘colloids’, defined broadly as a particle that has some linear dimension between 1 and 1000 nm [1]; the study of nanocrystals may be thought of as a new kind of colloid science [2]. Much of the early work on colloidal metal and semiconductor particles stemmed from the photophysics and applications to electrochemistry. (See, for example, the excellent review by Henglein [3].) However, the definition of a colloid does not include any specification of the internal structure of the particle. Therein lies the crucial distinction: in nanocrystals, the interior crystalline structure is of overwhelming importance. Nanocrystals must truly be ‘little solids’ (figure C2.17.1), with internal structures equivalent (or nearly equivalent) to that of bulk materials. This is a necessary condition if size-dependent studies of nanometre-sized objects are to offer any insight into the behaviour of bulk solids.

The definition above is a particularly restrictive description of a nanocrystal, and necessarily limits the focus of this brief review to studies of nanocrystals which are of relevance to chemical physics. Many nanoparticles, particularly oxides, prepared through the sol-gel method are not included in this discussion as their internal structure is amorphous and hydrated. Nevertheless, they are important nanomaterials; several textbooks deal with their synthesis and properties [4, 5]. The material science community has also contributed to the general area of nanocrystals; however, for most of their applications it is not necessary to prepare fully isolated nanocrystals with well defined surface chemistry. A good discussion of the goals and progress can be found in references [6, 7, 8 and 9]. Finally, there is a rich history in gas-phase chemical physics of the study of clusters and size-dependent evaluations of their behaviour. This topic is not addressed here, but covered instead in [chapter C1.1](#), Clusters and nanoscale structures, in this same volume.

-2-

Figure C2.17.1. Transmission electron micrograph of a TiO_2 (anatase) nanocrystal. The mottled and unstructured background is an amorphous carbon support film. The nanocrystal is centred in the middle of the image. This microscopy allows for the direct imaging of the crystal structure, as well as the overall nanocrystal shape. This titania nanocrystal was synthesized using the nonhydrolytic method outlined in [79].

We begin our discussion of nanocrystals in this chapter with the most challenging problem faced in the field: the preparation and characterization of nanocrystals. These systems present challenging problems for inorganic and analytical chemists alike, and the success of any nanocrystal synthesis plays a major role in the further quantitative study of nanocrystal properties. Next, we will address the unique size-dependent optical properties of both metal and semiconductor nanocrystals. Indeed, it is the striking size-dependent colours of nanocrystals that first attracted

the interest of chemical physicists. Finally, the thermodynamic properties of nanocrystals will be reviewed. The melting point reduction and unusual structural metastability observed in solids of confined size are important results in understanding the physics of these systems.

C2.17.2 PREPARATION OF NANOCRYSTALS

Obtaining high-quality nanocrystalline samples is the most important task faced by experimentalists working in the field of nanoscience. In the ideal sample, every cluster is crystalline, with a specific size and shape, and all clusters are identical. While such uniformity can be expected from a molecular sample, nanocrystal samples rarely attain this level of perfection; more typically, they consist of a collection of clusters with a distribution of sizes, shapes and structures. In order to evaluate size-dependent properties quantitatively, it is important that the variations between different clusters in a nanocrystal sample be minimized, or, at the very least, that the range and nature of the variations be well understood.

Reaching the goal of the ideal nanocrystal sample is not an easy task. There are few commercial sources for nanocrystals, and the chemical reactions used to make them can require involved synthetic methodology. On the other hand, the last decade has seen enormous progress in this area and many solids have now been prepared in the

-3-

nanocrystalline phase. For the most well studied materials, particle size distributions of less than 5% on the diameter are routinely obtained [10, 11 and 12]; more typically, size distributions of 10–20% are reasonable. Note that polydispersity for a colloidal system, referred to here as σ , is defined as the standard deviation of the particle diameters divided by average particle diameter.

While size distribution is important, control over the nanocrystal surface is equally important. The best nanocrystal syntheses provide avenues for nanocrystals to be purified, collected as powders, and then redissolved in appropriate solvents. This requires control over the surface chemistry, in order to control the solubility of the nanocrystals. Such flexibility allows these materials to be structurally characterized and then assembled into a wide variety of configurations for further experiments.

There are many ingenious and successful routes now developed for nanocrystalline synthesis; some rely on gas phase reactions followed by product dispersal into solvents [7, 9, 13, 14 and 15]. Others are adaptations of classic colloidal syntheses [16, 17, 18 and 19]. Electrochemical and related template methods can also be used to form nanostructures, especially those with anisotropic shapes [20, 21, 22 and 23]. Rather than outline all of the available methods, this section will focus on two different techniques of nanocrystal synthesis which together demonstrate the general strategies.

C2.17.2.1 REACTIONS OCCURRING IN RESTRICTED ENVIRONMENTS

A logical departure point for the synthesis of nanocrystals is to view the problem as one of limiting the growth of a bulk crystal; this is challenging because the large surface free energy of a nanocrystal makes it a metastable system, highly prone to fusion and aggregation. One particularly elegant and versatile solution is to precipitate solids inside reactors which are themselves of nanometre scale [24, 25, 26, 27 and 28]. Such nanometre-scale reaction environments can be formed by mixing water, surfactant and oil to create inverse micelles [29, 30]. These water pools have diameters that can be tuned from 5 to ~60 Å in radius by varying the water/surfactant molar ratio, thus providing a direct avenue for size control [31, 32 and 33]. Ionic salts can be solvated in the inverse micelles; when such solutions are exposed to a counterion which forms an insoluble solid with the original salt, small crystals of the solid form within the micelle environment. This process, referred to as arrested precipitation, can be used to grow nanocrystals with sizes which are roughly equivalent to the original micellar size. Surface control can be achieved by adding organic ‘capping’ agents to the final solutions. Depending on the solubility and capping group affinity, the nanocrystals may directly precipitate out of the micellar solution [34, 35] or may be recovered as a powder after the micelle phase is disrupted by the addition of an alcohol [36, 37]. The advantage of this approach is

that it is relatively easy, and can be applied to many different materials including metals [38, 39, 40 and 41], ceramics [42, 43, 44, 45, 46 and 47] and some semiconductors [34, 35, 36 and 37, 48]. Shape control is also possible in surfactant-based syntheses of metal nanocrystals [49, 50 and 51]. Cizeron *et al* [52] use surfactants to control not only particle size, but more critically the growth rates of different crystal faces, producing highly anisotropic nanoneedles with aspect ratios exceeding 100:1 (figure C2.17.2).

-4-

Figure C2.17.2. Transmission electron micrograph of a gold nanoneedle. Inverse micelle environments allow for a great deal of control not only over particle size, but also particle shape. In this example, gold nanocrystals were prepared using a photolytic method in surfactant-rich solutions; the surfactant interacts strongly with areas of low curvature, thus continued growth can occur only at the sharp tips of nanocrystals, leading to the formation of high-aspect-ratio nanostructures [52].

Though easy to implement and quite versatile, inverse micelle reactions have not generally produced the highest-quality nanocrystals. In such an environment the reaction necessarily occurs at room temperature. While crystalline metals are easily formed at these low temperatures, nanoparticles of semiconductors and oxides are often highly defective or even amorphous. This problem can be addressed to some extent by refluxing the nanocrystals in a high boiling point solvent after separating them from the micelle phase [35]. Another common problem with nanocrystals produced by this method is their relatively poor size distributions. Post-processing treatments, such as size-selective precipitation or filtration, are generally employed if nanocrystal monodispersity is of great importance [53, 54]. Pileni *et al* [54] recently used size-selective precipitation to narrow the size distribution of silver nanocrystals prepared in an inverse micelle reaction from 37% to 15% polydispersity. Perhaps the most severe limitation of the inverse micelle approach is that it can only form nanocrystals whose precursors are stable and solvated by water. More covalent semiconductors like silicon and gallium arsenide, as well as many II–VI materials like CdSe, require reactive organometallic precursors. Thus, alternative reactions which proceed in dry, organic solvents are necessary.

C2.17.2.2 PRECURSOR APPROACHES TO NANOCRYSTAL SYNTHESIS

This class of methods differ from inverse micelle methods in that the reactions are completed in organic solvents. Such solvents permit the reactions to proceed at much higher temperatures, leading to nearly perfect crystalline solids [55]. In addition, the use of organic solvents permits nanocrystals to be prepared from a wide variety of molecular precursors under oxygen-free and water-free conditions. Metal [12, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65 and 66], semiconductor [67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77 and 78] and ceramic nanocrystals [79, 80] have been generated using this basic strategy. These stringent controls over reaction conditions are important in the synthesis of covalent semiconductors, which require reactive organometallic starting materials. This can also be an advantage in the preparation of metal nanocrystals free from oxide or hydroxide contamination. Precursor methods have also shown remarkable success in producing highly monodisperse ($\sigma < 5\%$) nanocrystals, especially for II–VI semiconductor nanocrystals [10, 81]. For these reasons, this particular approach to nanocrystal synthesis is becoming a popular strategy despite the fact that it requires more involved synthetic methodology.

The first step in designing a precursor synthesis is to pick precursor molecules that, when combined in organic solvents, yield the bulk crystalline solid. For metals, a usual approach is to react metal salts with reducing agents to produce bulk metals. The main challenge is to find appropriate metal salts that are soluble in an organic phase.

One prevalent strategy for this involves the use of a phase transfer agent, such as tetraoctyl ammonium bromide, to bring gold and silver salts into an organic phase [12, 56, 57, 58, 59, 60, 61, 62 and 63]. Reduction of the metal salts occurs readily with the addition of sodium borohydride. Formation of the bulk solid is prevented by the saturation of the organic phase with capping molecules, which serve to limit crystallite growth [82]. Gold nanocrystals with average diameters of 2.5 nm and 20% polydispersity are the crude product of this reaction; fractional crystallization of these samples, however, can effectively size-separate these nanocrystals and provide samples with less than 1% polydispersity [12]. Rather than rely on phase transfer techniques, which do require exposure of the organic phase to water, gold complexes soluble in organic phases can be prepared directly. Upon heating, these decompose to form gold clusters [64, 65]. The extension of these general strategies to more reactive transition metals such as titanium and copper is also possible. For these systems, LiAlH_4 or hydrotriorganoborates are used to reduce metal salts in solvents such as tetrahydrofuran, producing nanocrystalline metals of a variety of sizes stabilized in organic phases. Bonneman *et al* [66] provide a comprehensive review of these versatile precursor strategies for nanocrystalline metals.

For covalent semiconductors the problem of creating any crystalline material in liquids at relatively low temperatures is much more challenging. The precursors are generally chosen to provide by-products that are stable as well as volatile at the reaction temperatures, thus providing a driving force for the reaction. For example, in one of the early reactions for making nanocrystalline GaAs, GaCl_3 and $\text{As}(\text{SiMe}_3)_3$ were used as precursors, since the silyl halide by-product was stable and volatile yielding a pure product of crystalline GaAs at temperatures as low as 240°C [78]. Since then, a variety of III–V semiconductor nanocrystals, including InP, have been produced through similar high-temperature reactions between reactive precursors [71, 72, 73 and 74, 76, 77, 83]. A different precursor strategy was employed for the formation of silicon and germanium nanocrystals. Here, the metal halides were reduced by alkali metals at high temperatures forming nanocrystals and salts as a by-product [67, 68 and 69].

Control over the size of the semiconductor nanocrystals formed in these reactions is possible, though the rationalization of the size control is not always straightforward. First, these strategies require the use of a strongly stabilizing solvent, such as tri-octyl phosphine oxide, which is thought to slow crystal growth because of its strong interactions with the growing crystallite surfaces. In perhaps the best characterized reaction, the formation of II–VI semiconductor nanocrystals, crystal growth is limited by a rapid quenching of the reaction temperature [10, 84, 85 and 86]. Particle nucleation occurs during a fixed period of time after injection of the cadmium precursor into hot mixtures of tri-octyl phosphine oxide and tri-octyl phosphine. Growth of these nuclei is highly temperature dependent, and the final nanocrystal size can be controlled by the reaction time at elevated temperatures, as well as the ratio of Cd:Se [11]. Typical size distributions formed by these reactions can be $\sigma < 5\%$ in the II–VI material systems [10, 81]. The III–V materials can achieve $\sigma = 20\%$ [87], and the group IV semiconductor nanocrystals achieve $\sigma \sim 30\%$ [69].

C2.17.2.3 OTHER CHEMICAL APPROACHES TO NANOCRYSTAL SYNTHESIS

The methods described above are by no means the only strategies for creating crystals of restricted size. Colloidal methods for creating nanoparticles are still used widely today, especially to make gold and semiconductor nanoparticles [16, 17]. These reactions have the advantage of providing nanoparticles in aqueous solutions, the ideal environment for electrochemical applications. Also, while gas phase clusters are not considered nanocrystals by the stringent definition given previously, it is possible to form nanocrystals in the gas phase and subsequently collect and disperse them into solvents. Such methods have been applied to the production of silicon [13, 88] as well as metal [89] nanocrystals.

C2.17.2.4 NANOCRYSTAL ASSEMBLY

In solution, nanocrystals are ideal spectroscopic samples; however many of their most important properties can only be realized when they are assembled into more complex structures. One way of building complex structures is to rely on the inherent tendency for monodisperse spheres to crystallize. Figure C2.17.3 shows the hexagonal close-

packed ordering of monodisperse silica nanoparticles; such crystallization does not require any inter-particle interaction, but occurs when highly uniform objects are driven to a minimum volume packing. This ordering has been observed in many nanocrystalline systems when crystallite size distributions fall below 5%; three-dimensional supercrystals of nanocrystals are the result [90, 91 and 92]. Crystallization can also be induced at air–liquid interfaces using Langmuir–Blodgett techniques. Thin monolayers of particle arrays thus formed can be transferred to any surface [93, 94]. Finally, high-coverage monolayers of nanocrystals or spatially patterned sub-monolayers can be formed on a variety of flat solid surfaces [14, 95, 96, 97, 98, 99, 100 and 101].

Figure C2.17.3. Close-packed array of sub-micrometre silica nanoparticles. When nanoparticles are very monodisperse, they will spontaneously arrange into hexagonal close-packed structure. This scanning electron micrograph shows an example of this for very monodisperse silica nanoparticles of ~250 nm diameter, prepared in a thin-film format following the techniques outlined in [236].

An equally important challenge for nanocrystal assembly is the formation of specific nanocrystal arrangements in solution. By using complementary DNA strands as tethers, Mirkin *et al* [102, 103] formed aggregates of gold nanocrystals with specific sizes; Alivisatos *et al* also used DNA to structure semiconductor nanocrystal molecules, though in this case the molecules contained only a few nanocrystals placed controlled distances from each other [104, 105 and 106]. The potential applications of biomolecular techniques to this area of nanoscience are immense, and the opportunities have been reviewed in several recent publications [107, 108, 109 and 110].

C2.17.3 CHARACTERIZATION OF NANOCRYSTALS

The goal of any nanocrystal characterization is to identify the position of every atom in a single nanocrystal, as well as

-7-

to determine the distribution of sizes and shapes present in a sample. Such precise characterization is possible in the case of some smaller metal and semiconductor clusters. These systems are amenable to new types of mass spectroscopy which can provide molecular weights of species up to 55 000 atomic mass units, thus permitting molecular composition and size to be precisely determined [111, 112, 113 and 114]. These systems are the exception, however, not the rule. More typically, nanocrystalline samples contain crystallites with thousands of atoms, molecular weights in excess of 100 000 amu, and diameters larger than 1 nm.

The problem of characterizing these larger nanocrystals is challenging and is, in its own right, an area of research. Some of the simplest characterization techniques are indirect: for example, the mean size of semiconductor nanocrystals can often be inferred from the sample's optical properties. These inferences typically rely on very simple models for the nanocrystal properties, and thus provide only very rough sizing estimates and no information about structure. Classic analytical methods of polymer and colloid science, such as chromatography and light scattering, can also be used to evaluate nanocrystalline samples [13, 115, 116, 117 and 118]. While they provide a measure of particle size and shape in solution, their applications to inorganic nanocrystals have been limited, in part because they provide little direct structural information. The most successful tools in this area have been adapted from material science and inorganic chemistry. These direct structural methods, when used together, provide a complete picture of the nanocrystal interior and its surface.

C2.17.3.1 MICROSCOPIES

In many ways the nanocrystal characterization problem is an ideal one for transmission electron microscopy (TEM). Here, an electron beam is used to image a thin sample in transmission mode [119]. The resolution is a sensitive function of the beam voltage and electron optics; a low-resolution microscope operating at 100 kV might

have a 2–3 Å resolution while a high-voltage machine designed for imaging can have a resolution approaching 1 Å. Since nanocrystalline samples range from ten to hundreds of angstroms in size, this type of microscopy allows both the interior crystal structure and the overall particle shape to be measured.

A single TEM picture of a nanocrystalline sample can provide an enormous amount of information ([figure C2.17.1](#)). Low-resolution TEM can also be used to determine sample distributions and shapes ([figure C2.17.2](#)) ([figure C2.17.4](#)) and ([figure C2.17.5](#)) [120]. Higher-resolution images show the discrete nature of the crystalline interior of nanoparticles and can detect the presence of certain crystalline defects ([figure C2.17.1](#)) and ([figure C2.17.6](#)) ; the Fourier transform of such images ([figure C2.17.6](#)) left panel) provides a measure of the lattice spacing and crystallographic parameters. Direct electron diffraction data can also be collected on fields of particles to verify the phase of the nanocrystal ([figure C2.17.7](#)).

-8-

Figure C2.17.4. Transmission electron micrograph of a field of ZrO_2 (tetragonal) nanocrystals. Lower-resolution electron microscopy is useful for characterizing the size distribution of a collection of nanocrystals. This image is an example of a typical particle field used for sizing purposes. Here, the nanocrystalline zirconia has an average diameter of 3.6 nm with a polydispersity of only 5% [80].

Figure C2.17.5. Transmission electron micrograph of a field of anisotropic gold nanocrystals. In this example, a lower magnification image of gold nanocrystals reveals their anisotropic shapes and faceted surfaces [36].

-9-

Figure C2.17.6. Transmission electron micrograph and its Fourier transform for a TiC nanocrystal. High-resolution images of nanocrystals can be used to identify crystal structures. In this case, the image of a nanocrystal of titanium carbide (right) was Fourier transformed to produce the pattern on the left. From an analysis of the spot geometry and spacing, one can determine that the nanocrystal is oriented with its [100] zone axis parallel to the viewing direction [217].

Figure C2.17.7. Selected area electron diffraction pattern from TiC nanocrystals. Electron diffraction from fields of nanocrystals is used to determine the crystal structure of an ensemble of nanocrystals [119]. In this case, this information was used to evaluate the phase of titanium carbide nanocrystals [217].

More sophisticated analyses of high-resolution TEM images can provide even deeper insight into subtle structural aspects of nanocrystals [121, 122 and 123]. Simulation of high-resolution images can, in principle, provide data concerning whether the average bond length in a nanocrystal is uniform or variable within the nanocrystal interior [124]. Another exciting prospect is the use of TEM to provide direct information about nanocrystal surfaces, including reconstructions and dynamic motions of atoms at surfaces [125]. In one case high-resolution studies of a gold nanocrystal surface led to the identification of a 2×1 surface reconstruction [126, 127].

Other forms of microscopy have been used to evaluate nanocrystals. Scanning electron microscopy (SEM), while having lower resolution than TEM, is able to image nanoparticles on bulk surfaces, for direct visualization of

-10-

nanocrystals in larger assemblies (figure C2.17.3). McEuen *et al* [128, 129] used a field emission SEM to detect the

presence or absence of single nanoparticles in small electrodes made lithographically; Bawendi *et al* [91] used SEM to determine the three-dimensional structure of arrays of CdSe clusters. Scanning tunnelling microscopy (STM) has also been successfully applied to metal nanocrystals; in these cases STM can be used both to image nanocrystals and to study their electrical properties [111, 130, 131, 132 and 133]. The use of scanning force microscopies for nanocrystal characterization is not as common, due to the relatively large probe sizes ($d > 50$ nm) required for force microscopy [134, 135]; however, the height resolution of force microscopy is quite good, of the order of 0.1 Å. The height of nanocrystals on surfaces has been used as a metric for nanocrystal diameter [58, 136]. Another difficulty with force microscopy is that lateral forces are large, and the probe can move nanocrystals unless they are tightly bound to the underlying surface. Intermittent contact-mode, or Tapping ModeTM, reduces these lateral forces and is a more appropriate choice for nanocrystal sizing.

C2.17.3.2 X-RAY DIFFRACTION

Although microscopic methods provide a direct visualization of nanocrystal samples, the images alone provide a misleading view of a nanocrystalline sample. Unreacted molecular species as well as small amorphous particles are difficult to see in many microscopies, yet they can comprise a large fraction of a supposedly nanocrystalline sample. In such low-purity samples, x-ray diffraction (XRD) studies would show no distinct crystalline features; highly pure nanocrystalline samples, in contrast, provide strong crystalline reflections (figure C2.17.8). The positions of these peaks provide an accurate fingerprint of the crystal structure of the nanocrystal. Such an unambiguous determination of nanocrystal structure is especially important, as many nanocrystalline materials adopt metastable crystal structures distinct from the bulk solid (figure C2.17.9) [137, 138].

Figure C2.17.8. Powder x-ray diffraction (PXRD) from amorphous and nanocrystalline TiO₂ nanocrystals. Powder x-ray diffraction is an important test for nanocrystal quality. In the top panel, nanoparticles of titania provide no crystalline reflections. These samples, while showing some evidence of crystallinity in TEM, have a major amorphous component. A similar reaction, performed with a crystallizing agent at high temperature, provides well defined reflections which allow the anatase phase to be clearly identified.

The breadth of the peaks in an x-ray diffractogram provide a determination of the average crystallite domain size, assuming no lattice strain or defects, through the Debye–Scherr formula:

$$t = \frac{0.9\lambda}{B \cos \theta_B}$$

where t is the thickness of the crystal, λ is the wavelength of the x-rays, B is the full width at half maximum of the

diffraction peak, and θ_B is the Bragg angle of the peak [139, 140]. Figure C2.17.9 shows an example of the line broadening observed in nanocrystalline samples of different size. It is especially valuable to compare the domain sizes determined from XRD with the sizing found in TEM. Good agreement between these two measurements is conclusive evidence that the nanocrystals are free from crystalline defects. More extensive analysis and simulations of the XRD patterns of nanocrystals can provide information on nanocrystal defect density and type as well as the presence and distribution of strain in the nanocrystal lattice [141].

Figure C2.17.9. Size-dependent changes in PXRD linewidths. PXRD can be used to evaluate the average size of a sample. In these cases, different samples of nanocrystalline titania were analysed for their grain size using the Debye–Scherr formula. As the domain size increases, the widths of the diffraction peaks decrease.

C2.17.3.3 SURFACE CHARACTERIZATION

The characterization of nanocrystal surfaces is a crucial issue, as surface chemistry and defects can dominate nanocrystal properties. A common question concerning nanocrystal surface is the nature of the bonding at the crystal–organic interface. X-ray photoemission (XPS) is a useful method for not only identifying the atomic composition of a sample, but also for determining the oxidation states of the nanocrystal atoms [84, 142]. In CdSe nanocrystals, for example, XPS indicates the presence of both selenium bound to cadmium as well as oxidized selenium at the surface [84]; similar XPS studies of gold nanocrystals have indicated that, even when passivated by thiols, samples only contain gold in the zero-valent state. Information concerning the dynamics and also coverage of the organic groups at

the nanocrystal surface can be found using solution state NMR [58, 143, 144]. The size of nanocrystals reduces the rotational averaging in the liquid phase; however proton signals from capping groups can be detected in many systems. Vibrational spectroscopies have also been applied to the problem of organic group geometry and coverage, especially in metal systems [57, 59]. Also, extended x-ray absorption fine structure (EXAFS) and other x-ray absorption spectroscopies have been applied to nanocrystal surface characterization [145, 146]. These methods are particularly powerful, as they can, in principle, measure the spatial distribution of bond lengths within a nanocrystal.

C2.17.4 OPTICAL PROPERTIES OF NANOCRYSTALS

The striking size-dependent colours of many nanocrystal samples are one of their most compelling features; detailed studies of their optical properties have been among the most active research areas in nanocrystal science. Evidently, the optical properties of bulk materials are substantially different from those of isolated atoms of the

same material. In principle, one can describe the optical properties of a nanometre-sized object as an intermediate between these two limiting cases, with a continuous evolution from atomic to bulk properties with increasing particle size. Practically speaking, the most common approaches have used the bulk optical behaviour as a starting point for predicting spectra; successive modifications are made to these descriptions in order to account for a variety of size-dependent effects. Schemes of this nature are necessarily limited, both because the size-dependent modifications are usually treated in a perturbative or approximate fashion, and because the modified theories do not, in general, converge to the atomic limit as the size of the nanoparticle decreases. Nonetheless, such approaches have enjoyed a great deal of success in predicting the optical properties of a wide variety of nanoparticles.

This section will outline the simplest models for the spectra of both metal and semiconductor nanocrystals. The work described here has illustrated that, in order to achieve quantitative agreement between theory and experiment, a more detailed view of the molecular character of clusters must be incorporated. The nature and bonding of the surface, in particular, is often of crucial importance in modelling nanocrystal optical properties. While this section addresses the linear optical properties of nanocrystals, both nonlinear optical properties and the photophysics of these systems are also of great interest. The reader is referred to the many excellent review articles for more in-depth discussions of these and other aspects of nanocrystal optical properties [147, 148, 149, 150, 151, 152, 153 and 154].

C2.17.4.1 THE OPTICAL PROPERTIES OF SEMICONDUCTOR NANOCRYSTALS

One of the most striking features of semiconductor nanocrystal samples is their vivid colours, which vary with the mean particle size. These changes in the optical properties are not due to structural changes in the material; rather they are a reflection of the fact that the nature of the excitations which determine the colour of these solids is perturbed by the change in the size of the system. In many bulk semiconductors, the characteristic size of the lowest-lying optical excitations is much larger than the size of a unit cell [155]. As the system shrinks, this excitation is confined to a region which is smaller than its natural size, and the associated electronic energy levels shift as a result. Figure C2.17.10 shows typical absorption spectra of spherical CdSe semiconductor nanocrystals, for several different mean particle sizes. Evidently, the lowest-lying excitation shifts continuously to higher energy as the size of the particle decreases. Indeed, it is possible to follow the evolution of this state continuously from very large (nearly bulk-like) crystallites down to only ~ 10 Å radius. In bulk semiconductors, this lowest energy absorption feature corresponds to an excited electron and hole which are bound via the Coulomb interaction, known as an exciton. Thus, the corresponding excitation in the nanocrystals is generally assumed to be of the same character, although perturbed by the confinement. In CdSe, for example, the bulk exciton is 57 Å in radius [155]; thus, when CdSe nanocrystals shrink

-13-

to or below this characteristic length scale, their optical properties show an exquisite sensitivity to nanocrystal size (figure C2.17.10). This basic observation of a blue shift in the absorption energy of the excitonic transition in smaller clusters has been observed in many different semiconductor nanocrystals [72, 156, 157].

Figure C2.17.10. Optical absorption spectra of nanocrystalline CdSe. The spectra of several different samples in the visible and near-UV are measured at low temperature, to minimize the effects of line broadening from lattice vibrations. In these samples, grown as described in [84], the lowest exciton state shifts dramatically to higher energy with decreasing particle size. Higher-lying exciton states are also visible in several of these spectra. For reference, the band gap of bulk CdSe is 1.85 eV.

An explanation for these size-dependent optical properties, termed ‘quantum confinement’, was first outlined by Brus and co-workers in the early 1980s, [156, 158, 159, 160 and 161] and has formed the basis for nearly all subsequent discussions of these systems. Though recent work has modified and elaborated on this simple model, its basic predictions are surprisingly accurate. The energy of the lowest-lying exciton state is given by the following simple formula:

$$E(R) = E_g + \frac{\hbar^2 \pi^2}{2\mu R^2} - \frac{1.8e^2}{\epsilon R}.$$

Here, E_g and ϵ are the band gap energy and the dielectric constant of the bulk semiconductor, and μ is the reduced mass of the exciton system, $1/\mu = 1/m_e + 1/m_h$. The second term, proportional to $1/R^2$, arises from a simple quantum confinement effect, just as in the well known particle-in-a-box problem of undergraduate quantum mechanics. An additional adjustment to the energy arises from a Coulombic effect. Because the electron and hole are forced to occupy a small volume, the wavefunctions of these two oppositely charged particles overlap spatially to a greater degree than in the bulk crystal. The third term, proportional to $1/R$, accounts for this enhanced overlap. [Figure C2.17.11](#) illustrates this result for several different semiconductor materials.

-14-

Figure C2.17.11. Exciton energy as a function of particle size. The Brus formula is used to calculate the energy shift of the exciton state as a function of nanocrystal radius, for several different direct-gap semiconductors. These estimates demonstrate the size below which quantum confinement effects become significant.

[Figure C2.17.12](#) depicts a comparison between experimentally determined exciton energies and those predicted by the Brus model, for CdSe nanocrystals. Given the level of approximation, the agreement is surprising. Nonetheless, the simple theory clearly overestimates the energies for the smallest crystallites. Recent work, both experimental and theoretical, has shown that the main deficiency of the quantum confinement model is that it fails to include molecular-level detail. For example, the Brus model assumes that the confining potential is spherically symmetric and infinitely high. High-resolution electron microscopy studies [162] as well as theoretical calculations [163] have suggested that the lattice structure and facets of nanocrystals lower the particle symmetry leading to intrinsic shifts in the confinement energies. Dielectric spectroscopy [164], as well as Stark absorption spectroscopy [165, 166]

have demonstrated that the ground state of the CdSe nanocrystals has a large static dipole moment. These measurements support the notion that the departure from perfect spherical symmetry can strongly influence the energies. Interactions between internal and surface states have also been shown to strongly influence the dynamics of the excited state, on time scales ranging from femtoseconds [167, 168] to nanoseconds [169, 170].

-15-

Figure C2.17.12. Exciton energy shift with particle size. The lowest exciton energy is measured by optical absorption for a number of different CdSe nanocrystal samples, and plotted against the mean nanocrystal radius. The mean particle radii have been determined using either small-angle x-ray scattering (open circles) or TEM (squares). The solid curve is the predicted exciton energy from the Brus formula.

While the Brus formula can be used to locate the spectral position of the excitonic state, there is no equivalent *a priori* description of the spectral width of this state. These bandwidths have been attributed to a combination of effects, including inhomogeneous broadening arising from size dispersion, optical dephasing from exciton–surface and exciton–phonon scattering, and fast lifetimes resulting from surface localization [167, 168, 170, 171]. Due to the complex nature of these line shapes, there have been few quantitative calculations of absorption spectra. This situation is in contrast with that of metal nanoparticles, where a more quantitative level of prediction is possible.

C2.17.4.2 THE OPTICAL PROPERTIES OF METAL NANOCRYSTALS

Like semiconductor nanocrystals, solutions of metal nanocrystals exhibit striking size-dependent colours, a fact which has fascinated scientists and artists alike for centuries. Gold colloids, in particular, have been used since the Middle Ages as colouring pigments for paints and especially stained glass. Faraday was the first to recognize their metallic character in 1857, and he remarked on their vivid colours. This colour arises from a sharply peaked resonance in the visible region of the spectrum, which occurs at much lower energy than in the bulk metal. Both the spectral position and width of this resonance are observed to vary with the size of the metal nanoparticle, suggesting, as in the semiconductor nanocrystals, that a fundamental excitation of the system is influenced by the restricted size.

The optical properties of metal nanoparticles have traditionally relied on Mie theory, a purely classical electromagnetic scattering theory for particles with known dielectrics [172]. For particles whose size is comparable to or larger than the wavelength of the incident radiation, this calculation is rather cumbersome. However, if the scatterers are smaller than ~10% of the wavelength, as in nearly all nanocrystals, the lowest-order term of Mie theory is sufficient to describe the absorption and scattering of radiation. In this limit, the absorption is determined solely by the frequency-dependent dielectric function of the metal particles and the dielectric of the background matrix in which they are

embedded. So, the size dependence of the optical properties enters only through the size-dependent dielectric function of the nanoparticles [172].

In the optical range, the dielectric function of a metal generally can be divided into two distinct contributions, arising from the intraband and the interband coupling. The former is generally described using a Drude formalism, whereas the latter is often described empirically, and differs dramatically for different metals. In nanometre-sized metals, the interband transitions, as in for example the 5d-to-conduction band transitions in gold, are generally assumed to be independent of the size of the crystallite. In contrast, the inelastic scattering time, which appears as a phenomenological parameter in the Drude model, is assumed to have a strong contribution from surface scattering [173]. A modified scattering rate of the form $\Gamma = \Gamma_0 + Av_F/R$ is often used [172, 174]. Here Γ_0 is the scattering rate in the bulk metal, v_F is the Fermi velocity and A is a constant of order unity. This form expresses the limitations on the mean free path of the free electrons as a result of the confining geometry.

Figure C2.17.13 presents a model calculation of the absorption of gold nanocrystals, using the formalism outlined above. The qualitative result is that, as metal colloids become smaller, the primary absorption peak shifts to lower energy, and broadens significantly. The peak shifts predicted are small, of the order of 0.1 eV for a 2 nm gold crystallite. In contrast, the peak widths are far more sensitive to size. This simple theory, and its variations, have been successful at explaining many experimental observations, especially for clusters greater than 3 nm in size [154]. This success is not surprising, given that the fundamental assumption has been the insensitivity of the interband transitions to the size of the crystallite. Unlike in the case of the semiconductor nanocrystals, where the transition involved highly delocalized exciton states, these band-to-band transitions involve the localized d-shell electrons of the metal. As a result, a clear quantum confinement effect has generally not been expected in metal nanocrystals. Recently, extremely detailed analyses of the optical spectra of highly monodisperse gold colloids suggest that some features of these spectra could be attributed to quantum confinement, in the form of a size-dependent interband dielectric function [111, 112]. Further work on the nonlinear optical properties of these materials may permit a more precise quantification of these effects.

Figure C2.17.13. A model calculation of the optical absorption of gold nanocrystals. The formalism outlined in the text is used to calculate the absorption cross section of bulk gold (solid curve) and of gold nanoparticles of 3 nm (long dashes), 2 nm (short dashes) and 1 nm (dots) radius. The bulk dielectric properties are obtained from a cubic spline fit to the data of [237]. The small blue shift and substantial broadening which result from the mean free path limitation are

clearly evident.

Some of the most interesting recent work in the optical properties of nanocrystals involves the study of single nanocrystals rather than ensembles, using near-field optical techniques. These relatively new optical methods can

be used to address individual nanoparticles, rather than ensembles. This can potentially eliminate from consideration the effects of sample inhomogeneity and, in addition, can give rise to new and interesting optical effects. Studies of both metal [175] and semiconductor [176, 177] nanocrystals have been reported.

C2.17.5 THERMODYNAMIC PROPERTIES OF NANOCRYSTALS

In order to use any material for commercial purposes, it is important to understand its phase behaviour. Bulk gold, for example, melts at 1065°C and thus would be an unwise choice as an electrical interconnect in a high-temperature environment; many ceramics can crack during thermal processing due to solid–solid phase transformations that lower the volume of the crystal [178]. The extrapolation of such bulk phase behaviour to the properties of nanocrystals is not a straightforward problem. Nanocrystals are intrinsically metastable materials which, given the right circumstances, would fuse to create bulk crystals. Indeed, metal nanocrystals prepared on surfaces under high-vacuum conditions do spontaneously fuse into larger grains [179, 180]. On the other hand, solutions of nanocrystals stabilized with organic agents can exist for months or even years with unchanging sizes. Evidently, the metastability of nanocrystals is a sensitive function of their surface bonding, but the nanocrystal surface affects the crystallite in two distinct ways. First, surface atoms can make up 5–40% of the mass of a nanocrystal, and thus contribute significantly to the overall thermodynamic properties of the material. Second, the nanocrystal surface chemistry can raise the activation barriers for many thermodynamically favoured processes. Thus, it is important to consider the surface in both the kinetic and thermodynamic treatments of phase behaviour.

This section will describe the current status of research in two different aspects of nanocrystal phase behaviour: melting and solid–solid phase transitions. In the case of melting, thermodynamic considerations of surface energies can explain the reduced melting point observed in many nanocrystals. Strictly thermodynamic models, however, are not adequate to describe solid–solid phase transitions in these materials.

C2.17.5.1 NANOCRYSTALS AT HIGH TEMPERATURES

In a classic study, Buffat *et al* used electron microscopy at high temperature to measure the melting point of gold nanocrystals as a function of their size [181]. They observed that smaller nanocrystals have lower melting temperatures; this size-dependent melting point varies as roughly $1/R$. Thus, a gold nanocrystal of 5 nm diameter, for example, melts at 885°C, 180°C lower than bulk gold. Since this original study, this behaviour has been observed in both metal and semiconductor nanocrystals [182, 183, 184, 185, 186, 187, 188, 189 and 190], using techniques ranging from electron microscopy [191, 192 and 193] to nanocalorimetry [194].

The simplest approach to understanding the reduced melting point in nanocrystals relies on a simple thermodynamic model which considers the volume and surface as separate components. Whether solid or melted, a nanocrystal surface contains atoms which are not bound to interior atoms. This raises the net free energy of the system because of the positive surface free energy, but the energetic cost of the surface is higher for a solid cluster than for a liquid cluster. Thus the free-energy difference between the two phases of a nanocrystal becomes smaller as the cluster size

decreases and a reduction in the melting point is observed [181, 187, 193]. A variety of more elaborate theories which treat the nanocrystal surface structure, as well as the exact treatment of lattice strain, can provide quantitative agreement with measurements [195, 196 and 197].

While the variation in the melting temperature of nanocrystals can be explained using classic thermodynamic arguments, the process by which nanocrystals, or even bulk solids, undergo melting is an active area of research. [198, 199] Nanocrystals offer ideal systems with which to explore the role of kinetics in melting. Nanocrystals embedded in solid media have been observed to superheat, existing as solids well above their melting point [200, 201]. The extent of the superheating and its dependence on heating rate are sensitive to the nanocrystal size. One explanation is that long-range density fluctuations are responsible for inducing melting in solids [202]; in

nanocrystals these modes may be restricted. Another important issue in the mechanism of bulk melting is the role of surfaces and defects [192, 203, 204]. Several studies suggest that surface melting occurs at temperatures below the bulk melting point. This phenomenon would have important consequences for the thermal stability of nanocrystals as it could lead to shape changes in isolated nanocrystals and fusion in tightly packed nanocrystal arrays [179, 180, 205, 206, 207, 208 and 209].

Melting is only one of many processes that nanocrystals can undergo when they are heated. Temperature-induced phase transitions are equally important in nanocrystals, especially in covalent materials such as oxides [210]. Unlike melting and the solid–solid phase transitions discussed in the next section, these phase changes are not reversible processes: they occur because the crystal structure of the nanocrystal is metastable. For example, titania made in the nanophase always adopts the anatase structure. At higher temperatures the material spontaneously transforms to the rutile bulk stable phase [211, 212 and 213]. The role of grain size in these metastable–stable transitions is not well established; the issue is complicated by the fact that the transition is accompanied by grain growth which clouds the interpretation of size-dependent data [214, 215 and 216]. *In situ* TEM studies, however, indicate that the surface chemistry of the nanocrystals play a crucial role in the transition temperatures [217, 218].

C2.17.5.2 NANOCRYSTALS AT HIGH PRESSURE

The ability to control pressure in the laboratory environment is a powerful tool for investigating phase changes in materials. At high pressure, many solids will transform to denser crystal structures. The study of nanocrystals under high pressure, then, allows one to investigate the size dependence of the solid–solid phase transition pressures. Results from studies of both CdSe [219, 220, 221 and 222] and silicon nanocrystals [223] indicate that solid–solid phase transition pressures are elevated in smaller nanocrystals.

The observation of elevated transition pressures in nanocrystals may at first appear to contradict the observation that the melting temperatures of these same systems are reduced. This is not a contradiction, though, because the important variable in both phase changes is the *difference* in the free energies of the two states. If the high-pressure crystal structure (rock-salt in the case of the II–VI nanocrystals) has a higher surface free energy than the low-pressure phase (wurtzite for II–VI nanocrystals), then the transition pressure will be elevated in small clusters for strictly thermodynamic reasons. This explanation is consistent with the observed elevation in the phase transition pressures observed in smaller nanocrystals, and was the first model proposed to describe this high-pressure behaviour [219].

More recently, studies of the hysteresis of these phase transitions have illuminated the importance of kinetic factors in solid–solid phase transitions [224]. The change between crystal structures does not occur at the same point when pressure is increasing, as when it is decreasing; the difference between this ‘up-stroke’ and ‘down-stroke’ pressure

provides a measure of the activation energy required for the transition. These experiments have been performed both as a function of cluster size as well as temperature for II–VI nanocrystals [224]. As the nanocrystal size increases, a larger number of atoms in the crystallite interior must move during the phase transition, so the kinetic barrier increases. However, in sufficiently large nanocrystals, there is a larger volume available and defect-nucleation is a viable pathway. This lowers the kinetic barrier as the bulk limit is approached. For more complete reviews of studies of pressure-dependent properties in nanocrystals see [225, 226].

C2.17.6 CONCLUSIONS

This review has covered many of the essential features of the physical chemistry of nanocrystals. Rather than provide a detailed description of the latest and most detailed results concerning this broad class of materials, we have instead outlined the fundamental concepts which serve as departure points for the most recent research. This necessarily limited us to a discussion of topics that have a long history in the community, leaving out some of the new and emerging areas, most notably nonlinear optical studies [152] and magnetic nanocrystals [227]. Also, the

study of the electrical transport behaviour of nanocrystals and nanocrystal assemblies is an area of growing interest. Both single-electron transport and collective transport through organized assemblies [128, 228, 229 and 230] promise to be of great scientific as well as technological importance. Finally, we note that we did not discuss the many possible applications for nanocrystals. These little solids offer many unique and tunable features which promise to make them important materials in areas as diverse as microelectronics [64, 231, 232, 233 and 234] and biotechnology [107, 235]. Finally, we note that a search of one particular on-line scientific abstract database, using the keyword 'nanocrystal', demonstrates a monotonic increase in the number of publications per year, each year since 1993. This highly unscientific measure is nonetheless quite satisfying, as it testifies to the health and vitality of this exciting field of chemical physics.

ACKNOWLEDGMENTS

We would like to acknowledge A P Alivisatos and C V Shank, as well as all past and current members of the Alivisatos group for their insight and help with many of the ideas and data presented in this chapter. We would also like to acknowledge Steve Robertson for inspired assistance with the references and figures.

C2.18 Etching and deposition

HP Gillis

C2.18.1 INTRODUCTION

Numerous technological processes involve removal of material from a solid surface by etching, or addition of new material to a solid surface (in this case called the substrate) by deposition. Both classes of reactions have long been studied in liquid solution [1]. Since about 1980 process demands of the microelectronics industry have stimulated development of both etching and deposition processes involving solid surfaces and gas phase reactants [2]. The general field of gas–surface reactions can be unified by classification into four groups, according to whether the products are volatile or involatile, and whether the reaction products incorporate atoms from the surface (see table C2.18.1). These reaction groups all share common fundamental concepts, and can be investigated by common techniques developed during the very active period of modern surface science since about 1975 [3]. These concepts and techniques have been introduced at several earlier points in this book. Regarding applications, the discussion of catalysis and corrosion in [chapter C2.7](#) and [chapter C2.8](#) respectively complement the present chapter.

Table C2.18.1. Classification of gas–solid reactions.

	Volatile products	Involatile products
Solid atoms incorporated	Etching	Corrosion
No atoms from solid	Catalysis	Deposition

Because surface chemical reactions occur at a localized geometrical interface between phases, transport processes are strongly coupled with these reactions. The overall reaction can be decomposed into a series of steps—attachment or ‘sticking’ of reactants to the surface; diffusion of reactants on the surface; formation of reaction product; disposition of reaction product—any one of which can be rate-limiting for the overall reaction. Fundamental progress in understanding etching and deposition reactions relies upon isolating one of these steps for investigation in simplified model circumstances, either theoretical or experimental. A comprehensive review published in 1994 summarizes such fundamental results from reactive molecular beam studies of both etching and deposition reactions. That review is highly recommended as an introduction to the field, since it also describes the fundamental concepts in adsorption dynamics and chemisorption, as well as the relevant experimental techniques [4].

In practical applications, gas–surface etching reactions are carried out in plasma reactors over the approximate pressure range 10^{-4} –1 Torr, and deposition reactions are carried out by molecular beam epitaxy (MBE) in ultrahigh vacuum (UHV: below 10^{-9} Torr) or by chemical vapour deposition (CVD) in the approximate range 10^1 – 10^3 Torr. These applied processes can be quite complex, and key individual reaction rate constants are needed as input for modelling and simulation studies—and ultimately for optimization—of the overall processes.

-2-

The objective of this chapter is to provide an introduction to etching and deposition for chemical physicists and physical chemists so they can select key fundamental questions in these complex processes for experimental or theoretical studies in much simpler model configurations. Since modern etching and deposition methods have developed mainly empirically, they are closely tied to and named after the experimental techniques used. We provide a brief introduction to this terminology, as well as a brief guide to the process literature, including review articles and advanced references. The bulk of this chapter is devoted to a discussion of selected themes and examples in etching and deposition where fundamental studies have already made advances. The goal of this discussion is to illustrate opportunities and approaches to these problems, not to provide a critical review of the present state of these fields.

C2.18.2 INDUSTRIAL IMPORTANCE OF ETCHING AND DEPOSITION

Etching (e.g., for decorating glass objects, for removing oxides and other impurities from the surfaces of metals) and deposition (e.g., for coating and passivating metallic surfaces) have a long and distinguished history in the chemical processing industries. The present discussion is limited to gas–surface reactions important in the microelectronics and optoelectronics industries.

C2.18.2.1 DRY ETCHING FOR PATTERN DEFINITION IN MICROELECTRONICS

The purpose of etching is to transfer features from a device design mask to an underlying film of device material, replicating accurately the cross-sectional profile of each feature. Various possible results are schematically illustrated in figure C2.18.1 where the mask is still in place after etching to show the connection between etch profile and the mask dimensions. In the earliest days of integrated-circuit fabrication, features 20–50 μm wide were transferred by wet etching into films about 1 μm thick, producing rounded, undercut or isotropic etching, illustrated in region A in the figure. As new design rules to increase the speed of devices and to pack devices more densely on the wafer required lateral dimensions below 1 μm , the errors due to undercut became intolerable and the need arose for a new method that would achieve anisotropic etching, to define straight sidewalls (B). Various implementations of plasma etching described below achieve this goal under proper conditions.

Figure C2.18.1. Schematic representation of various results of etching through a mask. The regions marked by letters are defined and described in the text.

-3-

All versions of plasma etching expose the sample and mask to ion bombardment in the presence of chemically reactive species. The interplay between these two components determines the net result of the etching process. Although the mechanism is still not understood in detail, it is recognized that ion-enhanced reactions at the bottom of the opening in the pattern (but not along the sidewalls) of the feature being transferred are essential for anisotropy. If ion bombardment overwhelms the chemical component of the etching process, the mask edges will be eroded and the profile will be overcut (C). Excessive ion component also produces trenching (D) because ions reflected from the sidewalls appear at the edge of the bottom and increase the ion flux (and the etch rate) in that region. Ideally, etch processes will be highly selective between materials; non-selectivity is illustrated in region E. In regions A–E small amounts of material are removed through the mask to define a recess into the film. In region F, much more material is removed to define a mesa in the film. Regions B and F illustrate the ideal features from which advanced devices are constructed.

Depending on conditions of ion energy and flux, temperature and chemical environment these features may receive ion bombardment damage while being etched. The term ‘etch damage’ includes effects such as creation of lattice defects or interstitials due to momentum transfer from the ions, ‘knock-on’ of various impurities into the substrate and electrical breakdown from non-uniform charge accumulations, all of which compromise the optical and electrical properties of the etched surface. Characterization of microstructural changes that constitute damage and development of new etching methods to reduce or eliminate damage, are major themes in present-day dry etching research. These newer methods of plasma etching are described below.

The most common form of anisotropic plasma etching, called reactive ion etching (RIE), is achieved by an AC glow discharge (usually at 13.56 MHz) between two metal electrodes in a reactive feed gas (figure (C2.18.2)(a)). RIE delivers ions to the sample with energy ~ 300 eV and therefore inflicts substantial damage, which must be removed in subsequent process steps. In electron cyclotron resonance (ECR) etching (figure (C2.18.2) (b)), microwave power is coupled into the cylindrical source chamber by an antenna and one or more electromagnet coils around the source generate the cyclotron resonance frequency. Coupling the excitation energy into the reactor by various types of inductive coil leads to inductively coupled plasma (ICP) etching, for which the electromagnets are not necessary. Both ECR and ICP can generate a very high-density plasma, in which arrival energy of the ions is controlled by independent RF electrical bias of the sample stage. Arrival energies can be controlled below ~ 50 eV, which is still sufficient to cause damage in many cases. A substantial literature exists on the design and performance of RIE, ICP and ECR systems [5]. Anisotropic etching is also achieved by chemically assisted ion beam etching (CAIBE) in which independent beams of ions and reactive species are directed to the sample (figure (C2.18.2) (c)). CAIBE provides much greater independent control over the identity, energy, direction of incidence and flux of both the ionic and reactive species than does RIE, ICP or ECR. Since the ion beams are extracted from broad-area plasma sources of the Kaufman type [6], ion energy must be ~ 200 eV to obtain useful current and ion-inflicted damage is common.

Dramatic progress has been achieved, largely through empirical engineering, in developing practical processes for etching silicon with fluorine species. Indeed, the ability to etch sub-micrometre features in Si CMOS device technology has played a key role in bringing the computer industry to its current highly developed state. Dry etching of III–V materials is less well developed, but is increasingly important due to the impact of III–Vs in the rapidly expanding areas of wireless and optical communication. The wide-bandgap group III nitride semiconductors, which are especially interesting as emitters in the blue region of the spectrum, present special challenges in dry etching [7].

C2.18.2.2 FUNDAMENTAL ISSUES IN DRY ETCHING

In order to design and optimize anisotropic dry etching processes, several issues must be understood:

- What is the mechanism by which ion-enhanced reactions give anisotropic etching?
- What are the underlying surface thermochemical reactions that are being enhanced?
- What controls the detailed evolution of the feature profile during etching? What is the relative importance of directed transport of neutral reactive species and of ion enhancement?
- What are the structure and composition of the surface during etching?
- How can damage be eliminated from the process?

Although substantial progress has been made, much work remains to be done, especially in the characterization and elimination of damage. Each of these issues invites study by methods of chemical physics and physical chemistry, especially when examined in a simplified model environment. Representative themes and examples, illustrating both progress achieved and remaining questions, are presented in [section C2.18.3](#).

C2.18.2.3 DEPOSITION PROCESSES IN MICROELECTRONICS AND OPTOELECTRONICS

While etching controls the lateral dimensions of microscopic devices in integrated circuits (figure C2.18.1), deposition controls their vertical dimensions, which are equally important in device function. Modern devices may comprise thin films of deposited material between 1 nm and 50 μm in thickness, which in turn may include numerous individual thinner layers. Each of these layers must be deposited with highly controlled and reproducible properties, including composition, thickness, strain, microstructure and surface morphology. Advanced optical and electronic devices from compound semiconductors require epitaxial growth, in which the crystalline orientation of the deposited film is registered with that of the substrate.

Numerous techniques have been developed for depositing films from vapours, ranging from straightforward evaporation to advanced chemical transport in which reactions are activated by heat, light or plasma. These have been surveyed in two comprehensive reviews [8, 9] and two popular interdisciplinary textbooks [10, 11]. The three most widely used chemically based techniques are:

- (1) *CVD*: gaseous reactants (precursors) delivered to a heated substrate in a flow reactor undergo thermal reaction to deposit solid films at atmospheric or reduced pressure, and volatile side products are pumped away. CVD is used for conductors, insulators and dielectrics, elemental semiconductors and compound semiconductors and is a 'workhorse' in the silicon microelectronics industry.
- (2) *Metallorganic chemical vapour deposition (MOCVD) or organometallic vapour phase epitaxy (OMVPE)*: in this variation of CVD, the precursors are organometallic compounds of the III–V or II–VI elements, a very large number of which are available. Because of chemical similarity in the various groups of elements, a wide range of compound semiconductor alloys can be produced, e.g. $\text{GaAs}_{1-x}\text{P}_x$, the basis of the familiar red light emitting diodes (LEDs) and lasers, and $\text{In}_x\text{Ga}_{1-x}\text{N}$, the basis of the new blue LEDs and lasers [12]. MOCVD is widely used for epitaxial growth of compound semiconductor heterostructures essential for optical and high-speed electronic devices.
- (3) *Metallorganic MBE (MOMBE)*: the 'solid source' Knudsen cells in conventional MBE are replaced with gaseous beams of organometallic precursors, directed toward a heated substrate in UHV. Compared to MOCVD, MOMBE eliminates gas phase reactions that may complicate the deposition surface reactions, and provides lower growth temperatures.

All three techniques have a vast and readily accessible literature, and are discussed regularly at numerous scientific conferences around the world.

C2.18.2.4 FUNDAMENTAL ISSUES IN CHEMICAL DEPOSITION OF THIN FILMS

The fundamental steps in CVD, MOCVD and MOMBE processes can be classified as follows [13]:

- (a) adsorption of precursors at the growth surface,
- (b) surface diffusion of precursors to growth sites,
- (c) surface reactions: incorporation of film constituents,
- (d) nucleation, followed by growth of film microstructure and topography,
- (e) desorption of by-products from surface reactions.

It is difficult to observe these surface processes directly in CVD and MOCVD apparatus because they operate at pressures incompatible with most techniques for surface analysis. Consequently, most fundamental studies have selected one or more of these steps for examination by molecular beam scattering, or in simplified model reactors from which samples can be transferred into UHV surface spectrometers without air exposure. Reference [4] describes many such studies. Additional themes and examples, illustrating both progress achieved and remaining questions, are presented in [section C2.18.4](#).

C2.18.3 SELECTED THEMES AND EXAMPLES IN ETCHING STUDIES

Plasma etching was introduced into silicon device fabrication technology in the middle 1970s in order to obtain the anisotropic pattern definition needed for device features smaller than 1 μm . Early processes used complex mixtures of fluorocarbon gases and additives selected to optimize anisotropy, selectivity and rate through time-consuming empirical studies. Almost immediately, model studies of essential features of the reactions in simpler environments were undertaken to obtain fundamental insights on which optimization could be rationally designed. Twenty-five years later, this is still a rich and productive field of research.

C2.18.3.1 EXPERIMENTAL STUDIES OF THERMAL ETCHING REACTION KINETICS AND DYNAMICS

It was quickly recognized that a purely thermal reaction between F atoms and Si surfaces was a key component of plasma etching. This reaction was studied in a series of UHV experiments where an effusive molecular beam of XeF_2 , which readily decomposed to give F atoms, was directed onto a Si surface. After some early controversies, careful mass spectrometric analysis in which the product flux was modulated demonstrated that the main reaction product was SiF_4 [14, 15]. Measured velocity and energy distributions of the SiF_4 products were non-Maxwellian for the temperature of the surface, showing excesses of both ‘cool’ and ‘hot’ molecules [16]. This suggests at least two modes of product desorption, both different from simple evaporation of weakly bound molecules. The overall dynamics of formation and desorption of SiF_4 is complicated, since the reaction occurs in a complex fluorosilyl ‘corrosion layer’ readily formed at the Si surface by the small and highly reactive F atoms [17]. This layer is described further in section C2.18.3.3. A series of studies by Engel and co-workers examined the effect on this reactive adlayer at the Si surface of using chlorine versus fluorine, and molecules versus atoms. In all cases coverage of etchant adequate to produce steady-state etching led to complex reactive adlayers [18].

In view of the complex kinetics and dynamics of the overall reaction, attention was directed to dynamical studies of individual steps, particularly the attachment of etchant molecules to surfaces. The emerging theme is that the sticking probability and the structure of the adsorbate layer depend strongly on the energy of the incoming molecules and on the structure of the surface, and that chemisorption can be highly site-selective. For example, at low incident kinetic energy where precursor-mediated chemisorption dominates, Cl_2 forms large islands of SiCl on $\text{Si}(111)-(7 \times 7)$, while at high incident energy direct activated chemisorption dominates, and Cl is adsorbed only at isolated sites [19].

-7-

The dangling bonds of a Si surface abstract one F atom from an incident F_2 molecule while the complementary F atom is scattered back into the gas phase [20]. This abstractive mechanism leads to F adsorption at single sites rather than at adjacent pairs of sites, as observed directly by scanning tunnelling microscopy [21]. Br atoms adsorb only to Ga atoms in the second layer of $\text{GaAs}(001)-(2 \times 4)$, where empty dangling bonds on the Ga atoms can be filled by electrons from the Br atoms [22].

C2.18.3.2 EXPERIMENTAL STUDIES OF ION-ENHANCED ETCHING REACTION KINETICS AND DYNAMICS

In what may be the single most influential experiment in the field of dry etching, John Coburn and Harold Winters of the IBM Almaden Research Centre in San Jose, CA, USA demonstrated that the rate of the F–Si thermal etching reaction is greatly enhanced if the Si surface is simultaneously bombarded with a beam of energetic Ar^+ ions and exposed to a flux of F atoms at thermal energies [23]: see figure C2.18.3. This phenomenon plausibly explained the origin of anisotropic etching in regions B and F of figure C2.18.1 since, under proper conditions of pressure and power, the electric fields in the plasma reactor could steer ions from the plasma onto the sample along its normal direction and enhance the rate only at the bottom of the feature being etched [24]. Ion-enhanced etching model studies, in which independent beams of energetic ions and electrically neutral reactive species were simultaneously directed onto the substrate in high vacuum or UHV with various *in situ* reaction diagnostic tools, constituted an important simplification of an essential step in plasma etching; many such studies followed the original example of Coburn and Winters.

The molecular mechanism of ion enhancement proved to be both subtle and complex. The complexity of the

intrinsic ‘corrosion layer’ in F–Si etching made it difficult to determine whether ion bombardment influenced the adsorption of reactant, formation of product or desorption of product [25]. Ion enhanced Cl–Si etching, which is not thermally spontaneous at room temperature, demonstrated that ion-induced recoil implantation of Cl into the Si lattice contributed substantially to the net reaction [26, 27 and 28]. Therefore, in steady-state ion-enhanced etching the ions contribute simultaneously to the formation and removal of the ‘corrosion layer’, and the only well defined experiment is to measure the kinetic energy distribution of each departing product species, as a function of ion beam energy and current density, by analogy with the sputtering of clean solids by inert ion beams [29]. Sputtering had already been explained by the linear cascade theory in which the incident ion transfers energy through a series of binary collisions with atoms in the solid as it penetrates beneath the surface [30]. The resulting fast recoils eventually cause atoms to be ejected from the solid with a kinetic energy distribution $\Phi(E) \propto E/(E+U_0)^3$ where U_0 is the surface escape energy, usually approximated as the sublimation energy of the solid [31]. Careful analysis of the data reviewed from several different ion-enhanced etching studies (Si(Cl₂; Ar⁺), Si(XeF₂; Ar⁺), Si(SF₆; Ar⁺), Si/SiO₂(Cl₂; Ar⁺), Si/SiO₂(XeF₂; Ar⁺)) showed that in all cases more than 80% of the molecules in each product species departed the surface with an energy distribution characteristic of a linear cascade [32, 33]. Each product species required a different value of U_0 ; the values determined were consistent with reasonable qualitative models of the ion-induced mixing layer or ‘corrosion layer’. To date no definitive quantitative description has been obtained, but the general trend is that in the energy range 0.5–2.5 keV ion-enhanced etching is dominated by cascade processes, the details of which vary with each gas–solid combination.

Model studies of the crystalline damage caused to the substrate by ion bombardment as a side effect of ion-enhanced etching relied upon Rutherford backscattering ion channelling measurements with glancing exit path geometry to enhance depth resolution of the damaged layer. During bombardment of Si with energies 250–1000 eV, argon and neon ions caused shallow damage (65–80 Å) while hydrogen ions caused damage 275–475 Å in depth depending on dose [34]. Progress in ion-enhanced etching up to 1992 has been reviewed by the founders of the field [35].

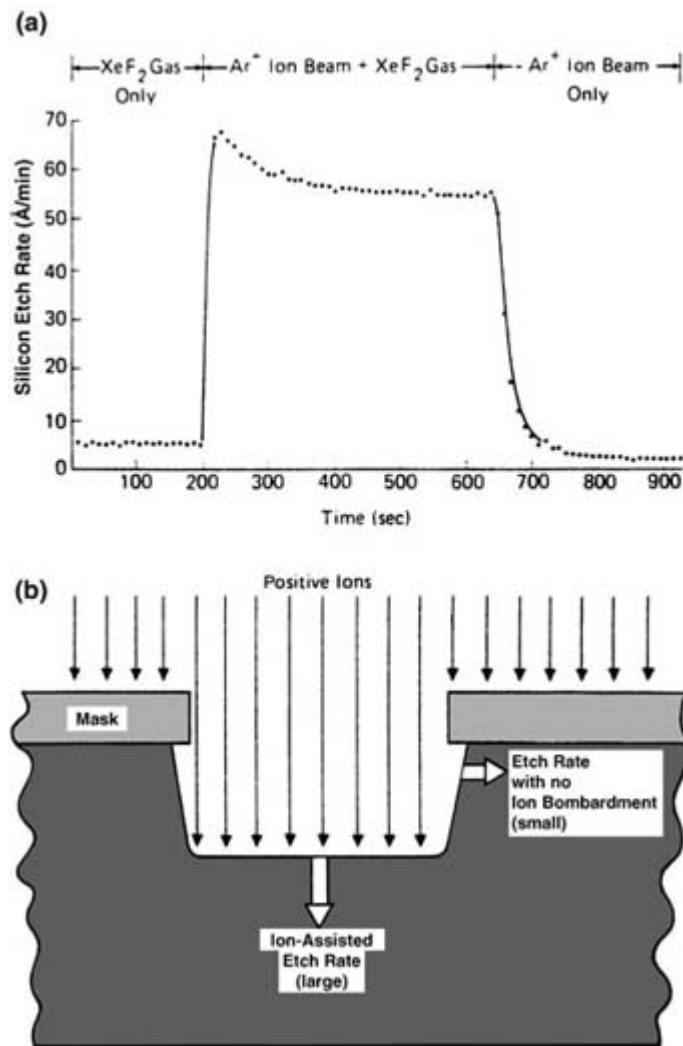

Figure C2.18.3. Relationship between ion-assisted etching and directionality in plasma etching. (a) Demonstration of the synergy between ion bombardment and reactive species during ion-assisted etching. (b) Ions incident on an etched feature. This situation prevails in glow discharges when the feature dimensions are much less than the plasma sheath thickness. Reproduced from [35]

More recent model experimental studies of ion-enhanced etching have emphasized the Si–chlorine combination with ion energies below 100 eV to simulate conditions in the newer ECR and inductively coupled high-density plasma etching systems which give highly anisotropic etching of high aspect ratio features with reduced damage in Si technology [36, 37 and 38]. As at higher ion energy, the collision cascade model describes the essential features of the process, with energy thresholds for removal of SiCl_x etch products lower than that of pure Si, in consequence of the reactive adlayer produced by chlorination of the surface.

C2.18.3.3 COMPOSITION AND STRUCTURE OF SURFACES EXPOSED TO ETCHANTS

The complexity of observed etching kinetics suggested that several species are present at the surface during steady-state reaction. Studies were begun to identify these species by surface analysis techniques to aid in clarifying the etching reaction mechanisms. This work has been developed farthest for Si–F etching, for which selected highlights are summarized as follows.

McFeely and co-workers used soft x-ray photoelectron spectroscopy (SXPS) to measure the changes in binding energies of Si(2p) levels after slight exposure to fluorine atoms via dissociative chemisorption of XeF₂ [39]. Using synchrotron radiation at 130 eV as the source enabled extreme surface sensitivity. Since this level is split into a

doublet by spin-orbit coupling, the $2p_{1/2}$ component was numerically removed from the data in order to simplify the spectrum and facilitate interpretation of peaks due to multiple species. [Figure C2.18.4](#) shows the results after exposing a clean Si(100)-(2 × 1) surface to 50 L of XeF₂. (The Langmuir (L), a convenient measure of exposing a surface to a steady background pressure of some gas for a specified time, is defined by 1 L = 1 × 10⁻⁶ Torr s. One Langmuir provides approximately one monolayer of adsorbate, if all molecules stick to the surface.) In addition to the peak for the bulk un-reacted Si, three new peaks appear with binding energy increases of approximately 1, 2 and 3 eV relative to the bulk peak. They have been assigned to SiF, SiF₂ and SiF₃ respectively. Examination of several other Si surfaces showed the same fluorosilyl species, independent of surface structure. The relative amounts of these species depended on surface structure in a manner rationalized by the number of dangling bonds available at each surface. Subsequent studies extended the exposure to 5 min at 5 × 10⁻² Torr of XeF₂, to examine conditions more typical of steady-state etching [40]. [Figure C2.18.5](#) shows the results, analysed as above. A new peak with binding energy approximately 4 eV higher than the peak for bulk Si is assigned to SiF₄, and the most abundant fluorosilyl species is SiF₃. These results are quite striking because they indicate that the etching reaction does not proceed by successive stripping of the outermost Si atomic layers, but rather by formation of a thick, highly fluorinated reaction layer—estimated to be about seven monolayers in thickness—in which the volatile reaction product SiF₄ can be trapped. Moreover, conversion of SiF₃ to SiF₄ appears to be a kinetic bottleneck in sequential fluorination reactions, but the complexity of the overall process prohibits identifying this step as rate-limiting.

-10-

Figure C2.18.4. Upper panel shows the 2p photoemission spectrum of the Si(111)-(2 × 1) cleaved surface after exposure to approximately 50 L of XeF₂. The lower panel shows the 2p_{3/2} component of the spectrum after background subtraction. In addition to the unshifted Si(2p_{3/2}), there are three chemically shifted satellites

corresponding to SiF, SiF₂ and SiF₃ in order of increasing binding energy. The dashed curves show the separate components, and the solid curve shows the sum of the four dashed components. Reproduced from [39].

-11-

Figure C2.18.5. Si(2p) spectrum of Si(111) reacted with 5×10^{-2} Torr of XeF₂, using photon energy of 130 eV. The top panel shows the raw data and the fitted background. The bottom panel shows the spectrum after background has been subtracted and fitted into five components: bulk Si and the four fluorosilyl peaks. The solid curve is the sum of the individual dashed component curves. Reproduced from [40].

Yarmoff and co-workers continued and extended this study, supplementing the SXPS measurements with photon stimulated desorption to obtain greater depth analysis of the fluorosilyl layer, and determined the thickness and composition of the fluorosilyl layer as a function of XeF₂ exposure on a Si(111)-(7 × 7) surface [41]. As exposure increases, the concentration of SiF₃ at the surface increases, and buries a relatively constant concentration of SiF and SiF₂ that remains near the interface with the unreacted Si substrate. More precisely, the reaction layer proceeds through four regimes, as shown in [figure C2.18.6](#).

-12-

Figure C2.18.6. The coverages of fluorosilyl groups in the reaction layer shown as a function of exposure. The coverages refer to monolayers of SiF_x groups. The smooth curves are drawn through the data points. Reproduced from [41].

- (1) *Initial exposure regime:* This involves fluorination and etching of atoms in the 7×7 reconstruction, during which the destruction of the surface states in the reconstruction is correlated with creation of the species SiF_2 and SiF_3 .
- (2) *Quasi-equilibrium exposure regime:* After the 7×7 structure has been removed, quasi-equilibrium between etching and growth of the reaction layer is established. The reaction layer is about one monolayer thick, and contains primarily SiF . Defects form near the surface, partly from the large reaction exothermicity.
- (3) *Transition to steady-state etching:* The surface becomes sufficiently disordered to disrupt the quasi-equilibrium, and the reaction layer becomes a 'tree' structure of fluorosilyl chain structures terminated by SiF_3 groups.
- (4) *Steady-state etching:* Steady-state etching commences when the tree structure is fully developed.

The authors analyse these results in considerable detail, demonstrating that both the structure of the surface and steric interactions between F atoms on neighbouring SiF_3 groups influence the reaction progress.

Analysis by SXPS rationalized an earlier demonstration that heavily n-doped Si etches more rapidly with F atoms than does heavily p-doped Si, and produces less SiF_3 in the volatile etch products [42]. After exposure to sufficient XeF_2 to achieve steady-state etching, heavily p-Si(111) and n-Si(111) samples were analysed by SXPS as described above [43]. The p-type sample showed a much thicker fluorosilyl layer and substantially greater SiF_3 concentration. Formation of Si-F bonds involves considerable charge rearrangement, especially in converting the electron-depleted SiF_3 centre to SiF_4 . This conversion should be facilitated in n-type samples where the Fermi level lies in the high density of filled electronic states, but impeded in p-type samples. Thus, the SXPS data explain both the relative rates and the relative product distributions between heavily p- and n-doped samples.

Analysis by SXPS has provided insights into dry etching of III-V materials by the halogens. The general conclusions from a comprehensive review of the field are summarized as follows [44]. Molecular halogens attach by dissociative chemisorption, forming sequentially mono-, di- and tri-halides. The result is competition between etching and surface passivation, governed by temperature, surface stoichiometry and surface crystallinity. When

passivation occurs, the adsorbate usually forms an ordered overlayer. When etching occurs, there appears to be little preference between the III atom and the V atom; attachment occurs at whichever atoms are exposed at the surface.

Detailed atomic-level description of the etching mechanisms requires data not only on composition and electronic structure of the surface, as revealed by SXPS, but also on the atomic structure of the surface. The scanning tunnelling microscope has been used to demonstrate that purely thermal etching reactions depend on, and in turn influence, surface morphology [45, 46 and 47]. Since thermal barriers to adsorption of etchant molecules and to desorption of etch products depend on local structural features, various competing reaction pathways can be observed as a function of temperature to determine the dominant effects. This method holds promise for describing the detailed evolution of surface morphology during etching [48].

C2.18.3.4 THEORETICAL MODELS AND SIMULATIONS OF ETCHING REACTIONS

The method of molecular dynamics (MD), described earlier in this book, is a powerful approach for simulating the dynamics and predicting the rates of chemical reactions. In the MD approach most commonly used, the potential of interaction is specified between atoms participating in the reaction, and the time evolution of their positions is obtained by solving Hamilton's equations for the classical motions of the nuclei. Because MD simulations of etching reactions must include a significant number of atoms from the substrate as well as the gaseous etchant species, the calculations become computationally intensive, and the time scale of the simulation is limited to the order of 10^2 ps. Nonetheless, these simulations provide considerable insight into the early stages of the etching reaction.

The central ingredient in MD simulations is the interaction potential [49]. The first potential function used in MD of Si-F₂ etching reactions was developed by Stillinger and Weber by parameterizing an empirical functional form to fit data for bulk Si, gaseous F₂, gaseous SiF_x and gaseous Si₂F₆ [50]. MD simulations based on this potential predicted that etching would occur only at temperatures near the melting point of Si, and that molecular F₂ did not scatter on the clean Si(100) surface, both contrary to experimental results. Subsequent MD simulations with this same potential predicted that F atoms incident on Si(100) with kinetic energy 3 eV did react spontaneously [51].

A more accurate potential function for Si-F₂ etching was developed by Carter and co-workers by carrying out highly correlated *ab initio* quantum chemistry calculations of the interaction of F₂ with Si(100) (treated as a cluster) and fitting their results to the functional form of the Stillinger-Weber (SW) potential [52]. As a result, the SW Si-F bonding well became deeper and the non-bonding terms less repulsive. These changes enabled further MD calculations to observe buildup of a fluorosilyl layer, which is the first stage of etching [53, 54]. Running sufficient repetitions of the simulation to enable statistical predictions revealed the influence of surface steps and defects, surface coverage, molecular orientation and molecular internal energy on formation of the fluorosilyl layer [55, 56, 57 and 58]. Subsequent MD simulations of F₂ with Si(100) in which the original SW potential was compared directly with the reparametrized version due to Weakliem, Wu and Carter (WWC) demonstrated that while WWC was an improvement over SW, neither predicted adequate dissociative chemisorption when compared with experimental results [59]. More sophisticated *ab initio* calculations are therefore required to represent more accurately the interactions between F₂ and Si(100).

These theoretical descriptions of the thermal etching reaction between F₂ and Si(100) have been reviewed in some detail in the context of *ab initio* methods in surface chemistry [60].

MD simulations based on the SW potential have been applied to ion-enhanced etching systems; selected examples are Ar⁺ bombardment of Cl/Si [61], Ar⁺ bombardment of fluorosilyl/Si [62], Cl⁺ and F⁺ bombardment of Si [63], fluorosilyl ion bombardment of Si [64] and Cl⁺ bombardment of Si in the presence of a thermal background flux of Cl atoms [65]. General conclusions are as follows: (a) sputter yield in the presence of reactive species is enhanced over that for pure Si; (b) predicted reaction products agree qualitatively with experimental results; (c) surface is roughened during etching and (d) weakly bound product species are produced during ion bombardment and can be removed by thermal desorption. However, no universal mechanism for ion-enhanced etching has been identified

and the detailed evolution of the product distribution is not revealed. This probably originates partly in the short time scale of the simulations compared to the overall reaction time scale, and partly in limitations of the potential functions employed.

Perhaps greater success has appeared in simulations that emphasize the short-time consequences of binary collisions, namely energy loss from the ions and angular effects, to assess the effects of ion bombardment on the profile of the etched features [66, 67 and 68]. Earlier studies of molecular beam scattering of energetic F atoms with a fluorinated Si surface had demonstrated the influence of directed energy transport of neutral reactive species on evolution of the etch profile [69]. These various effects can be combined to simulate the buildup of non-uniform charge distributions on patterned surfaces, which have dramatic consequences both for the shape of the etched profile and for inflicting etch damage [70, 71 and 72]. The relationship between plasma process parameters, non-uniform charging, etched profile and etch damage are presently areas of intense research activity, discussed regularly at the continuing conference series International Symposium on Plasma- and Process-Induced Damage [73].

C2.18.3.5 MODEL STUDIES OF PHOTON- AND ELECTRON-ENHANCED ETCHING

In order to avoid ion bombardment damage while achieving anisotropy, alternate means of enhanced etching have been explored. In a seminal early study, Houle showed that cw bandgap excitation generated hot carriers that enhanced the etching of both n- and p-Si(100) by XeF₂ [74]. Later developments are summarized in a conference proceedings [75]. At present, photoelectrochemical etching is the only wet etching method for the wide-bandgap III-nitrides [76]; it has proved especially sensitive to defect structure in the films [77]. Coburn and Winters [23] and Veprek [78] examined electron-enhanced etching of Si. Gillis and co-workers developed low-energy electron enhanced etching (LE4), in which electrons with kinetic energy 1–15 eV and chemically reactive species at thermal velocities are delivered simultaneously to the surface. LE4 is accomplished either in UHV with separate beams of electrons and molecules [79] or in a DC plasma. In DC plasma it has produced excellent anisotropy and smooth surfaces and maintained stoichiometry of compound semiconductor surfaces when etching Si [80], GaAs [81] and GaN [82, 83 and 84]. Recently LE4 has been used to transfer a hexagonal array of 18 nm holes on a 22 nm lattice constant from a biologically derived pattern into Si(100) [85]. High-resolution cross-sectional transmission electron microscopy showed Si lattice fringes at the perimeter of the etched holes, demonstrating that LE4 does not inflict lattice displacement damage on the substrate.

C2.18.4 SELECTED EXAMPLES OF DEPOSITION STUDIES

Deposition by chemical reaction is a vast field that cannot be surveyed in the limited space here. Two particular examples have been selected because they illustrate the close relation between fundamental surface chemistry research

and process development. Moreover, both show great promise for nano-fabrication, where film thickness must be controlled at the atomic level.

C2.18.4.1 HOMOEPITAXY OF GALLIUM ARSENIDE BY ATOMIC LAYER EPITAXY

As outlined in section C2.18.2.4 above, nucleation is a key early step in film growth. This leads to micro-crystallites with uncontrolled boundaries, the coalescence of which may lead to high defect densities that require thermal annealing or other post-growth treatment to produce high-quality films. The method of atomic layer epitaxy (ALE) was developed to achieve the final crystal form immediately in compound materials by exposing the growing surface sequentially to reactants providing one of the constituent atoms [86]. ALE relies on self-limiting adsorption/reaction at each step to grow crystalline films layer by layer with precise control of thickness and superb uniformity of thickness.

Substantial work has been devoted to achieving such results for homoepitaxy of GaAs(100) by sequential reactions of the substrate with trimethylgallium (TMGa) $(\text{CH}_3)_3\text{Ga}$ and arsine AsH_3 in CVD reactors and in MOMBE configurations [87, 88]. Successful ALE growth (1 monolayer/cycle) was achieved in narrow regions of temperature and exposure. Surface science studies showed that in similar regions of temperature and exposure, TMGa dissociatively chemisorbed on the Ga-rich reconstructions of GaAs(100) to produce significant coverage of methyl groups that stabilized the complete Ga monolayer [89]. Outside these regions, the coverage of methyl groups was insufficient, and self-limiting deposition in the TMGa cycle was lost. Various model mechanisms were proposed and debated [90, 91]. A second factor influencing self-limiting deposition of Ga is the change in stoichiometry of the GaAs(100) surface as it evolves from As-rich to Ga-rich during the TMGa cycle. None of the known adsorbate-free reconstructions of the polar GaAs(100) surface are ideally terminated at one monolayer coverage, and therefore cannot support the ‘ideal’ ALE process. By viewing step edges as reservoirs where surface atoms may be added or removed in order to fill incomplete terminations, Creighton proposed the Ga-rich GaAs(100)-(1 × 2)- CH_3 reconstruction as the key participant in ALE [92]. This surface consists of 0.5 monolayer of CH_3 adsorbed on a full monolayer of dimerized Ga atoms. The adsorbate stabilizes the surface at 1 monolayer of Ga, and enables the self-limiting adsorption of Ga needed for ALE. Two candidate stabilized surfaces have been identified for the arsine cycle: the As-rich surface of GaAs(100) has a γ -(2 × 4) reconstruction terminated with 1 monolayer of As, and in the presence of adsorbed H atoms a c (2 × 8)/(2 × 4) reconstruction that can be saturated with 1 monolayer of As. ALE growth is controlled in a complex way by the competing reaction kinetics on the Ga-rich and As-rich surfaces. None of the proposed mechanisms explains all the experimental results. Progress until 1996 has been reviewed in moderate detail [93].

C2.18.4.2 DEPOSITION OF OXIDE FILMS BY ATOMIC LAYER PROCESSING

The Si/SiO₂ interface is crucial to the function of silicon devices. As the dimensions of these devices continue to shrink, the thickness of the oxide layers will be reduced to ~3 nm. The need will also arise for conformal and uniform deposition on three-dimensional structures with high aspect ratios, which cannot be achieved with the standard line-of-sight deposition methods. These demands for precise thickness control, uniformity and conformality can be met by a variation of ALE in which oxides are deposited by an alternating sequence of self-limiting reactions; one element of the oxide is deposited in each of the reactions [94]. Because these layers are amorphous rather than epitaxial with the substrate, the method is known as atomic layer processing (ALP). George and co-workers have studied the fundamental surface chemistry in two ALP reaction sequences in order to identify conditions under which they are self-limiting, and have used the results to deposit high-quality oxide films.

-16-

Deposition of SiO₂ has been achieved by exposing the substrate to the binary reaction sequence $\text{SiCl}_4 + 2\text{H}_2\text{O} \rightarrow \text{SiO}_2 + 4\text{HCl}$. This is divided into the following ‘half-reactions’ in which species at the surface are indicated by asterisks [95]:

- (A) $\text{Si-OH}^* + \text{SiCl}_4 \rightarrow \text{SiO-Si-Cl}_3^* + \text{HCl}$;
 (B) $\text{Si-Cl}^* + \text{H}_2\text{O} \rightarrow \text{Si-OH}^* + \text{HCl}$.

Surface species during the reaction were detected by Fourier transform infrared spectroscopy, using the Si–Cl stretch at 625 cm⁻¹ and the SiO–H stretch at 3740 cm⁻¹. During the (A) half-reaction, the Si–Cl peak increased while the SiO–H peak declined. The opposite behaviour was seen during the (B) half-reaction. Figure C2.18.7 shows the integrated absorbances of these two peaks *versus* time during the (A) and (B) half-reactions. These results clearly demonstrate that both of the binary reactions are complete and self-limiting at 600 K and 10 Torr; at lower temperatures the reactions did not go to completion. Temperature-programmed desorption of SiO₂ in UHV after various numbers of AB reaction cycles demonstrated that the growth rate was ~0.11 nm per cycle. Analysis by Auger electron spectroscopy (AES) showed a peak at 83 eV characteristic of the Si–SiO₂ interface, which decreased as the films grew thicker. The only AES peaks that increased with growth were those characteristic of stoichiometric SiO₂. This study not only produced chlorine-free, stoichiometric SiO₂ films by self-limiting reactions, but also provided detailed insight into the molecular mechanisms involved. A related study examined the fundamental surface chemistry in the deposition of stoichiometric Al₂O₃ by the self-limiting sequential reactions of trimethyl aluminium $(\text{CH}_3)_3\text{Al}$ and H₂O [96]. Deposition of Al₂O₃ on well characterized porous membranes

demonstrated conformal coating of the pore walls [97].

Figure C2.18.7. The integrated absorbance of the Si–Cl stretching vibration at 625 cm^{-1} and the SiO–H stretching vibration at 3740 cm^{-1} as a function of time during the (A) SiCl₄ and (B) H₂O half-reactions at 600 K and 10 Torr. Reproduced from [95].

-17-

Progress up to 1996 has been reviewed in moderate detail [98]. Subsequent developments have been summarized for Al₂O₃ [99] and for SiO₂, [100] and deposition of Si₃N₄ has been reported [101].

C2.18.5 CONCLUDING COMMENTS

The examples discussed in this chapter show a strong synergy between fundamental physical chemistry and device processing methods. This is expected only to become richer as shrinking dimensions place ever more stringent demands on process reliability. Selecting key aspects of processes for fundamental study in simpler environments will not only enable finer control over processes, but also enable more sophisticated simulations that will reduce the cost and time required for process optimization.

C3.1 Transient kinetic studies

Robert A Goldbeck and David S Kliger

C3.1.1 INTRODUCTION AND HISTORICAL OVERVIEW

Transient, or time-resolved, techniques measure the response of a substance after a rapid perturbation. A swift 'kick' can be provided by any means that suddenly moves the system away from equilibrium—a change in reactant concentration, for instance, or the photodissociation of a chemical bond. Kinetic properties such as rate constants and amplitudes of chemical reactions or transformations of physical state taking place in a material are then determined by measuring the time course of relaxation to some, possibly new, equilibrium state. Determining how the kinetic rate constants vary with temperature can further yield information about the thermodynamic properties (activation enthalpies and entropies) of transition states, the exceedingly ephemeral species that lie between reactants, intermediates and products in a chemical reaction.

Relaxation kinetics may be monitored in transient studies through a variety of methods, usually involving some form of spectroscopy. Transient techniques and spectrophotometry are combined in time resolved spectroscopy to provide both the structural information from spectral measurements and the dynamical information from kinetic measurements that are generally needed to characterize the mechanisms of relaxation processes. The presence and nature of kinetic intermediates, metastable chemical or physical states not present at equilibrium, may be directly examined in this way.

The introduction in the 1920s of rapid mixing techniques to initiate chemical reactions first brought millisecond time resolution to the study of solution kinetics [1], overcoming the limitation of classical methods to reactions occurring in seconds or longer. Originally developed to use a continuous flow of reagents, the more reagent-conserving stopped flow approach is now commonly used and widely available in commercial instrumentation. Not only are bimolecular reactions studied by the rapid combination of reagents, but unimolecular reactions may also be initiated by rapid dilution, as in denaturant dilution studies of protein folding.

The millisecond barrier to fast kinetic studies was broken in the late 1940s and early 1950s by two developments: the flash photolysis method of Norrish and Porter [2] and the chemical relaxation techniques of Eigen [3], advances for which the three shared the 1967 Nobel Prize in chemistry. (The term relaxation techniques refers to kinetic methods in which a sudden change in an extensive parameter such as temperature, pressure, or electric field provides a perturbation from equilibrium small enough that any subsequent relaxation can be treated as a first order rate process, as discussed further below. This is distinguished from flash photolysis in which absorption of an optical photon creates a new physical or chemical state that is far from equilibrium.) The new techniques initially made possible transient kinetic studies of processes taking place on time scales as short as microseconds. The development of flash photolysis boosted the field of photochemistry tremendously by opening up transient photochemical and photophysical species such as free radicals and electronically excited states to direct observation and characterization. At the same time, the development of relaxation techniques opened up the field of fast solution kinetics by allowing researchers to directly follow the time evolutions of fast unimolecular and bimolecular reactions such as dissociations, isomerizations and near diffusion-controlled ionic association reactions.

The flash lamp technology first used to photolyse samples has since been superseded by successive generations of increasingly faster pulsed laser technologies, leading to a time resolution for optical perturbation methods that now extends to femtoseconds. This time scale approaches the ultimate limit on time resolution (Δt) available to flash photolysis studies, the limit imposed by chemical bond energies (ΔE) through the uncertainty principle, $\Delta E \Delta t \geq \frac{1}{2} \hbar$. Similarly, the most rapid relaxation method, temperature jumping by solvent absorption of a brief pulse of optical

or IR photons, is ultimately limited in time resolution by the energy redistribution processes, such as rotational and vibrational relaxations, leading to thermal equilibrium. These are of the order of picoseconds in condensed phases but can be much slower in the gas phase. The time scales applicable to some transient techniques are summarized in table C3.1.1. This article focuses on transient kinetic studies in the 10^{-9} to 1 s time regime. Ultrafast (femtosecond and picosecond) methods are covered elsewhere in the encyclopedia.

Table C3.1.1 Time-resolved methods and time scales.

Method	Time range (s)
Flow techniques	10^3 – 10^{-4}
Relaxation techniques	
Temperature jump	1 – 10^{-11}
Pressure jump	1 – 10^{-6}
Electric field jump	10^{-2} – 10^{-10}
EPR	10^{-5} – 10^{-10}
Flash photolysis	1 – 10^{-15}
Pulsed radiolysis	1 – 10^{-11}

C3.1.2 TIME RESOLVED PROCESSES

Fast transient studies are largely focused on elementary kinetic processes in atoms and molecules, i.e., on unimolecular and bimolecular reactions with first and second order kinetics, respectively (although conformational heterogeneity in macromolecules may lead to the observation of more complicated unimolecular kinetics). Examples of fast thermally activated unimolecular processes include dissociation reactions in molecules as simple as diatomics, and isomerization and tautomerization reactions in polyatomic molecules. A very rough estimate of the minimum time scale required for an elementary unimolecular reaction may be obtained from the Arrhenius expression for the reaction rate constant, $k = A e^{-E_a/RT}$. The quantity $k_B T/h$ from transition state theory provides an upper limit on the pre-exponential factor A that is of the order of 10^{13} s^{-1} , or a vibrational frequency, at room temperature. This leads to the estimate that a barrierless reaction can proceed over the course of tens or hundreds of femtoseconds. However, chemical reactions must often overcome a potential energy barrier associated with breaking bonds (while perhaps

-3-

forming others) and the addition of even a modest barrier slows the previous estimate considerably. An activation energy of only 23 kJ mol^{-1} (about 5% of a covalent bond energy), for example, will slow our hypothetical ultrafast reaction by four orders of magnitude and begin to bring it into the province of the fast kinetic methods discussed here. Moreover, entropic constraints often present in the transition state can further reduce the reaction rate constant by reducing A from the upper limit above.

The fastest bimolecular reactions are rate limited by the time it takes for reactants to diffuse toward one another. A typical diffusion-controlled bimolecular rate constant, k_D , is about $6 \times 10^9 \text{ l mol}^{-1} \text{ s}^{-1}$ for uncharged reactants dissolved in water at room temperature. (This is slower by a factor of 50 than the corresponding rate constant for binary collisions in a gas because of solvent viscosity.) We can define a pseudo-first-order rate constant, k_1 , for the bimolecular reaction of species A with B if one reactant, A for instance, is present in excess: $k_1 = k_D[A]$. This leads to an upper limit on the bimolecular reaction time constant of about half of a nanosecond for solution concentrations of A approaching 1 M, an estimate that will be proportionately slower for lower concentrations of

A. (The gas phase estimate is about 100 picoseconds for A at 1 atm pressure.) This suggests that the great majority of fast bimolecular processes, e.g., ionic associations, acid–base reactions, metal complexations and ligand–enzyme binding reactions, as well as many slower reactions that are rate limited by a transition state barrier can be conveniently studied with fast transient methods.

The absorption of a photon initiating photophysical and photochemical processes can itself be an extremely rapid event (as short as $\sim 10^{-15}$ s, for instance, given the $\sim 10^3$ cm^{-1} bandwidth typical of transitions in condensed phase polyatomic molecules and available in lasing media for ultrashort pulsed lasers). This has made light absorption a widely used trigger for fast kinetic studies. Ensuing photophysical and photochemical processes can take place on fast to ultrafast time scales. Unimolecular photophysical processes and their characteristic time scales include: fluorescence emission, 10^{-11} – 10^{-6} s; phosphorescence, 10^{-3} – 10^2 s; internal conversion (spin-conserving nonradiative relaxation) from higher excited states to the lowest excited state, 10^{-14} – 10^{-11} s; internal conversion from the lowest excited state to the ground state, 10^{-9} – 10^{-7} s; and intersystem crossing (spin-changing nonradiative relaxation) from the lowest excited singlet state to a triplet state, 10^{-11} – 10^{-8} s. Primary unimolecular photochemical processes, such as photodissociation into molecules, ions, or radicals, photo-isomerization or rearrangement and photoionization, proceed on excited state potential surfaces and typically are kinetically independent of temperature, as are primary bimolecular photochemical processes such as photodimerization, photoaddition, hydrogen atom abstraction and electron transfer to or from an excited acceptor or donor. (The kinetics of secondary, or dark, photochemical reactions proceeding from the products of primary photochemical processes will in general be dependent on temperature, however, as they take place on the ground state potential surface.) Primary photochemical processes generally compete kinetically with the photophysical processes of radiative and nonradiative relaxation as decay routes for the initially excited state. Additional bimolecular processes that may be generated by light excitation but which do not necessarily lead to permanent photoproducts include excimer and exciplex formation, the association of an excited species with a like or dissimilar ground state species, respectively, and quenching processes in which excitation energy is transferred to other species in either a contact or long-range interaction. As the above time scales suggest, current understanding of these photochemical and photophysical processes has benefited greatly from the application of fast time-resolved spectroscopic techniques.

-4-

C3.1.3 TRANSIENT SPECTROSCOPY

An apparatus for time-resolved spectroscopy can be schematically reduced to the basic elements shown in figure C3.1.1. The pump source in this figure is some device providing the perturbation needed to initiate changes in the sample to be studied. As discussed further below, this usually refers to a light source such as a laser when measurements are to be carried out on a fast time scale. However, this could refer to other types of perturbing device such as a stopped-flow apparatus, for example, to rapidly mix different reagents or a capacitor discharged across a sample cell to suddenly jump the sample temperature.

Figure C3.1.1. The basic elements of a time-resolved spectral measurement. A pump source perturbs the sample and initiates changes to be studied. Lasers, capacitive-discharge Joule heaters and rapid reagent mixers are some examples of pump sources. The probe and detector monitor spectroscopic changes associated with absorption, fluorescence, Raman scattering or any other spectral approach that can distinguish the initial, intermediate and final

states in a reaction.

A light source probes changes in the sample at various times after perturbation using some type of spectroscopy that can distinguish the initial reactant, intermediates and final product. A laser can be used to further excite the sample, producing fluorescence or Raman scattering that may be monitored as a function of time, for instance, or, alternatively, the absorption spectrum of the sample may be monitored using a variety of light sources that may be polarized or unpolarized, lasing or incoherent. Non-optical spectral techniques such as EPR [4] or NMR [5] can also be used to probe reaction dynamics, but in this chapter we will emphasize optical spectroscopies as these are most commonly used, particularly on fast time scales.

Finally, the detection system in figure C3.1.1 represents some device to detect the changes in the spectral properties of the probe beam caused by perturbing the sample. This is typically a photoelectric detector to record light coming from the sample, such as fluorescence or Raman scattering, or to record intensity changes of the probe light source in the case of absorption measurements. Probe and detection strategies can involve measurements made one wavelength at a time, using devices such as photomultipliers or photodiodes to record an intensity change as a function of time, or can involve multispectral measurements using photodiode arrays or charge-coupled devices to measure entire spectra at some specific time following application of the perturbation to the sample. In many cases, the goal is to obtain the time evolution of an entire spectrum monitoring some process of interest. This is accomplished with a single wavelength instrument by monitoring the time evolution of a signal at some wavelength and repeating this measurement at different wavelengths. Alternatively, with a multiwavelength instrument, one measures the spectrum at a specific time and repeats the spectral measurement at various times. It is also possible to accomplish this goal in a single measurement

-5-

using a streak camera, which records the spectral evolution over a range of wavelengths and delay times after a single perturbation. Streak cameras have been used mainly in ultrafast applications, however, as their high cost has tended to discourage applications to slower time regimes [6].

C3.1.4 RAPID MIXING

One can study a slow (minutes or longer) chemical reaction by mixing two chemicals in the sample compartment of a standard UV–vis spectrophotometer and measuring the spectrum as a function of time. Though perhaps not often thought of as such, this is a form of transient spectroscopy, albeit a slow one. To carry out such a measurement for a reaction which is complete on a time scale of milliseconds to seconds one needs to mix the chemicals and measure the spectra much more rapidly. For gases, this can be done by releasing reactants into a discharge flow apparatus, where they are mixed by diffusion and turbulence while being carried down a tube in an inert carrier gas such as helium. This is not, strictly speaking, a transient kinetic method, however, as the progress in time of the reaction is measured by the steady state detection of concentration as a function of distance travelled down the tube. For liquids, achieving satisfactory mixing times (not to mention conserving reactant) usually requires the use of a stopped-flow apparatus, as in figure C3.1.2 in which chemicals are rapidly forced into a sample cuvette by syringes whose plungers are quickly actuated at a specific time. A probe detection system is triggered immediately after the sample is mixed in this transient technique. Conductance may be monitored in the case of ionic solutions, whereas spectrophotometry provides a more general method for determining concentrations. Electronic detection methods provide the time resolution needed (oscilloscopes and transient recorders with response frequencies up to a few GHz are available) to monitor the conductance or spectral changes that accompany the reaction taking place. The rapid mixing approach is limited to the study of reactions taking place on time scales of milliseconds or longer simply because it takes this long for mixing to occur (although ultrarapid techniques have been developed to mix reactants on a 100 microsecond time scale [7]).

-6-

Figure C3.1.2. Stopped-flow apparatus with motor-driven syringes. Syringe plungers force the reactants A and B through a mixing chamber into a spectral cell. Kinetic data collection begins when the effluent syringe plunger is pushed out to contact an activation switch, about a millisecond after the initiation of mixing. (Adapted from Pilling M J and Seakins P W 1995 *Reaction Kinetics* (Oxford: Oxford University Press))

The example above of the stopped-flow apparatus demonstrates some of the requirements important for all forms of transient spectroscopy. These are the ability to provide a perturbation (pump) to the physicochemical system under study on a time scale that is as fast or faster than the time evolution of the process to be studied, the ability to synchronize application of the pump and the probe on this time scale and the ability of the detection system to time resolve the changes of interest.

C3.1.5 RELAXATION SPECTROSCOPY

How does one monitor a chemical reaction that occurs on a time scale faster than milliseconds? The two approaches introduced above, relaxation spectroscopy and flash photolysis, are typically used for fast kinetic studies. Relaxation methods may be applied to reactions in which finite amounts of both reactants and products are present at final equilibrium. The time course of relaxation is monitored after application of a rapid perturbation to the equilibrium mixture. An important feature of relaxation approaches to kinetic studies is that the changes are always observed as first order kinetics (as long as the perturbation is relatively small). This linearization of the observed kinetics means

that useful information about reactions involving higher order kinetic mechanisms may be obtained in a relatively simple manner. To see why this is so, consider the reaction:

The rate equation describing the kinetics of this reaction is

$$\frac{-d[A]}{dt} = \frac{-d[B]}{dt} = \frac{d[C]}{dt} = k_1[A][B] - k_{-1}[C].$$

If the equilibrium concentrations for A, B and C are a , b and c , respectively, the concentration changes resulting from the application of the perturbation will be

$$x = a - [A] = b - [B] = [C] - c$$

and we can then reduce the rate equation to

$$\frac{dx}{dt} = k_1(a - x)(b - x) - k_{-1}(c + x).$$

Expanding the right-hand side of this equation yields

$$k_1ab - k_1(a + b)x + k_1x^2 - k_{-1}c - k_{-1}x.$$

However, since the rate of change of all components is zero at equilibrium,

$$k_1ab - k_{-1}c = 0.$$

The perturbation being small, x^2 is negligible, so that

$$\begin{aligned}\frac{dx}{dt} &= -\{k_1(a + b) + k_{-1}\}x \\ &= -k_{\text{observed}}x.\end{aligned}$$

This shows that the observed rate for this process will follow first order kinetics, even though the reaction being studied is second order. Furthermore, both k_1 and k_{-1} may be determined by observing the kinetics at different starting concentrations that vary the quantity $(a+b)$.

C3.1.5.1 T JUMP

In a discharge T -jump apparatus, a capacitor is discharged across a sample cell containing conductive solution as shown in figure C3.1.3 in order to rapidly increase the temperature through Joule heating. Because equilibrium constants generally depend on temperature, the reaction mixture is rapidly triggered to change according to the kinetic scheme of the reaction under study. The change is given by van't Hoff's law:

$$\left(\frac{\partial \ln K}{\partial T}\right)_p = \frac{\Delta H^0}{RT^2}$$

which predicts that the equilibrium constant changes by about 2% per degree at room temperature for a reaction with a ΔH^0 value of 10 kJ mol⁻¹, for example.

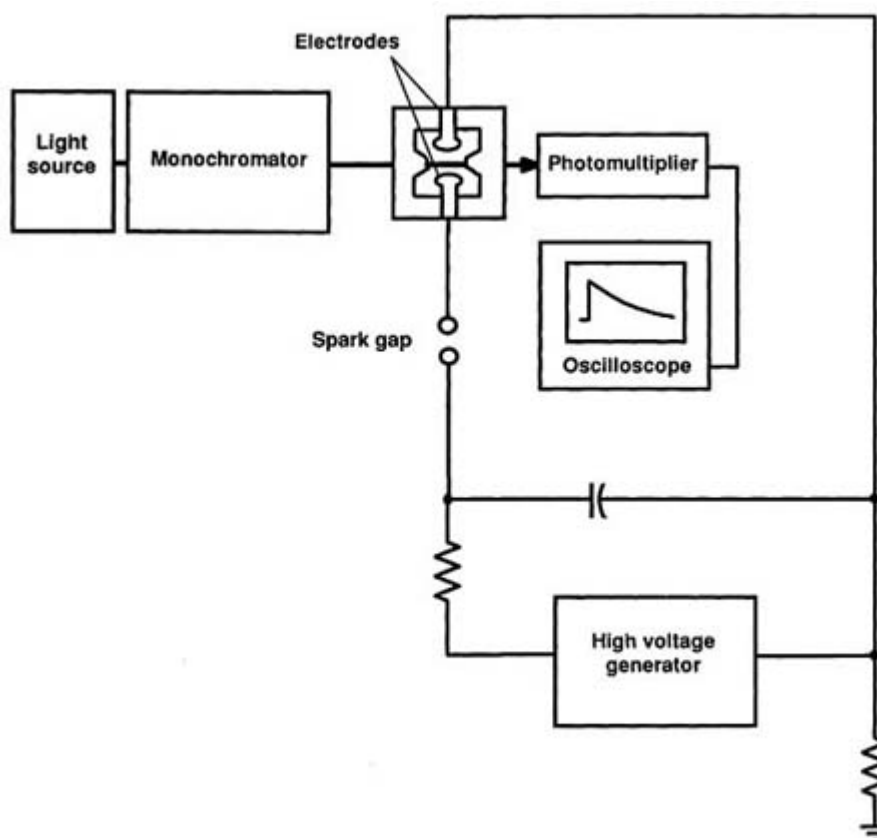

Figure C3.1.3. Schematic diagram of Joule heating T -jump apparatus for transient spectroscopy. (Adapted from French T C and Hammes G G 1969 *Methods Enzymol.* **16** 3.)

One can follow reactions of the order of microseconds or longer using a discharge T -jump. In a typical example, discharging 45 J of electrical energy into 10 cm³ of aqueous solution raises T by about 1 °C with an RC time constant of 1 μs for $R=20 \Omega$ (~0.5 M NaCl) and $C=0.1 \mu\text{F}$ (charged to 3×10^4 V).

-9-

C3.1.5.2 P JUMP

A sudden change in pressure can also be used to shift a chemical equilibrium, the change being given by the thermodynamic relation

$$\left(\frac{\partial \ln K}{\partial P}\right)_T = -\frac{\Delta V^0}{RT}$$

where ΔV^0 is the standard molar volume change for the reaction. This approach is less general than the T -jump method because relatively few reactions have significant volume changes. Examples are found, however, in the ionic association and dissociation reactions, in which solvation and electrostriction effects may produce a ΔV^0 of $\sim 10 \text{ cm}^3 \text{ mol}^{-1}$. In this case, a ΔP of 50 atm is required to produce a 2% change in K at room temperature. (Care must be taken in applying the constant T expression above for the change in K as it neglects the fact that a rapid P -jump is adiabatic and may be significantly non-isothermal, particularly in nonaqueous solvent.) Pressure jumps of the order of 10^2 atm with 10^{-5} s rise times may be obtained by rupturing a disc to suddenly admit a pressurized gas into a sample cell or, conversely, to suddenly release a pressurized gas from the cell [8, 9]. Differential P -jumps (~ 150 atm) can also be applied to study the kinetics of reactions at absolute pressures up to 2500 atm [10]. Because of the frequent need for high sensitivity in P -jump experiments, concentrations are often monitored using conductive measurements.

C3.1.5.3 E FIELD JUMP

The rapid application of a very high electric field ($|E| \sim 10^5 \text{ V cm}^{-1}$) can perturb chemical equilibria. This effect is described by the thermodynamic relation

$$\left(\frac{\partial \ln K}{\partial |E|} \right)_{P,T} = \frac{\Delta M^0}{RT}$$

where ΔM^0 is the change in standard molar polarization of the reaction. ΔM^0 is highest for reactions involving charge separations, e.g., ionic dissociations. Because of the resulting focus on conductive ionic reaction mixtures, pulsed fields of 10^{-6} s or shorter duration are typically used in order to limit Joule heating to acceptable levels. An interesting early application of the pulsed field technique was to measurement of the reaction rate constant for the prototypical proton transfer reaction $\text{H}^+ + \text{OH}^- \rightarrow \text{H}_2\text{O}$ [11]. The value measured, $1.3 \times 10^{11} \text{ M}^{-1} \text{ s}^{-1}$, is more than an order of magnitude faster than a typical diffusion controlled rate constant, reflecting the anomalously rapid diffusion of protons through water. Electric field jumps are also used to measure nanosecond electro-optic relaxation time constants for the dipole reorientations of biological macromolecules [12].

C3.1.6 FLASH PHOTOLYSIS

Laser-based pump strategies are generally necessary to study reactions taking place on time scales faster than microseconds. Lasers can be used to produce T -jumps on time scales faster than microseconds or to initiate reactions through rapid photochemical or photophysical processes. Lasers can also initiate ultrarapid mixing via a wide variety

-10-

of ‘caged’ compounds that release reactants upon photolysis [13]. Caged compounds contain a reactant moiety whose active site is blocked by a photolabile group. The cage can be rapidly photodissociated to produce a sample with reactants already microscopically mixed. One then studies the reaction on a time scale limited only by the time required for photodissociation and microscopic diffusion of reactants rather than by the time needed to macroscopically mix reagents. A similar approach can be used to rapidly change the pH of a solution to initiate a reaction or change a pH-dependent equilibrium. This can be done with compounds that exhibit dramatically different $\text{p}K_{\text{a}}$ values in their ground and excited states [14], such as sulphonated phenols [15, 16]. One can change the pH of a solution by several units within nanoseconds with such an approach. The acid–base chemistry involved is usually reversible, however, leading to eventual loss of the pH jump, often within a millisecond after excitation. Protons produced by irreversible photochemistry can provide more persistent jumps for use in single shot or flow experiments. The photoconversion of *o*-nitrobenzaldehyde to nitrosobenzoic acid, for example, produces a pH jump within a microsecond that persists for tens of milliseconds [17].

Lasers can also be used to produce T -jumps on time scales of picoseconds or longer in condensed phases such as liquid solutions. An intense pulsed laser, tuned to a solvent absorption, heats the solvent molecules on the time scale of the exciting laser pulse after rapid radiationless decay of the initial photoexcitation and rapid intra- and intermolecular energy transfer between the solvent and solute molecules’ degrees of freedom. Red or near-IR lasers are often frequency down-converted to reach the IR region where the solvent absorbs most efficiently. In aqueous solutions, for example, shifting the laser to the region around $1.5 \mu\text{m}$ results in strong absorption and temperature jumps of tens of degrees when the laser pulse is focused into a small volume. In a typical application, a 300 mJ pulse of $1.06 \mu\text{m}$ fundamental from a ns Nd:YAG laser is converted by a Raman shifter or OPO to a longer IR wavelength for efficient absorption by water. A conversion efficiency of 5%, for instance, produces 15 mJ of down-converted IR, which can be focused into a $1.5 \times 10^{-3} \text{ cm}^3$ absorbing volume to give a temperature jump of 10°C .

Reaction kinetics can be initiated most rapidly by the photoinitiation of a unimolecular reaction. With a sufficiently

fast excitation pulse, the speed of such reactions depends simply on intramolecular rates of energy transfer and the reaction dynamics themselves, precisely the properties one is often interested in studying. Researchers can study the photophysical properties of molecules by monitoring the spectra (e.g., absorption, emission or Raman) and dynamics of the excited states, or study the photochemical properties of excited states that decay through reactive channels such as isomerization, bond cleavage or ligand dissociation. It is also possible to initiate bimolecular photochemical reactions but these generally will occur on slower time scales involving the diffusion of reactant molecules to form reactive complexes.

The sensitivities of particular spectroscopic techniques to specific chemical features are described more fully in the next section. Perhaps the most common and versatile probes of reaction dynamics are time-resolved UV–vis absorption and fluorescence measurements. When molecules contain chromophores which change their structure directly or experience a change of environment during a reaction, changes in absorption or fluorescence spectra can be expected and may be used to monitor the reaction dynamics. Although absorption measurements are less sensitive than fluorescence measurements, they are more versatile in that one need not rely on a substantial fluorescence yield for the reactants, products or intermediates to be studied.

Unfortunately, the low resolution absorption spectra characteristic of condensed phase molecules at room temperature frequently do not provide a lot of information about the physicochemical nature of intermediates. Thus, time-resolved absorption measurements are often useful to initially characterize the kinetic characteristics of a reaction, but other spectroscopic methods may also be useful in probing more subtle or structure-specific mechanistic features. In the many cases in which one would like to obtain more information about the structural features of intermediates

-11-

than is available from absorption data, vibrational spectroscopies, including infra-red absorption measurements and Raman scattering, can be very useful. Often exquisitely sensitive to molecular structure, vibrational spectra contain much structural information, at least in principle, although their interpretation in terms of molecular structures may not always be straightforward in larger molecules because of spectral crowding.

It is also possible to obtain more structural information than is usually available from absorption data by making measurements with polarized light. Looking at linear dichroism (LD), the difference in absorption between linearly polarized light oriented parallel or perpendicular to a reference axis, as a function of time can provide detailed information about changes in orientation of that chromophore during the course of a reaction. An LD reference axis is determined in the molecular frame by the transition dipole of the chromophore used to photoinitiate the reaction, and in the laboratory frame by the polarization of the exciting laser. Measurements of differences in refractive index for parallel or perpendicularly polarized light (linear birefringence, LB) provide similar information and can sometimes be measured with greater sensitivity.

The use of circularly polarized light can further provide additional structural information. Time-resolved measurements of circular dichroism (CD), the difference in absorption intensity between left and right circularly polarized light, or optical rotatory dispersion (ORD), proportional to the difference in refractive index between circular polarizations, can provide information on kinetic changes in molecular structures exhibiting asymmetry. Changes in the helical content of proteins during the course of their reactions can be monitored by time-resolved CD measurements, for instance. It is also possible to induce a circular dichroism in a sample by the application of a magnetic field. Magnetic circular dichroism (and magnetic ORD) provides information complementary to that from natural CD (ORD) measurements, as discussed further below.

C3.1.7 SPECTROSCOPIC METHODS

C3.1.7.1 ULTRAVIOLET–VISIBLE ABSORPTION

Several strategies commonly used for time resolved optical absorption spectroscopy (TROA) are shown

schematically in [figure C3.1.4](#). Perhaps most common for microsecond to millisecond time-resolved measurements is the cw (continuous wave) probe approach ([figure C3.1.4\(a\)](#)). The probe can be a cw laser, provided a suitable wavelength is available, but cw xenon arc, tungsten filament or halogen lamps are most commonly used for UV–visible measurements, while glow bars have been used for IR measurements. Continuous probe sources offer the advantage of simplified timing—it is necessary to synchronize only the detection system and pump pulse. Two problems can offset this advantage, however. The first is the signal to noise ratio (S/N) of the data obtained with this method; the second is sample stability.

-12-

Figure C3.1.4. Schematic measurement traces depicting different probe strategies for transient spectroscopy and their typical time scales. Each panel represents the intensity of a probe beam against time. The small Gaussian at the bottom left of each panel represents the excitation (pump) pulse, defining the zero of time. (a) Strategy using a constant, cw light source as probe. The top line represents the probe light in the absence of laser pump excitation and the curved line represents a changing intensity after excitation of the sample. Time scales: milliseconds to seconds. (b) A cw arc lamp as in panel (a) augmented by a capacitive discharge across the arc to enhance intensity by a factor of 10–100. Time scales: microseconds to milliseconds. (c) A pulsed flashlamp is an alternative to the pulsed cw lamp in panel (b) that produces high power but low total energy from the probe light source, allowing for measurements on a faster time scale: nanoseconds to microseconds. (d) Pulsed lasers used for both pump and probe sources. Note that the pump pulse (left) is shown enlarged to emphasize the fact that the pump pulse must be much larger than the probe pulse. The probe pulse decreases in magnitude when the pump pulse excites the sample, creating a transient absorption. The probe pulse in the presence of the pump pulse is drawn wider only to make it easier to see in the figure. Time scales: nanoseconds to seconds. (e) With gated multichannel detection, the flashlamp probe in panel (c) is observed at a particular time delay after pump excitation, rather than monitored as a function of time as in single-wavelength detection. The probe pulse is diminished by the presence of transient absorption created by pump excitation, as measured by the spectra of the probe with and without pump sampled over a small range of delay times indicated by the ‘gate pulse’. The probe pulse and detector gate are kept overlapped as their joint time delay is varied to yield spectra as a function of time on time scales from nanoseconds to seconds.

The S/N of any light intensity measurement varies as the square root of the intensity (number of photons) produced by the source during the time of the measurement. The intensities typical of xenon arc lamps are sufficient for measurements of reasonable S/N on time scales longer than about a microsecond. However, a cw lamp will

produce few photons during measurement times faster than this and the signal will be noisy. This problem can be dealt with in

-13-

very stable samples by averaging many signals, but this approach is impractical for samples of moderate or high photolability. In fact, the cw probe approach can be problematic even with little signal averaging if the light source continues to irradiate a photolabile sample between data collection cycles. A modification of the cw probe approach improving the S/N of measurements on a nanosecond to microsecond time scale is shown in [figure C3.1.4\(b\)](#). The intensity of the cw lamp can be greatly increased (typically by a factor of several hundred) for times up to milliseconds by discharging a capacitor across an arc lamp just before firing the pump source [18].

The use of pulsed light sources such as lasers for both pump and probe, as shown in [figure C3.1.4\(c\)](#) [figure C3.1.4\(d\)](#) and [figure C3.1.4\(e\)](#) can achieve high S/N while avoiding photostability problems. The time delay between the probe and pump laser pulses can be varied over a wide range in measuring time-resolved absorption or emission. Sample photostability problems are avoided by proper adjustment of the (potentially very high) probe intensity. However, each single-wavelength, single-time measurement must be repeated at a number of wavelengths to obtain a spectrum. This process is further repeated at a number of time points to map out time-resolved spectra. This can again lead to sample deterioration in less photostable samples and can be tedious even for stable samples. A variation of this approach avoids the problem by using broad band pulsed light sources such as a laser-pumped dye, or 'soup' of laser dyes [19], or flashlamps as probe sources for multichannel measurements.

[Figure C3.1.4\(d\)](#) illustrates use of a pulsed xenon flashlamp probe source with a typical pulse width of several microseconds. This has the advantage of providing very high peak power for nanosecond measurements with high S/N, but low integrated intensity so that samples need not be exposed to excessive light from the probe source. For single-wavelength kinetic measurements, however, flashlamps have the disadvantage of being able to probe transient absorptions only for the duration of the flash, i.e., for microseconds or less.

All of the approaches described above can be used in a kinetic mode where the time evolution of absorption or emission signals are measured at one wavelength. As identifying transient intermediates often requires observing many wavelengths, an alternative is to replace photomultipliers or photodiodes with gated multichannel detectors such as intensified diode arrays ([figure C3.1.5](#)) or intensified CCDs to measure entire spectra. While these detectors can be used with cw sources, an optimal approach is to use gated multichannel detectors with flashlamps as depicted in [figure C3.1.4\(e\)](#) [20, 21].

-14-

Figure C3.1.5. Schematic diagram of an intensifier-gated optical multichannel analyser (OMA) detector. The detector consists of a microchannel plate (MCP) image intensifier followed by a 1024-channel Reticon photodiode array. Light dispersed across the semitransparent photocathode ejects photoelectrons. These are accelerated toward the entrance of the microchannels by the gate pulse. The photoelectrons collide with the channel walls to produce secondary electrons, which are accelerated in turn by the MCP bias voltage to produce further collisions and electron multiplication. Electrons leaving the microchannels are further accelerated by the phosphor bias voltage,

about 6 kV, until they strike the phosphor and produce light. Several hundred photons are produced for every MCP electron, providing further gain. This light, intensified by a factor of 10^6 over the amount produced when the gate pulse is off, is detected by the photodiode array. (From Lewis J W, Yee G G and Kliger D S 1987 *Rev. Sci. Instrum.* **58** 939–44.)

Figure C3.1.6 schematically shows the use of a flashlamp probe source to efficiently measure entire spectra at a given delay time. The flashlamp output extends from the UV into the IR spectral region. Multichannel detectors can typically measure intensities simultaneously at 500 to 1000 wavelengths over this range. The multichannel detector is gated on at the peak intensity of the flashlamp to provide maximum S/N for sampling times as short as 2–5 ns. The probe light source and detector gate can be delayed together to measure spectra with constant S/N over a wide time range. It is still necessary to carry out experiments at multiple delay times with this method to obtain kinetic information, but delay times can often be logarithmically spaced, as shown in figure C3.1.7 so that fewer in number are needed than the number of wavelengths needed to accurately record the spectra of intermediates. This is particularly true when using global fitting approaches, described below, which extract the maximum amount of information from time-resolved spectra.

-16-

Figure C3.1.7. Time-resolved optical absorption data for the Soret band of photolysed haemoglobin–CO showing six first-order (or pseudo-first-order) relaxation phases, I–VI, on a logarithmic time scale extending from nanoseconds to seconds. Relaxations correspond to geminate and diffusive CO rebinding and to intramolecular relaxations of tertiary and quaternary protein structure. (From Goldbeck R A, Paquette S J, Björling S C and Kliger D S 1996 *Biochemistry* **35** 8628–39.)

C3.1.7.2 FLUORESCENCE

Fluorescence, the spontaneous emission of light in a spin-allowed transition from an excited state to a lower energy or ground state, can provide a very sensitive means for detecting the concentrations of atomic and molecular species in transient kinetic studies. Being a null measurement, the sensitivity can be extraordinarily high. Indeed, it is possible to detect the presence of a single molecule in solution through its laser-induced fluorescence (LIF) [22]. Sensitivity levels more typical of kinetic studies are of the order of 10^{10} molecules cm^{-3} . A schematic diagram of an apparatus for kinetic LIF measurements is shown in [figure C3.1.8](#). A limitation of this approach is that only relative concentrations are easily measured, in contrast to absorption measurements, which yield absolute concentrations. Another important limitation is that not all molecules have measurable fluorescence, as radiationless transitions can be the dominant decay route for electronic excitation in polyatomic molecules. However, the latter situation can also be an advantage in complex molecules, such as proteins, where a lack of background fluorescence allows the selective introduction of fluorescent chromophores as probes for kinetic studies. (Tryptophan is the only strongly fluorescent amino acid naturally present in proteins, for instance.)

Figure C3.1.8. Schematic diagram of a transient kinetic apparatus using laser-induced fluorescence (LIF) as a probe and a CO₂ laser as a pump source. (From Steinfeld J I, Francisco J S and Hase W L 1989 *Chemical Kinetics and Dynamics* (Englewood Cliffs, NJ: Prentice-Hall).)

Determining a molecule's fluorescence lifetime (τ_F), typically of the order of nanoseconds for strong emitters, is frequently an object of transient kinetic study. A transient measurement of lifetime after excitation with a nanosecond flash lamp or pulsed laser (inexpensive subnanosecond pulsed nitrogen lasers are available for this purpose) can be accomplished by directly monitoring the time course of fluorescence intensity using a fast photomultiplier and transient recorder or boxcar integrator or, less directly, by measuring the statistical distribution of times between absorption and emission events (under low intensity illumination conditions) using a time-correlated single-photon counting apparatus [23, 24]. In general, the fluorescence lifetime can be shorter than the radiative lifetime (τ_R), given by the Einstein B coefficient for the emissive transition (usually estimated from the corresponding absorption band, as the same upper and lower states are usually connected by absorption and emission), because radiationless transitions and intermolecular excited state quenching can compete kinetically with emission in depopulating the excited state. A measurement of τ_F can thus be used to determine the total rate (k_{NR}) of nonradiative relaxation processes (internal conversion, intersystem crossing) and bimolecular quenching (k_Q): $k_{NR} + k_Q[Q] = 1/\tau_F - 1/\tau_R$, where $[Q]$ is the concentration of the quenching molecule.

Nonradiative relaxation and quenching processes will also affect the quantum yield of fluorescence, $\phi_F = k_R / (k_R + k_{NR} + k_Q[Q])$. Relative measurements of fluorescence quantum yield at different quencher concentrations are easily made in steady state measurements; absolute measurements (to determine k_{NR}) are most easily obtained by comparisons of steady state fluorescence intensity with a fluorescence standard. The usefulness of this situation for transient studies

of large molecules, such as biopolymers, lies in the ability to use the quasi-steady state fluorescence intensity of an embedded chromophore as a probe of dynamic changes in the solvent exposure of the chromophore (through changes in k_{NR}) or in long distance chromophore–chromophore quenching interactions (Förster energy transfer) over the 10^{-8} to 1s time regime. The rate of Förster (very weak coupling excitonic) energy transfer varies inversely as the sixth power of the chromophore to chromophore distance, making the observed fluorescence intensity a potentially sensitive ruler of intramolecular distances in static and time-resolved studies. Thus, for example, time-resolved measurements of tryptophan near-UV fluorescence intensity under steady state illumination can be used to

monitor conformational relaxations in aqueous proteins after rapid mixing with a denaturant that disrupts secondary and tertiary structure. As a protein's native structure unfolds, increased distance from a quenching group, such as the haem prosthetic group in haem proteins, can dramatically increase the fluorescence yield. In proteins lacking an internal quencher, increased exposure of tryptophan to the solvent enhances k_{NR} and reduces the fluorescence intensity.

C3.1.7.3 INFRARED ABSORPTION

Time-resolved spectroscopy in the IR region (TRIR) can give detailed information about structural changes in molecules by monitoring changes in the frequencies and absorption amplitudes of vibrational normal modes. The selection rule for vibrational transitions allows for those modes whose motions produce a change in electric dipole moment to be IR active. Changes in bond strengths or molecular symmetry accompanying intramolecular processes such as isomerizations, and the binding or dissociation of ligands in complexes, are examples of transient events that may be studied with TRIR. An apparatus for TRIR is shown schematically in [figure C3.1.9](#) [figure C3.1.10](#) shows the results of a TRIR study of the transient binding of CO to a copper atom in cytochrome *c* oxidase after photodissociation of the Fe–CO bond in this haem protein [25]. Evolution in the secondary structure of proteins may also be followed by measuring the TRIR of several vibrational bands arising from the peptide backbone: the N–H stretching vibration (3300 cm^{-1}), the C=O stretch, or amide I band ($1600\text{--}1700\text{ cm}^{-1}$) and the N–H bending vibration, or amide II band ($1520\text{--}1550\text{ cm}^{-1}$). TRIR of these bands has been used to directly monitor fast folding and unfolding reactions in the protein RNase A [26] and in small peptides [27], for example.

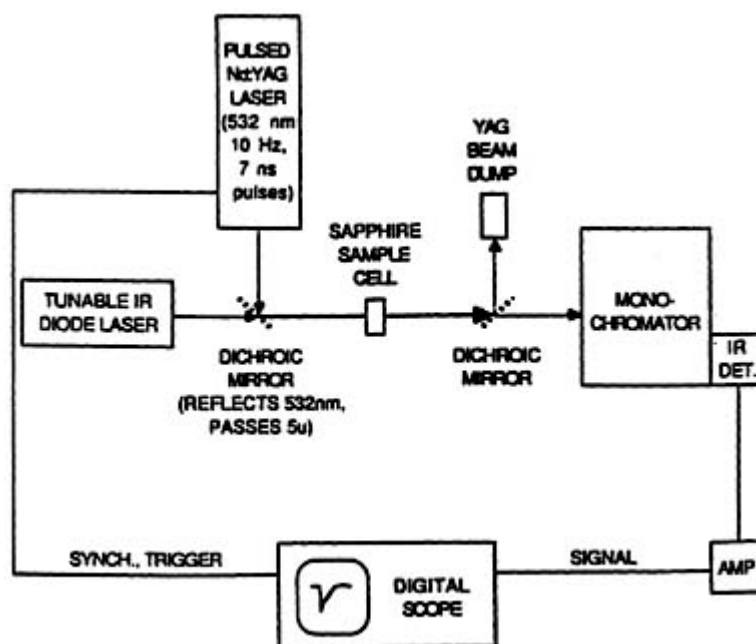

Figure C3.1.9. Block diagram for time-resolved infrared spectroscopy apparatus. (From Dyer R B, Einarsson Ó, Killough P M, López-Garriga J J and Woodruff W H 1989 *J. Am. Chem. Soc.* **111** 7657–9.)

-20-

Figure C3.1.10. (a) Steady state IR difference spectrum (dark minus light) of cytochrome *c* oxidase CO complex measured at low temperature (127 K). This protein contains a copper atom situated immediately adjacent to a haem iron, the latter binding CO with high affinity at equilibrium. The band at 2061 cm^{-1} shows the presence of a Cu–CO bond in the intermediate species frozen immediately after photolysis (light) of the equilibrium, Fe–CO bonded protein (dark). (b) The time evolution of the Cu–CO bonded intermediate after room temperature photolysis of the Fe–CO protein complex. The CO is transferred to the Cu atom within femtoseconds of photodissociation of the Fe–CO bond. The Cu–CO bond then thermally dissociates with a time constant of about $1.5\text{ }\mu\text{s}$ and freed CO diffuses out of the protein. (The two frequencies outside the Cu–CO band provide control measurements.) (From Dyer R B, Einarsdóttir Ó, Killough P M, López-Garriga J J and Woodruff W H 1989 *J. Am. Chem. Soc.* **111** 7657–9.)

The absorption intensities characteristic of IR transitions, the intensities of IR light sources and the sensitivities of IR detectors are relatively low compared with those for visible and UV wavelengths. These factors present a challenge for experimentalists wishing to accumulate data with signal to noise ratios sufficient to resolve time-dependent changes. An additional factor is the wide presence of IR active transitions in polyatomic molecules. While on the one hand this constitutes one of the primary advantages of the TRIR technique, it means on the other hand that transient IR signals are often detected against interfering background absorptions from the solvent or from peripheral modes in large molecules. For example, water, an important solvent in TRIR studies of biological

molecules, is also a strong IR absorber. Differential TRIR techniques are often used to overcome interference from such background absorptions.

Instead of the blackbody-radiation light sources commonly used in dispersive IR spectrometers, time-resolved studies often use pulsed xenon flash lamps or tunable CW diode lasers, which concentrate IR output intensity in time or frequency space, respectively. TRIR has typically been measured in single-wavelength, kinetic mode, as IR sensitive OMAs are not yet widely available. Kinetic IR signals are collected with photoconductive detectors using materials such as indium antimonide (InSb) or mercury–cadmium–tellurium (HgCdTe). However, complete nanosecond TRIR spectra have been recorded using a dispersive scanning spectrometer with an HgCdTe detector [28], although the spectral accumulation times tend to be long. Another approach to spectral mode TRIR has been to combine Fourier transform techniques (FTIR) with time-resolved spectroscopy [29].

C3.1.7.4 RESONANCE RAMAN SCATTERING

The Raman effect, the inelastic scattering of photons resulting in frequency shifts that reflect the vibrational and rotational energies of the scattering molecule, is used in transient spectroscopy to obtain time-dependent vibrational information that often complements that obtained from TRIR. Raman scattering arises from changes in the polarizability of a molecule associated with vibrational (and rotational) motions, rather than from changes in the dipole moment itself, as is the case in IR absorption spectroscopy. Raman selection rules therefore can in general be different from those for absorption. The two methods thus complement one another, particularly in small molecules. This is most true for molecules with a centre of symmetry. In this case, the selection rules are exactly complementary—all Raman active transitions are IR inactive, and vice versa. Raman spectroscopy also offers an advantage for transient studies of solutes in solvents such as water that are not strongly Raman active, e.g. transient studies of aqueous biomolecules.

Bringing the frequency of the photon into near resonance with an electronic transition enhances the intensity of the inherently weak Raman scattering process. The ratio of Raman to Rayleigh scattering intensity, typically 10^{-9} to 10^{-6} , is increased in resonance Raman by one to two orders of magnitude to give ratios of 10^{-8} to 10^{-4} . Time-resolved resonance Raman spectroscopy (TR³) thus offers greater S/N ratios and higher time resolution for transient studies. It also offers greater specificity in the time-resolved vibrational spectroscopy of large molecules, as compared with TRIR spectroscopy, in that only the vibrational modes associated with the nuclear structure of the resonant chromophore are enhanced. This is a particularly important advantage in very large molecules, such as biopolymers, where many overlapping IR and Raman active modes may be present [30, 31 and 32].

Raman spectroscopy requires an intense, monochromatic light source. The field thus developed rapidly when lasers became commercially available in the 1960s. Nanosecond TR³ measurements are now performed with several configurations using pulsed or CW lasers. A pump–probe two-pulse method giving both kinetic and spectral information about dynamic processes is frequently used. Kinetic information is obtained in this method by varying the delay time between pump and probe, as provided for by a digital delay generator in the apparatus shown in

figure C3.1.11. The ability to choose different pump and probe wavelengths in this method reduces the likelihood of spectral artifacts. For nanosecond TR³ measurements, the pump source is typically a low repetition rate, high pulse-energy laser, often a Nd:YAG or excimer laser with a pulse duration of several nanoseconds. The probe light source in a Raman measurement must also be intense—intense enough to generate detectable Raman scattering, but not so intense as to photoinitiate changes in the sample (recall that the probe is in near resonance with an electronic transition of a photoreactive molecule). The same laser types used as pumps are also used as probe sources, although they are generally coupled with a dye laser, hydrogen, deuterium or methane Raman shifter or, more recently, a nonlinear harmonic generation crystal or an optical parametric oscillator (OPO) to increase the selection of available wavelengths.

Figure C3.1.11. Apparatus for pump-probe time-resolved resonance Raman spectroscopy. (From Varotsis C and Babcock G T 1993 *Methods Enzymol.* **226** 409–31.)

Discriminating the small amount of light intensity in the Raman-shifted lines from the intense Rayleigh-scattered light of the probe laser places great demands on monochromator design, which must balance high wavelength resolution and stray-light rejection against signal throughput. Single, double and triple monochromators are used in TR³ measurements for correspondingly increased rejection of Rayleigh scattering. The addition of each grating typically introduces a throughput efficiency factor of roughly 30%, however, so that the overall efficiency of a triple monochromator is only about 3%. Single 0.75–1 m monochromators have output efficiencies ideal for TR³ experiments and may be used to measure Raman frequencies greater than 500 cm⁻¹. Notch filters combined with a single monochromator give Rayleigh rejection factors comparable to a double monochromator while maintaining greater throughput and are suitable for TR³ measurements at frequencies as low as 50 × 100 cm⁻¹ [30].

-23-

TR³ signals are preferably detected with a time-gated optical multichannel analyser (OMA), which allows the entire spectral change associated with each pump-probe pair to be recorded for a given time delay. Intensified diode array detectors, with optical quantum efficiencies of about 20%, can be gated with a high voltage pulse to capture the transient Raman signal of interest while suppressing interference from Rayleigh scatter and fluorescence falling outside the time window of the gate pulse. CCD (charge-coupled device) detectors are 2D arrays that have more recently become available for TR³ spectroscopy. They offer the advantages of low readout noise and higher quantum efficiencies in the IR region. Although also more sensitive to artifacts from cosmic rays, the narrow spikes these produce can be removed from affected data by using commercially available software.

C3.1.7.5 CIRCULAR DICHROISM AND OPTICAL ROTATORY DISPERSION

Circular dichroism (CD), the differential absorption of left *versus* right circularly polarized light, is the polarization spectroscopy perhaps best suited to detecting the presence of asymmetry in the structure or environment of molecular chromophores. Various time-resolved CD (TRCD) methods have been developed to take advantage of this sensitivity and obtain more detailed structural information about kinetic processes than is found from ordinary time-resolved absorption measurements [33]. Some examples of the processes studied with TRCD methods are: the effects of electronic excitation on the structure of chiral inorganic complexes, the changes in α -helical secondary

structure accompanying the folding reactions of proteins and the time evolutions of tertiary and quaternary structure in allosteric proteins, as reflected in the protein-environment-induced CDs of ‘reporter’ chromophores.

CD is a small effect. $\Delta\varepsilon/\varepsilon$, the ratio of the difference in circularly polarized extinction coefficients, $\Delta\varepsilon = \varepsilon_L - \varepsilon_R$, to total absorption, $\varepsilon = \frac{1}{2}(\varepsilon_L + \varepsilon_R)$, is typically only about 10^{-4} – 10^{-3} . Being so small, the measurement of CD with signal to noise ratios sufficient for static and time resolved studies requires special methods, each representing a different tradeoff between the factors such as time resolution, sensitivity to artifacts and experimental simplicity, that determine the method of choice for a particular kinetic study.

Kinetic CD measurements on slow time scales may be made on commercial CD instruments, which can be equipped for stopped-flow studies. Commercial CD instruments use rapid polarization modulation methods, introduced in the 1960s, and phase-locked detection to increase sensitivity. Linearly polarized light is passed through a photoelastic modulator (PEM), essentially a small quartz plate undergoing resonantly driven acoustic vibration, to produce time-varying elliptically polarized light cycling between left and right circular polarizations. The CD signal is detected as the AC component of the light intensity transmitted through the sample, normalized to the magnitude of the DC component and to a calibration factor (determined by measuring the CD of a standard substance) reflecting the relative gain of the AC and DC electronic amplification stages. Noise from instrumental sources, such as arc wander, containing frequency components lower than the modulator frequency is effectively filtered from the AC-modulated CD signal. However, the PEM resonant frequency, typically 1–100 kHz, not only sets an upper limit on the frequencies of the instrumental noise components suppressed, it also limits the maximum characteristic frequencies of the kinetic processes that may be studied. TRCD measurements on time scales faster than about a millisecond thus require unconventional methods.

An ellipsometric approach to CD measurements used for TRCD spectroscopy in the nanosecond regime is depicted schematically in [figure C3.1.12](#) [34]. The instrument used in this technique is based on a nanosecond Nd:YAG laser photolysis apparatus using a broad band microsecond xenon flash lamp as a probe. Rather than detecting the differential absorption of left and right circularly polarized light, the polarization state of elliptically polarized light is detected in this method, i.e., ellipsometry. The linearly polarized probe beam is passed through a strain plate, a fused

silica plate under slight mechanical compression, to produce highly eccentric elliptically polarized light. The CD signal is detected as the difference between right and left elliptically polarized light intensity transmitted through the sample and an analysing polarizer, normalized to the sum of the intensities and a proportionality factor determined by the pathlength and concentration of the sample and the magnitude of the strain plate retardance, δ . (No calibration against a CD standard is required in this method.) This can be written as $\Delta\varepsilon = (\delta/cI)/(I_{REP} - I_{LEP})/(I_{REP} + I_{LEP})$. The primary advantage of the near-null approach is that the signal is effectively amplified relative to the noise from instrumental sources by a factor inversely proportional to δ . The tradeoff for this increased sensitivity and time resolution is that more care must be taken to avoid potential interference from light scattering, fluorescence and optical artifacts—particularly those from linear birefringence present in the sample or optics—than is necessary for conventional PEM-based measurements. An instrument for nanosecond far-UV TRCD using this method is shown schematically in [figure C3.1.13](#).

Figure C3.1.12. Schematic diagrams of optical configurations for quasi-null detection techniques used in transient kinetic studies of (a) CD, (b) MCD and (c) ORD/LD. Elliptical polarization is provided in (a) and (b) by a horizontal prism polarizer followed by a fused silica plate of linear retardance $\pm\delta$, magnitude $\sim 1^\circ$, induced by mechanical compression indicated by arrows. CD of the sample adds to or subtracts from the net ellipticity of the beam detected by the vertical analysing polarizer, giving rise to the differential signal shown in the text. A solvent blank in an opposed applied field cancels the Faraday rotation of solvent and cell in (b). The polarizer axis is rotated to $\pm\beta$ from horizontal in (c), where $\beta \sim 1^\circ$. ORD or LD of the sample adds to or subtracts from the net rotation of the beam detected by the analysing polarizer, giving rise to a differential signal. (From Chen E, Goldbeck R A and Klinger D S 1997 *Annu. Rev. Biophys. Biomol. Struct.* **26** 325–53.)

-25-

Figure C3.1.13. Experimental configuration for far-UV nanosecond CD measurements using a frequency-upconverted Ti:sapphire laser as a probe source. P_1 and P_2 are MgF_2 Rochon polarizers at cross orientations. SP_1 is a strained transparent plate with about 1° of linear birefringence for quasi-null ellipsometric CD detection. Prism PM_1 and the iris I_7 select the far-UV fourth harmonic of the argon laser-pumped Ti-sapphire laser's near-IR fundamental output to probe the ellipticity of the sample. A second laser beam at 532 nm is used to pump CD

transients in the sample. (From Goldbeck R A, Kim-Shapiro D B and Kliger D S 1997 *Annu. Rev. Phys. Chem.* **48** 453–79.)

Ultrafast TRCD has also been measured in chemical systems by incorporating a PEM into the probe beam optics of a picosecond laser pump–probe absorption apparatus [35]. The PEM resonant frequency is very low (1 kHz) in these experiments, compared with the characteristic frequencies of ultrafast processes and so does not interfere with the detection of ultrafast CD changes.

In principle, optical rotatory dispersion (ORD) and circular dichroism contain identical information about molecular structure and can be interconverted using the Kramers–Kronig integral transforms [36]. CD, being limited to absorption bands and easier to interpret than ORD, became the preferred approach to the study of optically active molecules after the development of PEM-based CD spectrometers. From an experimental point of view, however, optical rotation (OR), the rotation of the polarization plane of light by a chiral substance, is easier to measure than circular dichroism. This fact accounts for the historical importance of OR (the beginnings of chemical kinetics as a quantitative discipline, for instance, can be traced to the use of OR measurements to determine reaction rates for sucrose hydrolysis by Wilhemy in 1850 [37]) and for the recent development of rapid time-resolved ORD methods for kinetic studies. A near-null polarimetric ORD method has been incorporated into several generations of flash photolysis instruments developed over the past few decades for time-resolved applications extending into the nanosecond time regime [33]. (This method also doubles as a very sensitive technique for measuring linear dichroism in anisotropic samples and is useful for studies of orientational relaxation after laser photoselection [38].)

C3.1.7.6 MAGNETIC CIRCULAR DICHROISM

Magnetic circular dichroism (MCD) is independent of, and thus complementary to, the natural CD associated with chirality of nuclear structure or solvation. Closely related to the Zeeman effect, MCD is most often associated with orbital and spin degeneracies in chromophores. Chemical applications are thus typically found in systems where a chromophore of high symmetry is present: metal complexes, porphyrins and other aromatics, and haem proteins are

-26-

prominent examples. Time-resolved MCD (TRMCD) spectroscopy is best suited to the study of kinetic processes directly affecting chromophore electronic structure, e.g., spin, oxidation and ligation state changes in metal complexes and metalloporphyrins. TRMCD is measured by adding a magnet—permanent, electric or superconducting—to the TRCD instrumentation described above. This is straightforward to do for PEM-based instruments, such as the ultrafast MCD apparatus of Xie and Simon [39]. Ellipsometric TRMCD measurements, on the other hand, require an additional optical component to compensate for rotation of the probe beam's polarization orientation by the Faraday effect of the transparent solvent and cell windows in the magnetic field [33].

C3.1.8 ANALYSIS OF TIME-RESOLVED SPECTRAL DATA

Transient kinetic studies measure a time-resolved record of some property of the sample, such as absorption, emission or conductance, that can be analysed for its kinetic components. The data are usually stored as a digital computer file containing a linear array of observations against time. In the case of spectroscopic measurements, this may be generalized to a rectangular array of spectra against time. The particular form of the analysis that is applied to the data in order to obtain rate constants and amplitudes is determined by knowledge about, or assumption of, a particular kinetic mechanism. Determining an unknown mechanism is often an iterative process in which possible models are tested until the most parsimonious mechanism consistent with the data is found. This mechanism can frequently be assumed to involve only first order or pseudo-first order rate processes in fast kinetic studies. In this case, the analysis of single-wavelength absorption data may be as simple as a linear regression plot of \ln (absorption) against time, the slope of which provides the rate constant for a simple exponential decay. More complicated analysis, i.e., nonlinear least squares multi-exponential fitting of absorption against time, is required if

more than one process is present.

Multichannel time-resolved spectral data are best analysed in a global fashion using nonlinear least squares algorithms, e.g., a simplex search, to fit multiple first order processes to all wavelength data simultaneously. The goal in this case is to find the time-dependent spectral contributions of all reactant, intermediate and final product species present. In matrix form this is $\mathbf{A}(\lambda, t) = \mathbf{BC}$, where \mathbf{A} is the data matrix, rows indexed by wavelength and columns by time, \mathbf{B} contains spectra as columns and \mathbf{C} contains time-dependent concentrations of all species arranged in rows.

A general first order mechanism can be written symbolically in matrix form as

$$\frac{dc(t)}{dt} = \mathbf{K}c(t)$$

where \mathbf{K} is the matrix of rate constants and $c(t)$ is a column vector of time-dependent concentrations. A general solution for the concentrations (found using eigenvalue techniques, for instance) is

$$c_i(t) = \sum_j M_{ij} [\mathbf{M}^{-1} c(t=0)]_j e^{[\mathbf{M}^{-1} \mathbf{K} \mathbf{M}]_{jj} t}$$

where \mathbf{K} is diagonalized by a similarity transform with matrix \mathbf{M} . An efficient approach to fitting the kinetic mechanism represented by the elements of \mathbf{K} to the data in \mathbf{A} is to first apply singular value decomposition (SVD) to

-27-

\mathbf{A} , $\mathbf{A} = \mathbf{USV}^T$, where \mathbf{S} is a diagonal matrix of singular values, and \mathbf{U} and \mathbf{V} are orthonormal matrices containing in this case spectral and temporal information, respectively (superscript 'T' indicates matrix transpose) [40]. (SVD is very similar to principal component analysis [41, 42].) The data are then filtered of random noise by discarding singular values that fall below a value determined by the magnitude of the noise, leaving the truncated matrix \mathbf{S}_r . (The corresponding columns of \mathbf{U} and \mathbf{V} are also discarded to obtain \mathbf{U}_r and \mathbf{V}_r .) The singular values remaining correspond to those columns of \mathbf{U} and \mathbf{V} containing spectrokinetic information filtered of noise. Their number, r , is the effective rank of \mathbf{A} . Besides providing a convenient deconvolution of the data into spectral and temporal components and filtering these into a more compact representation, SVD also provides physical information in that r gives a lower bound on the number of independent spectrotemporal components, or kinetic species, present in the system. Although the individual spectra in \mathbf{U}_r and evolutions in \mathbf{V}_r do not generally correspond to those of physical species, observed rate constants can be efficiently fitted to the aggregate temporal information in \mathbf{V}_r . These constants correspond to the diagonal elements of $\mathbf{M}^{-1} \mathbf{K} \mathbf{M}$, which we will call \mathbf{K}_{obs} . In the simplest case, that of simple decays proceeding in parallel, $\mathbf{K} = \mathbf{K}_{\text{obs}}$, i.e., \mathbf{M} is the identity matrix, \mathbf{I} . The elements of \mathbf{C} are calculated from the solution for $c_i(t)$ using \mathbf{K}_{obs} and known, or trial, values of $c_i(t=0)$. The spectra of intermediates are then calculated from $\mathbf{B} = \mathbf{U}_r \mathbf{S}_r \mathbf{V}_r^T \text{pinv}(\mathbf{C})$, where pinv is the matrix pseudoinverse (essentially a least squares solution to the overdetermined inversion problem). Finally, any assumptions about initial concentrations can be checked by comparing \mathbf{B} against known model spectra. For more general first order kinetic mechanisms, \mathbf{M} is calculated from $\mathbf{M}^{-1} \mathbf{K} \mathbf{M} = \mathbf{K}_{\text{obs}}$ and knowledge of, or assumptions about, branching ratios or equilibrium constants for any back reactions that may be present. Such assumptions, if necessary, can be tested by comparing the calculated spectra in \mathbf{B} to known model spectra. (It may be expedient to obtain the observed rate constants, without determining a mechanism, by simply choosing all $c_i(t=0) = 1$ and setting $\mathbf{M} = \mathbf{I}$, in which case the spectra in \mathbf{B} are sometimes referred to as 'b-spectra' in the literature.) The derivation of first order mechanisms from transient spectral data is discussed in more detail in [43].

The Arrhenius relation given above for the temperature dependence of an elementary reaction rate is used to find the activation energy, E_a , and the pre-exponential factor, A , from the slope and intercept, respectively, of a (linear) plot of $\ln(k(T))$ against T^{-1} . The standard enthalpy and entropy changes of the transition state (at constant

temperature and pressure) can be found for most types of reaction from

$$\Delta H_0^\ddagger = E_a - RT$$

and

$$\Delta S_0^\ddagger = R \ln(Ah/k_B T) - R.$$

These expressions are modified in the case of non-unimolecular gas phase reactions to

$$\Delta H_0^\ddagger = E_a - RT(1 - \Delta n^\ddagger)$$

-28-

and

$$\Delta S_0^\ddagger = R \ln(Ah/k_B T) - R(1 - \Delta n^\ddagger)$$

where $\Delta n^\ddagger = P\Delta V^\ddagger/RT$, ΔV^\ddagger being the standard volume of activation. The free energy of activation is found from $\Delta G_0^\ddagger = \Delta H_0^\ddagger - T\Delta S_0^\ddagger$.

The presence of nonlinearity in an Arrhenius plot may indicate the presence of quantum mechanical tunnelling at low temperatures, a compound reaction mechanism (i.e., the reaction is not actually elementary) or the ‘unfreezing’ of vibrational degrees of freedom at high temperatures, to mention some possible sources.

C3.2 Electron transfer reactions

Gilbert C Walker and David N Bertan

C3.2.1 INTRODUCTION

C3.2.1.1 WHAT IS CHEMICAL ELECTRON TRANSFER?

Chemical reactions involve the redistribution of electronic charge and changes in chemical bonding. Chemical bonds can reorient, disconnect, and reform during chemical reactions. These bonding changes are coupled, in turn, to changes in the structure (orientation, hydrogen bonding, polarization etc.) of the surrounding solvent. Bonding changes can be subtle or dramatic. The subject of this chapter is the special class of reactions in which an electron is displaced by distances much larger than the length of a single chemical bond; such reactions are known as ‘electron-transfer reactions’.

Electron transfer reactions are conceptually simple. The coupled structural changes may be modest, as in the case of ‘outer-sphere’ electron transport processes. Other electron transfer processes result in bond formation or

cleavage—inner sphere electron transfer—and are more complex. Despite their apparent simplicity, outer-sphere electron-transfer reactions play a central role in chemistry, from current flow at electrodes to the early events in photosynthesis and to radiation damage in DNA. Theories that predict the relationship between chemical structure, solvation, spectroscopy and electron transfer rates were developed extensively over the last 50 years; they provide a valuable unifying thread in this field of research [1].

C3.2.1.2 THE DIVERSITY OF CHEMICAL ET SYSTEMS

Much of this chapter concerns ET reactions in solution. However, gas phase ET processes are well known too. See [figure C3.2.1](#). The ‘harpoon mechanism’ by which halogens oxidize alkali metals is fundamentally an electron transfer reaction [2]. One might guess, from this simple reaction, some of the structural parameters that control ET rates: relative electron affinities of reactants, reactant separation distance, bond length changes upon oxidation/reduction, vibrational frequencies, etc.

Figure C3.2.1. A slice through the intersecting potential energy curves associated with the $K+Br_2$ electron transfer reaction. At the crossing point between the curves (R_x), electron transfer occurs, thus ‘harpooning’ the Br_2 species, which is then associated with K^+ at shorter distances. From [2].

Much of the motivation for examining ET processes comes from biology. Many processes in bioenergetics involve transmembrane electron transport. The cascade of biological reactions that leads to an electrochemical gradient starts with electron transfer [3]. In the photosynthetic charge separation of purple bacteria, for example, a photoexcited state of a magnesium chlorophyll ‘special pair’ undergoes picosecond time-scale electron transfer to a pheophytin and then to a quinone [4]. These redox-active species are imbedded in a membrane-spanning protein whose structure was determined in 1984. These reactions are the subject of intense experimental and theoretical interest.

In the 1980s, considerable attention turned to ET reactions in fixed donor–acceptor geometries with the goal of understanding the control of the fixed distance biological reactions. Locking in the donor–acceptor separation distance simplifies the interpretation of measured ET kinetics [5], by removing uncertainties associated with intermolecular motion and docking. The simplest approach is to freeze donors and acceptors in a matrix [6], generating an ensemble of fixed distances. Simplifying the interpretation even further came from synthesizing covalently linked donor–bridge–acceptor molecules [7, 8] ([figure C3.2.2](#)). Indeed, unimolecular ET structures have been studied in considerable depth in both gas and solution-phase environments [9].

Figure C3.2.2. Long-range charge separation occurs from the S1 state of the rigidly bridged molecule above. This figure shows predominantly emission from the charge separated state. Absence of local emission from the S1 state indicates that ET occurs on a subnanosecond time-scale. Curves: (1) $R = -H$, (2) $R = -CH_3$, and (3) $R = -OCH_3$. From Wegewijs B and Verhoeven J W 1999 Long-range charge separation in solvent-free donor-bridge-acceptor systems *Adv. Chem. Phys.* **106** 248.

Electron transport processes at surfaces often involve electron-tunnelling transport. For example, in the scanning tunnelling microscope (STM) (see section B1.19 and figure C3.2.3), electrons flow between delocalized initial and final states. Depending on the experimental design, the tunnelling can proceed through vacuum or through attached atoms and molecules. In closely related photochemical experiments, electrons are driven from a delocalized electrode state to a localized molecular species or another electrode through an ‘insulating’ molecular monolayer [10].

In solid state materials, single-step electron transport between dopant species is well known. For example, electron-hole recombination accounts for luminescence in some materials [11]. Multistep hopping is also well known. Models for single and multistep transport are enjoying renewed interest in the context of DNA electron transfer [12, 13, 14 and 15]. Indeed, there are strong links between the ET literature and the literature of hopping conductivity in polymers [16].

-4-

Figure C3.2.3. Schematic view of a scanning tunnelling microscope. From Chen C J 1993 *Introduction to Scanning Tunnelling Microscopy* (Oxford: Oxford University Press).

Consideration of the donor–bridge–acceptor systems just mentioned, in the presence of optical excitation, raises the question of whether the photoexcited state might have substantial charge transfer character. Indeed, excitation to charge-transfer excited states is observed in inorganic complexes; these transitions are known as metal–ligand, ligand–metal, and intervalence charge transfer bands. Intervalence bands are particularly diagnostic of bridge-mediated donor–acceptor interactions. The extent of excited state charge transfer is especially important in species such as the ‘special pair’ of chlorophylls in photosynthesis, as polarization of this excited state may influence its rate of ET [17].

Much of chemistry occurs in the condensed phase; solution phase ET reactions have been a major focus for theory and experiment for the last 50 years. Experiments, and quantitative theories, have probed how reaction-free energy, solvent polarity, donor–acceptor distance, bridging structures, solvent relaxation, and vibronic coupling influence ET kinetics. Important connections have also been drawn between optical charge transfer transitions and thermal ET.

C3.2.1.3 ET IN BIOLOGY

A substantial fraction of the named enzymes are oxido-reductases, responsible for shuttling electrons along metabolic pathways that reduce carbon dioxide to sugar (in the case of plants), or reduce oxygen to water (in the case of mammals). The oxido-reductases that drive these processes involve a small set of redox active ‘cofactors’, that is, small chemical groups that gain or lose electrons. These cofactors include iron porphyrins, iron–sulfur clusters and copper complexes as well as organic species that are ET active.

Many key protein ET processes have become accessible to theoretical analysis recently because of high-resolution x-ray structural data. These proteins include the bacterial photosynthetic reaction centre [18], nitrogenase (responsible for nitrogen fixation), and cytochrome *c* oxidase (the terminal ET protein in mammals) [19, 20]. Although much is understood about ET in these molecular machines, considerable debate persists about details of the molecular transformations.

C3.2.1.4 ET TECHNOLOGY: MEDICAL DIAGNOSTICS AND NANOSCALE ELECTRONICS

In addition to conventional applications in conducting polymers and electrooptical devices, a number of recent novel applications have emerged. Switching of DNA electron transfer upon single-strand/double-strand hybridization forms the basis for a new medical biosensor technology. Since the number of base pairs of length 20 is 4^{20} (or 10^{12}), a modest length DNA sequence, with ET properties that switch upon hybridization, can be employed to detect the presence of a complementary sequence. Many research efforts are engaged in devising ET-based biosensors to detect human disease and to sense the contamination of foodstuffs.

Small molecules are of the order of nanometres in linear dimensions. Conventional microelectronics technology employs features fully a hundred to a thousand times larger. As such, considerable interest is focused upon employing molecular species (together with and the rules of molecular ET) to devise ultra-small computing devices. Examples of recent advances include the demonstration of molecular-scale diodes (figure C3.2.4), prototypes for molecular scale memories, and single-electron devices [21, 22]. Remarkable physics arises in these devices. For example, in devices with dimensions of the order of the electron wavelength, conductivity is quantized; and current–voltage relations follow a stair-step pattern, rather than a simple linear relationship.

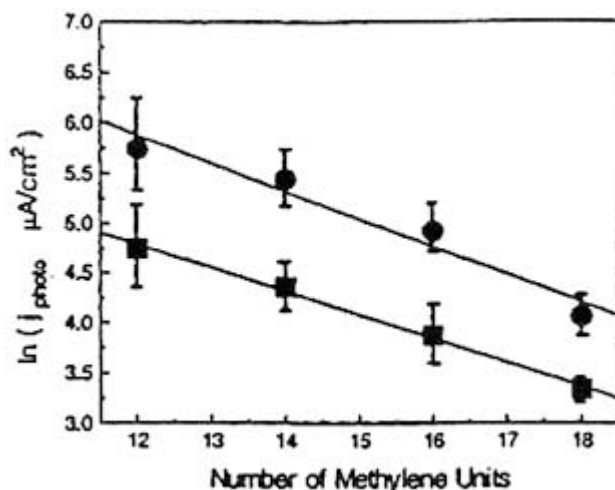

Figure C3.2.4. Plot of the log of photocurrent against number of methyl units in a alkylsilane based monolayer self-assembled on a *n* silicon electrode. The electrode is immersed in a solution with an electron donor. Best fits of experimental data collected at different light intensities: (○) 0.3 mW cm⁻²; (■) 0.05 mW cm⁻². From [10].

C3.2.2 ET THEORY AND EXPERIMENT

This section presents the basic theoretical principles of condensed phase electron transport in chemical and biochemical reactions.

-6-

C3.2.2.1 ADIABATIC ET THEORY

Modern electron transfer theory has its conceptual origins in activated complex theory, and in theories of nonradiative decay. The analysis by Marcus in the 1950s provided quantitative connections between the solvent characteristics and the key parameters controlling the rate of ET. The Marcus theory predicts an adiabatic bimolecular ET rate as

$$k_{\text{ET}} = A \exp\left(\frac{-\Delta G^*}{k_B T}\right) \quad (\text{C3.2.1})$$

where A is a collision frequency and ΔG^* is the free energy of activation for the donor–acceptor ET process when the redox species are in contact. Marcus theory leads to an ‘intersecting parabola model’ which results from the assumption that the distribution of nuclear configurations about the equilibrium is Gaussian in the distortion coordinate. In such a case, one finds that the activation energy is

$$\Delta G^* = \frac{(\Delta G + \lambda)^2}{4\lambda}. \quad (\text{C3.2.2})$$

Here λ is the ‘reorganization energy’ associated with the curvature of the reactant and product free energy wells and their displacement with respect to one another. Assuming a structureless polarizable medium, Marcus computed the solvent or outer-sphere component of the reorganization energy to be

$$\lambda_0 = (\Delta q)^2 \left(\frac{1}{\epsilon_0} - \frac{1}{\epsilon_s} \right) \left(\frac{1}{2a_1} + \frac{1}{2a_2} - \frac{1}{R} \right) \quad (\text{C3.2.3})$$

where Δq is the amount of charge transferred, ϵ_0 is the optical dielectric constant, ϵ_s is the static dielectric constant, a_1 is the donor radius, a_2 is the acceptor radius, and R is the donor–acceptor distance. Note that the outer-sphere reorganization energy is always positive, and grows with donor acceptor separation. For distances much larger than the donor/acceptor species size, the dependence of λ_0 on separation distance is weak. Reorganization energy is larger in polar solvents (compared to nonpolar solvents), where the difference between the optical and static dielectric constant (reciprocals) will be large. Reorganization energies are now computed routinely for much more complex media with contacts between regions with high and low dielectric constants.

C3.2.2.2 NONADIABATIC ET THEORY

In many instances the adiabatic ET rate expression overestimates the rate by a considerable amount. In some circumstances simply forming the the activated state geometry in the encounter complex does not lead to ET. This situation arises when the donor and acceptor groups are very weakly coupled electronically, and the reaction is said to be nonadiabatic. As the geometry of the system fluctuates, the species do not move on the lowest potential energy surface from reactants to products. That is, fluctuations into activated complex geometries can occur millions of times prior to a productive electron transfer event.

-7-

In this weakly coupled regime, ET in an encounter complex can be described approximately using a two-level system model [23]. As such, the time-dependent wave function is

$$\Psi(t) = i\Phi_A \sin\left(\frac{T_{DA}}{\hbar}t\right) + \Phi_D \cos\left(\frac{T_{DA}}{\hbar}t\right) \quad (\text{C3.2.4})$$

where Φ_D represents the donor wave function (acceptor for A) and T_{DA} is the donor–acceptor coupling. This coupling can be enhanced by mixing of the D and A states with each other via intervening bridge orbitals. Note that amplitude localized on donor or acceptor oscillates sinusoidally in time (neglecting relaxation processes) with a frequency determined by the strength of the donor–acceptor coupling, T_{DA} . Fermi’s golden rule of time-dependent perturbation theory can be used to compute the rate of ET based upon the short-time evolution of the system:

$$k_{\text{ET}} = \frac{2\pi}{\hbar} |T_{DA}|^2 \cdot \frac{1}{(4\pi\lambda k_B T)^{1/2}} \cdot \exp\left[-\frac{(\Delta G + \lambda)^2}{4\lambda k_B T}\right]. \quad (\text{C3.2.5})$$

Here we have treated the nuclear degrees of freedom classically as in the Marcus formulation [1].

C3.2.2.3 TUNNELLING BARRIERS

The new challenge that arises in making predictions of nonadiabatic electron transfer rates is to determine the electronic coupling element, T_{DA} . Simple orbital tunnelling analysis predicts that if (a) the donor is delocalized over N_D orbitals and the acceptor is delocalized over N_A orbitals, (b) the average of the donor and acceptor orbital energies are 2 eV removed from the bridging levels (based upon the electronic absorption properties of proteins), (c) the donor–acceptor distance is large (measured edge-to-edge between donor and acceptor in Å), and (d) the donor–acceptor interaction at ‘contact’ is 1 eV:

$$(\text{C3.2.6})$$

$$T_{\text{DA}}(eV) = \frac{1}{\sqrt{(N_A)}} \frac{1}{\sqrt{(N_D)}} (2.7) \exp[-0.72 R_{\text{DA}}] \propto \exp[-(\beta/2) R_{\text{DA}}].$$

This conjecture was made for protein ET systems in particular [24]. It was later found that the exponential decay constant, $\beta/2$, varies strongly as a function of bridging orbital symmetry and donor/acceptor energetics in both proteins and in smaller model compounds [25]. Considerable theoretical and experimental efforts have gone into determining this average decay parameter, and many studies of rigid donor–bridge–acceptor systems were motivated by a desire to address this question.

The distance decay of tunnelling through vacuum is more rapid than the decay for tunnelling through bond. Through space, the ‘barrier’ to tunnelling is essentially the binding energy of the donor/acceptor states. However, in a bridged system this barrier is generally much smaller, determined by the energy gap between the donor/acceptor states, the energies of the bridging orbitals, and the interaction strength among the orbitals. In large complex systems, the strength of this interaction is estimated from the tunnelling pathway model according to the formula [26]

$$T_{\text{DA}} = P \prod_i \prod_j \prod_k \varepsilon_i^{\text{bond}} \varepsilon_j^{\text{space}} \varepsilon_k^{\text{H-bond}} \quad (\text{C3.2.7})$$

where $\varepsilon_i^{\text{bond}} \approx 0.6$, $\varepsilon_j^{\text{space}} \approx 0.6 \exp[-1.7(R_{\text{bond}} - 1.4 \text{ \AA})]$ and $\varepsilon_k^{\text{H-bond}} \approx 0.36$. These factors are chosen in such a way that the ‘pathway product’ of equation (C3.2.7) joining the donor and acceptor sites in a protein or protein-protein complex is a maximum. Because there is a unique decay factor (ε) for each contact defined in a protein x-ray or NMR structure, the ‘strongest’ pathway can be determined by a relatively simple graph-search algorithm. The prefactor P can be chosen as in the square-barrier model described above (equation (C3.2.6)), or can be fitted to the experiment. Figure figure C3.2.5 shows the strongest pathways determined for a family of ruthenium modified cytochromes *c*. Pathway analysis also predicts that the average decay of coupling with distance depends upon protein secondary structure [26]. Ongoing studies utilizing modern quantum chemical methods are ‘summing up’ the large number of pathway contributions to the donor–acceptor coupling in an effort to make predictions of increasing quantitative reliability [27].

Figure C3.2.5. Strongest tunnelling pathways between surface histidines and the iron atom in cytochrome *c*. Steps in pathways are denoted by solid lines (covalent bonds), dashed lines (hydrogen bonds), and through-space contacts (dotted lines). Electron transfer distance to His 72 is 5 Å shorter than in His 66, yet the two rates are approximately

the same. The long-distance through space contact on the dominant pathway of His 72 accounts for this dramatic effect. From Langen R, Chang I J, Germanas J P, Richards J H, Winkler J R and Gray H B 1995 *Science* **268** 1733.

The pathway model makes a number of key predictions, including: (a) a substantial role for hydrogen bond mediation of tunnelling, (b) a difference in mediation characteristics as a function of secondary and tertiary structure, (c) an intrinsically nonexponential decay of rate with distance, and (d) pathway specific 'hot and cold spots' for electron transfer. These predictions have been tested extensively. The most systematic and critical tests are provided with ruthenium-modified proteins, where a synthetic ET active group can be attached to the protein and the rate of ET via a specific medium structure can be probed (figure C3.2.5).

-9-

The predictive power of pathway analysis is well illustrated with two of the Ru-modified systems of Gray and coworkers [29]. Consider, the His 72 and His 39 ruthenium-modified cytochromes *c* [28]. The ET rates in these proteins are about the same, despite the fact that the transfer distance is fully 5 Å shorter in the His 72 derivative. Average square barrier models with $\beta=1.4 \text{ \AA}^{-1}$ (equation (C3.2.6)) would predict the His 72 rate to be 1000 times faster. This equivalency of rates despite the great difference in distances is understood because the strongest pathways in the His 72 derivative contain a through-space tunnelling gap.

A large body of rate data in native and modified proteins was analysed recently in the context of the pathway model. Correcting for differences in activation free energies in different proteins (ΔG^*), rates fall into alpha-helical and beta-sheet 'zones' when plotting ET rate against distance in a wide range of native and modified proteins [29] (figure C3.2.6), consistent with one of the most fundamental predictions of the pathway model [26]. The average decay exponents in the two regions are approximately 1.1 \AA^{-1} (β -sheet) and 1.4 \AA^{-1} (α -helix), consistent with the pathway predictions.

Figure C3.2.6. Zones associated with the distinctive decay of electronic coupling through α -helical against β -sheet structures in proteins. Points shown refer to specific rates in ruthenium-modified proteins and in the photosynthetic reaction centre. From Gray H B and Winkler J R 1996 *Electron transfer in proteins* *Ann. Rev. Biochem.* **65** 537.

In addition to testing predictions of the pathway model in proteins, experiments have also examined the prediction that the decay across a hydrogen bond (from heteroatom to heteroatom) should be about as costly as the decay across two covalent bonds. Indeed, by synthesizing a family of hydrogen bonded and covalently bonded systems with equal bond counts (according to this recipe), it was demonstrated that coupling across hydrogen bonded

contacts is about as favourable as across covalent bonds [30] (figure C3.2.7).

-10-

Figure C3.2.7. A series of electron transfer model compounds with the donor and acceptor moieties linked by (from top to bottom): (a) a hydrogen bond bridge; (b) all sigma-bond bridge; (c) partially unsaturated bridge. Studies with these compounds showed that hydrogen bonds can provide efficient donor–acceptor interactions. From Piotrowiak P 1999 Photoinduced electron transfer in molecular systems: recent developments *Chem. Soc. Rev.* **28** 143–50.

C3.2.2.4 BRIDGE ORBITAL SYMMETRY EFFECTS IN CHEMICAL SYSTEMS

The simplest theoretical orbital-based estimate of the coupling interaction, T_{DA} , is provided by the McConnell relation:

$$T_{\text{DA}} \propto \left[\frac{V}{\Delta E} \right]^N. \quad (\text{C3.2.8})$$

Rewriting T_{DA} as an exponential,

$$\beta = -\frac{1}{\alpha} \ln \left| \frac{V}{\Delta E} \right| \quad (\text{C3.2.9})$$

-11-

where V is the interaction between neighbouring bonds in the bridge, ΔE is the energy gap between the redox active D/A orbitals and the bridge mediating bonds, and a is the distance between the neighbouring bonds. In a system that mediates coupling by more than one set of orbitals, this expression can be generalized. Nevertheless, [equation \(C3.2.9\)](#) provides a rough means of describing the physical aspects of bridge mediation. (figure C3.2.8).

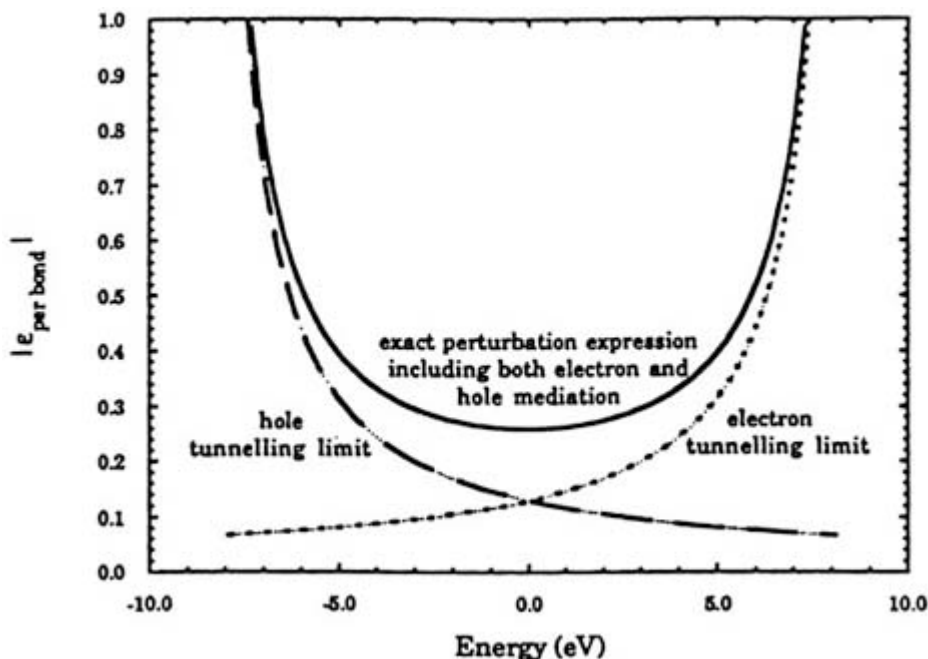

Figure C3.2.8. Dependence of the donor–acceptor coupling decay per bond, $|\epsilon \text{ per bond}|$, upon tunnelling energy. Average exponential decay parameter, β , is related to this decay per parameter by $\beta = (1/R_{\text{unit}}) \ln |\epsilon \text{ per bond}|$ for periodic bridges. R_{unit} is the spacing between repeating units in the bridge. Decay of the coupling with distance is softest ($|\epsilon \text{ per bond}|$ is closest to 1) for tunnelling energies near the frontier orbital energies of the bridge (which lie at -6 and $+7$ eV in this figure). From D N Beratan and J N Onuchic 1991 *Electron Transfer in Inorganic, Organic, and Biological Systems (Advances in Chemistry Series 228)* ed J R Bolton, N Mataga and G McLendon (Washington, DC: ACS Press).

Note that β is large in the limit that V is small comparable to ΔE . However, as the coupling strength increases or as the energy gap drops, β can become smaller. In fact, as the donor/acceptor states approach thermal energies (kT) of the bridge orbital energies, the golden rule ([equation C3.2.5](#)) treatments of the problem are no longer appropriate, and more elaborate models are called for. These models would include the possibility of multistate hopping and would need to consider the time-scales of hopping compared to the time-scales of thermal trapping on the individual sites.

The McConnell relation does not provide quantitative estimates of electronic propagation because (a) it does not include the influence of antibonding orbitals, (b) it neglects ‘through-space’ nonnearest neighbour interactions, and (c) it does not include contributions from multiple interfering coupling pathways.

It is now understood that inclusion of nearest and second-neighbour interactions is adequate for describing tunnelling interactions in many bridged systems [[31](#), [32](#)]. Moreover, tunnelling interactions have been dissected for various

bridge structures. This kind of analysis permits one to understand the nature of constructive and destructive interference interactions that arise in specific bridging species. The central nature of interference can be understood from the decay term $V/\Delta E$ in the McConnell relation. In a one-orbital model V is a negative number (a ‘resonance’ integral in the language of Hückel theory) but ΔE is positive (the D/A states lie at energies above the HOMO of the bridge). These V elements are readily calculated using quantum chemical methods ([figure C3.2.9](#)). As such, as

longer-length pathways are introduced, they will make contributions with sign that oscillates as their contributions drop in magnitude [31].

Figure C3.2.9. Both nearest neighbour and nonnearest neighbour coupling interactions mediate superexchange between the terminal pi-electron groups of rigid dienes with saturated bridging units. From [31].

Inclusion of coupling contributions from both bonding and anti-bonding orbitals give rise to a U-shaped dependence of coupling on D/A energetics (figure C3.2.8).

C3.2.2.5 INNER-SPHERE REORGANIZATION ENERGY

Whether adiabatic or nonadiabatic, it is the case that both solvent and intramolecular degrees of freedom respond to ET events. As such, the two rate expressions given above can be generalized such that

$$\lambda = \lambda_0 + \lambda_i \quad (\text{C3.2.10})$$

where λ_0 is the outer sphere (solvent) contribution to the reorganization energy and λ_i is the intramolecular or inner sphere contribution to the reorganization energy.

-13-

Rate formulations that treat the inner-sphere mode(s) quantum mechanically and the outer sphere modes classically are used rather widely. The rate expression for a single harmonic quantum mode is

$$k_{\text{ET}} = \frac{2\pi}{\hbar} |T_{\text{DA}}|^2 \cdot \frac{1}{(4\pi\lambda k_{\text{B}}T)^{1/2}} \sum \frac{e^{-S} S^n}{n!} \cdot \exp \left[\frac{(\Delta G + \lambda_0 + n\hbar\omega)^2}{4\lambda k_{\text{B}}T} \right] \quad (\text{C3.2.11})$$

where S is the inner sphere reorganization energy divided by the energy of the vibrational quantum ($\hbar\omega$) and the other terms are as defined above. This expression is used for interpreting experimental rate data. The major qualitative effect of the quantum mode is to slow the drop off of the rate in the inverted region (where $-\Delta G > \lambda$ and see section C3.2.2.6). ET rates have been formulated to include the effects of multiple quantum modes, anharmonic

potentials; rates valid beyond the golden rule regime have been established as well [32].

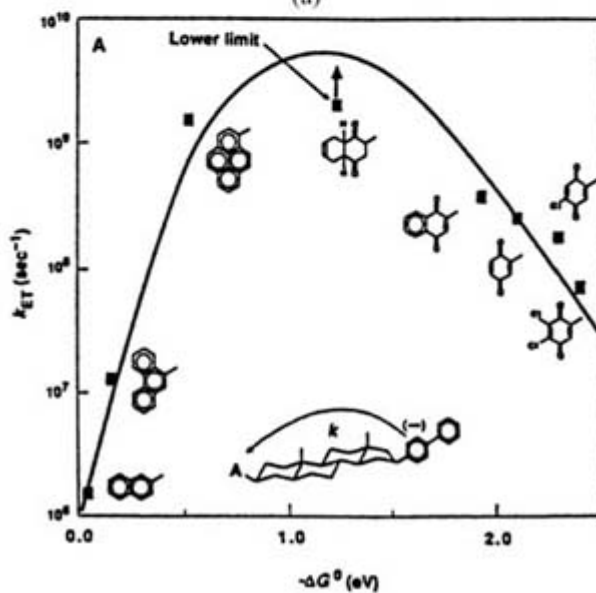

C3.2.2.6 FREE ENERGY – RATE RELATIONS

The form of the classical (equation C3.2.11) or semiclassical (equation C3.2.11) rate equations are ‘energy gap laws’. That is, the equations reflect a free energy dependent rate. In contrast with many physical organic reactivity indices, these rates are predicted to increase as $-\Delta G$ grows, and then to drop when $-\Delta G$ exceeds a critical value. In the classical limit, $\log(k_{\text{ET}})$ has a parabolic dependence on $-\Delta G$. When high-frequency chemical bond vibrations couple to the ET process, the dependence on $-\Delta G$ becomes asymmetrical, as mentioned above.

A tremendous effort was made in the 1980s to test the prediction of an inverted region. Covalently linked donor–acceptor species were constructed in such a way that the energies of the donor and acceptor groups (ionization potential of donor, electron affinity of acceptor) could be changed to vary ΔG (figure C3.2.10). Modelled loosely on photosynthetic ET systems, many of the structures contained porphyrin electron donors and quinone acceptors. Utilizing an essentially rigid chemical bridge removed ambiguity associated with a distribution of distances (and hence of T_{DA} values). Many practical limitations make mapping of the inverted region challenging, but there are now several examples of inverted behaviour for charge separation. Inverted behaviour was recently investigated in charge recombination reactions, that prove particularly amenable to study [33].

(a)

(b)

Figure C3.2.10.(a) Dependence of electron transfer rate upon reaction free energy for ET between biphenyl radical anions and various organic acceptors. Experiments were performed with the donors and acceptors frozen into organic (methyltetrahydrofuran) glasses. Parameters: 10^{-6} s; $\lambda_s=0.4$ eV; $\lambda_v=0.4$ eV; $\omega=1500$ cm^{-1} . From Miller J R 1987 *New J. Chem.* **11** 83. (b) Dependence of electron transfer rate upon reaction free energy for ET between biphenyl radical anions and various organic acceptors attached to each other by a rigid spacer measured methyl tetrahydrofuran solution. Parameters: $\lambda_s=0.75$ eV; $\lambda_v=0.45$ eV; $\omega=1500$ cm^{-1} ; $V=6.2$ cm^{-1} . From Closs G L and Miller J R 1988 Intramolecular electron transfer in organic molecules *Science* **240** 440.

C3.2.2.7 MARCUS CROSS-RELATION

A powerful application of outer-sphere electron transfer theory relates the ET rate between D and A to the rates of self exchange for the individual species. Self-exchange rates correspond to electron transfer in $D/D_{-}(k_{11})$ and $A/A_{+}(k_{22})$. These rates are related through the cross-relation to the D/A electron transfer reaction by the expression

where f_{12} is a value that is often of order unity [34].

The cross relation has proven valuable to estimate ET rates of interest from data that might be more readily available for individual reaction partners. Simple application of the cross-relation is, of course, limited if the electronic coupling interactions associated with the self exchange processes are drastically different from those for the cross reaction. This is a particular concern in protein/protein ET reactions where the coupling may vary drastically as a function of docking geometry.

C3.2.2.8 SOLVENT POLARITY-RATE RELATIONS

Electron transfer reaction rates can depend strongly on the polarity or dielectric properties of the solvent. This is because (a) a polar solvent serves to stabilize both the initial and final states, thus altering the driving force of the ET reaction, and (b) in a reaction coordinate system where the distance between reactants and products (DA and D^+A^-) is one, the strength of the solvent–electron coupling alters the curvature along a solvent nuclear coordinate of the diabatic representations for each electronic state. An incomplete but useful beginning point to understand this coupling is to think of the strength of the total dipolar field that a solvent, by reorganizing its nuclear charges, could project onto the axis of charge separation. It is easy to see that strongly polar solvents, like propylene carbonate or water, will exert a stronger coupling in this way than weakly polar solvents like toluene.

Formally, these effects enter the ET rate expressions by contributing to the reorganization energy, λ_0 , see equation (C3.2.3). The effects may be obtained either from spectroscopic parameters or from *a priori* models. The classical approach to obtaining λ_0 is to use dielectric continuum theory. In the case of two spherical reactants, the result appears in equation (C3.2.3) above. The validity of this approach has been tested often, though perhaps the best known examples are transition metal exchange reactions (figure C3.2.11). More recently, interest has focused on molecular representations of solvation shells and quantum effects on solvation rates that may be obtained from an analysis of the high-frequency solvent motions, particularly in the first solvent shell.

-16-

Figure C3.2.11. Log of the ET rate (Δ) against $(1/\epsilon_{op} - 1/\epsilon_s)$ for the bis(biphenyl) chromium⁺⁰ self-exchange reaction. From [34].

C3.2.2.9 INTERRELATIONSHIPS IN ET THEORY: OPTICAL VERSUS THERMAL ET

One of the most interesting aspects of the basic formulation of thermal electron-transfer theory (as portrayed in

figure [figure C3.2.10](#)) is that it is closely related to the Franck–Condon model for optical electronic transitions. This establishes a strong connection between spectroscopy and kinetics. Optical charge transfer spectra can be used to determine most (and in some cases all) of the required parameters for making rate-constant predictions using thermal electron-transfer theory [35]. λ and T_{DA} can be obtained from spectroscopic properties. This was first outlined in the late 1960s when it was shown that in a symmetric ($\Delta G=0$) system, $E_{op}=\lambda$. When T_{DA} is small and can be neglected, $E_{op}=\lambda+\Delta G_0$, in unsymmetrical systems. The use of the integrated oscillator strength of a charge transfer band to determine T_{DA} was also introduced. Using a Mullikan formalism, Hush showed that the electronic coupling element is related to the intensity of the charge transfer transition by

$$T_{DA} = \frac{(0.0206 \bar{\nu}_{\max} \epsilon_{\max} \Delta \bar{\nu}_{1/2})^{1/2}}{r_{DA}} \quad (\text{C3.2.13})$$

where $\bar{\nu}_{\max}$ and ϵ_{\max} are the frequency of the band maximum and the band width in wavenumbers, and r_{DA} is the donor–acceptor centroid distance in angstroms [36, 37]. This Mullikan–Hush expression has been extensively applied to outer sphere [38] and bridged ET systems [39].

C3.2.2.10 DYNAMICAL SOLVENT CONTROLLED RATES

Chemical changes are not irreversible unless there is some form of dissipation in the system. That is, the reaction free energy must be dispersed to a number of degrees of freedom distinct from the reaction coordinate. Models that include

-17-

dissipation predict that the reaction *mechanism* itself can be switched from adiabatic to nonadiabatic based upon the nature of the solvent relaxation. Solvent that relaxes ‘slowly’ induces multiple recrossings of the activated complex prior to relaxation away from the crossing region. The effect of this is to cause the onset of adiabatic-like behaviour earlier than might be anticipated. The rate expression that spans both dynamical regimes, assuming a Debye solvent with a single relaxation time, is

$$k_{ET} = \frac{k^{NA}}{1 + \kappa} \quad (\text{C3.2.14})$$

where the adiabaticity parameter is $\kappa = 4\pi T_{DA}^2 \tau / \hbar \lambda$, and k^{NA} is the nonadiabatic ET rate.

In Debye solvents, τ is the longitudinal relaxation time. The prediction that solvent polarization dynamics would limit intramolecular electron transfer rates was stated theoretically [40] and observed experimentally [41].

C3.2.2.11 VIBRATIONAL MODE COUPLING TO ET

The Franck–Condon principle reflected in the connection between optical and thermal ET also relates to the participation of high-frequency vibrational degrees of freedom. Charge transfer and resonance Raman intensity bandshape analysis has been used to determine effective vibrational and solvation parameters [42,43].

To make connection between the spectra and the ET process clearer, we note a simple model for the lineshape that includes a classical and a high-frequency degree of freedom. In this case the overall lineshape is

$$F(\nu) \propto \sum_n |\langle 0 | n \rangle| \cdot \exp \left[\frac{(\Delta G_n^0 + \lambda_0 - h\nu_{QM})^2}{4\lambda_0 k_B T} \right] \quad (\text{C3.2.15})$$

where λ_0 is the classical reorganization energy, and λ_1 is the reorganization energy in the quantum nuclear mode of frequency ν_{QM} . The free-energy difference between the charge-separated states then depends on the quantum number of the quantum nuclear mode, ($\Delta G_n^0 = (\Delta G^0 + n\hbar\nu_{QM})$). n is the index for the quantum mode.

This lineshape analysis also implies that electron-transfer rates should be vibrational-state dependent, which has been observed experimentally [44]. Spin-orbit relaxation has also been identified as an important factor in controlling the identity of both electron and vibrational-state distributions in radiationless ET reactions.

C3.2.2.12 COMPETITION BETWEEN INNER SPHERE AND OUTER SPHERE NUCLEAR POLARIZATION DYNAMICS

Early studies showed that the rates of ET are limited by solvation rates for certain barrierless electron transfer reactions. However, more recent studies showed that electron-transfer rates can far exceed the rates of diffusional solvation, which indicate critical roles for intramolecular (high frequency) vibrational mode couplings and inertial solvation. The interplay between inter- and intramolecular degrees of freedom is particularly significant in the Marcus inverted regime [45] (figure C3.2.12).

Figure C3.2.12. Experimentally observed electron transfer time in psec (squares) and theoretical electron transfer times (survival times, Tau a and Tau b) predicted by an extended Sumi-Marcus model. For fast solvents the survival times are a strong function of the characteristic solvent relaxation dynamics. For slower solvents the electron transfer occurs through the motion of intramolecular degrees of freedom. From [45].

C3.2.2.13 ORIENTATION IN INTERMOLECULAR ET

The electrostatic forces that control orientation also influence the D/A overlap and thus tunnelling probability. This balance is known to be manipulated in rather subtle ways in biological ET. In a small molecule system, the relative orientation of electron donor (dimethylaniline) and acceptor (coumarin 337) in a solvent/solute ET reaction was examined [46]. Figure figure C3.2.13 shows the time-dependent response that is measured at 500 nm after 400 nm electronic excitation of the coumarin. At early times, the transition moment probed at 500 nm belongs to coumarin. At later times after electron transfer from the dimethylaniline to the coumarin, the probed transition moment belongs to the dimethylaniline radical cation. The naïve expectation might be that the solvent molecules most stably oriented relative to the solute would preferentially undergo ET. In fact, it was found that the electron transfer occurred when the permanent dipole moments of the donor and acceptor were perpendicular, not antiparallel.

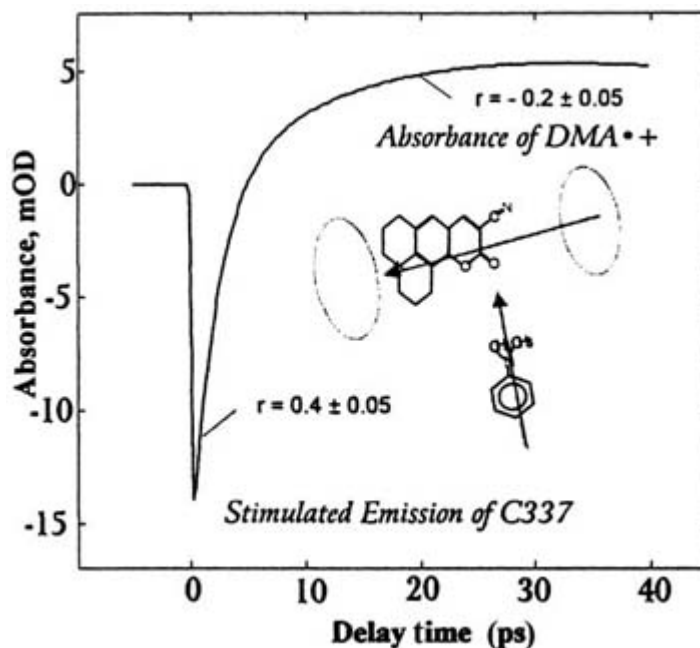

Figure C3.2.13. Orientation in a photoinitiated electron transfer from dimethylaniline (DMA) solvent to a coumarin solute (C337). Change in anisotropy, r , reveals change in angle between the pumped and probed electronic transition moments. From [46].

C3.2.2.14 ET IN PHOTOSYNTHETIC REACTION CENTRES

Electron transfer occurs in many steps in photosynthesis. Recently, considerable attention has been paid to the initial steps of charge separation. These initial steps occur in the picosecond time domain. A remarkable fact is that the photosynthetic reaction centre is highly symmetrical, with near C_2 symmetry in the cofactors but electron transfer occurs down only one path. It is believed that a slight asymmetry in the protein dielectric environment contributes to electron preference for one branch. Just how strongly the electron interacts with all of the nearby cofactors has also been an issue of interest; some argue that the electron passes along a transport chain, with identifiable populations at each cofactor, while others have argued that some cofactors participate only as superexchange mediators. Because the initial electron transfer processes are very fast (<3.5 ps in *Rhodobacter spheroides*) in photosynthetic reactions, these centres have also provided a testbed for analysing the role of nonequilibrium vibrations and their possible coherent coupling to electron transfer. Such coherences have been examined in smaller molecular systems [47, 48, 49 and 50] as well.

C3.2.2.15 LASER-FIELD DRIVEN ET COHERENCES

Calculations within the framework of a reaction coordinate degrees of freedom coupled to a bath of oscillators (solvent) suggest that coherent oscillations in the electronic-state populations of an electron-transfer reaction in a polar solvent can be induced by subjecting the system to a sequence of monochromatic laser pulses on the picosecond time scale. The ability to tailor electron transfer by such light fields is an ongoing area of interest [51] (figure C3.2.14).

Figure C3.2.14. Electron population difference $x(t) = P_d(t) - P_a(t)$ for three electron transfer reactions in the presence of a pulsed laser field. Frequency of the field is tuned to solvent reorganization energy $\lambda = 1$ eV and the field strength is such that coupling potential (charge transfer dipole moment times the field strength) is twice the laser field frequency. (a) Activationless reaction, $\Delta G^0 = \lambda$, (b) reaction with $\Delta G^0 = \lambda/2$, and (c) symmetric electron transfer with no bias. From [51].

C3.2.3 APPLICATIONS IN COMPLEX SYSTEMS

This section describes the application of the theoretical principles described above to specific structures and processes of current interest in electron transfer research.

C3.2.3.1 DNA ELECTRON TRANSFER

Over the last decade attention has turned to the nature of electron transport in DNA [52]. Although DNA electron transfer has been of interest for a much longer time, new methodologies for attaching redox active donors and acceptors at defined positions in complex macromolecules has driven a resurgence of interest. One of the principle issues in this field concerns the mechanism of charge transfer, that is, whether the reactions proceed by long-range (single-step) tunnelling or multistep hopping. These mechanisms are summarized in figure figure C3.2.15.

-21-

Figure C3.2.15. Schematic diagram showing (A) electron hopping between electron reservoirs *via* empty states of an intervening bridge, (B) tunnelling, and (C) hole hopping *via* filled states of an intervening bridge. From

Bockrath M, Cobden D H, McEuen P L, Chopra N G, Zettl A, Thess A and Smalley R E 1997 Single-electron transport in ropes of nanotubes *Science* **275** 1922–5.

β values reported for DNA electron transfer vary from 0.2 to 1.5 \AA^{-1} . Assuming that the reactions proceed by single-step tunnelling (see equation C3.2.5), explanations of the physical origin for this wide range of values include: (a) the stacking interactions (V of equation (C3.2.8)) might be highly variable because of variations in the nature of stacking or (b) changes in the energy denominator by changes in the average energetics of the redox active donor and acceptor orbitals. An alternative explanation for small apparent β values is that the process proceeds by multistep hopping (figure C3.2.15), where many very rapid short distance steps lead to a weak apparent distance dependence. Indeed, recent experiments involving oxidation of guanine, most likely fall in the regime of either tunnelling or multistate hopping, depending upon the details of the way in which the system is constructed.

Although the challenge of determining the distance dependence of ET in DNA seems academic, it is of considerably wider interest. There are now a number of companies developing medical diagnostic devices based upon changes in ET rates or electrode currents upon recognition and binding of single-stranded DNA. The sensitivity of these devices will depend upon how ET rates change upon oligomer binding, nature of base pair mismatches, and the solvation environment upon recognition.

C3.2.3.2 STM AND SINGLE MOLECULE CONDUCTIVITY

The invention of the scanning tunnelling microscope in the 1980s opened up new directions for electron transfer chemistry. The STM is discussed in detail in section B1.20 of this encyclopedia. Measurements of tunnelling current propagating through empty space and through various adsorbates provide a relatively direct probe of tunnelling propagation. Measurement of the current as a function of adsorbate layer thickness probes the decay parameter β directly (figure C3.2.16)). Single molecule bridged STM studies have mirrored results seen in solution chemistry: as the effective energy barrier is decreased and as the effective interaction between bridging units increases, β drops in size.

-22-

Figure C3.2.16. Dependence of measured resistance in an STM junction consisting of a ‘bare tip’ a tip with one Xe atom attached, and a tip with two Xe atoms. Note that the Xe atoms facilitate tunnelling (compared to empty space). From Yazdani A, Eigler D M and Lang N D 1996 Off resonance conduction through atomic wires *Science* **272** 1921–4.

An expression for the current across a molecular junction is developed by analogy with the description of unimolecular solution phase electron transfer. The conduction is written [20]

$$j = \frac{2\pi e}{\hbar} \sum_{i,f} f(E_i)[1 - f(E_f)]|T_{fi}|^2 \delta(E_i - E_f) \quad (\text{C3.2.16})$$

where f represents the fermi function and the sum is taken over states of the source electrode (i) and receiving electrode (f). When there are no molecular eigenstates of the molecule in the energy regime between the highest filled source electrode energy and lowest empty acceptor electrode, the conduction is limited by the tunnelling characteristics of the molecule. However, if eigenstates of the bridge fall in this gap, transport can involve a multistep hopping process. Indeed, as the voltage is varied and multiple eigenstates enter the gap, a molecular eigenstate staircase is seen in the current-applied voltage curves. Eigenstate staircases have been observed in carbon nanotube structures as well as in ‘break junctions’ bridged by molecules [21].

C3.2.4 FUTURE DIRECTIONS

We have surveyed the remarkable progress in the field of ET reactions, and have examined some of the key applications and successes of the theory. Many of the current frontiers of ET research lie in biological systems and in molecular-scale electronic devices.

C3.2.4.1 ENERGY FLOW INTO ET PROCESSES

The nitrogenase system reduces hundreds of millions of kilograms of nitrogen gas to ammonia each year, catalysing the reaction at ambient temperatures and atmospheric pressure. Nitrogenase consists of two proteins that contain

iron–sulfur and molybdenum–iron–sulfur clusters. Each (interprotein) electron transfer reaction is driven by the hydrolysis of two ATP molecules. The energy released as a consequence of ATP hydrolysis is about one-third of an electronvolt. A total of eight electrons must be delivered to the Mo–Fe protein to complete the catalytic cycle. It appears that the ATP consumed by nitrogenase drives substantial conformational changes that lead to protein–protein docking, an increase in ET driving force, and (following ET) protein–protein dissociation [53, 54]. Thus, ATP overcomes kinetic barriers to ET. This serves as an example of energy transduction from a storage species (ATP) to an ET process. The molecular mechanism of this process is the subject of great current interest. Equally challenging is to understand the way in which ET leads to transmembrane proton gradients, and how these gradients then drive the synthesis of ATP [3, 55] (figure C3.2.17)).

Figure C3.2.17. Diagram of a liposome-based artificial photosynthetic membrane showing the photocycle that pumps protons into the interior of the liposome and the CF_0F_1 -ATP synthase enzyme. From [55].

C3.2.4.2 PATHWAY FUNCTION

It is fairly clear that most biological electron transfer reactions fall in the weakly coupled regime (with a possible exception being the primary charge separation event in bacterial photosynthesis). However, there remains considerable debate concerning the functional significance of tunnelling pathways and of protein secondary and tertiary structure on the control of biological ET rates. The average decay constant for tunnelling through α -helix is predicted to be larger (rates drop more rapidly with distance) than for β -sheet structures. It was recently argued that this secondary structure effect is exploited to slow the rate of charge recombination in the photosynthetic reaction centre which is dominantly helical [56]. In contrast, the structure of cytochrome *c* oxidase appears to have direct beta strand-like pathways linking the redox centres to the oxygen reduction site. Since ET in this protein is thermal rather than

photochemical, and the reactions are exergonic, charge transfer recombination is not a competing reaction pathway.

With the emergence of increasingly high-resolution structural data for complex proteins, the influence of specific tunnelling pathways on protein function will be subjected to greater scrutiny. A particularly intriguing potential effect appears in the protein system that comprises the nitrogenase nitrogen fixing protein. When the two proteins dock to exchange electrons, it appears that there is a substantial structure change that ‘wires’ a tunnelling pathway. Following ET, the direct pathway is broken, electronically disconnecting the two redox centres. Since the protein dissociation reaction is particularly slow and the driving force of the reaction is not large, this disconnection could prove functionally important for localizing the electron at the proper site in the enzyme. Protein dynamics causes donor/acceptor interactions mediated by the protein to fluctuate. If fluctuations are sufficiently rapid, the root mean square coupling value should control the observed ET rate. A considerable open challenge is to understand what kinds of protein folds might have coupling interactions that are particularly sensitive to thermal fluctuations [57].

C3.2.4.3 INTERPRETING THE QUANTUM NATURE OF PROTEINS: REDUCED HAMILTONIANS AND CURRENT LOOPS

The complexity of protein structure motivates the development of new strategies for ‘information reduction’. One approach has been to devise hot and cold spot maps at the pathway level [26]. Other Hamiltonian based strategies have built ‘reduced’ Hamiltonians comprised of a subset of effective interactions that represent the interactions characteristics of the bridge [23] (figure C3.2.18). Density matrix approaches follow propagation of electron current density in two-level systems using equation C3.2.4, rather than tracking the wave function propagation. That is, the time domain rather than the energy domain quantum picture is analysed. Whereas electron amplitude decay and oscillation are seen in the wave function amplitude picture, vortices—closely associated with the nodal structure of the decaying wave function—appear in the current density maps [58].

-25-

Figure C3.2.19. In this ESDIAD experiment where H^+ ions are produced and collected (see text), an adsorbed acetate species is excited by an incoming electron. H^+ ions are emitted in the direction of the C–H bond in the upward pointing $-CH_3$ group in the species. Circular symmetry of figure indicates that C–H bonds are spinning around the vertical axis in the acetate species. From Lee J G, Ahner J, Mocutt D, Denev S and Jates J T Jr 2000 *J. Chem. Phys.* **112** 335.

Not all processes that involve charge redistribution move charge between spatially well-localized regions. Electron scattering events fall into this regime and lie at the boundaries of the topics that we have discussed. Electron scattering processes are often used to practical advantage to probe the structure and dynamics of chemisorbed molecules, for example. One of these, ESDIAD (electron stimulated desorption ion angular distribution), invented in 1974 [59], may be used to observe the bond directions in chemisorbed species. This method uses electrons to ionize adsorbed molecules, making either positive or negative fragment ions. The ions escape from the molecule in directions closely similar to those of the chemical bonds that are being ruptured by the excitation event. By measuring the emission directions of the ion fragments, the characteristics of the ruptured chemical bond can be observed. In figure figure C3.2.19, an adsorbed acetate species is excited by an incoming electron [60]. H^+ ions are emitted in the direction of the C–H bond in the upward pointing $-CH_3$ group in the species. In the example shown here, millions of individual acetate species have been ionized, and the statistical distribution of the H^+ emission directions is shown by the volcano-shaped figure at the top. The circular symmetry of the figure indicates that the C–H bonds are spinning around the vertical axis in the acetate species, so that an almost equal probability of H^+ emission exists in all azimuthal directions. If the surface is cooled to very low temperatures, the rotation of the $-CH_3$ group ceases, and a multibeam H^+ pattern is observed. Measuring the temperature dependence of the beam pattern broadening into the volcano pattern allows one to measure the energy required to make the $-CH_3$ group spin. Such information is of importance in many technologies dependent upon molecular motions on surfaces, such as semiconductor device fabrication, corrosion inhibition, and heterogeneous catalysis.

C3.3 Energy transfer in gases

George W Flynn

C3.3.1 INTRODUCTION

Almost all aspects of the field of chemistry involve the flow of energy either within or between molecules. Indeed, the occurrence of a chemical reaction between two species implies the availability of some minimum amount of energy in the reacting system. The study of energy transfer processes is thus a topic of fundamental importance in chemistry. Energy transfer in gases is of particular interest partly because very sophisticated methods have been developed to study such events and partly because gas phase processes lend themselves to very complete and detailed theoretical analysis.

In the gas phase molecules are generally separated by distances large compared to their diameters, and energy exchange between two different molecules occurs only when they collide, much like billiard balls on a pool table, or two trucks in a road accident such as that depicted in [figure C3.3.1](#). Nevertheless, despite these large separations, gas molecules collide at a very high rate. The formula for the collision rate, z , of a single molecule is [1]

$$z = \pi \sigma^2 \langle u \rangle n$$

where σ is the molecular diameter, $\langle u \rangle$ the mean speed and n the density of molecules. To get some feeling for the size of z , try to imagine a single nitrogen molecule in the atmosphere right in front of your nose. If you blink your eye, that molecule undergoes more than a billion collisions in the time it takes for your eye to open and close! Modern techniques for the study of such processes generally focus on single collision events. This would require a time resolution of better than a billionth of a second to investigate a nitrogen molecule in the atmosphere. Fortunately, for gases, the density n can be easily controlled thereby reducing z substantially. For the collisional energy transfer processes described in this chapter, pressures of 10^{-5} atmospheres are typically used, thereby

reducing the mean time between collisions to an experimentally manageable time scale of a few hundred thousandths of a second.

While collisions between atoms are very simple, since only translational motion is of importance, collisions between molecules are more complicated because of the internal degrees of freedom. For example, in a relatively simple collision between an argon atom and a linear CO₂ molecule, the atom has three translational degrees of freedom while the molecule has three translational, two rotational and four vibrational degrees of freedom. In principle, energy exchange among all of these degrees of freedom must be accounted for in any complete description of such a collision. Loss or gain of vibrational energy in molecular collisions is of special interest in chemistry because all reactions ultimately involve the breaking and making of chemical bonds, a process that is accelerated by putting energy into the vibrational degrees of freedom of a molecule.

-2-

Figure C3.3.1 A collision between a milk truck and a bread truck showing the well ordered truck contents at the top, the ‘scattering event’ in the middle and the post crash scrambling of the truck contents at the bottom.

C3.3.1.1 UNIMOLECULAR REACTIONS AND ENERGY TRANSFER

Of particular importance is loss of energy from molecules with ‘chemically significant’ amounts of vibrational energy. These are systems in which the molecule has sufficient energy to rupture a chemical bond. Chemical reactions of such highly vibrationally excited molecules, which normally take place on the ground electronic state potential energy surface, are often described by the Lindemann unimolecular reaction mechanism in which a substrate, S, is excited by collisions to S*, a level with energy sufficient to cause bond breaking or molecular rearrangement [2, 3 and 4]. S* is thus said to have a ‘chemically significant’ amount of energy. For large molecules, the time scale for decomposition of S* is sufficiently long that further collisions with the bath molecules can cause deactivation of the excited substrate, thus quenching the reaction process. The overall mechanism can be summarized by the equations

where B is a generalized representation for a bath molecule and P is the product, chemically distinct from S. Once the

-3-

molecule is excited in step (C3.3.1), the rate of production of product is a competition between unimolecular breakup of S* in step (C3.3.2) and quenching in step (C3.3.3). The importance of vibrational energy loss in step (C3.3.3) is therefore paramount in determining the overall efficiency with which S is converted to product via this mechanism. It would be difficult to exaggerate the importance of this quenching step, since an enormous number of thermal chemical reactions proceed via this mechanism or some variant of it.

One of the complexities that arises in studying the vibrational energy loss from highly excited molecules is the very, very large number of vibrational states (e.g. 10^{15} vibrational states per cm^{-1}) in molecules of even moderate size at chemically significant energies (100–400 kJ mol^{-1}). Because of this, directly probing the vibrational states of S*, with even the highest resolution laser devices, is essentially impossible. Nevertheless, such collisions can be monitored in great detail by using a simple trick provided that the bath molecule B is relatively small. This trick amounts to realizing that the collision of S* with B can be viewed through the ‘eyes’ of the bath molecule B [5, 6]. When B is a small molecule with well resolved and assigned vibrational and rotational spectroscopic transitions, more information about the quenching process (C3.3.3) can be obtained from probing the bath B than from probing the donor S*. If we return for a moment to the collision between the bread truck and the milk truck of figure C3.3.1 a typical approach for the police to use in reconstructing such an accident is to take pictures of the post-collision scene to establish the speed and position of the two trucks before the initial ‘scattering event’ occurred. The more detail available in the post-collision picture, the better the chance of accurately reconstructing the collision event. In principle, the condition and position of either truck is sufficient to establish most of the details of the collision.

C3.3.2 EXPERIMENTAL APPROACH

C3.3.2.1 GENERAL SCHEME

Experiments of the type described above rely on the availability of both high resolution and very intense laser sources throughout the ultraviolet, visible and infrared spectral ranges [7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17 and 18]. Figure C3.3.2 shows an energy level diagram and excitation scheme for a typical molecule. A short pulse of ultraviolet light from a laser excites a medium size molecule such as benzene or hexafluorobenzene to its first electronically excited singlet state,

The natural processes of intersystem crossing and internal conversion will quickly (e.g. 50 ns) carry the molecule from this excited electronic surface to the ground electronic surface *without a collision*,

The result is the preparation of molecules with a well defined energy E that is essentially pure vibrational energy in S_0 , the ground electronic state. (Laser excitation adds only $h/2\pi$ to the total angular momentum of the molecule and produces no increase in the translational energy.) This highly excited molecule S_0^* of energy E is our donor with chemically significant amounts of vibrational energy. Preparation of donor species in this way provides molecules

with

-4-

very well characterized energy and sets the origin of time at the laser pulse so that subsequent collisions can be studied if they occur on a time scale long compared to the laser pulse width and the molecular internal-conversion/intersystem-crossing time. Typical laser pulse widths are 10–30 ns while collision times can be controlled with pressure to take place on a time scale of several microseconds. (At a pressure of 20 mTorr, the mean time between collisions is about 4 μ s.)

Figure C3.3.2. A simple diagram showing a clean method for preparing molecules with a specific and large amount of vibrational energy $E_{vib} = 5 \text{ eV}$ (roughly 460 kJ mol^{-1}). A pulse from an excimer laser excites an allowed ($S_0 \rightarrow S_1$) electronic transition in the molecule. Intersystem crossing and internal conversion, occurring collision-free in the molecule, carry it onto the ground electronic surface. Collisions of the hot donor molecule, S^* , with bath molecules, B , depicted by the equation at the bottom of the figure, cause the molecule to lose energy with a probability $P(E, E')$, where $\Delta E = E' - E$.

Once prepared in S^*_0 with well defined energy E , donor molecules will begin to collide with bath molecules B at a rate determined by the bath-gas pressure. A typical process of this type is the collision between a C_6F_6 molecule with approximately 5 eV ($40\,000 \text{ cm}^{-1}$ or 460 kJ mol^{-1}) of internal vibrational energy and a CO_2 molecule in its ground vibrationless state 00^0_0 to produce CO_2 in the first asymmetric stretch vibrational level 00^0_1 [11, 12 and 13]. This collision results in the loss of approximately $\Delta E = 2349 \text{ cm}^{-1}$ of internal energy from the C_6F_6 ,

J and V represent the rotational angular momentum quantum number and the velocity of the CO_2 , respectively. The hot, excited C_6F_6 donor can be produced via absorption of a 248 nm excimer-laser pulse followed by rapid internal conversion of electronic energy to vibrational energy as described above. Note that the result of this collision is to produce one quantum of vibrational energy in the CO_2 00^0_1 state with a corresponding loss of the same amount of energy from the internal vibrational degrees of freedom of the donor.

Actually, collisions in which the bath becomes vibrationally excited are relatively rare, occurring with a typical probability of 1% per gas-kinetic collision [6, 8, 11 and 13]. More common are processes that produce rotational and translational excitation in the bath acceptor while leaving the molecule in its ground (vibrationless) 00^0_0 state,

-5-

Here the energy loss $\Delta E = E' - E$ from the donor shows up as translational energy through a change in the bath molecule velocity (V' going to V) and as rotational energy through a change in the rotational-angular-momentum quantum number (J' going to J).

C3.3.2.2 INFRARED DIODE LASER PROBING

To ‘view’ these collisions through the eyes of the bath acceptor molecule, we need only to probe the $\text{CO}_2(00^00; J, V)$ molecules exiting the collision. Much like the police visiting the post-collision-accident scene ([figure C3.3.1](#)) we ‘take a picture’ of the $\text{CO}_2(00^00; J, V)$ with a high resolution camera. Our camera is an infrared laser with sufficient resolution to identify all of the quantum numbers for molecular vibration of CO_2 , the rotational angular momentum quantum number J and the recoil velocity V . This probe, or picture-taking, step can be represented by the equation

where light from a narrow-band-infrared-diode laser (linewidth of 0.0003 cm^{-1}) operating at a wavelength of approximately $4.3\ \mu\text{m}$ is used to sense the arrival of molecules in the $00^00; J$ state by observing or probing the fully allowed infrared transition, $00^00; J \rightarrow 00^01; J \pm 1$, in CO_2 . Such is the resolution of these laser devices that essentially any state of the CO_2 bath molecule produced in the collision process can be probed and the population of each quantum state measured.

Even more remarkable is the fact that these infrared diode lasers have sufficient resolution to measure the Doppler lineshape for the $00^00; J \rightarrow 00^01; J \pm 1$ transition of the recoiling molecules, hence providing a probe of the CO_2 molecular recoil velocity, V . The absorption frequency for a molecule moving with a component of velocity V_z parallel to the direction of propagation of the infrared laser beam is $\nu = \nu_0(1 \pm V_z/c)$, where ν_0 is the absorption frequency for the molecule at rest and c is the speed of light. The \pm sign determines whether the molecule is travelling in the same or opposite direction as the light beam. For an isotropic distribution of molecules whose translational motion is at equilibrium at a temperature T , there is a range of V_z given by the Boltzmann distribution. The corresponding spread of absorption frequencies arising from this velocity distribution gives rise to an inhomogeneously broadened spectral line shape that can be described by a Gaussian function whose full width at half height is given by [19]

$$\Delta\nu = 2(3.581 \times 10^{-7})\nu_0(T/M)^{1/2}$$

where M is the molecular weight of the molecule, ν_0 the absorption frequency for a molecule at rest and T the absolute temperature. [Figure C3.3.3](#) shows the relative Doppler lineshapes for a CO_2 molecule at a temperature of 300 K corresponding to a moderate velocity spread along the laser probe direction, and 3000 K corresponding to a rather large velocity spread along the laser probe direction. Also shown for comparison is the laser line width that is much narrower than even the 300 K Doppler line shape for room-temperature CO_2 . For an experiment conducted at room temperature, bath molecules start with a 300 K Doppler lineshape corresponding to a Boltzmann velocity distribution at this temperature, but collisions with hot donors produce recoiling bath molecules that have velocities comparable to those typical for temperatures in the 1500–4000 K range. [Figure C3.3.3](#) indicates that such linewidths can easily be measured with modern, commercially available, high-resolution infrared lasers. While there is no *a priori* reason to

expect that molecules scattered by collisional energy transfer will have an isotropic Boltzmann distribution of velocities, experiments performed under simple gas-bulb conditions with molecules initially thermalized at

temperatures in the 200–400 K range have so far found that the spectral absorption lineshapes for recoiling molecules in these studies are Gaussian within experimental error and, therefore, can be characterized by a temperature T [5, 9, 12, 16].

Figure C3.3.3. A schematic drawing of the Doppler-lineshape profile for a typical infrared transition in a small molecule at $T = 300$ K and $T = 3000$ K. The width of the absorption profile scales as $T^{1/2}$ reflecting the thermal spread and isotropic distribution of molecular velocities. Such profiles are easily measured using a high-resolution infrared diode laser whose typical line profile, having a width of 0.0003 cm^{-1} , is also shown in the figure.

C3.3.2.3 EXPERIMENTAL APPARATUS

Figure C3.3.4 shows a schematic diagram of an apparatus that can be used to study collisions of the type described above [5, 9, 12, 16]. Donor molecules in a 3 m long collision cell (a cylindrical tube) are excited along the axis of the cell by a short-pulse excimer laser (typically 25 ns pulse width operating at 248 nm), and bath molecules are probed along this same axis by an infrared diode laser (wavelength in the mid-infrared with continuous light-output power of $100\text{ }\mu\text{W}$ in a bandwidth of 0.0003 cm^{-1}). The pump and probe beams are joined in front of the collision cell with a dichroic beamsplitter coated to reflect the ultraviolet laser light and pass the infrared laser light. The beams propagate collinearly along the cell axis. At the end of the cell the ultraviolet beam is discarded and the infrared beam passes through a monochromator to select the appropriate diode laser mode. About 10% of the infrared laser light is split from the main beam and sent through a reference cell, a scanning etalon, and a monochromator. This fraction of the light beam is detected with an InSb infrared detector and fed to a lock-in amplifier. The output of the lock-in amplifier can be used as an error signal and fed back to the diode-laser-control electronics to lock the diode either to a specific spectral reference line or to an etalon fringe. This reference loop is used to identify the exact frequency of the diode laser and to sweep the laser over small ranges (for Doppler profile measurements) by scanning the frequency of the etalon to which the laser can be locked. The reference cell also has electrodes for exciting a discharge in the reference gas in cases where the frequencies of interest originate in vibrational levels not populated at the ambient temperature of the cell.

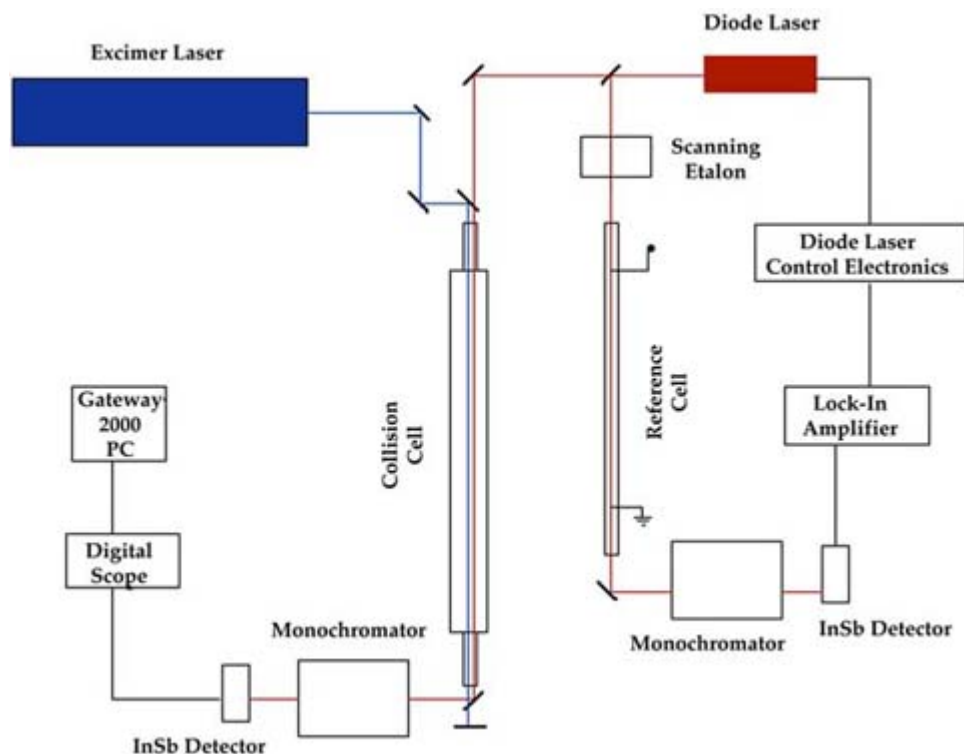

Figure C3.3.4. A schematic diagram of an apparatus described in the text for studying vibrational energy transfer to small bath molecules from donor molecules having chemically significant amounts of internal vibrational energy.

The infrared light passing through the collision cell impinges on a second InSb-solid-state detector (cooled to 77 K) producing both DC and AC signals at the detector output. Since most of the IR light is not absorbed by the sample, the DC signal that measures the continuous output level of laser light is much larger than the AC signal. It is in fact fluctuations in the DC light level that constitute one of the main noise sources in the experiment. Both AC and DC signals are fed to a high-speed transient recorder with at least two channels where the time-resolved ratio of the AC and DC currents is recorded and stored in memory. Single-collision data are obtained from this time-dependent absorption data. Signals from a series of ultraviolet laser pulses can be added in memory with subsequent signal averaging and noise reduction. The ratio of the AC and DC infrared light levels, $\Delta I/I$, is related to the pressure of absorbing molecules, P , the molecular absorption coefficient, α and the cell path length, L :

$$\ln[(\Delta I/I) + 1] = \alpha PL.$$

The path length is set by the experimental configuration while α is known for each transition (such as $00^0_0: J \rightarrow 00^0_1, J \pm 1$ or $00^0_1; J \rightarrow 00^0_2, J \pm 1$). Thus, a measurement of $\Delta I/I$ provides the partial pressure P of molecules produced in probed states such as $00^0_0; J$ or $00^0_1; J$. (Strictly, optical probing measures the *difference* in the partial pressures between the upper and lower states of the probed transition; however, in practice, the lower state population is always much larger than the upper state population so that the probe senses only the lower state population in the experiment.)

C3.3.3 DATA ANALYSIS

C3.3.3.1 KINETIC PROCESSES

As a first step in understanding the analysis of energy transfer experiments, it is worthwhile to summarize the steps in a typical experiment where C_6F_6 is the hot donor and carbon dioxide is the bath receptor molecule. First, excited C_6F_6 molecules ($C_6F_6^{(E)}$) are produced at energy $E = 41\,822\text{ cm}^{-1}$ by an excimer laser pulse (25 ns),

The C_6F_6 electronic state excited in this energy region rapidly interconverts (collision-free), on a time scale of less than 30 ns, to high vibrational energy levels of the electronic ground state. Collisions of this hot donor with CO_2 ‘inert’ bath gas then cause translational, rotational and vibrational excitation of the ν_3 stretching (00^01 ; 2349 cm^{-1}) vibrational state, as well as rotational and translational excitation in the ground vibrationless (00^00) level,

A tunable diode laser operating at $4.3\text{ }\mu\text{m}$ is used to probe the P and/or R branch bands of the following transitions,

Velocity recoils are measured at short times after the initial ultraviolet excitation pulse by probing the ‘nascent’ Doppler profiles for the different spectral lines probed in these last steps.

C3.3.3.2 INITIAL RATES TECHNIQUE

Using the above equations, the rate equation for production of bath molecules in a given quantum state due to collisions with a hot donor molecule can be written (e.g. for equation (c3.3.5))

$$d[CO_2(00^01, J, V)]/dt = k_r[C_6F_6^{(E)}][CO_2(00^00)]$$

where k_r is the rate constant for production of $CO_2(00^01, J, V)$ from collisions between $C_6F_6^{(E)}$ molecules excited to an energy E and initially unexcited $CO_2(00^00)$ bath molecules. For times t after the excimer laser excitation pulse that are short compared to the mean collision time in the gas, this equation can be solved to a good degree of approximation by using the initial rate technique with

$$[CO_2(00^01, J, V)] = k_r[C_6F_6^{(E)}]_0[CO_2(00^00)]t.$$

Here $[C_6F_6^{(E)}]_0$ is the initial concentration of excited donor molecules produced at time $t = 0$ by the excimer laser pulse, and $[CO_2(00^00)]$ is the concentration of bath molecules that, for all practical purposes, can be assumed constant. The infrared diode laser probe provides an experimental value for $[CO_2(00^01, J, V)]$, while the number of absorbed excimer laser photons provides a measure of $[C_6F_6^{(E)}]_0$. $[CO_2(00^00)]$ is known from the partial pressure of the bath gas in the cell and the time t is easily determined from the transient recorder time base, leaving only k_r to be determined from these experimentally measured parameters. Experiments of this kind provide three important pieces of data: (1) the distribution of populations in the final bath vibration/rotation state ($00^01, J, V$); (2) the distribution of recoil velocities, V , from a measure of the Doppler lineshape for the carbon dioxide spectral transition ($00^01, J, V) + h\nu(4.3\text{ }\mu\text{m}) \rightarrow (00^02, J \pm 1, V)$ and (3) the rate constant, k_r , or probability that a collision produces a CO_2 molecule with a given final J and V in the 00^01 vibrational state.

The initially excited C_6F_6 molecules can produce de-excited species, such as $C_6F_6(E')$, that are also able to excite CO_2 via collisions. This fact emphasizes the importance of choosing t short enough that a given bath molecule has time for only a single collision with an excited donor and does not collide a second time with either another hot donor or a bath molecule. Collisions with other bath molecules tend to relax the ‘nascent’ population and velocity distributions formed initially by collisions with the hot donor, while second collisions with excited donors produce ‘doubly’ excited bath molecules. In contrast, rotational and vibrational-state-population distributions, velocity distributions and k_T values measured at a time t after the excimer laser pulse corresponding to 0.1–0.25 of a gas kinetic collision provide data specific to a collision of a hot donor of energy E with a cold bath molecule. Thus, in experiments of this type, it is possible to correlate the donor energy, its vibrational density of states and other molecular properties with excitation probabilities, population distributions and the kinetic energy distributions of the scattered bath species.

C3.3.4 DEDUCING ENERGY TRANSFER MECHANISMS FROM POPULATION AND VELOCITY DISTRIBUTIONS OF THE SCATTERED BATH MOLECULES’ ROTATIONAL STATE POPULATION DISTRIBUTIONS FOR VIBRATIONAL EXCITATION OF THE BATH

Figure C3.3.5 shows typical data obtained from experimental studies of the type described above, where the hot donor is the nitrogen heterocycle pyrazine, $C_4H_4N_2$, initially excited by an excimer laser to an energy of $40\,640\text{ cm}^{-1}$. Here the process probed is excitation of a vibrationally-excited bath state where all three degrees of freedom of the bath—vibration, rotation, and translation—can become excited. In this particular case the vibrational state excited by collision is the first asymmetric stretch level of CO_2 , 00^0_1 that has 2349 cm^{-1} of vibrational energy, roughly ten times the mean thermal energy in these experiments ($kT = 208\text{ cm}^{-1}$, where k is Boltzmann’s constant). Shown in the upper half of the figure is a ‘Boltzmann plot’ of the natural log of the measured rotational state populations for just the 00^0_1 level, divided by their degeneracy, $2J + 1$, versus $J(J + 1)$ that is proportional to the molecular rotational energy. The slope of such plots ($-1/kT_R$) gives the temperature (T_R) describing the rotational state distribution for a system at equilibrium at temperature T_R [6, 9, 10 and 11, 13, 18]. There are two remarkable things about this figure. First, the rotational state population distribution does give a straight-line ‘Boltzmann plot’ suggesting that the CO_2 molecules, scattered into this excited vibrational level by collisions with vibrationally hot pyrazine molecules, have a ‘pseudo-equilibrium’ distribution. Second, and far more amazing, is that the temperature, T_R , deduced from the slope of this plot is only $383 \pm 40\text{ K}$, just slightly warmer than the initial, ambient cell temperature of 298 K !

Figure C3.3.5. The upper half of the figure is a ‘Boltzmann’ plot of the natural log of the population scattered into the $\text{CO}_2(00^0_1; J)$ vibration–rotation level divided by $2J + 1$, for collisions with an excited pyrazine molecule as depicted by the equation at the top of the figure. The slope of such a plot is $1/kT_R$ where k is Boltzmann’s constant and T_R is the temperature that characterizes the rotational-state distribution in the $\text{CO}_2(00^0_1)$ vibrational level. Shown in the lower half of the figure is a Doppler-lineshape profile for the $\text{CO}_2(00^0_1; J = 19) \rightarrow \text{CO}_2(00^0_2; J = 18)$ transition, where the molecules in $\text{CO}_2(00^0_1; J = 19)$ have been excited by the collision process depicted at the top of the figure. The best fit of the data (circles) to a Gaussian profile gives a translational temperature of 328 K, indistinguishable in this case from the ambient 298 K Doppler profile.

C3.3.4.1 VELOCITY PROFILES FOR VIBRATIONAL EXCITATION OF THE BATH

In the lower half of figure C3.3.5 is a plot of the spectral lineshape for the transition $00^0_1; J = 19 \rightarrow 00^0_2; J = 18$ that provides a measure of the recoil velocity distribution for molecules scattered into the $00^0_1; J = 19$ state. The width of this distribution is characterized by a temperature of $328 \pm 30 \text{ K}$ that is again only slightly larger than the 298 K gas temperature of the pre-excited molecules. These collisions have managed to insert into the bath acceptor molecules an energy equivalent to more than ten times the mean ambient energy of the initial molecular ensemble (before excimer laser excitation) without significantly exciting either the translational or rotational degrees of freedom of the molecule [6, 9, 10 and 11, 13, 18]!

In fact, the two observations represented by the upper and lower halves of [figure C3.3.5](#) paint a remarkably consistent picture of the physical process that leads to vibrational excitation of the bath molecules in collisions with molecules having chemically significant amounts of vibrational energy. Such collisions must be ‘soft’, taking place at some distance short of the repulsive potential wall for interaction of the two molecules. Note that an impulsive collision sampling the steep repulsive wall of the intermolecular potential of a highly vibrationally excited molecule with its rapidly oscillating ‘atomic pistons’ would perforce be kicked rather hard, thereby developing substantial translational recoil. Furthermore, since CO_2 is cigar shaped, it is nearly impossible to strike the

molecule anywhere along its molecular axis (except perpendicular to the axis at the C atom and parallel to the axis at the O atom end) without inducing significant rotational motion [20]. Long-range energy transfer of this type has been characterized for small molecules at low excitation energies [21, 22, 23, 24, 25, 26, 27, 28 and 29], but came as a complete surprise for encounters of the highly energetic nature described here. In such cases excitation of the vibrations of the acceptor is believed to arise from resonant vibrational-energy transfer in which the donor and the acceptor lose and gain, respectively, equal amounts of internal energy. Such an energy exchange is known to occur via long-range forces of which the most important is the transition-dipole–transition-dipole interaction moment. (The contribution to the dipole moments arises from vibrations of the molecules and is proportional to the derivative of the dipole moment with respect to the molecular, internal, nuclear coordinates) [21, 22, 23, 24, 25, 26, 27, 28 and 29]. It is worth emphasizing that such energy transfer processes do not occur with high probability in a typical collision. (The rate constant for the process depicted in [figure C3.3.5](#) has been measured and indicates that the probability for exciting all of the 00^0_1 molecules without regard to their rotational state designation, is about 1% per gas kinetic encounter [6, 8, 11, 13].)

C3.3.4.2 VELOCITY PROFILES FOR TRANSLATIONAL–ROTATIONAL EXCITATION OF THE BATH

In stark contrast to the results shown in [figure C3.3.5](#) are data obtained for collision processes that lead to no vibrational excitation of the bath molecule, leaving CO_2 in its ground vibrationless state, 00^0_0 , but in highly rotational excited levels [5, 9, 11, 12, 14, 16, 17]. The mean J for CO_2 at $T = 298$ K is 24, and [figure C3.3.6](#) shows linewidth data obtained for the transition $00^0_0; J = 72 \rightarrow 00^0_1; J = 71$ of CO_2 produced by collisions with methylpyrazine molecules excited to energies of 37 000 and 41 000 cm^{-1} , respectively. Such high rotational levels of CO_2 are essentially unpopulated at the cell temperature of 298 K. The linewidths measured for this transition correspond to temperatures of 1340 ± 250 and 1160 ± 220 K, respectively, a little over four times the initial ambient value, indicating significant recoil for this rapidly rotating molecule. Again, the picture presented by these data is very consistent if the behaviour of both the rotational and translational motions of the recoiling CO_2 bath molecule are considered. A hard, impulsive, collision that samples the repulsive wall of the methylpyrazine donor, with its rapidly oscillating atomic pistons, provides a significant kick to the bath acceptor molecule causing large translational recoil. Again, because CO_2 is cigar shaped, such a violent hit on the molecule almost always leads to significant rotational excitation accompanying the translational recoil [20]! While rate constant measurements for such processes indicate that the probability for exciting a given J level of 00^0_0 is of the order of 0.1–1% per gas-kinetic collision [5, 9, 11, 12, 14, 16, 17] the total excitation probability for this process, summed over all J levels in 00^0_0 , is probably greater than 90%. The key point is that a collision between a medium-sized donor, with very high levels of internal vibrational excitation, and a small bath acceptor molecule is most likely to put donor vibrational energy into rotation and translation of the bath with little going into overall bath rotation.

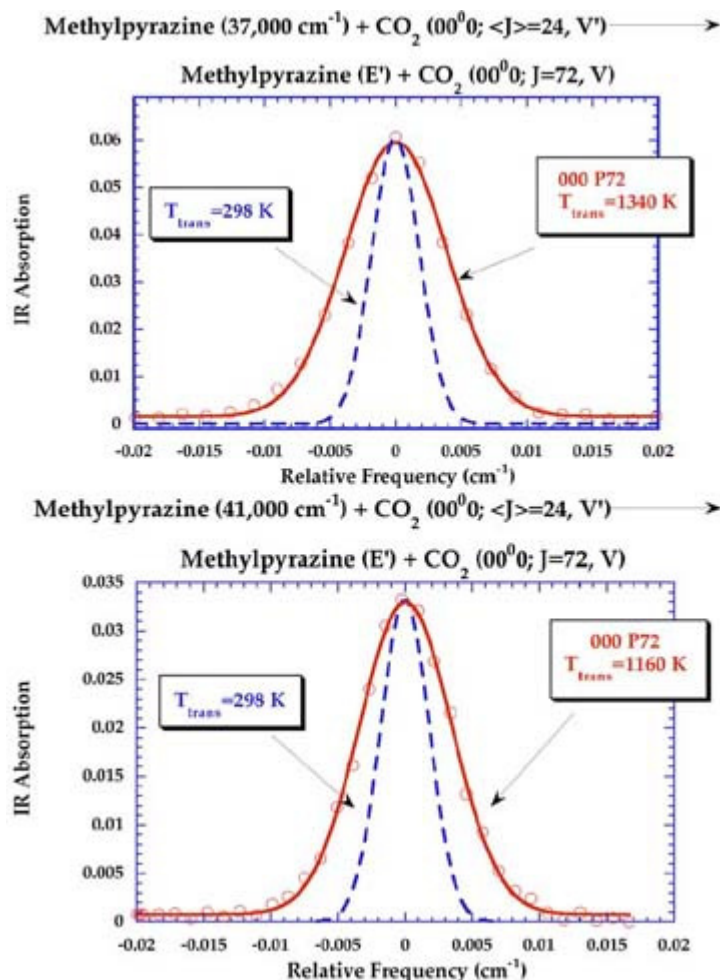

Figure C3.3.6. Doppler-line profiles for molecules scattered into the $\text{CO}_2(00^0_0; J=72)$ state by collisions with hot methylpyrazine molecules as depicted by the equations above each half of the figure. The energy of methylpyrazine in the upper half of the figure is $37\,000\text{ cm}^{-1}$ (excitation at 266 nm) while the energy of methylpyrazine in the lower half of the figure is $41\,000\text{ cm}^{-1}$ (excitation at 248 nm).

C3.3.4.3 QUALITATIVE CORRELATION OF ENERGY TRANSFER DATA TO THE INTERMOLECULAR POTENTIAL

Figure C3.3.7 shows a typical intermolecular potential and the types of recoil linewidth that are observed for collisions that sample the long- and short-range forces acting during a collision. For all cases studied so far, vibrational excitation of the bath acceptor species is accompanied by almost no excitation of translational or rotational motion. The clear signature of the kind of collision that samples the long-range, attractive part of the intermolecular potential is narrow recoil linewidths as shown in the upper half of Figure C3.3.7. Figure C3.3.8 shows what might be a typical trajectory for this kind of interaction—a distant fly-by in which energy exchange is brought about by long-range electrical forces acting at a distance. On the other hand, collisions that sample the steep repulsive part of the potential shown in the lower half of Figure C3.3.7 have a signature characterized by wide recoil linewidths as shown in the upper half of Figure C3.3.7. A typical ‘direct hit’ trajectory that samples this part of the potential is shown in figure C3.3.9.

Close encounters of the bath molecule with the rapidly vibrating atoms of the donor lead to strong recoil (and corresponding rotational motion) with accompanying loss of energy from the donor vibrations. The distant fly-by is characterized by vibration–vibration (resonant) energy transfer, while the impulsive, violent collision is characterized by vibration–translation/rotation energy transfer. It is reasonable to ask why these mechanisms are so clearly separated in nature, for example, why the vibrationally excited bath molecules do not have a recoil linewidth intermediate between their original, ambient value and the large recoil linewidths exhibited in vibration–

translation/rotation energy transfer. While a definitive answer to this question is at present lacking, some clues can be found in the nature of the bath vibrations that have been studied so far. In all cases investigated to date with this technique, the bath modes excited by collisional energy transfer have had vibrational states whose separation is large compared to the mean thermal energy ($h\nu \gg kT$). These are sometimes referred to as ‘stiff’ vibrations. There are good theoretical reasons to expect ‘soft’ acceptor modes with energy separations comparable to kT to be excited by a combination of both short- and long-range forces [30, 31, 32, 33, 34, 35, 36, 37, 38 and 39].

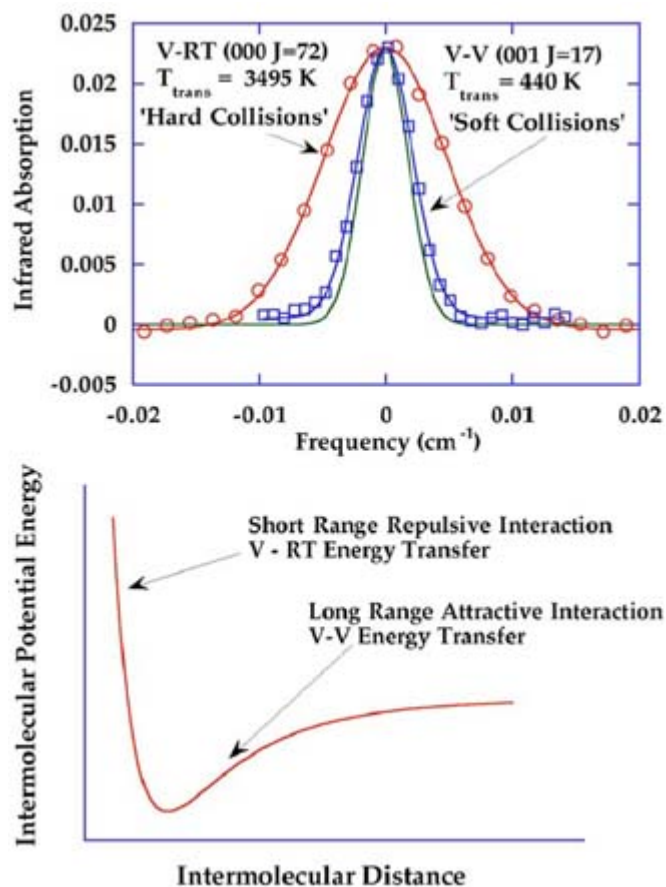

Figure C3.3.7. In the upper half of the figure are shown typical measured Doppler profiles for molecules scattered into the (00⁰0; $J = 72$) or (00⁰1; $J = 17$) states of CO₂ by collisions with hot pyrazine having an energy of 40 640 cm⁻¹. In the lower half of the figure is shown a typical intermolecular potential identifying the ‘hard’ and ‘soft’ collision regimes and the kind of energy transfer they effect.

Figure C3.3.8. A typical trajectory for a ‘soft’ collision between a hot pyrazine molecule and a CO_2 bath molecule in which the CO_2 becomes vibrationally excited.

Figure C3.3.9. A typical trajectory for a ‘hard’ collision between a hot donor molecule and a CO_2 bath molecule in which the CO_2 becomes translationally and rotationally excited.

C3.3.5 QUANTITATIVE DATA ANALYSIS

C3.3.5.1 MASTER EQUATION ANALYSIS OF UNIMOLECULAR REACTION DYNAMICS

The analysis of the data presented so far, while qualitative, has provided a clear picture of the general mechanisms for loss of energy from a molecule with chemically significant amounts of energy. Nevertheless, a quantitative representation of this information would be highly desirable to use as a bench mark for comparison with theory and in practical applications where rates of unimolecular reactions are modelled with master equation techniques [40, 41, 42, 43 and 44]. Figure C3.3.10 shows a schematic, energy-level diagram for a molecule undergoing unimolecular decomposition. Above the reaction barrier the molecule has sufficient energy to undergo decomposition at a rate k_E represented by the arrows going to the right. On the other hand, quenching collisions of the type we have been discussing carry molecules down to lower energy as represented by the downward arrows in the figure. When a quenching collision carries a molecule from an energy above the reaction barrier to an energy below this barrier, it snuffs out the reaction process. In the original Lindemann unimolecular reaction scheme [2], both k_E and the rate constant for quenching collisions were assumed to be the same, independent of energy. This assumption is too simple. Both k_E and k_q , the quenching rate constant, are energy dependent. Quenching collisions can not only bring molecules below the reaction barrier depicted in figure C3.3.10, they can also reshuffle molecules within the different energy states above the barrier, changing the rate of unimolecular decomposition because of the dependence of k_E on E . An expression that takes into account these different energy dependences is the master equation giving the rate of loss of substrate $S^*(E)$ at an energy E [40, 41, 42, 43 and 44]:

$$d[S^*(E)]/dt = k_{LJ}[B] \int_0^\infty \{P(E, E')[S^*(E')] - P(E', E)[S^*(E)]\} dE' - k_E[S^*(E)].$$

The last term in this expression is simply the unimolecular rate of loss of substrate $S^*(E)$, k_{LJ} is the Lennard-Jones rate constant, [B] the concentration of bath molecules and $P(E, E')$ the energy transfer probability distribution function. $P(E, E')$ gives the probability that a substrate molecule $S^*(E)$ at energy E will be carried to an energy E' in a collision with a bath quenching molecule. Note that, while k_E is a property of the substrate molecule alone, $P(E, E')$ depends on the identity of both substrate and bath molecules (as well as on the energies E and E'). From this expression, a full description of a unimolecular reaction process clearly requires a knowledge of the distribution function $P(E, E')$ for energy loss from the substrate $S^*(E)$.

-16-

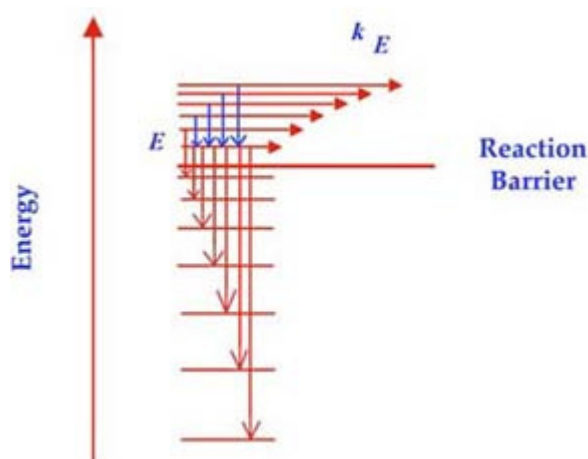

Figure C3.3.10. A schematic energy-level diagram for a molecule capable of undergoing unimolecular reaction above the energy depicted as the reaction barrier. Arrows to the right indicate reaction (collision-free) at a rate k_E that depends on the energy E . Down arrows represent collisional redistribution of the hot molecules both above and below the reaction barrier.

C3.3.5.2 EXTRACTING THE ENERGY TRANSFER PROBABILITY DISTRIBUTION FUNCTION $P(E, E')$

The data obtained in the infrared-diode-laser-probe studies described above provides quenching information at a given substrate donor energy E . By varying the laser excitation wavelength for production of vibrationally hot

species, equivalent data at other excitation energies can be obtained. Experiments of this type have already begun [45, 46 and 47]. Even to extract $P(E, E')$ at a single donor energy E by inverting the experimental data from these studies is a formidable task [15]. First, the information obtained provides a measure of the probability, $P(00^0_0; J, V)$, for producing a given final quantum state of the bath acceptor molecule, such as $00^0_0, J, V$, with a specific vibrational (00^0_0), rotational (J) and velocity (V) signature. In order to turn such a distribution into a $P(E, E')$ distribution, some method of identifying the initial state of the bath molecule must be found so that the energy change $\Delta E = E' - E$ occurring during the collision can be determined. (The conventional way to define ΔE gives it a negative sign for energy loss ($E' < E$) from the donor.) The initial state of the bath molecule consists of a Boltzmann distribution of velocities and rotational state populations described by the cell temperature T . Thus, each final state of the bath molecule can arise from a number of different initial states leading to a distribution of ΔE values. Fortunately, for large ΔE , this spread is not too significant because the initial distribution for cell temperatures near $T = 300$ K is not large. In addition, by studying the final $P(00^0_0; J, V)$ distributions as a function of cell temperature, the initial states of the bath that contribute significant population to a given scattered $00^0_0, J, V$ state can be narrowed still further [15, 16]. Second, in the case of translational motion, the quantity of interest is the energy transferred in the centre-of-mass frame that takes into account the recoil of both the bath acceptor and the donor. Thus, the data obtained in the experiments that measures the laboratory frame recoil velocities of the bath molecules, as described here, must be transformed into the centre-of-mass frame. The procedure for doing this is lengthy and has been described elsewhere [9, 12]. Third, the results for collision-induced scattering into a large number of different final states of the bath molecule must be summed in order to obtain the complete distribution function $P(E, E')$. Finally, there is no way at present to take into account (no experimental measure of) the change in rotational energy of the donor molecule during the collision. For heavy donors, this is not expected to cause much error in the determination of the distribution functions because angular-momentum constraints limit the maximum change in angular momentum during the collision [9, 20].

-17-

For heavy molecules with very small rotational state spacing, this limit on ΔJ puts severe upper limits on the amount of energy that can be taken up in the rotations of a heavy molecule during a collision. Despite these limitations, $P(E, E')$ distributions have been obtained by inverting data of the type described here for values of ΔE in the range $-1500 \text{ cm}^{-1} > \Delta E > -8000 \text{ cm}^{-1}$ for the two donor molecules pyrazine and hexafluorobenzene with carbon dioxide as a bath acceptor molecule [15, 16]. Figure C3.3.11 shows these experimentally derived probability distributions for events that leave the CO_2 bath molecule in its ground vibrational level 00^0_0 ('pure' vibration-rotation/translation energy transfer). Even though limited to large values of ΔE , these probability distribution functions are very revealing. First and foremost, we see that the probability for very large energy transfers (e.g. $-\Delta E = 6000\text{--}8000 \text{ cm}^{-1}$) is small but measurable. These so-called 'super collisions' were a great surprise when first discovered a number of years ago [48, 49, 50, 51, 52, 53, 54, 55 and 56]. The distributions in figure C3.3.11 can be thought of as the 'supercollision tail' of the $P(E, E')$ distribution function. A second interesting feature of the data in figure C3.3.11 is the difference between the two molecules. Evidently, $P(E, E')$ is significantly larger for hexafluorobenzene than for pyrazine at small ΔE . Since the *average* energy transferred in collisions of this type is always weighted heavily by low ΔE values, we would expect that the mean energy transferred from hexafluorobenzene to bath acceptors would be larger than the mean energy transferred from pyrazine to the same bath acceptors. Experimental measurements of these average energy transfer values have not yet been made for the same CO_2 quencher bath molecule, but the trends from self-quenching data indicate that C_6F_6 will have a substantially larger mean energy transfer value than pyrazine [57, 58]. Such a trend is consistent with the large number of low-frequency modes in C_6F_6 compared to pyrazine, a factor that usually drives up the mean-energy-transfer values. Finally, the probabilities for transferring large amounts of energy become larger in pyrazine than in C_6F_6 for ΔE values more negative than about -3000 cm^{-1} . While no data are generally available on the variation in 'supercollision' probability with molecular parameters, the trend in figure C3.3.11 can be rationalized by recognizing that pyrazine has more high-frequency vibrations than C_6F_6 . In transferring, e.g. 6000 cm^{-1} from pyrazine to CO_2 , only two C-H-stretch quanta are required, while four C-F-stretch quanta would be needed in the case of C_6F_6 [16]. As a general rule, energy-transfer probabilities increase if the number of vibrational quanta surrendered in the exchange process are minimized [30, 31, 32, 33, 34, 35, 36, 37, 38 and 39].

Figure C3.3.11. The energy transfer probability distribution function $P(E, E')$ (see figure C3.3.2) for two molecules, pyrazine and hexafluorobenzene, excited at 248 nm, arising from collisions with carbon dioxide molecules. Only those collisions that leave the carbon dioxide bath molecule in its ground vibrationless state $00^0 0$ have been included in computing this probability.

The probability distribution functions shown in figure C3.3.11 are limited to events that leave the bath molecule vibrationally unexcited. Nevertheless, we know that the vibrations of the bath molecule are excited, albeit with low probability in collisions of the type being considered here. Figure C3.3.12 shows how these $P(E, E')$ distribution functions of Figure C3.3.11 are changed if the probability for exciting the $\text{CO}_2(00^0 1)$ level is also included. Because such bath vibrational excitation is accompanied by essentially no translational or rotational energy gain, the probability increase from this channel is confined to a narrow region at 2349 cm^{-1} , the energy of the $\text{CO}_2 00^0 0 \rightarrow 00^0 1$ vibrational transition. Thus, the quantum nature of the bath vibrations, coupled with a mechanism in which bath vibrations are resonantly excited by vibration–vibration energy exchange from a hot donor, leads to the appearance of resonances or spikes in the $P(E, E')$ distribution function [15, 16]!

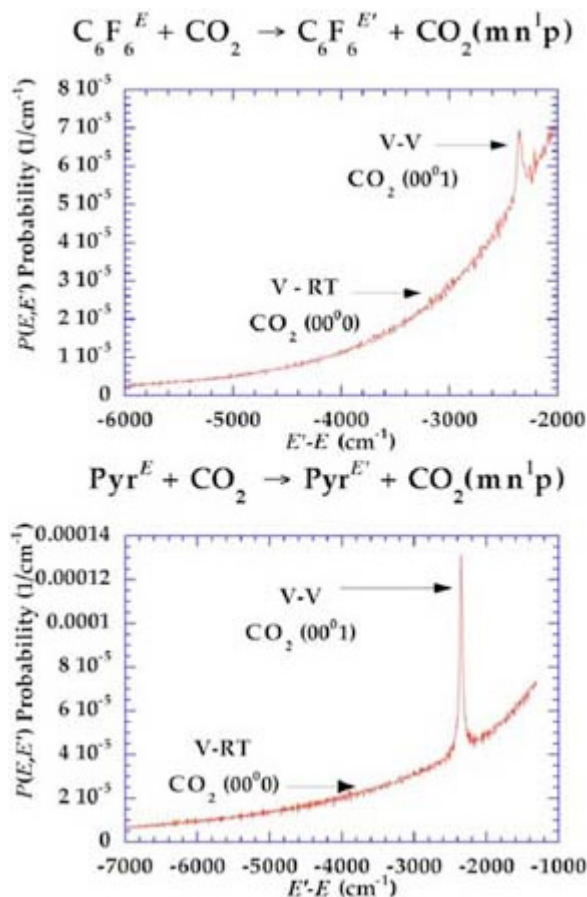

Figure C3.3.12. The energy-transfer-probability-distribution function $P(E, E')$ (see [figure C3.3.2](#) and [figure C3.3.11](#)) for two molecules, pyrazine and hexafluorobenzene, excited at 248 nm, arising from collisions with carbon dioxide molecules. Both collisions that leave the carbon dioxide bath molecule in its ground vibrationless state, 00^00 , and those that excite the 00^01 vibrational state (2349 cm^{-1}), have been included in computing this probability. The spikes in the distribution arise from excitation of the carbon dioxide bath 00^01 vibrational mode.

C3.3.6 SUMMARY

A variety of interconnected, bimolecular, collision studies have been described that employ laser devices to investigate the detailed energy disposal in product molecular species and to provide a direct experimental measure of the energy-transfer distribution function $P(E, E')$. A knowledge of this function is important both in testing detailed theoretical energy-transfer calculations and in modelling unimolecular chemical reactions using master-equation methods. Although there have been a number of extremely informative studies of the energy relaxation of highly vibrationally excited molecules in the past, with rare exception these studies are not able to follow all the degrees of freedom of the quencher molecules. The experimental approach described here, designed as it is to investigate the detailed dynamics of these collisions by *separately* probing the vibrational, rotational and translational degrees of freedom, can significantly increase our understanding of the mechanisms for these fundamental processes that are of such importance in studies of photochemistry, unimolecular and bimolecular reactions. All of these experiments provide data of fundamental chemical interest since the information obtained is sensitive to molecular-potential-energy surfaces and can serve as a test for necessarily approximate dynamical theories. In addition, many of the experimental data obtained will be of practical interest in the study and control of unimolecular chemical reactions and photochemical processes in the development of optically pumped molecular

lasers and in the development of an improved understanding of atmospheric chemical reactions.

ACKNOWLEDGMENTS

I am indebted to my students, post-doctoral fellows and collaborators, particularly Chris Michaels, Eric Sevy, Amy Mullin, Zhen Lin, Charles Tapalian, Professor Mark Muyskens and Dr Ralph Weston who have contributed to the insights and experimental efforts described here.

C3.4 Electronic energy transfer in condensed phases

Andrey A Demidov and David L Andrews

C3.4.1 INTRODUCTION

In condensed phase matter, the process of electronic excitation through the absorption of light commonly results in a system with an initially high degree of energetic instability. One of the most important and rapid means by which the system begins to accommodate its energy is a redistribution of excitation between the component optical centres (molecules or chromophores). The fundamental mechanism for this redistribution is the phenomenon of *electronic energy transfer*. At the molecular level this is a pairwise process in which the energy of electronic excitation held by one molecule transfers to another. As a result the former molecule, called the *donor*, imparts its energy of electronic excitation to the latter *acceptor*.

In modelling energy transfer in a bulk medium containing more than two chromophores or molecules, one has to consider all the individual pairwise processes and conduct the appropriate averaging. Such an approach is valid when excitation can be localized on individual molecules. This is called *localized excitation*; the localized energy is termed a *localized exciton*. The process of energy migration is then known as *incoherent energy transfer*, and the jump of an exciton from one molecule to another is a good way to describe it. The physical condition for incoherent energy transfer is weak coupling between the donor and acceptor species.

In the opposite case, i.e. strong coupling, the model of energy transfer changes. Then the donor and acceptor form a dimer-like structure as their excited states mix together and form a joint excited state split by twice the coupling energy. With such excitonic states we can no longer specify the molecular location of the electronic excitation, as it is 'spread out' between both molecules. Now we have to use a different language, and the issue is energy transfer between excitonic states.

In systems comprising a large number of molecules one can find various types of energy transfer. If the molecules are strongly coupled we observe multi-excitonic behaviour, where not just two but a number of excitonic excited states are formed. Energy transfer in this case is called *coherent energy transfer*. Generally it may happen that in a bulk medium some molecules have strong coupling, whereas others have weak coupling, resulting in a mixture of coherent and incoherent energy migration. Let us now consider in more detail the different mechanisms that lead to these types of electronic energy transfer.

C3.4.2 INCOHERENT ENERGY TRANSFER

In our everyday life we move in a world that we largely experience through processes of electronic energy transfer. For example, you can read the printed words on this page because the print absorbs radiation emitted by your source of light. At the atomic level that is a process of electronic energy transfer from, let us say, the excited tungsten atoms of your reading lamp to the atoms of carbon on the page. The same principle applies across cosmic scales as we peer up at

distant stars in the night sky, the very process of vision requiring molecules of rhodopsin in the retina to capture

photons of starlight and so enter an electronic excited state. In a very real sense this radiative process is a direct transfer of electronic energy from the star to the retina. Obviously the coupling between the donor and acceptor in such a case is close to zero.

The coupling remains relatively weak even at the other extreme of distance, where the energy transfer occurs within a single piece of matter and the donor and acceptor are separated by, let us say, only a few nanometres. Given the weak coupling, we still have incoherent energy transfer, but now the photon that conveys the energy has to be conceptualized as a virtual quantity—its involvement can only be inferred, and the energy transfer is for all practical purposes radiationless. This kind of energy transfer was first investigated by Förster in 1948 [1], and addressed with a perturbation theory based on dipole–dipole interaction between the excited donor and unexcited acceptor. Later the theory was rectified in a number of works [2, 3] and became the proven workhorse for much of the modern research on energy transfer in condensed matter [4, 5].

More recently Andrews and Juzeliunas [6, 7] developed a unified theory that embraces both radiationless (Förster) and long-range radiative energy transfer. In other words this theory is valid over the whole span of distances ranging from those which characterize molecular structure (nanometres) up to cosmic distances. It also addresses the intermediate range where neither the radiative nor the Förster mechanism is fully valid. Below is their expression for the rate of pairwise energy transfer w from donor to acceptor, applicable to transfer in systems where the donor and acceptor are embedded in a transparent medium of refractive index n :

$$\begin{aligned}
 w &= w_F + w_I + w_{\text{rad}} \\
 w_F &= \frac{9\kappa_3^2 c^4}{8\pi \tau_D n^4 R^6} \int F_D(\omega) \sigma_A(\omega) \frac{d\omega}{\omega^4} \\
 w_I &= \frac{9c^2}{8\pi \tau_D n^2 R^4} (\kappa_3^2 - 2\kappa_1 \kappa_3) \int F_D(\omega) \sigma_A(\omega) \frac{d\omega}{\omega^2} \\
 w_{\text{rad}} &= \frac{9\kappa_1^2}{8\pi \tau_D R^2} \int F_D(\omega) \sigma_A(\omega) d\omega.
 \end{aligned} \tag{C3.4.1}$$

In the above expression the three terms respectively represent a ‘Förster’ rate contribution, w_F ; a radiative (fluorescence) term, w_{rad} ; and an ‘intermediate’ term, w_I . The various parameters featuring in (C3.4.1) are defined as follows: $F_D(\omega)$ is the normalized spectrum of donor fluorescence; $\sigma_A(\omega)$ is the absorption cross section of the acceptor; ω is the optical frequency ($2\pi\nu$); c is the speed of light; τ_D is the radiative lifetime of the donor, n is the refractive index; and R is the distance between the donor and acceptor. Lastly, $\kappa_{1,3}$ are orientation factors (their detailed form to be given below). It may be noted that if the medium across which energy transfer occurs is not transparent, one has to take into account the frequency dependence of the refractive index, and in particular its imaginary part, leading to a more complex result (see [7]). One can find elsewhere the following alternative form of the Förster formula:

$$w_F = \frac{2\kappa^2}{3} \frac{1}{\tau_D} \left(\frac{R_0}{R} \right)^6 \tag{C3.4.2}$$

-3-

where R_0 is called the ‘critical’ or Förster radius. Obviously (C3.4.2) and the Förster component of (C3.4.1) are related, and the Förster radius is calculable from the overlap integral of the appropriate fluorescence and absorption spectra. Typical values of the Förster radius range over tens of ångströms, see [4, 8].

In (C3.4.1) we find three major forms of dependence on distance: R^{-6} , R^{-4} and R^{-2} which correspond to Förster, intermediate and radiative types of energy transfer. The intermediate part usually makes a significant contribution at distances of about a hundred or a few hundred nanometres, where all three components w_F , w_I and w_{rad} are comparable in magnitude. At shorter distances w_F dominates, whereas at larger distances w_{rad} dominates. It is

important to clarify the meaning of τ_D . It represents the rate of radiative transition of the donor from its excited state to the ground state, related to the measured fluorescence lifetime τ_{fluor} through the fluorescence quantum yield η , with $\tau_{\text{fluor}} = \eta \tau_D$. For example, chlorophyll *a* in various solutions exhibits a fluorescence lifetime of about 5–7 ns; with $\eta \sim 0.3$ –0.35, that makes $\tau_D \sim 15$ –20 ns [8, 9 and 10].

The κ factors in (C3.4.1) represent another very important facet of the energy transfer [4, 11]. These factors depend on the orientations of the donor and acceptor. For certain orientations they can reduce the rate of energy transfer to zero—for others they effect an ‘enhancement’ of the energy transfer to its maximum possible rate. Figure C3.4.1 exhibits the angles which define the mutual orientation of a donor and acceptor pair; in terms of those angles the orientation factors κ_1 and κ_3 are given by [6, 7]

$$\kappa_j = (\hat{\mu}_D \cdot \hat{\mu}_A) - j(\hat{R} \cdot \hat{\mu}_D)(\hat{R} \cdot \hat{\mu}_A) = \cos \alpha - j \cos \beta \cos \gamma \quad j = 1, 3 \quad (\text{C3.4.3})$$

where the case $j = 3$ is the conventional orientation factor, usually written simply as κ .

Figure C3.4.1. Example of the spatial orientation of three major vectors: $\hat{\mu}_D$, $\hat{\mu}_A$ and \hat{R} , unit vectors of the donor and acceptor transition dipole moments, and the donor–acceptor displacement-vector.

The dipole–dipole interaction which leads to (C3.4.2) and (C3.4.3) for energy transfer is in certain cases not applicable, as for example, if either the donor or acceptor transition is dipole (E1)-forbidden or exceptionally weak. Then, the coupling necessarily involves the electric quadrupole moment (E2), higher electric multipoles (E_n) or even magnetic multipoles (M_n), in each case leading to an orientation and distance of a different form. In the most common case of predominantly electric coupling, then if (E_n) and (E_m) are the leading non-zero moments of the donor and acceptor, the distance dependence takes the form $R^{-2(n+m+1)}$. Details of the functional form of the distance and angle dependence is discussed for example in [12, 13 and 14].

Knowledge of the pairwise energy transfer rates forms a basis for finding the average rate of energy transfer in an ensemble of N molecules. To this end, a system of ‘master equations’ is commonly employed [15, 16 and 17]. Then, the probability, p_i , to find excitation on molecule i can be calculated as:

$$\begin{aligned}
\frac{dp_1}{dt} &= -\frac{p_1}{\tau_1} - \sum_{j=2}^N w_{1j} p_1 + \sum_{j=2}^N w_{1j} p_j + F_1 \\
&\quad \vdots \\
\frac{dp_i}{dt} &= -\frac{p_i}{\tau_i} - \sum_{\substack{j=1 \\ j \neq i}}^N w_{ij} p_i + \sum_{\substack{j=1 \\ j \neq i}}^N w_{ij} p_j + F_i \\
&\quad \vdots \\
\frac{dp_N}{dt} &= -\frac{p_N}{\tau_N} - \sum_{j=1}^{N-1} w_{Nj} p_N + \sum_{j=1}^{N-1} w_{Nj} p_j + F_N.
\end{aligned} \tag{C3.4.4}$$

Here τ_i is the intrinsic lifetime of the excitation residing on molecule i (i.e. the fluorescence lifetime one would observe for the isolated molecule), w_{ij} is the pairwise energy transfer rate and F_i is the rate of excitation of the molecule i by the external source (the photon flux multiplied by the absorption cross section). The master equation system (C3.4.4) allows one to calculate the complete dynamics of energy migration between all molecules in an ensemble, but the computation can become quite complicated if the number of molecules is large. Moreover, it is commonly the case that the ensemble contains molecules of two, three or more spectral types, and experimentally it is practically impossible to distinguish the contributions of individual molecules from each spectral pool.

The measurement of fluorescence intensity from a compound containing chromophores of two spectral types is an example of a system for which it is reasonable to operate with the average rates of energy transfer between spectral pools of molecules. Let us consider the simple case of two spectral pools of donor and acceptor molecules, as illustrated in [figure C3.4.2](#) [18]. The average rate of energy transfer can be calculated as

$$k_{DA} = \frac{1}{N} \sum_{i=1}^N \sum_{j=1}^M w_{ij} g_i \tag{C3.4.5}$$

where N and M are the number of donor and acceptor molecules respectively and g_i is the probability to find excitation on the donor i , commonly we have $g_i \sim 1$. In this case the master equation system can be simplified as:

$$\begin{aligned}
\frac{dn_D}{dt} &= -\frac{1}{\tau^D} n_D - k_{DA} n_D + k_{AD} n_A + F_D \\
\frac{dn_A}{dt} &= -\frac{1}{\tau^A} n_A + k_{DA} n_D - k_{AD} n_A + F_A.
\end{aligned} \tag{C3.4.6}$$

In these equations n_D and n_A are the excited state populations of the donor and acceptor molecules¹ and τ^D and τ^A are the lifetimes of the donor and acceptor molecules in the excited state; the notation τ^D is used to distinguish it from the radiative constant τ^D (in other words $\tau^D = \tau_{\text{fluor}}^D$ for the donor); k_{DA} is given by (C3.4.5) and k_{AD} , the corresponding rate constant for the backward energy transfer from acceptors to donors can be found by the same means. Finally, F_D and F_A represent external sources of excitation, for example the absorption of laser light by the donor and acceptor molecules. Commonly, for example in the case of δ -pulse excitation (in practice an ultrashort laser pulse), (C3.4.6) yields exponential decay kinetics for $n_D(t)$ and $n_A(t)$. The opposite case of steady excitation (CW light), yields the equilibrium ratio

$$\frac{n_D}{n_A} = \frac{(F_D/F_A)\tau_A^{-1} + k_{AD}(F_D + 1)}{\tau_D^{-1} + k_{DA}(F_D/F_A + 1)} \quad (\text{C3.4.7})$$

Master equation methods are not the only option for calculating the kinetics of energy transfer and analytic approaches in general have certain drawbacks in not reflecting, for example, certain statistical aspects of coupled systems. Alternative approaches to the calculation of energy migration dynamics in molecular ensembles are Monte Carlo calculations [18, 19 and 20] and probability matrix iteration [21, 22], amongst others.

Figure C3.4.2. Schematic presentation of energy transfer between: (a) two donor molecules and six acceptor molecules; and (b) a general case of energy transfer involving a pool of N donor molecules and a pool of M acceptor molecules.

C3.4.3 POLARIZATION ANISOTROPY

Let us consider the case of a donor–acceptor pair where the acceptor, after capturing excitation from the donor, can emit a photon of fluorescence. If the excitation light is linearly polarized, the acceptor emission generally has a different polarization. Common quantitative expressions of this effect are the anisotropy of fluorescence, r , or the degree of polarization, P ;

$$r = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + 2I_{\perp}} \quad P = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + I_{\perp}} \Rightarrow r = \frac{2P}{3 - P} \quad (\text{C3.4.8})$$

where I_{\parallel} and I_{\perp} are measured components of the acceptor fluorescence parallel and perpendicular to the polarization of the incident excitation beam. The anisotropy of fluorescence is a valuable source of information about the structure of molecular complexes. The key factor determining the change in polarization is the angle α between the directions of the transition dipole moments of the donor, $\hat{\mu}_D$, and the acceptor, $\hat{\mu}_A$ (see [figure C3.4.1](#)). In the 1920s Levshin [23, 24] and Perrin [25] derived the following well known formula for an ensemble of randomly oriented donor–acceptor pairs

$$P = \frac{3 \cos^2 \alpha - 1}{3 + \cos^2 \alpha}. \quad (\text{C3.4.9})$$

This formula allows one to directly calculate the angle α , a microscopic parameter, by measuring the macroscopic value P (or equally the anisotropy r).

When applying polarization techniques one has to bear in mind that the above result is derived for an ensemble of independent donor–acceptor pairs with a ‘rigid’ structure—i.e., a system for which α is a constant. If we deal with an ensemble of randomly oriented donor and acceptor molecules the result is dramatically different, reflecting a very rapid loss of polarization ‘memory’. Then, one single act of energy transfer yields $r_0 = 1/25$ [2] and two or more energy transfer jumps, to all intents and purposes, totally destroys any polarization in the emitted fluorescence. This feature may be used as a powerful test for energy transfer in a sample of freely rotating or disordered molecules. If energy transfer occurs in a non-ordered system, the acceptor fluorescence is depolarized; if not, the fluorescence remains polarized. The one exception is where the angle $\alpha = 54.7^\circ$, the so-called ‘magic angle’, when the polarization will be zero anyway. In the case of incoherent energy transfer, the maximum magnitude of the anisotropy ($r = 0.4$) happens when the donor and acceptor have linear transition dipole moments oriented in parallel.

Naturally occurring molecular ensembles such as proteins from photosynthetic systems (plants, algae, photosynthetic bacteria, etc) are usually relatively rigid systems that contain various chromophores and hold them at fixed positions and orientations relative to each other. That is why, despite the numerous energy jumps between the chromophores, the resulting emitted fluorescence is polarized. The extent of this polarization thus affords invaluable information about the internal structure of molecular complexes.

-7-

C3.4.4 NONLINEAR PHENOMENA

C3.4.4.1 BLEACHING OF THE GROUND STATE

Equations (C3.4.5) and (C3.4.6) cover the common case when all molecules are initially in their ground electronic state and able to accept excitation. The system is also assumed to be impinged upon by sources F . The latter are usually expressible as the product $\sigma\Phi\hat{n}_0$, where σ is an absorption cross section, Φ is the photon flux and \hat{n}_0 is the population in the ground state. The common assumption is that $\hat{n}_0 \cong n_0$, i.e. practically all molecules are in the ground state because $n \gg n_0$. This is the assumption of linear excitation, where the system exhibits a linear response to the excitation intensity. This assumption does not hold when the extent of excitation is significant, i.e. when the rate of excitation inflow ($\sigma\Phi$) is larger than excitation dissipation, τ^{-1} . In this case we have a significant depletion of the ground state: $\hat{n}_0 = (n_0 - n) < n_0$, resulting in a nonlinear response from the ensemble.

C3.4.4.2 SINGLET–SINGLET (S–S) ANNIHILATION

Let us now consider the case where there is more than one exciton in the given molecular ensemble. The presence of two or more excess excitons not only creates two or more ‘holes’ in the ground state (see case (a) above) but it also opens up the possibility of two excitons being found on neighbouring molecules. Then the following two-stage process can take place [26]:

In the first stage, where at first we have two excitons S_1 , excitation jumps from one of the excited molecules to

another excited molecule. As a result, the latter molecule is promoted to a higher excited state S_n , while the former loses its energy and finds itself in the ground state S_0 . This is followed by the second step, a fast internal relaxation of the highly excited molecule from S_n to S_1 . Thus, where we started with two S_1 excitations we end up with only one, i.e. one excitation has effectively been annihilated (the energy lost through intramolecular relaxation ultimately manifests as heat). A simplified mathematical expression accounting for S–S annihilation in a homogeneous ensemble of molecules is as follows:

$$\frac{dn}{dt} = -\frac{n}{\tau} - \gamma n^2 + F. \quad (\text{C3.4.11})$$

The solution to this equation reflects a nonlinear response—the kinetics $n(t)$ are strongly dependent on the magnitude of F and/or the initial conditions $n(t=0)$.

S–S annihilation phenomena can be considered as a powerful tool for investigating the exciton dynamics in molecular complexes [26]. However, in systems where that is not the objective it can be a complication one would prefer to avoid. To this end, a measure of suitably conservative excitation conditions is to have the parameter $\sigma\phi\tau < 0.01$. Here τ is the effective rate of intrinsic energy dissipation in the ensemble if the excitation is by CW light, and $\tau = \tau_{\text{las}}$ is the

-8-

pulse duration if the source is a laser pulse faster than all dissipation processes: $1/\tau_{\text{las}} \gg \langle 1/\tau_i \rangle$.

One other common source of nonlinear response, singlet–triplet annihilation, is often the reason for a discrepancy between fluorometric and absorption kinetic measurements [27, 28 and 29].

C3.4.5 COHERENT ENERGY TRANSFER

C3.4.5.1 DIMER

Let us first consider the simplest case of two identical chromophores (or molecules) that are in interaction with each other such that their ‘dimer’ Hamiltonian can be written [30, 31] as

$$\hat{H} = \hat{H}_1 + \hat{H}_2 + \hat{V}_{12} \quad (\text{C3.4.12})$$

where \hat{H}_1 and \hat{H}_2 are the Hamiltonians of the individual molecules and \hat{V}_{12} is the operator for their dipole–dipole interaction

$$\hat{V}_{12} = (4\pi\epsilon_0)^{-1} [(\mu_1 \cdot \mu_2) R_{12}^{-3} - 3(\mu_1 \cdot \mathbf{R}_{12})(\mu_2 \cdot \mathbf{R}_{12}) R_{12}^{-5}] \quad (\text{C3.4.13})$$

each μ being an operator on molecular wavefunctions (see also figure C3.4.1 and equation (C3.4.3) for notation and definitions). The solution of the Schrödinger equation with the above Hamiltonian yields two wavefunctions:

$$\left. \begin{aligned} \Psi^+ &= \frac{1}{\sqrt{2}}(\Psi_{1a} + \Psi_{2a}) \\ \Psi^- &= \frac{1}{\sqrt{2}}(\Psi_{1a} - \Psi_{2a}) \end{aligned} \right\} \quad \Psi_{1a} = \varphi_{10}\varphi_{2a} \text{ and } \Psi_{2a} = \varphi_{1a}\varphi_{20}. \quad (\text{C3.4.14})$$

Here ϕ_{10} , ϕ_{20} and ϕ_{1a} , ϕ_{2a} are the wavefunctions of the non-excited and excited molecules if there is no interaction between them. In the case we consider the molecules do interact and as a result the dimer exhibits properties different from those of the monomers it comprises. In particular, the energy level of the excited state is different from the monomer—it is *split* into two states:

$$\left. \begin{aligned} h\nu^+ &= h\nu_{0a} + V_{12} \\ h\nu^- &= h\nu_{0a} - V_{12} \end{aligned} \right\} \quad (\text{C3.4.15})$$

termed symmetric and antisymmetric respectively. In (C3.4.15), V_{12} is the energy of dipole–dipole interaction between the monomers (the expectation value in the monomer product basis set of the operator given by (C3.4.13)). The dimer has a common ground state and excitation may terminate in either the ν^+ or ν^- excited state (see the solid arrows in [figure C3.4.3](#)). The transition dipole moments of these transitions are defined as:

-9-

$$\left. \begin{aligned} \mu^+ &= \mu_1 + \mu_2 \\ \mu^- &= \mu_1 - \mu_2 \end{aligned} \right\} \quad (\text{C3.4.16})$$

(see [figure C3.4.4](#)). The dipole strength of these transitions are calculated as

$$D^\pm = D_{0a}(1 \pm \cos \alpha) \quad (\text{C3.4.17})$$

where $\cos \alpha = \hat{\mu}_1 \cdot \hat{\mu}_2$ and α expresses the angle between transition dipole moments of unperturbed molecules, D_{0a} is the dipole strength of the individual monomer. One can see from (C3.4.17) that the total dipole strength is conserved, i.e. $D^+ + D^- = 2D_{0a}$. The singly excited dimer, in either its symmetric or antisymmetric state, can capture another photon and undergo transition to the doubly excited state ($\phi_{1a} \phi_{2a}$) of energy $2h\nu_{0a}$. Depending in what excited state the dimer was originally, ν^+ or ν^- , the resonance energy for the double excitation would be ν^- or ν^+ respectively, see [figure C3.4.3](#).

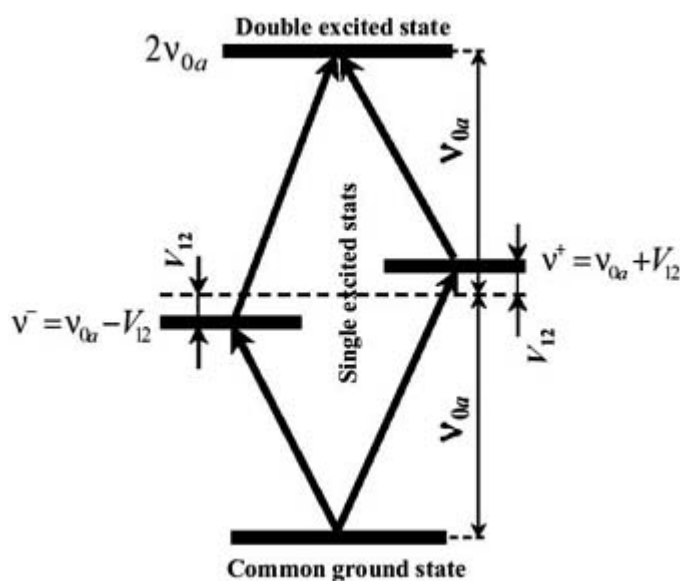

Figure C3.4.3. Energy levels of a dimer (complete description in text).

Figure C3.4.4. Definition of the dimer transition dipole moments μ^+ and μ^- on the basis of the monomer transition dipole moments μ_1 and μ_2 .

Now let us consider the implications of these results for energy transfer. First we recognize that there is no directed energy transfer of the form considered in the incoherent case. Molecules in the dimer cannot be recognized as well defined separate entities that can capture and translate excitation from one to another. The captured excitation belongs to the dimer, in other words, it is shared by both molecules. The only counterpart to energy migration relates to ‘internal’ transitions between the dimer states ν^+ and ν^- . In other words, if in the case of incoherent transfer, energy migrates between two or more distinct *sites* and an exciton is a localized entity that can at any time be localized on either of the molecules, then in the case of a dimer we have to change our language and speak about an internal transfer between energy *states*, as the excitation is delocalized between the contributing molecules [32].

Before moving further to the multimer case we should outline one further significant feature of a dimer. Dimer excited states have a well defined rotational strength [33, 34];

$$R_{\pm} = \pm \frac{\pi}{2} \nu_0 \mu^2 R(\hat{R} \cdot \hat{\mu}_2 \times \hat{\mu}_1) \quad (\text{C3.4.18})$$

i.e. the dimer has a definite circular dichroism (CD) in each of its excited bands, whereas the monomers it comprises may not. This is a useful test to verify if one has dimers or monomers in a sample. To confirm the presence of a dimer, the spectrum should exhibit two bands (‘+’ and ‘-’) manifesting CD of equal magnitude and opposite sign. Moreover, the dimer transition dipole moments μ^+ and μ^- are perpendicular to each other (see figure C3.4.4), yielding the linear anisotropy $r = (3\cos^2 90^\circ - 1)/5 = -0.2$ when the excitation is in the ‘+’ band and the response is recorded in the ‘-’ band. Also, the bleaching of the ground state measured in the ‘+’ and ‘-’ bands must happen synchronously because their ground state origin is common, whereas the ‘antibleach’ (absorption from the excited state into a higher state) and also stimulated emission would reflect the kinetics of an internal energy transfer between the dimer states.

Recent theoretical [35, 36 and 37] and experimental [38] research has revealed anomalous behaviour of the dimer anisotropy under certain excitation conditions. If the dimer is excited by broadband light that covers both excitonic transitions, or by a relatively narrow band properly positioned between the maxima of the excitonic transitions, the

anisotropy would have the maximum value $r = 0.7$. This magnitude far exceeds the theoretical limit $r = 0.4$ for uncoupled molecules.

C3.4.5.2 MULTIMER

When more than two chromophores exhibit significant coupling, the ensemble can be described as multimer. This means that the energy levels of individual molecules are replaced by a number of excitonic levels following the same rule as for a dimer and the wavefunctions of the multimer are linear combinations of the wavefunctions for the unperturbed molecules [30, 39, 40]. The number of excitonic levels is equal to the number of chromophores if there is no degeneracy. The light-harvesting antennae of photosynthetic bacteria and some other photosynthetic preparations are believed to be an example of a multimer [39, 40 and 41]. Energy migration in the multimer proceeds in a form of energy equilibration between excitonic levels in the same manner as described above.

C3.4.6 EXCHANGE MECHANISM OF ENERGY TRANSFER IN FORBIDDEN TRANSITIONS

In the previous section we analysed cases of energy transfer where transitions between excited and non-excited states are allowed, i.e. the common case of dipole–dipole interaction. In 1953 Dexter [42] offered a theory that revealed the possibility of energy transfer in the case of dipole-forbidden transitions. The major idea of this theory is that when the electron distributions of the donor and acceptor are close enough to strongly overlap, the energy of electronic excitation can pass directly to the acceptor, essentially being channelled by the overlapped electron clouds. According to this theory the probability of energy transfer is described as

$$P = \frac{2\pi}{\hbar} Z^2 \int F_d(E) F_a(E) dE \quad (\text{C3.4.19})$$

where

$$Z^2 \approx Y \frac{e^4}{k^2 R_0^2} \exp\left(-\frac{2R}{L}\right). \quad (\text{C3.4.20})$$

Here the parameter k is the dielectric constant of the medium; e is the charge of the electron; R_0 is the critical radius; R is the distance of donor–acceptor separation; and L is a parameter introduced as ‘an effective Bohr radius for the excited donor and unexcited acceptor’ (see the original paper, [42]). The constant of proportionality Y is a dimensionless scaling entity $\ll 1$. The coupling integral between the donor and acceptor (written in the energy domain) is analogous to the integrals introduced in (C3.4.1). The problem with this integral is that $F_a(E)$, which represents the absorption spectrum of the acceptor, cannot always be measured directly from experiment (if the transition is forbidden) but must rather be calculated—and the latter can be quite a complicated procedure [42, 43].

One can see that the Dexter exchange mechanism is exponentially dependent on the distance between the donor and acceptor, and as such it begins to play a visible role only at very short distances when the electron clouds begin to

overlap strongly. The exponential distance dependence manifest in (C3.4.20) essentially reflects a typical asymptote for the wavefunctions of the molecular orbitals. It should be emphasized that the Dexter mechanism will operate over short distances both for dipole–dipole forbidden and allowed transitions. With increasing distance between the donor and acceptor, the Förster mechanism will come into play for dipole–dipole allowed transitions, whereas in the forbidden case one should account for transitions via higher multipoles. A review on further developments in this area, including superexchange mechanisms, can be found in [44], and for an account of how the Dexter and Förster mechanisms seamlessly merge for the dipole-allowed case, the reader is referred to [45].

C3.4.7 NUCLEAR MOTIONS AND ENERGY TRANSFER

With the development of femtosecond laser technology it has become possible to observe in resonance energy transfer some apparent manifestations of the coupling between nuclear and electronic motions. For example in photosynthetic preparations such as light-harvesting antennae and reaction centres [32, 46, 47 and 49] such observations are believed to result either from oscillations between the coupled excitonic levels of dimers (generally multimers), or the nuclear motions of the chromophores. This is a subject that is still very much open to debate, and for extensive discussion we refer the reader for example to [46, 47, 50, 51 and 53]. A simplified view of the subject can nonetheless be obtained from the following semiclassical picture.

In light of the theory presented above one can understand that the rate of energy delivery to an acceptor site will be modified through the influence of nuclear motions on the mutual orientations and distances between donors and acceptors. One aspect is the fact that ultrafast excitation of the donor pool can lead to collective motion in the excited donor wavepacket on the potential surface of the excited electronic state. Another type of collective nuclear motion, which can also contribute to such observations, relates to the low-frequency vibrations of the matrix structure in which the chromophores are embedded, as for example a protein backbone. In the latter case the matrix vibration effectively causes a collective motion of the chromophores together, without direct involvement on the wavepacket motions of individual chromophores. For all such reasons, nuclear motions cannot in general be neglected. In this connection it is notable that observations in protein complexes of low-frequency modes in the range 40–150 cm⁻¹ reflect vibrational periods of about 200–800 fs, comparable to typical rates of donor–acceptor energy transfer.

C3.4.8 SPECTROSCOPIC METHODS AND TECHNIQUES

C3.4.8.1 PUMP-PROBE ABSORPTION

The spectroscopic methods called ‘pump-probe absorption’, or ‘pump-probe transient absorption’ involve the use of at least two laser pulses. One pulse excites the sample and the second probes changes in optical properties caused by the first pulse—thus, the first pulse is called the ‘pump’ and the second one the ‘probe’. Obviously there needs to be a time interval between these pulses as the pump pulse precedes the probe. A typical configuration for a one-colour pump-probe installation (probing at the same wavelength as the excitation) is presented in [figure C3.4.5](#). Experiments based on probing at a different wavelength from the excitation require the use of at least two source laser beams, though the two-colour experimental set-up has the same principal elements. In either case the time resolution is defined by the difference in the optical paths to the sample of the pump and probe pulses. The book [54] can be recommended

Figure C3.4.5. Typical scheme of a single-colour pump-probe experiment utilizing lock-in-amplifier detection.

Optical detectors can routinely measure only intensities (proportional to the square of the electric field), whether of optical pulses, CW beams or quasi-CW beams; the latter signifying conditions where the pulse train has an interval between pulses which is much shorter than the response time of the detector. It is clear that experiments must be designed in such a way that pump-induced changes in the sample cause changes in the intensity of the probe pulse or beam. It may happen, for example, that the absorption coefficient of the sample is affected by the pump pulse. In other words, due to the pump pulse the transparency of the sample becomes larger or smaller compared with the *unperturbed sample*. Let us stress that even when the optical density (OD) of the sample is large, let us say $OD \sim 1$, and the pump-induced change is relatively weak, say 10^{-4} , it is the latter that carries positive information.

Thus we are challenged by the problem of measuring a small signal against the background of one much stronger. The problem is usually solved by one of two means: (a) lock-in-amplifier detection; and (b) a boxcar type of detection (to some extent we can include double-input optical multichannel detection in this category).

- (a) *Lock-in-amplifier detection.* This method involves ‘chopping’ or rapidly switching the pump beam by a mechanical chopper or by an electro-optic or acousto-optic modulator. Figure C3.4.5 shows the set-up where this chopping is achieved by an optical modulator (OM) of the above kind. The chopping introduces alternating periods of time when the pump beam is affecting the sample and when it is not, causing the detected signal to fluctuate at the chopping frequency. In that case the detector, for example a photodiode or photomultiplier tube (PMT), would see a change in the intensity of the probe beam corresponding to the value of 10^{-4} OD. The next stage is to filter out this signal. This is achieved by using the device called a lock-in-amplifier, which is actually an amplifier with a very narrow spectral bandwidth. Tuned into resonance with the chopping frequency, it will register only the part of the total detected signal that is modulated by the chopping frequency, dumping all other components.
- (b) *Boxcar detection.* This also uses signals associated with ‘pump on’ versus ‘pump off’ conditions, but in a different manner. Whereas the lock-in detector measures *differences* in the intensity of the probe beam, the boxcar detector can measure signal *ratio*. The latter scheme involves the use of two channels with two

time/space gates. Through one gate the boxcar records the unperturbed probe beam (with the pump off), whereas through the other it records the probe beam with the pump on. The ratio of the perturbed over the unperturbed signals from the probe beam is the desired output.

The gates referred to above can be created in various ways. For example, suppose that the probe beam goes through the sample, but only half of its physical width (in the sample) is crossed with the pump beam. Now, if we have two photodiodes, one can measure the intensity of the perturbed part of the probe beam, whilst the second measures the unperturbed part; as a result of creating spatial gates, the two recorded output signals can be used to measure the

requisite ratio. At the same time, the signals from the detectors can be gated in time to improve the signal/noise ratio, i.e. the boxcar records signals only in the short time gate that opens in the presence of the light pulse signal. The rest of the time the gate is closed, and the boxcar receives no input. Averaging over a large number of input signals is another option that is used in boxcar instrumentation to improve signal/noise ratio.

C3.4.8.2 UP/DOWN CONVERSION

The nonlinear optical techniques of up- and down-conversion are based on mixing optical beams in a suitable crystal (BBO, LiNbO₃, KDP, etc) with the generation of new optical frequencies: the physical principle is as follows. If two beams having optical frequencies ω_1 , ω_2 and wavevectors k_1 , k_2 are mixed in a nonlinear optical crystal at the appropriate angle, a new optical frequency ω_3 can be coherently generated with the following conditions satisfied:

$$\omega_3 = \omega_1 \pm \omega_2 \quad \text{and} \quad k_3 = k_1 \pm k_2.$$

The sum-frequency case of $\omega_3 = \omega_1 + \omega_2$ is called up-conversion, the difference-frequency $\omega_3 = \omega_1 - \omega_2$ down-conversion, reflecting the increase or decrease of the generated optical frequency ω_3 from the input frequencies ω_1 and ω_2 .

Now, if we consider the ω_1 input as sample fluorescence caused by the excitation pulse (the pump) and ω_2 as the probe pulse, the process of up/down conversion affords a means of analysing the kinetics of sample fluorescence through observing the intensity of the ω_3 output. In this case the time selection happens in the nonlinear crystal, not in the sample. It is as if the probe beam creates a very narrow time-gate that results in generation of the ω_3 signal only when the gate is open. The kinetics is measured by delaying the time-gate versus the time of sample excitation by the pump pulse.

C3.4.8.3 STREAK CAMERA

Monitoring the kinetics of energy transfer in many systems calls for ultrafast (sub-picosecond) time resolution. Streak camera detection relies on fast electronics to achieve real-time detection of an ultrafast signal registering the transfer—usually a fluorescence signal. Modern streak cameras allow such measurements to be performed with picosecond resolution. The principle of detection is simple: the pump pulse excites the sample and triggers a fast electronic camera similar to the tube in a common oscilloscope. Fluorescence from the sample is collected by the input slit of the camera; the photons either hit the camera photocathode directly or are preamplified by use of an electro-optic amplifier. The beam of electrons so produced, created by the initial pulse of fluorescence and featuring its temporal profile, propagates towards the display phosphor screen. *En route* the beam is deflected by an electric field created by a fast generator triggered by the pump pulse. The result is a track on the phosphor screen with an intensity proportional to

the intensity of the fluorescence. Usually the streak camera is coupled with a CCD camera or a diode array to record this track.

C3.4.8.4 SAMPLE CELL

When performing measurements of energy transfer one has to pay attention to a number of factors that could invalidate the data. In particular, the ‘reset time’ of the sample (the time for conversion of excited molecules back to the ground equilibrated state) could be larger than the period between laser pulses. This creates a build-up of the excited states and/or intermediate products—the latter significantly complicating analysis of the collected data. Yet another complication relates to the local heating of the sample, which modifies the local optical properties from

those which apply under equilibrium ambient conditions (thermal lensing, for example). The common way to eliminate these problems is to refresh the sample in the laser-illuminated area at a rate equal to or faster than the laser pulse repetition. This can be achieved using a flow cell, shaking cell, spinning cell or flow jet. Another kind of problem occurs if the laser pulses have significant noise (exhibiting spatial/temporal spikes for example) and no longer can be considered as propagating with a smooth Gaussian profile. This is a problem which is difficult to overcome without improving the quality of the pulses.

In a flow cell the sample flows through a cuvette by use of a pump, the most popular kind being a peristaltic pump. A *shaking cell* is usually a cell that resides on a mount that can move laterally in a plane perpendicular to the laser beam(s). A *spinning cell* is a disc-like cell mounted on a motor shaft that rotates with a speed up to thousands of revolutions per minute. Finally the *flow jet* is an assembly in which liquid sample is ejected through the special jet nozzle to create a uniform fast stream of sample. The laser beam is focused in this stream. The spinning cell is generally the best choice to achieve the fastest refreshing rate in anaerobic conditions without damaging the sample molecules.

¹ The population of excited states (n) and the probability to find excitation on an individual molecule (p) are related by $n = pN$, where N is the total number of molecules.

FURTHER READING

We would like to recommend the following books for further reading. Recently (1999) Wiley published a book entitled *Resonance Energy Transfer* (ed D L Andrews and A A Demidov). This book contains a detailed overview of the major subjects briefly discussed in the present section. Previously, van der Meer *et al* [4] published a good work concerning the Förster mechanism of energy transfer, and in particular the impact of the orientation factor on the efficiency of energy transfer. Those who are interested in theoretical aspects of energy transfer in condensed matter are referred to the classic book ‘*Electronic Excitation Energy Transfer in Condensed Matter*’ by Agranovich and Galanin [2]. Copious examples of energy transfer in photosynthetic systems are presented in the books entitled *Bioenergetics of Photosynthesis* [10] and *Excitation Energy and Electron Transfer in Photosynthesis* (1987, edited by Govindjee, Kluwer Academic Publishers). Finally, a great many details and tips on practical applications of laser spectroscopy for the investigation of energy transfer, and its instrumentation, can be found in the book *Chemical Applications of Ultrafast Spectroscopy* by Fleming [54].

C3.5 Vibrational energy transfer in condensed phases

Lawrence K Iwaki and Dana D Dlott

C3.5.1 INTRODUCTION

Vibrational energy relaxation (VER) of molecules in condensed phases is a fundamental dynamical process [1, 2, 3, 4, 5 and 6]. Isolated molecules can undergo only *intramolecular* vibrational energy redistribution (IVR), and cannot lose vibrational energy except by slow radiative processes. VER is usually associated with condensed phases or high pressure gases [7]. VER refers to loss of energy from a specific vibrational mode (the ‘system’) to some or all of the other mechanical degrees of freedom (the ‘bath’). VER in condensed phases ordinarily occurs on the 10^{-13} – 10^{-9} s time scale, although slower VER has been observed in diatomics.

VER occurs as a result of fluctuating forces exerted by the bath on the system at the system’s oscillation frequency Ω [5]. Fluctuating dynamical forces are characterized by a force–force correlation function. The Fourier transform of this force correlation function at Ω , denoted $\eta(\Omega)$, characterizes the quantum mechanical frequency-dependent friction exerted on the system by the bath [5, 8].

The multiple roles of VER in essentially all condensed phase chemical processes have been extensively discussed [8]. In chemical reactions, the ‘system’ is the specific mode of the reactant (or a coupled set of reactant and solvent modes [8]) associated with the reaction coordinate. Chemical reactions are ‘catalysed’ by vibrational energy. The system becomes activated by vibrational energy from the bath. Then the barrier is crossed. Then that vibrational energy plus the enthalpy of reaction flows back into the bath (figure C3.5.1). Much has been written about dynamical effects of VER on barrier crossings [8, 9 and 10]. Chemical reactions are slower when VER is too slow, due to multiple barrier recrossings. Reactions are faster when VER is too fast, due to VER during the barrier crossing. The ‘Kramers turnover’ between these two regimes is located at the maximum possible rate, which is also that given by transition-state theory [8, 9] (figure C3.5.1). The VER rate is varied in practice by pressure-tuning solvent density, as in classic studies of photoisomerization of stilbene [11, 12] and boat–chair isomerization of cyclohexane [13, 14].

Figure C3.5.1. (a) Vibrational energy catalyses chemical reactions. The reactant R is activated by taking up the enthalpy of activation ΔH^\ddagger from the bath. That energy plus the heat of reaction is returned to the bath after barrier crossing. (b) VER influences chemical reaction rates by modulating the system during barrier crossing. For a particular VER rate, the reaction rate has a maximum at the Kramers turnover.

C3.5.2 BRIEF HISTORY OF VER

Condensed phase vibrational or vibronic lineshapes (vibronic transitions create vibrational excitations of electronic excited states) rarely provide information about VER (see example C3.5.6.4). Experimental measurements of VER need much more than just the vibrational spectrum. The earliest VER measurements in condensed phases were ultrasonic attenuation studies of liquids [15], which provided an overall relaxation time for slowly (>10 ns) relaxing small molecule liquids.

Lasers revolutionized VER measurements, providing the needed time resolution and specific state resolution. Even early nanosecond solid-state lasers (not tunable) could produce large vibrational populations in liquids or solids via stimulated Raman scattering (SRS) [16]. Early infrared (IR) lasers had limited tuning ranges, but could pump certain molecules (e.g. CO laser pumping solid CO [17]). An excellent history of early VER studies of small molecules is given by Oxtoby [5]. An amazing result from this era, due to Brueck and Osgood [18], is the incredible 56 s VER lifetime of liquid N₂, showing the average N₂ molecule undergoes $\sim 4 \times 10^{15}$ oscillations before VER.

Other early work, which continues to this day, involved vibronic relaxation [6] of large colored molecules such as chrysene [19], pyrene [20] and perylene [21], due to the relative ease of using visible or near-UV light to pump and probe these systems (see example C3.5.6.5 below).

Major breakthroughs in early ultrafast VER measurements were made in 1972 by Laubereau *et al* [22], who used picosecond lasers in an SRS pump–incoherent anti-Stokes Raman probe configuration, to study VER of C–H groups in ethanol and methanol ($\sim 3000 \text{ cm}^{-1}$), and by Alfano and Shapiro [23], who monitored both the decay of the initially excited C–H stretch excitation and the appearance and subsequent decay of a daughter vibration, a C–H bending vibration ($\sim 1460 \text{ cm}^{-1}$). Several reviews described these early studies of liquids [1, 6, 16].

Another important breakthrough occurred with the 1974 development by Laubereau *et al* [24] of tunable ultrafast IR pulse generation. IR excitation is more selective and reliable than SRS, and IR can be used in pump–probe experiments or combined with anti–Stokes Raman probing (IR–Raman method) [16]. Ultrashort IR pulses have been used to study simple liquids and solids, complex liquids, glasses, polymers and even biological systems.

C3.5.3 OVERVIEW OF VER PHENOMENA

C.3.5.3.1 SIMPLE (DIATOMIC) SYSTEMS

The simplest condensed phase VER system is a dilute solution of a diatomic in an atomic (e.g. Ar or Xe) liquid or crystal. Other simple systems include neat diatomic liquids or crystals, or a diatomic molecule bound to a surface. A major step up in complexity occurs with polyatomics, with several vibrations on the same molecule. This feature guarantees enormous qualitative differences between diatomic and polyatomic VER, and casts doubt on the likelihood of understanding polyatomics by studying diatomics alone.

-3-

Diatomic molecules have only one vibrational mode, but VER mechanisms are paradoxically quite complex (see examples C3.5.6.1 and C3.5.6.2). Consequently there is an enormous variability in VER lifetimes, which may range from 56 s (liquid N₂ [18]) to 1 ps (e.g. XeF in Ar [25]), and a high level of sensitivity to environment. A remarkable feature of simpler systems is spontaneous concentration and localization of vibrational energy due to anharmonicity. Collisional up-pumping processes such as

proceed spontaneously with a decrease in enthalpy and a decrease in entropy. For very long-lived vibrations equilibrium may be reached with quite highly excited vibrational states. Anex and Ewing [26] have observed collisional up-pumping of CO up to $v = 20$ for CO in liquid N₂, and high overtone emission was observed in a

monolayer of CO on NaCl by Chang and Ewing [27].

VER of diatomic molecules bound to surfaces [28] was first studied by Heilweil and co-workers [29], who used ultrafast IR to find a surprisingly long VER lifetime of 150 ps for OH stretching vibrations ($\sim 3650 \text{ cm}^{-1}$) on the surface of silica [30]. Guyot-Sionnest *et al* [31] found nanosecond lifetimes for H chemisorbed to Si(111) surfaces ($\sim 4000 \text{ cm}^{-1}$). Surface-bound diatomics have much shorter lifetimes on metals than on dielectrics or semiconductors, due to interactions with conduction electrons [32]. For example, when CO is bound to NaCl (100), its VER lifetime is in the millisecond range [27], but when CO is bound to Pt [33], its lifetime is a few picoseconds.

C.3.5.3.2 COMPLEX (POLYATOMIC) SYSTEMS

In polyatomics, a completely different VER process may occur, termed ‘ladder relaxation’, where energy is transferred from one excited vibrational mode to another mode on the same molecule (the ‘rungs’ of the ‘vibrational ladder’), while the bath takes up the remaining energy [34, 35]. Vibrational energy running down this ladder is termed a ‘vibrational cascade’. Ladder processes are so efficient that VER lifetimes of polyatomics in condensed phases hardly ever exceed one nanosecond. Due to short VER lifetimes in polyatomics, intermolecular energy transfer is thought to be noncompetitive with intramolecular ladder processes. However, there are not many data yet, and intermolecular transfer has been directly observed in a few studies. Apkarian and co-workers observed energy transfer among CH_3F molecules in a rare-gas matrix, resulting in vibrational up-pumping to $\nu = 2$ [36]. Ambroseo and Hochstrasser [37] observed energy transfer from pyrrole to benzene. Hong *et al* [38] observed energy transfer from OH stretch of alcohols to C–H stretch of nitromethane.

The most powerful technique for studying VER in polyatomic molecules is the IR–Raman method. Initial IR–Raman studies of a few systems appeared more than 20 years ago [16], but recently the technique has taken on new life with newer ultrafast lasers such as Ti:sapphire [39]. With more sensitive IR–Raman systems based on these lasers, it has become possible to monitor VER by probing virtually every vibration of a polyatomic molecule, as illustrated by recent studies of chloroform [40], acetonitrile [41, 42] (see example C3.5.6.6 below) and nitromethane [39, 43].

There does not yet exist a simple theory, analogous say to Marcus theory for electron transfer, which predicts VER rates of polyatomic molecular vibrations, or how those rates depend on vibrational frequency. A simple rule was proposed by Nitzan and Jortner [35]. Those authors identified three frequency regimes for VER, a lower-energy regime I where short-lived vibrations decay directly into the bath, an intermediate regime II where longer-lived vibrations undergo ladder relaxation and a higher-energy regime III where vibrations undergo ultrafast intramolecular

-4-

vibrational relaxation. This hardly rigorous rule has been observed (always with numerous exceptions) in several systems (see examples C3.5.6.5 and C3.5.6.6).

One simplifying motif for VER studies of polyatomic molecules is to probe a diatomic ligand bound to a more complex system. CO is a ubiquitous ligand and many studies have been made of VER of CO ligands, e.g. $\text{W}(\text{CO})_6$ in CCl_4 , where the VER lifetime is 280 ps but quite dependent on solvent [44, 44] or CO bound to metalloporphyrins [46, 47, 48 and 49] where the VER lifetime is ~ 20 ps and dependent on haem structure. CO has also been used to study VER of biomolecules, specifically haem proteins. For myoglobin and haemoglobin at 300 K, the CO VER lifetime was ~ 20 ps [46, 47, 50]. A study of CO bound to native and genetically engineered haem proteins showed that vibrational energy flows from CO to haem via π -electron coupling, and that VER rate could be influenced by the protein [50]. Recently, VER measurements have been made of proteins themselves. The $\sim 1600 \text{ cm}^{-1}$ amide I stretching vibrations of several proteins have been found to have an ~ 1 ps lifetime [51, 52 and 53].

C3.5.4 THEORY OF VIBRATIONAL ENERGY RELAXATION

Consider an excited condensed-phase quantum oscillator Ω , with reduced mass μ and normal coordinate q_Ω . The bath exerts fluctuating forces on the oscillator. These fluctuating forces induce VER. The quantum mechanical Hamiltonian is [54, 55]

$$\hat{H} = \hat{H}_\Omega(q_\Omega) + \hat{H}_B(Q) + \hat{V}(q_\Omega, Q) \quad (\text{C3.5.1})$$

where $\hat{H}_\Omega(q_\Omega)$ is the Hamiltonian for the oscillator Ω , $\hat{H}_B(Q)$ is the Hamiltonian for the bath, where Q represents collective bath coordinates, and \hat{V} represents the Hamiltonian for interaction between Ω and the bath. In solids these collective bath states are phonons, which extend from zero frequency to a cut-off frequency, the Debye frequency, ω_D . In liquids, the collective states have been termed instantaneous normal modes [56, 57 and 58]. Since these play the same role as phonons in VER [34, 56, 59, 60], we will call them liquid phonons or simply phonons.

The fluctuating forces $F(t)$ on the rigid oscillator Ω are characterized by a time-dependent force-force correlation function [54, 55],

$$\langle \hat{F}(t)\hat{F}(0) \rangle_Q = \frac{\text{Tr}[e^{-\hat{H}_B/kT} \hat{F}(t)\hat{F}(0)]}{\text{Tr}[e^{-\hat{H}_B/kT}]} \quad (\text{C3.5.2})$$

where

$$\hat{F}(t) = e^{i\hat{H}_B t} \hat{F} e^{-i\hat{H}_B t}$$

is the Heisenberg operator for the fluctuating forces and Tr denotes trace.

-5-

Equation (C3.5.2) is a function of bath coordinates only. The VER rate constant is proportional to the Fourier transform, at the oscillator frequency Ω , of the bath force-correlation function. This Fourier transform is proportional as well to the frequency-dependent friction $\eta(\Omega)$ mentioned previously. For example, the rate constant for VER of the fundamental ($\nu = 1$) to the ground ($\nu = 0$) state of an oscillator with frequency Ω is [54]

$$k_{1 \rightarrow 0} = \frac{1}{2\mu\hbar\Omega} \int_{-\infty}^{\infty} dt e^{i\Omega t} \langle \hat{F}(t)\hat{F}(0) \rangle_Q. \quad (\text{C3.5.3})$$

Equation (C3.5.3) shows the VER lifetime can be determined if the quantum mechanical force-correlation function is computed. However, it is at present impossible to compute this function accurately for complex systems. It is straightforward to compute the classical force-correlation function using classical molecular dynamics (MD) simulations. With the classical force-correlation function, a ‘quantum correction’ factor Q is needed [5],

$$k_{1 \rightarrow 0} = \frac{Q}{2\mu\hbar\Omega} \int_{-\infty}^{\infty} dt e^{i\Omega t} C(t) \quad (\text{C3.5.4})$$

where $C(t)$ is the classical force-force correlation function $C(t) = \langle F(t)F(0) \rangle$. For a harmonic bath, Bader and Berne [61] give the exact quantum correction,

$$Q = \frac{\hbar\Omega/kT}{1 - e^{-\hbar\Omega/kT}}. \quad (\text{C3.5.5})$$

Most realistic problems involve an anharmonic bath. How to determine \mathcal{Q} for an arbitrary anharmonic bath is not yet known. Other correction methods have been discussed, including the method proposed by Egelstaff [62].

In diatomic VER, the frequency Ω is often much greater than ω_D , so VER requires a high-order multiphonon process (see example C3.5.6.1). Because polyatomic molecules have several vibrations ranging from higher to lower frequencies, only lower-order phonon processes are ordinarily needed [34]. The usual practice is to expand the interaction Hamiltonian $\hat{V}(q_\Omega, \mathcal{Q})$ in equation (C3.5.2) in powers of normal coordinates [34, 63],

$$\begin{aligned}\hat{V} = & \sum_{\alpha} \frac{\partial \hat{V}}{\partial Q_{\alpha}} \Big|_{\{Q=0\}} Q_{\alpha} + \frac{1}{2!} \sum_{\alpha, \gamma} \frac{\partial^2 \hat{V}}{\partial Q_{\alpha} \partial Q_{\gamma}} \Big|_{\{Q=0\}} Q_{\alpha} Q_{\gamma} \\ & + \frac{1}{3!} \sum_{\alpha, \gamma, \delta} \frac{\partial^3 \hat{V}}{\partial Q_{\alpha} \partial Q_{\gamma} \partial Q_{\delta}} \Big|_{\{Q=0\}} Q_{\alpha} Q_{\gamma} Q_{\delta} \\ & + \frac{1}{4!} \sum_{\alpha, \gamma, \delta, \epsilon} \frac{\partial^4 \hat{V}}{\partial Q_{\alpha} \partial Q_{\gamma} \partial Q_{\delta} \partial Q_{\epsilon}} \Big|_{\{Q=0\}} Q_{\alpha} Q_{\gamma} Q_{\delta} Q_{\epsilon} + \dots\end{aligned}\quad (\text{C3.5.6})$$

For polyatomics, ordinarily only the last two terms of equation (C3.5.6), the cubic and quartic anharmonic terms, need be considered [34]. In a cubic anharmonic process, excited vibration Ω relaxes by interacting with two other states, say another vibration ω and one phonon (or alternatively two phonons). In the quartic process, Ω relaxes by interacting with three other states, say two vibrations and one phonon. The total rate constant for energy loss from Ω for cubic

-6-

coupling was given by Fayer and co-workers as [34]

$$K_{\Omega} = \sum_{\omega} [n_{\omega}(1 + n_{\Omega+\omega})\rho_{\Omega+\omega}C_{\Omega+\omega} + (1 + n_{\omega})(\alpha + n_{|\Omega+\omega|})\rho_{\Omega-\omega}C_{|\Omega-\omega|}] \quad (\text{C3.5.7})$$

where n_{ω} is the thermal occupation number,

$$n_{\omega} = (e^{\hbar\omega/kT} - 1)^{-1} \quad (\text{C3.5.8})$$

ρ_{ω} is the density of phonon states at ω , C_{ω} is a product of coupling constants which contains factors such as $\hbar/2\mu\omega$ and the derivatives of V in equation (C3.5.6) and $\alpha = 1$ if $\Omega > \omega$ or $\alpha = 0$ if $\Omega < \omega$. When $T \rightarrow 0$, all the thermal occupation factors in equation (C3.5.7) vanish, but the VER rate does not vanish. VER is then said to occur via spontaneous emission of phonons. As T is increased, two new thermally activated processes turn on. One involves stimulated phonon emission and the other phonon absorption. Spontaneous and stimulated emission processes convert Ω to a lower-energy vibration ω (down-conversion). Phonon absorption converts Ω to a higher-energy vibration ω (up-conversion). Figure C3.5.2 from Kenkre *et al* [34] shows all the possible VER processes which can occur via cubic or quartic anharmonic coupling.

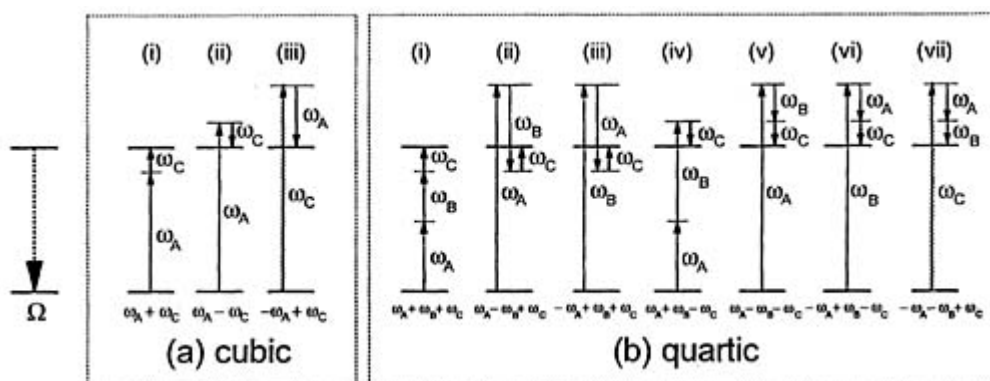

Figure C3.5.2. VER transitions involved in the decay of vibration Ω by cubic and quartic anharmonic coupling (from [34]). Transitions involving discrete vibrations are represented by arrows. Transitions involving phonons (continuous energy states) are represented by wiggly arrows. In (a), the transition denoted (i) is the ladder down-conversion process, where Ω is annihilated and a lower-energy vibration ω_A and a phonon ω_C are created.

C3.5.5 EXPERIMENTAL TECHNIQUES

Experimental techniques have been reviewed extensively, e.g. [6]. Only a brief discussion will be presented here.

C3.5.5.1 CREATING VIBRATIONAL EXCITATIONS

The easiest method for creating many vibrational excitations is to use convenient pulsed visible or near-UV lasers to pump electronic transitions of molecules which undergo fast nonradiative processes such as internal conversion (e.g. porphyrin [64, 65] or near-IR dyes [66, 67, 68 and 69]), photoisomerization (e.g. stilbene [12] or photodissociation (e.g. HgI_2 [8]). Creating a specific vibrational excitation Ω in a controlled way requires more finesse. The easiest method is to use visible or near-UV pulses to resonantly pump a vibronic transition (e.g. $S_0^0 \rightarrow S_1^\Omega$, where S_n denotes an electronic singlet state) of a coloured molecule [6]. Vibronic relaxation may be complicated by the presence of multiple electronic states (see example C3.5.6.1). Nonresonant pumping using visible or near-IR pulses can pump an S_0^Ω vibration by stimulated Raman scattering (SRS) [70]. SRS excites a specific vibration (with the largest Raman cross-section) but one cannot select which vibration that will be and the high intensities needed for SRS often produce unwanted parasitic optical effects. Resonant mid-IR pumping of specific vibrational transitions ($S_0^0 \rightarrow S_1^\Omega$) seems to produce fewer parasitic effects and has become increasingly popular, given recent improvements in tunable mid-IR pulse generation.

C3.5.5.2 PROBING VIBRATIONAL EXCITATIONS

Vibronic excitations are relatively easy to probe using resonant visible or near-UV processes such as vibronic absorption or vibronic fluorescence. Here we will concentrate mainly on probing vibrational excitations produced by mid-IR pumping. Two powerful but technically difficult techniques which are becoming increasingly important are probing by IR absorption (two-colour IR pump-probe method) or probing by incoherent anti-Stokes Raman scattering with a nonresonant pulse (IR-Raman method).

C3.5.5.3 EXPERIMENTAL TECHNIQUES

Schematic diagrams of modern experimental apparatus used for IR pump-probe by Fayer and co-workers [50] and for IR-Raman experiments by Dlott and co-workers [39] are shown in figure C3.5.3. Ultrafast mid-IR pulse generation by optical parametric amplification (OPA) [71] will not be discussed here. Single-colour IR pump-probe or vibrational echo experiments have been performed with OPAs or free-electron lasers. Free-electron lasers use

relativistic electron bunches travelling through periodic magnetic fields to generate tunable light pulses [72]. Two-colour IR pump–probe experiments use a pair of OPAs or one OPA and a continuous probe laser and a high-speed optical detection scheme [73]. In pump–probe experiments, the modulation of a weaker probe pulse by the pump pulse is monitored with an IR detector. Vibrational echo experiments (see example C3.5.6.4) use essentially the same apparatus, but instead two intense pulses are directed to the sample and a third pulse (the echo), emitted by the sample in a unique direction, is detected.

-8-

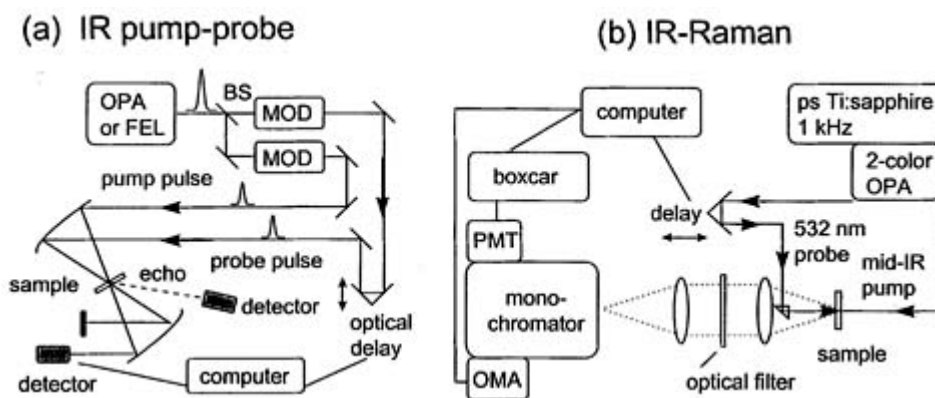

Figure C3.5.3. Schematic diagram of apparatus used for (a) IR pump–probe or vibrational echo spectroscopy by Fayer and co-workers [50] and (b) IR–Raman spectroscopy by Dlott and co-workers [39]. Key: OPA = optical parametric amplifier; FEL = free-electron laser; MOD = high speed optical modulator; PMT = photomultiplier; OMA = optical multichannel analyser.

For IR–Raman experiments, a mid-IR pump pulse from an OPA and a visible Raman probe pulse are used. The Raman probe is generated either by frequency doubling a solid-state laser which pumps the OPA [16], or by a two-colour OPA [39]. Transient anti-Stokes emission is detected with a monochromator and photomultiplier [39], or a spectrograph and optical multichannel analyser [40].

C3.5.5.4 INTERPRETING EXPERIMENTAL MEASUREMENTS

Most molecular vibrations are well described as harmonic oscillators with small anharmonic perturbations [5]. For an harmonic oscillator, all single-quantum transitions have the same frequency, and the intensity of single-quantum transitions increases linearly with quantum number ν . For the usual anharmonic oscillator, the single-quantum transition frequency decreases as ν increases. Ultrashort pulses have a non-negligible frequency bandwidth. For a 1 ps duration pulse, the bandwidth is at minimum $\sim 15 \text{ cm}^{-1}$; for a 100 fs pulse $\sim 150 \text{ cm}^{-1}$. We need to consider two cases, narrow-band pulses (bandwidth less than the anharmonicity) or broad-band pulses (bandwidth greater than the anharmonicity).

Consider narrow-band pulses pumping and probing the fundamental transition of an anharmonic oscillator Ω . The pulse will not be resonant with overtone transitions, so the oscillator is viewed as a two-level system. A two-level system can be saturated, so a pump–probe experiment can measure the VER rate by pumping the system and measuring the absorption recovery rate [45]. There is, however, an interpretation problem. It is difficult to distinguish between decay of Ω with direct repopulation of the ground state, and decay of Ω with population of a different vibration ω by the ladder process $\Omega \rightarrow \omega$ [74]. What the probe sees depends on the frequency shift of the Ω fundamental transition when ω is excited, caused by $Q_{\Omega}Q_{\omega}^2$ and other terms in equation (C3.5.6). If this shift is too small for the probe to resolve, then energy transfer from Ω to ω causes the Ω absorption to recover with decay rate constant K_{Ω} from equation (C3.5.7). If the shift is larger, absorption does not recover with rate constant K_{Ω} , but instead absorption recovery involves both decay constants K_{Ω} and K_{ω} . A two-colour pump–probe experiment greatly alleviates this problem, since a broadly tunable probe pulse could monitor fundamental and overtone transitions of both Ω [73] and ω transitions. Anti-Stokes Raman probing is perhaps even better, since the Raman pulse may simultaneously probe all transitions [40], including transitions of ω and Ω .

With broad-band pulses, pumping and probing processes become more complicated. With a broad-bandwidth pulse it is easy to drive fundamental and overtone transitions simultaneously, generating a complicated population distribution which depends on details of pulse structure [75]. Broad-band probe pulses may be unable to distinguish between fundamental and overtone transitions. For example in IR–Raman experiments with broad-band probe pulses, excitation of the first overtone of a transition appears as a fundamental excitation with twice the intensity, and excitation of a combination band $\Omega + \omega$ appears as excitation of the two fundamentals [76].

C3.5.6 VIBRATIONAL RELAXATION EXAMPLES

C3.5.6.1 DIATOMIC MOLECULES IN RARE GAS CRYSTALS

In rare gas crystals [77] and liquids [78], diatomic molecule vibrational and vibronic relaxation have been studied. In crystals, VER occurs by multiphonon emission. Everything else held constant, the VER rate should decrease exponentially with the number of emitted phonons (exponential gap law) [79, 80]. The number of emitted phonons scales as, and should be close to, the ratio Ω/ω_D , where ω_D is the Debye frequency. A possible complication is the perturbation of the local phonon density of states by the diatomic molecule guest [77].

Apkarian and co-workers used ultrafast spectroscopy to investigate vibrational relaxation of I_2 ($\Omega = 212 \text{ cm}^{-1}$) in solid Kr ($\omega_D = 50 \text{ cm}^{-1}$) and vibronic relaxation of XeF ($\Omega = 424 \text{ cm}^{-1}$) in solid Ar ($\omega_D = 65 \text{ cm}^{-1}$). I_2 , in a Kr lattice at 15 K, is photodissociated by a subpicosecond visible pulse and probed by transient absorption [81]. The impulsive photodissociation hurls the two I atoms against the walls of a Kr cage. The atoms recoil and then recombine to form nascent vibrationally excited I_2 . Figure C3.5.4 [81] shows the rate of ensemble-averaged vibrational energy loss from I_2 . In the first 5 ps, energy loss is fast and stepwise due to individual binary collisions. After that time, energy loss from any individual molecule most likely involves a stepwise relaxation, but ensemble averaging wipes out the details, so in the longer time region the ensemble averaged energy loss is exponential in time with a time constant of 12 ps. This VER process is much faster than VER of liquid O_2 discussed below, probably because the ratio $\Omega/\omega_D \sim 4$ is relatively small.

Vibronic relaxation of XeF in solid Ar at 25 K was studied by pumping vibronic transitions with a subpicosecond UV pulse, and detecting frequency-resolved emission with a fast optical gate [25]. XeF has two sites in Ar, one which emits only from the $B(^2\Sigma_{1/2})$ state and one which emits only from the $C(^2\Pi_{3/2})$ state. Very fast VER was observed in the C-emitting site. Excitation near $v = 20$ results in a return to $v = 0$ in 13 ps, about the same as I_2 in Kr. In the B-emitting states, a slower stepwise relaxation was observed. Figure C3.5.5 shows the possible modes of relaxation for B-emitting XeF and some experimentally determined time constants. Although a diatomic in an atomic lattice seems to be a simple system, these vibronic relaxation experiments are rather complicated to interpret, because of multiple electronic states which are involved due to energy transfer between B and C sites.

Figure C3.5.4. Ensemble-averaged loss of energy from vibrationally excited I_2 created by photodissociation and subsequent recombination in solid Kr, from [81]. The inset shows calculated transient absorption (pump-probe) signals for inner turning points at 3.5, 3.4 or 3.3 Å.

Figure C3.5.5. Vibronic relaxation time constants for B- and C-state emitting sites of XeF in solid Ar for different vibrational quantum numbers ν , from [25]. Vibronic energy relaxation is complicated by electronic crossings caused by energy transfer between sites.

C3.5.6.2 LIQUID OXYGEN

The VER lifetime of liquid O_2 is 280 ms at 70 K [82]. Predicting such a slow rate from theory is a formidable challenge taken up by Skinner and co-workers [54] in a recent paper. The fundamental frequency of O_2 is 1552 cm^{-1} , whereas the maximum characteristic frequency for motion in the liquid (analogous to ω_D) is $\sim 50 \text{ cm}^{-1}$, so an extremely high-order multiphonon process ($\Omega/\omega_D \sim 30$) is needed for VER [54].

VER in liquid O_2 is far too slow to be studied directly by nonequilibrium simulations. The force-correlation function, equation (C3.5.2), was computed from an equilibrium simulation of rigid O_2 . The VER rate constant given in equation (C3.5.3) is proportional to the Fourier transform of the force-correlation function at the O_2 frequency. However, there are two significant practical difficulties. First, the Fourier transform, denoted $\hat{C}(\Omega)$ in

[54] ($\hat{C}(\Omega)$ is not an operator but rather a classical mechanical function), is needed at a frequency $\Omega \gg \omega_D$ where its value is very small. It is difficult to compute $\hat{C}(\Omega)$ accurately at large Ω given the statistical noise in the simulation. Second, the simulation uses classical mechanics, and a quantum correction factor defined in equation (C3.5.4) is needed. The first problem is alleviated using the Wiener–Khintchine theorem [54]. Instead of Fourier transforming the correlation function over the time range of $-\infty$ to $+\infty$, it is more accurate to Fourier transform the fluctuating force itself over a finite time range of $-\tau$ to $+\tau$.

The computed Fourier transform is shown in figure C3.5.6. The O_2 frequency is $\Omega = 2.925 \times 10^{14} \text{ s}^{-1}$. Above $\Omega = 0.8 \times 10^{14} \text{ s}^{-1}$, is very noisy. The result from the Wiener–Khintchine theorem in figure C3.5.6 is believed to be accurate up to $\Omega = 1.5 \times 10^{14} \text{ s}^{-1}$. In order to extend the result to the needed high frequency, an *ansatz* was made that the correlation function $C(t)$ must have the form

$$C(t) = C_0 \frac{\cos(bt)}{\cosh(at)} \quad (\text{C3.5.9})$$

where the coefficients a and b are determined so that equation (C3.5.9) has the same short-time expansion, through order t^4 , as the exact correlation function [54]. By Fourier transforming equation (C3.5.9) analytically, a result for the VER rate can be determined,

$$k_{1 \rightarrow 0} = \frac{\pi Q C_0 \cosh(\pi \Omega / 2a) \cosh(\pi b / 2a)}{\mu \hbar \Omega a [\cosh(\pi \Omega / a) + \cosh(\pi b / a)]} \quad (\text{C3.5.10})$$

Figure C3.5.6 compares the result of this *ansatz* to the numerical result from the Wiener–Khintchine theorem. They agree well and the *ansatz* exhibits the expected exponential energy-gap law (VER rate decreases exponentially with Ω). The *ansatz* was used to determine the VER rate with no quantum correction ($Q = 1$), with the Bader–Berne harmonic correction [61] and with a correction based [83, 84] on Egelstaff’s method [62]. The Egelstaff corrected results were within a factor of five of experiment, whereas other corrections were off by orders of magnitude. This calculation represents the present state of the art in computing VER rates in such difficult systems, inasmuch as the authors used only a model potential and no adjustable parameters. However the *ansatz* procedure is clearly not extendible to polyatomic molecules or to diatomic molecules in polyatomic solvents.

Figure C3.5.6. The computed Fourier transform at frequency ω , $\hat{C}(\omega)$, of the classical mechanical force–force correlation function for liquid O₂ at 70 K from [54]. The VER rate is proportional to the value of $\hat{C}(\omega)$ at the O₂ vibrational frequency $2.925 \times 10^{14} \text{ s}^{-1}$, multiplied by the quantum correction Q . The solid line is obtained from direct Fourier transformation of the simulation. The thick solid line is obtained from the Wiener–Kjhintchine theorem, and the dashed line is an *ansatz* proposed by the authors.

C3.5.6.3 SMALL-MOLECULE REACTION DYNAMICS IN SOLUTION

Chemical reaction dynamics is an attempt to understand chemical reactions at the level of individual quantum states. Much work has been done on isolated molecules in molecular beams, but it is unlikely that this information can be used to understand condensed phase chemistry at the same level [8]. In a bath, the reacting solute’s potential energy surface is altered by both dynamic and static effects. The static effect is characterized by a potential of mean force. The dynamical effects are characterized by the force-correlation function or the frequency-dependent friction [8].

Photodissociation of a linear triatomic such as I₃⁻ [85, 86] or HgI₂ [8] to produce a vibrationally excited diatomic, or cage recombination of a photodissociated diatomic such as I₂ [78, 81] are classic model simple systems for reaction dynamics. Here we discuss the HgI₂ → HgI + I reaction studied by Hochstrasser and co-workers [87, 88 and 89]. The important issues are how energy is partitioned, the degree of coherence in the formation of the product and whether the reaction is adiabatic (solvent easily follows reactant motions) or nonadiabatic [8]. A nonadiabatic theory would be much more complicated.

Pumping HgI₂ in ethanol with a femtosecond UV pulse causes impulsive photodissociation, producing HgI with average vibrational quantum number $\nu = 15$ [88]. There are several possibilities for nascent HgI, as depicted in [figure C3.5.7](#) [8]. The smooth Gaussian function represents the ensemble-average of HgI vibrational displacements (vibrational wavepacket). In possibility A, there is no VER and no vibrational dephasing. All HgI fragments simply oscillate coherently. In B, VER is faster than a vibrational period, so HgI loses energy before vibrating even once.

An

-13-

ensemble of coherently vibrating ground state HgI results. In C, the VER rate is comparable to a vibrational period, so there will be some coherence in the ground state. In D, dephasing (caused by quartic anharmonic coupling to a dynamic bath) is faster than VER, so the wavepacket spreads (dephases) much faster than it loses energy.

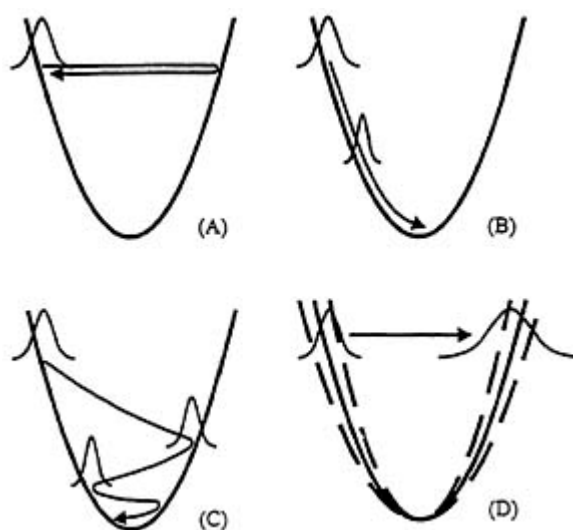

Figure C3.5.7. Possible modes of vibrational wavepacket (smooth Gaussian curve) motion for a highly vibrationally excited diatomic molecule produced by photodissociation of a linear triatomic such as HgI₂, from [8].

(A) no VER and no dephasing. (B) VER is faster than a vibrational period. Once the vibrational ground state is reached, the wavepacket begins to oscillate coherently. (C) The VER rate is comparable to a vibrational period so some coherence is seen in both excited and ground states. (D) Dephasing is faster than VER.

In HgI, possibility C is the best description [8]. The dephasing time constant is ~ 150 fs and the overall time for vibrational cooling is ~ 200 fs. Thus coherence is seen in the vibrational excited states, and in the ground state as well. A molecular dynamics simulation of rigid HgI in ethanol was used to understand the VER mechanism [90]. The computed frequency-dependent friction is shown in [figure C3.5.8](#) [90]. Notice this function is much more complicated than in liquid O_2 ([figure C3.5.6](#)), and an exponential gap law is not observed. The simulation results were used to conclude VER at the 130 cm^{-1} frequency of HgI was dominated by Lennard-Jones interactions between solute and solvent. The solvent nuclear response is a few times faster than the vibrational period, so the HgI–ethanol system is close to the adiabatic limit.

-14-

Figure C3.5.8. Computed frequency-dependent friction (inversely proportional to the VER lifetime T_1) from a classical molecular dynamics simulation of rigid HgI molecules in ethanol solution, from [90]. The HgI vibrational frequency is 125 cm^{-1} . The Lennard-Jones contribution to the friction dominates the Coulombic contribution at that frequency.

C3.5.6.4 TEMPERATURE DEPENDENCE OF VIBRATIONAL LINESHAPES

VER rates cannot be predicted from vibrational lineshapes alone [5] except for a few exceptional cases [2, 91]. The most detailed deconstruction of vibrational lineshapes to date is the work of Fayer and co-workers [92], who studied $W(CO)_6$ in glass-forming liquids including 2-methyl pentane (2MP; $T_g = 80$ K). The triply degenerate asymmetric $C\equiv O$ stretch of $W(CO)_6$ ($\Omega \sim 1980\text{ cm}^{-1}$) has a VER lifetime which is solvent and temperature dependent. In 2-MP at 300 K, the lifetime is ~ 150 ps.

Infrared absorption was used to measure the total lineshape. Vibrational echo spectroscopy (the vibrational analogue of spin echoes in magnetic resonance [93]) was used to remove inhomogeneous broadening, to reveal the underlying homogeneous lineshape. One-color pump–probe with magic-angle polarization was used to measure the VER lifetime. Pump–probe polarization anisotropy was used to measure the orientational relaxation rate.

The vibrational echo experiments yielded exponential decays at all temperatures. The Fourier-transform of the echo decay gives the homogeneous lineshape, in this case Lorentzian. The echo decay time constant is $4T_2$, where T_2 is the vibrational dephasing time constant, and the corresponding homogeneous linewidth $\Gamma_{\text{hom}} = 1\pi T_2$. At low temperature (~ 10 K) in 2-MP glass, the total linewidth is $\Gamma_{\text{tot}} = 300$ GHz (30 GHz = 1 cm $^{-1}$), whereas $\Gamma_{\text{hom}} \sim 1.5$ GHz.

-15-

Therefore, the absorption line is massively inhomogeneously broadened at low temperature. An inhomogeneous lineshape can be used to determine the static or quasistatic frequency spread of oscillators due to a distribution of environments, but it provides no dynamical information whatsoever [94, 95]. As T is increased to 300 K, the absorption linewidth Γ_{tot} decreases and Γ_{hom} increases. At 300 K, the lineshape is nearly homogeneously broadened and dominated by vibrational dephasing, because fast dephasing wipes out effects of inhomogeneous environments, a well known phenomenon termed ‘motional narrowing’ [95].

The homogeneous linewidth Γ_{hom} can be subdivided into distinctly different contributions,

$$\Gamma_{\text{hom}} = \frac{1}{\pi T_2} = \frac{1}{\pi T_2^*} + \frac{1}{2\pi T_1} + \Gamma_{\text{or}}$$

where T_2^* is the time constant for ‘pure dephasing’ processes which modulate only the oscillator phase, and Γ_{or} is the contribution from orientational relaxation [92]. Orientational relaxation refers either to molecular rotation (impossible below T_g) or interconversion among nearly degenerate $C\equiv$ stretching transitions of different symmetry [96]. The parameters T_2 , T_1 and Γ_{or} are measured from echo and pump–probe experiments, and T_2^* is computed by substituting those parameters into this equation.

Figure C3.5.9 shows all contributions to the homogeneous linewidth of $W(\text{CO})_6$ in 2-MP. Γ_{hom} increases from about 1.5 to 100 GHz from 10 to 300 K. Pure dephasing and orientational contributions to Γ_{hom} vanish as $T \rightarrow 0$, leaving only the VER contribution. As T is increased, the VER lifetime decreases slightly with increasing temperature. This counterintuitive temperature dependence is not seen explicitly in equation (C3.5.7). However, a thermal slowdown of VER can happen if the C_m or ρ_m factors decrease with increasing T and the occupation numbers $n_m(T)$ involve only high frequencies $\hbar\omega \gg kT$ [34]. The orientational contribution increases with T , but it never contributes much to the total lineshape. At ~ 50 K the homogeneous line undergoes a transition from VER dominance to pure dephasing dominance. Thus the VER contribution to the lineshape is hidden at lower temperatures by inhomogeneous broadening and, at higher temperatures, by pure dephasing.

-16-

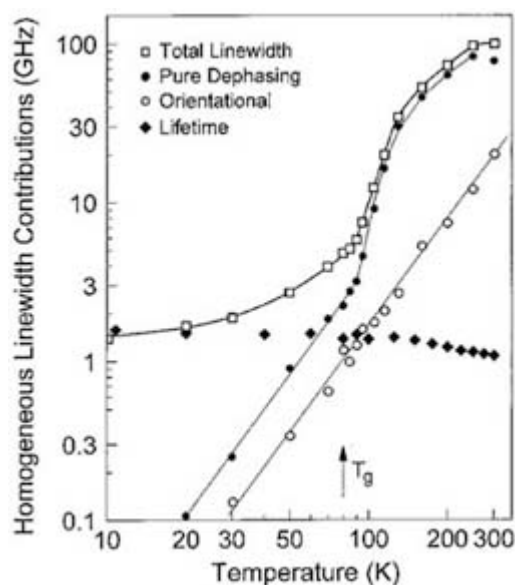

Figure C3.5.9. Contributions to the homogeneous linewidth of a C≡O stretching transition of $W(CO)_6$ ($\Omega \sim 2000 \text{ cm}^{-1}$) in a glass-forming liquid, 2-methyl pentane, from [92]. The total homogeneous linewidth Γ_{hom} is measured with vibrational echo spectroscopy, which removes inhomogeneous broadening. The VER lifetime τ_1^{hom} and orientational relaxation contribution Γ_{or} are measured with pump–probe experiments. The pure dephasing time constant τ_2^{h} is computed from the other results. VER dominates the homogeneous lineshape at low temperature. Pure dephasing dominates at high temperature.

C3.5.6.5 POLYATOMIC MOLECULES IN LOW-TEMPERATURE CRYSTALS—FREQUENCY DEPENDENCE

Much of our knowledge of the frequency dependence of VER rates in polyatomic molecules stems from low-temperature studies of molecular crystals [2] such as pentacene (PTC; $C_{22}H_{14}$) guest molecules in a crystalline naphthalene (N; $C_{10}H_8$) host. In naphthalene, the phonon cut-off frequency is $\sim 180 \text{ cm}^{-1}$ [97]. At low temperature, PTC has well resolved vibronic transitions ($S_0^0 \rightarrow S_1^{\Omega}$) in a convenient wavelength range for picosecond dye lasers (560–605 nm).

Vibronic relaxation of PTC/N was studied by Hesselink and Wiersma [98, 99], who used ultrafast vibronic echoes to measure dephasing rates of 16 PTC vibronic transitions at low temperature (1.5 K), where vibronic dephasing is dominated by VER. Their results are shown in figure C3.5.10. The lower-frequency vibrations ($< 350 \text{ cm}^{-1}$) have shorter lifetimes in the 2 ps range. The mid-frequency vibrations (350 to 1000 cm^{-1}) have generally longer lifetimes up to 40 ps. The higher-frequency vibrations ($> 1000 \text{ cm}^{-1}$) have shorter lifetimes. These results generally support the three-regime model proposed by Nitzan and Jortner [35]. Below regime I ($\leq 360 \text{ cm}^{-1}$), vibrations relax efficiently by two-phonon emission. Above 360 cm^{-1} vibrational lifetimes become longer (regime II) until IVR becomes dominant in regime III, because the vibrational density of states becomes large enough ($> 10^2 \text{ states cm}^{-1}$) for efficient IVR.

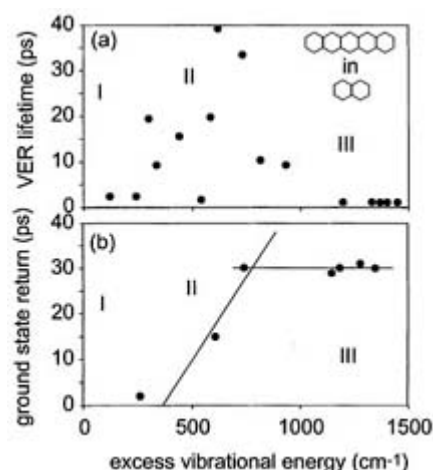

Figure C3.5.10. Frequency-dependent vibronic relaxation data for pentacene (PTC) in naphthalene (N) crystals at 1.5 K. (a) Vibrational echoes are used to measure VER lifetimes (from [99]). The lifetimes are shorter in regime I, longer in regime II, and become shorter again in regime III. (b) Two-colour pump–probe experiments are used to measure vibrational cooling (return to the ground state) from [102].

VER measurements of individual levels do not necessarily indicate the overall rate of vibrational energy loss from PTC molecules. Vibrational energy loss is a multistep process termed ‘vibrational cooling’ (VC) if ladder processes (vibrational cascades) are important [100]. Chang and Dlott measured VC rates in PTC/N with two-color pump probe experiments [101, 102]. The first pulse pumps an $S_0^0 \rightarrow S_1^0$ vibronic transition and the second pulse measures the return to S_1^0 by probing the $S_1^0 \rightarrow S_0^0$ transition. The return kinetics are nonexponential in time. By fitting the data to a VC model, time constants shown in figure C3.5.10 were extracted. The decay of regime I vibrations directly repopulates the ground state, so VER and VC rates are identical. The decay of regime II vibrations occur by a ladder process, so the VC rate increases higher up the ladder. The decay of regime III vibrations occurs by fast IVR. Some of that redistributed energy populates longer-lived regime II states, so in regime III the VC rate levels out at about the maximum VC rate in regime II.

C3.5.6.6 VER OF A POLYATOMIC LIQUID

The decay of C–H stretching (and OH and NH) vibrations in liquids has been studied by IR–Raman spectroscopy [6]. Early work on ethanol by Alfano and Shapiro [23] indicated that C–H stretch excitations ($\sim 3000\text{ cm}^{-1}$) decayed by populating C–H bending excitations ($\sim 1500\text{ cm}^{-1}$). However, until recently it was not known where the rest of the energy went, or the subsequent fate of the daughter C–H bending excitations. Dlott and co-workers used IR–Raman techniques to monitor the flow of vibrational energy through several polyatomic molecule systems [39, 41, 42]. Data for one example, acetonitrile ($\text{CH}_3\text{C}\equiv\text{N}$), are shown in figure C3.5.11 [6]. Acetonitrile is a model for nonassociated polar polyatomic liquids [103, 104 and 105].

Figure C3.5.11. IR–Raman measurements of vibrational energy flow through acetonitrile in a neat liquid at 300 K, adapted from [41]. An ultrashort mid-IR pulse pumps the C–H stretch, which decays in 3 ps. Only 1% of the energy is transferred to the C≡N stretch, which has an 80 ps lifetime. Most of the energy is transferred to the C–H bend plus about four quanta of C–C≡N bend. The daughter C–H bend vibration relaxes by exciting the C–C stretch. The build-up of energy in the C–C≡N bend mirrors the build-up of energy in the bath, which continues for about 250 ps after C–H stretch pumping.

An ultrashort mid-IR pulse excited a C–H stretching vibration ($\sim 3000\text{ cm}^{-1}$) of neat acetonitrile at 300 K. The loss of C–H stretching energy occurred in 3 ps. Only 1% of that energy was transferred to the C≡N stretch (2250 cm^{-1}), where it remained for ~ 80 ps. Most of the energy was lost from the C–H stretch by the process,

which accounts for the ~ 3 ps rise of excitation of the C–C≡N bending vibration ($\sim 400\text{ cm}^{-1}$). The C–H bending excitation decays in 15 ps, exciting lower-energy C–C stretch, C–C bend and C≡N bending modes. The C–C stretch and C–C bend decay with quite long lifetimes, in the 50 ps range. All vibrational energy is dissipated to the bath in ~ 250 ps. There is a net temperature increase of $\sim 10^\circ\text{C}$ in the bath, which accounts for the long-time-scale build-up of the C–C≡N bending population. Whereas C–H stretch lifetime measurements indicate a VER lifetime of 3 ps, vibrational cooling actually takes ~ 250 ps. Frequency-dependent VER lifetimes in acetonitrile generally support the model of Nitzan and Jortner [35], with an exception being the long-lived high-frequency C≡N stretch [41].

C3.5.7 CONCLUDING REMARKS

Understanding VER in condensed phases has proven difficult. The experiments are hard. The structurally simple systems (diatomic molecules) involve complicated relaxation mechanisms. The structures of polyatomic molecules are obviously more complex, but polyatomic systems are tractable because the VER mechanisms are somewhat simpler.

There are encouraging signs that condensed-phase VER is an important fundamental problem which is due for a major breakthrough. Theoreticians are finally having success in predicting VER rates of simple systems, and have begun to understand the multiple roles of VER in chemical reaction dynamics. Experimental technology has improved a great deal. As a result, we are beginning to accumulate data on several different molecular liquids and solids, vibrational energy flowing through a polyatomic molecule can be monitored in real time—even protein VER can be measured—and the first direct observations of chemical reaction dynamics in solution have been

reported. Nevertheless, much remains to be done in the areas of predicting and understanding VER rates, developing simple but robust conceptual frameworks and incorporating our emerging understanding of VER into theories of chemical reaction dynamics, electron transfer, protein dynamics and other condensed-phase dynamical processes.

C3.6 Chaos and complexity in chemical systems

Raymond Kapral and Simon J Fraser

C3.6.1 INTRODUCTION

Complex chemical mechanisms are written as sequences of elementary steps satisfying detailed balance where the forward and reverse reaction rates are equal at equilibrium. The laws of mass action kinetics are applied to each reaction step to write the overall rate law for the reaction. The form of chemical kinetic rate laws constructed in this manner ensures that the system will relax to a unique equilibrium state which can be characterized using the laws of thermodynamics.

Most chemically reacting systems that we encounter are not thermodynamically controlled since reactions are often carried out under non-equilibrium conditions where flows of matter or energy prevent the system from relaxing to equilibrium. Almost all biochemical reactions in living systems are of this type as are industrial processes carried out in open chemical reactors. In addition, the transient dynamics of closed systems may occur on long time scales and resemble the sustained behaviour of systems in non-equilibrium conditions. A reacting system may behave in unusual ways: there may be more than one stable steady state, the system may oscillate, sometimes with a complicated pattern of oscillations, or even show chaotic variations of chemical concentrations.

Analogous considerations apply to spatially distributed reacting media where diffusion is the only mechanism for mixing chemical species. Under equilibrium conditions any inhomogeneity in the system will be removed by diffusion and the system will relax to a state where chemical concentrations are uniform throughout the medium. However, under non-equilibrium conditions chemical patterns can form. These patterns may be regular, stationary variations of high and low chemical concentrations in space or may take the form of time-dependent structures where chemical concentrations vary in both space and time with complex or chaotic forms.

In this chapter we shall examine how such temporal and spatial structures arise in far-from-equilibrium chemical systems. We first examine spatially uniform systems and develop the theoretical tools needed to analyse the behaviour of systems driven far from chemical equilibrium. We focus especially on the nature of chemical chaos, its characterization and the mechanisms for its onset. We then turn to spatially distributed systems and describe how regular and chaotic chemical patterns can form as a result of the interplay between reaction and diffusion.

This account is not exhaustive but provides a guide to the main theoretical ideas and experimental methods that have emerged in this subject. Fuller accounts and broad background are given in recent books devoted to this topic [[1](#), [2](#), [3](#), [4](#) and [5](#)].

C3.6.2 CHEMICAL REACTIONS AS DYNAMICAL SYSTEMS

Consider a spatially homogeneous reacting mixture where concentration gradients are removed by stirring or rapid

diffusion of the chemical species. In this circumstance the instantaneous state of the system is described by a vector set of chemical concentrations for the n chemical species, $\mathbf{c}(t) = (c_1(t), c_2(t), \dots, c_n(t))$, whose evolution is specified by the ordinary differential equations (ODEs) of mass action kinetics

$$\frac{dc(t)}{dt} = R_M(c(t); k). \quad (C3.6.1)$$

Here $R_M(c(t); k)$ is a vector of reaction velocities which are usually nonlinear functions of the chemical concentrations whose form is determined by the reaction mechanism. The reaction velocities also depend on the chemical rate constants, collectively described by the vector $k=(k_1, k_2, \dots)$, for the steps in the reaction mechanism.

For a closed chemical system with a mass action rate law satisfying detailed balance these kinetic equations have a unique stable (thermodynamic) equilibrium, $\lim_{t \rightarrow \infty} c(t) = c_{eq}$. In general, however, we shall be concerned with chemical reactions that are maintained far from chemical equilibrium by flows of reagents into and out of a continuously stirred tank reactor (CSTR). In this case the chemical kinetic equation (C3.6.1) must be supplemented with flow terms

$$\frac{dc(t)}{dt} = R_M(c(t); k) - k_f(c(t) - c_r) \equiv R(c(t); \mu) \quad (C3.6.2)$$

where k_f is the flow rate constant and c_r the vector of the feed concentrations. We have denoted the reaction rate in this general non-equilibrium case by $R(c(t); \mu)$ with μ as symbol for the collection of all parameters that characterize R : rate constants, feed concentrations and flow rates. Suppose the flow terms increase from zero; then this open system's stable state moves from the thermodynamic equilibrium, c_{eq} , to a nearby, non-equilibrium steady state, c_s , on the so-called thermodynamic branch. This non-equilibrium stable state of the system is the solution, $c=c_s$, of $R(c; \mu)=0$. However, if the flow terms become sufficiently large, this steady state becomes unstable and is replaced by new, non-equilibrium states characteristic of this well stirred system. (Transients mimicking the behaviour of the non-equilibrium states can be observed in closed reactors starting from initial conditions that are far from equilibrium.)

It is convenient to analyse these rate equations from a dynamical systems point of view similar to that used in classical mechanics where one follows the trajectories of particles in phase space. For the chemical rate law (C3.6.2) the 'phase space', conventionally denoted by Γ , is n -dimensional and the chemical concentrations, c_1, c_2, \dots, c_n , are taken as orthogonal coordinates of Γ , rather than the particle positions and velocities used as the coordinates in mechanics. In analogy to classical mechanical systems, as the concentrations evolve in time they will trace out a trajectory in Γ . Since the velocity functions in the system of ODEs (C3.6.2) do not depend explicitly on time, a given initial condition in Γ will always produce the same trajectory. The vector R of velocity functions in (C3.6.2) defines a phase-space (or trajectory) flow and in it is often convenient to think of these ODEs as describing the motion of a fluid in Γ with velocity field $R(c; \mu)$.

C3.6.2.1 CHEMICAL ATTRACTORS

Because of the underlying dissipative nature of the chemical systems that the ODEs (C3.6.2) represent, they have another important property: any volume in Γ will shrink as it evolves. For a given set of initial chemical concentrations the time evolution under the chemical rate law will approach arbitrarily close to some final set of points in

Γ after transients have decayed. This final set of phase-space points is the *attractor*, and the set of all initial conditions that eventually reaches the attractor is called its basin of attraction.

Attractors can be simple time-independent states (points in Γ), limit cycles (simple closed loops in Γ) corresponding to oscillatory variations of the chemical concentrations with a single amplitude, or chaotic states (complicated trajectories in Γ) corresponding to aperiodic variations of the chemical concentrations. To illustrate

the representation of chemical dynamics in concentration phase space and the existence of chemical attractors, we consider the Willamowski–Rössler (WR) model chemical system based on the following reaction mechanism [6]:

The species A_1, A_2, \dots, A_5 are pool chemicals whose concentrations are assumed to be fixed by flows of reagents into and out of the reactor while X_1, X_2 and X_3 are the species whose concentrations vary with time. For mechanism (C3.6.3) the mass action rate law is the system of ODEs

$$\begin{aligned}
 \frac{dc_1}{dt} &= k_1 c_{A_1} c_1 - k_{-1} c_1^2 - k_2 c_1 c_2 + k_{-2} c_2^2 - k_4 c_1 c_3 + k_{-4} \\
 \frac{dc_2}{dt} &= k_2 c_1 c_2 - k_{-2} c_2^2 - k_3 c_{A_5} c_2 + k_{-3} c_{A_2} \\
 \frac{dc_3}{dt} &= -k_4 c_1 c_3 + k_{-4} c_{A_3} + k_5 c_{A_4} c_3 - k_{-5} c_3^2.
 \end{aligned}
 \tag{C3.6.4}$$

For this model the parameter set μ consists of the rate constants and the constant pool chemical concentrations $\{c_{A_i}\}$ (Most chemical rate laws are constructed phenomenologically and often have cubic or other nonlinearities and irreversible steps. Such rate laws are reductions of the full underlying reaction mechanism.)

For certain parameter values this chemical system can exhibit fixed point, periodic or chaotic attractors in the three-dimensional concentration phase space. We consider the parameter set

$\mu = \{k_1 c_{A_1} = 31.2, k_{-1} = 0.2, k_2 = 1.45, k_3 c_{A_5} = 10.8, k_{-3} c_{A_2} = 0.12, k_4 = 1.02, k_{-4} = 0.01, k_5 c_{A_4}\}$. The rate constant k_{-2} will be taken as the control or *bifurcation* parameter which is varied to examine how the system attractor changes. As an example, the single-banded chaotic attractor at $k_{-2}=0.072$ for the WR model is shown in [figure C3.6.1\(a\)](#).

-4-

Figure C3.6.1 (a) WR single-banded chaotic attractor for $k_{-2} = 0.072$. This attractor is projected onto the (c_1, c_2) plane. The maximum value reached by $c_1(t)$ is $c_1^{\max} \approx 54.1$ and the minimum reached by $c_1^{\min} \approx 2.5$. The vertical line, at $c_1 = 8.5$ for $\dot{c}_1 < 1$, shows the position of the Poincaré section of the attractor used later. (b) A projection, onto the $(c_1(t_1), c_1(t_2))$ plane, of the chaotic attractor reconstructed from the set of delayed coordinates $\{c_1(t), c_1(t_1), c_1(t_2)\}$, where $t_1 = t + \tau_1$ and $t_2 = t + \tau_2$, for $0 \leq t < \infty$, and fixed delays $\tau_1 = 137$ and $\tau_2 = 200$. Note that both $c_1(t_1)$ and $c_1(t_2)$ reach a maximum of c_1^{\max} and a minimum of c_1^{\min} so that the three-dimensional reconstructed attractor is

confined to a cube with sides of length $c_1^{\max} - c_1^{\min}$. The central hole of the attractor is bounded along the diagonal in a similar way.

C3.6.2.2 PHASE-SPACE RECONSTRUCTION

The description of chemical reactions as trajectories in phase space requires that the concentrations of all chemical species be measured as a function of time, something that is rarely done in reaction kinetics studies. In addition, the underlying set of reaction intermediates is often unknown and the number of these may be very large. Usually, experimental data on the time variation of the concentration of a single chemical species or a small number of species are collected. (Some experiments focus on the simultaneous measurement of the concentrations of many chemical species and correlations in such data can be used to deduce the chemical mechanism [7].)

The trajectory description problem of chemical reactions is resolved by using phase-space reconstruction from a single time series [8]; this method uses delayed data at times: $t, t+\tau_1, t+\tau_2, \dots, t+\tau_{n-1}$ for an n -dimensional attractor, where usually $n \leq 3$. One may show that in place of the set of all chemical concentration one may use, say, $c_1(t), c_1(t+\tau_1), c_1(t+\tau_2), \dots$ to represent trajectories in the concentration phase space. Such phase-space reconstruction methods all rely on Whitney's embedding theorem [9] which allows a multi-dimensional attractor to be reconstructed from a single time series. Since phase-space volumes contract for dissipative chemical systems, as noted above, the final attractor may have a dimension much smaller than the original n -dimensional phase space. The effective behaviour of the system may often be captured in a phase space of only few dimensions even though many chemical intermediates are involved. To illustrate this reconstruction method, the set of delayed c_1 coordinates for chaotic attractor shown in figure C3.6.1(a): namely $(c_1(t), c_1(t+\tau), c_1(t+\tau_2))$, for t going from zero to some large value, was used to reconstruct the topologically equivalent attractor shown in figure C3.6.1(b).

C3.6.3 CHEMICAL CHAOS

We shall now analyse the structure of a chemical strange attractor and describe why the dynamics may be classified as chaotic.

C3.6.3.1 STRANGE ATTRACTORS

We begin by describing the features of a strange attractor. Figure C3.6.1(a) was constructed from a single chaotic trajectory which corresponds closely to a chaotic strange attractor, meaning that any such chaotic trajectory would look similar. Any point in the basin of the attractor approaches it asymptotically. A point moving on the strange attractor at some time comes arbitrarily close to any other point lying in the attractor, so motion on the attractor is *ergodic*; this is necessary but not sufficient for chaotic behaviour. To be chaotic the motion on the attractor must be *sensitive to initial conditions*, so that as time increases points on the attractor, however close together they may be initially, separate to distances comparable to the size of the attractor over a sufficiently long time. The rate of separation is measured by the Lyapunov number. In order that such separation be compatible with bounded motion, i.e. with the observation that the strange attractor lies in a finite volume of phase space, the chaotic (phase-space) flow must stretch and fold back onto itself. If we imagine a parcel of (compressible) fluid in phase space we see that this folding implies creation of infinitely many layers like the repeated folding of mille-feuille pastry. Correspondingly, the chaotic attractor is the result of an infinity of similar foldings. This dynamical recursion produces a self-similarity or fractal structure in the chaotic attractor. In summary, the chaotic attractor displays (exponential) separation of points or orbit segments and self-similar structure in the way these orbit segments are arranged in space.

C3.6.3.2 POINCARÉ SECTIONS AND NEXT-AMPLITUDE MAPS

For the strongly contracting phase volumes associated with chemical reactions, the three-dimensional continuous-

time flow can be reduced to a one-dimensional discrete-time map as follows. We first construct the Poincaré section of the attractor flow. For the projection shown in [figure C3.6.1\(a\)](#) the flow is counter-clockwise implying \dot{c} above the central hole in the single-banded attractor. Therefore this flow will circulate round this hole and repeatedly intersect the Poincaré surface of section ($c_1 \equiv c_1^{\text{sect}} = 8.5$), indicated by the heavy vertical line in [\(C3.6.1\(a\)\)](#), from right to left. Suppose that at time t_0 the trajectory intersects this Poincaré surface at a point $(c_2(t_0), c_3(t_0))$; at time t_1 it makes its next or so-called *first* return to the surface at point $(c_2(t_1), c_3(t_1))$. This process continues for times t_2, t_3, \dots , the difference $t_{n+1} - t_n$ being the period of the n th first-return trajectory segment. The sequence of points generated by these intersections is the Poincaré section and is plotted in [figure C3.6.2\(b\)](#). The thin line-like form arises from the strong contraction of the flow onto the attractor; thus the attractor resembles a two-dimensional surface formed from extremely tightly compressed and folded layers; sufficiently close to the attractor the trajectories tend to separate from one another across the attractor band. The function that takes $(c_2(t_n), c_3(t_n))$ into $(c_2(t_{n+1}), c_3(t_{n+1}))$ is the Poincaré map. The line-like form of the Poincaré section and its single-valuedness as a function of either coordinate permits a one-dimensional representation of the two-dimensional Poincaré map. To do this second part of the next-amplitude map construction we plot the c_2 component of the Poincaré map corresponding to the n th intersection of the chaotic trajectory with the Poincaré surface, $c_2(n) \equiv c_2(t_n)$, versus its value at the $(n + 1)$ th intersection, $c_2(n + 1) \equiv c_2(t_{n+1})$. This next-amplitude map is displayed in [figure C3.6.2 \(b\)](#). The map has a quadratic extremum, a roughly parabolic shape, and is densely filled by intersection points. We may then represent trajectories of the flow by iterates of this

-6-

map. To represent these iterates graphically, we first draw the bisectrix of the map, i.e. the diagonal line B in [figure C3.6.2\(b\)](#). By construction, any point on the map whose abscissa is $c_2(n)$ has ordinate $c_2(n + 1)$. This ordinate is given by moving horizontally to the bisectrix. Moving vertically from the bisectrix to the map makes $c_2(n + 1)$ the new abscissa and $c_2(n + 2)$ the corresponding ordinate. These two steps correspond to an iteration of the next-amplitude map and the procedure can be repeated to obtain a discrete trajectory indicating how the chaotic attractor structure is built up. A portion of such a discrete chaotic trajectory is shown in [figure C3.6.2\(b\)](#).

Figure C3.6.2 (a) The (c_2, c_3) Poincaré surface of a section of the phase flow, taken at $c_1^{\text{sect}} = 8.5$ with $c_1 < 0$, for the WR chaotic attractor at $k_{-2} = 0.072$. (b) The next-amplitude map constructed from pairs of intersection coordinates $\{\dots, (c_2(n+1), c_2(n+2), c_2(n+1)), \dots\}$. The sequence of horizontal and vertical line segments, each touching the diagonal B and the map, comprise a discrete trajectory. The direction on the first four segments is indicated.

Figure C3.6.3 The spreading of an ensemble of four points on the WR chaotic attractor. (a) The initial tight, four-point ensemble of open circles (o) at $c_2 = 5.287 \dots$, $c_3 = 24.065 \dots$ and variable $c_1 = 2.884 \dots, 2.984 \dots, 3.084 \dots$, and $3.184 \dots$ spreading to the set of four filled circles (•) at time $t = 4.0$. The filled circles overlap in two pairs. (b) The spread from the same initial ensemble at time $t = 800.0$. The dispersion of the initial ensemble has the size of a full stop in the centre of the four overlapping open circles. The attractor is shown as a dust of stroboscopically plotted points so that the final ensemble of four filled circles (•) can be seen. One point lies on the inner edge of the central hole in the attractor. The density of the dust is an indicator of the *coarse-grained* density on the attractor.

-7-

C3.6.3.3 LYAPUNOV NUMBER AND FRACTAL DIMENSION

Chaotic attractors are complicated objects with intrinsically unpredictable dynamics. It is therefore useful to have some dynamical measure of the strength of the chaos associated with motion on the attractor and some geometrical measure of the structural complexity of the attractor. These two measures, the Lyapunov exponent or number [1] for the dynamics, and the fractal dimension [10] for the geometry, are related. To simplify the discussion we consider three-dimensional flows in phase space, but the ideas can be generalized to higher dimension.

As already mentioned, the motion of a chaotic flow is sensitive to initial conditions [11]; points which initially lie close together on the attractor follow paths that separate exponentially fast. This behaviour is shown in [figure C3.6.3](#) for the WR chaotic attractor at $k_{-2}=0.072$. The instantaneous rate of separation depends on the position on the attractor. However, a chaotic orbit visits any region of the attractor in a recurrent way so that an infinite time average of this exponential separation taken along any trajectory in the attractor is an invariant quantity that characterizes the attractor. If $\gamma(t)$ is a trajectory for the rate law ([c3.6.2](#)) then we can linearize the motion in the neighbourhood of γ to get

$$\frac{d\delta\mathbf{c}}{dt} = \left. \frac{\partial \mathbf{R}}{\partial \mathbf{c}} \right|_{\gamma} \delta\mathbf{c}. \quad (\text{C3.6.5})$$

The formal (or numerical) integration of this equation can be written as

$$\delta\mathbf{c}(t) = \mathbf{L}(t)\delta\mathbf{c}(0) \quad (\text{C3.6.6})$$

where $\mathbf{L}(t)$ is the displacement evolution matrix along γ and $\delta\mathbf{c}(t)$ is the solution of equation [C3.6.5] for initial displacement $\delta\mathbf{c}(0)$. Then the Lyapunov number is defined by

$$\bar{\lambda} = \lim_{t \rightarrow \infty} \frac{1}{2t} \ln[\text{Tr} \mathbf{L}^\dagger(t)\mathbf{L}(t)] \quad (\text{C3.6.7})$$

where L^\dagger is the adjoint of L . If the Lyapunov number $\bar{\lambda}$ is positive this indicates chaotic behaviour since $\bar{\lambda}$ is a measure of (the exponent for) the average rate at which trajectories separate on the attractor.

A chaotic attractor comprises line-like trajectory segments and so is topologically a one-dimensional object. However, the trajectories may lie arbitrarily close together in some regions of space, at least in the infinite time limit. In such regions a chaotic attractor has almost surface-like ‘filling’ properties. This unusual structure motivates the definition of a geometrical measure of chaos: the fractal, or more often, the box counting dimension of an attractor

$$D = \lim_{\varepsilon \rightarrow 0} \frac{\ln N(\varepsilon)}{\ln(1/\varepsilon)} = - \lim_{\varepsilon \rightarrow 0} \frac{\ln N(\varepsilon)}{\ln \varepsilon} \quad (\text{C3.6.8})$$

where, in two-dimensional or three-dimensional space $N(\varepsilon)$ is the minimum number of squares or cubes, respectively, of side ε that covers the attractor. This dimension can be calculated for the Poincaré section of the phase flow by covering it with successively smaller squares or for the entire attractor by covering it with successively smaller cubes

-8-

and measuring D as the slope of $N(\varepsilon)$ versus $\ln(1/\varepsilon)$ implied in (C3_6_8). This dimension is typically non-integer and is less than the phase-space dimension.

C3.6.3.4 EXPERIMENTAL OBSERVATIONS OF CHEMICAL CHAOS

The existence of chaotic oscillations has been documented in a variety of chemical systems. Some of the earliest observations of chemical chaos have been on biochemical systems like the peroxidase–oxidase reaction [12] and on the well known Belousov–Zhabotinskii (BZ) [13] reaction. The BZ reaction is the Ce-ion-catalyzed oxidation of citric or malonic acid by bromate ion. Early investigations of the BZ reaction used the techniques of dynamical systems theory outlined above to document the existence of chaos in this reaction. Apparent chaos in the BZ reaction was found by Hudson *et al* [14] and the data were analysed by Tomita and Tsuda [15] using a return-map method. Chaos was confirmed in the BZ reaction carried out in a CSTR by Roux *et al* [16, 17] and by Hudson and Mankin [18] who also used reconstruction from the electrode potentials of Pt and Br^- , and $d[\text{Pt}]/dt$ as independent variables. These demonstrations of true chemical chaos were achieved by a number of then new methods: power-spectral analysis [16, 19], trajectory reconstruction in phase space [16], and next-amplitude-map analysis [15, 20, 21]. The existence of true chemical chaos was signalled by a positive Lyapunov exponent calculated from the experimental return map. Since these early investigations, chaos has been documented in a variety of chemical systems. One aspect of these CSTR experiments was the observation that the stirring rate moved the bifurcation point(s) even if this rate was very large [22]. This effect depends on turbulent mixing and can be controlled but not eliminated by keeping the stirring rate constant. We now give examples of two related dynamical systems techniques used by experimentalists: phase-space reconstruction of chaotic attractors and the analysis of the associated next-amplitude maps. First, we discuss a study where an attractor was reconstructed from experimental data and then used to obtain a next-amplitude map [17].

Figure C3.6.4(a) shows an experimental chaotic attractor reconstructed from the Br^- electrode potential, i.e. the logarithm of the Br^- ion concentration, in the BZ reaction [17]. Such reconstruction is defined, in principle, for continuous time t . However, in practice, data are recorded as a discrete time series of measurements $\{X(t_i); i = 1, 2, \dots, i_{\max}\}$, consisting of thousands (i_{\max}) of data points. In our example $X(t_i)$ is proportional to $\ln[\text{Br}^-](t_i)$. The experimental attractor was reconstructed [17] in the space of the three variables, $X(t_i)$, $X(t_i + \tau)$ and $X(t_i + 2\tau)$, and C3.6.4(a) shows the projection of this attractor onto the $(X(t_i), X(t_i + \tau))$ plane. This attractor resembles that of the chaotic attractor shown in figure C3.6.1(a) and it can be demonstrated that the reconstructed attractor possesses the signatures of chaos: regions where trajectories locally spread or diverge and regions of re-injection and folding of the phase-space flow. Furthermore, we see that because the chaotic attractor is surface-like it has a fractal dimension close to two in spite of the fact that there are likely to be 30–40 chemical species involved in the

reaction so that the Euclidean dimension of the full concentration phase space is large. This points to the usefulness of phase-space reconstruction methods for low-dimensional chaotic attractors, especially for systems with a high but unknown phase-space dimensionality.

-9-

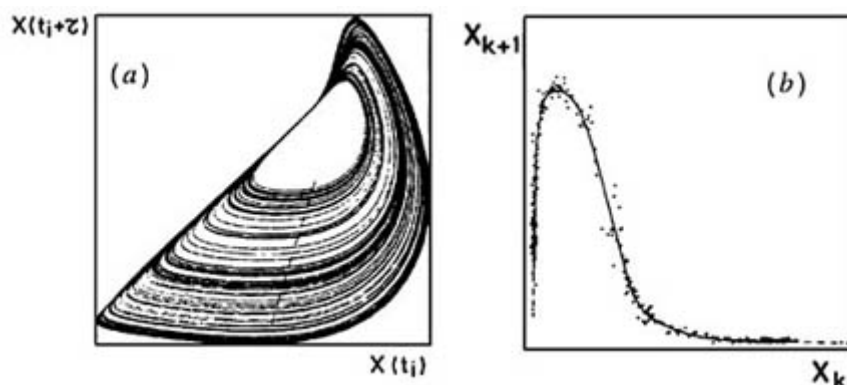

Figure C3.6.4 Single-banded chaotic attractor and next-amplitude map reconstructed from experimental data for the BZ reaction. (a) The reconstructed attractor projected onto the $(X(t_i), X(t_i + \tau))$ plane (see the text for a discussion of the notation). (b) The next-amplitude map in the (X_k, X_{k+1}) plane drawn from the surface of section taken at the dashed curve on the lower part of the attractor in (a). See the text for an explanation of the map construction. Reproduced by permission from Roux and Swinney [17].

We now examine how a next-amplitude-map was obtained from the attractor shown in figure C3.6.4(a) [17]. Consider the plane in this space whose projection is the dashed curve; i.e. a plane orthogonal to the $(X(t_i), X(t_i + \tau))$ plane. Then, for the k th intersection of the (continuous) trajectory with this plane, there will be a data point $(X(t_{i_k}), X(t_{i_k} + \tau), X(t_{i_k} + 2\tau))$ on the attractor that lies closest to the intersection of the continuous trajectory. A second discretization produces the set $\{X_k \equiv X(t_{i_k} + 2\tau) : k = 1, 2, \dots, k_{i_{\max}}\}$. This set is used in the construction of the next-amplitude map shown in figure C3.6.4(b) from the pairs of points $\{(X_k, X_{k+1}) : k = 1, 2, \dots, k_{i_{\max}} - 1\}$. This map has a single quadratic extremum, similar to that of the WR model described in detail earlier. Such maps (together with the technical constraint of negative Schwarzian derivative) [23] possess *universal* properties. In particular, the universal (U) sequence in which the periodic orbits appear [24] was observed in the BZ reaction in accord with this picture of the chemical dynamics.

C3.6.4 ROUTES TO CHAOS

The next problem to consider is how chaotic attractors evolve from the steady state or oscillatory behaviour of chemical systems. There are, effectively, an infinite number of routes to chaos [25]. However, only some of these have been examined carefully. In the simplest models they depend on a single control or bifurcation parameter. In more complicated models or in experimental systems, variations along a suitable curve in the control parameter space allow at least a partial observation of these well known routes. For chemical systems we describe period doubling, mixed-mode oscillations, intermittency, and the quasi-periodic route to chaos.

C3.6.4.1 THE PERIOD-DOUBLING ROUTE TO CHAOS

We first examine how chaos arises in the WR model using the rate constant k_{-2} as the bifurcation parameter. However, another parameter or set of parameters could be used to explore the behaviour. (Independent variation of p parameters

-10-

produces a p -dimensional bifurcation diagram.) In the context of experiments carried out in CSTRs the bifurcation parameter is usually taken to be the flow rate or a reservoir concentration. If we start with a value of $k_{-2} > 0.1715$ with all other rate constants fixed at the values given in [section C3.6.2](#), the WR reaction has a stable steady state or fixed point. We examine the sequence of transformations that takes place as k_{-2} decreases. At a certain value of $k_{-2} = k_{-2}^H \approx 0.1715$ the fixed point, $(c_1^H, c_2^H, c_3^H) \approx (8.801, 11.494, 15.048)$, loses its stability and the concentrations begin to oscillate with period T_0 . This is the Hopf bifurcation point and for $k_{-2} < k_{-2}^H$ the chemical attractor is a limit cycle. As k_{-2} decreases further the amplitude of the limit cycle grows (initially as $|k_{-2} - k_{-2}^H|^{1/2}$) until the system undergoes a further bifurcation at $k_{-2} \approx 0.1 \dots$ where the orbit undergoes a subharmonic bifurcation and its period doubles. To understand this bifurcation, imagine that the limit cycle lies on the surface of a Möbius band which is effectively a strip with a single twist in it. Motion on this band represents the slow relaxation of the system. At bifurcation the limit cycle becomes unstable but a stable orbit is born adjacent to it in the strip; this newborn orbit is geometrically equivalent to the edge of the Möbius strip as the width of the strip becomes arbitrarily small; because of the twist, the strip has only one edge of twice the length of the unstable limit cycle it contains. Therefore, the new stable orbit has twice the period of its parent limit cycle. An infinite sequence of these local twists or braids occur in the phase flow, generating an infinite subharmonic sequence of period-doubled orbits. The first two orbits of the main WR sequence are shown in [figure C3.6.5](#) there is a period-4 attractor at $k_{-2} = 0.095$. At the n th period doubling the period of the oscillation is $T_n \approx 2^n T_0$. In the limit $n \rightarrow \infty$ we arrive at the strange attractor where the time variation of the concentrations is no longer periodic. This is the *period-doubling route to chaos*.

Figure C3.6.5 The first two periodic orbits in the main subharmonic sequence are shown projected onto the (c_1, c_2) plane. This sequence arises from a Hopf bifurcation of the stable fixed point for the parameters given in the text. The arrows indicate the direction of motion. (a) The limit cycle or period-1 orbit at $k_{-2} = 0.11$. (b) The first subharmonic or period-2 orbit at $k_{-2} = 0.095$.

It is instructive to view this sequence of transformations in terms of a bifurcation diagram. We use the procedure described earlier to examine the chaotic orbit: the intersections of the periodic trajectories with the Poincaré surface are recorded for each value of the rate constant k_{-2} . In [figure C3.6.6](#) we plot the concentration c_2 on the Poincaré plane versus k_{-2} . One can clearly see the sequence of period-doubling bifurcations leading eventually to the chaotic attractor. One can understand the origin of this sequence of bifurcations by considering the next-amplitude map discussed earlier. We remarked in [section C3.6.3.2](#) that this map has the nearly parabolic functional form shown in [figure C3.6.2\(b\)](#) so that, after suitable scaling, we can write the next-amplitude map in the standard quadratic form $c_2(n+1) = \lambda c_2(n)(1 - c_2(n))$, thereby preserving the local and global features of the bifurcation [diagram C3.6.6](#). We know what happens

as the standard map parameter λ is changed. This reduction of the problem to the study of a quadratic map allows one to make a detailed examination of the universal properties of this route to chaos since the only requirement is that the map function be quadratic in the vicinity of its maximum. Such an analysis was carried out by Feigenbaum [26] where the following scaling relation was derived: let λ_n be the value of λ at the n th period doubling and λ_∞ be

its value in the $n \rightarrow \infty$ limit. Then for sufficiently large n , $\lambda_n - \lambda_c = \delta(\lambda_{n+1} - \lambda_c)$ with $\delta = 4.6692 \dots$ a universal number for such period-doubling cascades for quadratic maps.

Figure C3.6.6 The figure shows the c_2 coordinate, for $c_1 < 0$, of the family of trajectories intersecting the (c_2, c_3) Poincaré surface at $c_1 = 8.5$ as a function of bifurcation parameter k_{-2} . As the ordinate k_{-2} decreases, the first subharmonic cascade is visible between $k_{-2} \approx 0.1$, the value of the first subharmonic bifurcation to $k_{-2} \approx 0.083$, the subharmonic limit of the first cascade. Periodic orbits that arise by the tangent bifurcation mechanism associated with type-I intermittency (see the text for references) can also be seen for values of k_{-2} smaller than this subharmonic limit. The left side of the figure ends at $k_{-2} = 0.072$, the value corresponding to the chaotic attractor shown in figure C3.6.1(a). Other regions of chaos can also be seen.

C3.6.4.2 OTHER ROUTES TO CHAOS

In addition to the period-doubling route to chaos there are other routes that are chemically important: mixed-mode oscillations (MMOs), intermittency and quasi-periodicity. Their signature is easily recognized in chemical experiments, so that they were seen early in the history of chemical chaos.

MMOs have been observed in many experiments. Typically, a MMO consists of one or more large amplitude oscillations followed by several small amplitude oscillations. The size of the small oscillations may grow slowly. Suppose L large oscillations are followed by s small oscillations, where L and s are integers, then this MMO can be encoded by L^s . For example, one large oscillation followed by one small oscillation is written 1^1 , and so on. Since large and small have a specific meaning in a series of chemical experiments we may find only small oscillations, encoded 0^1 or only large oscillations encoded 1^0 in the series. Chaotic MMOs consist of L^s oscillations interspersed randomly by $L^{s'}$, L'^s , or $L'^{s'}$ oscillations. Experimental observations and theoretical descriptions for the origins of such oscillations have been given [27].

Intermittency, in the context of chaotic dynamical systems, is characterized by long periods of nearly periodic or 'laminar' motion interspersed by chaotic bursts of random duration [28]. Within this broad phenomenological

description, three kinds of intermittency have been distinguished theoretically and some detected experimentally [1, 29]. The onset of the laminar phase is statistical but its subsequent evolution is deterministic until the start of the next burst, whereas the behaviour of the chaotic phase is largely probabilistic. For this kind of onset of chaotic motion the bifurcation parameter, ϵ say, is close to its critical bifurcation value ϵ_c for periodic motion. As ϵ passes from a 'chaotic' value through ϵ_c the motion goes from intermittent to marginally stable, to strictly stable periodic motion.

The quasiperiodic route to chaos is historically important. It arises from a succession of Hopf bifurcations. As already noted, a single Hopf bifurcation results in a limit cycle. The next Hopf bifurcation produces a phase flow that can be represented on the surface of a torus (doughnut). This flow is associated with two frequencies: if the ratio of these frequencies is irrational then the torus surface is densely covered by the phase trajectory, whereas if

the ratio is rational the orbit winds periodically on the torus surface with both frequencies determining the overall period. However, a further Hopf bifurcation leads to an unstable torus flow which deforms into a chaotic flow. The nature of this instability was first discussed independently by Kupka and Smale; an equivalent theory of this breakdown of quasi-periodic flow to chaotic flow was proposed by Ruelle and Takens and was developed by them and Newhouse [30]. The quasiperiodic route to chaos was important because it was the first example of a transition to chaos that involved *few* modes, in contrast to the classical model of Landau of a gradual wandering into chaos as successive modes become unstable.

C3.6.5 CHEMICAL PATTERNS AND SPATIO-TEMPORAL CHAOS

Thus far we have considered systems where stirring ensured homogeneity within the medium. If molecular diffusion is the only mechanism for mixing the chemical species then one must adopt a local description where time-dependent concentrations, $c(\mathbf{r}, t)$, are defined at each point \mathbf{r} in space and the evolution of these local concentrations is given by a reaction-diffusion equation

$$\frac{\partial c(\mathbf{r}, t)}{\partial t} = R(c(\mathbf{r}, t); \mu) + D\nabla^2 c(\mathbf{r}, t) \quad (\text{C3.6.9})$$

where D is a matrix of diffusion coefficients. In addition to the temporal behaviour described above, one now has the possibility of chemical pattern formation which may lead to spatio-temporal chaos. In order to investigate chemical pattern formation under controlled non-equilibrium conditions, experiments are now carried out in continuously fed unstirred reactors (CFURs) [31]. In such reactors, well stirred reagent baths are in contact with a gel or porous medium within which the chemicals mix and react in the absence of stirring effects other than diffusion. Since the reagent baths are CSTRs they continuously supply and remove reactants and products from the reaction-diffusion medium, and chemical pattern formation can be controlled and maintained indefinitely. This has allowed experimentalists to make detailed studies of chemical pattern formation.

We shall describe some of the common types of chemical patterns observed in such experiments and comment on the mechanisms for their appearance. In keeping with the theme of this chapter we focus on states of spatio-temporal chaos or on regular chemical patterns that lead to such turbulent states. We shall touch only upon the main aspects of this topic since there is a large variety of chemical patterns and many mechanisms for their onset [2, 3, 5, 32].

C3.6.5.1 EXCITABLE MEDIA

Excitable media are some of the most commonly observed reaction-diffusion systems in nature. An excitable system possesses a stable fixed point which responds to perturbations in a characteristic way: small perturbations return quickly to the fixed point, while larger perturbations that exceed a certain threshold value make a long excursion in concentration phase space before the system returns to the stable state. In many physical systems this behaviour is captured by the dynamics of two concentration fields, a fast activator variable u with cubic nullcline and a slow inhibitor variable v with linear nullcline [33]. The FitzHugh-Nagumo equation [34], derived as a simple model for nerve impulse propagation but which can also apply to a chemical reaction scheme [35], is one of the best known equations with such activator-inhibitor kinetics:

$$\begin{aligned} \frac{du}{dt} &= -u^3 + u - v = R_u(u, v) \\ \frac{dv}{dt} &= \varepsilon(v - au + b) = R_v(u, v). \end{aligned} \quad (\text{C3.6.10})$$

Figure C3.6.7(a) shows the $\dot{u}=0$ and $\dot{v}=0$ nullclines of this system along with trajectories corresponding to sub- and super-threshold excitations. The trajectory arising from the sub-threshold perturbation quickly relaxes back to the stable fixed point. Three stages can be identified in the trajectory resulting from the super-threshold perturbation: an excited stage where the phase point quickly evolves far from the fixed point, a refractory stage where the system relaxes back to the stable state and is not susceptible to additional perturbation and the resting state where the system again resides at the stable fixed point.

Figure C3.6.7 Cubic ($\dot{u}=0$) and linear ($\dot{v}=0$) nullclines for the FitzHugh-Nagumo equation. (a) The excitable domain showing trajectories resulting from sub- and super-threshold excitations. (b) The oscillatory domain showing limit cycle orbits: small inner limit cycle close to Hopf point; large outer limit cycle far from Hopf point.

An excitable medium is a diffusively coupled array of such local excitable elements described by the reaction–diffusion equation (C3.6.9) with \mathbf{R} given by (C3.6.10) and $\mathbf{c} = (u, v)$. Imagine a local super-threshold perturbation applied to the system in the homogeneous resting state. Due to diffusive coupling, the perturbation will excite neighbouring regions of the medium. The originally perturbed region will then relax to the refractory stage where it is no longer susceptible

to perturbation, and finally back to the stable steady state. Consequently, a circular wave of excitation with a refractory tail will propagate outward through the medium (see figure C3.6.8(a)). If the excitable system is periodically stimulated in a local region of the medium (a pacemaker region) a target pattern comprising a set of concentric rings of excitation will be observed.

Figure C3.6.8 (a) A growing ring of excitation in an excitable FitzHugh–Nagumo medium. (b) A spiral wave in the same system.

If an excitable wave is broken, for instance by an obstacle or inhomogeneity in the medium, since the front velocity is smaller at the tip than the rest of the wave front, free ends of wave fronts will curl leading to the formation of spiral waves in the system. An example of a spiral wave is shown in figure C3.6.8(b). Excitable waves are seen in many chemical and biological systems. The often studied Belousov-Zhabotinskii (BZ) reaction was one of the first systems in which such waves were observed [13, 36]. Chemical waves of this type have been studied extensively in catalytic oxidation of CO on Pt[37]. In biological contexts, waves of this type occur in the aggregation stage of the slime mould *Dictyostelium discoideum* where the chemical signalling is through periodic waves of cAMP; also the Ca^{2+} waves in systems like *Xenopus laevis* oocytes and pancreatic β cells fall into this category 38. Electrochemical waves in cardiac and nerve tissue have this origin and the appearance and/or breakup of spiral wave patterns in excitable media are believed to be responsible for various types of arrhythmias in the heart [39, 40]. Figure C3.6.9 shows an excitable spiral wave in dog epicardial muscle [41].

Figure C3.6.9 Spiral electrochemical wave in dog epicardial muscle visualized using a voltage-sensitive dye. Reproduced by permission from Pertsov and Jalife [41].

-15-

The cores of the spiral waves need not be stationary and can move in periodic, quasi-periodic or even chaotic ‘flower’ trajectories [42, 43]. In addition, spatio-temporal chaos can arise if such spiral waves break up and the spiral wave fragments spawn pairs of new spirals [42, 44].

C3.6.5.2 OSCILLATORY AND CHAOTIC MEDIA

We described earlier how a stable steady state may give rise to a periodic oscillation through a Hopf bifurcation. The steady state of the FitzHugh–Nagumo model can undergo such a Hopf bifurcation. Consider the situation shown in figure C3.6.7(b) for $b = 0$ where there is a single fixed point at the origin $(u^*, v^*) = (0, 0)$. This fixed point is stable if $\varepsilon > a^{-1}$, $a < 1$, and becomes unstable at $\varepsilon = \varepsilon_H = a^{-1}$ through a Hopf bifurcation spawning a limit cycle encircling the origin.

Consider the analogue of such a bifurcation in a spatially distributed system and imagine tuning a bifurcation parameter μ (in the parameter set μ) in (C3.6.9) through such a bifurcation point, μ_H , and let $\lambda = |\mu - \mu_H|^{1/2}$ gauge the distance from the bifurcation point. One may then expand the local concentration about the steady state c^* as $c(\mathbf{r}, t) = c^* + A(\mathbf{r}, t)\hat{e} + \text{c.c.}$, where $A(\mathbf{r}, t)$ is a complex amplitude and \hat{e} is an eigenvector of the linearized reaction–diffusion problem. Then, in the vicinity of the Hopf bifurcation point, it is possible to transform the reaction–diffusion equation into a universal equation for the complex amplitude $A(\mathbf{r}, t)$ [45]:

$$\frac{\partial A(\mathbf{r}, t)}{\partial t} = A - (1 + i\beta)|A|^2 A + (1 + i\alpha)\nabla^2 A. \quad (\text{C3.6.11})$$

This complex Ginzburg–Landau equation describes the space and time variations of the amplitude A on long distance and time scales determined by the parameter distance from the Hopf bifurcation point. The parameters α and β can be determined from a knowledge of the parameter set μ and the diffusion coefficients of the reaction–diffusion equation. For example, for the FitzHugh–Nagumo equation we have $\alpha = (\mathbf{D}_v - \mathbf{D}_u)/[\omega_0(\mathbf{D}_v + \mathbf{D}_u)]$ and $\beta = -1/\omega_0$. The Ginzburg–Landau equation parameters may also be extracted from the experimental data and this has been done for the BZ reaction [46]. Through such an analysis one can study general features of oscillatory media,

independent of specific features of the reaction kinetics.

The complex Ginzburg–Landau equation also supports spiral wave solutions [47]. The core of a spiral wave is a point topological defect where the complex amplitude A vanishes [48]. In certain parameter regions, one finds a type of spatio-temporal chaos termed defect-mediated turbulence where the average number of topological defects is stationary but their instantaneous number fluctuates: defects of opposite topological charge may collide and annihilate or defects may nucleate in pairs as a result of ‘pinching’ of wave fronts [49]. [Figure C3.6.10](#) shows the system in the defect-mediated turbulence regime and illustrates distribution of spiral defects in the turbulent dynamics described above. Such defect-mediated turbulence has been observed in experiments on the BZ reaction [50]. [Figure C3.6.11\(a\)](#) shows the chemical pattern near the onset of the instability giving rise to spatio-temporal turbulence. Note that small well defined spirals can still be seen embedded in a sea of turbulent dynamics while in [figure C3.6.11\(b\)](#) well beyond the instability, one sees fully developed turbulence.

-16-

Figure C3.6.10 Defect-mediated turbulence in the complex Ginzburg–Landau equation. (a) The phase, $\arg(A)$, as grey shades. (b) The amplitude $|A|$, with a similar color coding. In the left panel topological defects can be identified as points around which one finds all shades of grey. Note the apparently random spatial pattern of amplitudes.

Figure C3.6.11 Defect-mediated turbulence in the BZ reaction. (a) Spatial structure close to the instability. (b) Fully developed spatio-temporal turbulence. The control parameter is the concentration of H_2SO_4 in the feed reactor. Reproduced by permission from Ouyang and Flesselles [50].

The local dynamics of the systems considered thus far has been either steady or oscillatory. However, we may consider reaction–diffusion media where the local reaction rates give rise to chaotic temporal behaviour of the sort discussed earlier. Diffusional coupling of such local chaotic elements can lead to new types of spatio-temporal periodic and chaotic states. It is possible to find phase-synchronized states in such systems where the amplitude varies chaotically from site to site in the medium whilst a suitably defined phase is synchronized throughout the medium [51]. Such phase synchronization may play a role in layered neural networks and perceptive processes in mammals. Somewhat surprisingly, even when the local dynamics is chaotic, the system may support spiral waves

[52, 53 and 54]. The origin of such spiral waves in chaotic media can again be traced to the phenomenon of phase synchronization. The notion of a defect at the core of the spiral remains valid even for these chaotic media, so the phase-coherent dynamics necessary for the existence of a spiral wave survives the amplitude turbulence. New phenomena can arise: in addition to point topological defects one can find synchronization line defects whose dynamics may be chaotic. Such synchronization line-defect dynamics has been observed in the BZ medium reaction [54, 55 and 56].

-17-

C3.6.5.3 TURING PATTERNS

If the diffusion coefficients of the chemical species are sufficiently different, new types of chemical instability arise which can lead to the formation of chemical patterns and ultimately to spatio-temporal chaotic behaviour.

One of the best known such instabilities is the Turing bifurcation proposed in 1952 as a possible mechanism for morphogenesis [57]. While the relevance of this type of pattern-forming instability for biological systems is still a matter of debate, such Turing patterns have been observed in laboratory chemical experiments [58, 59 and 60]. A Turing bifurcation involves the destabilization of a homogeneous steady state to form an inhomogeneous state or chemical pattern whose wavelength depends on the kinetic parameters and diffusion coefficients of the system. Turing bifurcations are often discussed in terms of activator–inhibitor kinetics like that of the FitzHugh–Nagumo equation above [61]. Consider two chemical species, X_1 and X_2 , with concentration vector, $\mathbf{c} = (c_1, c_2)$, that satisfies a two-variable reaction–diffusion equation where, as usual, $\mathbf{R}(\mathbf{c})$ describes the kinetics and \mathbf{D} is a diagonal diffusion-coefficient matrix with elements D_1 and D_2 . We suppose the system possesses a homogeneous stable steady state, \mathbf{c}^* , obtained from the solution of $\mathbf{R}(\mathbf{c}^*) = 0$. To determine the conditions for a Turing bifurcation to occur we consider the perturbation of this homogeneous steady state to *inhomogeneous* perturbations, $\mathbf{c}(\mathbf{r}, t) = \mathbf{c}^* + \delta\mathbf{c}(\mathbf{r}, t)$. We may linearize the reaction–diffusion to obtain

$$\frac{\partial \delta\mathbf{c}(\mathbf{r}, t)}{\partial t} = \mathbf{A}\delta\mathbf{c}(\mathbf{r}, t) + \mathbf{D}\nabla^2\delta\mathbf{c}(\mathbf{r}, t) \quad (\text{C3.6.12})$$

where $\mathbf{A} = (\partial\mathbf{R}/\partial\mathbf{c})_{\mathbf{c}=\mathbf{c}^*}$ is the matrix that specifies the chemical rate evolution about the steady state \mathbf{c}^* . To determine the stability of the steady state it is useful to examine the behaviour of the Fourier components of the concentration field, $\hat{\mathbf{c}}_k$, which satisfies the Fourier transform of equation C3.6.12:

$$\frac{\partial \delta\hat{\mathbf{c}}_k(t)}{\partial t} = (\mathbf{A} - k^2\mathbf{D})\delta\hat{\mathbf{c}}_k(t) \equiv \mathbf{B}\hat{\mathbf{c}}_k(t). \quad (\text{C3.6.13})$$

Now we may state the well known conditions for a Turing bifurcation. If $A_{11} < 0$ and $A_{22} < 0$ we say species X_1 is the activator and species X_2 is the inhibitor. Then, for a Turing bifurcation to occur we must have $\det \mathbf{B} = 0$, $\text{Tr } \mathbf{B} > 0$ and $A_{11}D_2 + A_{22}D_1 > 0$. The (unique) wavenumber at the bifurcation is

$$k_c = \left(\frac{\det \mathbf{A}}{D_1 D_2} \right)^{1/4}. \quad (\text{C3.6.14})$$

Furthermore, since the bifurcation must occur from a stable homogeneous steady state we must have $D_1/D_2 < 1$; i.e. the diffusion coefficient of the inhibitor is greater than that of the activator. The critical diffusion ratio at the bifurcation is

-18-

$$\frac{D_1}{D_2} = A_{22}^{-1} (\det \mathbf{A} - A_{12}A_{21} + 2(A_{12}A_{21} \det \mathbf{A})^{1/2}). \quad (\text{C3.6.15})$$

Consequently, when D_1/D_2 exceeds the critical value, close to the bifurcation one expects to see the appearance of chemical patterns with characteristic length $\ell = 2\pi / k_c$. Beyond the bifurcation point a band of wave numbers is unstable and the nature of the pattern selected (spots, stripes, etc.) depends on the nonlinearity and requires a more detailed analysis. Chemical Turing patterns were observed in the chlorite–iodide–malonic acid (CIMA) system in a gel reactor [58, 59 and 60]. Figure C3.6.12(a) shows an experimental CIMA Turing spot pattern [59].

Figure C3.6.12 (a) Turing spot pattern in the CIMA reaction. (b) Tio-temporal turbulence near the Turing bifurcation. Reproduced by permission from Ouyang and Swinney [59].

The Turing mechanism requires that the diffusion coefficients of the activator and inhibitor be sufficiently different; but the diffusion coefficients of small molecules in solution differ very little. The chemical Turing patterns seen in the CIMA reaction used starch as an indicator for iodine. The starch indicator complexes with iodide which is the activator species in the reaction. As a result, the complexing reaction with the immobilized starch molecules must be accounted for in the mechanism and leads to the possibility of Turing pattern formation even if the diffusion coefficients of the activator and inhibitor species are the same [62].

One may also observe a transition to a type of defect-mediated turbulence in this Turing system (see figure C3.6.12 (b)). Here the defects divide the system into domains of spots and stripes. The defects move erratically and lead to a turbulent state characterized by exponential decay of correlations [59]. Turing bifurcations can interact with the Hopf bifurcations discussed above to give rise to very complicated spatio-temporal patterns [63, 64].

C3.6.5.4 CHEMICAL FRONT INSTABILITIES

Another class of instabilities that are driven by differences in the diffusion coefficients of the chemical species determines the shapes of propagating chemical wave and flame fronts [65, 66].

As an example of chemical front instability consider a simple cubic autocatalytic reaction, $A + 2B \rightarrow 3B$, occurring in

a two-dimensional geometry where the ‘fuel’ A occupies the right-hand region and the autocatalyst occupies the left-hand region [67]. We suppose the reaction occurs under isothermal conditions which can be achieved for condensed phase reactions. The species B will consume the fuel A and the chemical front that separates the A and B species will move to the right. (For flame fronts one must generally couple the reaction kinetics to the variations in the temperature of the system.)

If the diffusion coefficient of species A is less than that of B ($D_A < D_B$) the propagating front will be planar. However, if D_A is sufficiently greater than D_B , the planar front will become unstable to transverse perturbations and chaotic front motion will ensue. To understand the origin of the mechanism of the planar front destabilization consider the following: suppose the interface is slightly non-planar. We would like to know if the dynamics will tend to eliminate this non-planarity or accentuate it. Let $D_B \gg D_A$. The situation is depicted schematically in figure C3.6.13 where large diffusion fluxes are indicated by \rightarrow and smaller diffusion fluxes by \dashrightarrow . For the part of the B front that protrudes into the A region, fast diffusion of B leads to dispersal of B and suppresses the autocatalytic reaction that requires two molecules of B . The front will have difficulty advancing here. In the region where A protrudes into B , A will react leading to advancement of the front. The net effect is to remove any initial non-planarity and give rise to a planar front.

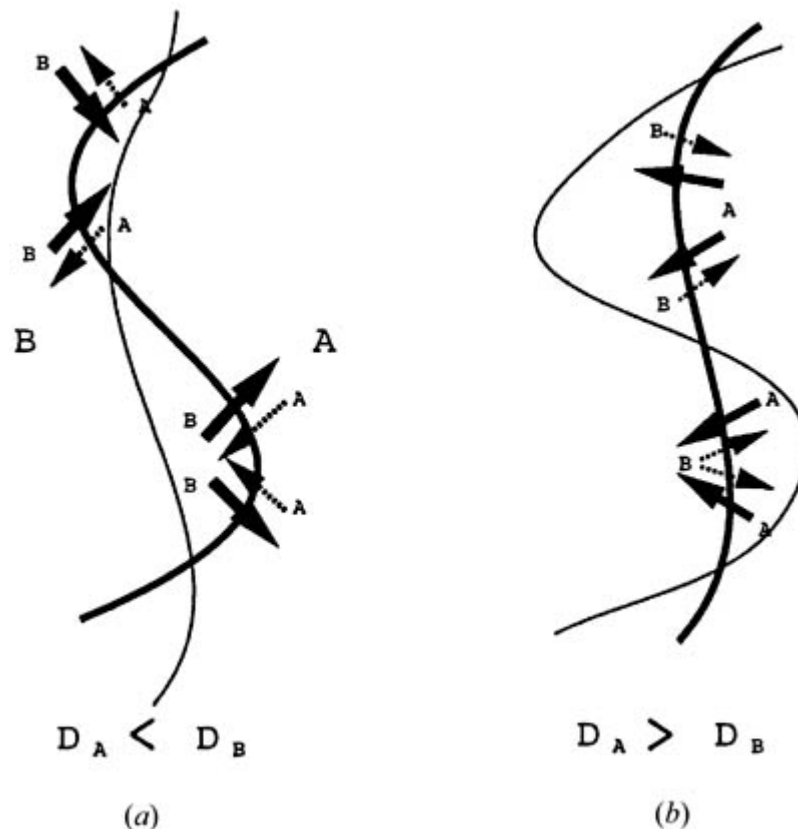

Figure C3.6.13 Schematic illustration of how the front instability arises for the case (a) $D_B \gg D_A$ and (b) $D_B \ll D_A$.

If $D_B \ll D_A$, in regions where B protrudes into A , rapid A diffusion will lead to conversion of A to B leading to front

advance. In regions where A protrudes into B , small diffusion of B into the A region does not favour the autocatalytic conversion so the front will not advance rapidly here. Consequently, any small non-planarity will grow to make the front even more non-planar. Therefore, we expect that for some ratio of diffusion coefficients, $d = D_A/D_B > 1$, the planar front will lose its stability [68]. An example of the front dynamics for $d = 5$ is shown in figure C3.6.14 where the minima in the front profile are plotted versus time. The resulting space-time plot shows the chaotic nature of the front dynamics. The (black) minima act like ‘particles’ in the system: they move and when they collide they coalesce to form a single minimum. If the distance between two minima is too large, a new minimum is formed. Thus, the average density of ‘particles’ per unit length of the interface remains constant but the instantaneous number of ‘particles’ fluctuates due to the creation and annihilation events for the minima.

Figure C3.6.14 Space–time (y,t) plot of the minima (black) in the cubic autocatalysis front $\phi(y,t)$ in equation C3.6.16 showing the nature of the spatio-temporal chaos.

In order to investigate such front instabilities quantitatively one may derive an equation for the profile $\phi(y,t)$ of the front directly from the reaction–diffusion equation. This Kuramoto–Sivashinsky equation [69]

$$\frac{\partial \phi(y, t)}{\partial t} = v \frac{\partial^2 \phi}{\partial y^2} - \frac{v}{2} \left(\frac{\partial \phi}{\partial y} \right)^2 - \kappa \frac{\partial^4 \phi}{\partial y^4} \quad (\text{C3.6.16})$$

describes a number of general features of such front dynamics. The parameters v , ν and κ may be related to the parameters in the original reaction–diffusion equation. The nonlinear term accounts for the fact that the velocity of the front depends on its curvature, while the gradient terms arise from diffusive effects. The coefficient of the fourth-order gradient is positive while the sign of v depends on the diffusion coefficient ratio d : for $d > d_c$, where d_c is a critical value of d , v changes from being positive to negative. This negative value of the ‘diffusion coefficient’ leads to an instability whose growth is controlled by the stabilizing fourth-order term. Instead of studying the full reaction–diffusion equation we may now explore the front dynamics directly through equation (C3.6.16). This equation yields front dynamics like that described above.

In addition to flame fronts, which have been extensively studied experimentally, front instabilities have been investigated for the isothermal cubic autocatalytic iodate arsenous acid system [70] as well as for polymerization

reactions where thermal and hydrodynamic effects lead to complicated front patterns [71]. Front instabilities also play a role in determining the labyrinth patterns seen in recent chemical experiments [72].

C3.6.6 CONCLUSION

Our understanding of the development of oscillations, multi-stability and chaos in well stirred chemical systems and pattern formation in spatially distributed systems has increased significantly since the early observations of these phenomena. Most of this development has taken place relatively recently, largely driven by development of experimental probes of the dynamics of such systems. In spite of this progress our knowledge of these systems is still rather limited, especially for spatially distributed systems.

Several important topics have been omitted in this survey. We have described only a few of the routes by which chaos can arise in chemical systems and have made no attempt to describe in detail the features of the different kinds of chemical strange attractor seen in experiments. A wide variety of chemical patterns have been observed and while the many aspects of the mechanisms for their appearance are understood, some features like nonlinear

pattern selection still present challenges and new patterns continue to be discovered. An ubiquitous class of chemical patterns that was not discussed here are those that arise from diffusion-limited aggregation (DLA) [73]. Such DLA clusters are seen in many contexts, including electrochemical deposition processes, and are often analysed using the concepts of fractal geometry [10] and wavelets [74, 75]. Also, methods for controlling chemical chaos [76] have not been discussed in this chapter although they have potential applications for both industrial processes and biological systems.

In spite of these limitations it is hoped that this chapter will provide an introduction to the unusual phenomena that chemically reacting systems exhibit when driven far from equilibrium and an indication of how these phenomena may be analysed. Although such systems were often regarded as curiosities in the past, it is now clear that they are the rule rather than the exception in nature and deserve our full attention.
