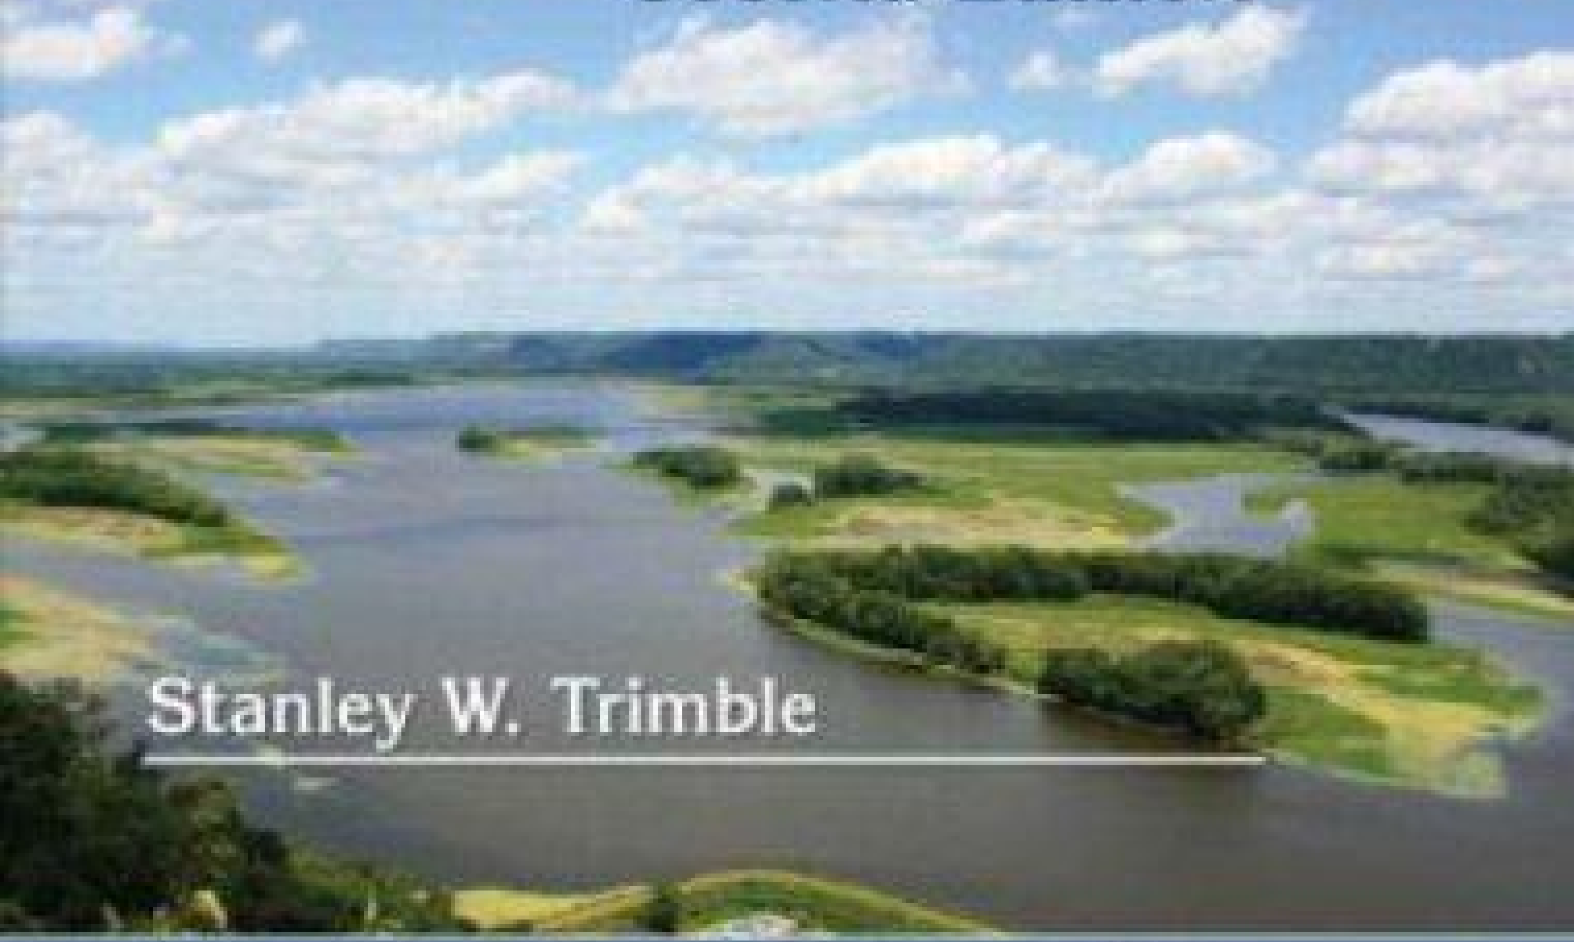
2 Volume Set

Encyclopedia of Water Science

Second Edition



Stanley W. Trimble

CRC Press
Taylor & Francis Group

Volume I–II

Encyclopedia of Water Science

Second Edition

Encyclopedias from Taylor & Francis Group

Agriculture Titles

Dekker Agropedia Collection (Eight Volume Set)
ISBN: 978-0-8247-2194-7 Cat. No.: DK803X

Encyclopedia of Agricultural, Food, and Biological Engineering
Edited by Dennis R. Heldman
ISBN: 978-0-8247-0938-9 Cat. No.: DK9381

Encyclopedia of Animal Science
Edited by Wilson G. Pond and Alan Bell
ISBN: 978-0-8247-5496-9 Cat. No.: DK2206

Encyclopedia of Pest Management
Edited by David Pimentel
ISBN: 978-0-8247-0632-6 Cat. No.: DK6323

Encyclopedia of Pest Management, Volume II
Edited by David Pimentel
ISBN: 978-1-4200-5361-6 Cat. No.: 53612

Encyclopedia of Plant and Crop Science
Edited by Robert M. Goodman
ISBN: 978-0-8247-0944-0 Cat. No.: DK1190

Encyclopedia of Soil Science, Second Edition (Two Volume Set)
Edited by Rattan Lal
ISBN: 978-0-8493-3830-4 Cat. No.: DK830X

Encyclopedia of Water Science
Edited by Stanley W. Trimble
ISBN: 978-0-8493-9627-4 Cat. No.: DK9627

Chemistry Titles

Encyclopedia of Chromatography, Second Edition (Two Volume Set)
Edited by Jack Cazes
ISBN: 978-0-8247-2785-7 Cat. No.: DK7851

Encyclopedia of Supramolecular Chemistry (Two Volume Set)
Edited by Jerry L. Atwood and Jonathan W. Steed
ISBN: 978-0-8247-5056-5 Cat. No.: DK056X

Encyclopedia of Surface and Colloid Science, Second Edition (Eight Volume Set)
Edited by P. Somasundaran
ISBN: 978-0-8493-9615-1 Cat. No.: DK9615

Engineering Titles

Encyclopedia of Chemical Processing (Five Volume Set)
Edited by Sunggyu Lee
ISBN: 978-0-8247-5563-8 Cat. No.: DK2243

Encyclopedia of Corrosion Technology, Second Edition
Edited by Philip A. Schweitzer, P.E.
ISBN: 978-0-8247-4878-4 Cat. No.: DK1295

Encyclopedia of Energy Engineering and Technology (Three Volume Set)
Edited by Barney L. Capehart
ISBN: 978-0-8493-3653-9 Cat. No.: DK653X

Dekker Encyclopedia of Nanoscience and Nanotechnology (Five Volume Set)
Edited by James A. Schwarz, Cristian I. Contescu, and Karol Putyera
ISBN: 978-0-8247-5055-8 Cat. No.: DK0551

Encyclopedia of Optical Engineering (Three Volume Set)
Edited by Ronald G. Driggers
ISBN: 978-0-8247-0940-2 Cat. No.: DK9403

Business Titles

Encyclopedia of Library and Information Science, Second Edition (Four Volume Set)
Edited by Miriam Drake
ISBN: 978-0-8247-2075-9 Cat. No.: DK075X

Encyclopedia of Library and Information Science, First Update Supplement
Edited by Miriam Drake
ISBN: 978-0-8493-3894-6 Cat. No.: DK8948

Encyclopedia of Public Administration and Public Policy, Second Edition (Three Volume Set)
Edited by Evan M. Berman
ISBN: 978-0-4200-5275-6 Cat. No.: AU5275

Encyclopedia of Wireless and Mobile Communications (Three Volume Set)
Edited by Borko Furht
ISBN: 978-0-4200-4326-6 Cat. No.: AU4326

Volume I–II

Encyclopedia of

Water Science

Second Edition

Library of Congress Cataloging-in-Publication Data

Trimble, Stanley Wayne.
Encyclopedia of water science / author, Stanley W. Trimble. -- 2nd ed.
p. cm.
Includes bibliographical references and index.
ISBN 978-0-8493-9627-4 (alk. paper) -- ISBN 978-0-8493-9617-5 (alk. paper) -- ISBN 978-0-8493-9616-8 (alk. paper) 1. Water-supply, Agricultural. 2. Water in agriculture. 3. Irrigation efficiency. I. Title.

S494.5.W3E54 2007
627.03--dc22 2007035897

Encyclopedia of Water Science, Second Edition

Stanley W. Trimble

Guy Fipps / *Agricultural Engineering Department, Texas A&M University, College Station, Texas, U.S.A.*

Markus Flury / *Center of Multiphase Environmental Research, Department of Crop and Soil Sciences, Washington State University, Pullman, Washington, U.S.A.*

Graham E. Fogg / *Hydrology, Department of Land, Air and Water Resources (LAWR), University of California–Davis, Davis, California, U.S.A.*

James L. Fouss / *Soil and Water Research Unit, Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Baton Rouge, Louisiana, U.S.A.*

Kent Frame / *California Department of Water Resources, Sacramento, California, U.S.A.*

Thomas G. Franti / *Department of Biological Systems Engineering, University of Nebraska, Lincoln, Nebraska, U.S.A.*

Gary W. Frasier / *U.S. Department of Agriculture (USDA), Fort Collins, Colorado, U.S.A.*

James R. Frederick / *Department of Crop and Soil Environmental Science, Pee Dee Research and Education Center, Clemson University, Florence, South Carolina, U.S.A.*

Marcel Fuchs / *Environmental Physics and Irrigation, Volcani Center, Institute of Soil, Water and Environmental Sciences, Agricultural Research Organization (ARO), Bet-Dagan, Israel*

Stuart R. Gagnon / *University of Maryland, College Park, Maryland, U.S.A.*

Devin Galloway / *U.S. Geological Survey (USGS), Sacramento, California, U.S.A.*

Anja Gassner / *Institute of Science and Technology, Universiti Malaysia Sabah, Kota Kinabalu, Sabah, Malaysia*

David K. Gattie / *Biological and Agricultural Engineering Department, College of Agricultural and Environmental Sciences, University of Georgia, Athens, Georgia, U.S.A.*

Glendon W. Gee / *Battelle Pacific Northwest National Laboratory, Richland, Washington, U.S.A.*

Timothy R. Ginn / *Department of Civil and Environmental Engineering, University of California–Davis, Davis, California, U.S.A.*

George Di Giovanni / *Department of Plant Pathology and Mircobiology, Texas A&M University System Agriculture Research and Extension Center, El Paso, Texas, U.S.A.*

David A. Goldhamer / *Kearney Agricultural Center, University of California, Parlier, California, U.S.A.*

Noel Gollehon / *Resource Economics Division, U.S. Department of Agriculture (USDA), Washington, District of Columbia, U.S.A.*

Andrew S. Goudie / *St. Cross College, Oxford, U.K.*

William L. Graf / *University of South Carolina, Columbia, South Carolina, U.S.A.*

Stephen R. Grattan / *Hydrologic Sciences, Department of Land, Air and Water Resources (LAWR), University of California–Davis, Davis, California, U.S.A.*

John R. Gray / *Office of Surface Water, U.S. Geological Survey (USGS), Reston, Virginia, U.S.A.*

Patricia K. Haan / *Biological and Agricultural Engineering Department, Texas A&M University, College Station, Texas, U.S.A.*

Ardell D. Halvorson / *Agricultural Research Service (USDA-ARS-SPNRU), U.S. Department of Agriculture, Fort Collins, Colorado, U.S.A.*

Dorota Z. Haman / *Agricultural and Biological Engineering, Institute of Food and Agricultural Sciences, University of Florida, Gainesville, Florida, U.S.A.*

Joel R. Hamilton / *Department of Agricultural Economics, University of Idaho, Moscow, Idaho, U.S.A.*

Clayton L. Hanson / *U.S. Department of Agriculture (USDA), Boise, Idaho, U.S.A.*

Gregory J. Hanson / *Plant Science and Water Conservation Research Laboratory (PSWCRL), Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Stillwater, Oklahoma, U.S.A.*

Mohamed M. Hantush / *National Risk Management Research Laboratory, U.S. Environmental Protection Agency (US-EPA), Cincinnati, Ohio, U.S.A.*

Michael J. Hayes / *National Drought Mitigation Center, University of Nebraska, Lincoln, Nebraska, U.S.A.*

Phillip D. Hays / *Department of Geosciences, University of Arkansas, Fayetteville, Arkansas, U.S.A.*

John V. Headley / *Aquatic Ecosystem Research Protection Branch, National Water Research Institute, Saskatoon, Saskatchewan, Canada*

Richard W. Healy / *U.S. Geological Survey (USGS), Lakewood, Colorado, U.S.A.*

David L. Higgit / *Department of Geography, National University of Singapore, Singapore, Singapore*

Robert W. Hill / *Biological and Irrigation Engineering Department, Utah State University, Logan, Utah, U.S.A.*

Curtis H. Hinman / *School of Agricultural, Human and Natural Resource Sciences, Washington State University, Tacoma, Washington, U.S.A.*

Michael C. Hirschi / *University of Illinois, Urbana, Illinois, U.S.A.*

Kyle D. Hoagland / *School of Natural Resources, University of Nebraska, Lincoln, Nebraska, U.S.A.*

Laurie Hodges / *Department of Agronomy and Horticulture, University of Nebraska, Lincoln, Nebraska, U.S.A.*

Arjen Y. Hoekstra / *Department of Water Engineering and Management, University of Twente, Enschede, The Netherlands*

Glenn J. Hoffman / *Biological Systems Engineering, University of Nebraska, Lincoln, Nebraska, U.S.A.*

James E. Hook / *NESPAL, University of Georgia, Tifton, Georgia, U.S.A.*

Jan W. Hopmans / *Department of Land, Air and Water Resources (LAWR), University of California–Davis, Davis, California, U.S.A.*

Terry A. Howell / *Conservation and Production Research Laboratory, Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Bushland, Texas, U.S.A.*

Joel M. Hubbell / *Idaho National Engineering and Environmental Laboratory (INEL), Idaho Falls, Idaho, U.S.A.*

Paul F. Hudak / *Department of Geography, University of North Texas, Denton, Texas, U.S.A.*

Paul F. Hudson / *Department of Geography and the Environment, University of Texas at Austin, Austin, Texas, U.S.A.*

Ray G. Huffaker / *Department of Agricultural Economics, Washington State University, Pullman, Washington, U.S.A.*

Rodney L. Huffman / *Department Biological and Agricultural Engineering, North Carolina State University, Raleigh, North Carolina, U.S.A.*

Frank J. Humenik / *National Center for Manure and Animal Waste Management, North Carolina State University, Raleigh, North Carolina, U.S.A.*

John Hutson / *School of Chemistry, Physics and Earth Sciences, Flinders University, Adelaide, South Australia, Australia*

Keith E. Idso / *Center for the Study of Carbon Dioxide and Global Change, Tempe, Arizona, U.S.A.*

Sherwood B. Idso / *U.S. Department of Agriculture (USDA), Tempe, Arizona, U.S.A.*

W. Jabre / *Department of Soils, Irrigation and Mechinization, American University of Beirut, Beirut, Lebanon*

C. Rhett Jackson / *Warnell School of Forest Resources, University of Georgia, Athens, Georgia, U.S.A.*

Sharad K. Jain / *National Institute of Hydrology, Roorkee, Uttarakhand, India*

Preface to Second Edition

Continuing and updating the *Encyclopedia of Water Science* over the past four years has been an exciting but daunting task. It has been exciting because the subject is so critical to life and living, and daunting because the original editors set such a high standard. As ever, water is the central focus in environmental science. In addition to all the critical factors cited in the Preface to the first edition, global warming has now become more certain so that water issues will become even more important.

My goals for this new edition have been to (1) expand the number of entries along the same subject areas found in the first edition, (2) revise old entries as needed and (3) expand into new subject areas. For the latter, the main thrust has been the science of streams, not only the engineering aspects, but also the natural ones including morphology and process. The latter, fluvial geomorphology, is my own field. Presumably, future editors will also insure that their own specialty is well covered too. We have also moved into entirely new fields such as *virtual water*. The number of entries has increased by more than 50 percent since the first edition.

There are many people to thank for making the second edition possible. First and foremost is the Editorial Advisory Board. While small in number for an undertaking of this magnitude, these people have been giants in their contributions. Not only have they recommended authors and referees and even refereed themselves, but they have also contributed fine entries, several in some cases. I want to mention in particular Mary Beth Kirkham, Andrew Goudie, Dennis Wichelns and Steve Parker without whose help this second edition would have been impossible. The second group of people who have made this possible are the authors who have given generously of their expertise and time. The third group is the referees. Usually with little or no thanks or credit, they have given of themselves to improve entries, sometimes being absolutely critical to making entries most effective.

The fourth group to which I owe a debt of gratitude is the editorial team at Dekker, now Taylor and Francis. They took care of countless details and helped me stay on track. In particular, Sapna Maloor, Susan Lee, and Laura Sylvest were outstanding as my editorial assistants. They saw to contacting authors and referees, all involving thousands of e-mail exchanges. And I must thank Claire Miller who oversaw the project and gave valuable direction. To all, thanks!

Stanley W. Trimble

27 July 2007

Preface to First Edition

All living things require water. More specifically, they require it daily and often in a nearly pure state. As world population increased from 2.5 billion people in 1950 to more than 6 billion in 2000, water demand escalated. One in five people on this planet does not have access to safe and affordable drinking water, and half do not have access to sanitation. With global population predicted to reach almost 8 billion by 2025, water management and treatment will become critical.

Most of the world's water is salt water, unsuitable for most uses. Fresh water makes up only 2.5% of the water supply and two-thirds of this is in the form of glaciers and permafrost, leaving less than 1% of the world's water available for use. Of this remaining 1%, agriculture is the biggest user of water withdrawals from groundwater and surface water supplies: Agriculture comprises 69% of water use compared with industrial and domestic users, who consume 21% and 10%, respectively. But as population growth continues and industrialization expands, there will be greater competition among all users and an increasing need for more efficient water use.

Food production during the past 50 years has kept pace with population growth. The increase in per capita grain production from 247 kg in 1950 to more than 300 kg today is due largely to increased irrigation requiring large amounts of water:

- Approximately 500 kg of water is required to produce 1 kg of potato, while wheat, maize, and rice require approximately 900, 1400, and 2000 kg, respectively, for each kilogram of grain.
- Around 95% of all agricultural land and 83% of the cropland depend entirely on precipitation to meet plant needs.
- Although the 17% of cropland that is irrigated uses an enormous amount of water, it produces almost 40% of the world's food and fiber needs.

Future food requirements will require even additional irrigated lands. However, while irrigation greatly increases food production, it can simultaneously degrade soil and water resources, leading to serious environmental problems.

In recent years, there has been a dramatic change in the way meat and dairy animals are handled. Large, concentrated animal feeding operations are becoming commonplace and require large amounts of water for both livestock consumption and manure and waste handling. These facilities can also present a potential pollution hazard for surface and groundwater resources.

Industrial and domestic water users often degrade water to the point that it must be treated before it can be used for other purposes or even returned to the environment. Wastewater treatment usually requires extensive facilities and expenditures to ensure environmental protection.

Efficient water use and water resource protection can be accomplished only by informed producers and policymakers with access to state-of-the-art information. The Encyclopedia of Water Science is designed and compiled to meet this need. An international team of hundreds of dedicated scientists, policymakers, educators, and others involved with water use have prepared nearly 250 entries addressing important topics ranging from water composition to irrigation water application to agricultural fields. An advisory board was important in planning the scope, and topic editors reviewed entries and offered advice to the editors and authors. We thank all these individuals for their efforts. The initial edition, to be updated quarterly online, addresses critical issues of water use. Perhaps more importantly, the authors have identified additional sources of information for readers who need further, in-depth resources. Published in both online and print formats, the encyclopedia's features will appeal to a wide range of users.

Thanks are also due to the staff of Marcel Dekker, Inc., for their efforts in handling the thousands of communications required to invite authors, review drafts, and manage other matters necessary to produce a publication of this magnitude. It was a great pleasure to work with Ellen Lichtenstein and Sapna Maloor. Their professionalism, commitment to excellence, and dedication are much appreciated and were the key to accomplishing this task. The information assembled will be a useful tool in helping humanity address and meet water use challenges of the 21st century.

INTRODUCTION

Several academic disciplines from the agricultural, environmental, and social sciences contribute to the field of agricultural water management. Successful agricultural water management enhances the prospects for farm profitability by efficiently meeting the water needs of crops and livestock while protecting the natural environment. Achieving these results requires a multidisciplinary approach: knowledge from many disciplines must be integrated into agricultural water management decisions.

OVERVIEW OF AGRICULTURAL WATER MANAGEMENT

Agricultural water management encompasses a wide range of activities that relate to managing water efficiently to grow food and fiber, while protecting water, and other elements of the natural environment, from degradation. The focus is on managing the quantity and quality of water resources/supplies. Agricultural water management encompasses:

- Crop irrigation, drainage, erosion control, nutrient and pest management.
- Animal production, especially manure management.
- Provision of safe drinking water for humans and animals.
- Groundwater and surface water quality protection.

AGRICULTURAL WATER MANAGEMENT DISCIPLINES

Academic disciplines are fields of study characterized by academic departments, scholarly journals, and professional societies. Those disciplines that address agricultural water management are as varied as agricultural water management issues. Academic disciplines usually associated with managing agricultural water quality and quantity are described below.

Descriptions of Specific Disciplines

Agricultural economics

Agricultural economics contributes to agricultural water management by addressing both farm-level business decisions and broader policy decisions related to water. Agricultural economists examine issues such as farm profitability under different irrigation systems; costs and benefits of government conservation programs; and the influence of cost-share rates on the adoption of best management practices to reduce non-point-source pollution.

Agricultural engineering

Agricultural engineering is concerned with the design and development of systems to identify, analyze, treat, and remediate water resources, particularly as they relate to agricultural activities. Agricultural engineers are also involved in the operation of environmental quality protection and control systems. Engineering principles are applied to monitoring, design, and operation of systems to evaluate the environmental impact of agricultural practices on surface water and groundwater quantity and quality. Emphasis areas include engineering design and operation of irrigation and drainage systems; erosion and sedimentation control structures; modeling of contaminant transport processes; and design of watershed monitoring and control systems utilizing simulation models, geographic information systems (GIS), and remote-sensing data. Specialized fields in agricultural engineering include land application of wastewater and controlled environments (such as water and wastewater treatment and operation systems for greenhouses; confined livestock facilities; and aquaculture). In all cases, the impact of these operations on water quality is of concern.

Agricultural law

Agricultural law covers the legal aspects of agricultural water use, including environmental impacts. The issues may relate to individual farm enterprises or to larger public policy questions. At the farm level, legal issues might include rights to water for irrigation, or liability for degradation of a stream. Broader public policy issues could include developing, implementing, and enforcing regulations specifying manure management practices that are protective of water quality.

Agricultural meteorology and climatology

Agricultural meteorology relates to agricultural water management in a number of ways. The type, timing, amount, intensity, and duration of precipitation are vitally important to agriculture. For example, long-term rainfall records are used in water quality models that examine agricultural contaminants in runoff or those that leach into groundwater. Agricultural meteorology also provides a knowledge base for irrigation scheduling.

The related field of climatology helps identify possible changes in precipitation patterns attributable to global climate change that could have an effect on agricultural water management. The study of climate variability also helps broaden our understanding of droughts and floods. Understanding of this variability can help agricultural water managers plan and prepare for extreme weather events.

Agronomy and soil science

Agronomy, and the associated disciplines of crop science, plant science, and horticulture, are all concerned with growing plants. Plant types range from alfalfa to tomatoes to turf grass, but all require water in the proper amount and at the proper time. These disciplines study plant water requirements and evaluate irrigation systems for their efficiency and effectiveness. The disciplines are also concerned with long-term effects of irrigation, particularly the buildup of salinity in soils and contaminated return flows. Land application of municipal wastewater and biosolids is also under the purview of these disciplines. Understanding the quality of irrigation water and its effects on plants and the environment is especially important in such waste management/crop production systems.

Nutrients in fertilizers and manures—applied to promote plant growth—and pesticides—applied to combat diseases and kill weeds and damaging insects—can harm water quality if not managed effectively. Agronomists study ways to optimize the amount, timing, and application methods of fertilizers and manures to ensure efficient plant growth while protecting groundwater and surface water quality. Similarly, agronomists help design integrated pest management programs that protect plant health while avoiding unnecessary applications of synthetic pesticides that may result in water contamination. To reduce sedimentation of water bodies by soil erosion, agronomists study cover crops and plant-related aspects of conservation tillage systems.

A closely related discipline, soil science, focuses on soil characteristics, responses to management, and effects of use. With regard to agricultural water management, soil scientists study the water-holding capacities and drainage characteristics of soils, the transport of nutrients and pesticides through the soil profile, and the effectiveness of conservation tillage systems in controlling erosion.

Animal science

Animal science deals with raising livestock and poultry. Animal scientists study the water quality and quantity requirements of various farm animals for optimum production. Since nutrients in manures can cause water quality problems, animal scientists address this problem by finding ways for animals to use nutrients in their feed more efficiently, thereby excreting less in the manure.

Aquatic biology

Aquatic biology is the study of living resources—and the factors affecting them—in freshwater systems. Agricultural activities may produce unintended, negative effects on aquatic organisms. For example, expanding cropland by clearing trees from a riparian area removes shading from the stream. Without this protection, stream temperatures may rise to a level unsuitable for cold-water fish. Aquatic biologists can assess the effect agricultural practices may have on aquatic life, both on the farm and downstream.

Environmental engineering

Environmental engineering is concerned with the physical, chemical, and biological control of water and wastewater treatment systems. All aspects of water and wastewater treatment systems are related to environmental engineering practices including collection, storage, stabilization, advanced chemical and biological treatment, and distribution systems. Environmental engineers are typically responsible for the design and operation of water and wastewater treatment plants. Specialized areas include engineering design and evaluation of conduit (pressurized) and open channel flow systems as well as hazardous waste treatment and disposal systems. Environmental engineers also model and evaluate the impact of municipal and industrial wastewater discharges on surface water and groundwater quality.

Forestry and natural resources conservation

Forestry and natural resources conservation also have relevance to agricultural water management. Specialists in these fields may study the establishment, growth, maintenance, and species composition of woody and herbaceous plants in riparian buffers; the effects of stream bank plantings to provide shade and cover and reduce stream bank erosion and other management methods to reduce sediment inputs to streams.

Hydrology and hydrogeology

Hydrology and hydrogeology are focused on water availability and movement as they relate to both surface and groundwater flow regimes. Hydrology is the scientific building block for scientific and engineering water management disciplines. Monitoring of precipitation, stream flows and groundwater flows, in space and time, are the basis for both short-term and long-term quantity and quality records. These records are used to evaluate agricultural and other land-use impacts on water resources, as well as to develop tools that provide predictive capabilities for impact analysis.

Hydrogeology—the integrated sciences of geology and hydrology—focuses on the various geologic formations and their hydraulic characteristics, providing opportunities to develop tools for the estimation of aquifer recharge and yield under different climates, land use, and water withdrawal scenarios. Hydrogeologists are also concerned with the vulnerability of aquifers to contamination from land uses in recharge areas. Studies in this area involve monitoring and evaluation of land-use practices and how they impact the natural aquifer quality parameters; water quality changes derived from land-use impacts; and the effect these quality changes may have on water supply withdrawals and return flows to streams.

Range science

Range science is concerned with rangeland ecology and the use of rangelands to meet human needs, including raising livestock for food. When animals graze in rangeland riparian areas, they may increase erosion and sedimentation, deposit manure and urine in or very near streams, and reduce stream shading by damaging adjacent vegetation. Stream water quality can suffer, and aquatic habitats can be negatively altered. Range scientists investigate ways to utilize rangelands for livestock grazing in ways that protect water quality and associated natural resources.

CONCLUSION

The broad spectrum of agricultural water management activities provides opportunities for many disciplines to contribute to the field. Some disciplines focus on biological, chemical, and physical aspects, while others address social and economic issues. Each discipline has tools and technologies that can be applied to improving agricultural water management, while addressing related environmental, economic, and social problems.

Acid Rain and Precipitation Chemistry

Pao K. Wang
Atmospheric and Oceanic Sciences, University of Wisconsin–Madison, Madison, Wisconsin, U.S.A.

INTRODUCTION

Acid rain is a phenomenon of serious environmental concern. By definition, acid rain refers to rainwater that is acidic. But in reality, it is more accurate to use the term *acid deposition* since not only rain but also snow, sleet, hail, and even fog can become acidic. In addition to the process where acids become associated with precipitation (called *wet deposition*), acid gases and particles can also be deposited on the earth surface directly (called *dry deposition*). However, since the name "acid rain" has become a household term and its formation is better understood than other types of acid deposition, the following discussions will focus on acid rain.

Whereas an aqueous solution is acidic if its pH value is less than 7.0, acid rain refers to rainwater with pH less than 5.6. This is because, even without the presence of man-made pollutants, natural rainwater is already acidic as CO_2 in the atmosphere reacts with water to produce carbonic acid:

$$CO_2 + H_2O(l) \Leftrightarrow H_2CO_3(l) \tag{1}$$

The pH value of this solution is around 5.6. Even though the carbonic acid in rain is fairly dilute, it is sufficient to dissolve minerals in the Earth's crust, making them available to plant and animal life, yet not acidic enough to cause damage. Other atmospheric substances from volcanic eruptions, forest fires, and similar natural phenomena also contribute to the natural sources of acidity in rain. Still, even with the enormous amounts of acids created annually by nature, normal rainfall is able to assimilate them to the point where they cause little, if any, known damage.

However, large-scale human industrial activities have the potential of throwing off this acid balance, and converting natural and mildly acidic rain into precipitation with stronger acidity and far-reaching environmental effects. This is the root of the acid rain problem, which is not only of national but also international concern. This problem may have existed for more than 300 yr starting at the time when the industrial revolution demanded a large scale burning of coal in which sulfur was a natural contaminant. Several English scholars, such as Robert Boyle in the 17th century and Robert A. Smith of the 19th century, wrote about the acids in air and rain; though, there was a lack of appreciation of the magnitude of the problem at that time. Individual studies of the acid rain phenomenon in North America started in the 1920s, but the true appreciation of the problem came only in the 1970s.

To address this problem, the U.S. Congress established the National Acid Precipitation Assessment Program (NAPAP) to study the causes and impacts of the acid deposition. This research established that the acid rain does cause broad environmental and health effects, the pollution causing acid deposition can travel hundreds of miles, and the electric power generation is mainly responsible for SO_2 (~65%) and NO_x emissions (~30%). Subsequently, Congress created the Acid Rain Program under Title IV (Acid Deposition Control) of the 1990 Clean Air Act Amendments. Electric utilities are required to reduce their emissions of SO_2 and NO_x significantly. By 2010, they need to lower their emissions by 8.5 million tons compared to their 1980 levels. They also need to reduce their NO_x emissions by 2 million tons each year compared to the levels before the Clean Air Act Amendments.

However, it may not be adequate to solve the acid emission merely at the national level. With increasing industrialization of the Third World countries in the coming century, one can expect great increase of the atmospheric loading of SO_2 and NO_x because many of these countries will burn fossil fuels to satisfy their energy needs. Clearly, some form of international agreements need to be forged to prevent serious environmental degradation due to acid rain.

THE CHEMISTRY OF ACID RAIN

Sulfuric acid (H_2SO_4) and nitric acid (HNO_3) are the two main acid species in the rain. The partitioning of acids in rain may be different in different places. In the United States, the partitioning is H_2SO_4 (~65%), HNO_3 (~30%), and others (~5%). While there are many possible chemicals that may serve as the precursors of acid rain, the two main substances are SO_2 and NO_x (and NO_x consists of NO and NO_2), and both are released to the atmosphere via the industrial combustion process. While power generation is the predominant source of these precursors, industrial boilers and

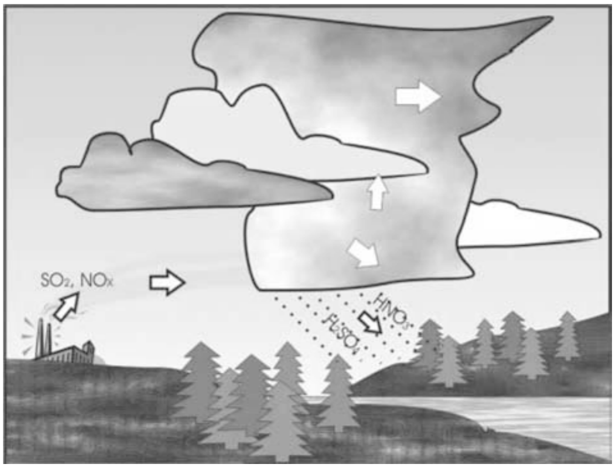

Fig. 1 A schematic of the acid rain formation process.

automobiles also contribute substantially. When these precursors enter the cloud and precipitation systems, acid rain occurs. Fig. 1 shows a schematic of the acid rain formation process.

Once airborne, these chemicals can be involved in milliards of chemicals reactions. The main paths that lead to acid rain formation are described as follows.

Sulfuric Acid

SO_2 is believed to be the main precursor for the formation of sulfuric acid drops. Its main source in the atmosphere is the combustion of fossil fuels. This is because sulfur is a natural contaminant in coal (especially the low grade ones) and oil. The following reactions are thought to occur when SO_2 is absorbed by a water drop (see e.g., Refs.[1,2]):

$$SO_2(g) + H_2O(l) \Leftrightarrow SO_2 \cdot H_2O(l) \tag{2}$$

$$SO_2 \cdot H_2O \Leftrightarrow H^+ + HSO_3^- \tag{3}$$

$$HSO_3^- \Leftrightarrow H^+ + SO_3^{-2} \tag{4}$$

$$SO_3^{-2} \xrightarrow{\text{oxidation}} SO_4^{-2} \tag{5}$$

The oxidant of the last step can be H_2O_2, O_3, OH, and others. There are still controversies about the identity of the oxidants.

Note that the equilibrium of the above reaction system is controlled by the pH values of the drop, and the presence of ammonia is often considered together with these reactions since it affects the pH of the drop. A detailed discussion of these reactions and their rates is given in Chapter 17 of Ref.[1].

Nitric Acid

The main ingredients for the formation of nitric acid are NO and NO_2 (and are often combined into one category, NO_x). It is commonly thought that the main path of nitric acid found in clouds and raindrops is the formation of gas phase, HNO_3, followed by its uptake by liquid water. Although there are reactions of NO_x with liquid water that can lead to nitric acid, they are thought to be unimportant due to their slow reaction rates.

The main reaction for HNO_3 formation is

$$NO_2 + OH + M \rightarrow HNO_3 + M \tag{6}$$

where M can be any neutral molecule. NO can be converted to NO_2 by the following reaction:

$$2NO + O_2 \rightarrow 2NO_2 \tag{7}$$

DROP-SCALE TRANSPORT PROCESSES OF ACID RAIN

The chemical reactions described earlier must be considered together with the transport processes to obtain a quantitative picture of the acid rain formation. This is especially true for SO_2 because absorption and reactions occur simultaneously. The convective transport influences the concentrations of different species and hence the reaction rates. Fig. 2 illustrates these processes schematically. These include the following.

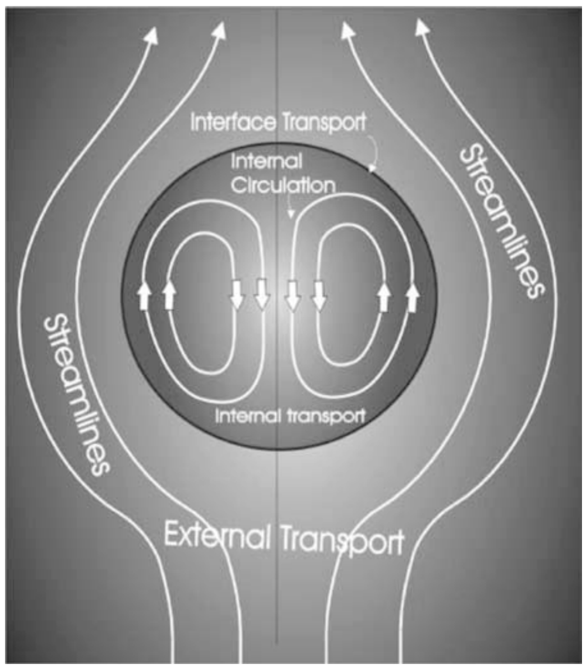

Fig. 2 A schematic of the drop-scale transport process of sulfur species involved in the acid rain.

External Transport

This refers to the transport of SO_2 gas toward the surface of the drop. It is a convective diffusion process (both convective transport and diffusional transport occur) and is influenced by the flow fields created by the falling drop and atmospheric conditions (pressure and temperature).

Interfacial Transport

Once SO_2 is adsorbed on the surface of the drop, it must be transferred into the interior for further reactions to occur. The time for establishing phase equilibrium is controlled by Henry's law constant and mass accommodation coefficient of SO_2.

Internal Transport

In the interior of the drop, reactions (2)–(5) occur. At the same time, these species are transported by both diffusion and internal circulation. The latter is caused by the motion of the liquid drop in a viscous medium and can influence the production rates of these species (see Ref.[1]).

ENVIRONMENTAL FACTORS INFLUENCING THE ACID RAIN FORMATION AND IMPACTS

Like many environmental hazards, the acid rain process is not driven by a few well-controlled physical and chemical processes, but involves complicated interactions between the chemicals and the environments they exist in. While the main ingredients of acid rain come from industrial activities, many other factors may influence the formation of acid rain and its impacts. The following are some of the most important.

Meteorological Factors

Acid rain occurs in the atmosphere and hence is greatly influenced by meteorological factors such as wind direction and speed, amount and frequency of precipitation, pressure patterns, and temperature. For example, in drier climates, such as the western United States, wind blown alkaline dust is abundant and tends to neutralize the acidity in the rain. This is the *buffering effect* of the dust. In humid climates, like the Eastern Seaboard, less dust is in the air, and precipitation tends to be more acidic.

Seasonality may also influence acid precipitation. For example, while it is true that rain may be more acidic in summer (because of higher demands for energy and hence more fossil fuel used), the snow in winter can also pick up substantial amount of acids. These snow-borne acids can accumulate throughout winter (if the weather is cold enough) and then are released in large doses during the spring thaw. These large doses of acid may have more significant effects during fish spawning or seed germination than the same doses at some less critical time.

Topography and Geology

The topography and geology of an area have marked influence on acid rain effects. Research from the U.S. EPA pointed out that areas most sensitive to acid precipitation are those with hard, crystalline bedrock and very thin surface soils. Here, in the absence of buffering properties of soil, acid rains will have direct access to surface waters and their delicate ecosystem. Areas with steep topography, such as mountainous areas, generally have thin surface soils and hence are very vulnerable to acid rain. In contrast, a thick soil mantle or one with high buffering capacity, such as most flatlands, helps keep acid rain damage down.

The location of water bodies is also important. Headwater lakes and streams are especially vulnerable to acidification. Lake depth, the ratio of water-shed area to lake area, and the residence time in lakes all play a part in determining the consequent threat posed by acids. The transport mode of the acid (rains or runoff) also influences the effects.

Biota

Acid rain may fall on trees causing damages. The kinds of trees and plants in an area, their heights, and whether they are deciduous or evergreen may all play a part in the potential effects of acid rain. Without a dense leaf canopy, more acid may reach the earth to impact on soil and water chemistries. Stresses on the plants will also affect the balance of local ecosystem. Additionally, the rate at which different types of plants carry on their normal life processes influences an area's ratio of precipitation to evaporation. In locales with high evaporation rates, acids will concentrate on leaf surfaces. Another factor is that leaf litter decomposition may add to the acidity of the soil due to normal biological actions.

Dov Pasternak
International Crops Research Institute for the Semi-Arid Tropics, Niamey, Niger

INTRODUCTION

Agricultural production in sub-Saharan Africa relies mainly on rain-fed systems.[1] In the semiarid and dry subhumid regions of Africa, these systems are neither sustainable nor profitable. Areas of monocultures of grains and legumes exhibit severe land degradation, mostly as a result of water and wind erosion.[2] Crop yields are very small, the commercial value of the common grains (millet and sorghum) is very low, and revenue is thus meager. On average, crop failures occur in two out of five years as a result of droughts. The final outcome of these processes is severe poverty.

Irrigated agriculture can help alleviate poverty and reduce the stress on natural resources, especially since many countries in dry Africa are rich in non-utilized water resources. For example, the combined annual discharge of the Niger and the Senegal rivers is about 40 billion $m^3\,yr^{-1}$, a value comparable with the 75 billion $m^3\,yr^{-1}$ of the Nile river. In addition, rich shallow aquifers underlie much of Sahelian Africa,[3] and there are phreatic shallow aquifers in the proximity of seasonal rivers. The large-scale utilization of such water reserves for irrigation is hampered by the relatively high costs of large water projects and of inputs and by low crop yields.[4] Furthermore, there is little motivation to initiate large-scale schemes, since international prices for irrigated commodities are relatively low.

In many areas of dry Africa, market gardens are the only form of irrigated agriculture.[4] These gardens are sustainable and profitable, because they supply perishable products such as fruit and vegetables that, for obvious reasons, cannot be imported from elsewhere. The importance of market gardens is growing steadily due to the rapid increase of urban population that can afford to buy fruits and vegetables in city markets. However, for the market gardens to be successful, many problems associated with climatic and social conditions and the lack of appropriate technologies have to be addressed first. One of the most important problems is that of irrigation. Most market gardens are irrigated by hand with watering cans. This activity is obviously extremely labor demanding and inefficient. In some places, surface irrigation (mainly basin irrigation) is also practiced. The drawbacks of this latter system are the relatively high energy input required for motorized water pumps and the low water use efficiency, particularly in sandy soils, from which a large proportion of the water is lost through seepage. Yields and quality of fruits and vegetables are low because of the inefficient supply of water and nutrients, the low quality of seeds, and ineffective pest and disease control methods.

BACKGROUND INFORMATION

In many countries (particularly those towards the north of the continent), market gardens operate only five months of the year (November–March). During the rainy season (July–October) there is shortage of labor for irrigation, since, at that time, all labor is directed to rain-fed fields. Furthermore, in the rainy season, it is difficult to control diseases and pests. The April–July period is very hot, and most vegetable species do not give good yields under conditions of severe heat. Furthermore, in the hot season, it is difficult to carry watering cans or to do any sort of work under the scorching sun.

Drip irrigation can provide the solution to the above-described problems. Drip systems can easily deliver water to the field in daily quantities required on the basis of transpiration demands. With this system, all plants receive the same quantity of water and fertilizers, and very low soil water tension is maintained throughout the day. These advantages lead to significant increases in yield and in improved product quality as compared with other systems.[5–9] An additional advantage is that drip irrigation is particularly suitable for saline water irrigation.[10]

Conventional drip-irrigation systems were designed for large surfaces and are too costly and difficult to maintain for small fields. In response to the need for systems suitable for small areas, Israeli drip-irrigation companies have recently developed low-pressure drip-irrigation (LPDI) systems for the small traditional greenhouses of China. Although the LPDI concept was first tested in Israel as long ago as the mid-1980s,[11] the system was not commercialized at that time, mainly because of problems of drip clogging. The recently developed LPDIs have large drip orifices that minimize clogging by impurities in the irrigation water.

The LPDI system has been adapted by us to become the basis of an integrated production system, designated the African Market Garden (AMG) [or in French, Jardin Potager Africain (JPA)] described below.

THE AFRICAN MARKET GARDEN

Technical Description and Operation of the LDPI System

The hydraulic performance of three different LPDI systems manufactured in Israel (Ein Tal, Netafim, and Plastro-Gvat) has been tested in the field.[12] In all the tested systems, the variation in water discharge from the first to the last dripper in a 12.5-m long drip lateral at a water pressure of 1.3 m did not fall below 90%, and at 1.8 m of pressure there were no differences in water discharge among individual drippers along a 12.5-m drip lateral.

A schematic presentation of the LPDI manufactured by Netafim is given in Fig. 1.

The system consists of the following elements: a water reservoir positioned at least 1 m above the field level, a water valve, a filter, distribution lines, and drip laterals. Additional details of the system are given in Fig. 1. The operation of the system is very simple. It involves filling of the reservoir to a particular level, cleaning the filter, and opening the tap. Irrigation is completed when the reservoir is empty. Once a week, the ends of all laterals are opened; the system is flushed for about 5 min to clean it from possible accumulated impurities; and the reservoir is drained.

The relationship between the reservoir size and the irrigated area is constant and depends on the daily evapotranspiration (ET) of the particular region. As an example, the average daily potential ET in Niamey for the 12 months of the year is given in Fig. 2. Two distinct seasons can be observed. A season of high ET of about 8 mm day^{-1} (February–May) and a season of lower ET of about 6 mm day^{-1} (June–February). The volume of the reservoir should be planned to accommodate the maximum daily quantity of irrigation water required in the particular region. In places with two distinct seasons, such as Niamey, two lines are drawn on the reservoir. In Niamey, the upper line indicates the volume that is needed to give the field a daily irrigation rate of 8 mm. The lower line indicates the volume that will supply 6 mm day^{-1}.

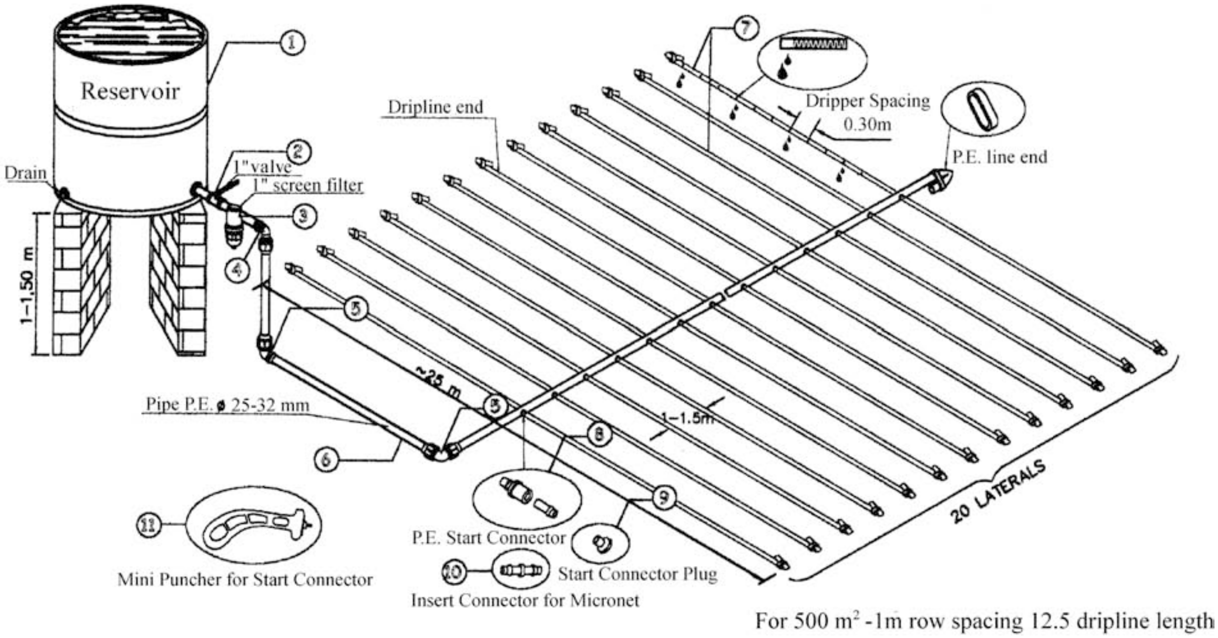

Fig. 1 Schematic presentation of the LDPI system: 1. Water reservoir; 2. plastic ball valve 1″ female thread; 3. plastic filter 1″ male thread (120 mesh); 4. P.E. quick-coupling elbow—25 mm × 1″, female thread; 5. P.E. quick-coupling elbow—25 mm; 6. main line—LDPE pipe 25 mm class 2.5; 7. dripline—LDPE integrated FDS dripline; 8. start connector—barbed type, for FDS dripline; 9. start connector plug; 10. insert connector for 8-mm dripline; 11. mini puncher for start connector. (Note: The illustration of the Netafim design does not infer any preference of the authors for the design of that company.)

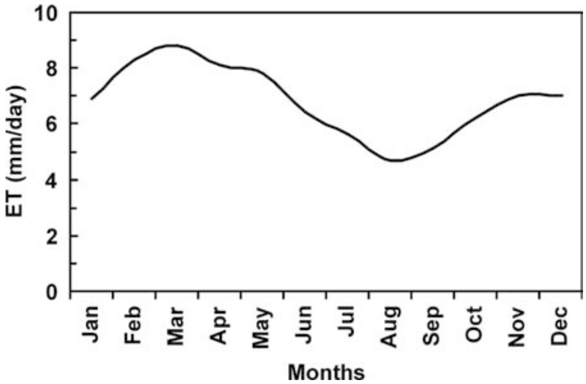

Fig. 2 Average monthly values of potential ET in Niamey, Niger. (From ICRISAT Sahelian Center-Niger.)

The "basic unit" concept was introduced to describe a system with a fixed ratio between the reservoir volume and the field size. For example, in Niamey, an area of $500\,m^2$ requires a reservoir with a volume of 4000 L ($4\,m^3$) to supply a peak daily water requirement of 8 mm. Two systems were developed: 1) a "thrifty" system, which caters for farmers with limited resources (in many instances these are women who operate small backyard gardens or small plots in communal gardens); and 2) a "commercial" system, which caters to larger-scale producers, particularly periurban farmers. The basic unit for the thrifty system consists of an old 200-L oil drum (these are available everywhere in Africa at low prices), supplying an area of $40\,m^2$ and giving a daily irrigation rate of 5 mm (compromises in the quantity of water have to be made for the sake of simplification). The system is very versatile. For example, the same reservoir and distribution lines can serve an area of $80\,m^2$ or an area of $120\,m^2$ by filling the reservoir two or three times a day, as required. Likewise, two or three (or more) barrels can be interconnected to provide a basic unit of $80\,m^2$ or $120\,m^2$. The same principles are applicable to the commercial version of the AMG.

Water, Salt Buildup, and Nutrition Management

The problem of salt buildup in the soil usually accompanies irrigation systems in various degrees of severity. Among the parameters involved in salt buildup are the ratio between the evaporative demands and precipitations (including irrigation), water quality, soil texture, and the ability of irrigation water to leach salts.

In arid and semiarid regions, evaporative demands are high (e.g., Fig. 2). To prevent rapid salt buildup it is recommended to keep the daily amount of irrigation water above (10–20%) plant water requirements. The excess amount of water is needed to leach salts away from the rhizosphere. In cases of saline irrigation water, leaching requirements increase. In general, salt accumulation tends to be more intensive and fast in fine- than in coarse-textured soils due to the much larger specific surface area (SSA) of the former, that provides tight interactions with soil water solution.

Water, as the vector of salt in soils, determines salt distribution in the soil profile. Water moves in the soil in three directions: 1) upward, due to evaporation and capillarity; 2) horizontally, by capillary action; and 3) vertically (downward), by gravitational forces. In conventional drip irrigation, with water discharge rates above $2\,L\,hr^{-1}$, salts are leached thus creating a gradient of salt concentration that increases from beneath the emitter to the margins of the wetted zone. It has been suspected that with the lower water discharge rates (0.3–$0.7\,L\,hr^{-1}$) of LPDI the vertical water vector is too weak to provide sufficient salt leaching. To clarify this point, we conducted a series of experiments, in which salt distribution in the soil profile was compared between water discharge rates of $0.3\,L\,hr^{-1}$ ($1.3\,mm\,hr^{-1}$) and $2\,L\,hr^{-1}$ ($8.0\,mm\,hr^{-1}$) in fine- and coarse-textured soils, respectively (Fig. 3).

The crop was sweet corn. The field was irrigated daily based on 80% evaporation from a class A USWB evaporation pan adjusted to the leaf area index (LAI) of the crop. The electrical conductivity (EC) of irrigation water containing soluble fertilizers was $1.5\,dS\,m^{-1}$. Soil samples were taken 75 days after sowing. There was no rain during the experimental period. Large differences occurred, as expected, between fine- and coarse-textured soils. In fine-textured soil, salt accumulation at the upper layer of soil profile (0–10 cm) was remarkably fast, with no influence of water discharge rates (Fig. 3A and B). Below that layer, the pattern of salt distribution was a reflection of water distribution. Indeed, salt leaching to the margins was less pronounced under 0.3 as compared with 2-L hr^{-1} emitters. Similar patterns of salt distribution, but to a much lesser extent, were observed in the coarse-textured soil (Fig. 3C and D).

Two conclusions can be derived from these observations. First, to ensure sustainability, the use of the LPDI system in fine-textured soils should be restricted to regions with a considerable rainy season (above $400\,mm\,yr^{-1}$), during which accumulated salts are discarded either by water runoff or leaching to deep soil layers.

The second conclusion relates to fertilizing management. The relatively weak salt leaching under LPDI emitters implies that it is not necessary to add expensive soluble fertilizers to every irrigation event, as practiced with conventional drip irrigation. The prevailing horizontal movement of water under the low-discharge dripper can become an advantage when a heavy dose of manure ("side dressing") is applied between the drip

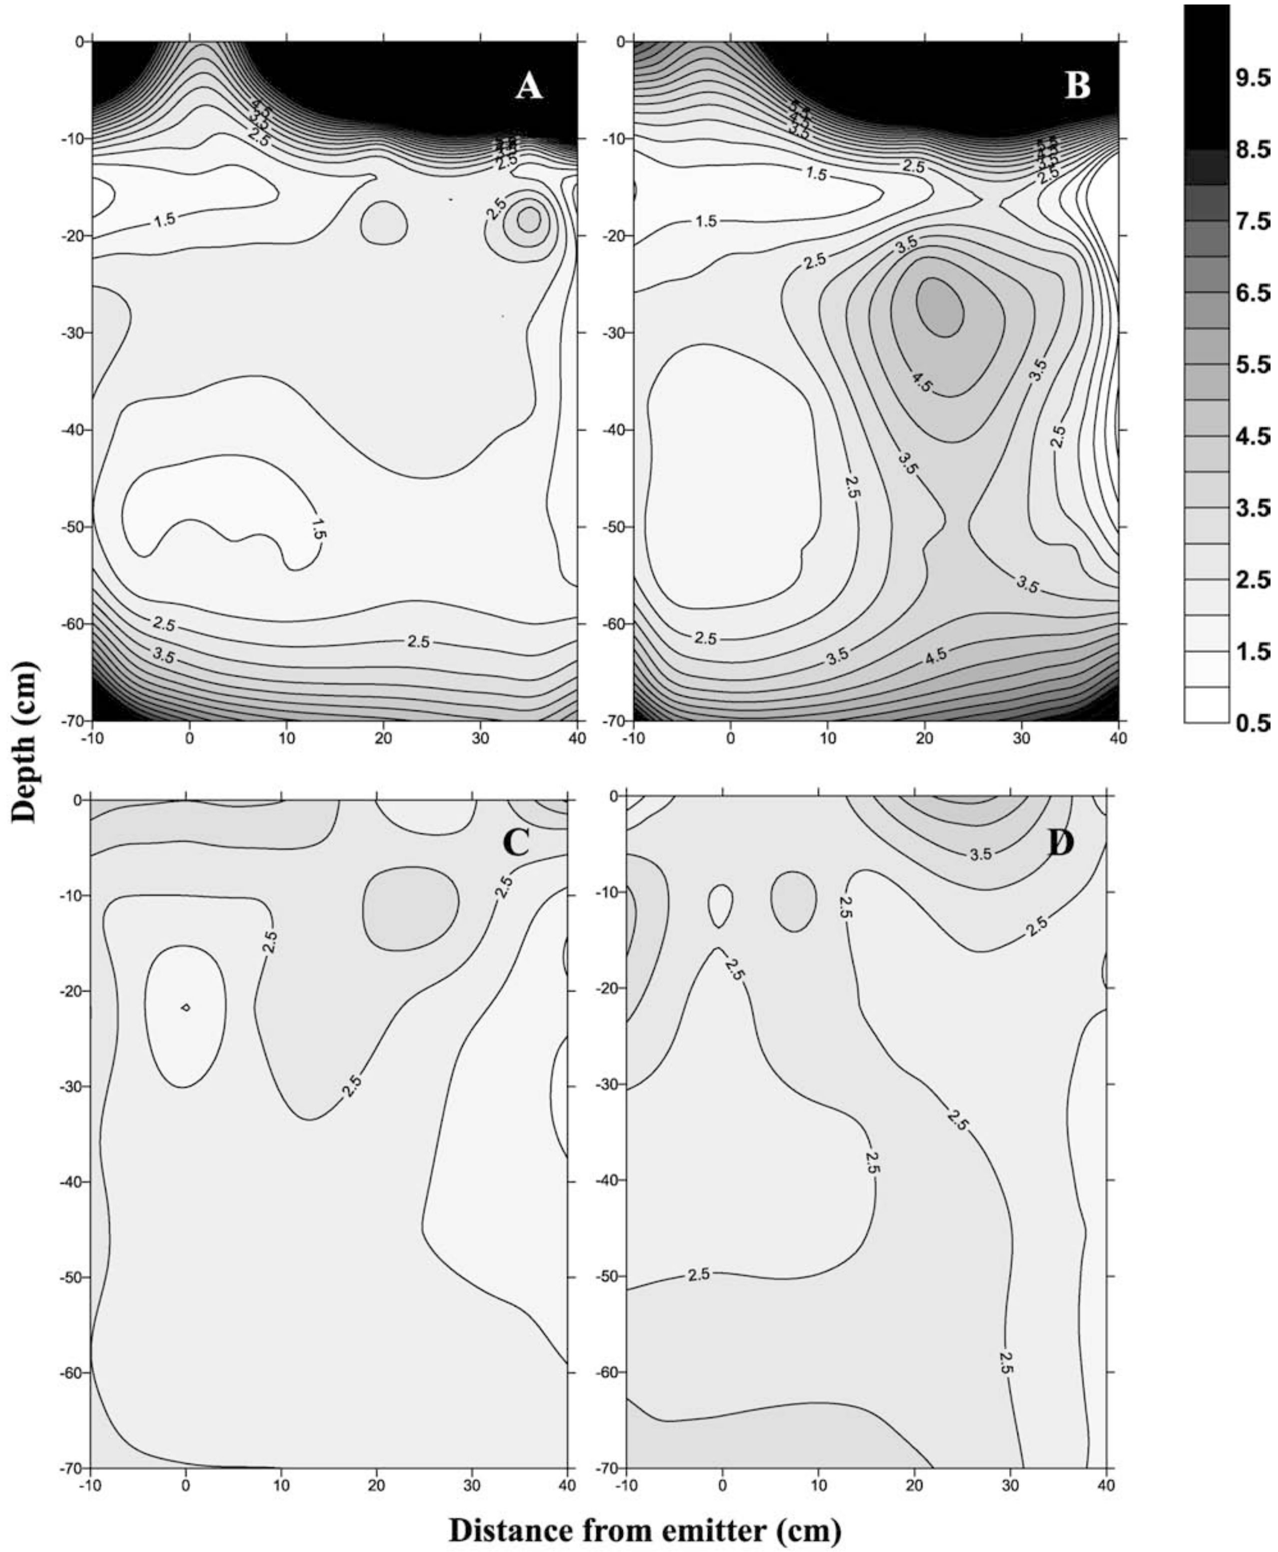

Fig. 3 Salt distribution (EC [$dS\,m^{-1}$] of saturated soil extracts) in the soil profile. Soil was sampled from 30 places at various depths and distances from the emitter. Drawings (produced using Surfer 7.0, Golden Software Ltd) represent soil profiles under 0.3-L hr^{-1} (A, C) and 2-L hr^{-1} (B, D) water discharge rates in fine- (A, B) and coarse-textured (C, D) soils, 75 day after sowing sweet corn. Amounts of irrigation water ($EC_I \sim 1.5\,dS\,m^{-1}$) were equal. The fine-textured soil was a silty clay loam containing 30% silt, 45% clay, and 25% sand. The coarse-textured soil contained 10% silt, 10% clay, and 80% sand.

lines. The roots will move towards the buried manure and draw most of the required nutrients from this source. Nevertheless, to guarantee a minimal supply of nitrogen to the crops, it is recommended that nitrogen, in the form of urea, be applied once a week at a rate of $0.5\,g\,m^{-2}$. The minimization of fertilizer application through water will prevent the formation of bacterial slime in the laterals, an important cause of drip clogging.

In a preliminary trial on lettuce in which soluble fertilizer was replaced by an application of organic manure, there was no difference in yield between the manured plots and the plots that received daily application of fertilizer through the irrigation system.

Effect of Rate of Emitter Discharge on Yield

At an average discharge of $1.5\,mm\,hr^{-1}$ and a daily ET of 6 mm, an irrigation cycle in the AMG lasts for 4 hr. In the light of reports that continuous irrigation may be beneficial to crop yields,[13–15] the effect of two different irrigation rates on sweet corn yield was tested (Table 1). It is evident from Table 1 that in both soil types prolonged irrigation has a slight positive effect on dry matter yield but does not affect ear yield. Thus, for corn (which under desert conditions suffers from water stress[15]), continuous application of water does not offer a significant advantage.

Crop Management

The typical market garden of Africa is characterized by the production of a mix of vegetables and fruit trees in a relatively small plot. The AMG thus also incorporates a mixture of crops. In hot dry areas, date palms are added to produce a three-layered production system (date palms, fruit trees, and annual crops). In a typical $500\,m^2$ plot, 9 date palms are planted (1 male and 8 female) in a 9×11 m configuration. Date palms, through their high transpiration rates and shading effects, produce a microclimate that facilitates reasonable growth of fruit trees and vegetables during the hot dry season. This date-palm-based production system is known as ‘‘oasis agriculture.’’ Date palms also improve the profitability of the system. At present-day prices, the income from 8 female plants is about $\$800\,yr^{-1}$. To prevent competition for water between the date palms and the other crops in the AMG, the drip laterals are looped around the stems of the palms to triple the amount of water given to the palms.

Table 1 Effect of two rates of irrigation on stover and ear yield of sweet corn fine- and coarse-textured soils

Irrigation intensity ($mm\,hr^{-1}$)	Stover DM yield[a] ($kg\,m^{-2}$)	Ear yield ($kg\,m^{-2}$)	Ears (m^{-2})
Fine-textured soil			
1.3	1.67a	2.45	6.17
8.0	1.25b	2.36	6.21
Coarse-textured soil			
1.3	1.25	2.06	6.32

CONCLUSION

The AMG—a new production system conceived in 1998—incorporates all the advantages of the conventional drip-irrigation system at a fraction of its cost. It is simple to operate and to maintain, and it provides significant increases in yield as well as considerable savings of energy and labor (this aspect is particularly important for women who operate small gardens). This system is applicable to all developing countries that require small-scale irrigation schemes.

The International Program for Arid Land Crops (IPALAC, which is managed by Ben-Gurion University of the Negev, Beer-Sheva, Israel) and Desert Margins Program (DMP, managed by the International Crops Research Institute for the Semi-Arid Tropics) have joined hands to disseminate the AMG system in semiarid Africa, starting in Ethiopia and in the Sahel. Recently, such systems were also installed in Rajasthan, India.

The AMG can therefore serve as a platform for the improvement of the small-scale irrigated agriculture in Africa. Its introduction will facilitate year-round production of irrigated fruit and vegetables, the incorporation of quality vegetable and fruit tree varieties, and the application of modern cost-effective methods for pest and disease management. An adoption of the AMG should significantly contribute to the alleviation of poverty—the most serious problem plaguing sub-Saharan Africa at the beginning of the 21st Century.

INTRODUCTION

Agricultural runoff is surface water leaving farm fields as a result of receiving water in excess of the infiltration rate of the soil. Excess water is primarily due to precipitation, but it can also be due to irrigation and snowmelt on frozen soils. In the early 20th century, there was considerable concern about erosion of farm fields due to rainfall. The concern was primarily related to the loss of valuable topsoil from the fields and the resulting loss in productivity (see Erosion and Productivity). With the passage of the Federal Water Pollution Control Act Amendments of 1972, the potential for pollution of surface water features such as rivers and lakes due to agricultural runoff was officially recognized and an assessment of the nature and extent of such pollution was mandated.[1,2]

Agricultural runoff is grouped into the category of non-point source pollution because the potential pollutants originate over large, diffuse areas and the exact point of entry into water bodies cannot be precisely identified (see Pollution, Point and Non-point Source). Non-point sources of pollution are particularly problematic in that it is difficult to capture and treat the polluted water before it enters a stream. Point sources of pollution such as municipal sewer systems usually enter the water body via pipes and it is comparatively easy to collect that water and run it through a treatment system prior to releasing it into the environment. Because of the non-point source nature of agricultural runoff, efforts to minimize or eliminate pollutants are, by necessity, focused on practices to be applied on or near farm fields themselves. In other words, we usually seek to prevent the pollution rather than treating the polluted water.

Due to the great successes made in treating polluted water from point sources such as municipal and industrial wastewater treatment plants, the relative significance of pollution from agricultural runoff has increased. Agricultural runoff is now considered to be the primary source of pollutants to the streams and lakes in the United States. It is also the third leading source of pollution in U.S. estuaries.[3] The water pollutants that occur in agricultural runoff include eroded soil particles (sediments), nutrients, pesticides, salts, viruses, bacteria, and organic matter.

AGRICULTURAL RUNOFF QUANTITY

Agricultural runoff occurs when the precipitation rate exceeds the infiltration rate of the soil. Small soil particles that have been dislodged by the impact of raindrops can fill and block soil pores with a resulting decrease in infiltration rate throughout the duration of the storm. As the excess precipitation builds up on the soil surface it flows in thin layers from higher areas of the field towards lower areas. This diffuse surface runoff quickly starts to concentrate in small channels called rills. The concentrated flow will generally have a higher velocity than the flow in thin films over the surface. The concentrated flow velocity may become rapid enough to cause scouring of the soil that makes up the channel sides and bottom. The dislodged soil particles can then be carried by the flowing water to distant locations in the same field or be carried all the way to a receiving water body. If the quantity of flow and the velocity of flow are large enough, the rills can grow so large that they cannot be easily repaired by typical earth moving machinery. When this happens, the rill has become a gulley.

The quantity of runoff from agricultural fields is not usually listed explicitly as a concern separate from the quality of the runoff. However, it should be considered because it transports the pollutants and can cause erosion of receiving streams due to excessive flows. If less runoff is allowed to leave a field, there is less flow available to transport pollutants to the stream. Also, if more water is retained on the field, there is likely to be a corresponding reduction in the amount of supplemental water that will need to be added through irrigation. Runoff quantity varies significantly due to factors such as soil type, presence of vegetation and plant residue, physical soil structures such as contoured rows and terraces, field topography, and the timing and intensity of the rainfall event.

Some agricultural practices increase the infiltration capacity of the soil while other practices can result in decreases. The presence of vegetation and plant residues on a field reduce runoff due to improving and maintaining soil infiltration capacity. Actively growing plants also reduce the amount of water in the soil due to evapotranspiration, thus making more room for infiltrating water to be stored in the soil profile. Bare soils increase runoff because there is nothing except the soil surface to absorb the energy of the falling raindrops. The rain, therefore, dislodges soil particles that will tend to seal the surface and reduce infiltration.

SOIL EROSION AND ASSOCIATED POLLUTANTS

One of the primary pollutants in agricultural runoff is eroded soil. In 1975, 223 million acres of cropland produced 3700 million tons of eroded sediments or an average of 17 tons of soil lost per acre of cropland per year (see various *Erosion* articles). It is estimated that cropland, pasture, and rangeland contributed over 50% of the sediments discharged to surface waters in 1977.[4] As noted above, the energy of raindrops can dislodge and transport soil particles. In the aquatic environment the eroded soil is called sediment. There are several concerns related to excessive sediments in aquatic systems. These include loss of field productivity, habitat destruction, reduced capacity in reservoirs, and increased dredging requirements in shipping channels.

Eroded sediments represent a loss of fertile topsoil from the field, which can reduce the productivity of the field itself. Soil formation is an extremely slow process occurring over periods ranging from decades to centuries.[5] Possible results to a grower from excessive erosion of their fields include increasing fertilizer and water requirements, planting more tolerant crops, and possibly abandoning the field for agricultural production (see the article *Erosion and Productivity*).

A second concern is that many of these sediments are heavy and will settle out in slow moving portions of streams or in reservoirs. The settled sediments can dramatically alter the ecology of the streambed. Aquatic plants, insects, and fish all have specific requirements related to composition of the streambed for them to live and reproduce.[6] Sediments in reservoirs reduce the volume of the reservoir available to store water. This may result in reduced production of hydroelectric power, reduced water availability for municipal supply, interference with navigation and recreation, and increased dredging requirements to maintain harbor navigability.

Another concern with eroded sediments is that they can transport other pollutants into receiving waters. The plant nutrient phosphorus, for example, is most often transported from the fields where it was applied as fertilizer by chemically bonding to clay minerals. Many agricultural pesticides also bond to eroded clays and organic matter. Once these chemicals have entered the aquatic ecosystem, many processes occur that can result in the release of the pollutants from their sediment carriers. Phosphorus, when released, can contribute to the eutrophication of lakes and reservoirs (see the articles *Eutrophication* and *Surface Water: Quality and Phosphorus Applications*). Pesticides and their degradation products can be toxic to aquatic life and must be removed from municipal water supplies (see the article *Pesticide Contamination: Surface Water*).

Erosion from animal agriculture such as feedlots and pastures can also result in the transport of sediments composed of animal manures (see the various *Manure Management* articles). These sediments can transport significant quantities of potential pathogens (viruses and bacteria). The animal manures are primarily organic in nature and can serve as a food source for natural bacteria in the receiving water. When these naturally occurring bacteria begin to utilize the organic matter in this way they may lower or deplete the water of dissolved oxygen as they respire and multiply. This use of oxygen by aquatic bacteria is known as biochemical oxygen demand (BOD). High levels of BOD can reduce stream oxygen level to the point that fish and other organisms that require dissolved oxygen suffer, die, or relocate, when possible, to more suitable habitats.[6]

DISSOLVED POLLUTANTS

Agricultural runoff can carry with it many pollutants that are dissolved in the runoff water itself. These may include plant nutrients, pesticides, and salts. Since these pollutants are dissolved in the runoff, control measures are most often aimed at reducing the volume of runoff leaving an agricultural field, or making the pollutants less available to be dissolved into the runoff water.

One of the major pollutants of concern in agricultural runoff is the plant nutrient nitrogen. Nitrogen is a relatively cheap component of most fertilizers and is necessary for plant growth. Unfortunately, nitrogen in the form of nitrate is highly soluble in water. Thus nitrate can be easily dissolved in runoff water. Just as it does in an agricultural field, nitrogen can promote growth of aquatic vegetation. Excess nitrogen and phosphorus in runoff can lead to the eutrophication of lakes, reservoirs, and estuaries (see the articles *Eutrophication* and *Surface Water: Pollution by Nitrogen Fertilizers*). Nitrogen in the form of ammonia can be dissolved into runoff from pastures and feedlots. Ammonia is toxic to many aquatic organisms, thus it is important to minimize ammonia in runoff.[7]

Many agriculturally applied pesticides are also soluble in water. They can be dissolved in runoff and transported into aquatic ecosystems where there is a potential for toxic effects. These pesticides must also be removed from drinking water supplies and, if concentrations are high or persistent, such treatment can be difficult and expensive. Stable, persistent pesticides can bioaccumulate in the food chain with the result that consumers of fish from contaminated waters might be exposed to higher concentrations than exist in the water itself.[8]

Runoff from agricultural fields can contain significant concentrations of dissolved salts. These salts originate in precipitation, irrigation water, fertilizers and other agricultural chemicals, and from the soil minerals. Plants generally exclude ions of chemicals that they do not need. In this way, dissolved salts in irrigation water, for example, can be concentrated in the root zone of the growing crop. Runoff can redissolve these salts and transport them into aquatic ecosystems where some, naturally occurring selenium for example, can be toxic to fish and other wildlife.[9]

Transport of fertilizers and pesticides from their point of application can result in significant environmental costs. This transport, or loss from the field, can also have significant negative economic impacts on the grower. Fertilizers lost from the field are not available to promote crop growth. Agricultural chemicals lost from the field, likewise, are not available to protect the plants from pests and diseases. In both cases the grower is paying for expensive inputs and paying to apply them. It is always in the growers' and the environment's best interests, therefore, to keep agricultural chemicals in the field where they are needed and where they were applied.

CONTROL OF AGRICULTURAL RUNOFF

One of the most direct methods of controlling pollution by agricultural runoff is to minimize the potential for runoff to occur. Other methods can be employed to reduce the amounts of sediments and dissolved chemicals in runoff. As a whole, management practices designed to minimize the potential for environmental damage from agricultural runoff are called best management practices (BMPs), (see the article *Nutrients: Best Management Practices*). Many times, practices aimed at controlling one aspect of agricultural runoff are also effective at reducing other components. This is due to the interrelationships between runoff volume, erosion, transport, dissolution, and delivery.

Maintaining good soil tilth and healthy vegetation can minimize runoff. This will promote increased infiltration and a resultant decrease in runoff. Other management practices such as terracing, contour plowing, and using vegetated waterways to convey runoff can result in decreased quantities of runoff by slowing the water leaving the field and allowing more time for infiltration to occur. Construction of farm ponds to receive runoff can result in less total runoff from the farm, lowered peak rates of runoff, and storage of runoff for use in irrigation or livestock watering.[2]

Control of water pollution by the mineral and organic sediments and associated chemicals in agricultural runoff is most effectively achieved by reducing erosion from the field. The primary method of reducing erosion is by maintaining a vegetative or plant residue cover on the field at all times or minimizing areas of the field that are bare. Techniques utilized to accomplish these tasks include conservation tillage, strip tillage, and the use of cover crops (see the article *Erosion Control: Tillage/Residue Methods*). Additional measures that can be employed at the edge of the field, or off-site include vegetative filter strips and farm ponds (see the article *Farm Ponds*).

Methods to control the loss of nitrogen and other plant nutrients from cropland include applying nitrogen in the quantity required by the crop and at the time the crop needs it (see the article *Nutrients: Best Management Practices*). This requires multiple applications and can be difficult for tall crops. For this reason, most, or all, of the nitrogen required by the crop is often applied at planting. Nitrogen fertilizers have often been applied based on general recommendations for the type of crop to be grown. Since nitrogen fertilizers are relatively inexpensive, growers have tended to over apply rather than under apply. Soil tests can tell a grower how much nitrogen is already in the soil and how much needs to be applied for a specific crop. Efforts have been made to make the nitrogen less soluble by changing the form of nitrogen applied to the field so that it becomes available to the plants (and, thus available for loss in runoff) more slowly.[10]

One method of controlling the loss of agricultural chemicals is to minimize their solubility in water. Another is to minimize their use through programs such as integrated pest management (IPM) where some crop damage is allowed until it reaches a point that it becomes economically justified to apply pesticides.[11] And a third approach is to make the chemicals more easily degraded so that they do their job and then degrade into other, less harmful, chemicals so that they do not stay around long enough to be influenced by runoff-producing rainfall events.

CONCLUSION

Agricultural runoff is one of the leading causes of water quality impairment in streams, lakes, and estuaries in the United States. It can transport large quantities of sediments, plant nutrients, agricultural chemicals, and natural occurring minerals from farm fields into receiving water bodies. In many cases the loss of these substances from the field represent an economic loss to the grower as well as a potential environmental contaminants. There are many methods by which the quantity of agricultural runoff can be reduced. Many of these methods are referred to generically as BMPs. Adoption of BMPs can also improve the quality (reduce contaminant concentrations) of the runoff that does leave the farm. By reducing the quantity and improving the quality of agricultural runoff, it will be possible to improve the water quality in our streams, river, lakes, and estuaries.

Agroforestry: Enhancing Water Use Efficiency

James R. Brandle
Xinhua Zhou
School of Natural Resources, University of Nebraska, Lincoln, Nebraska, U.S.A.

Laurie Hodges
Department of Agronomy and Horticulture, University of Nebraska, Lincoln, Nebraska, U.S.A.

INTRODUCTION

Agroforestry is the intentional integration of trees and shrubs into agricultural systems. Windbreaks, riparian forest buffers, alley-cropping, silvopastoral grazing systems, and forest farming are the primary agroforestry practices found in temperate regions of North America.[1] Placing trees and shrubs on the landscape changes the surface energy balance, influences the surrounding microclimate, and has the potential to alter water use and productivity of adjacent crops.[2,3]

In agricultural systems, water is often the major factor limiting growth. When water availability is limited as a result of limited supply or high cost, its efficient use becomes critical to successful production systems. For example, proper irrigation at the appropriate stage of crop development minimizes pumping costs and increases yield; reducing soil tillage conserves soil water and may enhance yield, and reducing surface runoff or trapping snow improves soil water storage for future crop use. These water conservation efforts contribute to the efficient use of available water and are determined primarily by management practices. In contrast, Tanner and Sinclair[4] distinguish between the efficient use of water and water use efficiency (WUE). WUE is primarily a function of physiological responses of plants to environmental conditions. This review focuses on WUE defined as the amount of biomass (or grain) produced per unit of land area for each unit of water consumed.[4]

Soil water may be consumed by evaporation from the soil surface or by the transport of water through the plant and subsequent evaporation from the leaf surface. The rate of water consumption is determined by the microclimate of the crop. Because agroforestry practices alter the microclimate of adjacent fields, they affect WUE of plants growing in those fields.

DISCUSSION

Windbreaks, riparian forest buffers or alley-cropping systems are the practices most likely to be integrated into crop production systems. In all three practices, trees and shrubs tend to be arranged in narrow barriers adjacent to the crop field. Microclimate responses downwind of any of these types of barriers are similar and the following discussion applies to all three types of barriers. As wind approaches these barriers, it is diverted up and over the barrier creating two zones of protection, a larger zone to the lee of the barrier (the side away from the wind) and a smaller zone on the windward side of the barrier. In these zones, wind speed is reduced and turbulence and eddy structure in the vicinity of the barrier are altered. As a result of these changes, the transfer coefficients for heat and mass between the crop and the atmosphere are altered; the gradients of temperature, humidity, and carbon dioxide concentration above the soil and canopy are changed;[5] and the plant processes of transpiration and photosynthesis are altered.[6]

McNaughton[5] defined two regions within the leeward zone of protection: the *quiet zone*, extending from the top of the barrier down to a point in the field located approximately $8H$ leeward (H is the height of the barrier) and a *wake zone*, lying beyond the quiet zone and extending from approximately $8H$ to a distance of $20H$ to $25H$ from the barrier. Within the quiet zone where turbulence is reduced, we expect conditions to be such that the canopy is "uncoupled" from the atmospheric conditions above the sheltered zone, while in the wake zone where turbulence is increased, we expect the canopy to become more strongly "coupled" to the atmosphere above. In both locations we would expect the rates of photosynthesis and transpiration to be altered and WUE to change.

The magnitude of change in wind speed, as well as the extent of microclimate modifications within the quiet and wake zones, are largely determined by the structure of the windbreak or barrier and the underlying meteorological conditions. Structure refers to the amounts of solid material and open space and their arrangement within the barrier. Dense barriers, for example, multiple rows of conifers, generally result in greater wind speed reduction but more turbulence.

More porous barriers, for example, single rows of deciduous species, result in less wind speed reduction but also less turbulence. The downwind extent of the protected area is generally greater for more porous barriers. As a result, narrow, less dense barriers (40–60% density) are typically used to protect crop fields.

The overall influence of wind protection on plant water relations is complex and linked to temperature, humidity, wind speed, and other meteorological conditions found in the protected zone, the amount of available soil water, crop size, and stage of development.[2,3,7] Until recently, the major effect of wind protection and its influence on crop growth and yield were assumed to be due primarily to soil water conservation and reduced water stress of sheltered plants.[8,9] There is little question that the evaporation rate from bare soil is reduced in the protected zone.[3] However, the effect of reduced wind speed on transpiration, evaporation from the plant canopy, and overall plant water status is less clear.[2,3,7]

According to Grace,[9] transpiration rates may increase, decrease, or remain unaffected by wind protection depending on wind speed, atmospheric resistance, and saturation vapor pressure deficit. Cleugh[3] suggests that as stomatal resistance increases, evaporation from the canopy may actually be increased with a reduction in wind speed. When stomatal resistance is high and water is limited, stomatal resistance controls the rate of evaporation from the leaf surface, not the amount of turbulence. Under these conditions a decrease in wind speed and turbulent mixing may increase the potential for evaporation from the leaf surface.[3]

Evaporation from the leaf surface consists of two phases, an energy driven phase and a diffusion driven phase. Movement of water through the plant and out the stomata is driven by the water potential gradient within the plant. This gradient is influenced by the plant's energy balance. On the lee side of the buffer, reduced wind speed and turbulent mixing lead to increases in leaf temperature and transpiration to meet the increased energy load on the plant. If adequate water is available, it is moved through the plant to the leaf surface and the potential for evaporation from the leaf surface is increased. If water is limited, the stomata partially or completely close, transpiration is reduced, and evaporation from the leaf surface declines.

In contrast, movement of water vapor across the leaf boundary layer is controlled by the vapor pressure gradient and the thickness of the leaf boundary layer. As wind speed decreases, the thickness of this boundary layer increases, the vapor pressure gradient decreases, and the rate of evaporation from the leaf surface decreases. The relative magnitude of the two processes determines whether or not transpiration and subsequent evaporation from the canopy are increased, decreased, or remain unchanged.[7,9,10]

While these theoretical considerations are important in understanding the process, several studies[11–13] have demonstrated a good correlation between wind protection, conservation of soil water, and enhanced crop yield. Even so, the effect of wind protection on WUE is neither constant throughout the growing period[7] nor is it consistent over varying meteorological conditions.

Agroforestry practices impact the water relations of the crop by affecting the loss of water through damaged leaves. On soils subject to wind erosion, windbreaks or other agroforestry buffers provide significant reductions in the amount of wind blown soil and subsequent abrasion of plant parts and cuticular damage.[9,14] Loss of cuticular integrity or direct tearing of the leaves[15] reduces the ability of the plant to control water loss.

Agroforestry buffers have a direct effect on the distribution of precipitation, both rain and snow. In the case of snow, a porous barrier will result in a more uniform distribution of snow across the field, providing additional soil water for the crop.[16] In the case of rain, the barrier has minimal influence on the distribution of precipitation across the field; however, in the area immediately adjacent to the barrier a rain shadow may occur on the leeward side. On the windward side, the barrier may lead to slightly higher levels of measured precipitation at or near the base of the trees due to increased stem flow or dripping from the canopy.

Trees and shrubs used in agroforestry practices also consume a portion of the available water. In the area immediately adjacent to the barrier, competition for water between the crop and the barrier has a negative impact on yield. These same areas are also subject to some degree of shading depending on the orientation of the barrier. These changes in radiation load influence the energy balance and thus the growth and development of the crop and the utilization of water.[2]

SUMMARY

In summary, agroforestry practices such as windbreaks, riparian forest buffers and alley-cropping systems generally improve both the efficient use of water by the agricultural system and the WUE of the individual crop. In the case of efficient water use, the evidence is clear. In the case of crop WUE, the evidence leaves some unanswered questions. How do we account for the varied crop yield responses reported in the literature? In many cases yields are increased but no clear relationship to crop water budget is shown. In other cases crop yield response is minimal. Under what meteorological conditions are the effects of agroforestry practices most valuable to water balance questions? Final crop yield is a integration of the environmental conditions over the entire growing season. Many different combinations of environmental conditions may result in similar plant responses. How do we address the numerous combinations of plant stress and plant growth to determine "a response" to wind protection? To answer many of these questions it will be necessary to intensify the numerical modeling methods developed by Wilson[17] and Wang and Takle.[18] With a better model to describe the turbulence fields and the transport of water, heat, and carbon dioxide as influenced by agroforestry practices, it should be possible to assess the numerous combinations of environmental factors influencing crop growth in these systems.

Alluvial Fan

INTRODUCTION

The term "alluvial fan" is used in both geomorphology and geology. An alluvial fan in the geomorphological sense is a semiconical depositional landform produced by fluvial and/or debris-flow processes. Fans have concave-up to straight long profiles but convex-up cross profiles. A body of deposits forming such a landform is also called an alluvial fan. Deltas and delta deposits may also have semiconical shapes but are mainly produced by marine processes and so are not alluvial fans. When alluvial fans enter a standing water body, they are described as fan deltas.

The apex of a fan corresponds to a point where a stream leaves a mountainous area and enters a flatter area. This point also corresponds to the boundary between the upper erosional area and the lower depositional area in a fluvial system. Fans may also occur where small tributary streams enter a larger river valley. The occurrence of fans reflects a relatively abundant sediment supply due to erosion in source basins, broad lowlands that allow the sedimentation to spread out, and sharp topographic boundaries between the mountains and lowlands. Such sharp boundaries often result from faults and tight folds and hence fans are characteristic of tectonically active regions. A series of coalescing fans along a relatively linear boundary between the mountain and the piedmont provides an apron-type topography, which has been called a bajada in arid regions and an alluvial slope in humid regions.

The deposition that causes fan formation is ascribable to the sudden increase in channel width and concurrent decrease in water depth and velocity when a stream leaves a narrow bedrock gorge for an unconfined flatter area. High permeability of clastic fan sediment facilitates further deposition since it reduces surface runoff. This effect seems to be more enhanced in dry regions where fans form under conditions of ephemeral flow. Downstream reduction in river gradient at a fan apex is usually too limited to induce fan deposition.

Fans occur under various environmental conditions: in arid regions such as the American Southwest and Spain; in humid regions such as Japan and northern India; and in high-latitude regions such as Alaska and Canada. Fans have been studied in the field and also in the laboratory using map measurements, analysis of digital data, and flume experiments.

FAN SIZE

The size of alluvial fans is highly variable (Fig. 1). Small fans with radii of tens to hundreds of meters can be observed along small steep drainages in almost any environment. The radius of a large fan can exceed 100 km but such large fans are rare because of space limitations in depositional lowlands. Fan area tends to correlate positively with source basin area reflecting the fact that larger source basins generally supply greater amounts of sediment and water to transport the sediment a greater distance. For a given source area, fan area tends to increase with increasing source basin slope as steep basins produce more sediment. Relationships between fan sizes and source basin topography also vary from region to region, depending on the age of the fan, and other environmental conditions such as the lithology of the source basins, precipitation, and the rate of tectonic deformation.

FAN SLOPE

The slope of alluvial fans is generally inversely proportional to fan area, source basin area and discharge, but positively proportional to source basin slope and particle sizes. There are two different opinions concerning the lower limit of fan slope that affect the definition of alluvial fans. Studies in arid regions suggest that fans are relatively steep with gradients larger than 1°. In humid regions, however, much gentler depositional landforms have been identified as fans (with gradients as low as 0.013°).[1] Blair and McPherson[2] indicated that alluvial fans have average slopes between 1.5° and 25°, whereas river gradients in flat sedimentary basins are significantly lower, rarely

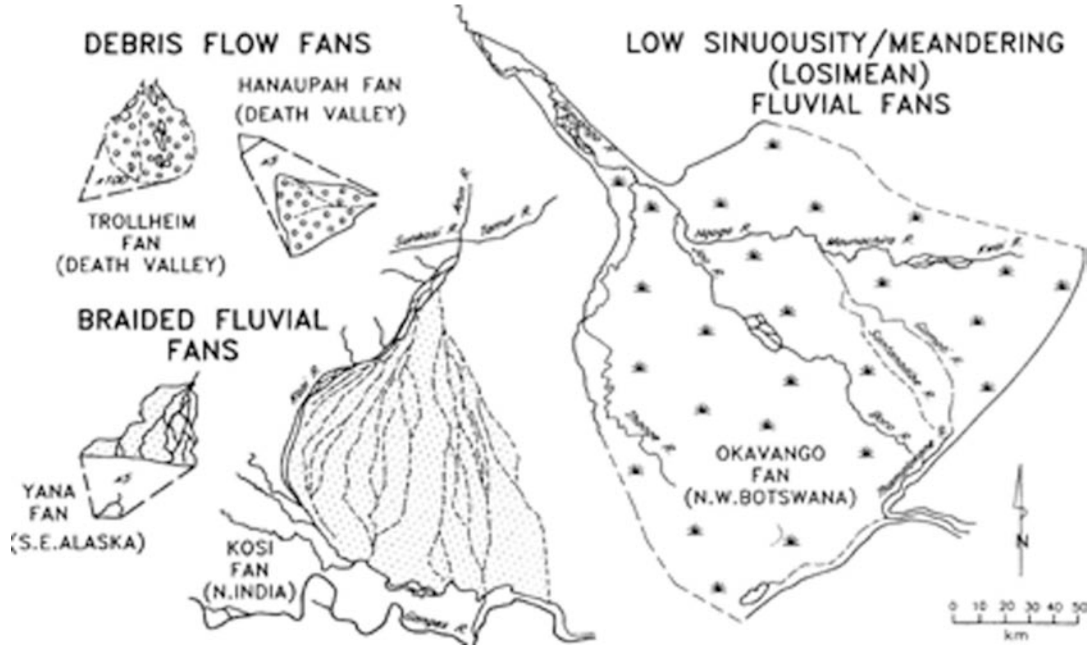

Fig. 1 A comparison of fan systems. *Source*: From Ref.[1].

exceeding 0.5°, resulting in a natural depositional slope gap of 0.5–1.5°. Thus, they renamed piedmont depositional landforms gentler than 0.5° (formerly classified as alluvial fans or fan deltas) as rivers or river deltas. Abrupt change in the depositional slope, associated with sudden change in riverbed material from gravel to sand, also occurs at the toes of humid-region fans,[3] but the river gradient is significantly lower than 0.5°. In addition, semiconical piedmont depositional landforms with gradients of 0.5–1.5° frequently occur in humid regions such as Japan, Taiwan, and the Philippines.[4] Therefore, it seems more appropriate to define alluvial fans based on their semiconical shapes rather than on their slopes.

FAN DEPOSITS AND SEDIMENTARY PROCESSES

The processes of sediment transport and deposition on alluvial fans are varied depending on the topographical and lithological properties of the source areas as well as the climatic conditions. Mass flows such as debris flows and mud flows tend to create small and steep fans, whereas fluvial processes play a major role in forming some large and gentle fans (Fig. 1). Debris flows provide poorly sorted fan deposits with boulders supported by a fine matrix and depositional lobes having well-defined margins. Fluvial processes provide more sorted and bedded fan deposits without distinct margins, and their gravel diameters tend to decrease downstream. Sediment transport processes whose characteristics are intermediate between fluvial processes and debris flows have also been observed on fans, including transitional debris flows, hyperconcentrated flows, sheet flows, and intermediate flows associated with sieve deposition.

Various types of fan deposits are often observed within a single fan or adjacent fans reflecting spatial and temporal variations in dominant geomorphic processes. In some fans, for instance, debris-flow deposits tend to predominate near the fan apex, while fluvial sediments often occur in the distal zone. Ancient fan sediments are also found in the geologic column.

CHANNEL FORMS AND FAN SEGMENTATION

Channels on non-entrenched active alluvial fans are generally wide, shallow, and unconfined. Thus, they are typically braided and tend to move laterally, migrating across the fan surface. The lateral shift of channels on arid fans is more intermittent and random than on humid fans. Meandering rivers may also form very gentle fans.[1]

Some alluvial fans are dissected with entrenched trunk channels. A common style of entrenchment is fan-head trenching associated with a reduced riverbed gradient. Deep fan-head trenching usually reflects reduced sediment load relative to discharge caused by climatic change or land-cover change in the source areas. Shallow fan-head trenching may be temporarily a part of alternate entrenchment and backfilling

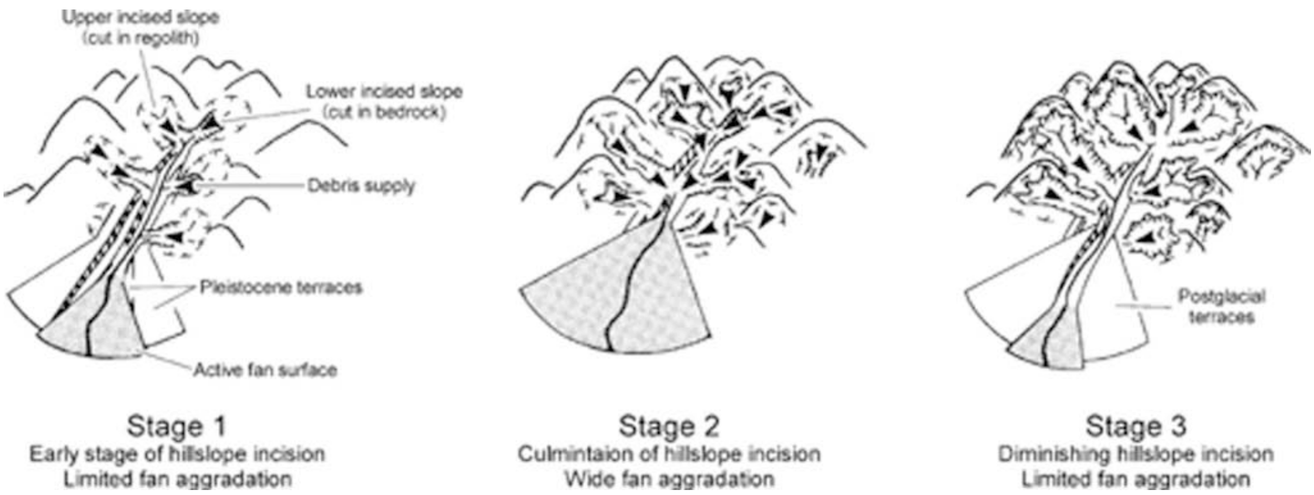

Fig. 2 A three-stage model showing responses of Japanese alluvial fan/source basin systems to increased rainfall at Pleistocene–Holocene transition. *Source*: From Ref.[6].

processes reflecting natural temporal variation in flood discharge or intrinsic slope thresholds.[5]

Non-temporary fan-head trenching leaves behind older inactive surfaces in the upper part of the fan, while an active fan surface occurs in the lower part. Inactive fan surfaces are generally more dissected, more vegetated, and covered with a thicker soil or weathered material. In desert regions, thick gravel coating by desert vanish, composed dominantly of fine-grained clay minerals including black manganese oxide and red iron oxide, is also indicative of older fan surfaces. The apex of the active fan surface immediately below the fan-head entrenched channel is called an intersection point. Long-term erosional and depositional changes may produce more than two intersection points, resulting in long profiles of fans with several segments having different slopes. A decline in base level below fans may lead to deep incision of fan surfaces. In this case, incision begins from the fan toe and propagates toward the apex. A series of base-level drops may form ‘‘fan-terraces’’ along the trunk stream flowing through a fan. The balance between river processes and tectonic movement also affects the presence or absence of fan trenching.

Relationships between Quaternary climatic change and the development of segmented alluvial fans have received special attention. Climatic conditions that favored fan deposition and entrenchment vary significantly depending on local conditions. For instance, a drier climate may lead to fan deposition because of increased hillslope sediment supply under less vegetated conditions, while it may also lead to fan entrenchment because of decreased discharge available to transport sediment to a fan. In addition, the mode of fan development, including channel trenching and backfilling, may change progressively while fluvial systems are responding to rapid climatic change (Fig. 2).[6]

ECONOMIC SIGNIFICANCE AND HAZARD

Alluvial fans can be important sources of both floodwater and ground water. Water flowing through permeable fan deposits is useful for irrigation and water supply, especially in arid regions. The ground water table tends to be low in the mid-fan, but high in the fan toe where abundant pure water is available from wells or springs. In addition, concentrations of heavy minerals, facilitated by repeated trenching and backfilling in the fan head, may provide placer deposits with economic values.

Floods on fans may pose serious problems for settlement and development.[7] Uncertainty as to the flood path on a fan especially in arid regions, high flow velocities with debris and active erosion, and deposition during flood events can make alluvial-fan flooding disastrous. Geomorphological analysis to separate active fan surfaces from inactive ones provides a basis for flood-hazard zoning on a fan.

CONCLUSION

Alluvial fans have attracted the attention of many geomorphologists and geologists, because fans respond to intrinsic and extrinsic change in various ways and provide a key to understand links between erosional and depositional systems. Although the characteristics of fans vary depending on regional environments, previous studies tended to focus on fans in arid regions and rarely dealt with a large dataset of humid and high-latitude fans. More research on non-arid fans is needed.

Ancient Greece: Agricultural Hydraulic Works

INTRODUCTION

Agricultural development requires hydraulic works including flood protection of agricultural areas, land reclamation, and drainage. In addition, in a Mediterranean climate, irrigation of crops is necessary to sustain agricultural production and, at the same time, water storage projects are necessary to remedy the scarcity of water resources during the irrigation period. In modern Greece, irrigation is responsible for more than 85% of the water consumption and, to provide this quantity, several large hydraulic works have been built. Similarly, in ancient times, Greeks had to develop technological means to capture, store, and convey water and simultaneously to make agricultural areas productive and protect them from flooding. Agricultural developments in Greece, traced to the Minoan and Mycenaean states,[1,2] were responsible for the increase of agricultural productivity, the growth of large populations, and the economic progress that led to the creation of classical civilization. Some examples of agricultural hydraulic projects of the ancient times chronologically extending from the Mycenaean to the Hellenistic period are discussed in this article.

THE EARLY DEVELOPMENTS AND THE MYTH OF HERACLES

Urban water projects such as water supply aqueducts and sewer systems have been common in many ancient civilizations. Archeological and historical evidence suggests that several such projects were constructed in ancient Greece, some of which are astonishing. Obviously, agricultural projects, in comparison to urban ones, are rougher and also exposed to damages and decay and thus can hardly be preserved for millennia. However, there is convincing evidence at several places of Greece and in several stages of the Greek civilization that important agricultural hydraulic works have been built. This evidence comes from mythology, scripts including epigraphs, and remnants of certain works.

The first actions of hydraulic engineering in mainland Greece are traced to around 1600 B.C.[3]; there is no written information about these actions, which, however, survived in the mythic folklore in the legend of the hero Heracles (also known with the Latin name Hercules). Even from the ancient times, several authors such as the historian Diodoros Siculus (90–20 B.C.), the geographer Strabo (67 B.C.–23 A.D.), and the traveler Pausanias (2nd century AD) explained Heracles in a historic way demystifying him from a mythic hero into a hydraulic engineer; this continues today.[3–5] The myth of Heracles fighting against Acheloos indicates the struggle of the early Greeks against the destructive power of floods. Acheloos, the river with the highest mean flow rate in Greece, was then worshipped as a god. As depicted on Greek vessels, Acheloos was metamorphosed into a snake and then a bull, but finally was defeated by Heracles who won Deianira as his wife. According to the historian Diodoros Siculus (IV 35) and the geographer Strabo (X 458–459), the meaning of the victory is related to channel excavation and construction of dikes to confine the shifting bed of Acheloos. There are no technical descriptions of these works; only some presumed remnants of dikes.[3]

From Strabo (IX 440) and Diodoros (IV 18), it is also known that similar structures had been built on another large river located at the Thessaly plain, Peneios at Larissa, which are again attributed to Heracles. Other labors of Heracles such as those of the Lernaean Hydra and the Augean stables also symbolize hydraulic works. Lernaean Hydra was a legendary creature in the form of a water snake with nine heads that lived in the Lerna swamp near Argos. Hydra possibly symbolizes the karstic springs of the area or the Lerna swamp itself, and its annihilation by Heracles has been interpreted as the drying up of the swamp. The Augean stables were cleaned by Heracles who diverted two rivers to run through the stables (a more sanitary-environmental labor).

THE MYCENAEAN GREECE AND THE LAND RECLAMATION SYSTEM IN KOPAIS

Archeological evidence traces the earliest significant hydraulic works in Greece to the Minoan civilization at Crete. These, however, were related to urban water developments and no traces of agricultural hydraulic projects have been found to date in Crete. Nevertheless, Platon[6] believed that the Minoans had practiced irrigation and developed irrigation and land reclamation projects. In addition, according to Marinatos,[7] many agricultural crops of the present day such as vegetables, cereals, olives, grapes, and aromatic species were grown in Minoan Crete.

After the decline of the Minoan civilization (ca. 15th century B.C.), the Mycenaean civilization in mainland Greece achieved supremacy. The great Mycenaean cities (Mycenae, Tiryns, and Pylos in Peloponnese and Thebes and Orchomenos in Boeotia, north of Athens) were noted for their heavy fortifications with their massive, cyclopean masonry, while Minoan cities were totally unfortified. Close to Thebes and Orchomenos, there was a large shallow lake, named Kopais, where the Boeoticos Kephisos River discharged. Natural karstic sinkholes (katabothres) discharged some of the water, above a certain level, toward the sea. At the end of the 19th century AD, the lake was permanently drained and converted into an irrigated plain, one of central Greece's most fertile agricultural areas. The modern drainage of Kopais has also revealed massive hydraulic engineering works that most probably drained it in late Mycenaean times (ca. 1450–1300 B.C.). According to Strabo (IX 406–407, 414–415), the draining of Kopais was achieved by the Minyae people who lived there. Huge earthen dykes furnished with cyclopean walls were built in Kopais. Three main canals with length 40–50 km, width 40–80 m, and parallel walls up to 2–3 m thick traverse the former lake area.[5,8] The whole project included the construction of polders (Fig. 1) and artificial reservoirs for floodwater retention and storage and the improvement of the drainage capacity of the natural sinkholes. The scale of this vast project, which includes the construction of the enormous citadel at Gla, another Mycenaean palatial site on a low limestone island rising up from the floor of the basin, dwarfs any other Mycenaean building project. According to Knauss,[9] the sophisticated hydraulic system in the Kopais and its advantages in developing the country and especially the agricultural production allow the hypothesis that Kopais was the "fat province" of Boeotia mentioned by Homer in Iliad, Book 7 (219–224). Knauss is so much impressed by the system as to write "As an hydraulic engineer of today, always advised to look for the best economic and ecologic solution of a given hydrotechnical problem, I admire my early colleagues in what they could do and what they did, with simple tools and materials, but with an intensive and sensitive observation of natural processes, some thousands years before modern hydraulic engineering could reach a similar standard."

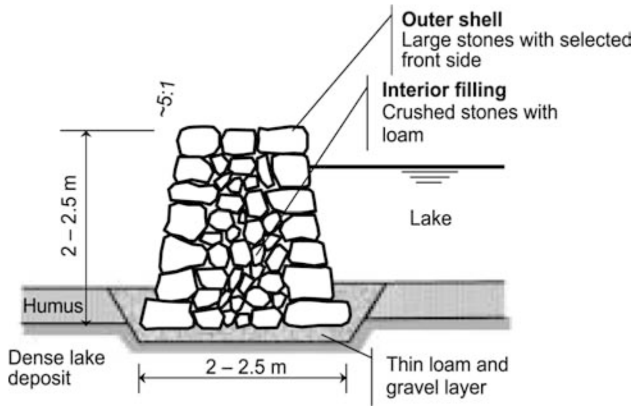

Fig. 1 Cross section of the polder dyke in Kopais made of loam-sealed stone. *Source*: From Ref.[10].

According to Strabo and newer evidence, the area became reflooded sometime later, probably because of earthquakes (ca. 1100 B.C.). Interestingly, in the case of Kopais, the myth relates Heracles with the destruction, rather than construction, of the project and the reflooding of the area, thus indicating that war actions (related to the intra-Mycenaean rivalry) probably contributed to the collapse of the project.

Another important project of the same Mycenaean period (ca. 1250–1200 B.C.) is the Tiryns dam. It seems that, during a flood, a stream south of Tiryns abandoned its bed and shifted to the north of the Tiryns. To protect the lower town from future floods, the inhabitants of Tiryns installed an artificial river diversion consisting of a 10-m-high and 300-m-long dam and a 1.5-km-long canal.[11] The dam is a huge earthen embankment lined with cyclopean masonry across the earlier streambed. Yet another massive hydraulic project of the same period has been found in Olympia. This includes a dyke in Cladeios river with length 800 m, width 3 m, and height 3 m and a dam in Alpheios river with length 1000 m, height 2 m at least, and width 30 m.[10] The two rivers may be those related to the Augean stables myth mentioned above, and it has been conjectured[10] that the project is related to an initial stage of the Olympic Games.

THE DRAINING OF THE LAKE IN PTECHAE AND THE GREEK INSTITUTIONS FOR CONSTRUCTING PUBLIC WORKS

The hydrotechnical skill achieved by the Mycenaean engineers on their land reclamation activities was lost in the centuries after the decline and finally the collapse of the Mycenaean world (ca. 1100–900 B.C.). Later, in the classical Greece civilization, the progress in construction of hydraulic projects is accompanied by improvement in the understanding of water-related natural phenomena. However, most findings of hydraulic works of that period are related to the urban rather than agricultural water use.

There is evidence, however, that the draining of the Kopais plain was also attempted at later times. Thus another salient work, a tunnel 2.5 km long, 1.8 m high, and 1.5 m wide leading from Kopais to the sea has been revealed. This would provide discharge capacity, additional to that of the natural sinkholes, for draining the lake. Shafts up to 60 m high were lowered at distances 40–200 m that helped excavating the tunnel, allowed some daylight, and made orientation easy. This tunnel has not been explored to date, and it is not known whether the project was completed and operated until it went damaged some time later or was never completed. Papademos[5] maintains that this tunnel was not built at Mycenaean times and it was never completed. Strabo (IX 406) mentions that draining works were executed in the Kopais Lake by Crates, engineer of Alexander the Great in 336–323 B.C..

At the same period, the draining of another lake in Ptechae, which is probably identified with the Dystos Lake in Southern Euboea, was performed. To validate the fact that scripta manent, the contract of this project was revealed in excavations in Chalkis in 1860.[5] The contract for draining and exploitation of the lake is between the Eretrians and the engineer-contractor Chairephanes. The project is what we call today BOOT (build, own, operate, transfer). The rather wordy (such as those of today) contract is written on a Pentelian marble stele (87 × 47 × 9 cm). On the surface, relief sculptures show the gods that were worshiped in the region, Apollo, Artemis, and Leto. A carved scripture in 66 verses signed by more than 150 people contains the construction contract, starting as ≪Κατὰ τάδε Χαιρεφάνης έπαγγέλλεται ’Ερετριευσιν ὲξάξειν καὶ ξηρὰν ποι ήσειν την λίμνην τὴν έν Πτέχαις . . . ≫ (In this, Chairephanes promises to the Eretrians that he will drive away the lake in Ptechae and make it land . . .). The first 35 verses are the main cotract. In the continuation, two resolutions of the parliament and the Demos are given. With the first one (verses 36–42), asylum is granted to Chairephanes and his collaborators for the whole duration of the contract, and in the second resolution (verses 42–60), the keeping of the contract is confirmed by oath to Apollo and Artemis. Moral and material sanctions (penalty for breach of contract) such as the confiscation of their property and the dedication of it to Artemis are foreseen against misdemeanors. A summary of the main contract is as follows (adapted from Ref.[5]):

1. Between the city of the Eretrians representing the 31 municipalities of the Eretrian region and the contractor Chairephanes, a contract is signed concerning the draining of the lake in Ptechae.
2. The draining works include the construction of drainage canals, sewers, and wells for the drainage of water to natural underground holes or cracks and miscellaneous protection works, including wooden or metallic railings.
3. Irrigation works, such as the construction of a reservoir with side length up to 2 stadia (360 m) for storing irrigation water, and sluice gates, are included in the project.
4. A 4-year construction period is agreed, which can be extended in case of war.
5. The contractor is granted the right to exploit the dried fields for 10 years (extended in case of war), commencing by the finishing of the drying works.
6. The contractor is granted the privilege of customs-free import of materials (stones and wood).
7. The contractor is obliged 1) to pay all labor costs without any charge for the people of Eretria; 2) to pay the amount of 30 talents in monthly installments as a rental for the exploit of the project for 10 years; 3) to maintain all works for the exploitation period to be in good condition after the finishing of the contract; 4) to compensate the land owners by 1 drachma per foot of land area that is to be expropriated for the construction of works; and 5) to avoid harm on private property as much as possible by locating the works in non-cultivating land.
8. In case of death of the contractor, his heirs and collaborators will substitute him in the relations to the city.
9. Penalties are enforced against any person trying to annul the contract.
10. The contractor is obliged to submit a good construction guarantee up to the amount of 30 talents.

Interestingly, the epigraph mentions that it would be erected in the temple of Apollo at Eretria and copies of it would be deposited at Megara and Andros. It appears that it was common practice in ancient Greece that detailed competition announcements, project specifications, and project contracts written on marble steles were erected in public sites so that everyone would have known all project details and, simultaneously, the breach of contract would be difficult;

as Tassios[12] puts it, if someone wished to avoid some terms, he would "stumble on them."

INTRODUCTION

The approach typically followed in problem solving today is represented by the sequence in the order: Understanding—data—application. However, historical evolution in the development of water science and technology (and other scientific and technological fields) followed the reverse order: application preceded understanding.[1] Thus, technological application in water resources started in Greece as early as ca. 2000 B.C.. Specifically, in the Minoan civilization and later in the Mycenaean civilization several remarkably advanced technologies have been applied for groundwater exploitation, water transportation, water supply, stormwater and wastewater sewerage systems, flood protection, drainage, and irrigation of agricultural lands. Much later, around 600 B.C., Greek philosophers developed the scientific views of natural phenomena for the first time ever. In these, hydrologic and meteorological phenomena had a major role, given that water was considered by the Ionic school of philosophy (founded by Thales of Miletus; ca. 624–545 B.C.) as the primary substance from which all things were derived. Even later, during the Hellenistic period, significant developments were done in hydraulics, which along with progress in mathematics allowed the invention of advanced instruments and devices, like Archimedes' water screw pump.

SCIENTIFIC VIEWS OF HYDROLOGIC PHENOMENA AND HYDRAULICS

It has been believed by many contemporary water scientists that ancient Greeks did not have understanding of water related phenomena, and had a wrong conception of the hydrologic cycle. This belief is mainly based on views of Plato (ca. 429–347 B.C.), who in his dialogue Phaedo (14.112) expresses an erroneous theory (based on Homer's poetical view) of hydrologic cycle; notably, his wrong theory was adopted by many thinkers and scientists from Seneca (ca. 4 B.C.–65 A.D.) to Descartes (1596–1650).

However, long before Plato, as well as much later, several Greek philosophers had developed correct explanations of hydrologic cycle, revealing good understanding of the related phenomena. In fact, as Koutsoyiannis and Xanthopoulos[2] note, the first civilization in which these phenomena were approached in an organized theoretical manner, through reasoning combined with observation, and without involving divine and other hyperphysical interventions, was the Greek civilization. The same authors catalog a number of ancient Greek contributions revealing correct understanding of water related phenomena. Thus, the Ionic philosopher, Anaximenes (585–525 B.C.) studied the meteorological phenomena and presented reasonable explanations for the formation of clouds, hail and snow, and the cause of winds and rainbow. The Pythagorean philosopher Hippon (5th century B.C.) recognizes that all waters originate from sea. Anaxagoras, who lived in Athens (500–428 B.C.) to Empedocles (ca. 493–433 B.C.) and is recognized equally as the founder of experimental research, clarified the concept of hydrologic cycle: the sun raises water from the sea into the atmosphere, from where it falls as rain; then it is collected underground and feeds the flow of rivers. He also studied several meteorological phenomena, generally supporting and complementing Anaximenes' theories; his theory about thunders, which was against the belief that they are thrown by Zeus, probably cost him imprisonment (ca. 430 B.C.). In particular, he correctly assumed that winds are caused by differences in the air density: the air, heated by the sun, moves towards the North pole leaving gaps that cause air currents. He also studied Nile's floods and attributed them to snowmelt in Ethiopia. The "enigma" of Nile's floods (which, contrary to the regime of Mediterranean rivers, occur in summer) was also thoroughly studied by Herodotus (480–430 B.C.), who seemed to have clear knowledge of hydrologic cycle and its mechanisms.

Aristotle (384–323 B.C.), in his treatise Meteorologica clearly states the principles of hydrologic cycle, clarifying that water evaporates by the action of sun and forms vapor, whose condensation forms clouds; he also recognizes indirectly the principle of mass conservation through hydrologic cycle. Theophrastus (372–287 B.C.) adopts and completes the theories of Anaximenes and Aristotle for formation of precipitation from vapor condensation and freezing; his contribution to the understanding of the relationship between wind and evaporation was significant. Epicurus (341–270 B.C.) contributed to physical explanations of meteorological phenomena, contravening the superstitions of his era.

Archimedes (287–212 B.C.), the famous Syracusan scientist and engineer considered by many as the greatest mathematician of antiquity or even of the entire history, was also the founder hydrostatics. He introduced the principle, named after him, that a body immersed in a fluid is subject to an upward force (buoyancy) equal in magnitude to the weight of fluid it displaces. Hero (Heron) of Alexandria, who lived after 150 B.C., in his treatise *Pneumatica* studied the air pressure, in connection to water pressure, recognizing that air is not void but a substance with mass consisting of small particles. He is recognized[3] as the first person who formulated the discharge concept in a water flow and made flow measurements.

Unfortunately, many of these correct explanations and theories were ignored or forgotten for many centuries, only to be re-invented during Renaissance or later. This was not restricted to water related phenomena. For example, the heliocentric model of the solar system was first formulated by the astronomer Aristarchus of Samos (310–230 B.C.), 1800 yr before Copernicus (who admits this in a note). Aristarchus also figured out how to measure the distances to the Sun and the Moon and their sizes. In addition, not only did ancient Greeks know that Earth is spherical, but also Eratosthenes (276–194 B.C.) calculated, 1700 yr before Columbus, the circumference of the earth, with an error of only 3%, by measuring the angle of the sun's rays at different places at the same time; in addition, the geographer Strabo (67 B.C.–23 A.D.) had defined the five zones or belts of Earth's surface (torrid, two temperate, and two frigid) that we use even today.

HYDRAULIC MECHANISMS AND DEVICES

The foundation of hydraulics after Archimedes led to the invention of several hydraulic mechanisms and devices with significant contribution to diverse applications from lifting of water to musical instruments. Although in past several devices were in use to lift water to a higher elevation, the first device that had the characteristics of a pump with the modern meaning is Archimede's helix or water screw. The invention of the water screw is based on the study of the spiral, for which Archimedes wrote a treatise entitled *On Spirals*, in 225 B.C.. This invention of Archimedes was first mentioned by Diodorus Siculus (first century B.C.; Bibliotheke, I 34.2, V 37.3) and Athenaeus of Naucratis (ca. 200 B.C.; Deipnosophistae, V) who transferred an earlier text (of the late 3rd century B.C.) by Moschion, describing a giant ship named Syracusia.

This pump is an ingenious device which functions in a simple and elegant manner by rotating an inclined cylinder bearing helical blades around its axis whose bottom is immersed in the water to be pumped. As the screw turns, water is trapped between the helical blades and the walls, and thus rises up to the length of the screw and drains out at the top (Fig. 1).

As mentioned by Athenaeus of Naucratis, the first use of the water screw must have been by Archimedes himself to remove the large amount of bilge water that would accumulate on the large ship *Syracusia*. There is historical and archaeological evidence that in past the use of the water screw was propagated to all Mediterranean countries as well as to the east up to India. It was rotated by a man or a draft animal. Its uses range from irrigation (e.g., in Egypt) to draining of water in mines (e.g., in Spain). In its original form, the screw of Archimedes is used even today in some parts of the world. For example, farmers in Egypt and other countries in Africa use it to raise irrigation water from the banks of rivers.

A modern version of the screw that is in industrial use today has two main differences from its original one: it is powered by a motor and the screw rotates

Fig. 1 Archimedes' water screw in its original form as depicted in an Italian stamp (not quite correctly from a technical point of view) along with a bust probably representing Archimedes (from http://www.mcs.drexel.edu/~crorres/Archimedes/Stamps/).

Fig. 2 Archimedes' water screw in its modern form, as implemented in the wastewater treatment plant of Athens (one of nine screws that pump 1 million m^3 per day).

inside the cylinder rather than the entire cylinder being rotated; the latter modification allows the top-half of the cylinder to be removed, which facilitates cleaning and maintenance. The modern screw is the best choice for pumping installations when water contains large sediments or debris, and when the discharge is large and the height small. Thus, the screw is used today mainly for pumping wastewater and stormwater runoff (Fig. 2). It has been also used in other types of applications such as pumping of oil and supporting blood circulation during surgical procedures.

Another pumping mechanism, the force pump was invented by engineer (initially barber) Ctesibius of Alexandria (ca. 285–222 B.C.) who was also the inventor of other instruments such as the hydraulic clock and hydraulis—a hydraulic musical instrument. The force pump has been described by Philon Byzantius (Pneumatica), Hero of Alexandria (Pneumatica, I 28), and Vitruvius (X 7, 1–3). This pump is composed of two cylinders with pistons that were moved by means of connecting rods attached to opposite ends of a single lever. The force pump was used in many applications, such as in wells for pumping water, boats for bilge-water pump, basement pump, mining apparatus, fire extinguisher, and water jets. Yet another pumping device, the chain pump was invented in Alexandria by an engineer Philon Byzantius (260–180 B.C.). This comprised a set of pots attached to a chain or belt that was moved by a rotating wheel. Several pneumatic devices and mechanisms including a steam boiler, a reactive motor, the organ (harmonium), and several jet springs have been invented by Hero of Alexandria.[4–6] Most of them were based on the siphon principle, or more generally, the combined action of air and water pressure. Ctesibius, Philon Byzantius, and Hero were the three most famous engineers of Hellenistic Alexandria, whose studies mark a significant progress in hydraulics. This progress allowed installation of advanced water supply systems like that of the citadel at Pergamon, in which pressure pipes (probably made of metal) were implemented. It also led to the great advances in the art of aqueducts during the Roman period.

Ancient Greece: Urban Water Engineering and Management

Demetris Koutsoyiannis
Department of Water Resources, School of Civil Engineering, National Technical University of Athens, Zographou, Greece

A. N. Angelakis
Regional Foundation for Agricultural Research, National Foundation of Agricultural Research, Heracleion, Greece

INTRODUCTION

Ancient Greek civilization has been thoroughly studied, focusing on mental and artistic achievements like poetry, philosophy, science, politics, and sculpture. On the other hand, most of technological exploits are still relatively unknown. However, recent research reveals that ancient Greeks established critical foundations for many modern technological achievements, including water resources. Their approaches, remarkably advanced, encompass various fields of water resources, especially for urban use, such as groundwater exploitation, water transportation, even from long distances, water supply, stormwater and wastewater sewerage systems, flood protection and drainage, construction and use of fountains, baths and other sanitary and purgatory facilities, and even recreational uses of water. The scope of this chapter is not the exhaustive presentation of what is known today about hydraulic works, related technologies and their uses in ancient Greece but, rather, the discussion of a few characteristic examples in selected urban water fields that chronologically extend from the early Minoan civilization to the classical Greek period. Agricultural hydraulic works like flood protection, drainage and irrigation of agricultural lands, and drainage of lakes were also in use in ancient Greece starting from the Mycenaean times, but are not covered in this chapter. Scientific advances in water resources as well as invention of hydraulic mechanisms and devices are presented in the entry *Ancient Greece: Hydrologic and Hydraulic Science and Technology.*

CLIMATIC AND HYDROLOGIC CONDITIONS

Unlike preceding civilizations such as those in Mesopotamia and Egypt, which were based on the exploitation of water of the large rivers such as Tigres, Euphrates, and Nile, the Greek civilization has been characterized by limited and often inadequate natural water resources. The rainfall regime and consequently the water availability over Greece vary substantially in space. Thus, the mean annual rainfall exceeds 1800 mm in the mountainous areas of western Greece whereas in eastern regions of the country may be as low as 300 mm. Interestingly, the most advanced cultural activities in ancient Greece appeared in semiarid areas with the lowest rainfall and thus the poorest water resources; for example, Knossos in Crete, Cyclades islands, and Athens have annual rainfall about 500 mm, 300–400 mm, and 400 mm, respectively. The potential evapotranspiration exceeds 1000 mm all over Greece, with the highest rates appearing in summer months. Thus, irrigation of cultivated areas during summer is absolutely necessary and becomes the most demanding water use in Greece. Under these climatic and hydrological conditions, Greeks had to develop technological means to capture, store, and convey water even from long distances, as well as legislation and institutions to more effectively manage water.

THE WATER SUPPLY IN MINOAN CIVILIZATION

Cultural advancements in the Minoan civilization can be observed throughout the third and second millennia B.C., which indicate that the main technical operations of water resources have been practiced in varying forms since ca. 3000 B.C.. During the Middle Bronze Age (ca. 2100–1600 B.C.) Crete's population in its central and south regions increased, towns were developed and the first palaces were built. At that time, a "cultural explosion'' occurred on the island. A striking indication of this is manifested, inter alia, in the advanced water resources management technologies applied in Crete at that time. The sanitary life style developed at this civilization can be paralleled to the modern standards. It is evident that in Minoan civilization extensive systems and elaborate structures for water supply, sewerage systems, irrigation, and drainage were planned, designed, and built to supply the growing population with water for the cities and for irrigated agriculture.[1]

In the early phases of the Late Bronze Age (ca. 1600–1400 B.C.), Crete appears to have prospered even more, as the larger houses and more luxurious palaces of this period indicate.[2] At this time, the flourishing arts, improvements in metal-work along with the construction of better-equipped palaces and an excellent road system, reveal a wealthy, highly cultured, well-organized society, and government in Crete, before the island's power collapsed following the destruction of the Minoan palaces.[3] The geological catastrophe through the eruption of the Santorini volcano in 1450 B.C. halted the Minoan civilization.

Our knowledge of how Minoan cities were supplied with potable water is mainly acquired from the Palace of Knossos. A few cisterns, fountains, and wells were also found at other archeological sites like Zakros, Mallia, Gortys, and other Minoan palaces and cities. At Phaistos some cisterns have been discovered too, but owing to the nature of the ground, no wells or springs have been found there.[1]

Even at Knossos, the sources of water and the methods used for supplying it are only partially understood. Several wells have been discovered in the Palace area, and a single well slightly to the northwest of the Little Palace. The latter, restored to its original depth of about 12.5 m and 1.0 m diameter, continues to furnish an excellent supply of potable water.[4] In the Protopalatial stage (ca. 1900–1700 B.C.), several wells were used for drawing drinking water. Their depth did not exceed 20 m and their diameter was not more than 5 m.[5] At least six such wells have been reported.[4] The most important and best known is the one found in the north-west of the Palace in the basement of the House A, which belongs to the first stage of the Middle Minoan period. According to Evans,[4] its upper circuit was mostly a patchwork of rubble masonry, recalling the construction of Roman wells in the site. However, below its crudely built upper "collar," the well was found to be cased in a series of terracotta cylinders of fine clay and of material so hard that it was initially mistaken for some kind of close-grained stone (Fig. 1).

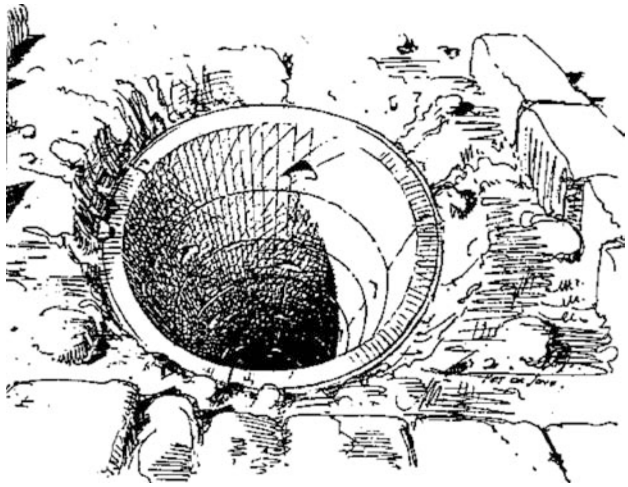

Fig. 1 Perspective view of well below House A, NW of Knossos Palace. *Source*: From Ref.[4].

The inhabitants of the Knossos Palace, however, did not depend on the water of the wells alone. There are indications that the water supply system of the Palace of Minos at Knossos was initially dependent on the spring water of Mavrokolybos and later on the Fundana, and other springs. Mavrokolybos, a pure limestone spring, is located at a distance of 700 m south of the palace and an elevation of about 115 m, whereas Knossos lies at an elevation of 85 m from sea level; Fundana, a typical karstic spring with excellent quality of water even today, is at a distance of about 5 km from the palace and at an elevation of about 220 m.

Water supply in the Palace was provided through a network of terracotta piping located beneath the palace floors. The pipes were constructed in sections of about 60–75 cm each. These pipes with their expertly shaped, tightly interlocked sections, date from the earliest days of the building and are quite up to modern standards (Fig. 2). The sections of the clay pipes resemble those used in Greece in classical times, though Evans considered the Minoan to have been designed more efficiently; each section was rather strongly tapped toward one end with the objective of increasing the rate of water flow, thus helping to flush any sediment through the pipe.[5]

On the basis of their accomplishments, it can be assumed that Minoan hydraulic engineers were, in a sense, aware of the basic hydrostatic law, known today as the principle of communicating vessels. It is manifested in the water supply of the Knossos Palace through pipes and conduits fed by springs; this is supported by the discovery of the Minoan conduit heading towards the Knossos Palace from Mavrokolybos which suggests a descending and subsequently ascending channel.[4,6] However, it appears that Minoans had only a vague understanding of the relationship between flow and friction.

In the Zakros Palace the water supply system depended on groundwater. Here the potable water came from the Main Spring. In the southwest corner of the Cistern Hall an opening leads into a small chamber where the water was collected and channeled into a square underground fountain built on the south; this was thought to correspond with the celebrated man made fountain of the *Odyssey* known as "Τυκτή" fountain.[7] The fountain was built of regular limestone, and there is a descending staircase with fourteen steps (Fig. 3). The room may also have served as a shrine. The water of the fountain is brackish today, of about 13.00 dS/m electric conductivity (EC), due to intrusion of seawater. However, this may well be an indication that some reduction in the distance of the palace from the coast has occurred.

Another comparable chamber in Zakros is a well–spring located near the southeast corner of the Central

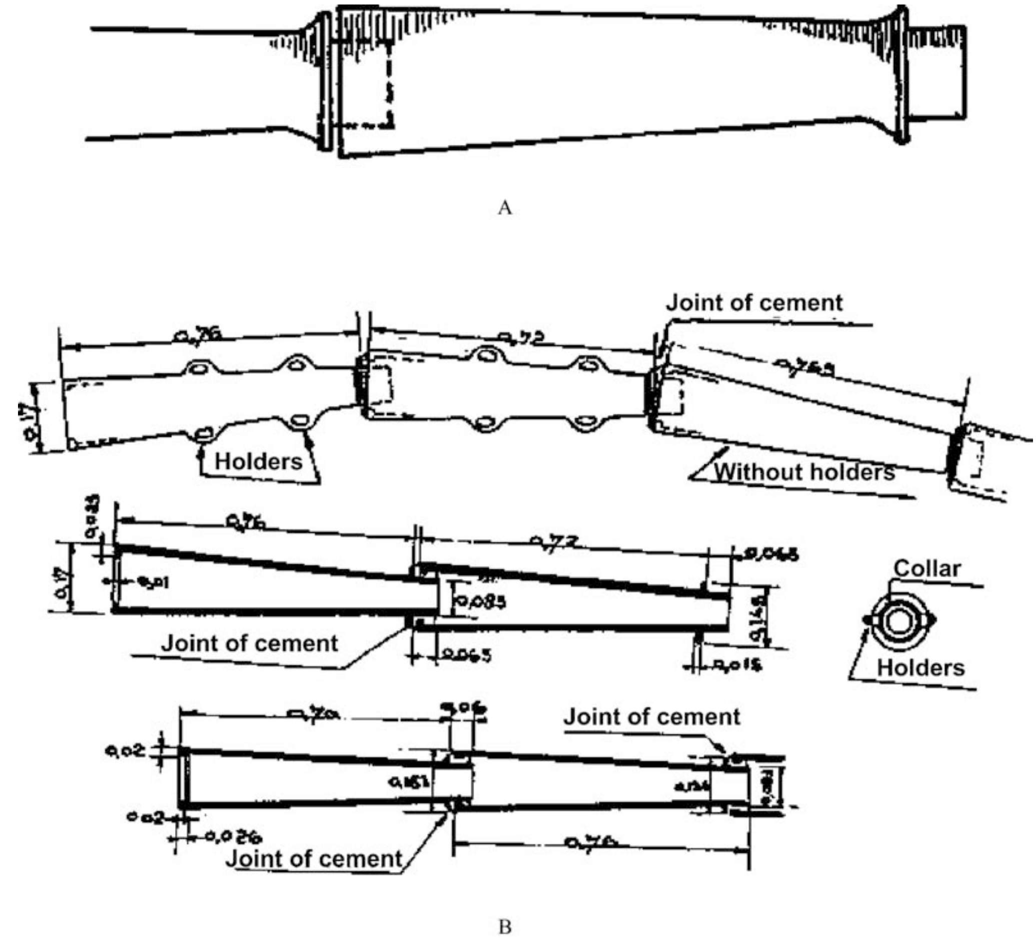

Fig. 2 Minoan water supply pipes (terracotta pipe sections): (A) overview, and (B) with real dimensions. *Source*: From Ref.[5].

Court; here again steps lead down into the chamber. The wood of the windlass was found in the water, along with an offering cup containing olives; this is a unique, remarkable find, since the olives were perfectly preserved, as though they had just been picked from the trees; unfortunately they maintained their relative freshness for only a few minutes after they were taken out of the water.[7] A view of this well-spring is given in Fig. 4.

In contrast to Knossos, where water was conveyed mainly from springs, and Zakros dependent entirely on groundwater, in Phaistos the water supply system was dependent directly on precipitation: here, the rainwater was collected from the roofs and yards of buildings in cisterns. Special care was given to securing clean surfaces in order to maintain the purity of water. Also, coarse sandy filters were used to treat the rainfall water before it flowed into the cisterns.

THE WATER SUPPLY OF SAMOS AND THE AWESOME FEAT OF EUPALINOS

The most famous hydraulic work of ancient Greece was the aqueduct of ancient Samos (located where Pythagoreio or Tigani village in the Samos island is currently present), which was admired both in antiquity (as recognized by Herodotus) and in modern times.[8–14] The most amazing part of the aqueduct is the 1036 m long "Ενπαλίνειονόρυγμα" or "Eupalinean digging," more widely known as Tunnel of Eupalinos. The aqueduct includes two additional parts (Fig. 5) so that its total length exceeds 2800 m. The aqueduct was the work of Eupalinos, an engineer from Megara. Its construction was commenced in ca. 530 B.C., during the tyranny of Polycrates and lasted for 10 yr. It was in operation until the 5th century A.D. and then it was abandoned and forgotten. Owing to the text of Herodotus, Guerin[8] uncovered the entrance of the aqueduct. The inhabitants of the island attempted to reuse the aqueduct in 1882 without success. Only 90 yr later, between 1971 and 1973, the German Archaeological Institute of Athens undertook the task to finally uncover the tunnel.

Herodotus (History, Γ, 60) called the tunnel "αμφίστομον" or "bi-mouthed," a characterization that caused curiosity to the readers (any tunnel has two openings or mouths). Only when the tunnel was totally explored was it understood that Herodotus

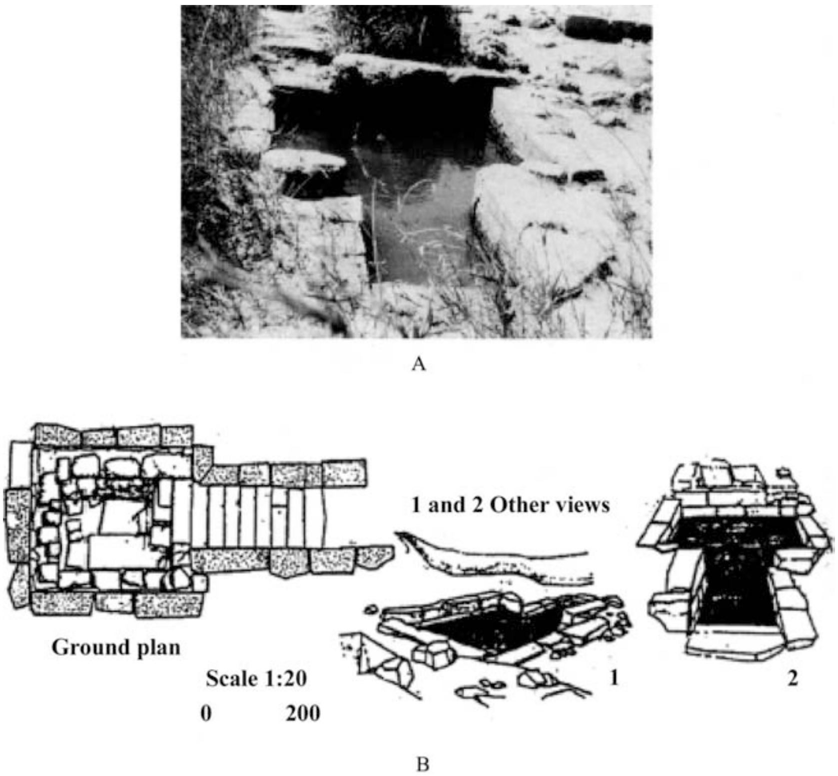

Fig. 3 Views of the "Τυκτη" fountain: (A) overall view and (B) scheme. *Source*: From Ref.[7].

meant that the construction of the tunnel was started from two openings. Today, it is very common that water transportation tunnels are constructed from two openings to reduce construction time; high-tech geodetic means and techniques like global positioning systems and laser rays are used to ensure that the two fronts will meet each other. The great achievement of Eupalinos is that he did this using the simple means available at that time; apparently, however, he had good knowledge of geometry and geodesy. Later, in the 1st century B.C., his achievement inspired the mathematician and engineer Hero (Heron) of Alexandria (Dioptra, III) who in his geometrical Problem #15 studied how "to dig a mountain on a straight line from two given mouths." His method is based on walking around the mountain measuring out in one direction, then turning at a right angle, measuring again, etc., and finally using geometrical constructions with similar triangles. Moreover, in modern times, it inspired many mathematicians, engineers, and archeologists who attempted to reconstruct the methods used by Eupalinos to build the tunnel, as, apart from the mention by Herodotus, no written document was found from that time about the project.

Fig. 4 Well-spring located in the eastern wing of the Zakros Palace. *Source*: From Ref.[7].

Today, most of the questions have been answered but not all. For example, there is evidence that Eupalinos did not follow Hero's method, which would produce a large error. Most probably, Eupalinos walked over the mountain and put poles up along the path in a straight line. When the workers were digging they could try to line themselves up with these poles. This also leaves room for error; as shown in Fig. 5, there was a small departure in the two axes that Eupalinos implemented (NA and SF), which is now estimated to 7 m. Another question is: what led Eupalinos to leave the straight line NA at point A and follow the direction AB? A plausible explanation is given by Tsimpourakis:[14] Eupalinos found a natural fracture or rift and broadening this rift, he was able to proceed much faster. At the end of the rift, he attempted to correct the departure from the initial axis, following the route BC, but C was past this axis. Again according to

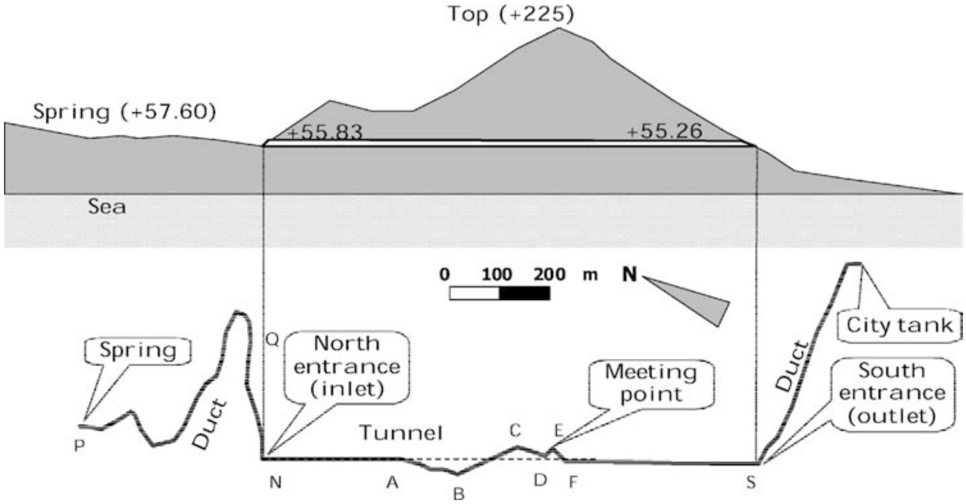

Fig. 5 Sketch of the Tunnel of Eupalinos (above: vertical section; below: horizontal plan).

Tsimpourakis,[14] when the two teams of workers (each consisting of two people) were simultaneously at points C and F, they realized (hearing the sounds of the opposite team's excavating tools) that there were close to each other. Then, guided by the sounds of tools they managed to meet at point E. Hermann Kienast of the German Archaeological Institute of Athens proposed a different explanation: the last meters of the two routes of the tunnel (sections CDE and FE) were ingeniously designed rather than coincidentally followed: both teams were directed at points C and F to change direction to the right and then at D the northern one turned to the left on purpose; with this trick it is mathematically sure that the two lines would intersect.

Interestingly, the floor of the tunnel was done virtually horizontal, as observed from the elevations shown in Fig. 5; one would expect that it should have some slope for the water to flow. The choice of a horizontal tunnel is related to the excavation from both sides. In a sloping tunnel, the front of the upper section would be inundated (mostly from groundwater), so that the workers could not dig. Another reason is the fact that the horizontal tunnel was easier to control and build with the simple instruments and tools of that time and facilitated the meeting of the two fronts (indeed, the difference in the elevation of the two sections at point F is only 0.60 m).

However, this horizontal tunnel could not operate as an aqueduct, simply because the water would not flow horizontally. Therefore, Eupalinos excavated a slopping duct below the floor of the tunnel, shown in the photo of Fig. 6. Its bottom, where clay pipes were arranged, is located 3.5 m and 8.5 m in the inlet (N) in the outlet (S), respectively, below the floor of the tunnel; the large depth at the inlet is another question mark of the project, whose discussion is out of the scope of this chapter. At points where the depth becomes too large (in about two-thirds of the tunnel length) Eupalinos preferred to make a second tunnel, the water tunnel, below the main tunnel, the access tunnel. The water tunnel is about 0.60 m wide whereas the access tunnel is about 1.80 m × 1.80 m. The

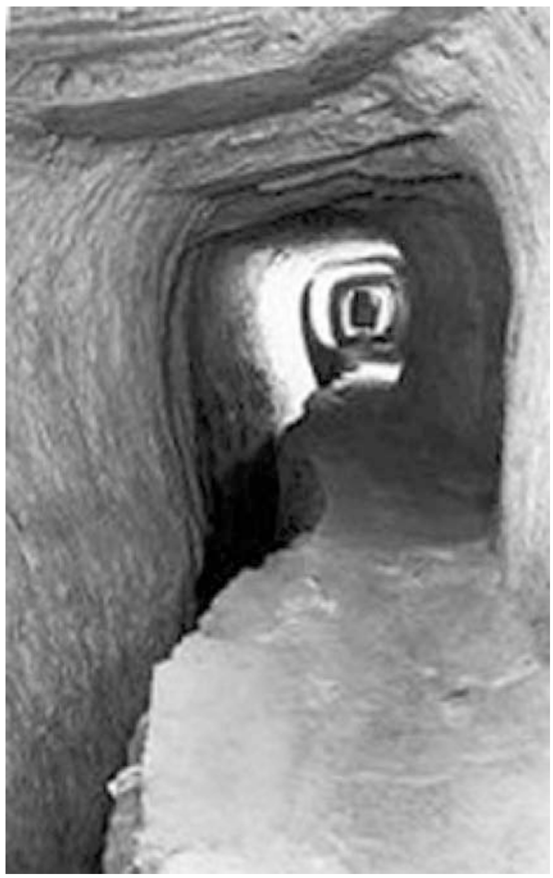

Fig. 6 The Tunnel of Eupalinos. The duct is shown to the left.

construction of the water tunnel was easy and fast, provided that the access tunnel was completed; 28 vertical shafts were constructed for easy access to the water tunnel and many teams of workers must have been worked simultaneously to dig it. The outer parts of the aqueduct were constructed in a similar manner. Thus, section PQ of the north duct (Fig. 5) was constructed as an open channel whereas section QN was a tunnel with five shafts.

What Eupalinos did was not the only solution to the problem of conveying water to Samos. A simple alternative solution was to continue the simple and fast method of section PQN constructing a chain of open channels and tunnels at small depths with shafts. In this solution, the route from point N to S would be around the mountain. Not only is this alternative solution technically feasible, but also it is technically easier, less expensive, and faster. Why Eupalinos preferred his unorthodox and breakthrough solution? How did he persuade the tyrant Polycrates to support this solution? These are unanswered questions. Probably he wished to build a monument of technology rather than simply solving a specific water transportation problem.

THE SUSTAINABLE URBAN WATER MANAGEMENT IN ATHENS

Water management in ancient Athens, the most important city of antiquity with a population of more than 200,000 during the golden age (5th century B.C.), is of great interest. Athenians put great efforts into the water supply of their anhydrous city. The first inhabitants of the city chose the hill of Acropolis for their settlement due to the natural protection it offered and the presence of three natural springs,[15] the most famous being ‘‘Clepsydra.’’ However, natural springs in Acropolis and elsewhere were not enough to meet water demand. Therefore, Athenians used both groundwater, by practicing the art of drilling of wells, and stormwater, by constructing cisterns. In addition, the water from the two main streams of the area, Kephisos and Ilissos, whose flow was very limited in summer, was mainly used for irrigation.

Archeological evidence reveals that the city had developed an important system of public water supply consisting of wells, fountains, and springs and there were also a number of private springs and wells. There are indications that a primitive distribution system was in place underneath the city, consisting of underground connections of wells;[15] this expanded all around the city to the outskirts.[16] The most important public work was the Peisistratean aqueduct, built in the time of the tyrant Peisistratos and his descendants (ca. 510 B.C.). The exact location and route of the aqueduct is not well known to date. It is known, however, that it carried water from the foothill of the Hymettos mountain, probably from east of the Holargos suburb at a distance around 7.5 km,[17] to the center of the city near Acropolis. The greater part of it was carved as a tunnel at a depth reaching 14 m. In other parts it was constructed as a channel, either carved in rock or made of stone masonry, with depth 1.30 m–1.50 m and width 0.65 m.[18] In the bottom of the tunnel or channel, a pipe made of ceramic sections was placed (Fig. 7). The pipe sections had elliptic openings with ceramic covers in their upper part for their cleaning and maintenance; the ends of the sections were appropriately shaped, so that they could be tightly interlocked, and were joined with lead.

In the recent excavations for the construction of the metro, the widespread use of such ceramic pipes

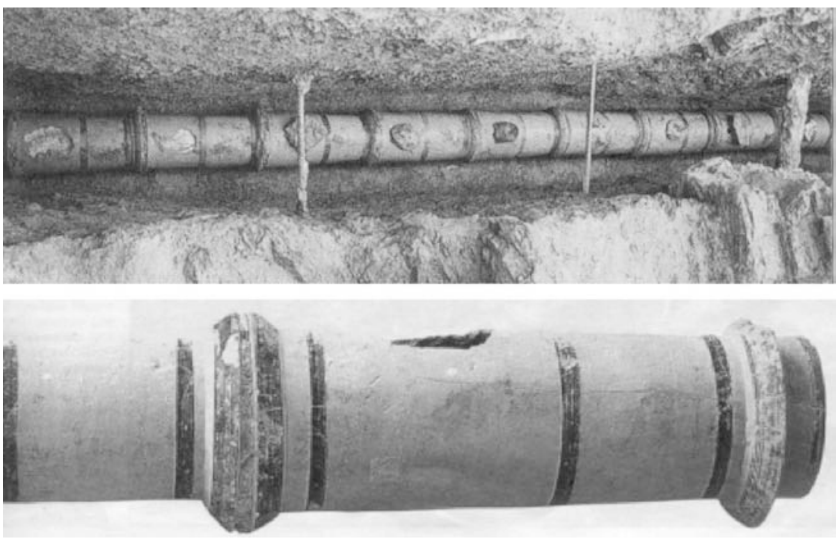

Fig. 7 Part of the Peisistratean aqueduct (top) and detail of the pipe sections and their connection (bottom). (Photos reproduced from newspaper Kathimerini.)

was revealed. Similar pipes were also used for sewers. Sewers of large cross section, most probably storm sewers, were built of stone masonry; some of them were natural streams, like Heridanos, that were covered (Fig. 8).

Apart from the structural solutions for water supply and sewerage, the Athenian civilization developed a legislation and institutional framework for water management. The first known laws are due to Solon, the Athenian statesman and poet of the late 7th and early 6th century B.C., who was elected archon in 594 and shaped a legal system by which he reformed the economy and politics of Athens. Most of his laws have been later described by Plutarch (47–127 A.D.), from whom it could be learnt that:

> Since the area is not sufficiently supplied with water, either from continuous flow rivers, or lakes or rich springs, but most people used artificial wells, Solon made a law, that, where there was a public well within a hippicon, that is, four stadia (4 furlongs, 710 m), all should use that; but when it was farther off, they should try and procure water of their own; and if they had dug ten fathoms (18.3 m) deep and could find no water, they had liberty to fetch a hydria (pitcher) of six choae (20 L) twice a day from their neighbors; for he thought it prudent to make provision against need, but not to supply laziness (Plutarch, Solon, 23).

MacDowell[19] conjectures that these laws have been kept unchanged through the classical period. As the city's public system grew and aqueducts transferred water to public fountains, private installations like wells and cisterns tended to be abandoned. But, the latter would be necessary in times of war because the public water system would be exposed; therefore, the owners were forced by decree to maintain their private facilities in good condition and ready to use.[20] Other regulations protected surface waters from pollution.[19] An epigraph of ca. 440 B.C. contains the "law for tanners," who are enforced not to dispose their wastes to Ilissos river.[15]

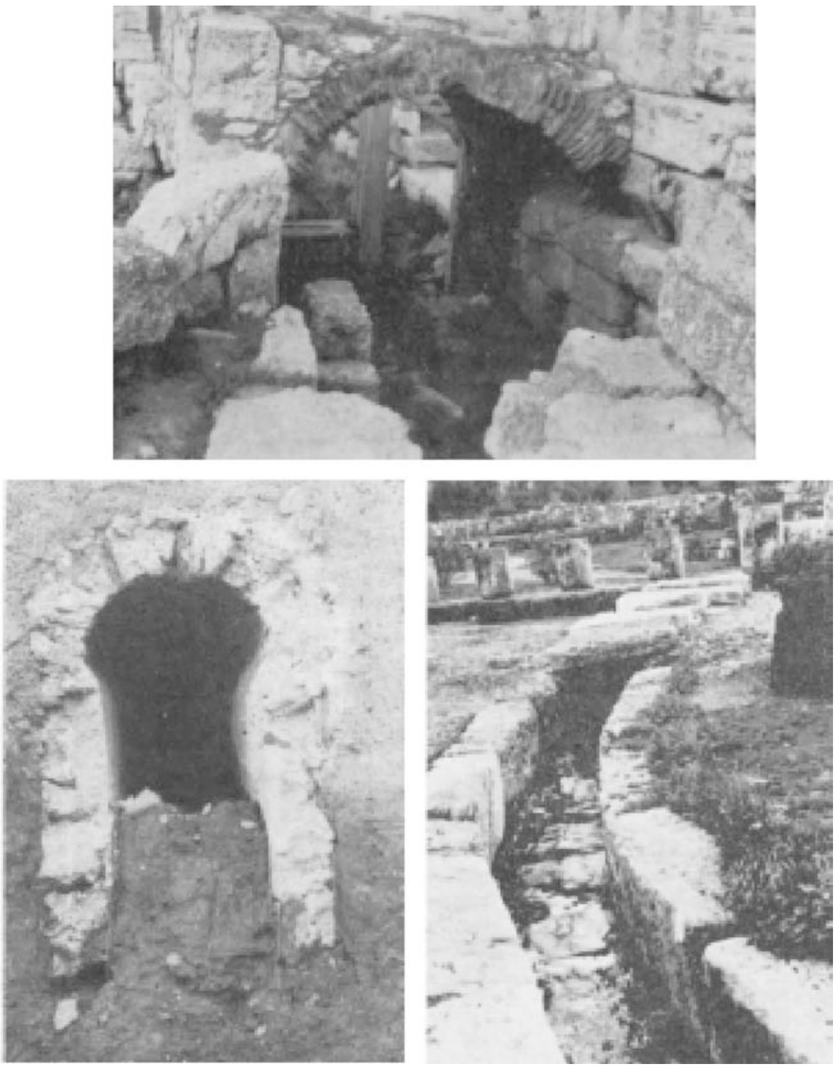

Fig. 8 The Heridanos stream converted into a sewer at Ceramicos (up) and two tributary sewers (down) at Ceramicos (left) and Agora (right). *Source*: From Ref. [18].

A distinguished public administrator, called "κρουνῶνεπιμελητής", that is, officer of fountains, was appointed to operate and maintain the city's water system, and to ensure keeping of regulations and fair distribution of water. In addition, a number of guards were responsible for the proper daily use of the public springs and fountains. From Aristotle (Athenaion Politeia, 43.1) it is learnt that the officer of fountains was one of the few that were elected by vote whereas most other officers were chosen by lot; so important was this position within the governance system of classical Athens.[17] Themistocles himself had served in this position. In 333 B.C. the Athenians awarded a gold wreath to the officer of fountains Pytheus because he restored and maintained several fountains and aqueducts. The entire regulatory and management system of water in Athens must have worked exceptionally well and approached what today we call sustainable water management. For example, modern water resource policymakers and hydraulic engineers emphasize the non-structural measures in urban water management and the importance of small-scale structural measures like domestic cisterns, which reduce the amount of stormwater to be discharged and provide a source of water for private use.

The importance of water in Athens was not only related to the basic uses like drinking, cooking, and cleaning. Water was also related to the beauty of the city; this is revealed from the many fountains that Athenians constructed and the depictions thereof on vessels. Given that vessels were used to export goods, they can be regarded as sort of advertisement of the city's beauty. Another important water use in Athens was in public baths, cool or warm, called "βαλανεία" (later passed in Latin as balineae or balneae), which, interestingly, at times were common for men and women (what we call today bains mixtes), and were related to enjoyment, health, socialization, and culture.[21] Later, the Romans took up and extended the Greek water technology including, of course public fountains and balneae, which became a matter of luxury and prestige. As a sort of requital, the Roman emperor Hadrian (117–138 A.D.) showed particular interest for Athens; at his time the famous Hadrianic aqueduct was commenced, which conveyed water from mountains, Parnes and Pentele, to Athens covering a distance of 25 km. This aqueduct was in operation until the middle of the 20th century.

Antitranspirants: Film-Forming Types

Zvi Plaut
Volcani Center, Institute of Soil, Water and Environmental Sciences, Agricultural Research Organization (ARO), Bet-Dagan, Israel

INTRODUCTION

As most of the water absorbed by plants is lost by transpiration, reducing plant transpiration could conserve irrigation water and minimize plant water stress. The term *antitranspirants* refers to a series of compounds intended for this purpose. A decrease in transpiration rate can be achieved either by covering the canopy with film-forming polymers, or by regulating stomatal aperture. Substantial research has investigated the effects of various antitranspirants on transpiration, other physiological activities, and growth. As it was assumed that polymers were less permeable to CO_2 than to water, and that the chemicals that close the stomata inhibit photosynthesis as much as transpiration, research on antitranspirants became limited. Thus, it is surprising that a large number of studies on antitranspirants were conducted thereafter. Many (but not all) of those that were conducted during the last two decades will be assessed herein.

The present entry will deal with film-forming polymers, whereas compounds regulating stomatal aperture will be delineated in the next. Table 1 presents a list of polymers, giving commercial and chemical names or nature and references.

TRANSPIRATION, PLANT WATER STATUS, AND YIELD

The main objective of antitranspirants is to reduce transpiration rate while maintaining or even increasing productivity and yield. If less water is transpired, the storage of water in the soil will be higher, and its availability will be increased and prolonged. Therefore the effect of film-forming polymers on productivity will be more distinctive in crops that are sensitive even to moderate water stress (e.g., potatoes). In fact, potatoes responded very positively to antitranspirants such as Vapor Gard, Folicote, or other wax emulsions.[1–4] The decrease in transpiration reduced water uptake by up to 40%.[1] The increase in yield was mainly due to larger tubers, rather than to an increase in their number, suggesting that soil water was more abundant and available for extension growth of the tubers. Moreover, the gradient in water potential between tubers and leaves was smaller than in untreated plants,[2] allowing better transport of assimilates from leaves to tubers. In some cases, an increase was found only in tuber size, not in total yield.[5] Similarly, an increase in the yield of onion was found to be due to larger bulbs.[6] An increase in yield connected to a decrease in transpiration was also outlined for other crops treated with film-forming polymers,[7,8] and can be attributed to improved plant water status and foliar hydration.[9] The decrease in transpiration may also induce earlier fruit ripening and improve quality (e.g., decline blossom-end rot in peppers).[10] Furthermore, using antitranspirants after harvest of fruit trees drastically reduced the rate of transpiration, without affecting growth and fruit yield the following year.[11] According to a simulation model for tomatoes, antitranspirants enhanced vegetative growth more than it increased fruit yield.[12]

Under dryland farming, or with very limited availability of irrigation water, the quantity of saved water is of less importance than under conditions of full irrigation, whereas the response of crop yield to antitranspirants is significant. Increases in yield using film-forming antitranspirants were demonstrated by several investigators, who did not refer to the actual decrease in transpiration. An increase was found with Folicote in corn,[13] with Vapor Gard in sweet corn,[14] with pinolene in snap beans,[15] and with Vapor Gard in pepper.[10,16]

There are conditions under which the shape and appearance of the plant are major factors in determining its quality, whereas dry matter production is only of secondary importance (e.g., in flower crops). A reduction in the rate of transpiration, which can be achieved by antitranspirants, may increase leaf water content and produce a more vigorous plant. Growth and dry matter production have been neglected in floricultural studies. A good example for this is the effect of several film-forming antitranspirants on producing higher-quality hydrangea florets[17,18] and Cineraria flowers.[19] The studies showed a reduced transpiration rate, which also resulted in a smaller drop in xylem water potential and less water stress than in other crops when irrigation was terminated.[20]

Table 1 A list of film-forming antitranspirants used by the investigators cited in this review (arranged alphabetically)

Commercial name	Chemical name or nature	User
All-safe	Di-1-*p*-menthene	[18]
Anti-stress 550	Latex of acrylic polymer	[8,27]
Aquawiltless	Wax emulsion	[26,28]
Clear Spray	Latex of acrylic polymer	[19,26,28]
Cloud Cover	Latex of acrylic polymer	[18,23]
DC-200	Silicone (dimethyl–siloxane polymer)	[26,28]
Folicote	Hydrocarbon wax emulsion	[1,4,5,6,10,13,17–20,25,26,28,34]
Elvanol 71-30	Hot H_2O-soluble polyvinyl alcohol	[20]
Envy	Hydrophylic polymer	[18]
Exhalt 4-10	Polyenpenes and polyethylenes	[17,26,28]
Linseed Oil	Linseed oil	[9]
Magen 2001	Acrylic polymer	[22]
Moisturin-R	Latex emulsion	[24]
Pinolene	Di-1-*p*-menthene	[15,16]
Protec	Carboxylated hydrophilic polymer	[26,28]
Vapor Gard	Di-1-*p*-menthene	[1,3,6,7,10–12,14,17,19,20,23,26,28,30,31,34]
Wilt Pruf	Di-1-*p*-menthene	[17,20,23,26,28,32]

Unidentified materials are not listed.

WATER VAPOR CONDUCTANCE AND CO_2 FIXATION

The mechanism of the effects of antitranspirants on yield and transpiration cannot be concluded from most of the reported studies. It is possible that mesophyll conductance was a rate-limiting factor in photosynthesis equal or greater than stomatal conductance, so the decrease in stomatal conductance would reduce transpiration more than photosynthesis.[21] However, even if the film reduces conductance of CO_2 more than H_2O, there is probably a marked improvement of plant water status that could promote growth and yield, regardless of gas exchange rates. We tried in a recent study to clarify this dilemma by simultaneous determination of water vapor conductances and CO_2 fixation rates in the absence of any water stress.[22] The study, which was conducted on several crop plants treated with a film-forming material, ruled out the possibility that improved water status was the reason for higher yields (Fig. 1). Although the curvature was not the same for the three plants, the change in water vapor conductance was large at fully open stomata, when the interference for transpiration was minimal but the changes in CO_2 fixation were much smaller. This can serve as evidence, rather than speculation, that mesophyll conductance was involved in the determination of CO_2 fixation, and was responsible for the lower rates of CO_2 fixation.

IMPROVEMENT OF GROWTH AFTER TRANSPLANTING

Plants are subject to water stress when the rate of water loss exceeds the rate of uptake. This may easily occur when the root system is sparse or inactive (i.e., when seedlings of trees or herbaceous plants are transplanted). Restricting the rate of water loss shortly after transplanting can be achieved by film-type antitranspirants, which may lead to better survival and establishment of the seedlings. This was found for Chinese elm, white spruce, and white pine;[23] scarlet oak, green ash, and Turkish hazelnut;[24] and seedlings of annual plants.[25] Film-forming antitranspirants were also used for tissue-cultured plantlets before their transfer to growth media in a greenhouse.[26,27] The transfer of such plantlets from in vitro conditions to the greenhouse may result in rapid desiccation, and the use of films was found to improve survival rates. However, Pospisilova et al.[28] claimed that most film-forming antitranspirants were ineffective in retaining plant vigor, whereas abscisic acid (ABA) alleviated transplantation shock.

IMPROVED PRESERVATION AND QUALITY DURING STORAGE

Whole plants as well as detached organs (mainly fruits) are subjected to dehydration during storage.

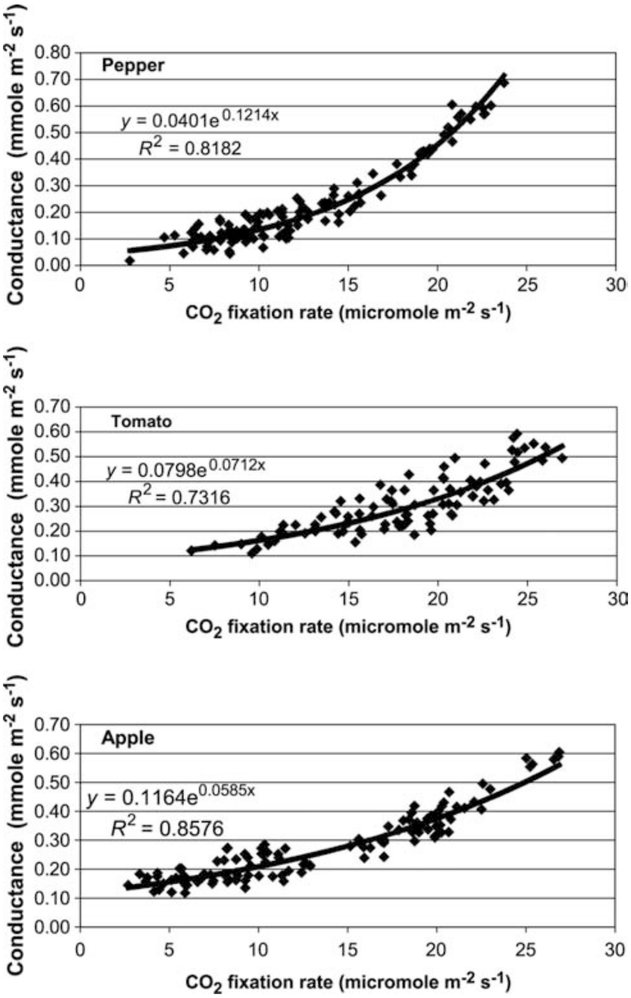

Fig. 1 Ratio between water vapor conductance and CO_2 fixation rates of pepper, tomato, and apple leaves sprayed with a film-forming antitranspirant. *Source*: From Ref.[22].

Film-forming antitranspirants have been recommended for decreasing dehydration, extending the period of storage and maintaining quality during shipment. This was shown for rose plants packed after harvesting, which lost less weight during storage and resumed better growth than untreated plants.[29] Vapor Gard was found to delay ripening, extend shelf life, reduce weight loss, and improve flavor in mango and avocado fruits.[30,31]

CONTROL OF FOLIAR DISEASES

Film-forming antitranspirants can also control foliar diseases in several plants, mainly ornamentals. Vapor Gard effectively controlled powdery mildew on *Hydrangea macrophylla* and *Lagerstroemia indica*.[32] Other film-forming polymers were found to control powdery mildew, gummy stem blight, *Alternaria* leaf blight, and *Ulocladium* leaf spot of cucurbit plants.[33] This effect was attributed to interference with the adhesion and penetration of the germ into the leaf. Similarly, the infestation of *Puccinia* recondite could be successfully suppressed in wheat seedlings by several film-forming antitranspirants.[34]

CONCLUSION

The potential of film-forming antitranspirants to reduce transpiration was reviewed in detail by Gale and Hagan[35] in 1966. Although it was claimed that these compounds are of marginal value for improving plant water status simultaneously with improving productivity,[36] it was shown that they can be effective for several purposes. Water status of crop plants, which are sensitive to water shortage, was improved and their yield was increased; vigor and vitality of flower crops was increased. Crops grown under dryland conditions and limited available water responded by better growth. Additional potential uses of film-forming materials are better establishment of young seedlings and improved preservation of cut plants and harvested fruits.

Antitranspirants: Stomata Closing Types

Zvi Plaut
Volcani Center, Institute of Soil, Water and Environmental Sciences, Agricultural Research Organization (ARO), Bet-Dagan, Israel

INTRODUCTION

It was shown that changes in stomatal conductance can affect transpiration rate more than the rate of assimilation (see the chapter "Antitranspirants: Film-Forming Types"). Compounds that artificially decrease stomatal conductance, by inducing partial closure, may also be used to reduce transpiration. Whereas films are always located outside the leaf tissue, these compounds must be inside the leaf. They are either taken up by roots, transported to the leaves, and finally reach the epidermis, or absorbed directly by the leaf. It is expected that these compounds will affect metabolic reactions responsible for changes in the osmotic potential of guard cells or change the permeability of guard cell membranes or rigidity of cell walls. It is also expected that these compounds will have no significant side effects, mainly harmful effects; natural compounds such as plant hormones were thus more acceptable as antitranspirants.

THEORETICAL BACKGROUND

The possibility of reducing transpiration from plants was very attractive in the past, and many studies were conducted in this field during the 1950s and 1960s (e.g., the reviews by Gale and Hagan[1] and Waggoner[2]). This can be achieved either by thin transparent films covering the canopy, as described in the above-mentioned chapter, or by materials that will induce stomatal closure and thus decrease leaf water vapor conductance, which are described in the present article. The theoretical background for using such antitranspirants is based on the possibility of reducing water vapor conductance more than conductance of CO_2 into the leaf. Both transpiration, namely, diffusion of H_2O vapor from leaf to atmosphere and diffusion of CO_2 from atmosphere to leaf can be described by the following two equations, as shown by Jones.[3]

$$T = (e_l - e_a)/Pa(r_a + r_s) \quad (1)$$

$$A = (\rho_a - \rho_\Gamma)/Pa(r_a' + r_s' + r_m') \quad (2)$$

In the equations, T and A represent the rates of transpiration and assimilation, e_l and e_a the water vapor pressure of leaf and air, respectively, at their temperatures. Similarly, ρ_a and ρ_Γ represent the atmospheric and leaf internal partial pressure of CO_2, respectively, and r_a, r_s, and r_m' the air boundary layer, stomatal, and mesophyll resistances, respectively (without prime referring to water vapor and with prime to CO_2). If constant environmental conditions are assumed, then the ratio between T and A will be as follows:

$$T/A \sim (r_a + r_s)/(r_a' + r_s' + r_m') \quad (3)$$

Because the denominator, representing CO_2 assimilation, contains an extra term, it may be expected that under high stomatal resistance (equivalent to lower conductance, which is its reciprocal) assimilation rate will be less reduced than transpiration rate. This is the basis for decreasing stomatal conductance with antitranspirants, as water-use efficiency (WUE) is expected to increase.

TYPES OF ANTITRANSPIRANTS

Antitranspirants can be classified according to their chemical structure, mode of action, function, or purpose of application and the treated crop. The primary classification used in the present article is according to the function of the material. Table 1 gives commercial and chemical names or nature and references. The most common "stomata-closing materials" are phenyl mercuric acetate (PMA) and abscisic acid (ABA). Although PMA was considered toxic in many cases and the effect of artificially added ABA was short,[4] numerous studies were conducted on their use as antitranspirants. Reflecting materials such as kaolin, which are used to reduce the energy load of the foliage and may thus indirectly reduce transpiration, cannot be considered antitranspirants, because they have no direct effect on stomatal aperture or on leaf conductance. Several investigators documented a decrease in transpiration in canopies sprayed with kaolin.[5–7] However, the increase in yield and in WUE[8,9] can be attributed to the prevention of photoinhibition

Table 1 List of materials regulating stomatal aperture used by the investigators cited in this review

Commercial name	Chemical name or nature	User (see list of references)
ABA	Abscisic acid	[11,14,20,21]
Alachlor	2-Chloro-2,6-diethyl-*N*-(methoxy methyl)acetanilide	[10,13]
Ambiol	Derivative of 5-hydroxybenzimizole	[20]
Aspirin	Acetylsalicylic acid	[11]
Atrazine	6-Chloro-N2-ethyl-N4-isopropyl-1,3,5 triazine-2,4-diamine	[11]
B-9	Diaminozide	[13]
Chitosan	Waste product from shells of shrimp, crabs, and lobsters	[15]
CCC (Cycocel)	Chlormequat (2-chloro-*N*,*N*,*N*-trimethylethanaminium)	[11,13]
8-HQ	8-Hydroxyquinoline	[5,13,14,20,22,23]
Paraquat	1,1′-Dimethyl-4,4′-bipyridinium dichloride	[24]
PMA	Phenyl mercuric acetate	[5,10,12–14,17,19,22,23]

Unidentified materials are not listed.

and enhanced photosynthesis (probably photosystem II) rather than being an effect on transpiration.

TRANSPIRATION, PLANT WATER STATUS, AND YIELD

The effect of stomata-closing materials on transpiration and growth is not unequivocal. The rate of transpiration was reduced, plant water status was improved, and growth of sweet corn was enhanced by PMA,[10] ABA, chlormequat, and atrazine.[11] Coudret et al.[12] on the other hand indicated that dry matter production was decreased by PMA in two species of *Plantago*. Amaregouda et al.[13] found no effect of PMA on the yield of groundnuts, although plant water status improved. These inconsistent results may be due to toxic effects of these materials on some crops or at specific growth stages, and damage to leaves.[14,6] The use of this group of antitranspirants will thus need a further painstaking evaluation of each compound for every crop and growth stage. Recently a natural compound, chitosan, was shown to induce stomatal closure of pepper, decrease transpiration, and reduce water use, while maintaining biomass production and yield.[15] Another compound, GLK-8923, was claimed to serve as an antitranspirant when added to the growing medium.[16] However, as reduced transpiration was obtained by decreasing the osmotic potential of the medium, plant water status and growth were worsened, similar to the effect of salinity or restricted water supply; thus it cannot be considered an antitranspirant.

The response of crop yield to antitranspirants is, in some cases, of more importance than the saving of water. An increase in yield with stomata-closing materials can be shown for several crops: tomatoes with PMA and 8-HQ, sweet corn with PMA and alachlor,[10] chickpeas with PMA,[17] soybeans with silica, which accumulated in the leaf epidermal cells,[18] and green grams with PMA.[19] These increases in yield can be mainly attributed to milder water stress as compared with untreated plants and is reflected in higher water and osmotic potentials.[5] In plants exposed to drought and treated with several growth regulators (ABA, polyamines, and an antioxidant, Ambiol) higher rates of photosynthesis and lower Ci/Ca ratios, as compared to untreated plants, were outlined. This will also increase WUE.[20,21]

An improvement in plant water status and relative water content was also found with stomata-closing chemicals such as PMA, 8-hydroxyquinoline in tomato and onion plants,[22,23] and paraquat in rice.[24]

CONCLUSION

Stomatal closing antitranspirants were believed to act as superior transpiration inhibitors, as they are taken up by the plant, and transported to new growing and expanding organs, in contrast to films, which have to be reapplied. Moreover, they are supposed to be more stable and not damaged like external films by winds or other environmental factors. In fact, stomatal closing materials were, in many cases, effective in reducing transpiration, improving plant water status and increasing yield, as was shown. However, their use was more limited than those of film-forming materials, due to side effects in many plants, which may cause damage to plants at various developmental stages. Moreover, the lifetime of several such materials may be limited, which may also limit their effectivity.

Aquifers

Miguel A. Marino
Hydrology, Civil and Environmental Engineering, and Biological & Agricultural Engineering, University of California–Davis, Davis, California, U.S.A.

INTRODUCTION

An aquifer is a geologic formation that can transmit, store, and yield significant quantities of water. An aquifer can be confined (one bounded above and below by impervious formations), unconfined (one with a water table serving as its upper boundary), or leaky (one that can gain or lose water through adjacent semipervious formations). In addition to the aforementioned porous-media aquifers, there are karst aquifers in which water flow is concentrated along fractures, fissures, conduits, and other interconnected openings. The hydraulic properties of aquifers (e.g., transmissivity and storativity) are best determined by testing the aquifers in place. Water contained in an aquifer is called ground water and is commonly extracted by means of a well. The quality of ground water determines, to a large extent, its suitability for a particular use, such as irrigation, public water supply, etc. Human activity poses a threat to ground-water quality and already has resulted in incidents of ground-water pollution or contamination. Because ground water tends to move slowly, it may take many years after the start of pollution before contaminated water shows up in a well. The best way to protect the quality of ground water is to prevent its contamination.

AQUIFERS

An aquifer is a geologic formation that yields significant quantities of water (e.g., coarse sand and gravel formation). In contrast, an aquiclude is a formation that may contain water but cannot transmit it in significant quantities. A clay stratum is an example. For all practical purposes, an aquiclude can be considered an impervious formation. An aquitard is a semipervious formation, transmitting water very slowly compared with an aquifer. It can, however, permit the passage of large quantities of water over a large (horizontal) area. An aquitard is often called a semipervious layer or a leaky formation. An aquifuge is an impervious formation that neither contains nor transmits water. Solid granite is an example.

An aquifer can be regarded as an underground-storage reservoir. Water enters the aquifer naturally through precipitation or influent streams—and artificially through wells or other recharge methods. Water leaves the aquifer naturally through springs or effluent streams—and artificially through pumping wells. Fig. 1 is a schematic representation of several aquifers and observation wells.[1]

A confined aquifer, also called artesian aquifer or pressure aquifer, is bounded above and below by impervious formations. Water in a well penetrating such an aquifer will rise above the base of the upper confining formation; it may or may not reach the ground surface. A well that penetrates a confined aquifer is called an artesian well—it is called a flowing well if the water level in the well reaches, or exceeds the elevation of, the ground surface. The water levels in a number of wells penetrating a confined aquifer are the hydrostatic-pressure levels of the water in the aquifer at the well sites. The water levels define an imaginary surface called the piezometric or potentiometric surface.

An unconfined aquifer, also called phreatic aquifer or water-table aquifer, is one with a water table (phreatic surface or surface of atmospheric pressure) serving as its upper boundary. Actually, above the water table is a capillary fringe often neglected in ground-water studies. A special case of an unconfined aquifer is the perched aquifer. It occurs wherever an impervious (or relatively impervious) stratum of limited horizontal area supports a ground-water body that is above the main water table. A well that taps an unconfined aquifer is called a water-table (or gravity) well. The water level in such a well corresponds approximately to the position of the water table at that location.

Ground-water levels can be measured to estimate the piezometric-surface or water-table distribution in an aquifer or to determine fluctuations in hydraulic head over time. Maps of ground-water levels are used to estimate ground-water flow direction and velocity, to assess ground-water vulnerability, to locate landfills and wastewater disposal sites, etc.

Aquifers, whether confined or unconfined, that can gain or lose water through adjacent aquitards or semipervious formations are called leaky aquifers. A confined aquifer that has at least one semipervious confining bed is called a leaky-confined aquifer. An unconfined aquifer that rests on a semipervious

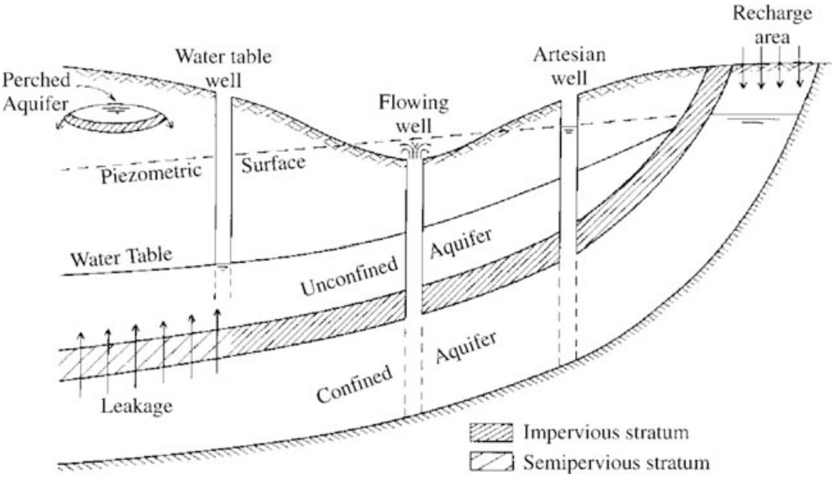

Fig. 1 Schematic of several aquifers and observation wells. *Source*: From Ref.[1].

stratum is called a leaky-unconfined aquifer. Leakage across semipervious formations can be significant.

Fig. 1 shows an unconfined aquifer underlain by a confined one. In the recharge area, the confined aquifer becomes unconfined. A portion of the confined and unconfined aquifers is leaky, with the amount and direction of leakage governed by the difference in piezometric head across the semipervious stratum.

In addition to the aforementioned types of aquifers, there are karst aquifers made up of soluble rock strata at or near the earth's surface in which water flow is concentrated along fractures, fissures, conduits, and other interconnected openings.

Aquifer elasticity is the main mechanism responsible for volumes of water released from or added to storage in aquifers. In confined aquifers, water is derived from storage primarily by the elastic properties of both the aquifer matrix and the water. In unconfined aquifers, water released from storage is due mainly to gravity drainage (drainage of the pore space above the lowered water table) and partly to elastic storage (as in confined aquifers). In leaky aquifers, water is derived from storage in the main (confined) aquifer, gravity drainage if the aquifer is unconfined, and elastic storage in aquitards, and induced vertical leakage across these units.

The general properties of aquifers to transmit, store, and yield water (e.g., transmissivity, storativity, and leakage factor) are usually referred to as hydraulic properties of aquifers, or simply aquifer parameters. Because of the many factors on which these parameters depend, numerical values must depend on experimental determination. Although various laboratory techniques are available,[2,3] more reliable results are obtained from field tests[1–6] of the aquifers in place.

The transmissivity of the aquifer determines the ability of the aquifer to transmit water through its entire thickness. In confined aquifers, the transmissivity is represented as the product of hydraulic conductivity and aquifer thickness, in the direction normal to the base of the aquifer (the hydraulic conductivity expresses the ease with which a fluid is transported through a porous medium). Because in unconfined aquifers the saturated thickness extends from the water table to the base of the aquifer, the transmissivity varies in time as the water table often fluctuates in response to recharge and pumping.

The storage capacity of an aquifer is quantified by its storativity, also called the storage coefficient. The storativity indicates the relationship between changes in the volume of water stored in an aquifer and corresponding changes in the elevations of the piezometric surface, or the water table. It can be defined as the volume of water that a column of the aquifer, of unit cross-section, releases from or adds to storage per unit decline or rise of piezometric surface (confined aquifers) or water table (unconfined aquifers). In a confined aquifer, the storativity is caused by the compressibility of the water and the elastic properties of the aquifer. In an unconfined aquifer, the storativity is due mostly to dewatering or refilling the zone through which the water table moves (e.g., water removed by gravity drainage) and partly to water and aquifer compressibility in the saturated zone. A certain amount of water, however, is held in place against gravity in the pores between grains under molecular and surface-tension forces. Thus, the storativity of an unconfined aquifer is less than the porosity by a factor called specific retention (the ratio between the volume of water that a soil will retain against gravity and the total volume of the soil). Reflecting this phenomenon, the storativity of an unconfined aquifer is often called specific yield (the ratio between the volume of water that a soil will yield by gravity and the total volume of the soil). Also often used in this context is the term, effective porosity.

A parameter characterizing a leaky aquifer is the leakance, or coefficient of leakage, of the semipervious formation. It is a measure of the ability of this formation to transmit vertical leakage and is defined by the ratio of the hydraulic conductivity of this formation to its thickness. The reciprocal of the leakance can be thought of as the resistance of the semipervious formation. Another parameter, the leakage factor, is the root of the ratio of the transmissivity of the aquifer to the leakance of the semipervious formation. It determines the areal distribution of the leakage.

The quality of water contained in an aquifer determines, to a large extent, the suitability of the water for a particular use, such as irrigation, public water supply, etc. The quality of ground water is a consequence of all processes and reactions that have acted on the water from the moment it condensed in the atmosphere to the time it is discharged by a well.[2] Human activity poses a threat to ground-water quality and already has resulted in incidents of ground-water pollution or contamination.[2,6] The latter refers to the presence of a chemical or biological agent in the ground water in such a concentration that it renders the water unfit for a certain use. Because ground water tends to move slowly, it may take many years after the start of pollution before contaminated water shows up in a well. The best way to protect the quality of ground water is to prevent its contamination.

Aquifers: Artificial Recharge

Steven P. Phillips
U.S. Geological Survey (USGS), Sacramento, California, U.S.A.

INTRODUCTION

Limited freshwater resources in many parts of the world have led to the development of artificial recharge techniques for conveying surface water and reclaimed wastewater to groundwater reservoirs for later use and for other applications. Other applications include using artificial recharge to create a barrier to saltwater intrusion, reduce land subsidence, raise water levels, and improve water quality by using the natural filtering capabilities of aquifer systems. Subsurface storage of water has many advantages over surface storage, and often is the more physically and economically viable alternative. The worldwide use of artificial recharge likely will increase in the future with continued growth in population and associated competition for finite freshwater resources.

DEFINITION

Artificial recharge has been defined in many ways, varying with points of view and the evolution of applications and methods. It is generally defined by Todd[1] as ‘‘the practice of increasing by artificial means the amount of water that enters a groundwater reservoir.’’ These artificial means include various forms of surface infiltration and direct well injection. For this discussion, forms of enhanced, induced, and incidental recharge, as defined by Bouwer,[2] will be excluded. Enhanced recharge is the increased infiltration of precipitation; it is controlled primarily through vegetation management. Induced recharge is the increased flow of surface water into the aquifer system caused by the placement of wells or other collectors near surface-water bodies. Incidental recharge is caused by leakage of water and sewer pipes, excess irrigation, and other human activities not designed to cause groundwater recharge. Also excluded from this discussion is a recharge from the injection of saltwater used to enhance petroleum recovery, and from deep disposal of wastes.

APPLICATIONS

Artificial recharge programs began in the late 19th century in the United States, and well before that in Europe. It was recognized early on that storing water in the groundwater system held certain advantages over traditional surface storage, including proximity to water sources and points of use, limited engineering and construction costs, and little or no evaporative losses. Prior to the mid-20th century, the primary application of these early programs was enhancement of groundwater resources for drinking and agricultural purposes. Surface water generally was captured when it was available and stored in the groundwater system for later use during high-demand periods. An annotated bibliography of early artificial recharge work is provided by Todd.[1]

Research during the early period of artificial recharge spawned a number of modern applications.[3] These applications include purification of wastewater or poor-quality surface water, creation of barriers against the intrusion of saltwater and other contaminants, abatement of land subsidence, and other environmentally or economically driven applications.

METHODS

Surface Infiltration

The most common form of artificial recharge is surface infiltration, whereby engineered systems allow an increased infiltration of water through subsurface materials to the water table. Although surface infiltration systems are subject to losses from evaporation and may unintentionally attract insects and waterfowl, they often are an efficient and economical means of artificial recharge. Common surface infiltration systems are shown in Fig. 1.

Surface infiltration systems can be divided into two categories: in-channel and off-channel.[2] In-channel systems use temporary or permanent dams or levees designed to impede flow and raise the water surface in existing surface-water channels. The raised water surface increases in-channel storage and the area of the streambed through which infiltration occurs, thereby increasing recharge. Often, in-channel systems are self-cleaning, as fine particles that impede infiltration are removed during high flows, but associated dams and levees require maintenance.

Off-channel systems involve the use of water from any source to fill existing or constructed basins, pits,

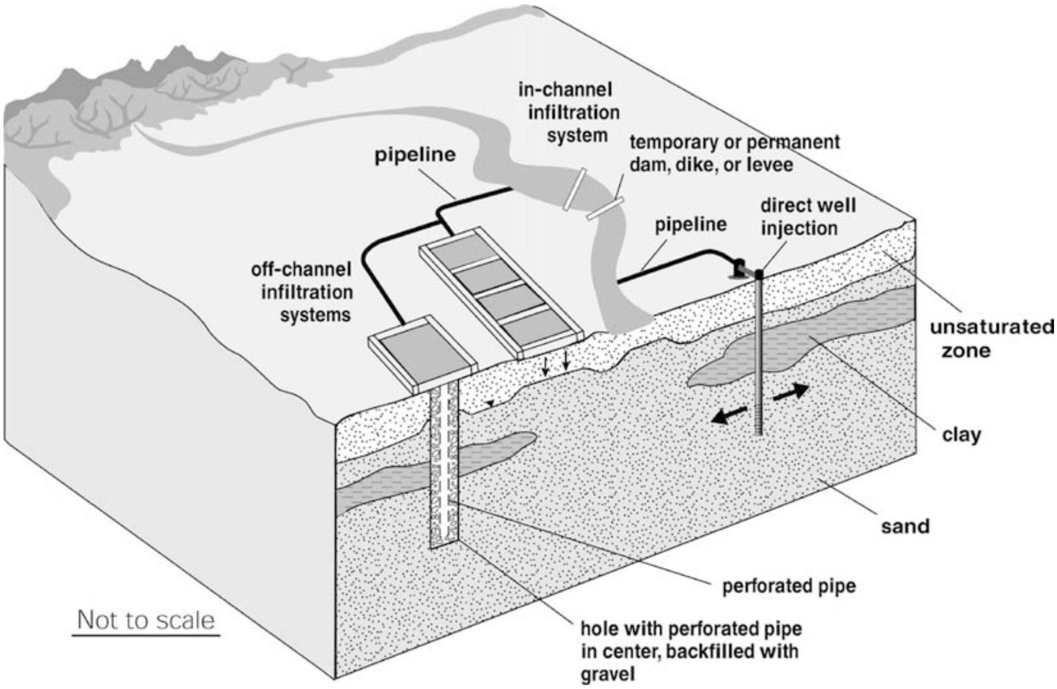

Fig. 1 Diagram showing examples of artificial recharge systems.

ponds, and other structures for surface infiltration. Favorable site conditions for off-channel systems include available and affordable land, an unconfined aquifer that has sufficient transmissivity to keep the water table below the infiltration surface, permeable surface soils for sufficient infiltration rates, a lack of poorly permeable subsurface units that impede downward flow to the water table, and a source of water that has low suspended solids and compatible chemical and biological characteristics.

The site conditions for off-channel systems, if unfavorable, can be altered in some circumstances. Poorly permeable surface soils and (or) deeper fine-grained units above the water table can be penetrated with trenches or holes backfilled with sand or gravel to enhance their capacity to transmit water vertically. These trenches or holes can be used alone, with water delivered through perforated pipes, or in combination with basins or other surface impoundments.

If sediment concentrations or other suspended solids in the source water are too high, rapid clogging of infiltration basins can occur. Pretreatment of the source water in a reservoir or dedicated basin allows solids to settle, sometimes with the help of coagulants. Some chemical and biological processes can also cause clogging, which often is addressed by filtering and disinfecting during pretreatment. Post-treatment clogging generally is controlled by maintenance of infiltration basins, which involves periodic cleaning of the basin bottom.[2]

Additional considerations for surface infiltration systems include the presence of soluble or dissolved potential contaminants in the subsurface, and desirable soil types for various applications. Knowledge of the presence and distribution of natural and anthropogenic contaminants in the vicinity of a proposed artificial recharge site is required to avoid introducing contaminants to the groundwater system and (or) transporting them to undesired locations. Specific soil types are preferable for some applications. For example, a coarse-grained homogeneous soil is preferable for achieving maximum recharge. A finer-grained soil that has higher capacity for sorption may be preferable for sites that use poor-quality source water.

Direct Well Injection

Direct well injection is becoming a common method of artificial recharge. For this method, water is pumped or gravity-fed through wells into confined and unconfined aquifers, and sometimes into the unsaturated zone.[2,4] The same wells used for injection often are used to recover the water. Direct well injection generally is more expensive than surface infiltration because of costs of well construction and water treatment requirements. However, injection allows water to bypass poorly permeable soils and subsurface units to allow rapid recharge of deep aquifers through thick unsaturated zones, avoids transport of near-surface contaminants to the saturated zone, and requires little land, enabling strategic well placement. These attributes make direct well injection particularly useful in urban settings and in areas where the unconfined aquifer is too contaminated to use surface infiltration methods.

Clogging is a key design and operational consideration for direct well injection because recharge water must pass through a very small area, the well screen and borehole wall, to enter the aquifer system. Clogging is one of the reasons that injection rates typically are about one-third to one-half of the extraction rate, though this ratio varies widely from site to site.[5] Suspended solids are a common cause of clogged injection wells. Most suspended solids can be removed in reservoirs or basins as described previously and (or) through specially designed piping systems and filters. However, the small amount that typically remains in the recharge water often is the primary clogging agent. The management strategy most often employed is periodic extraction from the well, which removes much of the caked solids.

Clogging can also be caused by biological growth, mineral precipitates, and air or gas bubbles. Growth of existing or introduced microorganisms can rapidly clog an injection well, and generally is managed by using continual low-level disinfection and periodic shock treatments with chlorine.[4] Mixing of water types during injection can cause precipitation of minerals on the well screen and within the gravel pack and aquifer materials. Commonly, geochemical modeling is done during the design phase to determine the potential for adverse geochemical reactions; adjustments of pH or other properties of the recharge water are sometimes made during operations to avoid mineral precipitation. Air introduced into the well through free-falling water or cavitation in pipes can enter the aquifer system and lodge in pore spaces, effectively reducing the hydraulic conductivity of the aquifer materials and thus the rate of injection. Dissolved gases coming out of solution have a similar effect. These reductions in hydraulic conductivity can be avoided through proper system design and pretreatment of source water.

ISSUES

Public Health

Public health issues associated with artificial recharge are most often raised in connection with the use of treated wastewater. There is much interest in expanding the use of wastewater for artificial recharge, because it is a continuous and increasing source of water and more stringent regulations have increased disposal costs.[5,6] Artificial recharge can improve the quality of treated wastewater through microbial degradation and sorption of some organic constituents; however, there are well-understood and emerging pathogens and other potential toxicants for which diligent monitoring and active research are required to protect public health.[7] However, defined, data from ongoing studies and active projects, which include potable and non-potable uses, suggest that wastewater is a viable source of water for artificial recharge.[5,6]

Environmental

Artificial recharge can have environmental effects that may be important to predict prior to implementation.[5] Flow in streams and other water bodies can increase with a rise in the water table, or decrease with diversions to recharge facilities. The quality of surface water and groundwater can be improved, degraded, or changed in some way that affects the end use of the water. Land subsidence can be reduced by slowing or reversing water-level declines. Development of a shallow water table can cause waterlogging and increased salinity. Reduced pumping lifts saves energy, reducing the environmental effects of energy production. A good understanding of these and other potential environmental effects of artificial recharge projects is a key to their long-term viability.

THE ROLE OF SCIENCE

Artificial recharge involves complex hydraulic, chemical, and biological responses and interactions in a groundwater system.[7] The role of science is to generate an understanding of these complexities through monitoring and analysis, and to develop tools to aid in the planning and management of artificial recharge projects.

Monitoring and Analysis

A set of methods has evolved over the years for monitoring and analyzing the effects of artificial recharge projects.[2,4,8] However, shortcomings in these methods and a number of existing and emerging issues continue to drive research efforts. Microgravity surveying is a geophysical technique that has been used recently to better define water-table changes associated with artificial recharge.[9] New tracer methods using existing and introduced chemicals, isotopes, and heat are improving our ability to track recharged water.[7] Recent research shows that the introduction of organic matter through artificial recharge and the composition of the organic matter may affect the evolution of groundwater chemistry and the formation of disinfection byproducts. A large body of research is focused on addressing the fate of compounds introduced through artificial recharge of treated wastewater, which is needed to safeguard public health. Other research efforts include development of more sophisticated modeling techniques for predicting complex biochemical processes and microbial transport; improving methods for detecting microbial pathogens; and determining the potential for mobilization of arsenic and other trace elements.[7]

Planning and Management Tools

Successful planning and management of an artificial recharge project often requires consideration of many water-management objectives, water-routing capabilities, economics, and hydraulic effects. Simultaneous consideration of these diverse factors can be accomplished by using optimization techniques designed to identify an efficient way to meet an objective, given a set of constraints. The linkage of a predictive groundwater flow model with optimization techniques (a simulation/optimization model) allows for simultaneous consideration of the flow system and physical and (or) economic constraints determined by water-resource managers. Simulation/optimization models have been applied to groundwater problems for decades[10,11] and have been used in the planning and management of artificial recharge projects (e.g., Refs.[12,13]).

Aquifers: Ogallala

B. A. Stewart
Dryland Agriculture Institute, West Texas A&M University, Canyon, Texas, U.S.A.

INTRODUCTION

The Ogallala aquifer underlies about 174,000 mi^2 of land in the U.S. Great Plains. States with the largest land areas above the aquifer are Nebraska, Texas, Kansas and Colorado with smaller amounts in New Mexico, Oklahoma, South Dakota, and Wyoming (Fig. 1). The aquifer extends approximately 800 mi north to south and 400 mi east to west. The aquifer consists of sand and gravel beds that generally lie from 50 to 300 ft beneath the surface and are 150–300 ft thick. In some areas, however, the saturated thickness of the aquifer exceeds 1000 ft.[1]

The water contained in the Ogallala aquifer is essentially fossil water taken 10,000–25,000 yr ago from the glacier-laden Rocky Mountains before it was geologically cut off by the Pecos River and the Rio Grande.[2] More than 3 billion acre-feet (an acre-foot is a foot of water on 1 acre, or 325,851 gal) are stored in the aquifer.

The amount of water that can be extracted from an aquifer is primarily a function of two characteristics—hydraulic conductivity and specific yield. Hydraulic conductivity is the rate of water flow in m^3/sec through a cross-sectional area of 1 m^2 under a hydraulic gradient of 1 m/m at a temperature of about 15°C. Specific yield is the ratio of the volume of water that the saturated aquifer will yield by gravity drainage to the total volume of the aquifer. The hydraulic conductivity governs how fast water can be pumped from an aquifer and the specific yield indicates how much water can be pumped. Gutentag et al.[1] reported that 76% of the aquifer had specific yields of 10–20%, although the values ranged from less than 5 to 30% and averaged 15.1%. Thus, as an average, pumping enough to drop the water level of the aquifer 100 cm will yield 15.1 cm of water at the surface.

USE OF WATER FROM THE AQUIFER

The area underlain by the Ogallala aquifer is semiarid with average annual precipitation ranging from about 375 in. to 625 in. There is also wide variability both within and between years. The annual precipitation ranges for any given year from about 50% of average to 200% of average. Because of the low and varied precipitation, much of the area has no year around water supply from surface supplies. The Ogallala aquifer, therefore, became the lifeblood for development of the Great Plains. Opie[2] tells of Gropp homesteading 20 mi northwest of Garden City, Kansas in 1887. For 2 yr, Gropp rolled a large barrel of water three-fourths of a mile from a neighbor's well until he hand-dug his own 70-m-deep well. Windmills became widely used through the Great Plains to supply water for livestock and homesteads.

The Great Plains was largely developed by livestock producers and dryland farmers. Crop production, however, was highly variable because of the erratic precipitation. As technologies for pumping water improved, irrigation became common and now uses more than 90% of the water pumped from the Ogallala aquifer.

Although some irrigation from the Ogallala aquifer using windmills occurred in the late 1800s, it was limited and sporadic. The drought of the 1930s spurred irrigation development because the precipitation was so low that crops could not be produced otherwise. The major expansion occurred during the 1950s when another drought occurred at the same time that there were technological advances in well drilling and pumping plants, readily available nitrogen fertilizer, inexpensive energy, profitable crop prices, development of hybrid grain sorghum, and available financing. Irrigation from the Ogallala aquifer increased from about 800,000 ha in 1949 to 5.2 million ha in 1978. During this period, approximately 60 cm of water was pumped annually from the aquifer for every irrigated hectare.[1]

Irrigation developed most rapidly in the beginning in the southern part of the Ogallala aquifer area because this area was more drought prone, the depth to the water table was less, and the land was generally flat making it relatively easy to apply water and run it down the rows. Many of the soils in the northern plains were too rolling and too sandy to irrigate by running water down furrows so irrigation development was slowed until reliable center-pivot sprinkler systems became available.

The major problem facing the Ogallala aquifer region today is not knowing how long the water supply will last. Also, the increase in energy prices has also had major impacts on irrigation at different times. In some cases and in some years, the cost of pumping the water is greater than the benefits derived.

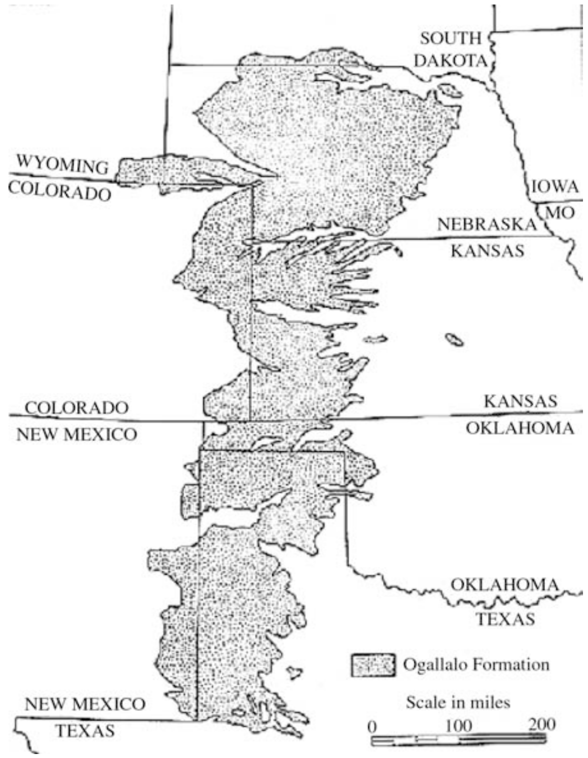

Fig. 1 The area underlain by the Ogallala Aquifer.

The distribution of the water in the Ogallala is very different among the states. Nebraska has 36% of the land (but most of it unsuitable for cultivation) above the aquifer and in 1980 had 66% of the drainable water in storage. Texas had 20% of the land but only 12% of the drainable water comparing closely with Kansas that had 17% of the land and 10% of the drainable water.

The water rights that govern the pumping of water from the aquifer vary for different states. In Nebraska, for example, the water is public property. However, the owner of land is entitled to appropriate the ground waters found under the land, but the owner cannot extract and appropriate them in excess of a reasonable and beneficial use upon the land owned, especially if such is injurious to others who have substantial rights to the waters, and if the natural underground supply is insufficient for all users, each is entitled to a reasonable proportion of the whole. In contrast, Texas law gives the overlying landowner the right to capture and use ground water beneath the land, regardless of the impact on adjoining or more distant users of the supply.[3]

The future of irrigation from the Ogallala aquifer is not clear. While only a relatively small percentage of the total water in the aquifer has been removed, essentially all of the recoverable water has been removed in some portions of the aquifer. The ratio of the volume of drainable water remaining to the volume of water depleted by 1980 was about 19 for the entire aquifer area. Even in Texas, the State with the greatest depletion, 3.4 times as much water remains as has been removed. In some areas, however, the volume of water remaining in the aquifer was less than the volume that had been removed.[1] Depletion since 1980 has continued, although at a somewhat slower rate in most areas because of declining well capacities, higher energy prices, and lower grain prices. It is generally believed that irrigation will decline in much of the Ogallala aquifer region both in areas and in the amount of water applied per hectare. Irrigation in the Texas High Plains has already declined from more than 2.4 million ha to about 1.8 million ha. The efficiency of water use, however, is increasing as a result of improved irrigation systems and crop management practices. This will enable irrigation to continue longer than otherwise would be feasible and irrigation will continue for many portions of the Ogallala aquifer area even in Texas nearly indefinitely.

Many cities, towns, and rural homes depend on water from the Ogallala aquifer. For the most part, there will be sufficient water for domestic uses even when there is no longer sufficient water for irrigation. Irrigation requires huge amounts of water and pumping for irrigation usually stops well before all the water that can be pumped is removed. Thus, there is usually adequate water remaining for domestic use even in areas where irrigation is no longer feasible.

The future of the Ogallala aquifer is unknown. Although some of the early settlers in the area thought there were underground rivers flowing beneath the land, it is clearly understood today that the water stored in the aquifer accumulated over eons of time. The rate of recharge is almost negligible in relation to the rate that water has been pumped since the 1950s. The way that the aquifer is used in the future will be shaped by many factors, but most importantly by the ability and willingness of the people to manage the water in the Ogallala as a non-renewable resource.

INTRODUCTION

Aquifer recharge was defined by Meinzer[1] and Heath[2] as water that moves from the land surface or the unsaturated zone into the saturated zone. This definition excludes saturated flow between aquifers, which avoids double-accounting in large-scale studies, so it might be more precisely called "aquifer-system" or "saturated-zone" recharge. *Recharge rate* designates either a flux $[L^3/T]$ into a specified portion of aquifer, or a flux density $[L/T]$ into an aquifer at a point. Sources of water for recharge include precipitation that infiltrates, permanent or ephemeral surface water, irrigation, and artificial recharge ponds. Recharge may reach the aquifer directly from portions of rivers, canals, or lakes,[3] though usually it first travels by various means through the unsaturated zone.

Recharge varies considerably with time and location. Temporal variation occurs, for example, with seasonal or short-term variations in precipitation and evapotranspiration (ET). This variability is especially evident in thin unsaturated zones, where recharge may occur within a short time of infiltration. In deep unsaturated zones, recharge may be homogenized over several years so that it may occur with essentially constant flux even though fluxes at shallow depths are erratic. Spatial variation occurs with climate, topography, soils, geology, and vegetation. For example, a decrease of slope or increase of soil permeability may lead to greater infiltration and greater recharge. Many applications use a concept of recharge that is time-averaged or areally averaged.

Both the amount of infiltration and the fraction of it that becomes recharge tend to be greater with more abundant water, so the recharge process is most efficient if infiltration is concentrated in space and time. Because ET may extract most or all of the water that infiltrates, water is more likely to become recharge if it moves rapidly below the root zone. Temporal concentration occurs during storms, floods, and snowmelt, when ongoing processes such as ET are overwhelmed. Spatial concentration typically occurs in depressions and channels, where higher water contents promote rapid movement by increasing the hydraulic conductivity (K), the amount of preferential flow, and the downward driving force at a wetting front. Quantitative estimation of recharge rate contributes to the understanding of large-scale hydrologic processes. It is important for evaluating the sustainability of ground water supplies, though it does not equate with a sustainable rate of extraction.[4] Because it represents a first approximation to the rate of solute transport to the aquifer, the recharge rate is also important to estimate contaminant fluxes and travel times from sources near the land surface. Methods for obtaining a quantitative estimate of recharge mostly require a combination of various types of data which themselves may be hard to estimate, so in general it is wise to apply multiple methods and compare their results.

WATER BUDGET METHODS

The water balance for a basin can be stated as

$$P + Q_{\mathrm{on}}^{\mathrm{sw}} + Q_{\mathrm{on}}^{\mathrm{gw}} = \mathrm{ET}^{\mathrm{sw}} + \mathrm{ET}^{\mathrm{uz}} + \mathrm{ET}^{\mathrm{gw}} + Q_{\mathrm{off}}^{\mathrm{sw}} + Q_{\mathrm{off}}^{\mathrm{gw}} + Q_{\mathrm{bf}} + \Delta S^{\mathrm{snow}} + \Delta S^{\mathrm{sw}} + \Delta S^{\mathrm{uz}} + \Delta S^{\mathrm{gw}} \quad (1)$$

where P is precipitation and irrigation; Q_{on} and Q_{off} are water flow on and off of the site, respectively; $Q_{\mathrm{off}}^{\mathrm{sw}}$ is runoff; Q_{bf} is baseflow (ground water discharge to streams or springs); and ΔS is change in water storage. Superscripts refer to surface water, ground water, unsaturated zone, or snow, and all parameters are in units of L/T (or volume per unit surface area per unit time). For the saturated zone only, a water balance can be written for a defined area as

$$R = \Delta Q^{\mathrm{gw}} + Q_{\mathrm{bf}} + \mathrm{ET}^{\mathrm{gw}} + \Delta S^{\mathrm{gw}} \quad (2)$$

where R is recharge and ΔQ^{gw} is the difference between ground water flow off of and onto the basin. This equation implies that water arriving at the water table: 1) flows out of the basin as ground water flow;

2) discharges to the surface; 3) is evapotranspired; or 4) goes into storage. Substitution in Eq. (1) produces a simpler form of the water balance:

$$R = P + Q_{\mathrm{on}}^{\mathrm{sw}} - Q_{\mathrm{off}}^{\mathrm{sw}} - \mathrm{ET}^{\mathrm{sw}} - \mathrm{ET}^{\mathrm{uz}} - \Delta S^{\mathrm{snow}} - \Delta S^{\mathrm{sw}} - \Delta S^{\mathrm{uz}} \quad (3)$$

Water budget methods include all techniques based, in one form or another, on one of these water balance equations.

The most common water budget method is the "residual" approach: all other components in the water budget are measured or estimated and R is set equal to the residual. Water budget methods can be applied over a wide range of space and time scales. The major limitation of the residual approach is that the accuracy of the recharge estimate depends on the accuracy with which other components can be measured. This limitation can become significant when the magnitude of R is small relative to other variables. The time scale for applying water budget methods is important, with more frequent tabulations likely to improve accuracy. If the water budget is calculated daily, P can greatly exceed ET on a single day, even in arid settings. Averaging over longer time periods tends to dampen out extreme precipitation events and hence underestimate recharge. Annual recharge estimated with water budgets range from 23 mm in a region of India[5] to 400 mm at a site in the eastern United States.[6]

Watershed, surface water flow, and ground water flow models constitute an important class of water budget methods that have been used to estimate of recharge (e.g., Ref.[7]). An attractive feature of models is their predictive capability. They can be used to gauge the effects of future climate or land-use changes on recharge rates.

METHODS BASED ON SURFACE WATER OR GROUND WATER DATA

Fluctuations in ground water levels can be used to estimate recharge to unconfined aquifers according to

$$R = S_{\mathrm{y}}\mathrm{d}h/\mathrm{d}t = S_{\mathrm{y}}\Delta h/\Delta t \quad (4)$$

where S_{y} is specific yield, h is water table height, and t is time. The method is best applied over short time periods in regions with shallow water tables that display sharp water-level rises and declines. Analysis of water-level fluctuations can also, however, be useful for determining the magnitude of long-term change in recharge rates caused by climate or land-use change. The method is only appropriate for estimating recharge for transient events; recharge occurring under steady flow conditions cannot be estimated. Difficulties lie in determining S_{y} and ensuring that fluctuations are due to recharge, not to changes in pumping rates or atmospheric pressure or other phenomena. Recharge rates estimated by this technique range from 11 mm over a 26-month period in Saudi Arabia[8] to 541 mm yr^{-1} over 1 yr for a small basin in the United States.[9]

Ground water levels can also be used to estimate flow, Q, through a cross-section of an aquifer that is aligned with an equipotential line. Multiplying K by the hydraulic gradient normal to the section times the area of the section calculates Q. Recharge is determined by dividing Q by the surface area of the aquifer upgradient from the section.

Methods of estimating recharge based on surface-water data include the Channel Water Balance Method (CWBM) and determination of baseflow by hydrograph separation. The CWBM involves measuring discharge at two gauges on a stream; the difference in discharge between the upstream and downstream gages is the transmission loss. This loss may become recharge, ET, or bank storage. Hydrograph separation involves identifying what portion of gauged stream flow is derived from ground water discharge. Rutledge and Daniel[10] developed an automated technique for this purpose and applied the method to estimate recharge at 15 sites. Drainage areas for the sites ranged from less than 52 km^2 to more than 5200 km^2; estimated annual recharge was between about 13 cm and 64 cm.

DARCIAN METHODS

Applied in the unsaturated zone, Darcy's law gives a flux density equal to K times the driving force, which equals the recharge rate if certain conditions apply. Matric-pressure gradients must be measured or demonstrated to be negligible. Some types of preferential flow are inherently non-darcian and if important would need to be determined separately. Accurate measurements are necessary to know K adequately under field conditions at the point of interest. For purposes requiring areal rather than point estimates, additional interpretation and calculation are necessary.

In the simplest cases, in a region of constant downward flow in a deep unsaturated zone, gravity alone drives the flow. With a core sample from this zone, laboratory K measurements at the original field water content directly indicate the long-term average recharge rate.[11]

In the general case, transient water contents and matric pressures must be measured in addition to K.[12] Transient recharge computed with Darcy's law can relate to storms or other short-term events, or provide data for integration into temporal averages.

TRACER METHODS

Increasing availability and precision of physical and chemical analytical techniques have led to a proliferation in applications of tracer methods for recharge estimation. Isotopic and chemical tracers include tritium, deuterium, oxygen-18, bromide, chloride, chlorine-36, carbon-14, agricultural chemicals, dyes, chlorofluorocarbons, and noble gases. In practice, concentrations measured in pore water are related to recharge by applying chemical mass-balance equations, by matching patterns inherited from infiltrating water, or by determining the age of the water. Tracer methods provide point and areal estimates of recharge. Multiple tracers used together can test assumptions and constrain estimates.

The most common tracer for estimating recharge is chloride. Chloride continually arrives at the land surface in precipitation and dust. Chloride is conservative in many environments and is non-volatile. Under suitable conditions,

$$R = P[\mathrm{Cl_p}]/[\mathrm{Cl_r}] \tag{5}$$

where P is precipitation and $[\mathrm{Cl_p}]$ and $[\mathrm{Cl_r}]$ are chloride concentrations in precipitation and pore water, respectively. Chloride mass-balance methods can be applied to unsaturated profiles[13] and entire basins.[14]

Isotopic composition of water provides a useful tracer of the hydrologic cycle. The isotopic makeup of precipitation varies with altitude, season, storm track, and other factors. Recharge estimates using isotopic varieties of water usually employ temporal or geographic trends in infiltrating water.

Non-conservative tracers can indicate the length of time that water is isolated from the atmosphere, that is, its "age." Recharge rates can be inferred from water ages if mixing is small. If ages are known along a flow line,

$$R = \theta L/(A_2 - A_1) \tag{6}$$

where θ is volumetric water content, A_1 and A_2 are ages at two points, and L is separation length. One point is often located at the water table. Preindustrial water can be dated by decay of predominately cosmogenic radioisotopes, including carbon-14 and chlorine-36. The abundance of tritium and other radioisotopes increased greatly during atmospheric weapons testing, labeling recent precipitation. Additional compounds for dating modern recharge include chlorofluorocarbons, krypton-85, and agricultural chemicals.[15,16]

Heat is yet another tracer of ground water recharge. Daily, seasonal, and other temperature fluctuations at the land surface produce thermal signals that can be traced through shallow profiles.[17,18] Water moving through deeper profiles alters geothermal gradients, which can be used in inverse modeling to obtain recharge rates.[19]

OTHER METHODS

Additional geophysical techniques provide recharge estimates based on the water-content dependence of gravitational, seismic, and electromagnetic properties of earth materials. Repeated high-precision gravity surveys can indicate changes in the quantity of subsurface water from recharge events.[20] Similarly, repeated surveys using seismic or ground-penetrating-radar equipment can resolve significant changes in water-table elevation associated with transient recharge.[21] In addition to surface-based techniques, cross-bore tomographic imaging can provide detailed three-dimensional reconstructions of water distribution and movement during periods of recharge.[22]

Aquifers: Transmissivity

Mohamed M. Hantush
National Risk Management Research Laboratory, U.S. Environmental Protection Agency (USEPA), Cincinnati, Ohio, U.S.A.

INTRODUCTION

Evaluation of groundwater resources requires the knowledge of the capacity of aquifers to store and transmit ground water. This requires estimates of key hydraulic parameters, such as the transmissivity, among others. The transmissivity T (m^2/sec) is a hydraulic property, which measures the ability of the aquifer to transmit ground water throughout its entire saturated thickness. It is defined as the product of the hydraulic conductivity K (m/sec) and the saturated thickness B (m), in the direction normal to the base of the aquifer:

$$T = KB \tag{1}$$

CONCEPTS

Fig. 1 illustrates a confined unit, or permeable unit sandwiched between impervious or semipervious layers. The hydraulic (or piezometric) head gradient in the two piezometers tapping the aquifer and separated by a unit distance is unity, since they measure a drop in the hydraulic head of magnitude one. The flow through the shaded window of height B and unit width normal to the flow direction is the aquifer transmissivity T. This follows from Darcy's law, which requires that groundwater flow rate per unit area normal to the flow direction is equal to the hydraulic conductivity, if the hydraulic head gradient is unity.

In unconfined aquifers, however, the transmissivity is not as well defined as in confined units. The saturated thickness h (m) extends from the water table vertically down to the aquifer bed in an unconfined aquifer. The transmissivity varies in time in unconfined aquifers, since the water table often fluctuates in response to recharge from the overlying vadose zone or dewatering of the aquifer by pumping. It decreases during pumping and increases during recharge.

In stratified formations the hydraulic conductivity distribution is also stratified and can actually vary from one location to another by orders of magnitude. With this variability and that of the saturated thickness, $B(x,y)$, the transmissivity is given by the integral of the hydraulic conductivity over the saturated thickness[1]

$$T(x,y) = \int_0^{B(x,y)} K(\mathbf{x})dz \tag{2}$$

where $\mathbf{x}$ denotes the Cartesian coordinates (x,y,z). As an illustration of the use of Eq. (2), for a layered confined aquifer composed of N distinct layers, each with thickness b_i and constant hydraulic conductivity K_i, the transmissivity at any given point in the horizontal plane is given by

$$T = BK_{\mathrm{A}}, \quad B = \sum_{i=1}^{N} b_i, \quad K_{\mathrm{A}} = (1/B)\sum_{i=1}^{N} b_i K_i \tag{3}$$

where K_{A} is the arithmetic mean of the hydraulic conductivity.

TRANSMISSIVITY OF AQUIFERS

Table 1 shows range of values of T which may be encountered in common aquifers of thicknesses in the range of 5–100 m. In general, transmissivities greater than $0.015\,m^2/sec$ represent good aquifers for water-well exploitation.[2] Karstic limestones, in which sizable proportions of the original rock has been dissolved and removed, are highly transmissive aquifers. Alluvial valleys, which are predominantly unconsolidated sand and gravel, are among the most productive aquifers in the United States.[3] Permeable basalts and fractured igneous and metamorphic rocks have a relatively large transmissivity and serve as good aquifers. Non-karstic limestones, silt, glacial till, and solid igneous and metamorphic rocks are the least transmissive and make poor aquifers. Sandstone aquifers have a low transmissivity, but they are significant sources of potable water.

RELATIONSHIP TO GROUNDWATER FLOW

The concept of aquifer transmissivity is widely used in the analysis of hydraulics of water wells. It is introduced when the groundwater flow in aquifers is

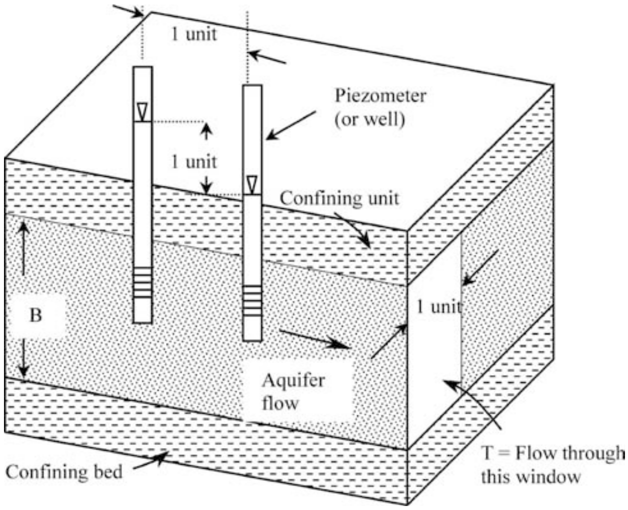

Fig. 1 Illustration of transmissivity in a confined aquifer.

essentially horizontal. This is commonly the case in aquifers whose lateral extensions are much greater than their thicknesses and where the equipotential lines are nearly vertical. The groundwater flow rate **Q** (m^2/sec) integrated over the saturated thickness of the aquifer, per unit aquifer width, is related to the transmissivity through the Darcy relationship:

$$\mathbf{Q} = -T\nabla\varphi \tag{4}$$

where $\mathbf{Q} = Q_x\mathbf{i} + Q_y\mathbf{j}$ and $\nabla\varphi = (\partial\varphi/\partial x)\mathbf{i} + (\partial\varphi/\partial y)\mathbf{j}$. Q_x and Q_y are the flow rates per unit width in the x and y directions, respectively, and **i** and **j** are the unit length orthogonal vectors in the x and y directions, respectively. Eq. (4) in combination with the groundwater flow balance equation describe essentially horizontal groundwater flow in aquifers.

Table 1 Representative values of transmissivity for aquifers of thicknesses 5–100 m

Material	Transmissivity (m^2/sec)[a]
Unconsolidated	
Gravel	5×10^{-3}–100
Sand	5×10^{-7}–1
Silt	5×10^{-9}–2×10^{-3}
Glacial till	5×10^{-12}–2×10^{-4}
Rocks	
Karst limestone	5×10^{-6}–2
Permeable basalt	1×10^{-6}–2
Fractured igneous and metamorphic rocks	4×10^{-8}–3×10^{-2}
Limestone, dolomite	5×10^{-9}–2×10^{-4}
Sandstone	5×10^{-10}–6×10^{-4}

[a]Values are estimated from representative values of hydraulic conductivity.

ANISOTROPY AND PRINCIPAL DIRECTIONS

Implicit in Eq. (4) is that the transmissivity is invariant to the orientation in the (x,y) plane. If the transmissivity is dependent on the direction of flow in an aquifer, the aquifer is said to be anisotropic. This anisotropy stems from the anisotropy of the hydraulic conductivity, and when the latter is the same in all directions, the aquifer is said to be isotropic. In natural aquifers the transmissivity is anisotropic, and groundwater flow rate, in this case, is given by the following general form:

$$\mathbf{Q} = -\mathbf{T}\cdot\nabla\varphi, \quad \mathbf{T} = \begin{bmatrix} T_{xx} & T_{xy} \\ T_{yx} & T_{yy} \end{bmatrix} \tag{5}$$

in which **T** is the second order symmetric tensor of transmissivity of an anisotropic aquifer.[1] It is equal to the product of the hydraulic conductivity tensor and the aquifer saturated thickness. As an example, the component T_{xy} gives the contribution of a unit hydraulic gradient in the y-direction to the flow rate in the x-direction Q_x, and the component T_{xx} gives the contribution of a unit hydraulic gradient in the x-direction to Q_x. The four elements appearing in Eq. (5) depend on the chosen coordinate system. The principal directions of anisotropy are defined as the orientation θ from the original x–y coordinates to the new ξ–η coordinate system (Fig. 2), such that the off diagonal elements in the transformed system are zero,

$$\mathbf{T} = \begin{bmatrix} T_{\xi\xi} & 0 \\ 0 & T_{\eta\eta} \end{bmatrix} \tag{6}$$

where $T_{\xi\xi}$ and $T_{\eta\eta}$ are the principal transmissivities. Both are related to the transmissivities in the original x–y coordinates (T_{xx}, T_{yy}, and T_{xy}) and the orientation θ by simple algebraic relationships.[1] The transmissivity in the major direction of anisotropy $T_{\xi\xi}$ is greater than in the minor direction $T_{\eta\eta}$. Fig. 2 illustrates the

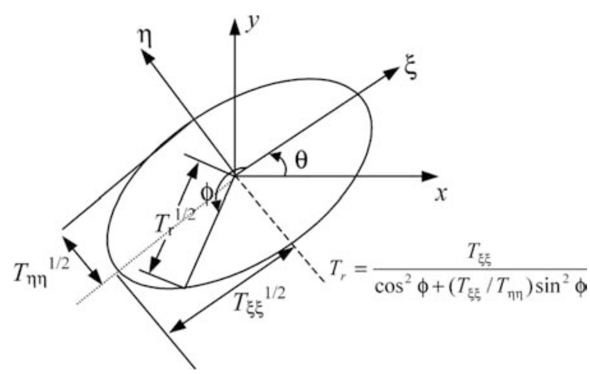

Fig. 2 Ellipse of directional transmissivity.

transmissivity ellipse in the principal direction coordinates and the relationship between the directional transmissivity T_r and the principal components $T_{\xi\xi}$ and $T_{\eta\eta}$. Anisotropy with respect to transmissivity can be estimated using aquifer test analysis.[4]

METHODS OF ESTIMATION

Estimation of aquifer transmissivity through analysis of aquifer test data is a standard practice in the evaluation of groundwater resources. Aquifer test is an in-situ method for estimating field scale transmissivity in which the water bearing materials are tested under natural conditions. In this test, the well is pumped at a given (usually constant) rate and drawdown (i.e., drop in elevation of the water level in the well from its initial static position) is observed and recorded in time in the pumping well itself and possibly in at least one observation well in the vicinity. In this method, a logarithmic plot of the applicable well-flow equation, called a "type curve," is superimposed on a logarithmic drawdown-time plot, called a "data curve," and the transmissivity is then estimated using a graphical matching technique.[5,6,7] This technique assumes the aquifer is homogeneous and requires experience and judgment of qualified persons conducting these tests, because observed drawdown variations with time and distance from the pumped well may be interpreted in several ways and therefore subject to uncertainty. The performance of graphical matching techniques depends largely on the selection of the well-flow equation that most accurately resembles the flow system under consideration.

Evaluation of groundwater resources in regional aquifers requires estimates of the transmissivity at locations where it is not available. This can be achieved by solving the "inverse problem" for the unknown parameters. In this method, the flow domain is overlain by a discrete mesh of nodal points, and the groundwater flow equation is approximated by a set of algebraic equations, one for each nodal point. Unknown T values at the nodal points are identified by trial and error or automatically, by a gradient-based search technique.[8] The optimal set of transmissivities is the one that produces the best match, such as minimizing the sum of weighted least square errors between the observed hydraulic heads and those obtained from the solution of the algebraic equations at the measurement points. Many of the restrictive assumptions often made in aquifer test analysis are relaxed in the numerical methods for solving the inverse problem. However, these techniques may suffer from non-uniqueness and instability of the solutions, and can result in unrealistic estimates for T, e.g., negative values or solutions fluctuating between imposed lower and upper bounds of the transmissivity.[8] Current trends in hydrology account for local-scale spatial variation of the transmissivity using statistical methods in which this property can be idealized as a space random function. Field evidence support that transmissivity is lognormally distributed.[9] The geostatistical approach[10] combines process understanding of groundwater flow in aquifers with statistical estimation methods to provide an effective tool for mapping transmissivities over regional aquifers, by making use of their in-situ estimates inferred from aquifer tests and hydraulic head measurements. The literature on aquifer properties estimation is rich in innovative approaches for estimating both the transmissivity spatial structure and its values at locations where measurements are not available.[8,10,11]

Aral Sea Disaster

Guy Fipps
Agricultural Engineering Department, Texas A&M University, College Station, Texas, U.S.A.

INTRODUCTION

The Aral Sea is one of the worst ecological disasters on our planet. What was once the world's fourth largest inlet sea, the Aral Sea has lost over 60% of its surface area, two-third of its volume, declined 40 m in depth, and has fallen to the eighth largest inland body of water in the world.

The cause is attributed to a vast expansion of irrigation in the Central Asian Republics beginning in the 1950s, which greatly reduced inflows to the Sea. The diversion of water for massive irrigation development was done deliberately by Soviet Union officials, unconcerned about the consequences of their actions.

The environmental, social, and economic damage has been immense. Winds pick up dust from the dry seabed and deposit it over a large populated area. The dust likely contains pesticide and chemical residues that are blamed for the serious rise in mortality and health problems in the region. The Sea, and the now exposed dry seabed, may also be contaminated by runoff from a former Soviet military base and a biological weapons lab. The ecosystem of the Aral Sea has collapsed, and climate changes in the Aral Sea Basin have been documented. Hundreds of agreements have been signed since 1980s on programs designed to address the "Aral Sea Problem" which, to date, have not been effective at preventing the continuing shrinking of the sea.

THE ARAL SEA BASIN

The Aral Sea is located in Central Asia and lies between Uzbekistan and Kazakhstan in a vast geological depression, the Turan lowlands, in the Kyzylkum and Karakum Deserts. In the 1950s, the sea covered 66,000 km^2, contained about 1090 km^3 of water, and had a maximum depth of about 70 m. The Aral Sea supported vast fisheries and shipping industries. At that time the sea was fed by two rivers, the Amu Darya (2540 km) and the Syr Darya (2200 km), which originate in the mountain ranges of central Asia and flow through the five republics of Uzbekistan, Kazakhstan, Kyrgyzstan, Tajikistan, and Turkmenistan.

The two rivers provide most of the fresh water used in Central Asia. In the last 50 years, about 20 dams and reservoirs and 60 major irrigation schemes have been constructed. About 82% of river diversions are for agricultural use and 14% is for municipal and industrial use (Table 1).

Water demand due to population growth and industrial expansion continues to increase (Table 2). Since 1960, the population of the Central Asian republics has increased 140% and totals over 50 million. Likewise, industrial production using large amounts of water has also increased. Examples include steel production which rose 200%, cement production by 170%, and electricity generation by a factor of 12.

The total inflows to the Aral Sea began decreasing rapidly in the 1960s, and by 1990 the storage volume of the sea has decreased by 600 km^3 (Table 3). As the water level fell, salinity levels have tripled, rising from about 1000 ppm to just under 3000 ppm today. By the 1980s, as the Aral Sea problem became well known in the Soviet Union, government officials proposed ambitious projects to divert water from other rivers, including ones in South Russia and Siberia, to be transported to the Aral Sea in massive canals. However, these plans died with the breakup of the Soviet Union.

The decrease in sea level has now split the Aral Sea into two separate water bodies: the Small and Large Aral Seas (Maloe More and Bol'shiye More) each separately fed by the Syr Darya and the Amu Darya, respectively. The once vast Amu Darya delta which once covered 550,000 ha has now shrunk to less than 20,000 ha.

IRRIGATION AND COTTON

For thousands of years, Central Asian farmers diverted water from the Amu Darya and Syr Darya Rivers, transforming desert into green oases and supporting great civilizations. Historically, irrigation water use was conducted at a sustainable level. The creation of the Soviet Union and the collectivization of farmlands resulted in the end for traditional agricultural practices. Beginning as early as 1918, Soviet leaders began expanding irrigated land in Central Asia for export and hard currency. Cotton was known as "white gold." The USSR became a net exporter of cotton

Table 1 Average water supply and demand in the Aral Sea Basin

Total water available	km^3	%
Amu Darya Basin	84.3	64
Syr Darya Basin	47.8	36
Total	132.1	100
Water Demand		
Agriculture		
Amu Darya Basin	44.8	81.6

Syr Darya	0.8	
Total	97.3	100

by the 1930s, and by the 1980s, was ranked fourth in the world in cotton production.

The policy of emphasizing cotton production was accelerated in the 1950s as Central Asia's irrigated agriculture was expanded and mechanized. In 1956, the Kara Kum Canal was opened, diverting one-third of the flow in the Amu Darya to new cultivated areas in the deserts of Uzbekistan and Turkmenistan. The year 1960 represents the critical junction when the Aral Sea began to drop. Irrigated cotton production and water diversions continued to be expanded until the break-up of the Soviet Union (Table 4).

Estimates are that upwards of 80% of the workforce is employed in agriculture. The main agricultural crops in the basin are cotton (6.4 million ha), forage (1.7 million ha), rice (0.4 million ha), and tree crops (0.4 million ha).

Some Central Asian irrigation experts estimate that only 20–25% of the water diverted from the rivers is actually used by the crops, the rest being lost in the canals that transport the water to the fields and due

Table 3 Decline of the Aral Sea during the 1980s and total estimated inflows from the Amu Darya and Syr Darya rivers

		Aral Sea	
Year	Inflows (km^3)	Volume (km^3)	Surface area (km^2)
1911–1960	56.0	1064	66,100
1981	6.0	618	50,500
1982	0.04	583	49,300
1983	2.3	539	47,700
1984	7.9	501	46,100
1986	0.0	424	41,100
1987	9.0		
1988	23.0		41,000
1989		300	30,000

to inefficient irrigation practices used on-farm. It is believed that over the past decade, adequate maintenance, repair, and renovation of the irrigation infrastructure were not performed at a meaningful level, and water losses from deteriorating canals, gates, and other facilities have increased.

Most land is under furrow irrigation, with drip irrigation accounting for about 5% of the irrigated cropland (used primarily on orchard crops), and sprinkler irrigation accounts for about 3%. Even though the water saving benefits of gated pipe are well known in the region, less than one-sixth of the farms use this technology. Reasons may include costs and product availability. Most farms follow the centuries' old practice of cutting earthen canals with shovels in order to divert water into the field. The volume of water available at these farm ditches is not sufficient to provide an even distribution of water over the field. As a result, water logging and soil salinity now affects about 40% of all the cultivated land in the region.

MUYNAK AND ARALSK

Of all the villages affected by the drying of the Aral Sea, Muynak is the best known. Historically, Muynak was located on an island of the vast Aral

Sea delta at the convergence of the Amu Darya River in Karakalpakstan (a semi-autonomist republic in Uzbekistan). In 1962, the island became a peninsula. By 1970 the former seaport was 10 km from the sea. The retreat of the sea accelerated and the town was 40 km from the sea by 1980, 70 km in 1995, and close to 100 km today.

Over 3000 fishermen once worked the abundant waters around Muynak which supported 22 different commercial species of fish. In 1957, Muynak fishermen harvested 26,000 tons of fish, about half of the total catch that year taken from the Aral Sea. Muynak also produced 1.1 million farmed muskrat skins which were used to produce coats and hats.

The Kazakhstan city of Aralsk, was once located on the northern edge of the Aral Sea, and like Muynak, had major fisheries and commerce industries. A major shipping and transport industry existed between these two cities. As the Aral Sea skunk, Aralsk found itself farther and farther from the shore which had retreated nearly 129 km by the 1980s. In the early 1990s, a dam was built just to the south of the mouth of the Syr Darya, to protect the northern part of the Aral Sea, letting the southern portion of the Aral Sea evaporate. Although only 10% of the water in the Syr Darya River reaches the northern part of the Aral Sea, the Little Aral has risen 3 m since the construction of the dam, and the shoreline has crept to within 16 km of the town.

ENVIRONMENTAL PROBLEMS

The Aral Sea is an unfortunate example of an old Uzbek proverb: "at the beginning you drink water, at the end you drink poison.'' As the rivers flow through cultivated areas, they pick up fertilizers, pesticides, and salts from runoff, drainage water and groundwater flow. In the 1960s, it was common for about 550 kg ha^{-1} of chemicals to be applied to cotton fields in Central Asia, compared to an average of 25 kg used for other crops in the Soviet Union. Residues of these chemicals are now found on the dry seabed. Estimates are that millions of tons of dust are picked up from the seabed and distributed over the Aral Sea region.

The Sea may have been contaminated from runoff from by two former USSR military installations in the area. A chemical weapons testing facility was located on the Ust-Jurt Plateau (north shore), and was closed in the mid-1980s. Renaissance Island (Vorzrozhdeniya Island), located in the central Aral Sea, was the site of the former USSR Government's Microbiological Warfare Group which produced the deadly Anthrax virus. Some scientists believe that some containers holding the virus were not properly stored or destroyed. As the Aral Sea continues to dry and water levels recede, the ever-expanding island will soon connect to the surrounding land. Scientists fear that reptiles, including snakes that have been exposed to the various viruses, will move onto the surrounding land and possibly infect the humans living around the shores of the Aral Sea.

The Area Sea once supported a complex ecosystem, an oasis in the vast desert. Over 20 species of fish are now extinct. Karakalpakstan scientists believe that a total of about 100 species of fish and animals that once flourished in the region are now extinct, as are many unique plants.

Residents believe that there is a direct correlation between the drying of the sea and changes in climate of the Aral Sea Basin. The moderating effect of the

Fig. 1 This NASA photograph (STS085-503-119) was taken in August 1997 and looks toward the southeast. The Amu Darya River is visible to the right and the Syr Darya on the left. The Aral Sea is now separated into the Small Aral to the north and the Large Aral to the south. Shown are the approximate extent of the Aral Sea in 1957 before a massive expansion of irrigation diversions from the rivers.

sea has diminished and temperatures are now about 2.5°C higher in the summer and lower in the winter. Rainfall in the already arid basin has decreased by about 20 mm.

THE HUMAN TRAGEDY

Over the last 50 years, there has been a large increase in mortality, illnesses, and poor health in the region. Some estimate that 70–90% of the population of Karakalpakstan suffer some an environmentally induced malady. Tuberculosis is rampant. Hardest hit are women and children. Common health problems include kidney diseases, thyroid dysfunctions, anemia, bronchitis, and cancers.

CONCLUSION

Some accounts are that since 1984, hundreds of international agreements have been signed to address Aral Sea problems. The early agreements had the goals of first stabilizing the Sea, then slowly increasing flows to restore its ecosystem. In 1992, the Interstate Commission for Water Coordination was formed by the five central Asian republics, which also accepted, in principle, to adhere to the limits on water diversions as set during the Soviet era in 1984 and 1987. To date, however, no progress has been made on stabilizing or reversing the declining inflows. With no water reaching the Aral Sea from the Amu Darya, scientists predict that this portion of the sea (the Large Aral Sea) will disappear by 2020 (Fig. 1).

Arctic Hydrology

Bretton Somers
H. Jesse Walker
Department of Geography and Anthropology, Louisiana State University, Baton Rouge, Louisiana, U.S.A.

INTRODUCTION

After a discussion about the boundaries of the Arctic, its hydrological elements are analyzed. It is noted that, in the Arctic, the solid phase of water dominates the landscape during most of the year. In the solid phase, water occurs as snow, river and lake ice, sea ice, glacial ice, and ground ice. Ground ice is integral to permafrost, which is nearly continuous. Although all of the hydrologic elements can be considered separately as though each is in storage, they are in fact interconnected and should be considered as an integral part of a cycle that progresses through all three phases among the atmosphere, lithosphere, and cryosphere. Recent research has shown that many of the Arctic's hydrologic elements are changing rapidly.

THE ARCTIC

Although no one denies the existence of the region known as the Arctic, few actually agree on its southern boundary. Astronomers usually use the Arctic Circle, oceanographers use the distribution of sea ice, biologists use the tree line, and cryosphere specialists use a permafrost boundary.[1] In one way or another, all of these boundaries are of significance to hydrologists, because they must contend with distributions that often spread well beyond the Arctic. For example, many of the rivers that drain into the Arctic Ocean originate in temperate latitudes (Fig. 1), the Arctic Ocean is impacted by flow from both the Atlantic and Pacific Oceans, and the atmosphere can be affected by non-arctic weather patterns. Nonetheless, the main hydrologic factor that distinguishes the Arctic from other climatic zones is the long period of time during which snow and ice dominate the landscape. From a regional standpoint, the Arctic may best be considered a moderately-sized ocean almost completely surrounded by a fringe of land, i.e., a configuration that is the opposite of its counterpart in the Southern Hemisphere, the Antarctic.

THE OCEAN, RIVERS, LAKES, AND GLACIERS

The major features of the Arctic are the Arctic Ocean with its numerous bordering seas, the rivers that drain into it, its lakes and ponds, and the numerous islands (many with glaciers) that occur north of the continents (Fig. 1). Some scientists contend that the Arctic Ocean should be classified as a Mediterranean sea rather than an ocean because in addition to being nearly surrounded by land, it occupies less than 4% of the Earth's ocean area and only about 1% of the Earth's ocean volume.

The Arctic Ocean is also unique in that it is only 40% as large as the continental area that drains into it. The rivers that enter the ocean vary greatly in size and discharge. Included among them are four of the Earth's 12 longest—the Yenisey (5870 km), the Ob (5400 km), the Lena (4400 km), and the Mackenzie (4180 km). They contribute nearly 60% of the fresh water that drains from the continents.[2] This total equals some 11% of the Earth's runoff from the continents. Because of its unique relationship between land and sea, the Arctic Ocean is impacted more by water draining into it than any other ocean.[3]

In addition to its seas, rivers, and islands, the Arctic also possesses numerous lakes and ponds. Most Arctic lakes are small. One of the most studied lake types is the oriented lake. Generally elliptical in shape, oriented lakes originate as thaw lakes and range in length up to several kilometers. However, by far, the most common bodies of water dotting the land surface are small ponds whose existence is partly the result of the poor drainage and limited infiltration that characterizes permafrost environments.

Glaciers in the Arctic, except for the Greenland ice cap, are generally limited to the Canadian and Russian arctic islands. Arctic glaciers are major contributors of water and ice bergs to the ocean.

SNOW, ICE, AND PERMAFROST

One of the unique characteristics of water is that it is the only chemical compound that occurs on Earth in three phases, i.e., as a gas (water vapor), a liquid, and a solid. In its solid phase, water appears as snow, surface ice (river, lake, and sea ice), and ground ice.

Snow

Although snow is not limited to high latitudes, it is there that it is nearly ubiquitous. Over most of the

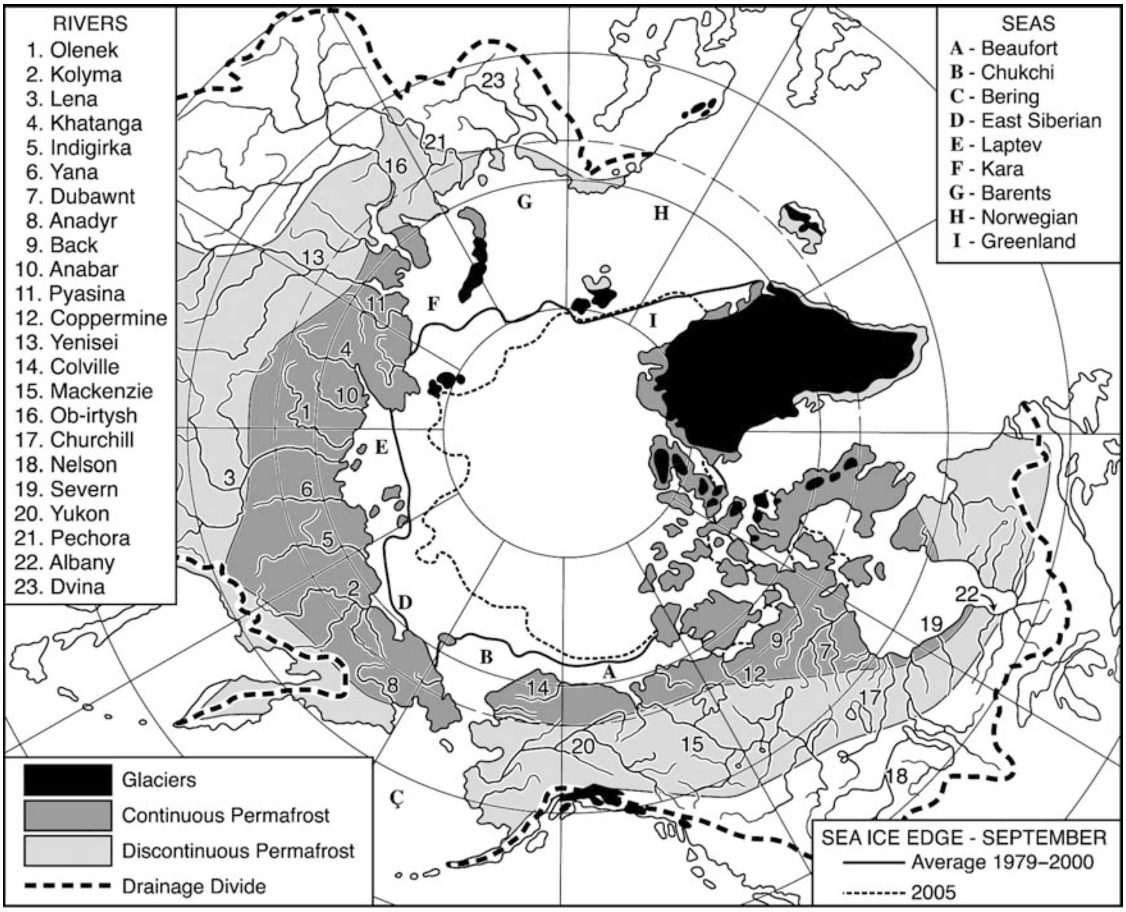

Fig. 1 Map of the Arctic showing the major rivers, permafrost distribution, September sea-ice locations, and bordering seas in the Arctic Ocean. *Source*: From Ref.[9].

Arctic, it covers the surface for nine or more months. Snow fall is related to the volume of water vapor in the air, a volume that is temperature dependent. Therefore, the actual amount of snow that falls is limited in quantity. Once it falls, it tends to retain its solid form until melt season. However, because most of the Arctic has low-lying vegetation (tundra), snow drifting is extensive. On flat surfaces, such as lake ice, the snowpack is thin or even missing. Uneven surfaces, such as river banks, trap snow into sizable drifts, some of which may last through most of the summer.

Snow is important in several major ways in the Arctic. Because it is highly reflective, much of the sun's energy that reaches it is returned to space. The reflected energy, or albedo, of fresh snow is more than 75%, whereas that from water is usually less than 30% and from tundra less than 20%.[4] Further, snow, because of its low thermal conductivity, is a good insulator—affecting the occurrence and maintenance of permafrost and in helping keep vegetation and fauna from freezing. Snow, when it melts, provides the bulk of the water that feeds the rivers and streams that drain into the Arctic Ocean. Because the melt season is relatively short and the melt rate is rapid, most rivers in the Arctic have peaks of discharge that correlate closely with river breakup (Fig. 2).

River and Lake Ice

In the Arctic, the temperature regime is such that surface ice, whether on rivers, lakes, or the sea, is present for most of the year. On fresh-water bodies, the ice reaches thicknesses of about 2 meters. Because most of the ponds and many of the streams have depths less than that, water freezes to the bottom. In deeper lakes and rivers, water will remain in the liquid state beneath the ice. In some rivers, especially those originating in lower latitudes (Fig. 1), flow continues throughout the winter beneath the ice. Ice in the deeper lakes lasts longer than ice on rivers, where breakup follows after snow-melt water enters the river channels.

Sea Ice

Some authors maintain that sea ice is the most dramatic feature of the Arctic. Formed by the freezing

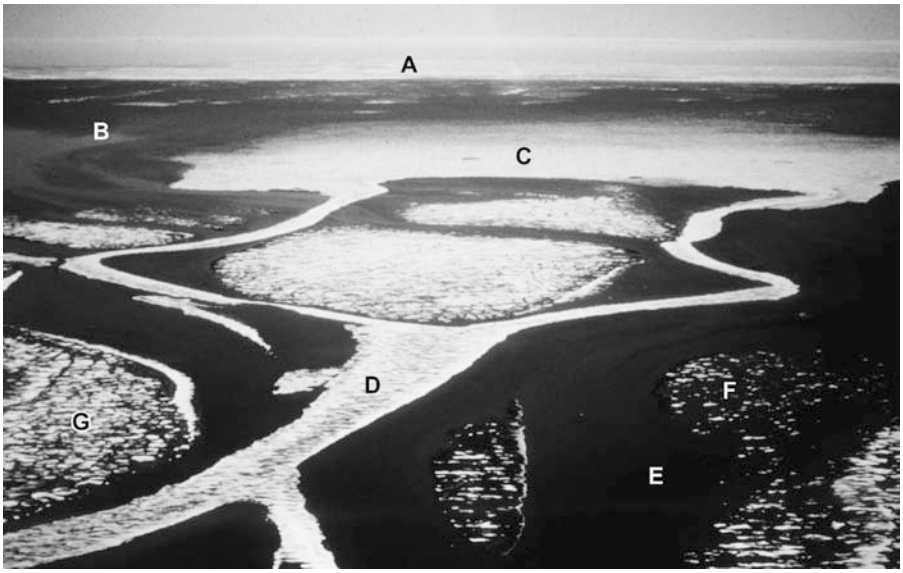

Fig. 2 The mouth of the Colville River, Alaska showing the distribution of snow, water, river ice and sea ice during breakup. Fig. 3 Conceptual model of the arctic hydrologic cycle. *Source*: From Ref.[3].

of sea water, sea ice covers nearly all of the Arctic Ocean during winter when it is attached to much of the continental coastline of Siberia and North America. Except for a narrow band of fast ice, the bulk of the sea ice is in motion, steered by ocean currents and winds. Its predominant direction of flow is clockwise. Because its motion is erratic, pressure ridges many meters high and open bodies of water, known as leads, develop. First year sea ice averages about 2 meters in thickness whereas ice that survives through the summer becomes thicker during the following winter. The minimum extent of sea ice in the Arctic is in September (Fig. 1). Sea ice suppresses the energy exchange between the ocean and the atmosphere, affects the circulation of ocean currents, and dampens wave action.[5]

Permafrost and Ground Ice

Permafrost is defined as earth material in which the temperature has been below 0°C for two or more years. Because it is defined only by its temperature, water is not necessary for its existence. However, most permafrost, which underlies more than 20% of the Earth's land area, does contain ice in various amounts and forms. Ground ice occurs in the pores of the soil as lenses or veins and in large forms such as ice wedges.[6] By volume, pore ice is the largest, although ice wedges are more conspicuous. Where ice wedges are well developed, they may occupy as much as 30% of the upper 2 or 3 meters of the land surface. Their surface expression is distinctive and takes the form of ice-wedge polygons. In the Arctic, permafrost is continuous (Fig. 1) except beneath those water bodies that are more than 2 meters deep and do not freeze to the bottom during winter. Permafrost is also present beneath near-shore waters off Siberia and North America.

Associated with permafrost is the active layer—the portion of terrain that thaws and freezes seasonally. The active layer can vary in thickness from a few centimeters to several meters, depending mainly on vegetation cover and soil texture.

THE HYDROLOGIC CYCLE IN THE ARCTIC

In the above discussion, each hydrologic element was considered individually, as if it was a pool of water in storage as a gas, a liquid, or a solid. However, in reality, the hydrologic elements are interconnected and mobile, moving from one phase to another through time. The examination of water from this standpoint is best done through the concept of the hydrologic or water cycle, a cycle that is considered the most fundamental principle of hydrology.[7] The conceptual model (Fig. 3) illustrates hydrologic links among the atmosphere, the land, and the ocean.[3] As a concept, it can be applied to small units within the hydrosphere or large units such as the Arctic. In the Arctic, the movement of water from one phase or location is, to a large extent, dependent on freeze-thaw cycles of snow, ice, and permafrost.

ARCTIC HYDROLOGY AND THE FUTURE

In recent years, research on climate change has increased dramatically. Much of it has been conducted in and about the Arctic and especially about arctic hydrology. Numerous changes in the hydrologic elements of the Arctic have been recently documented. Included are a shortening of the snow-cover season, later freeze-up and earlier breakup of river, lake, and sea ice, increased fresh-water runoff, melting glaciers, the degradation of permafrost and an increase in active-layer thickness, increased groundwater flow, decreased sea-ice extent (Fig. 1), and decreased albedo, among others. Recently (2005), Dan Endres of the National Oceanic and Atmospheric Administration, in a discussion on climate change, stated that: "Whatever is going to happen is going to happen first in the Arctic and at the fastest rate."[8] This is a prophecy that is especially applicable to virtually every hydrologic and ecological element in the Arctic.

Boron

Rami Keren
Volcani Center, Institute of Soil, Water and Environmental Sciences, Agricultural Research Organization (ARO), Bet-Dagan, Israel

INTRODUCTION

Boric acid is moderately soluble in water. Its solubility increases markedly with temperature due to the large negative heat of dissolution. Boron is considered as a typical metalloid having properties intermediate between the metals and the electronegative non-metals. Boron has a tendency to form anionic rather than cationic complexes. Boron chemistry is of covalent B compounds and not of B^{3+} ions because of its very high ionization potentials. Boron has five electrons, two in the inner spherical shell ($1s^2$), two in the outer spherical shell ($2s^2$), and one in the dumbbell shaped shell ($2p_x^1$).[1] In the hybrid orbital state, the three electrons in the 2s and 2p orbitals form a hybrid orbital state ($2s^1\ 2p_x^1\ 2p_y^1$), where each electron is alone in an orbit whose shape has both spherical and dumbbell characteristics. Each of these three orbits can hold one electron from another element to form a covalent bond between the element and B (BX_3). This leaves one 2p electron orbit that can hold two electrons, which if filled would completely fill the eight electron positions (octet) associated with the second electron shell around B. BX_3 compounds behave as acceptor Lewis acids toward many Lewis bases such as amines and phosphines. The acceptance of two electrons from a Lewis base completes the octet of electrons around B. Boron also completes its octet by forming both anionic and cationic complexes.[1] Therefore, tri-coordinate B compounds have strong electron-acceptor properties and may form tetra-coordinate B structures. The charge in tetra-coordinate derivatives may range from negative to neutral and positive, depending upon the nature of the ligands.

For the unshared oxygen atoms bound to B, they are, probably, always OH groups. Thus, in accordance with the electron configuration of B, boric acid acts as a weak Lewis acid:

$$B(OH)_3 + 2H_2O = B(OH)_4^- + H_3O^+ \qquad (1)$$

The formation of borate ion is spontaneous. The first hydrolysis constant of $B(OH)_3$, K_{h1}, is 5.8×10^{-10} at 20°C,[2] and the other K_{h2} and K_{h3} values are 5.0×10^{-13} and 5.0×10^{-14}, respectively.[3] A dissociation beyond $B(OH)_4^-$ is not necessary to explain the experimental data, at least below pH 13.[4,5] Boron species other than $B(OH)_3$ and $B(OH)_4^-$, however, can be ignored in soils for most practical purposes. The first hydrolysis constant of $B(OH)_3$ varies with temperature from 3.646×10^{-10} at 178 K to 7.865×10^{-10} at 318 K.[6]

Both $B(OH)_3$ and $B(OH)_4^-$ ion species are essentially monomeric in aqueous media at low B concentration ($\leq 0.025\ \mathrm{mol\,L^{-1}}$). However, at high B concentration, polyborate ions exist in appreciable amount.[7] The equilibria between boric acid, monoborate ions, and polyborate ions in aqueous solution are rapidly reversible. In aqueous solution, most of the polyanions are unstable relative to their monomeric forms $B(OH)_3$ and $B(OH)_4^-$.[8] Results of nuclear magnetic resonance[9] and Raman spectrometry[10] lead to the conclusion that $B(OH)_3$ has a trigonal-planar structure, whereas the $B(OH)_4^-$ ion in aqueous solution has a tetrahedral structure. This difference in structure can lead to differences in the affinity of clay for these two B species.

BORON–SOIL INTERACTION

The elemental form of boron (B) is unstable in nature and found combined with oxygen in a wide variety of hydrated alkali and alkaline earth-borate salts and borosilicates as tourmaline. The total B content in soils, however, has little bearing on the status of available B to plants.

Boron can be specifically adsorbed by different clay minerals, hydroxy oxides of Al, Fe, and Mg, and organic matter.[11] Boron is adsorbed mainly on the particle edges of the clay minerals rather than the planar surfaces. The most reactive surface functional group on the edge surface is the hydroxyl exposed on the outer periphery of the clay mineral. This functional group is associated with two types of sites that are available for adsorption: Al(III) and Si(IV), which are located on the octahedral and tetrahedral sheets, respectively. The hydroxyl group associated with this site can form an inner sphere surface complex with a proton at low pH values or with a hydroxyl at high pH values. The B adsorption process can be explained by the surface complexation approach, in which the surface is considered as a ligand.[12] Such specific adsorption, which occurs irrespective of the sign of the net surface charge, can occur theoretically for any species capable of coordination with the surface metal ions. However, because oxygen is the ligand commonly coordinated to the metal ions in clay minerals, the B species $B(OH)_3$ and $B(OH)_4^-$ are particularly involved in such reactions. Possible surface complex configurations for B—broken edges of clay minerals—were suggested by Keren, Grossl, and Sparks.[12]

Keren and Bingham[11] reviewed the factors that affect the adsorption and desorption of B by soil constituents and the mechanisms of adsorption. Soil pH is one of the most important factors affecting B adsorption. Increasing pH enhances B adsorption on clay minerals, hydroxy-Al and soils, showing a maximum in the alkaline pH range (Fig. 1).

The response of B adsorption on clays to variations in pH can be explained as follows. Below pH 7, $B(OH)_3$ predominates and since the affinity of the clay for this species is relatively low, the amount of adsorption is small. Both $B(OH)_4^-$ and OH^- concentrations are low at this pH; thus, their contribution to total B adsorption is small despite their relatively strong affinity for the clay. As the pH is increased to about 9, the $B(OH)_4^-$ concentration increases rapidly. Since the OH^- concentration is still low relative to the B concentration, the amount of adsorbed B increases rapidly. Further increases in pH result in an enhanced OH^- concentration relative to $B(OH)_4^-$, and B adsorption decreases rapidly due to the competition by OH^- at the adsorption sites. Adsorption models for soils, clays, aluminum oxide, and iron oxide minerals have been derived by various workers.[13–17]

In assessing B concentration in irrigation water, however, the physicochemical characteristics of the soil must be taken into consideration because of the interaction between B and soil. Boron sorption and desorption from soil adsorption sites regulate the B concentration in soil solution depending on the changes in solution B concentration and the affinity of soil for B. Thus, adsorbed B may buffer fluctuations in solution B concentration, and B concentration in soil solution may change insignificantly by changing the soil-water content (Fig. 2). When irrigation with water high in B is planned, special attention should be paid to this interaction because of the narrow difference between levels causing deficiency and toxicity symptoms in plants.

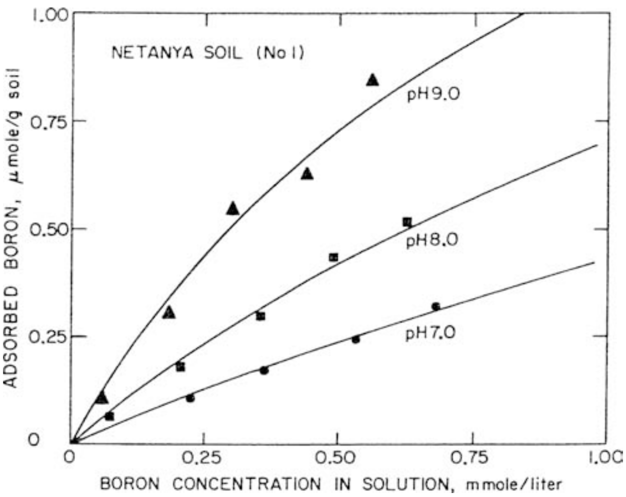

Fig. 1 Boron adsorption isotherms for a soil as a function of solution B concentration and pH. Bold lines—calculated values. *Source*: From Ref.[28].

BORON–PLANT INTERACTION

Boron is an essential micronutrient element required for growth and development of plants.

Many of the experimental data suggest that B uptake in plants is probably a passive process. There are clear evidences, however, that B uptake differs among species.[18] Several mechanisms have been postulated to explain this apparent paradox.[18–20] Boron deficiency in plants initially affects meristematic tissues, reducing or terminating growth of root and

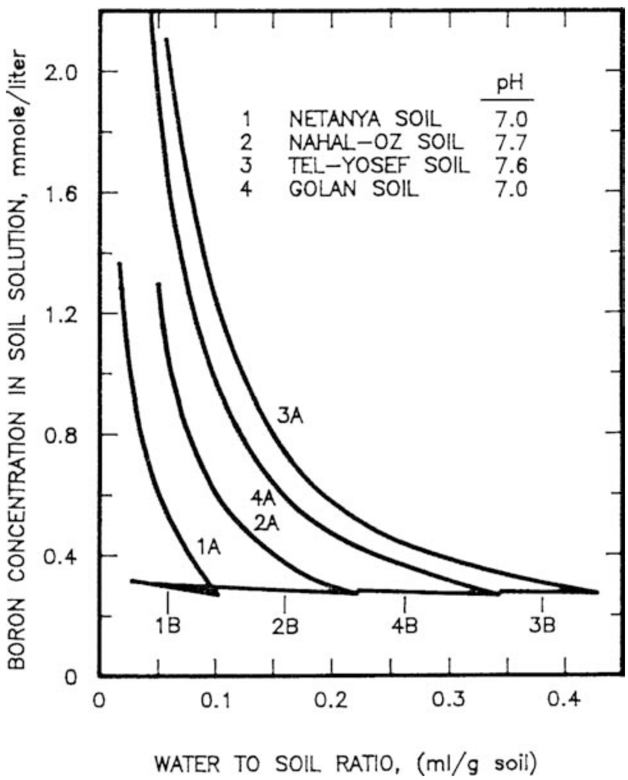

Fig. 2 Boron concentration in soil solution as a function of solution-to-soil ratio for a given total amount of B. (A) No interaction between B and soil, (B) Boron adsorption account for. *Source*: From Ref.[28].

shoot apices, sugar transport, cell-wall synthesis and structure, carbohydrate metabolism and many biochemical reactions.[21,22] Tissue B concentrations associated with the appearance of vegetative deficiency symptoms have been identified in many crop species. It is essential to remember that for B, as for phosphorus and several other plant nutrient elements, deficiency may be present long before visual deficiency symptoms occur.

Excess and toxicity of boron in soils of semi-arid and arid areas are more of a problem than deficiency. Boron toxicity occurs in these areas either due to high levels of B in soils or due to additions of B in irrigation water. A summary of B tolerance data based upon plant response to soluble B is given by Maas.[23] Bingham et al.[24] showed that yield decrease of some crops (wheat, barley, and sorghum) due to B toxicity could be estimated by using a model for salinity response, suggested by Maas and Hoffman.[25]

There is a relatively small difference between the B concentration in soil solution causing deficiency and that resulting in toxicity symptoms in plants.[11] A consequence of this narrow difference is the difficulty posed in management of appropriate B levels in soil solution.

The suitability of irrigation water has been evaluated on the basis of criteria that determine the potential of the water to cause plant injury and yield reduction. In assessing the B in irrigation water, however, the physicochemical characteristics of the soil must be taken into consideration because the uptake by plants is dependent only on B activity in soil solution.[26,27] Boron uptake by plants grown in a soil of low-clay content is significantly greater than that of plants grown in a soil of high-clay content at the same given level of added B (Fig. 3). This knowledge may improve the efficacy of using water of different qualities, whereby water with relatively high B levels could be used to irrigate B-sensitive crops in soils that show a high affinity to B. Such water can be used for irrigation as long as the equilibrium B concentration in soil solution is below the toxic concentration threshold (the maximum permissible concentration for a given crop species that does not reduce yield or lead to injury symptoms) for the irrigated crop. The existing criteria for irrigation water, however, make no reference to differences in soil type.

Bound Water in Soils

Sally D. Logsdon
National Soil Tilth Laboratory, U.S. Department of Agriculture (USDA), Ames, Iowa, U.S.A.

INTRODUCTION

General reviews on bound water discuss the historical development, and show that water associated with hydrophobic surfaces is more rigid than water associated with hydrophilic surfaces. These reviews show that bound water has higher heat capacity, higher relative viscosity, reduced self-diffusion, reduced dielectric constant, and lower density than free water. This entry will emphasize the latest information on bound water in soils and clay, and what knowledge is incomplete.

BODY OF TEXT

Properties of free water are discussed by Oster. Bound water has been designated by terms such as vicinal water,[1] hygroscopic water,[2] or simply water associated with interfaces[3,4] or colloids such as clays.[5] Bound water cannot be isolated to study its properties because bound water only exists as part of the system to which it is bound.

Early Work on Clays

Clays are the inorganic colloids in soils. Low[5] summarized earlier studies by considering the clay–water system to be near equilibrium. Then he assumed that slight changes in the partial specific property because of small additions of water would not significantly upset the equilibrium; that is, changes would be due only to the water, not to the whole system. This colloid-associated water has lower density, higher apparent mean heat capacity, and higher viscosity, higher expandability, and lower specific entropy than free water. Activation energies for ion migration were higher in bound water than free water.[6] Ion mobility was decreased when there was only one or two layers of sorbed water.[7] McBride and Baveye[8] have experimentally confirmed higher viscosity close to clay surfaces. As an example, Fig. 1 shows the decrease in change of specific heat capacity as water is added to a Na-montmorillonite.[9] Sposito and Prost[10] question the assumption of near equilibrium even at high water contents and indicate that the assumption definitely does not apply to the first layers of adsorbed water. Fig. 2 diagrams bound water clustering around the countercations associated with the 2:1 clay. Note that the cations (small circles in Fig. 2 in center of cluster) and their associated water clusters occupy sites on internal and external surfaces of the clay.

The time dependence of bound water relates to the mechanism affecting motion of the water molecules. Sposito and Prost[10] discuss a V structure of water which shows vibrational motion around 10^{-10}–10^{-11} sec and a D structure of diffusional motion for timescales greater that 10^{-4} sec. Between these two extremes, water, as a polar molecule, can be subject to movement that orients the molecule back and forth in response to an alternating electrical field. Free water can continue to oscillate back and forth even at timescales down to around 10^{-12} sec, but ice only down to around 10^{-7} sec. The various forms of bound water can continue to oscillate between these extremes. These timescales are related to the inverse of the frequency.

Relation to Dielectric Properties

The frequency-dependent dielectric spectra are used to examine the frequency-dependent oscillations. The time or frequency when half of the molecules are no longer able to oscillate is called the relaxation time or frequency. At frequencies lower than the relaxation frequency, the relative dielectric constant (relative to that of a vacuum) is high, and at frequencies higher than the relaxation frequency, the dielectric constant is low. At high frequencies, free water can continue to oscillate and still has a high dielectric constant. At these same high frequencies, bound water cannot oscillate and has a lower dielectric constant. Many studies have examined the effect of bound water in lowering the dielectric constant of the system at high frequencies, but have failed to realize that the same mechanism would not extend to lower frequencies when bound water can also oscillate with a larger dielectric constant.

Dielectric Determination of Soil Water Content

Dielectric properties are used to determine soil water content, assuming that all of the water has a dielectric

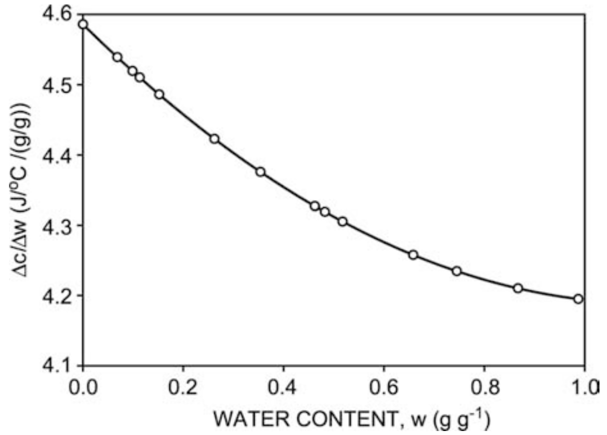

Fig. 1 The change in specific heat capacity as water is added to the system for a sodium montmorillonite. *Source*: From Ref.[9].

constant around 80.[11] Many studies have data that do not fit assumed relations unless some of the water is assumed to be bound water with a lower dielectric constant than free water. Volumetric mixing models are often used to explain such data, using measured or assumed volume fractions and dielectric properties for each component of the system. Dobson, Ulaby, and Hallikainen[12] assumed that soil was made of four components: air, soil solids, free water, and bound water. They used two mixing model approaches to explain the reduction in bulk dielectric constant for soils with much bound water. Sihvola[13] discusses a variety of mixing models and their assumptions. One class are the power law mixing models, and the other class are based on modifications of the Maxwell–Wagner approach for two component systems in which one component is continuous and the other component is discontinuous. The equations can be altered depending on shape of the inclusions, multiple inclusions,

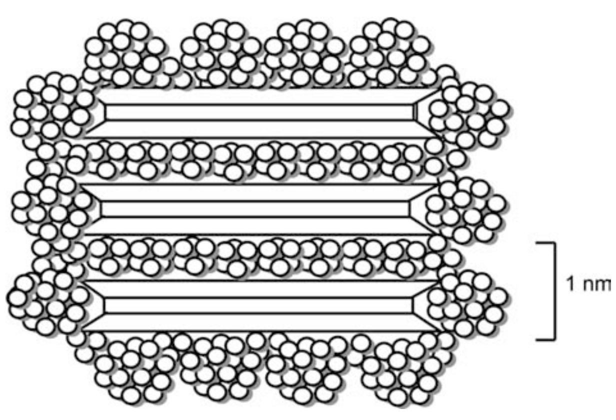

Fig. 2 Diagram of a 2:1 clay showing water molecules clustered around the countercations in interlayers and on external surfaces.

layers around inclusions, orientation of anisotropic inclusions, which (or both) of the components have electrical conductivity, and multiple inclusions. Difficulties arise because dielectric properties vary with frequency of the alternating current and are complex numbers with real and imaginary components. Another difficulty is that soil is a multicomponent system (air, soil solids, and water with varying degrees of binding), in which more than one component may be continuous.

Many have assumed that bound water has the same dielectric constant as ice, i.e., 4,[2,11,14] but Dirksen and Dasberg[15] could not fit their data unless a large value was chosen, around 30 for a Vertisol soil–water mixture or 50 for smectite clay–water mixture. Laird[16] assumed a logistic curve to describe the dielectric of bound water between the first adsorbed layer (dielectric constant of 4) and bulk or free water (dielectric constant of 80).

Assuming a lower dielectric constant for bound water has not adequately explained the data in which the dielectric constant is larger than expected in soils with a lot of bound water. This has mainly been a problem at high water contents and high temperatures[15,17–19] or when the measurement frequency is lower than that from measured dielectric constants in the field,[20] or with long cables,[19] or for a capacitance or other system that used a lower measurement frequency.[11,21]

Dielectric Spectra of Clay–Water Systems

Although several studies have examined dielectric spectra in a qualitative sense, one of the first to mechanistically examine the imaginary dielectric temperature spectra was Calvet.[22] He examined humidified smectites saturated with various divalent cations. He divided the spectra into two electrical conductivity components and two relaxation components, each of which had a temperature dependence. Ishida and Makino[23,24] examined Na-saturated clays at a range of frequencies, but only one temperature. For the slurries and gels of smectites, they identified three relaxation components, after subtracting the electrical conductivity component. Dudley et al.[25] likewise measured slurries of smectite but included three temperatures. They subtracted the electrode polarization component and observed an electrical conductivity component and a relaxation component.

One of the difficulties in these studies is attributing all the observed relaxations to bound water alone. Bound water is part of a system in which polarization can be induced in macromolecules and colloids because of migration of charge carriers either in the double layer of dispersed colloids[26] or to proton hopping on external or internal surfaces of humidified soil.[27]

The frequency range for the polarization as a result of migration of charge carriers may overlap with the frequency range for relaxation as a result of oscillation of bound water.

CONCLUSION

Water bound to colloids has been shown to be more rigid than free water but not as rigid as ice. The properties of bound water are determined only indirectly because bound water can only be measured as part of the system to which it is bound. Early work emphasized properties of water bound to the inorganic colloids in soils, i.e., clays. Later work on bound water developed because the bulk dielectric constant measured at high frequencies showed reduced dielectric constants for soils high in montmorillonite clays. The reduced dielectric constants for bound water occur because of the increased rigidity, which decreases the ability of the water molecules to oscillate in an alternating electrical field.

Currently, there is increased interest in examining soil dielectric properties across a range of frequencies. These dielectric spectra show the soil–water system shift from freely oscillating at low frequencies to no oscillations at high frequencies. Although this shift is sharp for free water, the dielectric spectra for soils and clays show a broad frequency range of gradual change. This suggests that multiple mechanisms are operating. Not only is water oscillating, but also polarities develop in the bound water–colloid system at lower frequencies. The dielectric properties of bound water are difficult to separate from the induced polarities of the bound water–colloid system. Careful experimental determination of dielectric spectra combined with model development will enable us to separate these components and utilize the dielectric spectra as a characterization tool for soil–water systems.

Brahmaputra Basin

Vijay P. Singh
Department of Biological and Agricultural Engineering, Texas A&M University, College Station, Texas, U.S.A.

Sharad K. Jain
National Institute of Hydrology, Roorkee, Uttarakhand, India

INTRODUCTION

According to the Hindu belief, Brahmaputra means "son of the Creator, Lord Brahma." The source of this river lies in the Kanglung Kang Glacier in the southwestern part of the Tibetan plateau at an elevation of 5300 m (82° 10′E, 30° 30′N) near Konggyu Tso Lake. The Brahmaputra River then traverses a distance of 2880 km before joining the Bay of Bengal (see Fig. 1).

The basin is of irregular shape: the maximum east-west length is 1540 km and the maximum north-south width is 682 km. The basin lies between 23° N and 32° N latitude and 82° E and 97° 50′E longitude. The characteristics of the Brahmaputra River in different parts of the basin are given in Table 1.

TOPOGRAPHY

The course of the Brahmaputra River can be divided into three reaches: upper, middle, and lower. In the upper reach, it flows for 1625 km mainly to the east, almost parallel and north to the Himalayas. Here, the river is known as Tsangpo, or "the purifier." Near the eastern end of the basin, Tsangpo takes a hairpin bend and enters India at Kobo in Arunachal Pradesh. Here, the river is first known as Siang and then Dihang. At Pasighat, Dihang's maximum discharge is 29,643 m^3/s. From Pasighat up to the Indo-Bangladesh border (640 km), the river passes through alluvial plains. At Kobo in Assam, Dihang meets two major tributaries, Dibong and Lohit, and the combined river is known as Brahmaputra. This reach contains Majuli, which is the biggest river island (area 900 km^2) in the world.

In the lower reach from the confluence of the Tista River near Bahadurabad to Goalundo, Brahmaputra gets a new name: Jamuna. At Goalundo, Jamuna joins another major river, Ganga-Padma, and the combined river flows as Ganga-Padma for 80 km. Near Rajabari, another major tributary, Meghna, joins and the combined river flows for 32 km as Meghna River. A little downstream, Meghna trifurcates and outfalls into the Bay of Bengal forming broad estuaries. The main tributaries of Brahmaputra are: Nayang Chu, Yarling Chu, Subansiri, Manas, Jia-Bharali, Sankosh, Teesta, and Meghna.

HYDROMETEOROLOGY OF THE BASIN

The Himalayas divide the basin into two distinct climatic zones (Fig. 2). The northern part, being on the rain shadow side of the monsoonal system, in the Tibetan plateau is cold, dry, and arid. The southern part, being on the "wet" side of the monsoonal system, is relatively warm and humid, and experiences high rainfall. The western part of the Brahmaputra valley experiences hot summer in April and May.

The Monsoon is the most important factor responsible for seasonal weather variation. In summer, warm moist air moves northward bringing rain, especially on the south slopes of the Himalayas. About 65–80% of the average annual rainfall takes place in this period. Rainfall during July and August is the highest. The wettest place on the Earth, Mausynram, which receives 11,872 mm of rainfall in an average year, is located in the Khasi hills. The Tibetan plateau and higher reaches of mountain ranges above 3000 m receive snowfall during winters.

In winter, cold dry airflow from central Eurasia flows southward and is warmed as it passes over the Himalayas, bringing generally pleasant conditions. The average annual rainfall in the basin varies from less than 400 mm on the north side of the Himalayas to more than 6000 mm on the south side of the Himalayas. The mean annual rainfall over the catchment, excluding the Tibetan part, is around 2300 mm. The variability of annual rainfall is 20%. The highest recorded 1-hr rainfall is 97.5 mm at Saralpara, Tikpai sub-basin.

DISCHARGE

Brahmaputra is a perennial river. Typical annual discharge hydrographs of the river for five stations are shown in Fig. 3. The maximum and minimum discharges of the Brahmaputra River at different

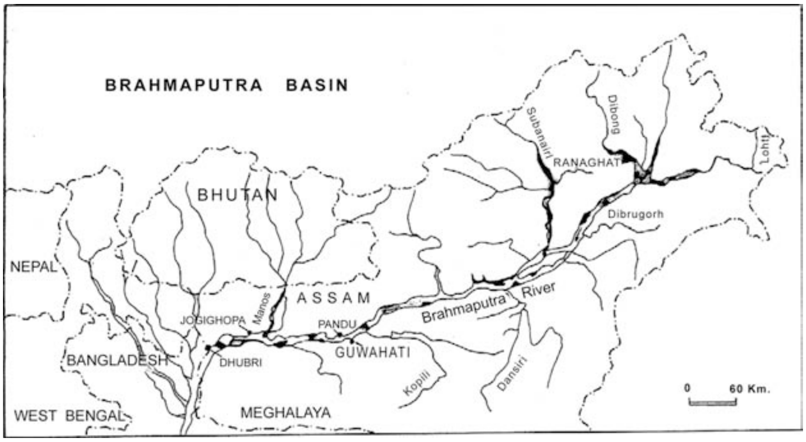

Fig. 1 The Brahmaputra Basin. *Source*: From Ref.[1].

sites are furnished in Table 2. The recorded maximum discharge of major tributaries is given in Table 3. At Bahadurabad in Bangladesh, the average discharge during the monsoon period is 31,850 m^3/s.

Flooding is an acute problem in the Brahmaputra valley. On average, flooding affects an area of 1 million ha in Assam. The main reasons for frequent floods are the narrowness of the valley, high rainfall, and encroachment of flood plains. Floods have frequently created havoc in the region; the floods of 1987, 1988, 1992, and 1995 were particularly severe. The maximum observed flood peak at Pandu was 72794 m^3/s in 1962.

In the basin, flood-prone area is 3.15 million ha. The flood management works so far adopted have been mainly embankments, drainage channels, town protection works, and erosion control works. The length of embankments was increased from 6000 km in 1954 to 15,675 km in 1990 besides improvement of 30,857 km of drainage channels. These measures have afforded a reasonable flood protection to an area of 1.635 million ha.

CROPPING PATTERN

The major crops in the basin are rice, wheat, maize, and other cereals, pulses, oilseeds, jute, sugarcane, and potato. The horticultural crops are fruit crops, plantation crops, tuber crops, and spices. Commercial cultivation of ornamentals has begun recently. Rice is by far the most important crop of Assam. Winter or Kharif rice (known as ''Sali'') occupies 70% of the area under rice and is cultivated from June to December. ''Ahu'' or autumn rice occupies 25% of the area under rice, the crop season is from March to July. Pulses are cultivated primarily during the Rabi season. Jute is the primary fiber crop. Important horticultural and plantation crops include orange, banana,

Table 1 Salient features of the Brahmaputra Basin

Location	Catchment area in that part (km^2), % of total area	Average gradient	Topography
Upper Reach: Source to Indo-China border, Tibet (China)	293,000 (50.52%)	1:385	High Tibetan Plateau
Middle Reach:	195,000 (33.62%)

SEDIMENT TRANSPORT

The sediment yield of the Brahmaputra River is very high; the yield at Guwahati is $755\,m^3$ per km^2 of catchment area; the maximum and minimum sediment concentrations are 679 and 36 ppm, respectively. The average annual sediment load at Bahadurabad in Bangladesh is 735 million metric tons. Here, 12.5% sediment is coarse, 14.2% medium, and 73.3% fine.

Downstream of Pasighat, Brahmaputra is highly braided. The width of the river from Kobo to the Indo-Bangladesh border varies from 6 to 18 km except in nine places where it traverses through deep and narrow throats. The main reasons of high sediment load are: Brahmaputra is a geologically young river, the catchment area falls in a seismic belt, rainfall intensity is high and slopes are steep. Besides, ‘‘Jhumming’’ (shifting cultivation) greatly increases sediment load.

HYDROPOWER

The hydropower potential of the Brahmaputra basin in India is 34,920 MW at 60% load factor. But so far, less than 2% has been developed. Completed projects include Loktak, Kyrdem Kulai, Umtru-Umaim Stage I, II, and III. The dams under construction include Kapili Stage I and II, Lower Kapili, Thoubal, and Gumti. Three reasons for poor development of hydropower in the region are: difficult terrain, lack of demand, and non-availability of bulk transmission corridors. Major identified multipurpose projects are

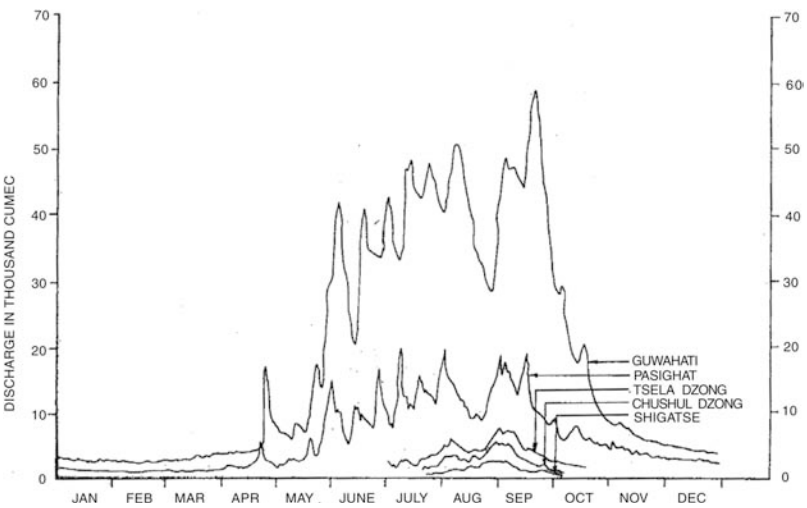

Fig. 3 Discharge hydrographs of the Brahmaputra River at different sites. *Source*: From Ref.[1].

Table 2 Recorded maximum discharge of the Brahmaputra River at some sites

Site (State, Country)	Catchment area (km^2)	Recorded maximum discharge (m^3/s)
Shigatse (Tibet, China)	88,620	3,380
Tseladzong (Tibet, China)	186,730	10,200
Pasighat (AP, India)	249,000	29,640
Guwahati (Assam, India)	424,100	72,794

Table 3 Observed maximum discharge of major tributaries of Brahmaputra

Tributary	Gauging site	Maximum discharge (m^3/s)
Subansiri	Chawidhowghat	18,799
Jia-Bharali	N.T. Road	9,939
Manas	Mathanguri	10,842
Dibong	Jiagaon	11,205
Lohit	Digarughat	12,350

Dihang group of dams (13,250 MW), Subansiri group (6000 MW) and Tipaimukh (1500 MW). These projects can also provide other significant benefits.

FLORA AND FAUNA

The forests of Brahmaputra Basin contain a great diversity of flora and fauna. Five major groups of forests in Assam are: (1) Tropical Wet Evergreen; (2) Tropical Semi-evergreen; (3) Tropical Moist Deciduous; (4) Littoral and Swamp; and (5) Tropical Dry Deciduous. The Brahmaputra valley harbors five big mammals—Rhino, Tiger, Wild Buffalo, Gangetic Dolphin, and Elephant. Famous national parks are: Kaziranga, Manas, Nameri, Dibru-saikhowa, and Orang. The Kaziranga National Park (KNP) is a place of international importance with its mega-diversity in flora, fauna, and ecosystem. The Great Indian One Horn Rhino is found here.

WATER QUALITY

Brahmaputra flow contains very high amount of sediments. Surface suspended sediments range from fine sand to clay, the size fraction greater than 12 μm constituting an important size population. The groundwater is generally mildly alkaline with a pH value ranging from 6.5 to 8.5; total dissolved solids are low. The chloride (10–40 ppm) and bicarbonate (50–350 ppm) values are quite low. The iron content ranges from a fraction to as high as 50 ppm. At greater depths, groundwater is free from much of iron. The total hardness varies as $CaCO_3$ generally varies from 50 to 300 ppm. In some places, good quality water is available at 14–30 m depth.

CONCLUSIONS

The Brahmaputra Basin is unique with a wide variety of climate, topography, and ecology. It is hoped that its immense water resources will help in overall development of the basin.

Canal Automation

Albert J. Clemmens
U.S. Water Conservation Laboratory, Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Phoenix, Arizona, U.S.A.

INTRODUCTION

Canal automation refers to a wide variety of hydraulic structures, mechanical and electronic hardware, communications, and software used to improve the operation of canals that transmit water and deliver it to users. Early canal automation consisted of hydro/mechanical devices used to adjust a single canal gate, with the intent of controlling the adjacent water level or flow rate. These local devices evolved over time to include mechanical/electric controllers and finally to electronic control, although many hydro/mechanical gates are still used successfully. A major shift in canal automation resulted from the use of radio or hardwire communication to control all canal structures from a single location. Today, commercially available supervisory control and data acquisition (SCADA) systems are used for remote, manual supervisory control of canals. The use of a centralized control station (particularly SCADA systems) has also led to the use of computers for the automatic remote control of entire canals. A variety of devices, methods, and control algorithms have been developed for canal automation. These are summarized in Refs.[1,2].

BACKGROUND

The objective of canal operations is to deliver a certain rate or volume of water to a particular location, for example to a reservoir, to a farm canal, etc. Canals differ radically in operation from pressurized pipelines, where users simply open an outlet to receive water. If an outlet to a canal is opened, the flow generally causes the water level (pressure or head) to drop, but only in the vicinity of the outlet. That pressure drop moves upstream only gradually and may never reach the upstream source of the canal. The increase in demand can literally empty the canal. A canal can operate as a demand system only if there is sufficient storage within the canal to handle immediate changes in demand. Even so, if an increase in demand is not matched by an increase in the canal inflow, canal volume and water levels will drop. More often, demand changes are prearranged or scheduled.

Check structures are used in canals to provide a higher head on outlet structures (e.g., users' delivery gates), and a head that is independent of canal flow rate. These check structures usually consist of a series of gates and/or weirs (Fig. 1). Methods to control the flow rates through a canal outlet usually consist of either an automatic flow-rate-controlled outlet (discussed later) or a manually controlled outlet with (manual or automatic) control of the water level upstream from the outlet structure, which if held constant usually provides constant flow (Fig. 2). The later method is the most common approach.

The canal section between two check structures is often called a canal pool. Automatic control methods differ in where within the canal pool the water level is to be controlled, at the upstream end, at the downstream end, or some average value (and associated pool volume). Even when outlet devices have some automatic controls, they generally only maintain constant (or near constant) flow within a range of upstream water levels.

FLOW-RATE CONTROL

Flow-rate control is most frequently applied to the head of a canal. (The outlet of one canal is the head of another.) Automatic control of flow rate at a canal outlet (or headgate) has been accomplished primarily by two methods; hydro/mechanical flow-rate control devices and mechanical/electric or electronic feedback control from a flow-measurement device, where the gate itself can serve as the measuring device. If the measurement device is a weir or flume, then a constant water-level device (discussed in the next section) can be used to adjust the outlet to maintain constant flow. Flow-rate control at canal check structures is also used with some volume and downstream-water-level controllers. However, this assumes that mismatches between inflow and outflow will be adjusted by other control actions upstream. Otherwise, flow-rate control is not sustainable.

UPSTREAM WATER-LEVEL CONTROL

The most common method of manual canal control is upstream water-level control, where check gates are

Fig. 1 Check structure with motorized check gates and a manual outlet gate shown as part of SCADA automatic control screen.

adjusted to maintain a constant water level on the upstream side of each check structure. Canal inflow is set to match the demand, usually manually. Upstream flow changes are automatically passed through each check structure as it maintains its upstream level. However, upstream water-level control will cause all

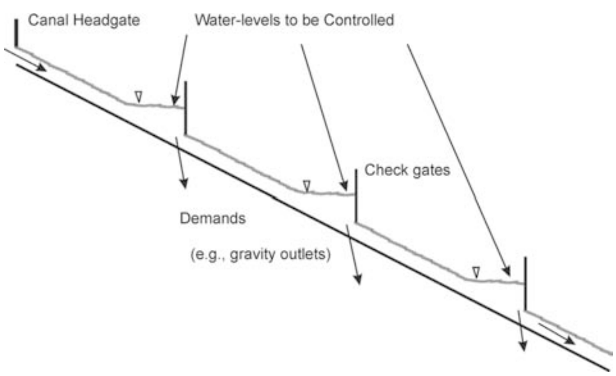

Fig. 2 Profile drawing of canal with check gates and outlets.

errors in canal inflow and outflow to move to the downstream end of the canal, causing either shortages or surpluses there, regardless of the type of automatic control. In addition, a series of automatic upstream water-level controllers can, if not properly set or adjusted, cause the flow rate at the downstream end of the canal to oscillate.

A variety of automatic methods have also been developed for upstream control. The simplest is a duckbill weir, which is a very long fixed (no moving parts) weir, where the change in water level for a large change in flow is very small (a decrement). Neyrpic gates use a float on the upstream side of the gate to adjust gate position to maintain a constant upstream level, again with a decrement (Fig. 3). Several other hydro/mechanical gates have also been used, e.g., controlled leak gates. More details and references can be found in Ref.[2]. Electrical/mechanical devices have also been used to maintain constant upstream water levels.[3] In general, these have not proven to be reliable and have been essentially replaced with electronic

Fig. 3 Amil gate for constant upstream level control.

devices. Programmable logic controllers (PLCs) and remote terminal units (RTUs) have been used to maintain constant upstream levels locally at the structure with PI or PID type logic (proportional, integral, derivative). Such control can usually be conveniently programmed into SCADA software for remote operation.

DOWNSTREAM WATER-LEVEL CONTROL

Under downstream control, the controller adjusts the check gate to maintain the water-level downstream from the check structure. It is far easier to control the level immediately below the check structure; however, in general outlets are located at the downstream end of each canal pool, making the level to be controlled far from the check structure. This complicates the control and makes downstream control difficult to apply without a thorough control-engineering approach. Early attempts at downstream water-level control adjusted each check structure based on one downstream water level[3]—as a series of local controllers (Fig. 4). This has proven not to be very effective, and a more centralized approach can dramatically improve control.[4]

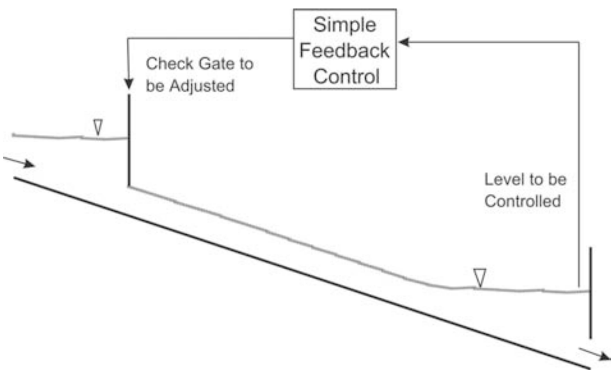

Fig. 4 Schematic drawing of downstream water-level control for a single canal pool.

CONSTANT VOLUME CONTROL

Canal water levels and volumes are related. If precise control of water levels is not critical, it is sometimes easier to control the canal pool volumes. Volume control methods measure one or more water levels and convert this to a pool volume. When the pool volume deviates from a target, a volume error is determined, and an adjustment is made to the pool inflow rate. This change in pool inflow can be computed pool by pool with simple logic (such as Bival[1]) or can be determined from a centralized perspective (such as Dynamic Regulation[1]). The rate of change of pool volume can also be used to determine the difference in pool inflow and outflow, and pool inflow volume can then be adjusted to bring inflow into balance with outflow. Target pool volumes can also be varied to provide more balanced control of the canal, e.g., all pools reduced in volume in the response to canal inflow limitations. Volume control is very effective for the control of pools with pumped outlets that are not very sensitive to level. This control method is not as effective for gravity outlets, unless the outlets themselves have automatic controls.

ROUTING DEMAND CHANGES (GATE STROKING)

As discussed above, demand changes in a canal cannot be handled strictly by feedback because downstream water-level response may never reach the upstream end of the canal. Thus, most canal flow changes are prescheduled. Flow changes made at the head of a canal arrive at downstream outlets at some later time.

Knowledge of this time delay allows operators to schedule a change in flow at the canal headgate so that the flow change will arrive at the outlet gate at the desired time. Unfortunately, the sudden flow change made upstream arrives only gradually at the downstream checks, making the exact timing difficult to predict. A variety of schemes have been developed to compute these flow change schedules automatically. Some use numerical methods to solve the governing equations of flow. These have proven to be unreliable and difficult to implement. More simple, volume-based procedures have proven more effective.

CENTRALIZED CONTROL

Remote monitoring of a canal, or a canal network, from a central location allows an operator to provide more timely control at check gates than if that control were done by the same individual locally, traveling from check to check. Supervisory control and data acquisition systems provide automatic data collection (including communication with remote sites), display, and archiving. In addition, all of the other automatic control feature discussed earlier can be implemented from a central control station. This has some advantages in terms of reliability, accountability, and safety. Some functions can be performed locally, but in general control is improved if they are based on operations from a centralized perspective.

INTRODUCTION

The analysis of water has become a common and important task for industry, municipalities, and agriculture in response to today's increased public awareness and participation in conserving, protecting, and improving the quality of water resources. Analytical chemistry methods are used for the identification of one or more analytes or constituents and properties in a sample and the determination of the concentration of these components. The identification of components in water is called a qualitative analysis while the determination of relative amounts is a quantitative analysis.

Quantitative analyses provide data describing the quantity of the analyte in a measured amount of sample. The results of environmental analysis for water are commonly expressed in relative terms as parts of analytes per unit of sample, such as percent (%), parts per million (ppm), milligrams per liter ($mg\,L^{-1}$) or parts per billion (ppb), and micrograms per liter ($\mu g\,L^{-1}$). With recent improved technology, parts per trillion detections can be obtained for some constituents. Special methods allow detections of individual molecules in some cases.

DATA QUALITY

To produce quality data the sample must accurately reflect the matrix or media from where it was collected. Sampling is more efficient in liquid than solid matrices, such as soil, due to the chemical properties of water and the homogeneity of solutes. However, the increased risk to biological systems and public health associated with contaminated water complicates the decision of which methods will provide the data necessary to make informed decisions about the quality of the water, the protection of human health, and the protection of the environment. Data Quality Objectives (DQO) must be formulated that outline considerations such as regulatory compliance and guidance, accuracy, target analytes, required analytical method performance, availability and reliability of field measurement, number of samples needed to be analyzed, and cost of analysis. In summary, DQOs can be defined as those sampling and analytical objectives that provide the number of samples and the quality of results needed to satisfy the decision making process. Because the success or failure of an analysis is often critically dependent on the proper method selection, the decision of which analytical method to request is difficult and is only made easier with experience. A good working relationship with a qualified laboratory can prove an invaluable asset to the data collector.

The analysis of water can be divided into common groupings, organic and inorganic analytes, which require varied analytical methods. A clear establishment of DQOs to support the decision making process requires an understanding of those methods and the methods which meet the regulatory requirements. The U.S. Environmental Protection Agency has developed a series of documents that outline the DQO process which can be accessed on the internet.[1–3] Gilbert[4] has published a very useful handbook, "*Statistical Methods for Environmental Pollution*" which addresses statistical implications of sampling and data quality analysis.

Before developing a sampling plan, due to the large number of methods and variability of techniques, care must be taken to determine the accuracy and sensitivity requirements for the application and then determine holding times, preservatives, sample size, and containers required by the method chosen to meet the DQO. A listing of approved methods for National Pollutant Discharge Elimination System (NPDES) permits including sample containers, preservatives, and holding times is available in 40 CFR part 136 and can be easily downloaded from the web by following the links from the site www.access.gpo.gov/nara/cfr. The regulation, which governs the activity that is being analyzed or monitored, will provide guidance and identify the method required to meet regulatory compliance. It is important to carefully research the project requirements, because several analytes have no holding time (such as pH; see the entry *pH*) and must be analyzed in the field. Field methods offer flexibility and reduced cost; however, accuracy is still dependent on the equipment, personnel, and the quality assurance plan that outlines training, calibration, maintenance, and procedure. Due to the large number of methods and complexity of their quality assurance requirements, a qualified laboratory should be consulted to determine which method will yield data of sufficient quantity and quality to meet the DQOs.

ANALYTICAL METHODS AND PROTOCOLS

It is important to understand that the various regulations require specific analytical methods. Within these regulations, different methods maybe required based on the media type (soil, water, sewage, etc.) Specific methods[5–8] have been established by the EPA, professional organizations, and even the state agencies for these various matrices (i.e., soil, water, and sewage). EPAs SW846 methods[5] for the evaluation of solid waste are used for the evaluation of solid waste which includes water and are used in this discussion because they are commonly used in water analysis and the methods are easily downloaded from the web at (http://www.epa.gov/epaoswer/hazwaste/test/main.htm). EPA also published EPA-600[6] series for water and EPA-500[7] series for drinking water, but the method's advantages and disadvantages remain the same for each series of methods. It is important to note that subtle differences do exist for method procedures and quality control and the method series prescribed in the regulations should be utilized.

ANALYTICAL METHODS FOR INORGANIC CONSTITUENTS

The analytical methods for inorganic constituents in water for environmental monitoring are commonly subdivided into wet chemistry and metals. These methods are used for analyzing nutrients and elemental analytes, and are associated with water quality parameters and metal contamination. These methods are usually requested for waters that are accepting treated municipal and industrial effluents or that have suspected impacts from sewage, agriculture, and industry.

WET CHEMISTRY

Wet chemistry methods are the classical bench methods and include common water quality parameters [i.e., pH, biochemical oxygen demand (BOD), hardness, and alkalinity] utilizing colorimetric, potentiometric, gravimetric, titration, and chromatographic determinations. These methods have varying degrees of sensitivity and accuracy.

METALS

Techniques for the analysis of trace-metal concentrations include direct-aspiration or flame atomic absorption spectrometry (FLAA), graphite-furnace atomic absorption spectrometry (GFAA), inductively coupled argon plasma-atomic emission spectrometry (ICP-AES), inductively coupled argon mass spectrometry (ICP-MS), and cold-vapor atomic absorption spectrometry (CVAA). Each of these methods has advantages and disadvantages that should be addressed before selection of an analytical procedure.

FLAA

FLAA is the most common method utilized by small commercial laboratories, municipalities, and industrial laboratories because of the affordability and ease of operation. FLAA commonly uses an acetylene/air flame as an energy source for dissociating the aspirated sample into the elemental state enabling the analyte to absorb light from a specific wavelength. Since each element has to be analyzed separately using that metal's specific wavelength, there is reduced risk for matrix interference. The sensitivity is usually acceptable for most applications, but currently technological improvements are lowering allowable analyte limits that will strain the FLAA capabilities. SW846-7000[5] outlines the general method and associated digestions, interferences, and sensitivity.

GFAA

GFAA replaces the flame with a heated graphite furnace that allows the experienced analyst to remove matrix interferences and concentrate the analyte of concern by using temperature profiles and matrix modifiers. This method requires more exacting analyst intervention and interpretation making it more difficult than FLAA. The method does increase sensitivity and when coupled with ZEEMAN has a very low background interference. GFAA greatly enhances the ability to analyze Selenium and Arsenic that can prove difficult to analyze with other methods. The method has the potential of positive interferences from memory effect, smoke producing matrices, organic materials, and carbide formation and is extremely dependent on the skill of the analyst. GFAA requires a stringent QC program to ensure that matrix interferences have no adverse effect on the analyte of concern.

SW846-7000[5] outlines the general method and associated digestions, interferences, and sensitivity.

ICP

ICP allows rapid simultaneous or sequential analysis of many metals making it the major method utilized by large commercial laboratories. ICP instruments are expensive and complicated analytical instruments requiring skilled analysts and exacting quality control procedures. ICP-AES methods are susceptible to high single element interferences in matrices high in salts or other elements making trace analysis of other elements in these matrices problematic. Arsenic and selenium lack sensitivity due to physical properties but can be enhanced using a hydride aspiration system. Lead, antimony, and thallium also have sensitivity problems on the ICP-AES but can be analyzed at low levels using ICP-MS or GFAA. ICP-MS greatly enhances sensitivity for metals making it the preferred method when the analyses of very low concentrations are required. The main interference is selenium that has mass interference with the argon dimer. SW846-6010[5] outlines the general method and associated digestions, interferences, and sensitivity.

CVAA

CVAA is the technique used for the analysis of mercury by using a selective digestion method. Although this method is extremely sensitive, it is subject to interferences from sulfide, chlorine, and organic compounds. There are several models of instruments for mercury but all require a thorough quality assurance plan to ensure the accuracy of the results. SW846-7470[5] outlines the general method and associated digestions, interferences, and sensitivity.

ANALYTICAL METHODS FOR ORGANIC CONSTITUENTS

The analysis of organics in water offers the data collector a variety of challenges due to the sheer number of methods and analytes. The decision of which method to utilize is determined by regulations, desired data quality, and cost. It should be noted that there are usually multiple methods that can quantify a compound requiring an experienced data collector to determine which method meets the requirements in the DQOs.

Organic chemical methods can be divided into those that determine total organic matter present and individual organic compounds or groups of compounds.

Total Organic Matter Present

Total organic methods measure such parameters as BOD,[6] chemical oxygen demand (COD),[6] total organic carbon (TOC),[8] oil and grease,[5,6] total recoverable petroleum hydrocarbons (TRPH),[5,6] oil and grease in sludge,[5] total phenols,[5,6] and surfactants.[6] A detailed discussion is included on BOD and COD in the article titled *Oxygen Measurement: Biological–Chemical Oxygen Demand*.

Individual Organic Constituents or Groups

A very detailed discussion would be needed to address the methods used to analyze the vast numbers of naturally occurring and man-made organic compounds found in water. EPA SW-846 provides a good listing of methods. Internet services, such as Toxnet (http://toxnet.nlm.nih.gov/), can also be useful tools. Toxnet is a cluster of databases on toxicology, hazardous chemicals, and related areas. One database, the Hazardous Substances Data Base, provides detailed descriptions of specific compounds as well as analytical methods. Numerous methods are typically presented in the HSDB (http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?HSDB). If the data are to be used to satisfy a regulatory requirement, the investigator must select the method that is approved by the appropriate regulatory agency.

Organic chemicals are typically analyzed using one or more of the following technologies: gas chromatographic technique (GC), halogen sensitive detector (HALL), photoionization detector (PID), flame ionization detector (FID), electron capture detector (ECD), nitrogen phosphorous detector (NPD), flame photometric detector (FPD), high performance liquid chromatography (HPLC), and various extraction methods such as purge and trap (P and T), separatory funnel extraction, and continuous liquid–liquid extraction.

The environmental field separates organic contaminants by their physical properties into volatile and semivolatile components. If the compound can be purged from an aqueous sample using an inert gas, the compound is considered volatile, and if the compound requires extraction using a solvent, it is considered a semivolatile compound. The separation of compounds into these groups greatly affects the sampling techniques utilized. Volatile components require sampling with zero headspace in 40 mL vials[2] with a Teflon septum. It is important that there is no air in these samples because it can significantly alter the results. Semivolatiles can be collected in liter glass jars with Teflon liners and are not as sensitive to air as volatiles. A qualified laboratory should be consulted to obtain proper sample containers, volumes, and preservatives and can also assist in the determination of which method best matches the project requirements.

CHROMATOGRAPHY

Although there are numerous detectors utilized in the quantitation of organic compounds, the methods introduced in this article will all use GC to separate and isolate individual components. In GC the vaporized components of a sample are separated as a result of partition between the mobile and stationary phases in the column. An analyst controls the separation of individual components by choice of column, method of injection, method of extraction, volume of injection, temperature program, and carrier gas flow. This separation allows the analyst to assign a retention time that a particular compound will elute off the column and identify that compound on the chromatogram. This proves to be an effective qualitative procedure if the matrix contains a small number of analytes. The identification of compounds from a highly contaminated or complex matrix tests the ability of the chromatography and requires intervention of the analyst to interpret the chromatogram or to manipulate the sample to produce more highly resolved chromatography. The effects of analyst intervention will usually reduce the limit of quantification by introducing dilution factors to achieve good baseline separations of the individual for identification. The actions of the analyst must be strictly controlled by experience and the laboratory's quality assurance plan to maintain the integrity of the data. Chromatography is the method of separation for identification, but the eluted sample is then passed onto a detector to quantify the amount of an analyte present in the original sample. The ability to meet the required analytical limits for organic compounds is extremely dependent on the effects of the matrix and the experience of the laboratory performing the analysis.

TWO-DIMENSIONAL DETECTORS

The choice of detectors is varied and is determined by the regulatory requirements and the cost of the analysis. Two-dimensional detectors utilize the retention time and response of a component to identify and quantify the compound and are extremely sensitive if operated by an experienced analyst. There are multiple types of detectors to consider when making a decision, but the regulatory requirements usually identify the detector required for compliance. These detectors all have unique qualities that aid in isolating the types of compounds that are being analyzed and the proper detector can increase sensitivity and decrease interferences. Some commonly used detectors include FID which measures all hydrocarbons, PID which measures aromatic hydrocarbons, and ECDs which are sensitive to halogens, peroxides, and nitro groups. These types of detectors provide sensitivity for quantitation but rely on the chromatography for identification increasing the risk of miss identifying compounds which coelute or miss quantifying compounds in highly contaminated matrices.

THREE-DIMENSIONAL DETECTORS

The mass selective detector (MS) is a 3-D detector that utilizes retention time, response, and mass spectrum to identify and quantify the analyte of concern. Like the 2-D detectors, MS detectors rely on the chromatography to separate the compounds and the response to quantify the compounds but then utilized the mass spectral data to confirm identification. This technique is not as sensitive as the 2-D detectors but is much more accurate removing the possibility of miss identification. Utilizing the MS is preferred when analyzing a complex matrix, but usually increases the cost of analysis. As in all analytical methods, the quality of the data is heavily dependent on the quality of the analyst and the laboratory. SW846-8000 series outlines the general methods and associated extractions, interferences, and sensitivity of organic analysis.

When analyzing an aqueous sample the decision of which analytical method to utilize is difficult and critical to the success of the project. The data collector must meet the requirements established in DQOs to ensure that the data collected is of sufficient quality and quantity to make supportable decisions. The quality of data is determined by sampling, analytical methods, and the quality plans of all the parties involved in collection of the data. The manager must make informed decisions when selecting an analytical method that will fulfill the requirements of the project while balancing cost, time, and risk.

CONCLUSION

With increased industrialization and agriculture, the quality of our water resources will become a critical issue. The need to monitor water resources such as agricultural effluents, groundwater resources, and surface water resources will increase dramatically. The existing and emerging technology will allow analysis of chemicals in water at levels approaching molecular levels. These developments, however, can be very costly. The challenge in developing a plan for water analysis sampling is to develop a plan that satisfies the data quality needed to satisfy the decision making process. This includes balancing both the quality and quantity of samples to characterize the water to address protection of human health and the environment and regulatory standards.

Chemigation

William L. Kranz
Northeast Research and Extension Center, University of Nebraska, Norfolk, Nebraska, U.S.A.

INTRODUCTION

Chemigation is the practice of distributing approved agricultural chemicals such as fertilizers, herbicides, insecticides, fungicides, nematicides, and growth regulators by injecting them into water flowing through a properly designed and managed irrigation system. The term chemigation was originally coined to describe the concept of applying commercial fertilizers that were needed for crop production. Field research, and advances in sprinkler and chemical injection technology have stimulated the use of chemigation as a major crop production tool. Today chemigation is one of the more efficient, economical, and environmentally safe methods of applying chemicals needed for successful crop, orchard, turf, greenhouse, and landscape operations.

Chemigation began with the application of commercial fertilizers through irrigation systems in the late 1950s.[1] Later tests were initiated on sprinkler application of herbicides to selectively control weeds in field crops, fruit and nut orchards, rice, and potatoes.[2,3] These research efforts led the way for what has become a major research topic to identify management and equipment required for chemical application in agricultural and non-agricultural production settings.

The primary use of chemigation is to apply chemical directly to the soil using a range of irrigation water distribution systems. For example, drip/trickle, sprinklers, and some surface irrigation systems are commonly used to apply commercial fertilizers. However, federal regulations limit application of restricted use pesticides to systems that can safely and uniformly apply a chemical to a specific site at a rate specified on a chemical label. Though estimates vary greatly, chemigation is used to apply fertilizers on nearly four million hectares in the United States.[4] Specialists in Florida, Texas, and Wyoming report that more than 50% of their irrigated land received at least one chemigation application.[5]

ADVANTAGES OF CHEMIGATION

Chemigation offers producers of food and fiber many advantages that result from using existing equipment and timeliness of chemical applications. Advantages of chemigation include the following:[6,7]

- Uniformity of chemical application is equal to or greater than other means of application.
- Timeliness and flexibility of application are greater.
- Improved efficacy of some chemicals.
- Potential for reduced environmental risks.
- Lower application costs in some cases.
- Less mechanical damage to plants.
- Less soil compaction.
- Potential reduction in chemical applications.
- Reduced operator hazards.
- Application cost savings for multiple applications.

DISADVANTAGES OF CHEMIGATION

Chemigation also requires additional equipment and management to obtain successful results. Some of the disadvantages of chemigation include:[6,7]

- Chemical application accuracy depends on water application uniformity.
- Longer time of application than other methods.
- Some pesticide labels prohibit chemigation as a means of application.
- Potential for source water contamination.
- Additional capital costs for equipment.
- Potential for increased legal requirements in some states.
- Increased management requirements by the operator.

CHEMIGATION EQUIPMENT

Safe and efficient chemigation requires that the irrigation equipment, injection device, and safety equipment be properly installed and maintained. Fig. 1 provides an overview of equipment necessary for chemigation systems using groundwater. State and federal regulations specify the type of irrigation water distribution system that can be used and the required safety equipment. It is up to the irrigator to ensure the use of appropriate equipment and procedures.

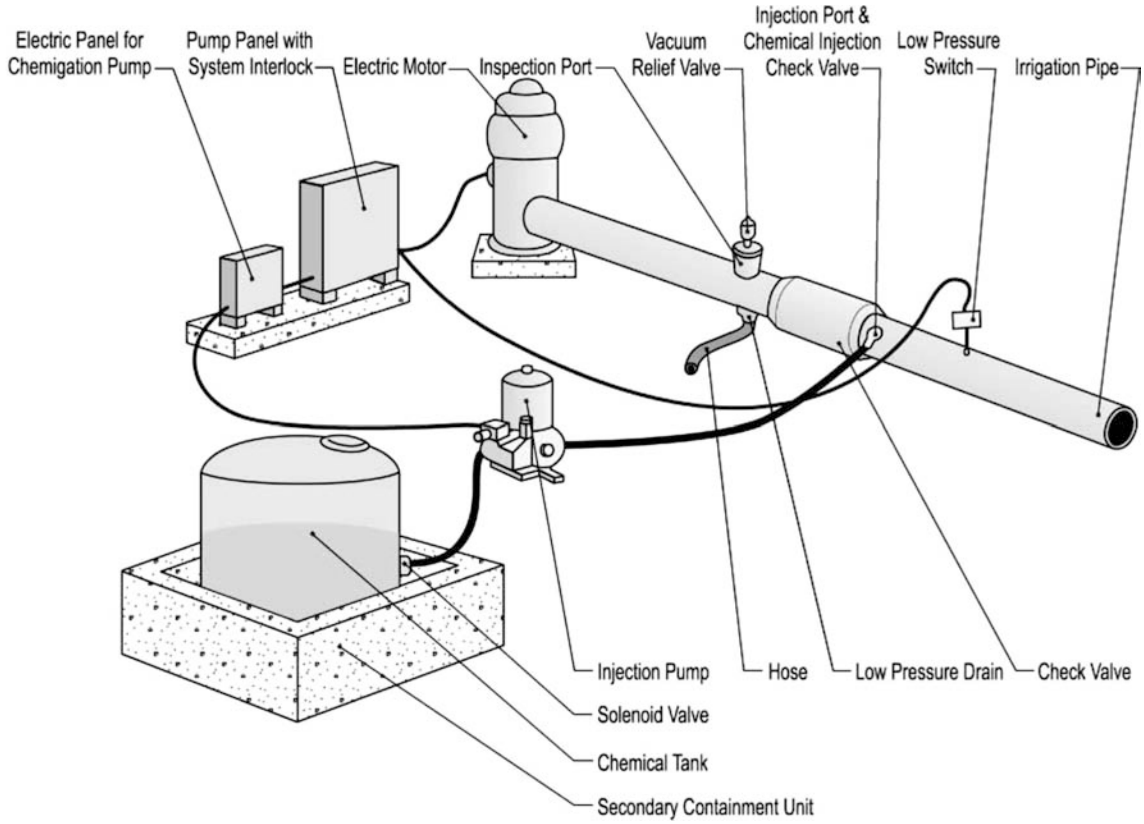

Fig. 1 Chemigation injection and safety equipment commonly required when pumping groundwater. (Drawing courtesy of Midwest Plan Service, Ames, IA.)

Irrigation Equipment

Chemigation requires equipment capable of applying chemicals uniformly and with differing amounts of water, accurate and dependable injection equipment, and safety equipment for source water and worker protection. Appropriate sprinkler design and high application volumes can solve problems associated with canopy penetration and deposition that impact some aerial applications. Uniform water application can precisely place and incorporate chemicals in the soil and limit leaching of soluble chemicals from the zone of application.

Several different types of irrigation equipment can and are being used to distribute chemicals via chemigation. Most chemigation is conducted using either sprinkler or drip/trickle irrigation systems. Center pivot and linear-move systems are most commonly used for chemigation since prescription applications can be made with a high degree of uniformity. Drip/trickle systems are commonly used to place precise amounts of plant nutrients near the zone of plant uptake thus increasing chemical use efficiency.

In general, surface irrigation systems have limited potential for chemigation. Water distribution in furrow systems is typically non-uniform along the row and among rows. Thus, in-field variation in water infiltration results in chemical application uniformity that is below levels desired for chemigation. Development of surge-flow systems can improve distribution uniformity, however, the question remains whether consistent results are possible and whether producers have sufficient experience to make equipment adjustments when necessary. Level basin irrigation systems offer improved uniformity of water application, but water quality concerns have limited the use of chemigation.

Injection Equipment

Chemical injection can occur using either active or passive devices. Active devices use an external energy supply to create pressures at the injector outlet that exceed the irrigation pipeline pressure. Injection pumps are often powered by constant speed or variable speed electric motors. Typical examples include piston, diaphragm, rotary, and gear pumps. However, most new installations use either piston or diaphragm pumps (Fig. 2). These injection devices are relatively expensive. Component selection allows the injection of commercial fertilizers, acids, or pesticides. Intermittent end guns and corner systems can lead to variable chemical application by constant rate injectors due to changes in the irrigation rate per hour.[8] Application errors of approximately 20% are possible when corner systems are used with a constant rate injection device. When the irrigation rate will change during a chemigation event, it is preferable to use a variable rate injection device.

Passive devices take advantage of pressure differentials that result from using a throttling valve or pitot tube unit to add chemical to water flowing through a pipeline. Chemicals are metered into the system using a venturi meter or orifice plate. These systems have low capital cost requirements. However, pumping cost may be greater since irrigation pump outlet pressure must be equal to the water distribution system pressure plus the friction loss associated with the throttling valve. In addition, changes in pumping pressure directly impact chemical injection rates which can lead to non-uniform chemical applications.

Selection criteria for injection devices include potential injection rates, available power supply, and the type of chemical to be injected. A single injection device is typically not capable of covering the range of injection rates and chemical types that could conceivably be applied via chemigation. Hence, if plant nutrients and pesticides are to be applied, two injection devices are desirable. Diaphragm injection devices offer greater chemical compatibility, ease of calibration, and precise injection rates which make them good choices for pesticide injection. Commercial fertilizers are less caustic and require relatively high injection rates which make high capacity piston and diaphragm injection devices good options. Research has noted that injection equipment calibration was necessary for each injection device and operating pressure.[9] Manufacturing tolerances and pipeline pressure impacted the rate of chemical injection. Further, performance tests conducted on new and used diaphragm pumps found that proper maintenance is required to ensure long-term accuracy of chemical injection rates.[10]

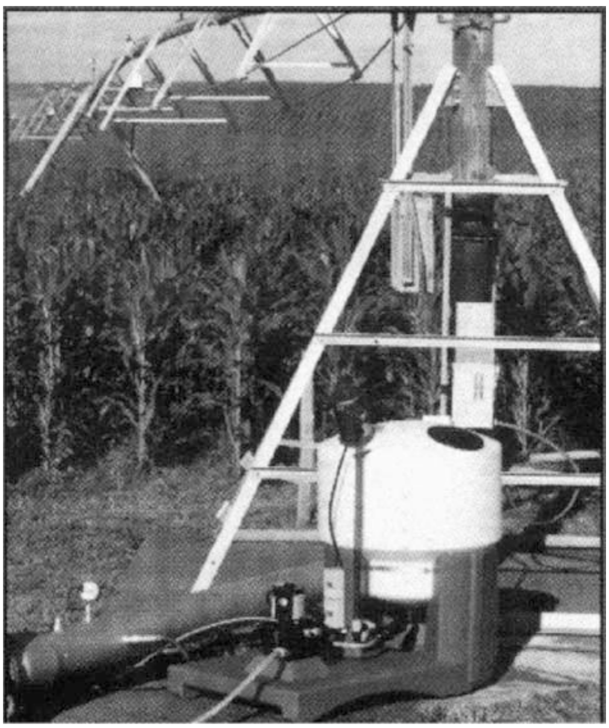

Fig. 2 Typical portable injection equipment for center pivot installations. (Photo courtesy of Agri-Inject, Inc., Yuma, CO.)

Safety Equipment

State and federal regulations differ regarding safety equipment that is required for chemigation. For example, the Nebraska Chemigation Act requires the safety equipment also found in many state regulations.[11] Most requirements are met through installation of a backflow protection device. Requirements typically include (Fig. 3):

1. A mainline check valve to prevent concentrated chemical and/or dilute chemical solution from flowing back into the water source.
2. A chemical injection line check valve to prevent flow of chemical from the chemical supply tank into the irrigation pipeline and to prevent flow of water through the injection system into the chemical supply tank.
3. Vacuum relief valve to prevent back siphoning of concentrated chemical and/or dilute chemical solution into the water source.
4. Low pressure drain to prevent back flow of chemical and/or dilute chemical solution into the water source should the mainline check valve fail.
5. An inspection port to ensure that the mainline check valve and low pressure drain are functioning properly.
6. An interlock between the injection system and the irrigation pumping plant to prevent injection of concentrated chemical into the irrigation pipeline should there be an unexpected shutdown of the irrigation pump.

American Society of Agricultural Engineers have published EP409.1 Safety Devices for Chemigation[12] which recommends the addition of a two-way interlock between the injection system and irrigation pumping plant and a normally-closed solenoid valve on the outlet of the chemical supply tank to prevent chemical

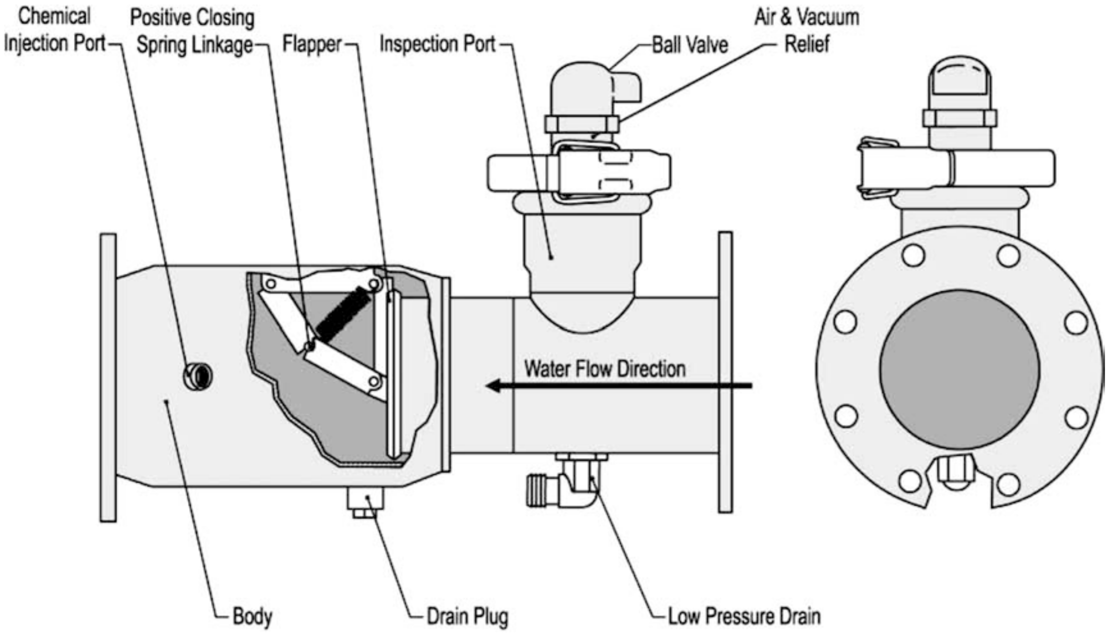

Fig. 3 Mainline check valve used to prevent flow of chemicals into a water source. (Drawing courtesy of Midwest Plan Service, Ames, IA.)

spills attributed to chemical injection line or injection device failures. The engineering practice also encourages the positioning of a fresh water source near the chemical supply tank for washing chemicals that may contact skin, the use of a strainer on the chemical tank outlet to prevent fouling of injection equipment, the grading of the soil surface to direct flow away from the water supply, the location of mixing tanks and injection equipment safely away from potential sources of electrical sparks to prevent explosions, and the use of components that are well suited to a range of chemical formulations.

MANAGEMENT PRACTICES

Management flexibility based on chemical placement, application rate and mobility in the soil, water quality, application cost, and weather factors make chemigation a unique and effective production tool. Chemigation provides the opportunity to synchronize fertilizer applications to match plant needs and incorporate and, if needed, activate pesticides to increase efficacy. Equally important, chemigation provides the opportunity to reduce chemical applications by eliminating the need for insurance-type applications. Fields can be scouted for disease or pests and chemical applied only if damage or pest numbers exceed economic thresholds. Soil and plants can be monitored to determine fertilizer needs, making near real-time adjustments in the time of application and chemical formulation possible. Individual nozzle controls make site-specific applications well within reach.[13] However, a considerable amount of work remains to ascertain if site-specific applications are economical and to incorporate management tools into system controls.

CONCLUSION

Chemigation has gradually become one of the most effective means of chemical application available for crop production and landscape systems. Advantages of highly uniform prescription applications outweigh the potential disadvantages in most cases. Effective chemigation hinges on the selection of appropriate irrigation systems, chemical injection devices, and safety equipment. Through proper management, chemigation is poised to be a production practice that can help increase the quality and quantity of food produced worldwide.

Chernobyl Accident: Impacts on Water Resources

Jim T. Smith
Centre for Ecology and Hydrology, Winfrith Technology Centre, Dorchester, Dorset, U.K.

Oleg Voitsekhovitch
Ukrainian Hydrometeorological Institute, Kiev, Ukraine

INTRODUCTION

The Chernobyl nuclear power plant is situated next to the river Pripyat, which is an important component of the Dnieper river–reservoir system, one of the largest surface water systems in Europe (Fig. 1). After the Chernobyl accident in April 1986, radioactive fallout on the Pripyat and Dnieper catchments threatened to wash downriver into the Kiev Reservoir, a major source of drinking water for the city of Kiev, and to other areas downstream where the river–reservoir system is also used for significant fisheries and irrigation. The radioactive contamination of aquatic systems, therefore, became a major issue in the immediate aftermath of Chernobyl.[1–3] In this entry, we will outline the major impacts of the accident on water resources, covering contamination of rivers, lakes, and reservoirs as well as uptake to fish and impacts on ground- and irrigation waters.

RADIONUCLIDES IN RIVERS, LAKES, AND RESERVOIRS

Initial radioactivity concentrations in river water were relatively high as a result of direct fallout onto the river surfaces and washoff of contamination from the surrounding catchment. During the first few weeks after the accident, however, activity concentrations in river waters rapidly declined because of physical decay of short-lived isotopes and as radionuclide deposits became absorbed to catchment soils. In the longer term, relatively long-lived radiocesium and radiostrontium formed the major component of river water contamination.

To our knowledge, there are few data of radionuclide concentrations in small streams in the Chernobyl area during the early phase of the accident. Most available data are for large rivers. Table 1 shows a summary of available measurements of radionuclide activity concentrations in a large river, the Pripyat, at Chernobyl at various times after the accident. Comparison with Generalised Derived Limits for radionuclides in drinking water shows that radionuclide concentrations in drinking water were a cause for concern in the weeks–months after the accident, but on longer timescales, activity concentrations in rivers were significantly below drinking water limits. Though long-term levels of radiocesium and radiostrontium in rivers were generally lower than drinking water standards, temporary increases in activity concentrations during flooding of the River Pripyat caused serious concern in Kiev and other towns over the safety of the drinking water supply and other types of water use.

Lakes and reservoirs around Europe were contaminated by fallout to lake surfaces and transfers of radionuclides from their surrounding catchments. Radioactivity concentrations in water declined relatively rapidly in reservoirs and in those lakes with significant inflows and outflow of water, as radionuclides were "flushed" out of the system. In the areas around Chernobyl, however, there are many lakes with no inflowing and outflowing streams ("closed" lake systems). Cycling of radiocesium in these closed systems led to much higher activity concentrations in water and aquatic biota than were seen in open lakes and rivers. Bed sediments of lakes and reservoirs are an important long-term sink for radionuclides. In the long term, approximately 99% of the radiocesium in a lake is typically found in the bed sediment. In Lake Kozhanovskoe, Russia, approximately 90% of the radiostrontium was found in the bed sediments during 1993–1994.[4]

RADIONUCLIDES IN FISH

Bio-accumulation of radionuclides (particularly radiocesium) in fish resulted in activity concentrations (both in Western Europe and in the former Soviet Union, fSU), which were in many cases significantly above guideline maximum levels for consumption (guideline levels vary from country to country but are approximately 1000 Bq kg^{-1} or 1 kBq kg^{-1} in the EU).

In the Chernobyl Cooling Pond, ^{137}Cs levels in carp (*Cyprinus carpio*), silver bream (*Blicca bjoerkna*), perch (*Perca fluviatilis*), and pike (*Esox lucius*) were of order 100 kBq kg^{-1} w.w. in 1986, declining to a

Fig. 1 Pripyat–Dnieper river–reservoir system showing Chernobyl and Kiev with the Kiev Reservoir in between. *Source*: From Ref.[1].

few tens of $kBq\,kg^{-1}$ in 1990.[5,6] In the Kiev Reservoir, activity concentrations in fish were in the range 0.6–1.6 $kBq\,kg^{-1}$ wet weight (in 1987) and 0.2–0.8 $kBq\,kg^{-1}$ w.w. (from 1990 to 1995) for adult non-predatory fish and 1–7 $kBq\,kg^{-1}$ (in 1987) and 0.2–1.2 $kBq\,kg^{-1}$ (from 1990 to 1995) for predatory fish species. In small lakes in Belarus and the Bryansk region of Russia, activity concentrations in a number of fish species varied within the range 0.1–60 $kBq.\,kg^{-1}$ w.w. during the period 1990–1992.[7,8] It was estimated that about 14,000 lakes in Sweden had fish with ^{137}Cs concentrations above 1500 $Bq\,kg^{-1}$ (the Swedish guideline value) in 1987.[9] In a small lake in Germany, levels in pike were up to 5 $kBq\,kg^{-1}$ shortly after the Chernobyl accident[10] (Fig. 2). In Devoke Water in the English Lake District, perch and brown trout (*Salmo trutta*)

Table 1 Radionuclide levels (dissolved phase) in the R. Pripyat at Chernobyl

RN	Half-life	Guideline limit ($Bq\,L^{-1}$)	Radionuclide concentration in water ($Bq\,L^{-1}$)			
			01/05/86	02/05/86	9/8/86	1987
^{137}Cs	30.2 yr	100	250	555		1.8
^{134}Cs	2.1 yr	90	130	289[1]		0.94[1]
^{131}I	8.1 day	20	2100	4440		0
^{90}Sr	28 yr	50	30			1.5
^{140}Ba	12.8 day		1400			
^{99}Mo	3 day		670			
^{103}Ru	40 day	800	550	814		
^{106}Ru	365 day	80	183	271		
^{144}Ce	284 day		380			
^{141}Ce	33 day		400			
^{95}Zr	65 day		400	1554		
^{95}Nb	35 day		420			
^{241}Pu	13 yr	300	33		0.6	
$^{239+240}Pu$	2.4×10^4 yr 6.6×10^3 yr	7	0.4		0.0074	

The guideline limit is the UK Generalised Derived Limit for drinking water and shows the level of each radionuclide, which would result in a 1 mSv dose to consumers. The accident occurred on April 26, 1986 and radionuclides continued to be emitted for a 10 day period. *Source*: From Ref.[5,20–23].

contained around $1\,kBq\,kg^{-1}$ in 1988 declining slowly to a few hundreds of Bequerels per kg in 1993.[11,12]

The contamination of fish following the Chernobyl accident was a cause for concern in the short term (months) for less contaminated areas (for example, parts of the UK and Germany) and in the long term (years–decades) in the Chernobyl affected areas of Ukraine, Belarus, and Russia and parts of Scandinavia.

RADIONUCLIDES IN GROUNDWATER AND IRRIGATION WATER

Transfers of radionuclides to groundwaters have occurred from waste disposal sites in the 30 km exclusion zone around Chernobyl. Health risks from groundwaters to hypothetical residents of these areas, however, were shown to be low in comparison with external radiation and internal doses from foodstuffs.[13] Although there is a potential for off-site (i.e. out of the 30-km zone) transfer of radionuclides from the disposal sites, these workers concluded that this will not be significant in comparison with washout of surface deposited radioactivity.

Radionuclides could potentially contaminate groundwater by migration of radioactivity deposited on the surface soils. It is known, however, that long-lived radionuclides such as ^{137}Cs and ^{90}Sr are relatively immobile in surface soils and transfers from surface fallout to deep groundwaters are expected to be very low in comparison with transfers from surface runoff to rivers and lakes. After fallout from nuclear weapons testing in the 1960s, it was observed that ^{90}Sr in Danish groundwater was approximately 10 times lower than in surface streams.[14] These authors also observed that after Chernobyl, despite measurable quantities of ^{137}Cs in surface streams, activity concentrations were below detection limits in groundwater. Short-lived radionuclides are not expected to affect groundwater supplies since groundwater residence times are much longer than their physical decay time.

Even in the Chernobyl exclusion zone, the groundwater contamination has not occurred on a large scale. In the majority of cases, significant contamination of the groundwater took place locally only as a result of local dispersion of radionuclides from the shallow underground radioactive storage facilities and from the temporary waste disposal sites. Because of retardation, there was a very low rate of transport through geological media. According to a number of studies, radionuclide groundwater fluxes did not pose a significant risk of secondary contamination of the surface water in the Pripyat River (and will not do so in the future), because of the high efficiency of natural attenuation factors in the area around Chernobyl.

A large amount (about 1.8 million hectares) of agricultural land in the lower Dnieper basin is irrigated. Accumulation of radionuclides in plants on irrigated fields can take place because of root uptake of radionuclides introduced with irrigation water and owing to direct incorporation through leaves after sprinkling.

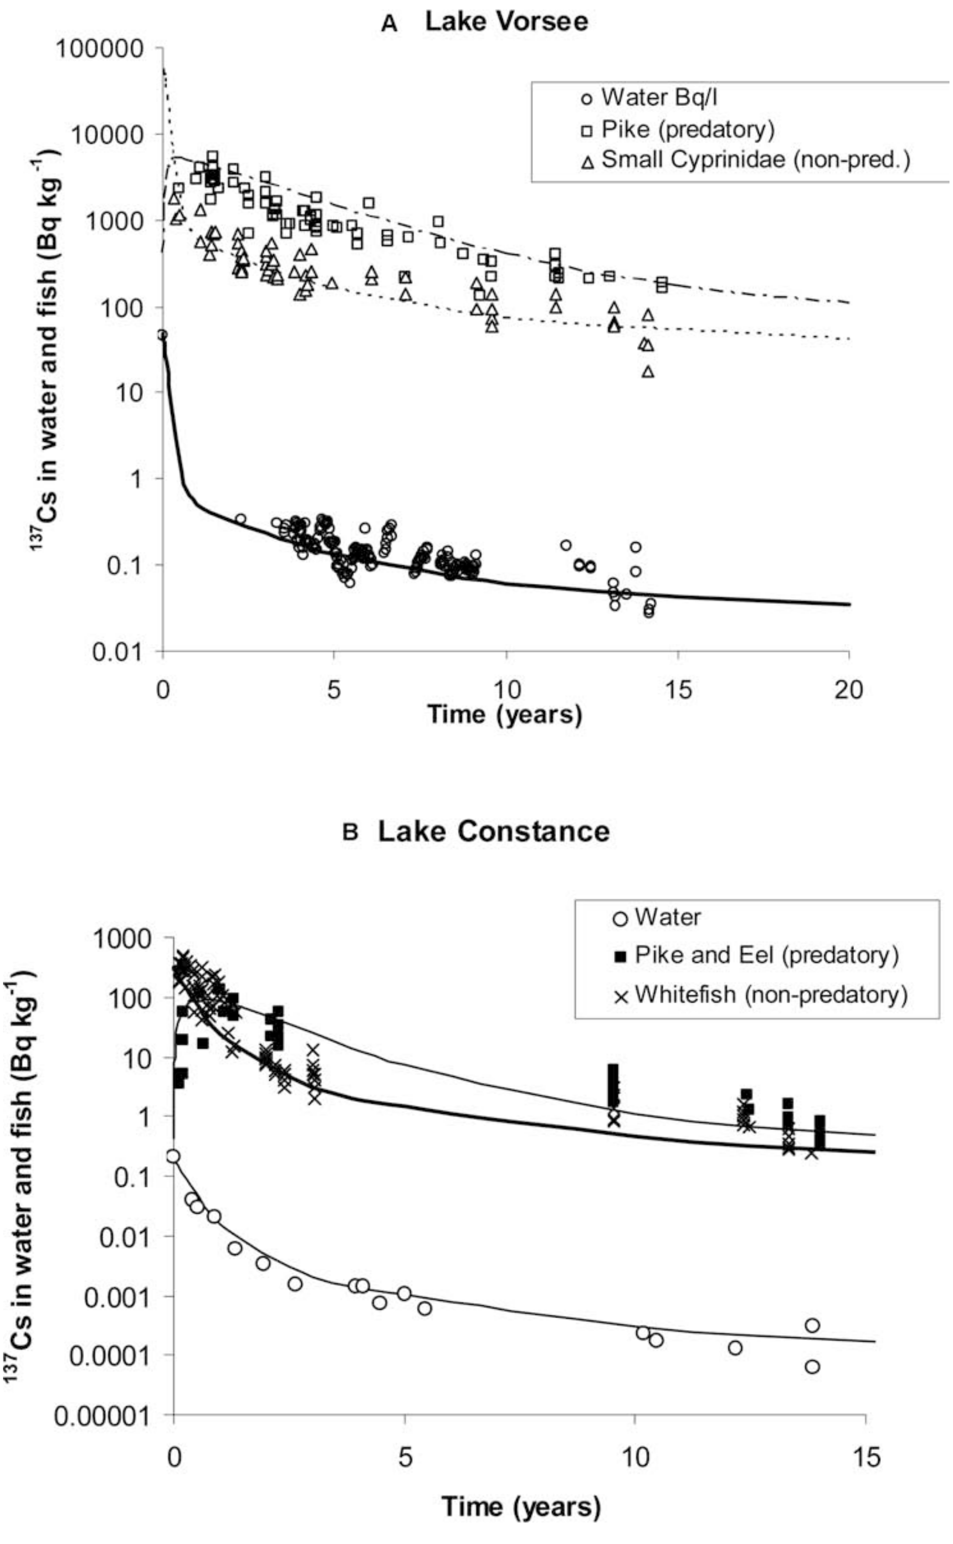

Fig. 2 Change in the ^{137}Cs activity concentration in water and fish of (A) a small shallow lake in Germany, Lake Vorsee, and (B) the large, deep Lake Constance. *Source*: Adapted From Ref.[10,19] using data kindly supplied by Gregor Zibold, Fachhochschule Weingarten, Germany.

However, recent studies[3] have shown that in the case of irrigated lands of southern Ukraine, radioactivity in irrigation water did not add significant radioactivity to crops in comparison with that which had been initially deposited in atmospheric fallout and subsequently taken up in situ from the soil.

RADIATION EXPOSURES VIA THE AQUATIC PATHWAY

Doses from ^{137}Cs and ^{90}Sr contamination of water-bodies in the most affected countries (Ukraine, Russia, and Belarus) are difficult to quantify. Doses from the freshwater pathway (including fish and irrigation water) to the people of Kiev were relatively low, being around 2–5% of doses via terrestrial foodstuffs in the most contaminated areas and up to 10% of terrestrial doses in relatively much less contaminated downstream areas of the Dnieper.[3,15] Radionuclides in the Pripyat River could potentially have led to significant doses in the first months after the accident through consumption of drinking water (Table 1). It is quite likely, though, that there was significant reduction in activity concentrations within the water supply system, so these doses are most likely to be over-estimates. Measures taken to reduce radioactivity in drinking water and fish are reviewed in Refs.[3,16].

In rural parts of the Chernobyl contaminated areas of the former Soviet Union during 1994–1995, it was found that the so-called "wild foods" (mushrooms, berries, freshwater fish, game animals) had radiocesium contents, which were around one order of magnitude higher than agricultural products (e.g., milk or meat). Whole body monitoring of people living close to Lake Kozhanovskoe, Bryansk, showed[17] that ^{137}Cs intake by the population was strongly correlated with levels of consumption of freshwater fish. In rare situations like this, where people consume fish from the (few) highly contaminated "closed" lakes, the ingestion dose can be dominated by ^{137}Cs from fish.

In Western Europe, consumption of freshwater fish does not form an important part of the diet, but sports and commercial fisheries may be of economic importance in some areas. In Norway, where fallout levels were among the highest in Western Europe, consumption of freshwater fish declined by up to 50% in the more contaminated areas, and the sale of freshwater fish to the general public was prohibited in these areas.[18] These authors also reported that the sale of fishing licences in parts of Norway declined by 25% after Chernobyl.

CONCLUSIONS

The Chernobyl accident had a major impact on water bodies in Ukraine. Though, in the long term, contamination of surface water systems was generally below drinking water limits, major remediation works had to be put in place to demonstrate that water supplies were being protected. Bio-accumulation of radiocesium in freshwater fish meant that guideline levels were exceeded in areas close to Chernobyl and in some parts of Western Europe.

INTRODUCTION

The Chesapeake Bay is the largest estuary within the U.S.A.[1] Fresh water flows to the Chesapeake Bay from a watershed that covers an estimated 166,709 km^2, including portions of Delaware, Maryland, New York, Pennsylvania, Virginia, Washington, DC, and West Virginia (Fig. 1). The ecological productivity of the estuary has made it an important resource for Native Americans, European immigrants, and current residents in the region.[2] The population in the contributing watershed in recent years has swelled to over 15 million people, resulting in extensive direct and indirect impacts that are now a focus of a large-scale restoration effort led by the US Environmental Protection Agency.[1]

DISCUSSION

Located along the Mid-Atlantic coast of the U.S.A. within the limits of Maryland and Virginia, the Bay is approximately 304-km long, has an estimated surface area of 11,603 km^2, a width that ranges from 5.5 to 56 km, and an average depth of approximately 6.4 m.[1] Salinity in the tidal portions of the estuary transition from "fresh" conditions (i.e., 0–5 parts per thousand (ppt) salt concentration) at the northernmost end to "marine" conditions (30–35 ppt salt concentration) at the southern boundary with the Atlantic Ocean.

Evidence indicates that the modern Chesapeake Bay began forming approximately 35 million years ago with a meteorite impact in the proximity of what is now the confluence of the Bay with the Atlantic Ocean.[2,3] The impact created a topographic depression that influenced the location and alignments of several large river valleys, including those associated with the present day Susquehanna, Rappahannock, and James Rivers. Since then, the river valleys have been periodically exposed and flooded in response to cycles of global glaciation and associated fluctuations in sea level. The most recent, the Wisconsin glaciation, began retreating approximately 18,000 years ago. The retreat resulted in a rise in sea level by almost ninety meters, drowning the river valleys and forming the current Bay.

Eleven large rivers drain the Bay's watershed, the Susquehanna River from Pennsylvania and New York providing the largest contribution with an average of 98 million m^3/day flowing into the northern end of the estuary. The rivers drain one or more of five different physiographic provinces within the watershed, including the Appalachian Plateau, Ridge and Valley, Blue Ridge, Piedmont, and Coastal Plain (Fig. 1).[4] Each province's geologic composition and history creates dramatically different landscape settings from the western to eastern sides of the drainage basin. The Appalachian, Ridge and Valley, and Blue Ridge are characterized by mountainous terrain, a dominance of sandstone along ridge tops, and several carbonate valleys. The Piedmont has less relief, is dominated by metamorphic rocks, and is characterized by a surface that has been dissected by dendritic stream channel networks. Further to the east, the Coastal Plain is characterized by thick layers of unconsolidated geologic materials overlying bedrock deep beneath the surface. Waterways that flow from the Piedmont into the Coastal Plain traverse the "Fall Zone," a region that is easily distinguished by waterfalls coincident with an abrupt drop in the underlying bedrock elevations. Major ports and cities were developed along the Fall Zone, including Washington, DC, Baltimore, Maryland, and Richmond, Virginia, because of their locations at the upstream terminus of navigation from tidal waters and proximity to hydropower sources.

The Chesapeake Bay estuary is naturally dynamic and characterized by physical conditions that can be stressful to aquatic organisms. The salinity gradient broadly governs the spatial distribution of aquatic habitat types. Alterations in currents, wind, and freshwater inputs can cause salinity conditions to vary over time. The shallow depths also cause colder winter and warmer summer water temperatures compared to the open ocean. These spatial and temporal fluctuations can create physiologically challenging conditions. However, many organisms have adapted and use the abundant nutrients and physical habitat in different

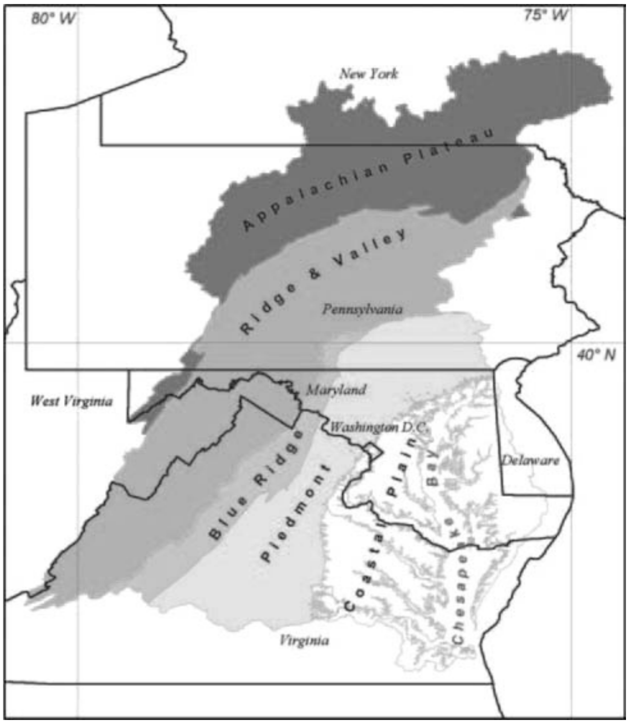

Fig. 1 The Chesapeake Bay estuary and its watershed, including physiographic provinces and state boundaries. (Courtesy of M. Herrmann, Maryland Department of Natural Resources.)

portions of the estuary for specific periods of their life cycles or seasons of the year. As a result, the Bay supports an estimated 3600 species of plants, fish, and animals, including 348 finfish and 173 shellfish species. Some of the most notable of these include striped bass, American shad, blueback herring, blue crab, and the American oyster.[5] The name "Chesapeake" itself was coined from the Algonquin American–Indian word "Chesepiooc" meaning "great shellfish bay."[5]

Archaeologists estimate that Native American inhabitants first arrived in the Bay region from the south or west approximately 12,000 years ago as the ice sheets associated with the Wisconsin glaciation began to retreat and temperatures increased.[2] The first inhabitants are presumed to have been nomadic; however, archeological evidence suggests that selective food production started as early as 5000 years ago and settled towns began to be formed approximately 1300 years ago as the population density in the region increased. Recovered artifacts provide evidence of the extensive use of the Bay by the early inhabitants for travel, communication, tools, and food.

The first recorded European contact with the Chesapeake Bay region was by the Italian captain, Giovanni da Verrazano in 1524.[2] The English established one of the most well known early settlements at Jamestown, Virginia in 1607. English colonization expanded through expeditions to the north in the Bay, partly led by the famed Captain John Smith. Immigration to the region increased throughout the 1600s and much of the area was settled by the mid-1700s. The colonists made extensive use of the resources provided by the estuary, its wetlands, and tributaries. Shellfish, including oysters, blue crabs, and hard and soft clams, were harvested from shallow water areas.[2] The numerous piles of oyster shells that can be found near Coastal Plain tidal areas provide support for written claims of the extensive oyster beds that existed in the Bay when the European colonists arrived. Traps and nets were used to harvest finfish, including herring, striped bass, and shad. Migratory waterfowl, such as ducks and geese, were also plentiful food sources.

The rapid growth in the human population since European colonization of the Chesapeake Bay region dramatically increased the harvest of finfish, shellfish, waterfowl, and mammals naturally supported by the estuary. Extensive landscape alterations also caused direct and indirect physical changes to the Bay and its tributaries. The combination of overharvesting, pollution, and physical alterations has severely impacted the ecosystem and many of the species that historically flourished in the estuary.[1] Dramatic declines have been documented by the harvest records of popular commercial fisheries such as shad and striped bass. Records indicate a decline in the catch of blue crabs per unit of effort since the 1940s. The oyster harvest is currently at less than 1% of historic levels, although this reduction is partly attributed to disease. Many other species not harvested commercially have also been affected by the alterations in the Bay ecology that have accompanied European settlement and population growth.

One of the most important impacts to the Chesapeake Bay has been the increased erosion rates and downstream sedimentation caused by extensive deforestation of the watershed.[6] The influx of sediment into the tidal estuary has reduced the water depths in many embayments that once served as navigable ports.[7] Elevated suspended sediment inputs during storm events also increase turbidity in the tidal water column.[6] The resulting decrease in water clarity, which has been exacerbated by algal blooms associated with nutrient runoff pollution, reduces submerged aquatic vegetation (SAV) growth in shallow areas (i.e., depths less than 2 m). SAV coverage on the Bay bottom is estimated to have declined from approximately 80,900 hectares in 1937 to 15,400 hectares in 1984.[1] The loss has negative implications for a variety of species that use the vegetation for habitat, including blue crabs and juvenile finfish.

An extensive effort to restore the Bay has been undertaken by the US federal government in coordination with states in the watershed.[1,8] A large part of this effort has been focused on the recovery of the historic SAV distributions, as well as reversal of the abnormally low oxygen levels that now occur in the main stem of the Bay and its major tidal tributaries during summer months.[1,9] As with the water clarity problems, the low dissolved oxygen is related to excess nutrient inputs, mainly nitrogen and phosphorous, which stimulate algal production. The oxygen depletion occurs because of algal decomposition, resulting in, estuarine habitat degradation. Substantial reductions in nutrients from watershed runoff have been concluded to be necessary to achieve restoration goals related to both SAV and low dissolved oxygen.[1,9]

CONCLUSIONS

The Chesapeake Bay is a large and historically productive estuary on the Mid-Atlantic coast of the U.S.A., with extensive fisheries and wildlife resources. The Bay ecosystem has been impaired by watershed alterations and overharvesting accompanying human population growth in the region, thereby inspiring an extensive government-supported restoration effort. A large part of the restoration focuses on sediment and nutrient pollution associated with runoff from the contributing watershed.

Chromium

Bruce R. James
Natural Resource Sciences, University of Maryland,
College Park, Maryland, U.S.A.

Chemical–
Desalination

INTRODUCTION

Chromium is a heavy metal that is essential for human health in its trivalent form [Cr(III)], but may cause cancer if inhaled in the hexavalent state [Cr(VI)]. Trivalent Cr is only sparingly-soluble in neutral to alkaline natural waters, but it can be oxidized to Cr(VI) by manganese (III,IV) (hydr)oxides, hydrogen peroxide, ozone, chlorine gas, hypochlorite, and other electron acceptors. Hexavalent Cr can be reduced to Cr(III) by elemental iron and iron(II), sulfides, easily-oxidized organic compounds, and other electron donors. Both oxidation and reduction reactions of chromium are governed by redox potential (Eh) and acidity of natural waters (pH).

OCCURRENCE OF CHROMIUM IN NATURAL WATERS AND WATER SUPPLIES

Concerns surrounding the presence of chromium (Cr) in natural waters and drinking water supplies must address a paradox of this heavy metal related to the contrasting solubilities and toxicities of its common oxidation states in natural environments: Cr(III) and Cr(VI). Chromium(III) is essential for human health in trace amounts as an activator of insulin,[1] but it exists predominantly in nature in cationic forms that are typically only sparingly-soluble in near-neutral pH soils, plants, cells, and natural waters.[2] In contrast, Cr(VI) is anionic and much more soluble than Cr(III) over the pH range of natural systems. It is toxic to many cells, is classified by USEPA as a Class A carcinogen by inhalation, and is a regulated contaminant of drinking water supplies.[3] When soluble Cr is detected in natural waters, especially at high concentrations, it is usually Cr(VI) derived from industrial wastes containing Cr(VI) or possibly resulting from the oxidation of certain forms of Cr(III) in soils or sediments.[4,5]

The balance of the different forms and the solubilities of Cr(III) and Cr(VI) in natural waters is governed by pH, aeration status (Eh or oxidation–reduction potential), and other environmental conditions (Table 1). Understanding and predicting the oxidation state, solubility, mobility, and bioavailability of Cr in water are further complicated by the fact that Cr(III) can be oxidized (lose three electrons) to form Cr(VI); whereas Cr(VI) can gain three electrons and be reduced to Cr(III).[6,7] Natural variation and human-induced changes in pH and the oxidation–reduction status of soil and water can control the solubility of Cr. As a result, purification of drinking water supplies and treatment of waste waters contaminated with Cr are possible through chemical and microbiological processes that modify the acidity and the relative abundance of oxidizing and reducing agents for Cr.[8,9]

Chromium is the seventh most abundant metal on earth with an average content of 100 mg/kg in the earth's crust and 3700 mg/kg for the earth as a whole,[10] principally as Cr(III) in unreactive, insoluble minerals, such as chromite ($FeO{\cdot}Cr_2O_3$). Roasting chromite ore under alkaline, high temperature conditions oxidizes Cr_2O_3 to soluble Cr(VI), a widely-used starting material for production of stainless steel, pressure-treated lumber, chrome-tanned leather, pigments, chrome-plated metals, and other common products used in modern societies.[11] As a result, Cr(VI) remaining in chromite ore processing residue, chrome plating bath waste, paint aerosols, and other industrial wastes may enrich soils and contaminate surface waters and groundwater that are supplies for domestic uses, irrigation, and industrial processes.

In contrast to these concentrated, anthropogenic sources of Cr(VI); naturally-occurring sources of Cr are predominantly Cr(III) and occur at low concentrations. Ultramafic and basaltic rocks (and soils developed from these parent materials), however, may contain up to 2400 mg Cr/kg, and can release small fractions of the Cr contained in them as Cr(VI), either through dissolution of Cr(VI) minerals or possibly via oxidation of Cr(III). As a result, Cr(VI) has been detected in groundwater ($<$0.05–0.5 mg/L) in arid regions dominated by these alkaline, Cr-rich rocks and soils. A concentration of Cr(VI) of 7.5 mg/L in pH 12.5 groundwater from Jordan is the highest known level that is not due to human influence. Naturally-occurring Cr in alkaline, aerobic ocean water exists

Table 1 Oxidation states and forms of chromium in natural waters

Oxidation state	Form	Name	Chemical conditions of water under which it is found and pertinent reactions in natural waters
Chromium (III) (trivalent chromium)	$Cr(H_2O)_6^{3+}$	Hexaquochromium(III)	pH $<$ 3.5; strong affinity for negatively-charged ions (e.g., phosphate) and colloid surfaces (e.g., living cells and phyllosilicate clays or fulvic and humic acids); green color
	$Cr(H_2O)_5OH^{2+}$	Monohydroxychromium(III)	First hydrolysis product formed at pH $>$ 3.5 upon dilution of or addition of base to solutions of Cr(III); green
	$Cr(H_2O)_4(OH)_2^+$	Dihydroxychromium(III)	Second hydrolysis product of Cr(III); may dimerize and polymerize to form large molecular weight cations in planes of octahedra; green
	$Cr(H_2O)_3(OH)_3^0$	Chromium hydroxide	Metastable, uncharged hydrolysis product that precipitates as the sparingly-soluble $Cr(OH)_3$
	$Cr(H_2O)_2(OH)_4^-$	Hydroxochromate	Fourth hydrolysis product of Cr(III) that may form at pH $>$ 11; may oxidize to Cr(VI) by O_2
	Cr(III)–organic acid complexes and chelates	For example: chromium citrate, chromium picolinate, chromium fulvate	Soluble complexes and chelates in which water molecules of hydration surrounding $Cr(H_2O)_6^{3+}$ are displaced by carboxylic acid and N-containing ligands; formation is pH- and concentration-dependent; blue–green–purple colors, depending on ligand binding Cr(III)
Chromium (VI) (hexavalent chromium)	H_2CrO_4	Chromic acid	Fully-protonated form of Cr(VI) formed at pH $<$ 1; see Fig. 2 for key Eh values for redox
	$HCrO_4^-$	Bichromate	Form of Cr(VI) that predominates at 1 $<$ pH $<$ 6.4; yellow; see Fig. 2 for key Eh values for redox
	CrO_4^{2-}	Chromate	Form of Cr(VI) that predominates at pH $>$ 6.4; yellow; see Fig. 2 for key Eh values for redox
	$Cr_2O_7^{2-}$	Dichromate	Form of Cr(VI) that predominates at pH $<$ 3 and in concentrated solutions ($>$1.0 mM); rapidly reverts to $HCrO_4^-$ or CrO_4^{2-} upon dilution or pH change; orange

principally as Cr(VI) at concentrations in the range of 3–7.3 nM (0.16–0.38 μg/L).[12]

Based on the known carcinogenicity of Cr(VI) to humans by inhalation, and due to uncertainty about its long-term effects on human health via ingestion in drinking water, the USEPA has set a maximum contaminant level for total Cr [Cr(III)-plus-Cr(VI)] in drinking water in the United States of 100 μg/L.[3] This valence-independent standard is based on research results that showed no observed adverse effects of Cr(III) or Cr(VI) at 25,000 μg/L in drinking water given to rats, and after factoring in ''uncertainty'' and ''safety'' factors. The standard is based on total, soluble Cr (rather than Cr(VI) alone) because USEPA assumed that (a) Cr(III) is in dynamic equilibrium with Cr(VI) and could be oxidized, (b) the reduction of Cr(VI) to Cr(III) in the stomach and digestive tract is incomplete, and (c) despite the low toxicity of Cr(III), it may react with DNA in cells. The State of California has proposed the first valence-specific drinking water standard (public health goal) for Cr(VI) at 2.5 μg/L, an action based on a desire to be highly-protective of human health and drinking water quality.[13]

SOLUBILITY CONTROLS OF CHROMIUM CONCENTRATIONS IN WATER

Most inorganic compounds of Cr(III) are less soluble in water than are those of Cr(VI) because Cr(III) cations have high ionic potentials (charge-to-size ratio) and hydrolyze to form covalent bonds with OH^- ions (Table 1). When three OH^- anions surround the Cr^{3+} cation, it is particularly stable in water as the sparingly-soluble compound, $Cr(OH)_3$ (Table 2). Upon aging and dehydration, $Cr(OH)_3$ slowly converts to the more crystalline, less soluble Cr_2O_3.[12] Incorporation of Fe(III) or Fe(II) into solid phases and precipitates containing Cr(III) renders the Cr(III) less soluble, often by a factor of 1000 in the solubility product (Ksp).[14,15] In the pH range of 5.5–8, Cr(III) reaches minimum solubility in water due to this hydrolysis and precipitation

Table 2 Solubility in water at pH 7 of selected chromium compounds

Oxidation state of Cr	Compound name	Formula	Approximate solubility (moles Cr/L)
Chromium (III)	Chromium(III)hydroxide	$Cr(OH)_{3\ (am)}$	10^{-12}
	Chromium(III) oxide	$Cr_2O_{3\ (cr)}$	10^{-17}
	Chromite	$FeO{\cdot}Cr_2O_{3\ (cr)}$	10^{-20}
	Chromium chloride	$CrCl_3$	Highly soluble
	Chromium sulfate	$Cr_2(SO_4)_3$	Highly soluble
	Chromium phosphate	$CrPO_4$	10^{-10}
	Chromium fluoride	CrF_3	1.2×10^{-3}
	Chromium arsenate	$CrAsO_4$	10^{-10}
Chromium (VI)	Potassium chromate	K_2CrO_4	3.2
	Sodium chromate	Na_2CrO_4	5.4
	Calcium chromate	$CaCrO_4$	0.14
	Barium chromate	$BaCrO_4$	1.7×10^{-3}
	"Zinc yellow" pigment	$3ZnCrO_4{\cdot}K_2CrO_4{\cdot}Zn(OH)_2{\cdot}2H_2O$	8.2×10^{-3}
	Strontium chromate	$SrCrO_4$	5.9×10^{-3}
	Lead chromate	$PbCrO_4$	1.8×10^{-6}
	Chromium jarosite	$KFe_3(CrO_4)_2(OH)_{6\ (cr)}$	10^{-30}

reaction, an important process that controls the movement of Cr(III) in soils enriched with industrial waste waters and solid materials. Under strongly acidic conditions (pH < 4), unhydrolyzed $Cr(H_2O)_6^{3+}$ cations exist in solution; while $Cr(OH)_4^-$ forms under strongly alkaline conditions (pH > 11), particularly in response to adding base to solutions of soluble salts of Cr(III), e.g., $CrCl_3$, $Cr(NO_3)_3$, or $Cr_2(SO_4)_3$.

Other anions besides OH^- coordinate with $Cr(H_2O)_6^{3+}$ and displace water molecules of hydration to form sparingly-soluble compounds and soluble chelates (Table 2). In water treatment facilities and in natural waters; phosphate ($H_2PO_4^-$ HPO_4^{2-}, PO_4^{3-}), arsenate ($H_2AsO_4^-$, $HAsO_4^{2-}$, AsO_4^{3-}) and fluoride (F^-) may form low solubility compounds with Cr(III). Organic complexes of Cr(III) with carboxylic acids (RCOOH, e.g., citric, oxalic, tartaric, fulvic) remain soluble at pH values above which $Cr(OH)_3$ forms. By increasing the solubility of Cr(III) in neutral and alkaline waters, such organic complexes enhance the potential for absorption of Cr(III) by cells. Stable, insoluble complexes of Cr(III) also form with humic acids and other high molecular aggregate weight organic moieties in soils, sediments, wastes, and natural waters.[16]

With the exception of chromium jarosite (Table 2), Cr(VI) compounds are more soluble over the pH range of natural waters than are those of Cr(III); thereby leading to the greater concern about the potential mobility and bioavailability of Cr(VI) than Cr(III) in natural waters. The alkali salts of Cr(VI) are highly soluble, $CaCrO_4$ is moderately soluble, and $PbCrO_4$ and $BaCrO_4$ are only sparingly-soluble. In colloidal environments containing aluminosilicate clays and (hydr)oxides of Al(III), Fe(II,III), and Mn(III,IV) (e.g., in soils and sediments), Cr(VI) anions may be adsorbed similarly to SO_4^{2-}. Low pH and high ionic strength promote retention of $HCrO_4^-$ and CrO_4^{2-} on positively-charged sites, especially those associated with colloidal surfaces dominated by pH-dependent charge. Such electrostatic adsorption may be reversible, or the sorbed Cr(VI) species may gradually become incorporated into the structure of the mineral

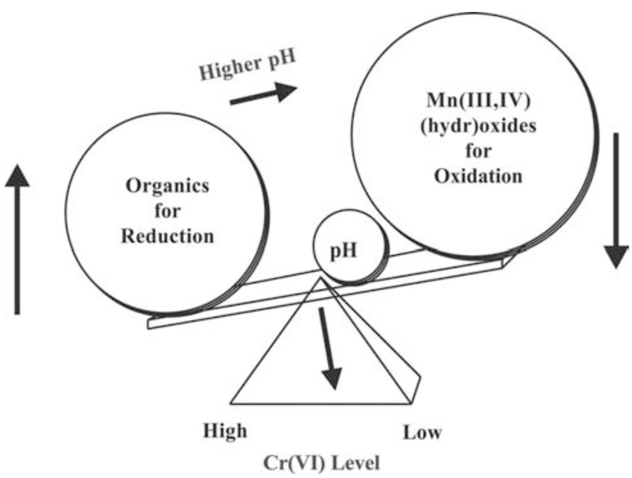

Fig. 1 Seesaw model depicting a balance of the oxidation of Cr(III) by Mn(III,IV)(hydr)oxides and the reduction of Cr(VI) by organic compounds, with the pH acting as a sliding control (master variable) on the seesaw to set the redox balance for given quantities and reactivities of oxidants and reductants. The equilibrium quantity of Cr(VI) in the water is indicated by the pointing arrow from the fulcrum.

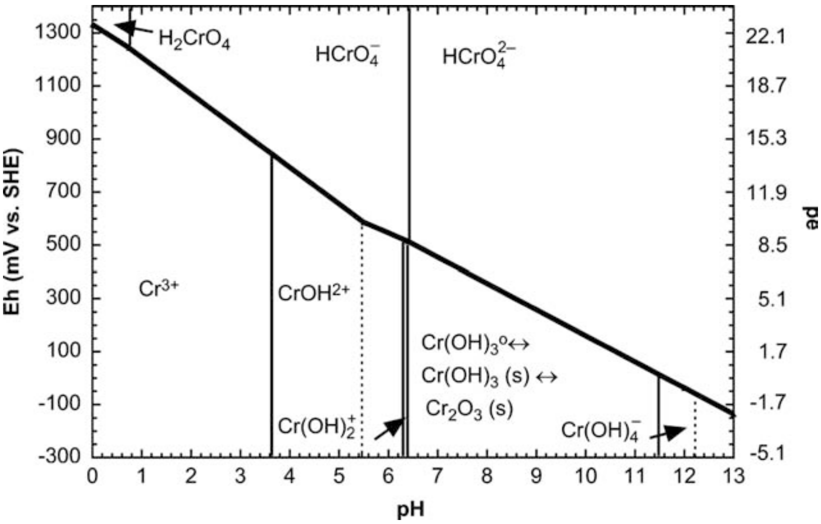

Fig. 2 Eh–pH diagram illustrating the stability fields defined by Eh (redox potential relative to the standard hydrogen electrode, SHE) and pH for Cr(VI) and Cr(III) at 10^{-4} M total Cr. The vertical dashed lines indicate semi-quantitatively the pH range in which $Cr(OH)_3$ is expected to control Cr(III) cation activities in the absence of other ligands besides OH^-.

surface (chemisorption). Recently-precipitated $Cr(OH)_3$ can adsorb Cr(VI) or incorporate Cr(VI) within its structure as it forms, thereby forming a Cr(III)–Cr(VI) compound.[17]

OXIDATION–REDUCTION CHEMISTRY OF CHROMIUM IN NATURAL WATERS

The paradox of the contrasting solubilities and toxicities of Cr(III) and Cr(VI) in natural waters and living systems is complicated by two electron transfer reactions: Cr(III) can oxidize to Cr(VI) in soils and natural waters; and Cr(VI) can reduce to Cr(III) in the same systems, and at the same time. Understanding the key electron transfer processes (redox) and predicting environmental conditions governing them are central to treatment of drinking water, waste waters, contaminated soils, and to predicting the hazard of Cr in natural systems.[18] The metaphor of a seesaw (Fig. 1) is useful in picturing the undulating nature of the changes in Cr speciation in water due to oxidation of Cr(III) and reduction of Cr(VI). A balance for the two redox reactions is achieved in accordance with the quantities and reactivities of reductants and oxidants in the system (e.g., organic matter and Mn(III,IV) (hydr)oxides), as modulated by pH as a master variable.[8]

The thermodynamics (energetics predicting the relative stability of reactants and products of a chemical reaction) of the interconversions of Cr(III) and Cr(VI) compared to other redox couples can be used to predict the predominance of Cr(III) or Cr(VI) in water supplies (Fig. 2). The Eh variable defines the predicted

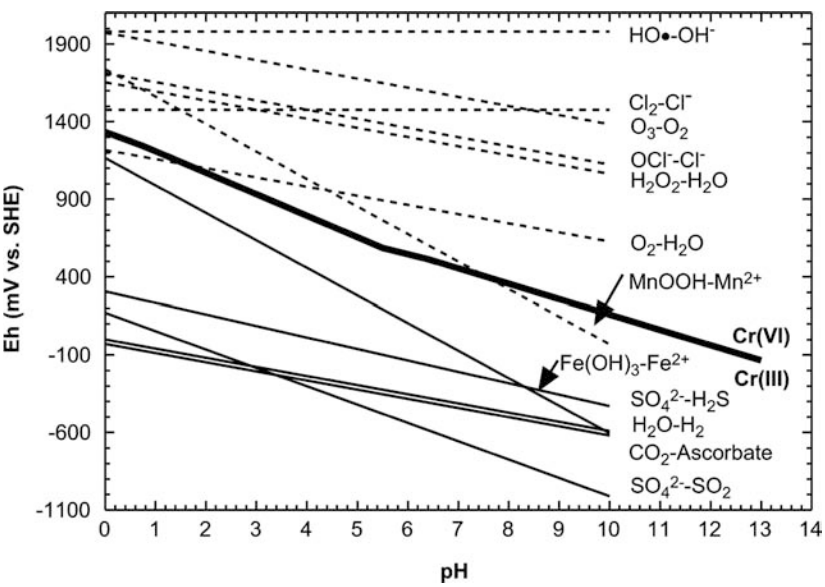

Fig. 3 Eh–pH diagram showing potential oxidants for Cr(III) in natural waters as dashed lines above the bold Cr(VI)–Cr(III) line; and potential reductants for Cr(VI) below the line. Each line for an oxidant (first species of the pair) and reductant (second species) combination represents the reduction potential (in mV) at a given pH established by that oxidant–reductant pair (e.g., O_3–O_2). The oxidant member of a pair for a higher line is expected to oxidize the reductant member of the lower line, thereby establishing the area and species between the lines as thermodynamically favored to exist at chemical equilibrium.

voltage (electron pressure) that must be applied at a given pH to reduce Cr(VI) to Cr(III), and this pressure increases (lower Eh values) as pH increases, as shown in an Eh–pH diagram (Fig. 2). Certain electron-poor species may act as oxidants (electron acceptors) for Cr(III), especially soluble forms of Cr(III), in the treatment of water supplies or in soils enriched with Cr(III) (Ref.[19], Fig. 3). Examples are those above the bold line for Cr(VI)–Cr(III) on the Eh–pH diagram: Cl_2, OCl^-, H_2O_2, O_3, and MnOOH. In contrast, electron-rich species may donate electrons to electron-poor Cr(VI) and reduce it to Cr(III): Fe^{2+} [or Fe(0)], H_2S, H_2, ascorbic acid (and organic compounds, generally), and SO_2. Sunlight may affect the kinetics of both oxidation and reduction reactions for Cr, a relevant fact for natural processes in lakes and streams and for treatment technologies for drinking water purification. Depending on pH, temperature, and the concentrations of oxidants and reductants, Cr(VI)-to-Cr(III) ratios in natural waters may be predicted.

Predictions of the likelihood of Cr(III) oxidation and Cr(VI) reduction occurring are important for water treatment and for establishing health-based regulations and allowable limits for Cr(VI) and Cr(III) in water supplies. In agricultural soil–plant–water systems, Cr(VI) added in irrigation water or formed via oxidation of Cr(III) will reduce to Cr(VI) if electron donors (e.g., Fe^{2+}, H_2S, and organic matter) and Eh–pH conditions are sufficiently reducing (Refs.[4,17] Fig. 2). If not reduced, Cr(VI) may leach from surface soils to subsoils and groundwater. Therefore, predictions of Cr bioavailability and mobility in natural waters must consider redox reactions of this heavy metal.

Conservation: Tillage and No-Tillage

Paul W. Unger
Conservation and Production Research Laboratory, Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Bushland, Texas, U.S.A.

INTRODUCTION

Conservation tillage is any tillage or tillage and planting system that results in at least a 30% cover of crop residues on the soil surface after planting the next crop.[1] It is used mainly to control soil erosion, but it also helps conserve water. In comparison, conventional tillage refers to tillage operations normally used for crop production that bury most residues and result in <30% cover after planting. Tillage that incorporates all residues into soil is clean tillage.

Tillage methods such as sweep, chisel, paraplow, subsoiling, slit, and strip rotary can usually qualify as conservation tillage. Even disk tillage may qualify, provided adequate residues are retained on the surface. The ultimate conservation tillage method is no-tillage (or zero tillage) for which the next crop is planted without any soil disturbance since harvesting the previous crop. A special planter usually is needed to prepare a narrow, shallow seedbed for the seed being planted.[1] Sometimes, no-tillage is used in combination with a subsoiling operation that facilitates crop seeding and early plant root growth, but which leaves the surface residues virtually undisturbed, except for the slot caused by the subsoiling implement.[1]

Adequate residues are not always produced to provide 30% cover [e.g., dryland (non-irrigated) crops]. Also, a crop such as cotton (*Gossypium hirsutum* L.) may not produce enough residue under some conditions to satisfy the required ground cover for conservation tillage. Under such conditions, some conventional or even clean tillage methods can provide for soil and water conservation. Any tillage method that results in a rough or ridged surface helps reduce soil erosion by wind. Listing (ridge-forming tillage) commonly is used to help control wind erosion in the cotton-producing area of West Texas where residue amounts usually are low (personal observation). Even plowing that brings erosion resistant clods to the surface helps control wind erosion on some sandy soils.[2] Any tillage method that impedes or prevents water flow across the surface helps reduce soil erosion by water and usually helps conserve water. Listing on the contour retains water on the surface, thus reducing erosion and conserving water. Furrow diking in conjunction with listing improves water retention where contour tillage is not used.[3] Graded-furrow tillage allows excess water to flow slowly from land, thus reducing the potential for erosion; it also provides water conservation benefits.[4]

ADVANTAGES AND DISADVANTAGES OF USING CONSERVATION TILLAGE AND NO-TILLAGE

Advantages

Compared with clean tillage, advantages of different conservation tillage types, including no-tillage, include improved erosion control, a cleaner environment, greater water conservation, equal or greater crop yields, less equipment and maintenance cost, lower energy and labor requirements, and greater net returns. Erosion control benefits with conservation tillage result from retaining more residues on the soil surface. For controlling erosion by wind, residues shield the surface and reduce wind speed at the surface to below the threshold required for erosion to occur. Erosion by water is reduced because residues reduce the rate and amount of water flow across the surface. Residues also result in less soil particle detachment and transport due to raindrop splash and flowing water. The value of surface cover provided by crop residues for controlling erosion by wind and water is illustrated in Fig. 1.[5]

Greater water conservation with conservation tillage results from residues retarding the rate of water flow across the surface, thus providing more time for infiltration. Residues also shield the surface against raindrop impact, thus dissipating the energy of raindrops, reducing surface sealing, and maintaining favorable infiltration rates. Residues reduce soil water evaporation by shading the soil and slowing the wind at the soil surface. Of course, the soil must have adequate storage capacity for the water to be retained for later use by crops.

Use of conservation tillage reduces erosion, thus resulting in a cleaner environment. Erosion by wind damages crops, causes health and visibility problems, clogs roads and waterways, damages machinery and homes, and pollutes the air. Erosion by water damages

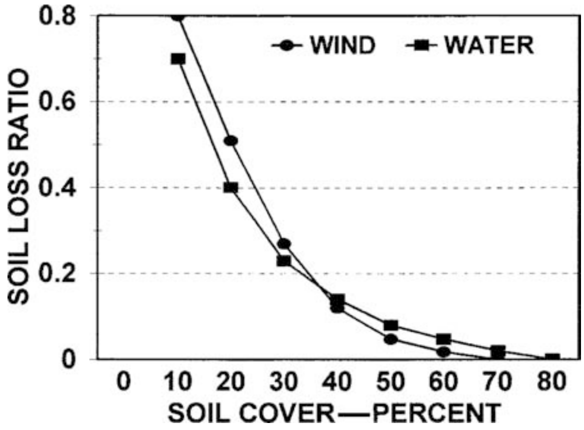

Fig. 1 Relationship between soil loss ratio (soil loss with cover divided by soil loss from bare soil). (Redrawn from Fig. 10 in Ref.[5].)

crops, roads, machinery, and homes. It also pollutes water with soil particles, chemicals adhering to the particles, and chemicals dissolved in water.

Crop yields are affected by numerous factors. Yields with conservation tillage systems often are greater than with clean tillage, provided no major problems are encountered. Yield increases, especially with no-tillage, usually are attributable to greater soil water conservation, especially in subhumid and semiarid regions without irrigation. More favorable soil temperatures may be involved also. In warm or hot regions, high soil temperatures may injure plants, and surface residues with no-tillage result in temperature decreases of up to 10°C,[6,7] which result in better crop performance. In cool regions, low temperatures with no-tillage usually are detrimental to crop yields because planting is delayed beyond the optimum date.[8]

Advantages of lower equipment inventories, equipment maintenance, and energy and labor requirements with conservation tillage are interrelated. With most conservation tillage methods, and especially no-tillage, tillage frequency and intensity are lower than with clean tillage. As a result, less equipment may be needed, smaller tractors may be satisfactory (for no-tillage), andthe tractors and equipment are used less frequently.This results in less equipment maintenance and in lower fuel and labor requirements. Some fuel energy savings, however, may be partially offset by the energy required to produce herbicides and fertilizer, especially where no-tillage is used. The no-tillage system is based on using herbicides for weed control, and more nitrogen fertilizer is used under some conditions, especially when first converting to the system.

As for yields, many factors affect net returns for a crop production system. However, if production costs are not greater and yields are equal to or exceed those with clean tillage, then net returns should be equal or greater with conservation tillage, especially with no-tillage, because equipment inventories and maintenance and labor and energy requirements are lower.[9,10]

Disadvantages

Problems with conservation tillage, especially no-tillage, occur under some conditions.[8,11–13] A greater use of herbicides results in concern regarding the potential for polluting soil and water resources. Lower soil temperatures in cool regions delay crop planting, thereby potentially reducing crop yields. On poorly drained soils, additional water retained by using no-tillage aggravates the excess soil water problem, thus generally reducing crop yields. Some weeds are difficult to control with herbicides, which, along with the high cost of some herbicides, may increase production costs. The possible need for new equipment may also increase production costs, especially when a change to a no-tillage system is first made. Because crop residues are retained on the surface when a no-tillage system is used, there is the potential for increased pest problems (insects, diseases, rodents). Problems are greater with some insects and less with others, indicating that insect populations must be closely evaluated regardless of tillage system used. Organisms of some plant diseases are carried over to the next crop when residues are retained. Surface residues also provide shelter for rodents, which may be detrimental for the production of some crops. Other possible disadvantages include limited residue availability, greater soil compaction, and a need for greater managerial ability. Certainly, conservation tillage and no-tillage are not suitable for all conditions. However, with good management, most problems (real or potential) can be minimized or avoided.

RESULTS ACHIEVED BY USING CONSERVATION OR NO-TILLAGE

The value of conservation and no-tillage farming methods for controlling erosion, conserving water, and increasing crop yields has been shown in numerous studies. Because of space limitations, however, only few examples will be given. Probably the most dramatic example regarding the value of no-tillage for controlling erosion occurred during a rainstorm on watersheds planted to corn (*Zea mays* L.) in Ohio.[14] Treatments were clean tillage with sloping rows (land slope 6.6%), clean tillage with contour rows (land slope 5.8%), and no-tillage with contour rows (land slope 20.7%). On the respective treatment areas, rainfall was 140, 140, and 129 mm; runoff was 112, 58, and 64 mm; and sediment loss was 50.7, 7.2, and 0.07 Mg ha^{-1}.

Chemical–Desalination

Even though the slope was much greater, soil loss was negligible from the no-tillage area. Runoff also was low, which provided an opportunity to store more soil water, but soil water information was not given.

After harvesting irrigated winter wheat (*Triticum aestivum* L.), moldboard-, rotary-, disk-, sweep-, and no-tillage treatments were imposed to manage the residues during the fallow period until planting dryland grain sorghum [*Sorghum bicolor* L. (Moench)] 10–11 mo later at Bushland, Texas. Weed control was similar with all treatments. Plant available soil water contents averaged 149, 143, 158, 179, and 207 mm at sorghum planting and sorghum grain yields averaged 2.56, 2.19, 2.37, 2.77, and 3.34 Mg ha^{-1} with the respective treatments. Greater water contents and yields with conservation tillage (sweep and especially no-tillage) resulted from more residues retained on the surface than with other treatments. The residues resulted in greater infiltration and lower evaporation, but the effect of the different processes could not be determined.[15]

A field study at Akron, Colorado, clearly showed the value of surface residues with conservation tillage (minimum- and no-tillage) for reducing evaporation. Soil water contents 1 day after a 13.5-mm rain were similar to the 15-cm depth where conventional-, minimum-, and no-tillage treatments were imposed after harvesting winter wheat. The treatments resulted in 1.2, 2.2, and 2.7 Mg ha^{-1} of surface residues, respectively. After 34 rainless days, the soil had dried to a $<0.1\ m^3\ m^{-3}$ water content to 12-, 9-, and 5-cm depths, respectively.[16] The value of surface residues for reducing evaporation also was shown under laboratory conditions.[17,18]

CONCLUSION

Conservation tillage and no-tillage farming systems are based on retaining sufficient crop residues on the soil surface, mainly to control erosion. Other benefits include water conservation; environmental protection; equipment, energy, and labor savings; and often greater net returns to the producer. Some disadvantages occur under some conditions and the systems, especially no-tillage, may not be suitable for all conditions. Most disadvantages, however, can be overcome or minimized by careful management.

Consumptive Water Use

Freddie L. Lamm
Research and Extension Center, Kansas State University, Colby, Kansas, U.S.A.

INTRODUCTION

Consumptive water use is defined as the total quantity of water used in a given period of time as transpiration from the crop shoots and leaves, the water evaporated from the wetted soil or crop surfaces, and the small amount of water used in the building of plant tissue. In general, less than 1% of the consumptive water use is incorporated into plant tissue (i.e., split in the light reaction of photosynthesis and then incorporated), so consumptive water use is often used synonymously with the term evapotranspiration (sum of evaporation and transpiration). The principal factors affecting the magnitude of consumptive water use are the amount and orientation of actively transpiring plant tissues, atmospheric conditions, soil-water reserves, and soil texture.

ORIGIN

The term consumptive water use apparently originated in the United States during the early part of the twentieth century[1,2] to describe water and/or irrigation requirements of crops. One of the earliest recorded documentations of the term was by the American Society of Civil Engineers in 1930.[3] Although worldwide, evapotranspiration is probably a more highly utilized term, consumptive water use is still used in the United States, particularly in federal and state management agencies and legal institutions. In European countries, evaporation is sometimes used instead of evapotranspiration in a context that covers evaporative losses from water surfaces, soil, or plants.[4]

UTILIZATION

Information about consumptive water use is utilized in the planning, development, and management of almost all water resources and supply projects, not just irrigation projects. For example, water-resource planners must have estimates of consumptive water use of forests and rangelands when determining long-term yield (runoff) from such lands in planning for reservoirs. Consumptive water use estimates are utilized in planning of wastewater-reuse systems, so that a given parcel of land is not overloaded hydraulically with water, resulting in excessive runoff or deep percolation. Government agencies often rely on estimated consumptive water use values to develop interstate river and stream compacts and to mediate disputes arising from these compacts. Legal institutions may carefully differentiate consumptive water use from the total water diverted from a resource, to determine what water is truly lost from a surface and/or ground water basin. Conversely, a legal institution might be more keenly interested in promoting crops that maximize the consumptive water use, if evapotranspiration is being utilized to clean up or reduce a contaminated water source.

The time scale for which consumptive water use is determined depends on the needs of the end-user. A modern irrigator may schedule irrigation based on hourly, daily, or weekly estimates of consumptive water use. The same irrigator, in planning for a new irrigation system, might need to extend these estimates to include monthly and seasonal estimates. In planning, irrigation system application amounts for a single irrigation event, it is good design practice to match the peak consumptive water use for the critical crop growth periods. In planning the overall irrigation system size, it is necessary to consider the consumptive water use over the entire season to ensure that sufficient seasonal water is available for the planned irrigated area. Similarly, a wastewater-reuse system operator may need to know the consumptive water use of a crop during distinct short periods of time to prevent hydraulically overloading the soil. That same operator might use annual-consumptive water use to size the wastewater-storage reservoirs and land area used for application. Hydrologists and other water-resource planners may use time scales ranging from hourly to as much as a decade, depending on their accuracy needs and the intended use of the information.

PARTITIONING OF CONSUMPTIVE WATER USE

It is difficult to make generalizations about the partitioning of consumptive water use into the major components of evaporation and transpiration. The amount of evaporation from the wetted soil and the wetted cropped surfaces depends heavily on how often those surfaces are wetted by precipitation or irrigation and the ratio of soil to crop surface. Although there is no single value that can adequately describe the evaporation fraction of consumptive water use, a seasonal value of 20% may be of sufficient accuracy in many cases. Transpiration depends more heavily on the amount of actively growing leaves and shoots, their exposure to atmospheric conditions, and the ability of the plant roots to extract water from the soil layers. Nevertheless, the partitioning of these two major components is of great importance in managing water resources.

Evaporative Component

Evaporation from soil surfaces is generally described as occurring in two or three phases, the energy-limiting stage, the rapidly-falling stage, and the slowly-falling rate stage (Fig. 1). Early work described the process as three phases.[5] It was later recognized that the latter two stages could be adequately described as one soil-limiting stage by expressing evaporation as decreasing with the square root of time.[6,7] The first stage of soil evaporation when the soil surface is wet occurs at a rate that is only limited by the energy available (atmospheric demand and latent heat in soil storage) to evaporate water. The soil-limiting stage begins when water does not diffuse to the soil surface in sufficient quantity to meet the evaporative demand of the available energy.

Direct evaporation from plant tissues encompasses water that is temporarily trapped (canopy interception storage) on the plant leaves and shoots following rainfall or sprinkler irrigation. This water may be in the form of droplets on leaves or larger amounts trapped in leaf whorls or joints between the leaf and the shoot. This evaporation generally occurs at a rate that is only limited by the amount of energy available for evaporation. However, this evaporative loss will temporarily suppress plant transpiration during the evaporation period.[8] Canopy interception storage and the resultant evaporative loss will vary with plant type and structure and with the ratio of evaporative demand to precipitation rate. On an annual basis, these evaporative losses can be a significant factor in forest hydrology, ranging from 20% to 40% for conifer forests and 10% to 20% for hardwood forests.[9] Direct evaporative losses from interception storage following a single precipitation or sprinkler irrigation event for a fully developed corn canopy is approximately 1.5–2.5 mm.[10–13]

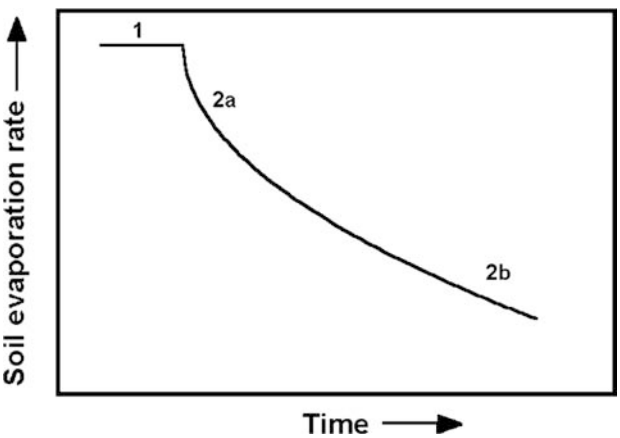

Fig. 1 Typical soil evaporation as related to time since wetting. Stage 1 is only limited by available energy. The soil limiting stages 2a (rapidly falling) and 2b (slowly falling) are a function of the square root of time since the end of stage 1.

Transpiration

The other major component of consumptive water use, transpiration, is usually larger than the evaporation component because the plant has multiple transpiring surfaces exposed to the atmospheric demand, and the plant roots and stem can also transport water from deeper soil layers to the transpiring crop surfaces. Attempts to directly measure transpiration also have their limitations, similar to difficulties with measuring the evaporative component. These attempts include measurements of plant water use from large pots,[14,15] alternate lysimeter comparisons,[16,8] using portable translucent field chambers in the field,[17] measuring water flowrate in plant stems,[18] modeling of evaporation and transpiration processes,[19,20] and algebraic manipulations of the E and T components using a combination of measurement methods that partially define a given component.

MODELING OF CONSUMPTIVE WATER USE

Although the various evaporation and transpiration processes have been studied for centuries,[21] Penman[22] is often credited with the pioneering research in establishing a modern physical basis for modeling evaporation and transpiration. Even recent efforts to encourage adoption of a more standardized method of calculating evapotranspiration[23,24] use the basic framework outlined by Penman. Because crop type, size, and leaf orientation all can affect evapotranspiration, the term reference evapotranspiration is often used to express evapotranspiration based on atmospheric demand for a given reference crop under specific growth conditions. A modern equation to calculate reference evapotranspiration gaining credibility

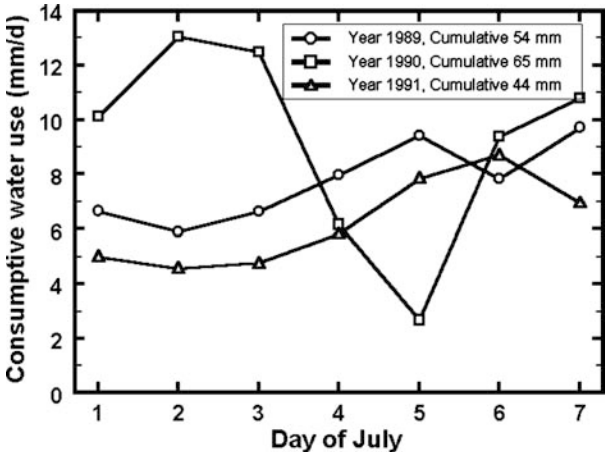

Fig. 2 Variation in consumptive water use of corn (*Zea mays* L.) over a 7-day period in July for the years 1989–1991 at Colby, Kansas. Note that cumulative consumptive water use amounts for the three years varied from 44 mm to 65 mm for the 7-day period.

and acceptance is referred to as the FAO-56 Penman–Monteith equation.[23] Major atmospheric variables in this equation are net radiation, air temperature, wind speed, and the saturation vapor pressure deficit. Soil heat flux is another variable in the equation, but can sometimes be neglected, depending on the time step of the calculation. Crop and soil coefficients are then used to modify the reference evapotranspiration to determine the consumptive water use for the period of interest. Crop coefficients generally vary with crop and stage of growth and often are empirically derived or calibrated for a given locale. Soil coefficients are used to decrease the calculated consumptive water use when soil water redistribution begins limiting water transport to the transpiring surfaces.

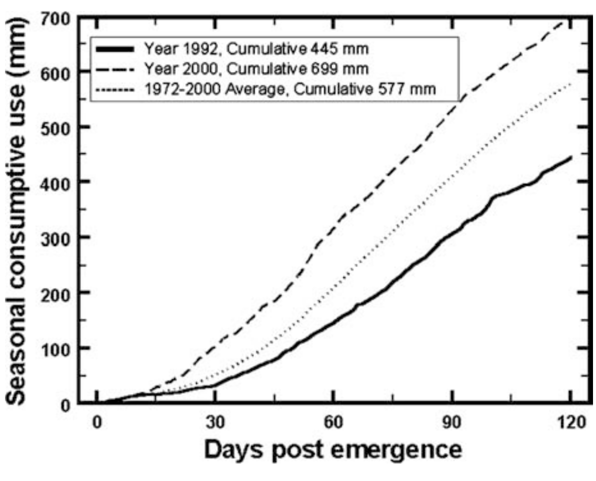

Fig. 3 Variation in seasonal consumptive water use of corn (*Zea mays* L.) at Colby, Kansas between an extremely cool, damp year (1992) and an extremely hot, dry year (2000) as compared to the long term-average value.

In some regions of the world, consumptive water use may not vary much on a daily or annual basis. In other areas, such as the U.S. Great Plains, moving atmospheric fronts may drastically change values from one day to the next (Fig. 2) and general climatic conditions may result in large cumulative differences between years (Fig. 3). These temporal variations emphasize that using historical averages for consumptive water use may have limited value in some regions for accurate short-term forecasting or irrigation scheduling.

Crop Coefficients

Richard G. Allen
Research and Extension Center, University of Idaho, Kimberly, Idaho, U.S.A.

INTRODUCTION

Crops and vegetation on the earth's surface vary in height, amount of leaf area, amount of soil shaded, color, amount of stomatal control to evaporation, and amount of soil wetness beneath the canopy. All of these factors affect, to some degree, the amount of evapotranspiration (ET) from the crop or vegetation. Rather than assigning parameters for all of these terms during the process of predicting ET from a specific type of vegetation using an ET equation, as covered in the entry on Evapotranspiration Formulas, the impacts of these variables are often lumped into a single parameter, termed the crop coefficient, K_c. This approach is done to reduce the complexity and time requirement for predicting ET for each type of crop or vegetation, and relies upon a common "reference ET" for a defined type of reference vegetation to represent the change in ET caused by variation in weather parameters. K_c is defined as the ratio of ET from a crop or soil surface to ET from the reference surface. Reference ET is the ET from a fully vegetated surface covering the soil, and normally represents ET from clipped grass (termed ET_o) or alfalfa (termed ET_r).

OVERVIEW

In general, four primary characteristics distinguish crop ET from reference ET: 1) crop cover density and total leaf area; 2) resistance of foliage epidermis and soil surface to the flow of water vapor; 3) aerodynamic roughness of the crop canopy; and 4) reflectance of the crop and soil surface to short wave radiation.

When the K_c is known, crop ET (ET_c) is calculated for a specific time period as:

$$ET_c = K_{co}ET_o \text{ and } ET_c = K_{cr}ET_r \quad (1)$$

where K_{co} is the K_c for the grass ET_o basis and K_{cr} is the K_c for the alfalfa ET_r basis. Because reference ET represents nearly all effects of weather, K_c varies predominately with specific crop characteristics and only a small amount with climate. This enables the transfer of standard values and curves for K_c between locations and climates. This transfer has led to the widespread acceptance and usefulness of the K_c approach. K_c has been primarily developed and applied to agricultural situations. However, K_c is generally valid for natural vegetation and conditions including open water, although it can have large spatial variability. In situations where K_c has not been derived by ET measurement, it can be estimated from fraction of ground cover or leaf area index (LAI), using procedures in Refs.[1,2].

K_c varies during the growing season as: the plants develop, the fraction of ground covered by vegetation changes, and the plants age and mature (Fig. 1). K_c varies according to the wetness of the soil surface, especially when there is little vegetation cover. Under bare soil conditions, K_c has a high value when soil is wet and its value steadily decreases as the soil dries (Fig. 2).

CROP COEFFICIENT CURVES

Two different approaches are used to calculate K_c. The simpler approach uses a single K_c curve that represents time-averaged effects of evaporation from the soil surface. The result is a relatively smooth, consistently increasing or decreasing K_c curve (Fig. 2). The second K_c approach separates the K_c into two coefficients, with one coefficient, the basal crop coefficient, termed K_{cb}, representing K_c for a dry soil surface (with or without vegetation) having little evaporation but full transpiration. The second coefficient, the evaporation coefficient, K_e, represents the evaporation component from the soil surface (Fig. 2). The value for K_e changes daily as the soil surface wets or dries, whereas the value for K_{cb} is more consistent day-to-day:

$$K_c = K_s K_{cb} + K_e \quad (2)$$

where K_s [0–1] represents the reduction in K_c due to environmental stresses, primarily from soil water shortage or soil salinity. All four terms are dimensionless. In application of the dual $K_{cb} + K_e$ procedure, a daily calculation must be made to estimate water content and associated evaporation rate from the soil surface, so that the approach is relatively computationally intensive. However, estimates can be up to 50% more accurate for any particular day, as compared with the single K_c approach, especially for the first few days following soil wetting during initial and development

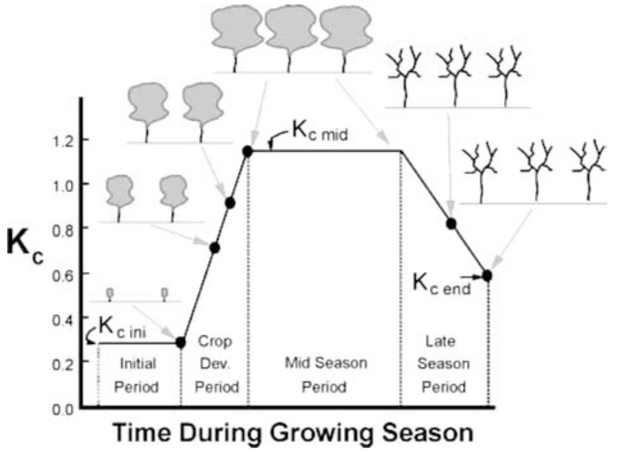

Fig. 1 General K_c curve showing relationship between stage of growth and K_c. *Source*: After Ref.[1].

periods. The dual procedure is applied on a daily time-step and is readily adapted to spreadsheet programs.

Time-averaged (single) K_c is used for planning studies and irrigation or water resources systems design where averaged effects of soil wetting are appropriate. The dual K_c approach is better for irrigation scheduling, soil water balance computations, and research where specific effects of day-to-day variation in soil wetness are important.

K_c (or K_{cb}) changes during a growing season, reflecting changes in the vegetation and ground cover. Initially, K_c is small, generally between 0.1 and 0.4, and K_{cb} is between 0.0 and 0.2. K_c increases during the period of rapid plant growth until it reaches a maximum value at the time of near maximum ground cover. Towards the end of the growing cycle, K_c decreases as plants age, ripen, or die due to natural or cultural practices.

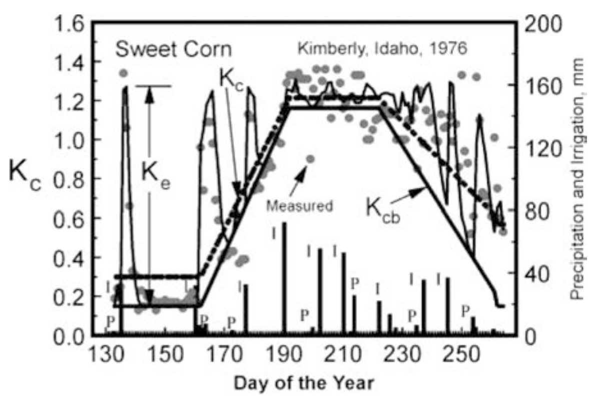

Fig. 2 Basal K_{cb}, soil evaporation coefficient K_e, and time-averaged (single) K_c (dotted line) curves for a crop of sweet corn grown near Kimberly, Idaho during 1976. Also shown are actual measurements of K_c (dots) determined from weighing lysimeters. (Data from Dr. J.L. Wright, USDA-ARS, Kimberly.)

Styles of Crop Coefficient Curves

Fig. 3 illustrates two common shapes used to represent K_c curves for growing seasons. Smooth curves as in Ref.[3] exhibit a smoothed change in K_c with time, whereas linearly shaped K_c curves as in Ref.[1] are constructed using four line segments. Both shapes are useful and valid for predicting K_c.

Definition of Growing Periods within the Growing Season

A growing season can be divided into four basic periods as shown in Fig. 1. The initial period represents the period following planting of annuals until about 10% ground cover or following initiation of leaves for perennials. The development period extends from the end of the initial period until the crop reaches ''effective full cover.'' Mid-season extends from effective full cover to when plant vigor or greenness begin to decrease. The late-season period extends from end of mid-season until harvest or crop death. Information on relative lengths of growing periods of crops is found in Ref.[1].

Effective full cover for row crops occurs when leaves between rows of plants begin to intermingle, or when plants reach nearly full size, if no intermingling occurs. For crops taller than 0.5 m, effective full cover is reached when the average fraction of ground surface shaded by vegetation at solar noon is about 0.7–0.8. Effective full cover for many crops begins at flowering. Plants may continue to grow in both height and leaf area after the attainment of effective full cover. Effective full cover can be predicted when the crop reaches an LAI of 3, where LAI is defined as the total area of leaves (one side only) per unit area of ground. The beginning of the late season is generally signaled by the beginning of yellowing or senescence of leaves for annual crops, leaf drop, or browning of fruit.

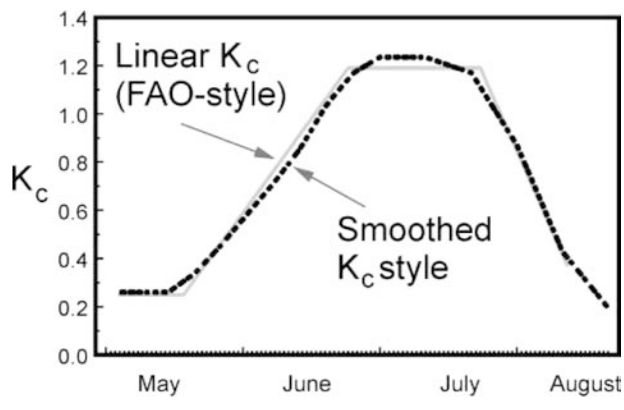

Fig. 3 Typical styles of crop coefficient curves.

Construction of a Linear K_c Curve

Only three defined values for K_c are required to construct the linear K_c curve: K_c during the initial period ($K_{c\,ini}$), K_c during the mid-season period ($K_{c\,mid}$), and K_c at the time of harvest or crop death ($K_{c\,end}$). In addition, lengths of the four growing season periods, in days, are needed.

Grass-based K_c*s*. General values for $K_{c\,ini}$, $K_{c\,mid}$, and $K_{c\,end}$ and basal $K_{cb\,ini}$, $K_{cb\,mid}$, and $K_{cb\,end}$ for primary types of crops and conditions are listed in Table 1 from Ref.[1]. These values are K_{co} based on grass reference ET_o as defined by the FAO-56 Penman–Monteith equation. Details on calculating ET_o are given under the entry on Evapotranspiration Formulas and in Ref.[1]. The Penman–Monteith method was selected by FAO-56 as the best method for standardized calculation of reference ET from a clipped cool-season grass. Cool-season grass is a standard for ET_o worldwide because it can be grown over a wide range of climates and is relatively easy to maintain. Generally, ET_o is computed by ET equation rather than measured. K_c and K_{cb} are listed for specific crops in Refs.[1–4].

There is close similarity in K_c among crops having similar characteristics, e.g., among crops in the vegetable groups, since plant height, leaf area, ground coverage, and water management are similar. $K_{c\,ini}$ values in Table 1 are approximate. Graphs and equations in Ref.[1] provide better estimates for $K_{c\,ini}$ that account for frequency of wetting and soil type.

Alfalfa-based K_c*s*. Wright[3,4] established crop coefficients for crops common to central and northern latitudes of the Western United States. These coefficients are based on the alfalfa reference ET_r represented by the 1982 Kimberly Penman Equation.[3] Alfalfa is sometimes preferred as the reference crop rather than clipped grass because it is taller than grass and has ET that is more similar to maximum ET from many agricultural crops.[3] Therefore, K_{cr}s based on ET_r generally peak at values of 1.0. Values for K_{cr} cannot be interchanged with values for K_{co} and vice versa. Values for K_{co} average about 15%–30% higher than K_{cr}.

Crop Coefficients Applied to Hourly Time Periods

For many crops the ratio of ET_c to ET_o or ET_r is relatively constant during the day. Therefore, K_c is relatively constant during the day, also, as shown in Fig. 4 for a sugar beet crop near Kimberly, Idaho.

Table 1 Time-averaged single crop coefficients, and basal crop coefficients for well-managed crops in subhumid climates, for use with ET_o

	Single K_c			Basal K_{cb}		
Crop	$K_{c\,ini}$	$K_{c\,mid}$	$K_{c\,end}$	$K_{cb\,ini}$	$K_{cb\,mid}$	$K_{cb\,end}$
Small vegetables	0.7	1.05	0.95	0.15	0.95	0.85

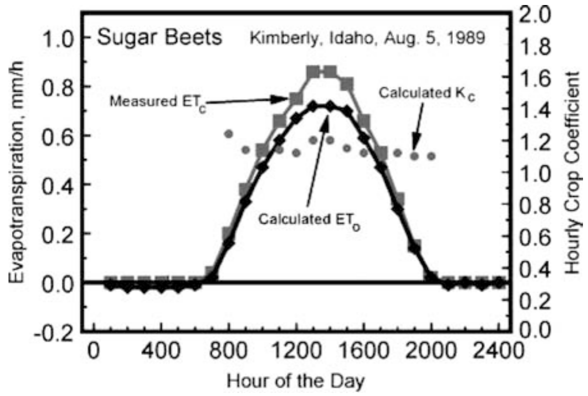

Fig. 4 Measured ET_c (by precision lysimeter) and calculated ET_o and K_c for a sugar beet crop near Kimberly, Idaho for hourly periods during August 5, 1989. (Data from Dr. J.L. Wright, USDA-ARS, Kimberly.)

ET_o was calculated using the FAO Penman–Monteith ET_o method.

ADJUSTMENT OF K_{CO} TO ACCOUNT FOR EFFECTS OF CLIMATE

$K_c s$ based on grass ET_o (K_{co}) are somewhat impacted by general climate. Under humid conditions, K_{co} does not exceed about 1.05–1.10 because the vapor pressure deficit (VPD) driving ET is small and K_{co} becomes less dependent on the differences between the aerodynamic characteristics of crop and reference. Under arid conditions, the effect of differences in aerodynamic characteristics between crop and grass reference become more pronounced because the VPD of the air is relatively large. Hence, K_{co} for tall crops under arid conditions can be as high as 1.2 or more. Because alfalfa ET_r is more aerodynamically rough, values for K_{cr} generally do not vary with climate.

K_C DURING NON-GROWING PERIODS

The value for K_c for periods following crop harvest or death will depend on the average water content of the soil surface and amount of vegetation or mulched cover remaining. When the soil surface is mostly bare, K_c can be set equal to $K_{c\,ini}$, and figures and equations for $K_{c\,ini}$ from Ref.[1] can be applied. When dead and dry vegetation or mulch covers the soil surface, K_c will be less than $K_{c\,ini}$. K_c following harvest can be estimated using guidelines in Chapters 9 and 11 of Ref.[1].

COEFFICIENTS FOR LIMITED WATER

The value for K_c is reduced when soil water content of the plant root zone is too low to sustain transpiration at the level predicted by Eq. (1). The reduction is accomplished by multiplying K_{cb} (in Eq. (2)) or the single K_c (in Eq. (1)) by the water stress coefficient, K_s, predicted for effects of limited water as

$$K_s = \frac{\theta - \theta_{WP}}{\theta_t - \theta_{WP}} \tag{3}$$

where θ is mean volumetric soil water content in the root zone ($m^3\,m^{-3}$), θ_t is the threshold θ for the root zone, below which transpiration is decreased ($m^3\,m^{-3}$), and θ_{WP} is the soil water content at the wilting point ($m^3\,m^{-3}$). Eq. (3) is applied when $\theta \geq \theta_t$, and $K_s = 1.0$ for $\theta \exists \theta_t$.

Crop Development Models

Peter S. Carberry
Sustainable Ecosystems, Agricultural Production Systems Research Unit (APSRU), Commonwealth Scientific and Industrial Research Organisation (CSIRO), Toowoomba, Queensland, Australia

INTRODUCTION

With crop development models there exists a hierarchy of approaches, which operate at varying levels of complexity, both in terms how component processes are addressed and in the way these processes are represented mathematically and within software products. The complexity of a model is partly determined by the nature of the issue that motivated model development, and partly by the data available to run the model. Nevertheless, crop simulation models generally simulate the changing state of a crop–soil system given initial system conditions, management interventions to the system, and values for the environmental variables that drive the system. Timesteps for data input and output are generally daily, although shorter durations are sometimes used for component processes. While crop yield is a primary output of such models, changes in other state variables, such as soil water or fertility status, are also often of interest. There are a number of reviews of crop simulation models and their make-up (e.g., Ref.[1]).

The majority of crop models can be described as stand-alone software, where growth of a single crop is simulated in response to climatic and soil conditions and to information on crop management. Less common are cropping systems models, which simulate multiple crop species growing in sequence or in combination. The soil component mostly consists of a soil water balance but, in some cases, it may also include a soil nutrient balance. Daily maximum and minimum temperatures, solar radiation, and rainfall are the most common climatic inputs, although pan evaporation, wind speed, and relative humidity are also sometimes used. In response to these inputs, most models simulate key physiological processes, including phenological development, leaf canopy development, radiation interception, conversion of absorbed energy into photosynthates, and partitioning of assimilates between plant components, including yield (Fig. 1).

The simulation of crop transpiration, soil water extraction by roots, water evaporation from the soil surface, and reduced growth under conditions of water deficit result in almost all crop models being responsive to variable soil water contents. This basic framework, or close derivatives of it, have formed the basis of much of the quantitative analysis of crop growth and resulted in the integration of this knowledge into many of the current crop simulation models.

PHYSIOLOGICAL DETERMINANTS OF CROP GROWTH

Thermal Time

Crop duration is often highly correlated with temperature such that crops will take different times from sowing to maturity under different temperature regimes. The concept of thermal time is the mechanism used to represent a crop's evolved requirement to accumulate a minimum time for development through each essential growth stage. Thermal time is also referred to as heat units, day-degrees, or growing degree days and has units of °C day.

Thermal time each day (δTT, °C day) is calculated from a broken linear function of temperature (T), using the following three equations:

$$\delta TT = 0 \quad T < T_b \text{ or } T > T_m$$

$$\delta TT = T - T_b \quad T_b < T < T_o$$

$$\delta TT = (T_o - T_b)[1 - (T - T_o)/(T_m - T_o)] \quad T_o < T < T_m$$

where T_b is a base temperature, T_o an optimum temperature, and T_m a maximum temperature beyond which development ceases. Values for T_b, T_o, and T_m differ for different crops, although as a general rule summer-growing crops have values in the order of 10°C, 30°C, and 40°C, respectively, while the values for winter-growing crops are closer to 0°C, 20°C, and 35°C.

Crop Phenology

The phenology of most crops can be described using distinct developmental phases—e.g., 1) sowing to germination; 2) germination to emergence; 3) a period of vegetative growth after emergence during which the plant is unresponsive to photoperiod; 4) a photoperiod-induced phase (PIP), which ends at floral

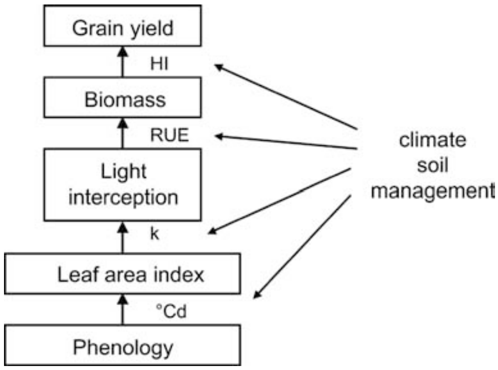

Fig. 1 A basic framework describing the physiological determinants of crop growth, development and yield—terms are described in the text.

initiation; 5) a flower development phase, which ends at 50% flowering; 6) a lag phase prior to commencement of grain filling; 7) a linear phase of grain filling; and 8) a period between the end of grain filling and physiological maturity. These phases are generally modeled as functions of temperature (1)–(8) and photoperiod 4). The sequence of these phases provides the developmental time course against which growth processes such as carbon accumulation and partitioning can be mapped.

Daily thermal time (δTT) is accumulated during each phase of development until accumulated thermal time thresholds (θ) are satisfied and then development progresses to the next phase. A set, cultivar-specific, thermal time is often required to complete most developmental phases. As most crops are photoperiod-sensitive, the duration of the PIP changes as photoperiod changes. Photoperiod (hr) is equal to daylength plus civil twilight. The thermal time requirement for PIP (θ_{PIP}) is recalculated each day during PIP as a function of daily photoperiod (p), photoperiod sensitivity of the cultivar (p_s, °C day hr^{-1}) and its maximum optimal photoperiod (p_b). For plants where flowering is hastened under short daylength, i.e., short-day plants (generally summer growing crops),

$$\theta_{\mathrm{PIP}} = p_s(p - p_b)$$

where, for photoperiods less than or equal to p_b, θ_{PIP} equals zero. For plants where flowering is hastened under long daylengths, i.e., long-day plants (generally winter-growing crops),

$$\theta_{\mathrm{PIP}} = p_s(p_b - p)$$

and θ_{PIP} equals zero for photoperiods greater than or equal to p_b. Progress (r) through PIP can be calculated as

$$r = \Sigma(\delta TT/\theta_{\mathrm{PIP}})$$

and PIP ends when r is greater than or equal to 1.

Leaf Area Development and Light Interception

A crop's canopy can be defined in terms of its photosynthetically active or green leaf area, made up of the total lamina area of emerged leaves less the area already senesced. The daily change in plant leaf area (ΔA, mm^2 plant^{-1}) can be described using functions in the form

$$\Delta A = \lambda \delta TT - \Delta S$$

where δTT is daily thermal time (°C day), λ is increase in plant leaf area per unit of thermal time (mm^2 plant^{-1} °C day^{-1}) and ΔS is change in leaf area senescence (mm^2 plant^{-1}).

Leaf area index (L, mm^2 mm^{-2}) is the ratio of green leaf area of the crop per unit of ground area and is the parameter required to describe the light relations of crop canopies. Thus the amount of light intercepted (I) has been adequately described using Beer's law,[2] such that

$$I = I_o(1 - e^{-kL})$$

where I_o is incoming daily solar radiation (MJ m^{-2}) and k is the light extinction coefficient of the canopy. The value of k increases for situations where efficacy of light interception increases, for example with narrow row spacing or for genotypes with horizontal leaf inclination.

Assimilate Accumulation

Biomass accumulation under optimal growth conditions can be linearly related to cumulative light interception for a number of crops.[3] The slope of this relationship, the amount of dry matter produced per unit of solar radiation intercepted, is termed the crop radiation use efficiency (RUE, g MJ^{-1}). Radiation use efficiency is used as a species-specific parameter to approximate the net result from the processes of photosynthesis and respiration, which many earlier-developed crop models simulated explicitly.[4]

The daily increase in crop biomass (ΔW, g m^{-2}) can be estimated by

$$\Delta W = \varepsilon I$$

where ε is RUE ($g\,MJ^{-1}$) and I is the amount of intercepted solar radiation ($MJ\,m^{-2}$). This equation assumes that photosynthetic gains and respiratory losses are in balance. Values of RUE are higher for C_4 species ($1.2\,g\,MJ^{-1}$–$1.6\,g\,MJ^{-1}$) than C_3 species ($0.8\,g\,MJ^{-1}$–$1.2\,g\,MJ^{-1}$).

Assimilate Partitioning and Crop Yield

Crop biomass results from the daily accumulation of the increase in above-ground biomass (ΔW) over the duration of the crop. Biomass is partitioned into plant components (leaf, stem, flower, grain, root) using partitioning coefficients (η_L, η_S, η_F, η_G, η_R) the values of which are dependent on developmental stage. The daily increase in dry weight of grain (ΔW_G, $g\,m^{-2}$) can be estimated as

$$\Delta W_G = \eta_G \Delta W + \tau_G W$$

where W and ΔW are total plant biomass and the amount of its daily increase, and η_G and τ_G are, respectively, the proportions of new assimilates partitioned and existing assimilates remobilized to the grain component. Most increase in grain yield depends on $\eta_G \Delta W$ during the grain-filling period, but assimilate reserves ($\tau_G W$) can also contribute to grain yield, especially in maintaining grain growth when assimilate supply is limited.

Some models predict grain sink demand by predicting values for grain number (grains $plant^{-1}$) and grain growth rate (mg $grain^{-1}$) (e.g., Ref.[5]). Alternatively, other models employ an input parameter that sets the potential daily increase in harvest index (HI) to predict demand.[6] Harvest index is the ratio of grain yield to above-ground biological yield (W_G/W).

Actual grain weight is predicted from the balance between assimilate supply and grain sink demand. For instance, when ΔW during grain filling is greater than sink demand, $\eta_G < 1$ and $\tau_G = 0$, whereas, if ΔW is less than sink demand, $\eta_G = 1$ and $\tau_G > 0$.

Plant Water Relations

Crop water uptake, soil evaporation, rainfall infiltration and runoff, and soil water redistribution and drainage are simulated within a crop model's soil water balance. Daily crop water uptake from the soil is a consequence of the balance between crop water demand and soil water supply.

Crop water use is strongly correlated with biomass production[7]—as the leaf stomata open in order to take up CO_2 for photosynthesis, water is also lost in transpiration. This relationship between the potential amount of daily biomass produced relative to the amount of water transpired represents an apparent transpiration efficiency (TE, $g\,m^{-2}\,mm^{-1}$). However, any direct measure of TE will change from day to day depending upon the humidity of the atmosphere, quantified as a vapor pressure deficit (VPD, kPa). On low humidity (high VPD) days, more water is required to be transpired to produce the same amount of biomass as on high humidity (low VPD) days. In many crop models, a T coefficient (TE_C, kPa) is set for each crop species and it represents the inherent efficiency of biomass production per water use—its units are kPa/$g\,m^{-2}/mm^{-1}$, which collapses to simply kPa if one considers that $1\,kg = 1\,m^3$ water. Values of TE_C are generally higher in C_4 crops (~0.009 kPa) than in C_3 crops (~0.005 kPa).

Daily crop transpiration demand (ΔE_p, mm) can thus be estimated by

$$\Delta E_p = \Delta W \times \nu/(\tau \times 1000)$$

where τ is TE_C (kPa), ν is VPD (kPa), ΔW ($g\,m^{-2}$) is the potential daily increase in crop biomass and 1000 is the factor for converting weight:volume of water.

An alternative approach to estimating crop transpiration demand is to assume that atmospheric demand, set by daily potential evapotranspiration (E_O), drives crop transpiration such that

$$\Delta E_p = E_O I/I_o$$

where I/I_o is proportional daily light interception as calculated from Beer's Law. Potential evapotranspiration can be calculated from climatic parameters by either the Penman–Monteith[8] or the Priestley–Taylor[9] or simply derived from measurements of pan evaporation.

Soil water supply to a crop is defined as the maximum amount of soil water that can be extracted on a daily basis from the root zone. Crop water supply is therefore a function of rooting depth, the amount of plant available water in each soil layer, and the ability of the crop roots to extract soil water. Depth of rooting is generally assumed to increase from soon after emergence at a constant rate (~10–30 mm day^{-1}) until either the maximum depth of the soil profile is reached or until root extension ceases at a nominated phenological stage (usually around flowering). The calculation of available water for each soil layer is the difference between the soil water content (SW, mm mm^{-1}) on a day and the crop lower limit (CLL, mm mm^{-1}) of soil water content.

The potential root water uptake (ω, mm) by plants from each soil layer can be calculated as a function of available soil water, root length density, and the diffusivity of water per unit of root length

($mm^{-3}\,mm^{-1}$).[5] However, neither root length density nor water uptake per unit of root length is easily determined experimentally. Alternatively, soil water supply from a layer (S_i, mm) can be simulated as

$$S_i = \phi_i k l_i$$

where ϕ_i (mm) is the available soil water and kl_i is the rate constant for layer i. The kl constant for each layer is empirically derived from experimental data on crop water extraction and it amalgamates the effects of both root length density and soil water diffusivity, which limit the rate of water uptake.[10] Values of kl typically vary between 0.01 for deep layers with low root length densities to 0.10 for surface layers with high root length densities.

Daily assimilate accumulation, transpiration, and leaf development are decreased below potential values when water deficits occur by using the ratio of potential root water uptake to actual plant evaporative demand. Similar methods of simulating water deficit have been used to predict delays in plant phenology and seedling mortality.

APPLICATION OF CROP DEVELOPMENT MODELS

Modeling is not new to research on cropping systems. In fact, modeling goes back to at least the 1950–60s.[11,12] Since then, investment in simulation modeling has grown in line with the rapid advances in computers themselves. Well-known examples of significant and sustained modeling efforts would include the models developed at the University of Wageningen,[13] the CERES,[5] and CROPGRO[14] suite of crop models contained within the DSSAT software[15] and the APSIM systems simulation model.[16]

Crop development models can be used to simulate the effects of agronomic management on crop growth and development—the comparison of alternative production scenarios using simulated crop performance is a key component of agricultural operations research. The effects of site selection, crop genotype, sowing time, sowing depth, plant population, irrigation regime, nitrogen fertilizer rate, previous cropping history, and fallowing may all be dealt with by many crop models. However, not all determinants of system performance (e.g., the incidence of pest and disease) may be addressed in any one crop model. Nevertheless, there are numerous examples of the use of simulation models in the assessment of agricultural production strategies (e.g., Ref.[17]).

Crop Plants: Critical Developmental Stages of Water Stress

Zvi Plaut
Volcani Center, Institute of Soil, Water and Environmental Sciences, Agricultural Research Organization (ARO), Bet-Dagan, Israel

INTRODUCTION

Developmental stages at which crop plants are more sensitive to water deficit as compared to others are known as critical stages. Restricting water supply during these stages may affect productivity more severely than during other periods. Early irrigation timing studies[1] demonstrated that stress sensitivity was greatest from floral development through pollination. The possibility to increase water-use efficiency with minimal damage to crops by determining sensitive growth stages will be outlined based on recent studies. Most studies are concerned with two major objectives: 1) to determine sensitive growth stages in order to avoid any stress during this period; and 2) to determine insensitive growth stages in order to save water and cause minimal damage to the crop. Differences in sensitivity at different developmental stages of a given crop may depend on growing conditions, environmental factors, and crop cultivars and may thus result in disagreement among investigators.

FIELD CROPS

Wheat

Wheat was shown to be most sensitive to water stress during booting through early grain filling.[2] Water application prior to boot stage and during advanced grain filling was found to have limited effect on grain yield. The decrease in grain yield was most marked when the optimal water availability, which was 70% of total available soil water within the root zone, was reduced by 33% during the sensitive growth stage.[3] Similar results were obtained with various cultivars as well as at very different locations.[4–7]

The effect of water stress at the vegetative stage was not only relatively low, but plants could easily recover from this stress.[6] However, the stage of tillering, which is prior to or at the beginning of the vegetative stage, was found to be quite sensitive to water stress.[8,9] Water stress at this stage may reduce the number of tillers, which can result in severe yield losses.

Corn

Full irrigation of corn throughout its entire growing season was claimed to be more profitable than any irrigation regime applying deficit irrigation.[10] It was, thus, advised to reduce the area of grown corn rather than the application of water, if water is rate limiting. Other investigators claimed that corn is able to tolerate short periods of water deficit during its vegetative stage, and is more sensitive between late vegetative growth and grain filling. Optimal irrigation scheduling, at this critical stage, decreased the consumption of water with minimal yield losses.[11] Insufficient water application during this period resulted mainly in a decrease in kernel number.

It seems that the discrepancies shown for corn response to irrigation timing may be explained on the basis of different plant biomass available to support grain yield. It was found that grain yield of corn was closely linked to the accumulated biomass.[12] Fig. 1 presents the range of grain yield and crop biomass of two different field experiments, which differ markedly in initial biomass production, but show similar relationship between biomass production and grain yield. In order to produce maximal biomass, sufficient water supply is needed throughout the season as shown earlier. When the produced biomass is limiting, optimal water supply is especially needed at the critical time of flowering and grain filling, when the utilization of constituents stored in the vegetative organs takes place.

Sorghum

Sorghum is sensitive to water stress at equivalent growth stages as corn, but its sensitivity is lower. The sensitive stage is from heading through grain filling.[13] A stress sensitivity index was introduced by Meyer, Hubbard, and Wilhite [14] which can be calculated from the following equation:

$$Y/Y_{\mathrm{p}} = \Pi\left(\sum \mathrm{ET}_i / \sum \mathrm{ET}_{\mathrm{p}i}\right)^{\lambda_i} \qquad (1)$$

in which Y and Y_{p} are actual and potential yields, when moisture is not limiting. ET_i and $\mathrm{ET}_{\mathrm{p}i}$ are actual and potential evapotranspiration rates for the i growth stages. The symbol Π is a multiplication

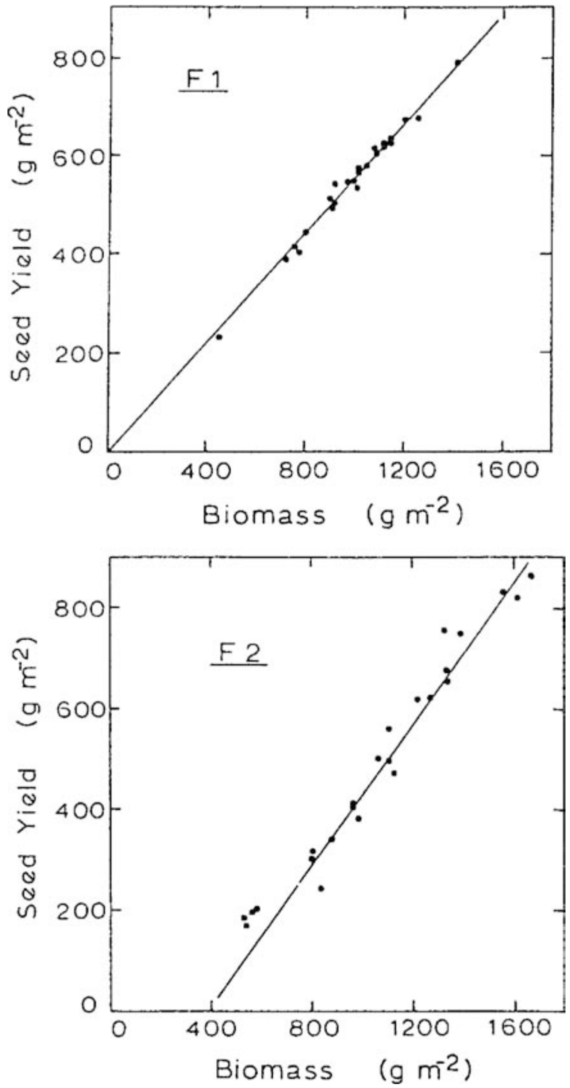

Fig. 1 Maize grain yield vs. crop biomass for individual plots in Florida Exp. Solid line was obtained from linear regression analysis.

factor and λ_i is the sensitivity index of the crop to water stress at the i stage. The calculated values of λ_i for sorghum at different growth stages were 0.04, 0.20, and 0.18 for vegetative, from panicle initiation through anthesis, and grain filling, respectively.[15] These values were much lower than those calculated for corn: 0.06–0.18, 1.54, and 0.03 for vegetative, reproductive, and ripening growth stages, respectively.[14]

In sweet sorghum, the critical stage of water stress was found to be at a much earlier stage, namely during leaf growth.[16] Water stress at this stage reduced biomass by 30% when compared with unstressed plants.

Rice

Water stress occurring during the vegetative stage had a relatively small effect on grain yield in rice.[17] The effect of water stress on yield was most severe when it occurred during panicle development. Stress at this stage delayed anthesis and reduced the number of spikiests per panicle to 60% of the fully irrigated control while drought during grain filling decreased yield by 40% of the control only.

Soybean

No distinct sensitivity of specific developmental stages was outlined for soybean. Internode length and plant height were affected when plants were stressed during both vegetative and flowering stages.[18] This may repress the number of flowers and pods, but could also be a result for enhanced flower and pod abortion.[19] Stress at the stage of seed filling reduced the size of the seeds.

Beans

The analysis of crop sensitivity to water stress at different growth stages is more appropriate if stress intensity is comparable and the quantities of water, which are applied, are similar. Typical results of such an experiment are presented in Table 1 for Black beans.[20] Seed yield was mostly decreased in both years, when water was eliminated during the reproductive stage and all yield components (pods per plant, seeds per pod, and seed weight) were affected. Moreover, plants did not make use of later applied water.

Application of water to field beans (*Vicia faba*), during or shortly after flowering, increased bean yield even under high rates of rainfall.[21] There are other indications,[22] showing that a period of mild water stress during flowering of field beans followed by large quantities of water after flowering was optimal for achieving high grain yield. Conditions of extremely low water stress throughout the growing period may result in decreased dry-matter partitioning to reproductive organs.

The sensitivity of mung bean to water stress at different growth stages was not well defined. It was outlined that irrigation at vegetative and pod development stages was needed in order to assure and improve yield.[23] However, when irrigation is applied during one developing stage only, flowering seems to be the most critical stage.[24] Nonetheless, it was recommended to avoid water stress during two out of three growth stages—vegetative, flowering, and pod filling and maturation.

Peas

Field peas responded positively to irrigation at the vegetative growth stage.[21] This was found, in particular,

for more drought-sensitive cultivars. Irrigation of field peas throughout the growing season gave, however, the highest yield but a lower water-use efficiency.

Groundnuts

Groundnuts seem to be most sensitive to water stress during pod development rather than during flowering or even pegging.[25] Water stress during this stage reduced pod yield by 56% as compared to 27% and 45% at the other two stages, respectively.

Moreover, moderate water stress during the pre-flowering phase was outlined by other investigators to enhance subsequent pod growth.[26] Greater synchrony of pod set in moderately stressed plants resulted in a greater proportion of mature pods at the final harvest.

Cotton

Cotton is a crop of different water requirements throughout its growing season. The requirement is quite low during vegetative growth but increases during the reproductive period, which occurs in most cotton growing regions when transpiration demand is also maximal. The peak in water requirement remains throughout flowering until maturation (opening) of the first boll, when the requirement decreases again (Fig. 2). In order to avoid stress during flowering, it was recommended to apply 3–4 irrigations according to ET.[27] Exposure of the crop to water stress during vegetative growth will avoid excessive vegetative growth, and minimize the consumption of stored assimilates that may compete with reproductive growth. The timing of the first irrigation, which terminates the early stress period, can be set according to several parameters, out of which plant water potential is mostly recommended.[28] The optimal leaf water potential for the initiation of the irrigation season was about $-1.8\,MPa$.[28]

Sunflowers

Sunflowers are known as being fairly tolerant to water stress and may produce an acceptable yield under dryland farming.[29] A relief of water stress by irrigation will, however, enhance production of achenes and of achene oil considerably.[30] The most sensitive growth stage was found to be between stem elongation and the end of flowering. All yield components were found to be affected by irrigation.

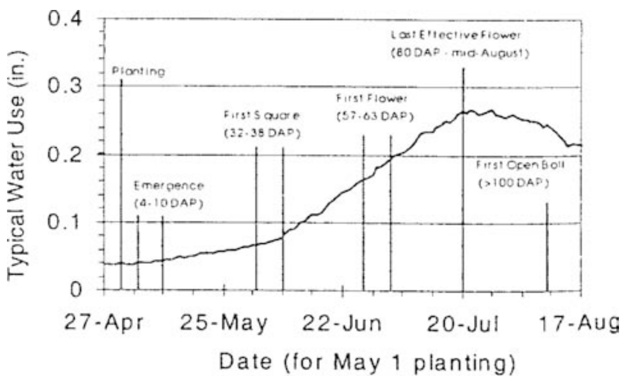

Fig. 2 Estimated typical water use for cotton based on 30-yr-mean maximum temperatures recorded at the University of Arkansas Northeast Research and Extension Center.

VEGETABLE CROPS AND POTATOES

Flowering and fruit set are known to be the most sensitive stage for all crops in which the fruit or grains are the edible organs like garden peas, fresh corn, tomatoes, oilseed rape, watermelon, and others. Water stress at this stage reduced yield by 43–60%, but only by 32–50% at the second most sensitive stage, which was fruit enlargement or grain filling. The vegetative and ripening stages were much less sensitive.[31,32] In vegetable crops, which are grown for their vegetative organs (as cabbage and onion), no distinct sensitivity was found at any particular developmental stage. Katerji, Mastrorolli, and Hamdy[33] who maintained similar stress intensities (according to predawn Ψ_p) at different growth stages, came to a similar conclusion for pepper.

In potatoes, which are essentially parts of the group in which vegetative organs are consumed, withholding water during tuberization caused a sharp decrease in yield and hindered physiological processes.[34] Continuous drought between tuber initiation and final tuber growth reduced yield as well. As far as quality is concerned, even slight water stress during tuber bulking was found to have deleterious effects on specific tuber gravity, dry matter and starch content, and chip yield. This implies that frequent irrigations are essential at this stage.[35]

Cassava, which is mainly grown for animal feed and alcohol production from its starchy tubers, is also part of this group. Water stress during bulking of the underground tubers was found to be very detrimental.[36] This was in fact related to the leaf area and assimilates production rather than to tuber bulking.

FRUIT TREE CROPS

Apples

Reducing the amount of applied water during the growing season was shown to have only slight affects on fruit yield and quality.[37,38] Since restriction of shoot growth is desirable, mainly due to practical reasons, this may even be considered as a positive effect of stress. Water stress may also improve quality of apple fruits depending on timing. It was shown that withholding irrigation during the last 90 day prior to harvest resulted in advanced fruit maturity, more yellow skin color, higher total soluble solids (TSS), and increased flesh firmness during storage, and had hardly any effect on yield. Application of a similar stress during the initial 100 day after full bloom hardly improved the fruit quality. The response of irrigation withdrawal throughout the season gave similar results to late withdrawal, while the control (fully irrigated) trees responded similarly to the early withdrawal of irrigation.[39]

Prunes

It was shown many years ago that prunes are tolerant to water stress, as it took 4 yr of no irrigation to decrease trunk growth and 5 yr to decrease fruit yield.[40] These results were obtained with widely spaced trees on a deep soil. It was found much later that prunes responded by decreased fruit load and fruit hydration, smaller fruits, and increased flowering when subjected to water stress for 75 day of the lag phase during fruit growth. This effect on fruit load was even more critical under conditions of shallow soil, as water storage was limiting.[41]

Apricots

Two critical periods of water stress were outlined: the second exponential fruit growth period and immediately after harvest.[42] Water stress during the first period resulted in decreased yield and quality, as the harvested fruits were smaller. The response to the second period of stress was a reduction in yield, in the following year, due to increased drop of young fruits.

Citrus

Fruit yield of clementine citrus was especially sensitive to water stress during flowering and fruit set. This was in addition to the effect of water stress on fruit yield throughout the year.[43] Fruit quality and vegetative growth were affected by water stress during the ripening period. Clementines seem to be more sensitive to water stress as compared to other citrus species, which were studied earlier.[44] Fruit size seems to be the most sensitive parameter responding to stress. Valencia oranges were also found to be stress sensitive and their critical sensitivity periods were flowering and fruit cell enlargement. In grapefruit and naval oranges, flowering and fruit cell division were most sensitive.[45] Juice content and the ratio of TSS to acid (TSS/acid) of the juice were also reduced if conditions of water stress prevailed during cell enlargement.

INTRODUCTION

The primary purpose of retaining or capturing snow by residue management in semiarid regions is to increase the supply of soil moisture for subsequent crops. Snow retention and capture are of major benefit in regions, such as the North American Great Plains, where blowing snow can result in considerable loss of moisture from the landscape. This moisture is often needed to supplement seasonal rainfall and to bolster spring crop production. In the Great Plains, rainfall during the growing season is typically low and is quickly lost from the surface or shallow depth in the soil due to high evaporative demand.[1]

Managing snow on the landscape is also beneficial for moderating soil temperatures and protecting dormant plants from freezing and desiccating. This is particularly important in cold regions where lethal soil temperatures can occur in the absence of snow cover during winter. Snow cover aids in reducing the depth of soil freezing which, in combination with duration of soil freezing, can affect hydrological processes such as infiltration and runoff. Snow retention or trapping also reduces the loss of water associated with sublimation of blowing snow. Sublimation can result in a substantial loss of precipitation in cold regions. Indeed, sublimation of blowing snow has been found to comprise 15–40% of the annual snowfall in the Canadian Prairies and up to 45% of annual snowfall in the arctic region of North America.[2]

POTENTIAL FOR SOIL WATER INCREASE

A relatively large portion of the annual precipitation occurs in the form of snow in the cold, semiarid regions of the United States and Canada. In the Northern Great Plains of the United States, about 20% of the annual precipitation of 250 mm to over 500 mm occurs in the form of snow.[3,4] Steppuhn[1] indicated that in the Canadian Prairies, 20–30% of the annual precipitation of 300 mm yr^{-1} to over 500 mm yr^{-1} occurs as snowfall. Staple and Lehane,[5] Zentner et al.,[6] and Pomeroy and Gray[7] report somewhat different values for precipitation falling as snow on the Canadian Prairies. These studies suggest that from 30% to nearly 40% of annual precipitation occurs in the form of snow. The shortage of precipitation to sustain maximum crop production in cold, semiarid regions requires the use of management techniques that conserve winter precipitation. Conservation of winter precipitation is vital in the Great Plains where economical production of spring wheat requires the annual withdrawal of about 250–400 mm of water from the soil.[8] Indeed, Greb[9] suggested that sustainable crop production can only be attained in the Great Plains as a result of soil water recharge occurring from snowmelt.

Crop residues are only effective in retaining or trapping blowing snow to a depth equivalent to the height of the residue.[10] Surface winds are moderated by exposed residue elements, thus deposition will occur within the residue canopy as long as the elements can effectively retard wind velocity. Once the residue canopy is filled with snow, there is little or no obstruction of the horizontal wind by the residue elements; thus, no further deposition will occur. Implicit in the capture of snow by crop residues is the recharge of moisture within the soil profile. Staple, Lehane, and Wenhardt[11] found in Saskatchewan that recharge of the soil profile from snowmelt was greater in fields covered with stubble than in low-residue fallow. Stubble height also influences snow depth and therefore soil water recharge during winter. Soil water recharge is generally accentuated by taller stubble as a result of greater retention or trapping of snow in taller stubble during winter.[12,13] The extent of recharge, however, is dependent on the rapidity of snowmelt as well as on other soil physical properties such as soil water content and frost depth. Soil frost may prevent infiltration of snowmelt and enhance runoff. Thus, snow retention does not always impact soil water. In fact, Sharratt[10] found, in the northern U.S. Corn Belt, that stubble height had little effect on over-winter changes in soil water content despite large differences in snow depth. Soil water recharge was greater for stubble cut near the soil surface than at either a 30-cm or 60-cm height despite a thicker snow pack in the 30-cm and 60-cm stubble. Although Greb, Smika, and Black[14] found that loose stubble, as a result of autumn tillage, was less efficient at retaining blowing snow than undisturbed, well-anchored stubble at several locations across the Great Plains, soil water storage in early spring was the same for the loose and well-anchored stubble.

EFFECT OF ADDITIONAL WATER ON CROP YIELD

In the semiarid region of Saskatchewan, yield of wheat is dependent on precipitation received during the growing season as well as on soil water reserves at the time of sowing. de Jong and Rennie[15] found that spring wheat yield was influenced to a greater extent by precipitation than by soil water reserves. They reported a yield increase of 70–200 $kg\,ha^{-1}$ for every 25-mm increase in growing season precipitation, but did not find a positive yield response to an increase in soil water storage at the time of sowing. In contrast, a 10-yr study at Swift Current, Saskatchewan indicated an average spring wheat yield increase of 80 $kg\,ha^{-1}$ for a 13-mm increase in soil water storage due to enhanced snow cover from a trap strip maintained in a wheat stubble field. However, the yield response to soil water storage doubled during years with a dry growing season.[6] Staple and Lehane[16] summarized 12 yr of data on water use by spring wheat at seven Experimental Substations in southern Saskatchewan and found an average yield increase of 235 $kg\,ha^{-1}$ for each additional 25 mm of water used by the crop.

In the Northern Great Plains of the United States, wheat yield is also dependent on precipitation and soil water storage. Cole[17] summarized results from studies at a number of sites of the relationship of spring wheat yield to annual precipitation and found yield increases of 145–215 $kg\,ha^{-1}$ from each 25-mm increase in precipitation above a base of 205–255 mm. A positive yield response of wheat to stored soil moisture was found by Johnson[18] who reported an increase in yield of 50–290 $kg\,ha^{-1}$ for every 25 mm of water stored over winter.

Crop residues may not always bolster wheat yield as a result of enhancing soil water recharge over winter. Indeed, Cutworth and McConkey[19] found that yield was greater when wheat was grown in taller stubble due to a more favorable microclimate in taller rather than shorter stubble during the growing season. In the absence of differences in soil water content in the early growing season, greater yield in taller stubble was attributed to lower evaporative demands in taller than in shorter stubble.

EFFECT ON SOIL TEMPERATURE, FROST, AND RUNOFF

A series of studies on the effect of corn stubble height and residue cover on soil temperature, frost depth, and spring thaw have been conducted by the Agricultural Research Service in West-Central Minnesota. In a 3-yr study by Benoit et al.,[20] tillage and residue practices, which retained more residue on the soil surface, resulted in greater snow cover and therefore reduced frost depth and hastened thaw and warming of the soil in early spring. They found practices that retained or trapped an additional 0.1 m of snow on the surface reduced seasonal frost penetration by 0.21 m. In a subsequent study, Sharratt, Benoit, and Vorhees[21] found that standing corn stubble trapped more snow during winter and hastened warming and thawing (by as much as 20 day) of the soil as compared with prostrate corn residue or a bare soil. They later found that soil under 60-cm height corn stubble thawed as much as 15 day earlier than under 30-cm height stubble, and at least 25 day earlier than under 0-cm height stubble. However, net radiation and maximum soil temperature in the early spring were generally higher for soils without residue cover vs. soils with residue cover.[10]

Taller stubble not only has a larger capacity to trap more snow during winter, but also prolongs the period of snow cover during winter.[10] The potential for runoff, therefore, is likely greater for taller stubble. Indeed, Willis, Haas, and Carlson[3] found that taller stubble not only hastened snowmelt runoff, but also partitioned more of the snowmelt to runoff than did shorter stubble.

TECHNIQUES TO ENHANCE SNOW CAPTURE

Uniform Height Stubble

Leaving a uniform cover of standing stubble is the simplest technique of retaining snow on the soil surface in windy regions. If sufficient snow is available and the residue is dense, snow will fill to the top of the stubble.[10] The water density of freshly fallen snow is typically about 10% of its depth (e.g., 300 mm of snow will contain 30 mm of liquid water), but when blown and settled into stubble or drifts, the water density of snow may range from 18% to 35%.[7] Thus, stubble of 40-cm height might capture as much as 140 mm of water. The quality of standing stubble will also influence snow capture. Stubble weakened by subsurface tillage in autumn will likely bend as a result of the weight of the snow load or shear stresses exerted by the wind and thus reduce the efficiency of snow capture compared to undisturbed, well-anchored stubble.[14]

Alternate Height Stubble

Stubble can be cut at alternate heights, high (30–60 cm) and low (15–30 cm), in subsequent passes of a swather. Snow might fill all of the short stubble and part of the tall stubble. The taller stubble might not fill completely. Pomeroy and Gray[7] indicated that using the technique added 31 mm of water to the soil via snowmelt as compared to a uniform canopy of short stubble.

Leave Strips

Narrow (0.30 m) barriers of a standing crop can be left without harvesting. Under proper conditions, the loss of income from the grain would be offset by the cost of additional water gained from snow trapped between barriers. The barriers should be oriented perpendicular to the prevailing wind direction and spacing would be about 20 times the height, based on results generated from several locations.[1]

Trap Strips

Trap strips are similar to leave strips in that narrow (0.40–0.60 m) strips of tall stubble are left in the field with stubble rows oriented perpendicular to the prevailing wind direction. Trap strips are formed by the use of a deflector attachment on the swather or combine, which bends the stems sideways, and only the heads and a small part of the stem are removed at harvest. The strips are 250–350 mm taller than adjacent stubble. The strips are more effective at trapping snow when strips and spacing are relatively narrow (width 0.75 m and spacing 5 m) than when strips are wider and more widely spaced (width 1.5 m and spacing 10 m).[7] Results of a 10-yr study at Swift Current, Saskatchewan showed trap strips conserved 13 mm more soil water than short standing stubble (45 mm vs. 32 mm). Increase ranged from 0 mm in years with minimal snowfall to 48 mm in years when snow accumulations were favorable.[6]

Permanent Vegetation Barriers

Permanent vegetation barriers consist of rows of trees, shrubs, or plants. When used for snow management, they are often referred to as living snow fences. The amount of snow trapped by this type of barrier is influenced by the porosity and height of the vegetation. Porosity varies with species and spacing between individual trees, shrubs, or plants. For uniform spreading of snow across a field, vegetation density should be no more than 40%.[22] Snow capture is optimized when the porosity of the vegetation approaches 50%; at this porosity, the snowdrift can be expected to extend as much as 25 times the barrier height.[22] Greater barrier densities result in shorter, deeper deposits and less benefited area. Greater non-uniformity of depth of snow results in greater differences in soil drying and problems in seeding; part of the area may be too dry while other areas may be too wet to be seeded in a timely manner.[22]

Snow Ridges

Snow ridges formed mechanically and perpendicular to the prevailing wind can act as wind barriers and collect blowing snow. The practice has potential value but it has not been widely used. The snow trapping effect is much the same as from a solid fence.[7] If the ridge does not consolidate after plowing it can be removed by high winds,[1] and success will be diminished if melting occurs before the snow fall period is concluded.

CONCLUSION

Snow capture by standing stubble has potential to increase soil moisture to enhance spring cropping in cold semiarid regions of the United States and Canada. Snow capture techniques such as permanent vegetation barriers or snow ridges are useful but require maintenance or construction each winter and are not widely used.

Cyanobacteria in Eutrophic Freshwater Systems

Anja Gassner

Martin V. Fey
Department of Soil Science, University of Stellenbosch, Matieland, Stellenbosch, South Africa

INTRODUCTION

Aquatic systems in an urban environment are subjected to massive anthropogenic nutrient input in the form of either non-point (stormwater) sources or point sources (industry, sewage). Most of these water bodies progress from low-productivity or oligotrophic settings to productive mesotrophic conditions to overenriched eutrophic or hypertrophic conditions. The response to the so-called ‘‘cultural’’ eutrophication is excessive production of undesirable algae and aquatic weeds and oxygen shortages caused by their senescence and decomposition. Cyanobacterial (blue-green) algal blooms have become a serious water-quality problem around the world. From a human perspective it is desirable to prevent or minimize such processes for both aesthetic and health reasons. Algal blooms lower drinking water quality by production of often odorous and toxic compounds; the toxins produced in many blue-green algae have caused health problems for wildlife, livestock, pets, and humans in contact with contaminated water. Given the variety of uses of urban water bodies for recreation, housing development, fish farming, and nature reserves, management guidelines and increasing awareness are urgently needed. The objectives of this article are to give a short introduction to freshwater blue-green algae, the key environmental factors that lead to their proliferation, and the subsequent environmental problems and to present management strategies.

FACTORS LEADING TO CYANOBACTERIAL DOMINANCE

The taxonomic composition of phytoplankton communities, the abundance and the relative dominance of the different species and groups present, undergo seasonal changes. This process of continuous community change is termed succession. Under undisturbed conditions, most phytoplankton populations are of relatively short duration. Typically, the growth and decline cycle of one specific population lasts, on average, 4 to 8 weeks. The ‘‘seasonal paradigm’’ of phytoplankton succession[1] describes the typical pattern of phytoplankton succession corresponding to the prevailing nutrient cycle in temperate, undisturbed lakes: a spring maximum of diatoms, sometimes followed by a second maximum in the autumn, an early summer maximum of Chlorophyceae (green algae) and a late summer maximum of Cyanophyta (blue-green algae).

It is generally accepted that with excess nutrients in the water column, in particular phosphorus, the phytoplankton flora deviates from the traditional seasonal community pattern with a shift toward cyanobacterial dominance. However, it must be stressed that nutrient limitation does not, in itself, provide cyanobacteria with the ability to become dominant; it is the combination of a multitude of abiotic and biotic factors. Enrichment experiments demonstrated that the maximum biomass of temperate lakes is ultimately limited by the phosphorus supply.[2] Increasing supplies of phosphorus lead to an increase of phytoplankton growth until other essential nutrients become limited. The first nutrient to become limited after phosphorus is usually nitrogen. Cyanobacteria are the only species that are able to fix atmospheric nitrogen. Whereas other algae become nitrogen limited, the ascendancy of nitrogen-fixing cyanobacteria is favored.

Apart from their ability of fixing atmospheric nitrogen, cyanobacteria feature some adaptations that enable them to outcompete other species. Eutrophic conditions result in large suspended stocks of phytoplankton, which reduce light penetration. Cyanobacteria possess gas vacuoles to control buoyancy. When subjected to suboptimal light conditions, they respond by increasing their buoyancy (regulated by the rate of photosynthesis) and move nearer to the surface and hence to the light.[2] Additionally, the possession of chlorophyll *a* together with phycobiliproteins allows them to harvest light efficiently and to grow in the shade of other species. Cyanobacteria are supposed to be more tolerant of high pH conditions and have an additional selective advantage at times of high photosynthesis because of their ability to use CO_2 as carbon source.[3] Some genera are able to offset the effects of photoinhibiting UV radiation encountered by near-surface populations. The resistance to photoinhibition is achieved by producing increased amounts of carotenoid pigments, which act as ''sunscreens.''[4] Once established, cyanobacteria are able to inhibit the growth of other algae by producing secondary metabolites that are toxic to species of other genera.[5]

CONSEQUENCES OF CYANOBACTERIAL BLOOMS

Like any phytoplankton, bloom proliferation of blue-green algae reduces water quality in terms of human water use but also results in a reduction in diversity of the aquatic species assemblage at all trophic levels. The presence of ''pea soup green'' water, the accumulation of malodorous decaying algal cells, and the buildup of sediments rich in organic matter lead to user avoidance with the associated problems and implications for water quality management. The most obvious sign of an advanced blue-green algae bloom is the formation of green ''scum,'' which leads to deoxygenation of underlying waters, subsequent fish kills, foul odors, and lowered aesthetic values of affected waters.[6] In addition, certain genera and species produce taste and odor compounds, typically geosmin and 2-methyl isoborneol, which cause non-hazardous but unpleasant problems for suppliers and users of potable water.[4]

The most serious public health concerns associated with cyanobacteria arise from their ability to produce toxins. Since the first published reported incidence of mammal deaths related to a toxic cyanobacterial bloom in 1978, more then 12 species belonging to nine genera of blue-green algae have been implicated in animal poisoning.[7] For human exposure, routes are the oral route via drinking water, the dermal route during recreational use of lakes and rivers, or consumption of algal health food tablets. Toxins produced in a random and unpredictable fashion by cyanobacteria are called cyanotoxins and classified functionally into hepatotoxins, neurotoxins, and cytotoxins. Additionally, some cyanobacteria produce the lesser toxic lipopolysaccharides (LPS) and other secondary metabolites that may be of potential pharamacological use.[8] One of the most tragic encounters of humans with cyanobacterial toxins led to the deaths of 60 dialysis patients due to contaminated water supply used in a hemodialysis unit.[9] Presently, a drinking water guideline of $1\,\mu g\,L^{-1}$ of toxin has been developed and implemented only for microcystin-LR.[4] Haider et al.[8] stress that the biggest challenge for water treatment procedures for the removal of cyanobacterial toxins is that one is faced with soluble and suspended substances. Thus, the most common treatment, chlorination, in general has been found not to be an effective process in destroying cyanotoxins.

MONITORING AND MANAGEMENT OF ALGAL BLOOMS

Drinking water treatment strategies are not always successful in removing algal toxins. Thus, detection of early-stage (emergent) blooms of cyanobacteria, especially if the bloom has not started to produce toxins, is important to allow municipalities and recreation facilities to implement a response plan. It has been shown that remote sensing technology can be used to estimate the concentration and distribution of cyanobacteria through measurement of the concentration of the pigment phycocyanin.[10]

Once detected, the growth of nuisance algae is prevented by the use of chemicals; the commonest is copper sulfate. Other algicides include phenolic compounds, amide derivatives, quaternary ammonium compounds, and quinone derivatives. Dichloronaphthoquinone is selectively toxic to blue-greens. The inherent problem of algicides is that on cell lysis, toxins contained in the algae cell are released into the surrounding water. In 1979, almost 150 people had to be hospitalized for treatment of liver damage after a reservoir contaminated with *Cylindrospermopsis* was treated with copper sulfate.[4] Biological control by zooplankton is, in principle, possible, although not always practical or effective because of the low nutrient adequacy, toxicity, and inconvenient size and shape of most blue-green algae. The only zooplankton reported to successfully graze on blue greens is *Daphnia* sp., but it tends to decrease with increasing nutrient content of the water[11] More effective is the use of microorganisms, as certain chytrids (fungal pathogens) and cyanophages (viral pathogens) specifically infest akinetes and other heterocysts, whereas Myxobacteriales (bacterial pathogens) can affect rapid lysis of a wide range of unicellular and filamentous blue-greens, although heterocysts and akinetes remain generally unaffected.[12]

The consensus regarding the management of blue-green algal blooms is the management of excess nutrient loads into receiving water bodies.[13,14] Management options can be divided into two broad categories: catchment management (decrease of nutrient export) or lake management (decrease of internal nutrient supply). Catchment options are, e.g., management of urban and agricultural runoff, biological and chemical treatment of wastewater, nutrient diversion, and implementation of legislation. Lake management options are dredging, chemical sediment treatment, and biomanipulation.[13]

CONCLUSIONS

Cyanobacteria pose a serious threat to ecosystem health and human livelihood. From a human perspective, the most serious threat associated with blue-greens are their toxins. Routes for human exposure are the oral route via drinking water, the dermal route during recreational use of lakes and rivers, or consumption of algal health food tablets. Removal of these algae and their toxins from water bodies poses a great logistical problem. However, it is important to understand that the proliferation of blue-greens and thus the presence of their toxins is a response to human-induced ‘‘cultural’’ eutrophication. Increasing awareness of the need of proper watershed management is urgently needed among municipalities and stakeholders, especially because chlorination has been shown not to be very effective in removing toxins from the water.

Dam Removal

Desiree Tullos
Biological and Ecological Engineering, Oregon State University, Corvallis, Oregon, U.S.A.

Gregory Jennings
Biological and Agricultural Engineering, North Carolina State University, Raleigh, North Carolina, U.S.A.

INTRODUCTION

Why Dam Removal?

There are more than 75,000 dams over 5 ft in height in the United States and 40,000 dams over 50 ft tall worldwide.[1–3] The deleterious effects of these large and small dams are well documented in the literature. Dams fragment the continuity of rivers both longitudinally and laterally, restricting and delaying the exchange of materials and migration and dispersal of organisms from upstream and from the floodplain,[4–7] fragmenting key elements of the interactions and life history of riverine ecosystems.[8–10] Dams generally modify natural flow regimes by storing larger flood events and increasing base flows, consequently altering the biological and physical features of rivers.[7,11–16] Reservoirs also store sediment and modify habitats,[17,18] with geomorphic responses of the downstream reaches varying,[19,20] but generally characterized by coarsening of the surface bed material, incision of the riverbed, homogenization of bed features, bank erosion and failure, and loss of riparian vegetation and complexity[17,21–25] in response to the reduced supply of sediment. The shift from lotic to lentic environment upstream of dams results in a shift in species composition,[13] frequently displacing native taxa with exotics[26,27] and increasing opportunities for predators of endangered species.[28] Modification of temperature regimes may also occur,[11,13,15] obscuring emergence or growth cues.[11] The spatial extent of effects from larger dams is greater than small dams, with trapped sediment resulting in habitat loss and change in biological community compositions at the coast.[29]

A growing concern over these adverse ecological, social, and economic impacts[30] is reflected in the increasing frequency of dam removal (Fig. 1). As Federal Energy Regulatory Commission (FERC) licenses on non-federal structures expire, dam owners may be required to meet new fish passage criteria, with the expense of fishway design and construction making removal more economically favorable. Further, with 85% of dams in the United States at the end of their working life by 2020,[31] the age of structures with their associated safety declines, as well as new policies and funding sources to support removal projects[32] also explain the increased frequency of dam removal.

LOGISTICS OF DAM REMOVAL

The strategy for removing a dam has been reported as the single most critical factor for managers influencing the outcome of removal[33] and the removal of dams may occur in a number of ways. Dams may be completely removed from the river or breached and partially removed, leaving bulkheads and sills in the river as structural artifacts. Dams may be removed instantaneously or dewatered and removed in stages, allowing the channel to erode reservoir sediments more slowly over time. The previous option (instantaneous removal) tends to be more common at small dam sites where rapid headcut erosion is less likely to initiate lateral erosion through gully walls. In contrast, larger dams tend to be slated for removal by staged breaching, allowing terraces to form in the stored sediment, stabilizing the material and preventing lateral erosion. Dams tend to be removed during periods of low flow when transport capacity limits the suspension of fine sediment.[17] To further reduce the rate and extent of erosion during removal, reservoirs may be drawn down gradually, sediment screens and traps may be installed, and stability measures may be taken.[34]

Whether in response to concern for downstream habitats or owing to a hazard posed by contaminants attached to reservoir sediments,[18,35] managers may choose to: (1) remove the sediment stored behind the dam, typically by dredging or by conventional excavation after reservoir drawdown; or (2) leave the sediment in place, with or without some structural stabilization of sediment stored behind the dam. Stabilization practices may include regrading, revegetating, or armoring exposed sediment to reduce erosion,[36,37] or construction of grade control structures to fix the elevation of the riverbed. Owing to the cost of removal and structural stabilization, sediment is often left in place at small dam removals, allowing the river to

erode through the reservoir sediments at a rate that depends on the hydrologic regime, sorting and volume of stored sediments, removal strategy, and width of the reservoir relative to the width of the channel.[32]

UNCERTAINTY IN THIS EMERGING SCIENCE

A great deal of uncertainty about the consequences of dam removal exists,[38,39] particularly related to the extent, magnitude, and timing of physical and ecological outcomes.[32,39] Confident predictions of ecosystem responses to dam removal are unrealistic,[40] and experience with and documentation of dam removal is limited.[32] Although approximately 450 dams have been removed in the last 100 years,[41] less than 5% of these removals resulted in published ecological research.[39] This work is both difficult to obtain and of limited value because of unsystematic data collection and lack of comprehensive reporting.[32,39] As a consequence of a lack of examples from which to derive expectations and insufficient documentation and analysis, the practice and science of dam removal are essentially new.

An integrated scientific approach including both assessments and experiments is considered by some[38] to be our greatest need in the current development of conceptual models for the dominant processes influencing ecosystem responses to dam removal.[25] The information gained by more rigorous studies and reporting of current dam removals will help to more realistically assess and predict impacts of future dam removals. With improved quality and consistency of published monitoring data and methods, scientists, managers, and the public will be better prepared for holding informed discussions on the benefits and risks of dam removal.[32]

OUTCOMES OF DAM REMOVAL

While there is substantial uncertainty about the outcomes of dam removal, some general conclusions may be drawn about ecological responses, especially in light of some baseline information regarding the spatial and temporal influence of the dam on geomorphology of the river. Removal of dams may not reverse all of the adverse impacts previously described over all spatial scales, and recovery of river ecosystems following dam removal may not occur over immediate temporal scales. Biological recovery most likely follows geomorphic processes returning to equilibrium (Fig. 2), the timing of which will be driven by various features of the river and removal, including time of sediment accumulation, river velocity, channel gradient, and removal strategy.[42] Some features of ecosystem recovery are expected immediately following removal while others will take much longer to respond (Fig. 2), with the timing of these responses varying with dam size and influence on the river.

Immediately following removal, sediment stored behind the dam is expected to mobilize both episodically and chronically.[43] An equilibrium channel will incise through the stored sediment, forming a new floodplain and increasing the supply of sediment downstream.[25,44] The short-term outcomes of the disturbance associated with removal and the subsequent reservoir erosion may initially inhibit downstream recovery. Downstream increases in suspended sediment occur for some period following removal,[45] resulting in homogenization and modification of bed features (e.g. pools and riffles) and burial of coarse-grained material,[25] spawning grounds downstream may be smothered with fine sediments, abrasive sediment may damage macrophytes,[18] algae and invertebrates may be scoured from mobile substrates and unable to attach to fine material deposited

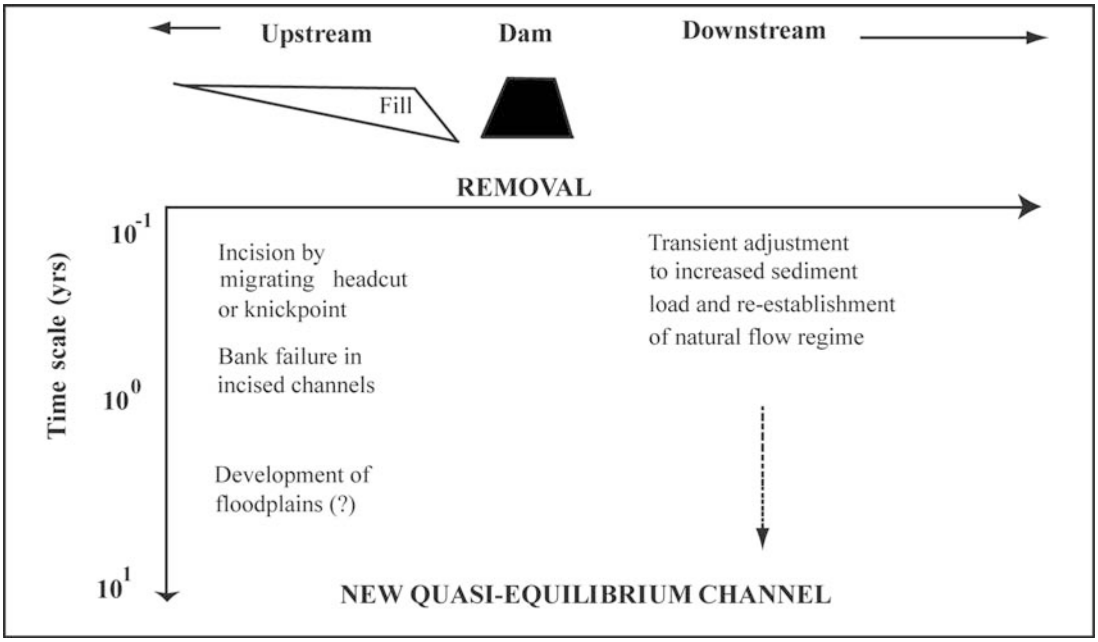

Fig. 2 Timescale of geomorphic processes associated with dam removal. (Pizzuto, JE. Effects of dam removal on river form and process. Bioscience **2002**, *52*, 683–691. Copyright, American Institute of Biological Sciences.)

downstream[18,46] while other habitats may be smothered and inaccessible.[45]

However, it may be argued that these short-term risks associated with dam removal are largely outweighed by the long-term benefits (Fig. 3) of reconnecting fragmented rivers. For example, the removal of two dams and subsequent restoration of natural sediment transport regime along the Elwha River in Washington is expected to promote tremendous recovery of nearshore habitats for native biota, including fish, shrimp, and hardshell clams, the latter of which were replaced by exotic biota when shoreline erosion owing to

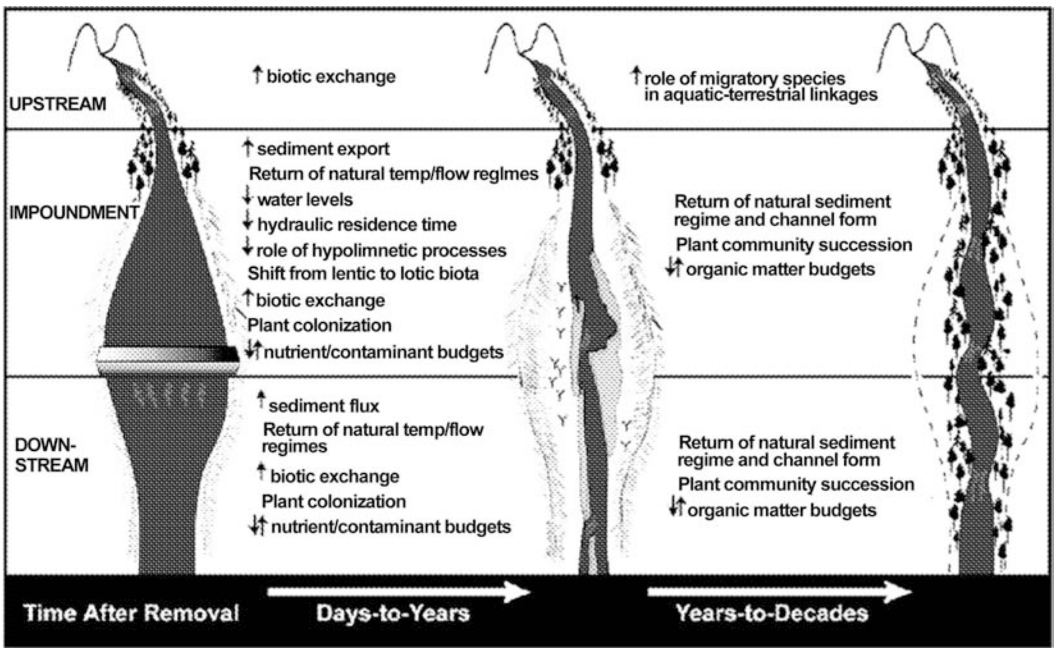

Fig. 3 Spatial and temporal framework of key responses to dam removal, including the direction of change associated with removal. (Pizzuto, JE. Effects of dam removal on river form and process. Bioscience **2002**, *52*, 683–691. Copyright, American Institute of Biological Sciences.)

decreased sediment supply from the dams resulted in armoring of the substrates.[29] In many rivers regulated by large dams, it is hypothesized that temperatures in the river will decrease following dam removal. As is the case again in the Elwha River, this restoration of more natural temperature regimes is critical to recovery of salmon as current maximum daily water temperature during low water years are attributed to increased infection of *Dermocystidium* bacteria, which attack salmon as they migrate inland from the ocean.[40]

Another benefit of dam removal is the reconnection of the channel to an active floodplain, including the backwater areas that are used for spawning and habitat by various aquatic organisms.[47,48] In addition to providing access to instream and riparian habitats, dam removal promotes restoration of food chains and habitat building processes, supporting piscivorous predators (i.e., common mergansers, great blue heron, and belted kingfishers) and juvenile fishes and other aquatic predators that will benefit from the nutrients provided by salmon carcasses.[40]

Darcy's Law

Keith C. Cameron
Graeme D. Buchan
Centre for Soil and Environmental Quality, Lincoln University, Canterbury, New Zealand

INTRODUCTION

In simple flow systems in nature, the fundamental law of flow is linear, i.e., the flow rate increases in direct proportion to the "driving force" for the flow, where the driving "force" is the gradient (rate of change with distance) of some so-called "potential." For example, the flow of heat obeys Fourier's law, with the heat flux proportional to the gradient of temperature, T. (T is sometimes called the *thermodynamic potential*). For the flow of liquid water in permeable materials, it fell to the French hydraulics engineer, Henry Philibert Gaspard Darcy (1800–1858) to show that the flow obeys a similar law ("Darcy's law"), with the flow rate proportional to the gradient of the *hydraulic potential*. More generally, we now know that Darcy's law applies to flow of most simple liquids in any porous (and permeable) medium.

Historical

In the early 19th century, the city of Dijon in France had a water supply among the worst in Europe.[1] Darcy was a civil engineer, born in Dijon, and set himself the task of improving the city's water supply. He decided to investigate the filtration of water by sands and gravels, reported in 1856 in his report *Les Fontaines Publiques de la Ville de Dijon*.[2] Using simple but ingenious equipment (see Fig. 1), he arrived at his universal law for the mass flow of liquids in permeable materials.[3] Thus, Darcy joined the "famous four" who revealed the simplicity (yet paradoxically the complexity) of Nature's most basic laws of flow: Fourier's law for heat flow; Ohm's law for electric current; Fick's law for gas diffusion; and Darcy's law for liquid flow in materials.

THEORY OF LIQUID FLOW IN PERMEABLE MEDIA

Saturated Flow: Darcy's Law

Darcy[2] first established his flow equation for water flow in saturated sand (Fig. 1). He found that the flow rate per unit cross-sectional area, q, through the pipe in Fig. 1 is proportional to the difference in head h between the ends, and inversely proportional to length L:

$$q = K(h_B - h_C)/L \tag{1}$$

where K is a proportionality constant.

In more general form, for flow along the x-direction:

$$q = -K\,\mathrm{d}h/\mathrm{d}x \tag{2}$$

Here q (in units of $\mathrm{m\,sec^{-1}}$) is the "Darcy velocity." This is the average apparent velocity of the water, as if it were flowing across the entire area, solids as well as pores. $K = K_{sat}$ (also in $\mathrm{m\,sec^{-1}}$) is the saturated *hydraulic conductivity*, and $\mathrm{d}h/\mathrm{d}x$ is the driving force for flow, i.e., the gradient of the hydraulic head h (meters head of water) in the direction of flow, x (m).

K_{sat} is strongly controlled by the pore space of the permeable medium, especially the pore sizes.[4] For soils, K_{sat} varies enormously with texture. See Table 1. K_{sat} is approximately a measure of the maximum drainage rate of a soil. For example, a sandy soil may have $K_{sat} \approx 5 \times 10^{-5}\,\mathrm{m\,sec^{-1}} = 180\,\mathrm{mm\,hr^{-1}}$ while a clay soil may have $K_{sat} \approx 10^{-8}\,\mathrm{m\,sec^{-1}} = 0.036\,\mathrm{mm\,hr^{-1}}$. Thus, a rainfall of only $1\,\mathrm{mm\,hr^{-1}}$ would drain freely into the sand, but would cause surface ponding on the clay. Soil structure also controls pore sizes and hence K_{sat}, e.g., a soil with a tightly packed platy structure will have lower K_{sat} than one with open, porous "granular" structure.

Unsaturated Flow: Buckingham–Darcy Equation

Soils are mostly unsaturated, and the generalization of Darcy's law to unsaturated flow was developed by Buckingham.[5] He reasoned that hydraulic conductivity $K(\theta)$ is a function of the soil volume occupied by the conducting water, i.e., the volumetric water content θ. Also, the pressure potential h becomes negative, since water is now under suction. Thus we can again assume Darcy's law, Eq. (2), but now $K = K(\theta)$ decreases very rapidly as soil loses water. See Fig. 2.

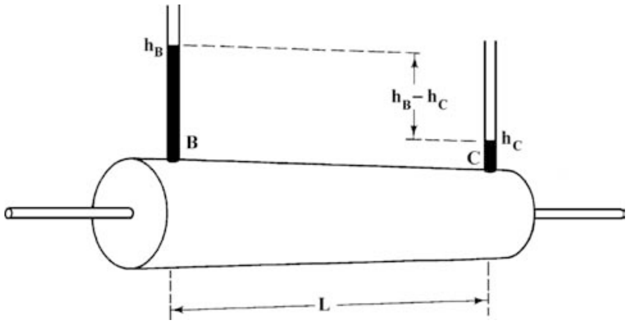

Fig. 1 Horizontal pipe filled with sand to demonstrate the experiment of Darcy (1856). His original equipment was actually vertically oriented, which would add an extra term to the head difference in Eq. 1, equal to the height difference $z_B - z_C$. *Source*: From Ref.[6].

The actual water velocity between the grains is greater than the Darcy velocity, with an average value $v = q/\theta$. Note that ν is an average value, and masks a microscopically complex flow pattern in the tortuous, multisized pore space, with a range of speeds and directions. An extreme example of the microscopic variability of flow velocity occurs in water flow through soils with strong structure development, e.g., with large cracks or wormholes. Here, water can be fast-tracked along the large macropores by so-called ''bypass flow.'' (This phenomenon can fast-track contaminants to groundwater, and also contributes to the *dispersion* of solutes during their transport.)

Note that the hydraulic conductivity depends not only on the architecture of the soil pore space, but also on the properties of water itself, especially its viscosity. For example, water's viscosity almost doubles from 30 to 0°C. So soil water flows more slowly in winter than in summer. In order to extend Darcy's law to other liquids, it is desirable to transform the hydraulic conductivity (which is specific to water only) to a more absolute measure of the ''conductivity'' of the permeable material, independent of the fluid. This leads to the ''intrinsic permeability:''

$$\kappa = K(\mu/\rho g) \tag{3}$$

Here μ is the viscosity of water, ρ is the density of water, and g is the acceleration due to gravity. In Eq. (3), the dependence of K on the properties specific to water has been factored out. (ρg represents the ''heaviness'' of water, or the amount of pressure produced by a water column of unit height). κ is now controlled only by the properties of the permeable medium, and can be used for any other liquid (e.g., oil) that might flow in the medium. Incidentally, like many famous scientists, Darcy has a unit named after him. The ''darcy'' is a unit of the intrinsic permeability κ, but is in such antiquated (pre-SI) units, that it is now little used, except by petroleum engineers.[6]

Table 1 Typical values of saturated hydraulic conductivity for soils, ranging from sand to clay

Drainage class of soil	Saturated hydraulic conductivity, K_{sat} (mm hr^{-1})	Approximate soil texture class
Class 1: very slow	<1	Clay
Class 2: slow	1–5	Clay loam
Class 3: moderately slow	5–20	Silty clay loam
Class 4: moderate	20–60	Silt loam
Class 5: moderately rapid	60–125	Loam
Class 6: rapid	125–250	Sandy loam
Class 7: very rapid	>250	Sand

Source: From Ref.[10].

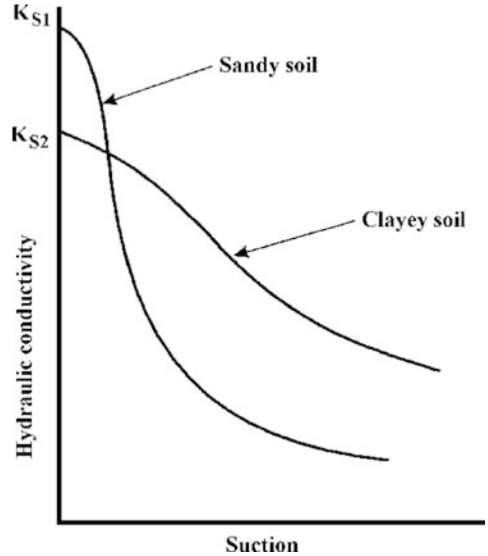

Fig. 2 Hydraulic conductivity $K(\theta)$ of two soils of contrasting texture. K_{s1} and K_{s2} are the conductivities at saturation. K decreases dramatically as water content θ decreases. *Source*: From Hillel, D. *Environmental Soil Physics*; Academic Press: San Diego, CA, 1998; 208.

APPLICATIONS

Soil Water Flow

Darcy's law is used extensively in soil science, in drainage theory, and in most models of water and solute transport in soil. Fig. 2 shows how the hydraulic conductivity function $K(\theta)$ is strongly influenced by soil

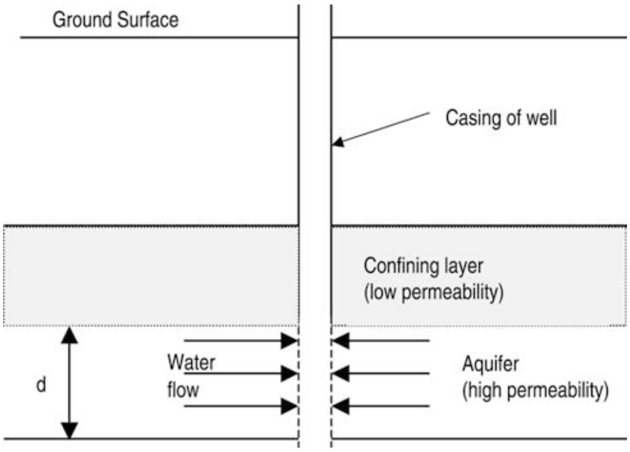

Fig. 3 Schematic of an aquifer layer supplying water to a groundwater well. The aquifer's supply capacity depends on its "transmissivity," i.e., its saturated hydraulic conductivity K_{sat} multiplied by its thickness d. The aquifer is "confined" by an impermeable layer above.

texture. Paradoxically, coarse-texture soils (e.g., sands), while more conductive than fine-texture soils (e.g., silt loams) at saturation (Table 1), lose their conductive capacity at low suctions, due to rapid desaturation of their large pores. This has interesting practical applications, e.g., in sports turf soils. A gravel layer beneath a sandy root zone provides excellent drainage at saturation, but then desaturates, becomes almost nonconductive, arrests drainage from the root zone, and hence enhances root zone moisture retention.

Groundwater Flow

Groundwater is a major source of irrigation and municipal water in many parts of the world, and is commonly pumped either from shallow groundwater layers, or from deeper aquifers, which are either permeable gravels or rock layers. Darcy's law again applies to the saturated flow. However, groundwater hydrologists are interested in the ability of an aquifer, with thickness d, to deliver water to a well which cuts across the aquifer. See Fig. 3. The aquifer's supply capacity is thus controlled by the product $K \times d$ of aquifer conductivity K and its thickness d, a quantity called "transmissivity."[7]

Two-Phase Flow: Flow in Oil Reservoirs

Above, we described Darcy's law for a single fluid. Multiphase flow occurs where several (usually two) non-miscible liquids share the pore space. It occurs in oil reservoirs if they contain both oil and water. Darcy's law was generalized in 1949 by Muskat (see Ref.[8]) to describe the more complex flow of two phases together. The generalized form of Darcy's law is used by oil exploration scientists. This form also applies in groundwater that has been contaminated by so-called NAPLs: "non-aqueous phase liquids," or organic liquids immiscible in water. Thus, Darcy's law can be applied to oil extraction, and to the remediation of polluted groundwater.

Chemical–Desalination

Further Complexities

Anisotropic materials

Some properties of materials may be anisotropic, i.e., for directional phenomena (such as water flow) the controlling property depends on the direction. For example, in sedimentary deposits K perpendicular to the stratification is usually less than K parallel to it. In clay subsoils, the clay particles (typically plate-shaped) may be preferentially orientated in the horizontal plane, and vertical conductivity will then be much less than horizontal conductivity, improving the layer's ability to act as a barrier layer to vertical contaminant transport. A result of anisotropy is that in 3-D flow, the velocity flow lines are not parallel to the head gradient.

Vapor flow

Fluids can be transported in the *vapor* as well as the liquid phase. However, Darcy's law applies strictly only to the mass flow of liquids, not to the flow of vapor, which moves by gas diffusion. Vapor diffusion also obeys a simple proportional law (Fick's Law), but is driven most strongly by gradients of temperature T. This leads to "coupled flows." For example, in a moist soil near the ground surface, the vertical (z-) gradient $\mathrm{d}T/\mathrm{d}z$ can be very strong. Then heat and moisture flows occur simultaneously and in linkage: water is distilled from warmer to cooler regions, and carries latent heat energy, as well as the water itself.[9]

Databases

Rosemary Streatfeild
Owen Science and Engineering Library, Washington State University, Pullman, Washington, U.S.A.

INTRODUCTION

A database is an electronic bibliographic or full-text product providing access to publications in either a general or subject specific area. Information on water science can be accessed through a number of different databases, some with a focus on water resources, while others provide relational coverage. Most researchers, looking for as much information on their topics as available, will use more than one product to locate materials.

Databases are available through vendors on different platforms and through variable subscription options. They differ in coverage, content, search and retrieval methods, source materials, and access modes. Most provide more than one search level, varying in the number of searchable fields and level of expertise, and employ search features such as Boolean operators, truncation and proximity methods, phrasing and limiting that differ by vendor. Help pages, indexes, and controlled-language thesauri accompany most packages to assist with searching.

Other features commonly engaged by database vendors include display options, selection of citations (''marking'') for printing, downloading and emailing, saving and retrieving searches, combining searches, linking to online catalogs and full-text electronic journals, and alerting services. The addition of new materials (''updating'') occurs regularly, but each vendor follows its own schedule.

DATABASES

Agnic[1] offers agricultural information provided by the National Agricultural Library (NAL), Land-Grant Universities, and other institutions, each providing information on a discrete area of emphasis. Subject coverage includes Water Quality; Government, Law and Regulations; Plant Sciences; Aquaculture and Fisheries; Earth and Environmental Sciences, and Forestry. Descriptions of each record are included, along with accessibility links. A thesaurus and search tips are provided. Update schedules and years of coverage are established by the respective institutions that provide the information.

Agricola,[2] a database provided free by the NAL, includes citations from materials relating to agriculture, forestry, life sciences, and other related disciplines dating from the 15th century. It is available also on CSA (2), Community of Science (4), Dialog (5), Ebsco (6), OCLC (9), Ovid (10), Silverplatter (11), and STN (12) platforms. The NAL version is divided into the Online Public Access Catalog (Books, etc.) and Journal Article Citation Index (Articles, etc.). It is updated daily from over 5000 sources.

AGRIS,[3] sponsored by the Food and Agricultural Organization of the United Nations and available in English, Spanish, and French, offers an international perspective on agriculture and related subjects. Available on CD-ROM (updated quarterly) and on the Internet (updated monthly) from 1975, there are over 144,000 records. Sources include journal articles, books, technical reports, and gray literature from all countries that participate in the UN program. A thesaurus (AGROVOC) is provided. Coverage is in many subject areas including water resources and management, aquatic sciences and fisheries, agriculture, natural resources, and pollution. The database is bibliographic only, but information is provided about document availability. There is also a personalized search profiling service provided. Dialog (5) and Silverplatter (11) supply *AGRIS* on their platforms also.

AgroBase, produced by the Government Research Center[4] at the National Technical Information Service, combines *AGRIS* and *AGRICOLA* into one database, with a total of over 5.5 million records, many including abstracts, with coverage from 1970 to present.[5] Topics include water quality, aquatic sciences and fisheries, hydrology, and hydroponics. It is available on the NISC (6) *BiblioLine* platform and is updated monthly.

Applied Science and Technology Abstracts, from H. W. Wilson Co. (13), provides over 1,000,000 records from more than 600 sources in the fields of chemistry, engineering, physics, and others. The dates covered are from 1983, with abstracts provided from 1994. The database is updated weekly (*WilsonWeb*) or monthly (*WilsonDisc*). There is also a full-text version dating from 1997, which is updated four times weekly. Other platforms include Dialog (5), Ebsco (6), OCLC (9), Ovid (10), and Silverplatter (11).

Aquatic Biology, Aquaculture and Fisheries Resources is an anthology of thirteen files available through NISC (6) on their *BiblioLine* platform, and on CD-ROM. The database dates from 1971 and is updated quarterly. It contains over 888,600 records with abstracts on the science and management of aquatic organisms and environments. Subject coverage includes the ecology, biology, nutritional and environmental aspects of fish and aquatic environments. There are 13 file sources, which include *ASFA: Aquatic Sciences and Fisheries Abstracts Part*1: *Biological Sciences and Living Resources*, and several abstracting services relating to aquaculture.

ASFA: Aquatic Sciences and Fisheries Abstracts, produced by Cambridge Scientific Abstracts (2), is available through the Internet and on CD-ROM. It provides international information in the science, technology, and management of marine, freshwater, and brackish water environments and organisms. The database dates from 1978 and is updated monthly. Internet platforms include Dialog (5), Ovid (10), SilverPlatter (11), and STN (12). There are over 717,000 bibliographic records, many with abstracts, in aquaculture, biology, ecology, the environment, marine sciences, oceanography, pollution, and water. A thesaurus is available.

BIOSIS Previews, from the BIOSIS organization,[6] combines Biological Abstracts with Biological Abstracts/Reports, Reviews, Meetings (RRM) to provide references from journals, books, meetings, reviews, and other publications. Platforms include Dialog (5), Ebsco (*Biological Abstracts* and *BasicBIOSIS* only) (6), ISI (7), Ovid (10), Silverplatter (11), and STN (12). It has approximately 13 million records dating from 1969 to the present from over 5500 international sources, and is updated weekly. Subject coverage is life science topics including sources relating to water. The records are bibliographic with abstracts.

Biological and Agricultural Index, from H. W. Wilson Co. (13), covers the literature in the fields of biology and agriculture since 1983, including subject areas relating to water. It is available on CD-ROM (updated monthly) and through the Internet (updated weekly) on OCLC (9), Ovid (10), Silverplatter (11), and *WilsonWeb* and *WilsonDisc* platforms and is bibliographic only. *Biological and Agricultural Index Plus* is also available, providing full-text and abstracts of 45 journals from 1994, and updated weekly.

CAB ABSTRACTS, available on CD-ROM and the Internet, is a bibliographic database compiled by CAB International (1) of its print abstracts. It covers the international literature in areas such as agriculture, forestry, horticulture, and the management and conservation of natural resources dating back at least 10 yr. Sources include scientific journals, monographs, books, technical reports, theses, reviews, conference proceedings, patents, annual reports, bibliographies and guides, and translated journals. There are over 3.5 million records in the database, which is updated weekly, and a thesaurus is provided. Other platforms include Dialog (5), Ovid (10), and Silverplatter (11).

Chemical Abstracts is produced by Chemical Abstracts Service (CAS) (2) and made available electronically on their *SciFinder Scholar* platform. It is also available through Dialog (5). The database contains over 16 million citations and abstracts from journal articles, patents, reviews, technical reports, monographs, conference and symposium proceedings, dissertations, and books dating back to 1967 from over 8000 sources worldwide. Subject coverage is of all facets of pure and applied chemistry, including water and aquatic sciences. The database is updated weekly.

Current Contents is available in CD-ROM and Internet formats from ISI (7) in seven discipline areas including *Agriculture, Biology and Environmental Sciences, Life Sciences,* and *Physical, Chemical and Earth Sciences.* It provides access to complete bibliographic information for a 2-yr backfile, which is updated daily, from articles, editorials, meeting abstracts, commentaries, and other significant items of over 8000 scholarly journals and more than 2000 books. Dialog (5), Ovid (10), and Silverplatter (11) make *Current Contents* available on their platforms.

EiCompendex, available on the Internet through Engineering Village, is produced by Engineering Information, Inc.[7] and provides comprehensive interdisciplinary bibliographic information relating to engineering and technology dating back to 1970. It is updated monthly. There are over three million summaries from over 5000 sources including journal articles, technical reports, conference papers and proceedings, and Web sites. This database is also available on Dialog (5), Ebsco (6), Ovid (10), and Silverplatter (11) platforms.

Environmental Sciences and Pollution Management, produced by CSA (2) and available on OCLC (9) and Ovid (10) platforms, contains over one million records about aquatic pollution, water resource issues, and other subject coverage from over 4000 sources since 1981. It is updated monthly. Abstracts and bibliographic citations are provided.

General Science Abstracts, from the H.W. Wilson Co. (13), provides indexing since 1984, and abstracts since 1993 of 191 periodicals. The database focuses on student and non-specialist coverage of several fields, many relating to water resources. There are 615,000 records which are updated weekly (*WilsonWeb*) or monthly (*WilsonDisc*). A full-text version is also available for 57 periodicals dating from 1996, which is updated four times weekly. *General Science Abstracts* is available as well on the OCLC (9), Ovid (10), and Silverplatter (11) platforms with abstracts only.

GeoArchive, produced by Geosystems (United Kingdom) and available on circular CD-Rom and the Internet from Oxmill Publishing,[8] contains international information covering geological, hydrological, and environmental sciences dating from 1974. It is also available through Dialog (5) with over 628,000 bibliographic records and is updated monthly. It is also included in NISC's *Marine, Oceanographic and Freshwater Resources* database. Sources include journals, magazines, conference proceedings, doctoral dissertations, technical reports, maps, and books. Indexing is by the thesaurus, *Geosaurus*.

GeoRef, provided by the American Geological Institute,[9] covers the geology of North America since 1785 and international geology since 1933. It is available on CD-ROM (with monthly updates) and through the Internet (updated twice monthly) from many vendors including CSA (2), Community of Science, Inc. (4), Dialog (5), Ebsco (6), OCLC (9), SilverPlatter (11), and STN (12). There are over 2.2 million bibliographic records with abstracts from journals, books, maps, conference papers, reports, and theses, and a thesaurus is provided. The print equivalent is *Bibliography and Index of Geology*.

Groundwater and Soil Contamination Database, provided by the American Geological Institute,[9] provides complete bibliographic information for over 60,000 references from 2500 serial titles published since 1975. It is updated quarterly with worldwide coverage of the literature in geology, hydrology, and the environment, with emphasis on reports of the U.S. Geological Survey and other US government departments.

Hydrology InfoBase, produced by Geosystems (United Kingdom) and available on CD-Rom and the Internet from Oxmill Publishing,[8] is a database subset of *GeoArchive* (above). It covers information from international sources in all fields relating to hydrology, including geomorphology, soil science, water–rock interactions, water resources, energy, pollution, agriculture, forestry, engineering, and environment dating from 1970. It includes bibliographical references with abstracts.

Marine, Oceanographic and Freshwater Resources contains materials dating back to 1964 from 14 different sources, and is available from NISC (8) on *BiblioLine* or CD-ROM. It is updated quarterly, with over 1,000,000 records, and provides coverage on international marine and oceanic information, and estuarine, brackish water, and freshwater environments. Subject areas include environmental quality; limnology and freshwater environments; physical oceanography; pollution, acid rain, and global warming; sea-level fluctuations; biological oceanography and ecology. Sources include *Part 1*: *Aquatic Sciences and Fisheries Abstracts* (above), *Part* 2: *Ocean Technology, Policy and Non-Living Resources* and *Part* 3: *Aquatic Pollution and Environmental Quality, Oceanic Abstracts, National Oceanic and Atmospheric Administration*, and others available from United States and international institutions.

National Oceanic Atmospheric Administration's Library and Information Network[10] is a 23-institution consortium providing nine collections dating back to 1820. Subject areas include hydrographic surveying, oceanography, meteorology, hydrology, living marine resources, and meteorological satellite applications. The database contains more than 127,000 bibliographic records from over 9000 serial titles, 1500 active journal subscriptions, 35,000 reports, and meteorological data publications from 100 countries, as well as 1000 rare books. Materials can be requested for loan.

NTIS (National Technical Information Service) database[11] is available from the Government Research Center (URL: http://grc.ntis.gov/) and is a central source for government information. It provides access to over 2,000,000 titles produced by government agencies since 1964. Subjects include agriculture, energy, the environment, and other science and technology areas. Descriptive summaries and bibliographic records are provided. Ebsco (6), NISC (8), Ovid (10), Silverplatter (11), and USGovSearch[12] also offer access to this database through their platforms.

Science Citation Index Expanded, from ISI (7) and available on CD-ROM and through the Internet as part of the *Web of Science*, is a citation index dating back to 1945, updated weekly. It provides bibliographic information, author abstracts, and cited references found in 3500 of the world's leading scholarly science and technical journals covering more than 150 disciplines. The *Web of Science* covers more than 8000 international journals in the sciences, social sciences, arts and humanities, and offers access to electronic full-text journal articles.

Selected Water Resources Abstracts (SWRA)[13] provides over 10,000 abstracts dating from 1977 (and earlier) to 1997 from worldwide technical literature covering a wide variety of topics relating to water resources. Sources include journals, monographs, conference proceedings, reports, and U.S. Government documents. Subject coverage includes groundwater, water quality, water planning, and water law and rights. The complete SWRA print records dating back to 1967 are available through *Water Resources Abstracts*. See also the USGS WRSIC Research Abstracts database[14] and the Universities Water Information Network.[15]

Waternet, a bibliographic database provided by the American Water Works Association (AWWA),[16] provides over 50,000 citations and abstracts from journals, books, proceedings, government reports, and technical papers from publishers around the world. It is available in CD-ROM format, and updated twice a year. Document delivery services are offered.

Water Resources Abstracts is a database maintained by CSA (2). It was formerly produced by the Water Resources Scientific Information Center[14] of the U.S. Geological Survey.[17] It is available in CD-ROM and Internet formats on Dialog (5), NISC (8), and Silverplatter (11) platforms. With over 360,000 records, the database provides citations and abstracts for water resources from 1967 and is updated monthly. Print sources include *Water Resources Abstracts* (1994–present), *Selected Water Resources Abstracts* (1967–1994), *Water Quality Instructional Resources Information System* (1979–1989), and the *WRSIC Thesaurus*.

Water Resources Worldwide, available from NISC (8) on its *BiblioLine* platform and CD-ROM, provides coverage of industrial and environmental aspects of water, wastewater, and sanitation from international sources including South Africa's *WATERLIT*, Canada's *AQUAREF*, CAB Abstract's *Aquatic Subset* and the Netherlands' *DELFT HYDRO* databases. Emphases include water in arid lands, aquatic information relevant to agricultural practice, and engineering and related technological disciplines. Updated quarterly, there are over 531,300 citations and abstracts dating back to 1970.

Deltas

Paul F. Hudson
Department of Geography and the Environment, University of Texas at Austin, Austin, Texas, U.S.A.

INTRODUCTION

The world's major deltas are relatively young geomorphic features, having formed since the middle Holocene when sea level reached its current height. The term "delta" was coined by the Greek historian Herodotus about 2500 B.C. because of the similarity in shape between the Nile delta and the Greek letter Δ. Although marine deltas are the largest and most studied, the first conceptual model for understanding deltaic processes and sedimentary deposits was established by the famous geomorphologist G. K. Gilbert in the late 1800s in a study of paleo Lake Bonneville, U.S.A. The Mississippi delta is the most studied deltaic system in the world, although the geometry of this fluvial dominated delta is quite distinct from most other large deltas. Nevertheless, the conceptual framework developed from numerous early studies of the Mississippi delta system has been employed as a form-process model for understanding deltas around the world.

Deltas are formed where a river discharges into a marine or lacustrine receiving basin and represent unique coastal environments. Debouching of sediment at a river mouth results in immediate sorting and deposition, the process of delta formation. An individual delta typically has multiple channels that branch from the main-stem river channel. These distributary channels deliver sediment to a broad area, resulting in the formation of a delta lobe. Such distributaries are typically in multiple stages of development and carry different proportions of streamflow. While deltas form at the river mouth, the delta plain includes inactive delta lobes adjacent to the active delta lobe. The major controls on delta plain evolution include those associated with the watershed (i.e., fluvial) and receiving basin. Because deltas are transitional boundaries between land and water, they are associated with a variety of freshwater, brackish, and marine environments, and thus represent diverse ecological settings.

FORM AND PROCESS

While our understanding of deltaic processes stems largely from research on marine deltas,[1] the study of lacustrine deltas should be of increased interest because lake levels fluctuate more rapidly than global sea levels, and thus represent an ideal opportunity to examine the influence of base-level changes.[2] Indeed, global proliferation of dam construction during the 20th century provides a unique opportunity to examine deltaic sedimentation because of a rapid increase in base level imposed by infilling of large reservoirs, while controlling for scale (drainage area), geology, and climate.

Sediment sorting and deltaic sedimentation begin as sediment is discharged into a standing body of water. This initiates a regressive sequence of deltaic deposits that prograde over marine deposits, as illustrated in Fig. 1. The basic model of sedimentation includes three major deltaic deposits: a distributary mouth bar comprises sands and coarse silts, low-angle delta front deposits comprise fine silts and clay, and thinly laminated clay deposited beyond the river mouth as a prodelta base.[3] These deposits coincide with topset, foreset, and bottomset beds, respectively, originally described by G. K. Gilbert in 1890.[4]

A delta lobe is associated with the position of the main-stem channel, whereas delta plains comprise multiple delta lobes in various stages of growth and erosion. Thus, it is important to note that a delta plain is dominated by fluvial controls at the river mouth, while other processes dominate distal regions of a delta plain. A combination of these processes produces a suite of landforms associated with the stage of delta lobe development or the "delta cycle." The occurrence of multiple delta lobes is evidence for delta switching, or avulsion of the main-stem channel. Subsidence begins as coarser sediments prograde over the clayey prodelta base deposits. As surface accretion rates become less relative to rates of subsidence, marine processes begin to rework older deltaic deposits.[5,6] The "delta cycle" (Fig. 2) is associated with distinct sequences of change, including: 1) initial progradation; 2) enlargement of delta lobe; 3) abandonment and transgression; and 4) reoccupation and growth of a new delta.

Initial Progradation

Deltaic sedimentation begins because of an abrupt reduction in stream competence at the transition from

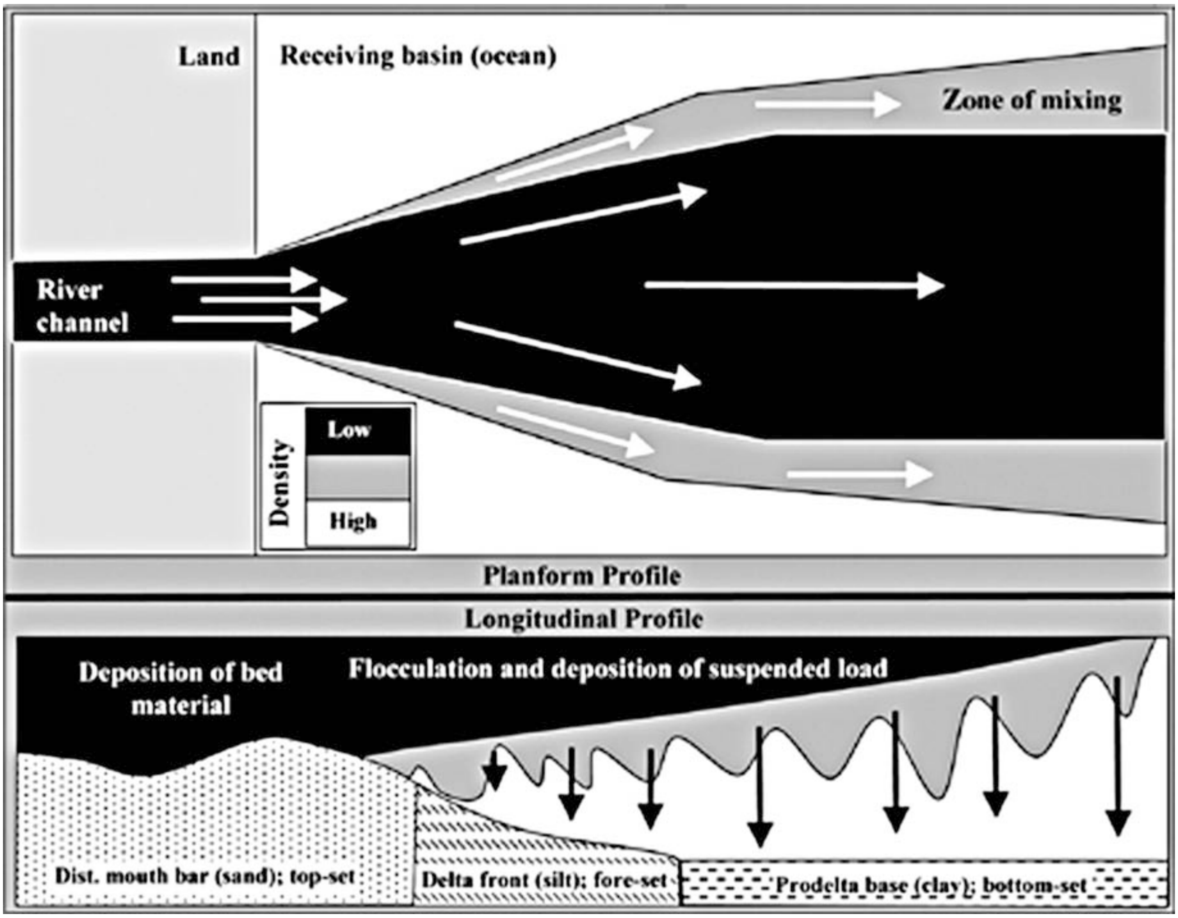

Fig. 1 Planform: sediment mixing where river suspended sediment loads are discharged into a marine setting, a hypopycnal condition occurs because the streamflow is less dense than the saline marine waters of the receiving basin. Longitudinal: model of sediment sorting and typical deltaic deposits of a delta lobe.

channelized flow to open water, resulting in deposition of the river's sandy bed load and formation of a river mouth bar. Channel bifurcation occurs as flow is diverted around the bar, initiating a distributary network. The distance to which the suspended sediment is transported into open water depends on discharge magnitude and wave energy, in addition to density differences between streamflow and water in the receiving basin (fresh or saline). Streamflow density is less than saline ocean water, a hypopycnal condition, resulting in a buoyant sediment plume transporting fine sediments far beyond the river mouth (Fig. 1). Under low energy conditions, silt is deposited as a sloping delta-front, but clay is transported over a much broader prodelta base. Together, these three deltaic deposits form a large subaqueous delta lobe extending far beyond subaerial distributary channels. Denser sandy distributary mouth bar deposits prograde over fine-grained delta-front and pro-delta base deposits, resulting in a coarsening-up grain size sequence, the classic sedimentological signature of a delta facies. Annual flooding and deposition of coarse sediments along natural levees increase their height and weight and result in channel extension.

Enlargement of the Delta Lobe

After bifurcation of the main-stem river mouth, distributary channels prograde and eventually bifurcate, resulting in a distributary channel.[5] Progradation of sandy distributary channels results in a subaerial delta finger. A continuum of environments is located between adjacent distributary channels, including freshwater swamps near the channel, brackish marsh, and saline interdistributary bays toward the coast.[7] Landward of the coastal interface flooding delivers inorganic silts and clays, resulting in accretion of the delta plain. Marsh and swamp deposits result in organic delta plain peats, which can be radiocarbon dated to establish the chronology of delta evolution.[8] Large flood events occasionally breach natural levees

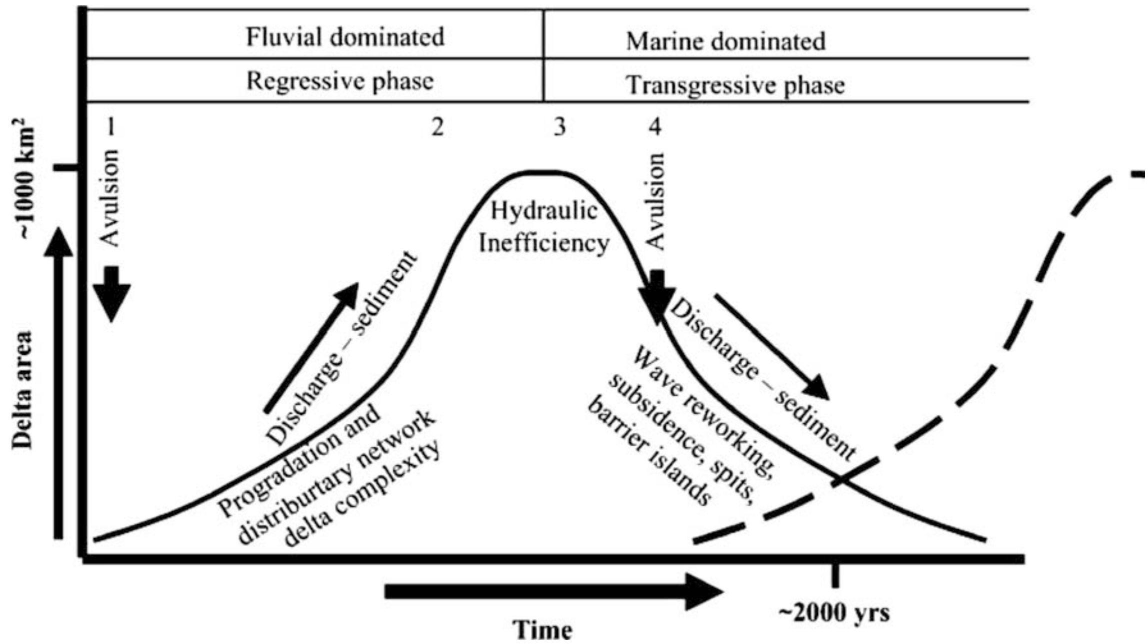

Fig. 2 The delta cycle, showing the time-dependent nature of deltaic environments: 1) initial progradation; 2) enlargement of delta lobe; 3) abandonment and transgression; and 4) reoccupation and growth of a new delta.

and deliver coarse silts and sands to low energy fine-grained marsh environments. Continued diversion of suspended sediments through the crevasse outlet produces a subdelta, replicating the form and functioning of main-stem deltas within compressed spatial (approximately 10^{-2} km^2) and temporal scales (approximately 10^{-2} yr).

Abandonment and Transgression

Distributary network extension and progradation has important consequences to the life-span of a delta lobe and diversity of ecological environments. Channel extension reduces stream gradient and, with diversion of streamflow into multiple channels, reduces hydraulic efficiency. This increases the probability of main-stem channel avulsion and formation of a new delta lobe. Progradation also establishes a vertical coarsening-up particle size trend. Fine-grained pro-delta base deposits are compacted by heavier sandy deposits, which initiate delta subsidence; a critical control on delta evolution. A major reason for delta subsidence is clay flocculation (clumping), which occurs when negatively charged colloidal clay enters a marine (saline) environment (Fig. 1). As denser delta finger sands prograde onto the prodelta base, porous flocculated clays are compacted, ultimately causing delta lobe subsidence. The amount of active delta lobe subsidence is generally countered by accretion of fresh flood deposits, preventing major erosion. However, in an abandoned delta lobe, after fluvial processes have ceased, marine processes become dominant and rework deltaic deposits into a transgressive suite of coastal landforms. The delta finger is initially reworked into flanking recurved spits, which eventually are separated from the transgressive (landward retreating) mud flats and are converted to narrow barrier islands.[9]

Reoccupation and Growth of a New Delta

The final stage of the delta cycle is initiation of a new delta lobe complex, or reoccupation of an old distributary course, following avulsion of the main-stem channel. This results in a vertical ''stacking'' of delta lobes, representing predictable changes in depositional and ecological environments.[7] Until the 1950s, it was believed that delta lobe switching (main-stem avulsion) was an abrupt process. However, sedimentologists now understand that the process requires hundreds of years, with the discharge of a drainage basin being shared between old and new delta lobes.[6,8] The bathymetry of the receiving basin influences the new delta lobe geometry, which is in part a function of the Holocene depositional history. A shallow and wide receiving basin results in a broad lobate delta lobe with a dendritic pattern of distributaries, such as the older Lafourche or newer Atchafalaya delta lobes within the Mississippi delta plain. In contrast, a narrow and elongate delta lobe, which extends further out to sea,

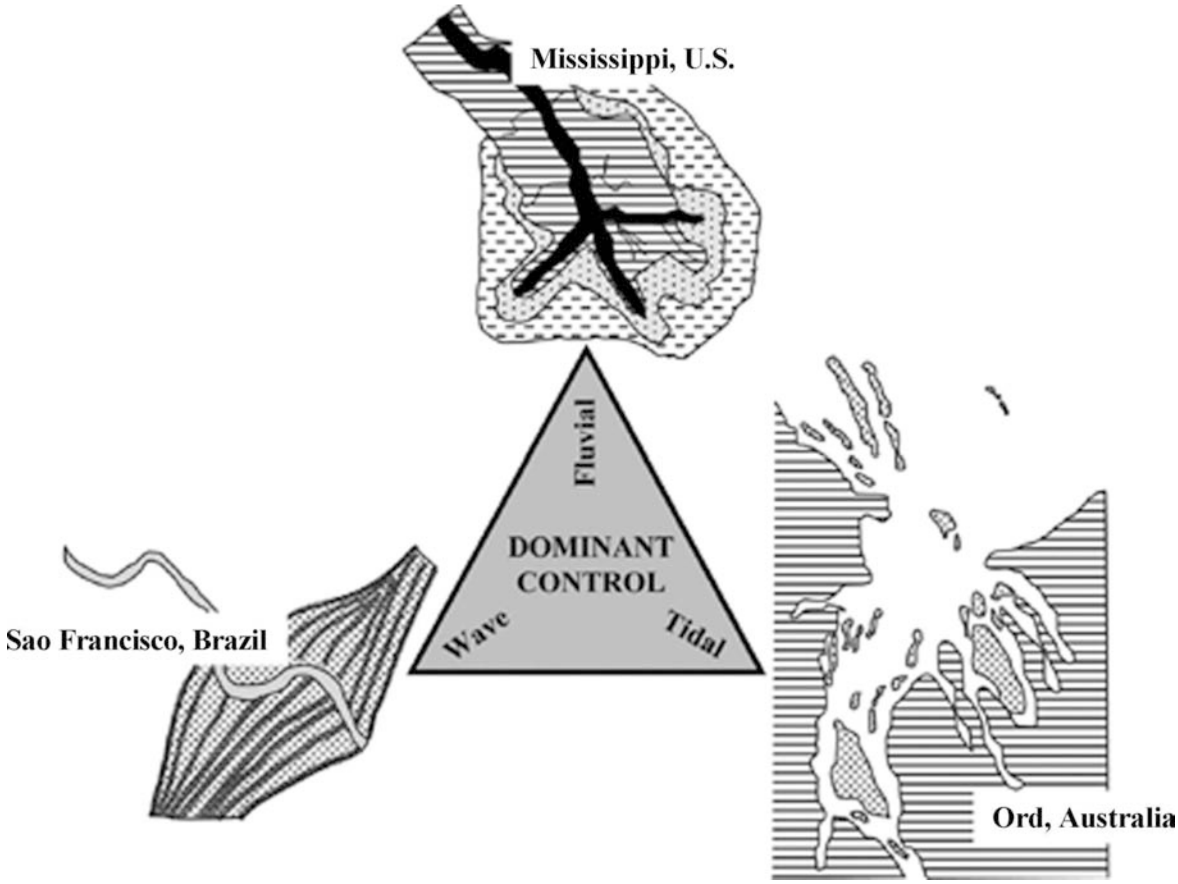

Fig. 3 Dominant controls on delta morphology with examples of end-members. Fluvial: the delta finger (sandy distributary mouth bar and levee deposits) is seen prograding over the silty delta front and the large fine-grained prodelta base. Wave: course river deposits are reworked by strong littoral drift processes into parallel beach ridges. Tidal: the large tidal flux reworks coarser river deposits into elongated sand bars oriented with (normal) to the river channel.

is formed where the receiving basin is confined by older subaqueous delta lobes. Indeed, the modern Mississippi delta lobe extends to the edge of the continental shelf. Thus, in comparison to other major delta lobes the geometry of the classic ‘‘bird's foot'' Mississippi delta may be quite unique.

DELTA PLAIN STYLE

Although the above model of delta formation remains widely accepted, it is important to note that the style and pattern of deltaic sedimentation varies tremendously depending on river discharge and sediment load (fluvial controls) as well as wave energy and tidal regime (marine controls) of the receiving basin.[1] Delta plain geometry is strongly related to the dominant processes that influence dispersal and reworking of fluvial sediments (Fig. 3). Early researchers[1,3,5] placed deltas into a tripartite classification scheme that considered planform geometry and fluvial, wave, or tidal processes. Fluvial dominated deltas extend far beyond the primary coastline and form when discharge and sediment load are deposited without being immediately reworked by waves or tides. Such deltas are ‘‘constructional,'' with the Mississippi being the prime example (Fig. 3). Small rivers discharging to open marine environments are unlikely to form fluvial dominated deltas because of low discharge and sediment loads. However, smaller rivers flowing into coastal bays or lakes may develop elongated deltas because the energy of the receiving basin is comparatively lower. Fluvial dominated deltas, however, are probably less common than marine dominated deltas. Wave dominated deltas, such as the Sao Francisco delta in Brazil, have coarser sediments rapidly reworked into linear sand bodies, becoming spits and sand ridges oriented parallel to the coastline because of the significance of littoral drift (Fig. 3). In contrast to wave dominated deltas, tidal dominated deltas such as the Ord of Australia have large embayed river mouths and estuaries. The large tidal flux reworks sands into linear sand bodies oriented with the river channel or perpendicular to the coastline (Fig. 3).

CONCLUSIONS

River deltas are young but complex geomorphic environments that exhibit spatial and temporal variability in form and process in response to fluvial and marine controls. Delta formation begins when a river debouches sediment into a standing body of water. This initiates the formation of three distinctive deltaic deposits: sandy distributary mouth bar, silty delta front, and a prodelta base of flocculated clay. River mouth progradation results in a coarsening-up vertical sequence, and, with time, denser sands compact soft underlying clay. Subsidence occurs as the distributary network shuts down because of a reduction in hydraulic efficiency. This is followed by main-stem avulsion and delta lobe switching, which may involve reoccupation of an older delta lobe.

Deltas have been important to humans for millennia and continue to be of great interest because of dependence upon deltaic resources. In an era of global sea level rise and rapidly growing populations along the world's coastlines, it is critical to understand the fundamental processes, which influence deltaic environments. The model of delta formation discussed here provides a general framework for understanding deltas. Because each river delta and the anthropogenic factors that influence it are unique, study of deltaic processes will continue to be a rich area of research for a variety of disciplines.

Desalination

Fawzi Karajeh
Fethi BenJemaa
Office of Water Use Efficiency, California Department of Water Resources, Sacramento, California, U.S.A.

INTRODUCTION

Desalination, also known as desalinization or desalting, is the process of removing dissolved salts and minerals from saline water to produce fresh potable water. Desalination was explored very early in history and its use goes back to ancient times, where simple distillation techniques were employed. Nowadays, brackish water and seawater desalination is becoming a common practice to meet fresh water needs in many parts of the world, especially in the arid regions of the Middle East and North Africa, and in many island communities such as the Canary Islands and Malta. Desalination technology is also used to treat wastewater effluents for reuse and to improve the quality of fresh water for potable and industrial uses. Most desalination processes are based either on thermal distillation or membrane separation technologies. Among the technologically proven and commercially utilized desalination processes are: reverse osmosis (RO), electrodialysis (ED), electrodialysis reversal (EDR), multieffect distillation (MED), multistage flash distillation (MSF), and vapor compression [mechanical (MVC) or thermal (TVC)]. Key issues associated with the use of desalination include cost, energy use, and environmental impacts of brine disposal and feedwater intake.

DESALINATION PROCESSES

Thermal Processes

Thermal desalination processes are based on distillation, which consists of heating a saline solution to induce water to evaporate leaving the salt behind, the vapor is then condensed to produce pure water. Simple distillation consumes a considerable amount of energy, making it impractical as a water supply option. However, modern thermal desalination processes employ more efficient distillation techniques through the regulation of the evaporation pressure and the use of more efficient heat exchangers and heat recovery methods in a multistage setting. These processes take advantage of the relationship between pressure and the boiling point, making it possible to evaporate water at a number of successive stages, each operating at lower temperature and pressure than the preceding stage. Among such processes are MED, MSF, and vapor compression (VC).

Multieffect distillation is based on the concept of a multitude of successive effects where water is repeatedly evaporated at increasingly lower pressures and temperatures without the need for additional energy. Vapor produced at a given effect is used for heating and evaporating additional quantities of water in the subsequent effect, while operating at a slightly lower pressure (Fig. 1). The vapor then passes through a heat exchanger where it condenses while preheating the incoming saline feedwater.

MSF is similar to MED and consists of a multitude of successive stages operating at progressively lower pressures. Feedwater enters the system backward from the last stage toward the first; as it travels, it gains energy and serves for condensing vapor flashing at each stage. The feedwater gains sufficient heat at a high pressure until it reaches the first stage where the pressure drops and sudden evaporation (flashing) occurs. Flashing continues in each stage at lower temperatures and pressures (Fig. 2). Unlike MED, the evaporation and condensation phases in the MSF process both occur within the stage. MSF plants are generally of large scale, with capacities reaching tens of MGD, and a typical plant can be composed of 15–25 stages.

VC is a distillation-based process where the evaporating heat is obtained via compressing vapor rather than direct heat exchange. Depending on the procedure used for compression, we identify two vapor compression processes: MVC, where a mechanical compressor is used (Fig. 3), and TVC, where a steam ejector is used. Generally, VC plants have built-in capacities ranging from few gallons to few MGD.

Membrane Processes

Membranes are used as barriers to filter out particles, salts, and chemicals from water in a selective manner. Various types of membrane separation methods have been developed. The most widely used processes for water desalination are RO, ED, and EDR.

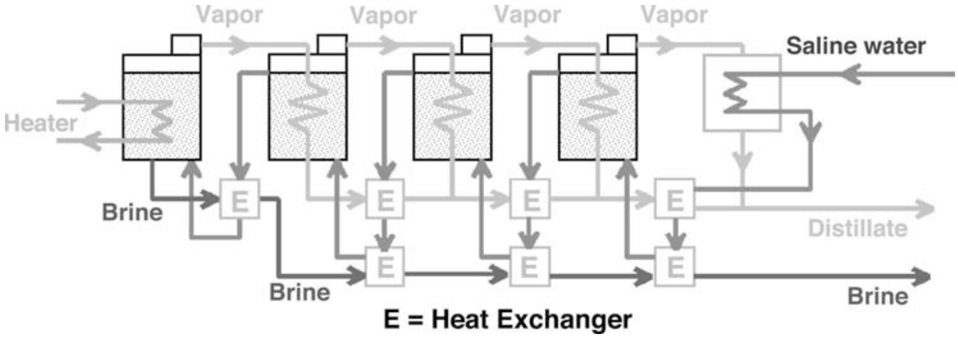

Fig. 1 Multieffect distillation process.

RO, a pressure-driven process, is a relatively new technology gaining ground over other processes by the end of the twentieth century. Feed saline water is pressurized against a semipermeable membrane that allows the passage of water whereas salts are retained; as a result, high-quality product water is obtained and the remaining portion of feedwater, which becomes more concentrated in salt, will be rejected as brine. Osmosis is a natural phenomenon that occurs when two solutions are separated with a semipermeable membrane, causing water to flow from the side of low solute concentration to the side of high solute concentration. RO employs pressure to counteract and exceed the natural osmotic pressure, reversing the normal osmotic flow, in order to squeeze water out of a concentrated solution (Fig. 4). A typical RO plant (Fig. 5) operates in three main stages: 1) the pretreatment stage—fine filtration and addition of acid and other chemicals to inhibit bacteria growth and precipitation of sparingly soluble salts; 2) the RO module—where high-pressure pumps are used to enable water passage through the membrane; 3) the posttreatment stage—stabilization of water before its use (this includes pH adjustment and the removal of residual chemicals and gases). RO membranes are generally encapsulated in cylindrical modules in a spiral wound configuration or as hollow fibers or capillary tubes.

ED and EDR are electrically driven processes where an electric potential causes the ions of the saline solution to migrate toward the electrodes passing through selective membranes. Successions of two types of selective membranes (cation-permeable and anion-permeable) are alternatively arranged between the electrically charged electrodes. In EDR, polarity of the electrodes is periodically reversed to prevent scaling. The spaces between successive membranes (anionic and cationic) are called cells. Anions (−) pass through the anion-permeable membrane toward the positive pole. Likewise, cations (+) pass through the cation-permeable membrane toward the negative pole. As a result of this electric separation process, the concentration of ions increases in some cells and decreases in others. Demineralized water is then collected from the cells in which the solution is diluted and a concentrate is discharged from cells where concentration increases (Fig. 6).

Other membrane processes that are commonly used for water softening and treatment include nanofiltration (NF), ultrafiltration (UF), and microfiltration (MF). NF is similar to RO, except that the membranes remove multivalent salts more efficiently than monovalent salts. UF and MF have larger pore sizes that allow the excellent removal of suspended solids, but not the removal of metallic ions and salts.

Other Processes

A number of other desalination processes that are not widely used include freezing, air humidification and dehumidification, and membrane distillation.

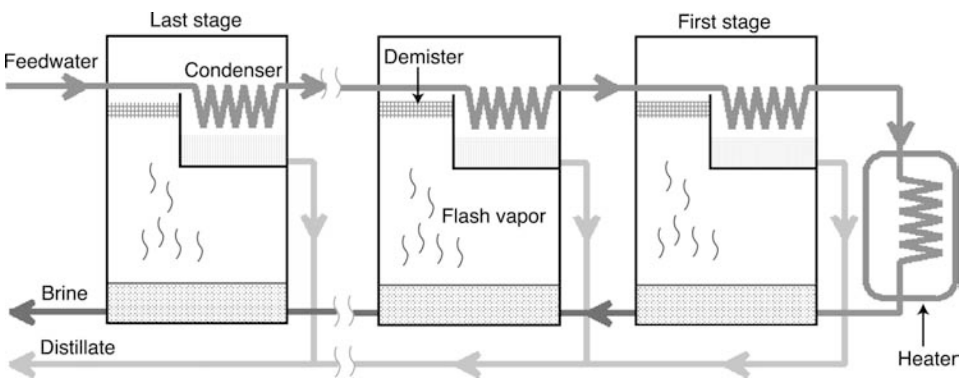

Fig. 2 Multistage flash distillation process.

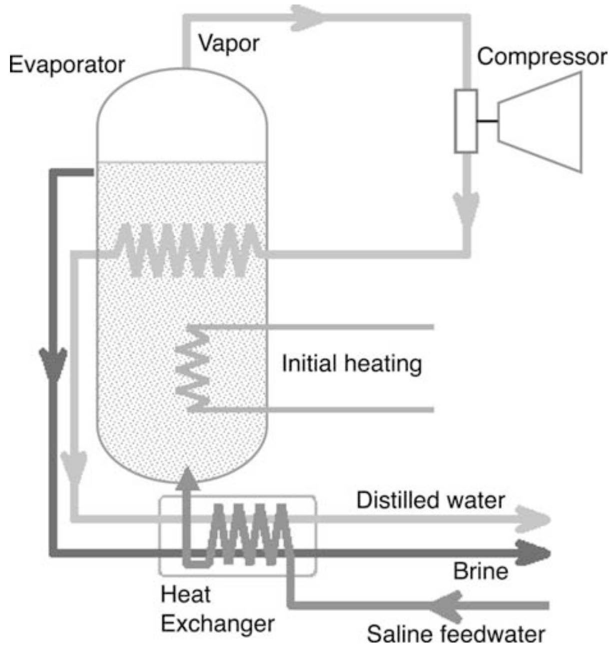

Fig. 3 Mechanical vapor compression process.

Freezing is based on the fact that ice crystals, even when formed within a saline solution, are constituted of pure water only. This process consists of separating ice crystals from the saline solution to produce fresh water.

Air humidification is a process that mimics the natural hydrologic cycle, which perpetually purifies water through an evaporation and condensation sequence. Air is heated, then placed in contact with water to produce vapor (humidification). The moisture-saturated air is then cooled, causing moisture to condense. The historical glass-covered solar stills can be classified under this category. However, more complex humidification and dehumidification systems were developed in recent years.

Membrane distillation is a process combining distillation and membranes. Saline water is heated to produce vapor that will pass through a hydrophobic membrane, which is permeable to vapor but not to water. Vapor is then condensed on the other side of the membrane to produce fresh water.

PRETREATMENT AND POSTTREATMENT

Prior to any desalination process, feedwater requires adequate pretreatment consisting primarily of the removal of suspended solids and particulates to prevent fouling and the addition of antiscalants to prevent mineral scale build-up. An optimized pretreatment process allows desalination plants to run more efficiently and at higher water recovery rates. After passing through the desalination process, desalinated water is stabilized by adding back some mineral components so as to ensure balance and optimum taste for public consumption and for compatibility with the existing distribution system. The water is then chlorinated to ensure conformity with health and drinking water quality standards.

KEY ISSUES FACING DESALINATION

The traditional and main constraint preventing the widespread use of desalination is the associated cost. The high cost is often attributed to the large quantity of energy needed by the desalination process. Besides energy use, others factors may also substantially drive up the cost such as chemicals needed for treatment and cleaning, fouling and corrosion of various components, source water quality, operation and maintenance costs, and requirements for concentrate disposal.

Other issues and concerns that may need special attention include the environmental and ecological impacts associated with brine disposal (effects of high salinity, residual chemicals as well as high discharge temperatures to receiving water ecosystems including aquatic life, plants and wildlife), the effects of surface feedwater intakes on aquatic life (entrainment and impingement of fish, larvae, and marine organisms), and the effects of well intakes on groundwater

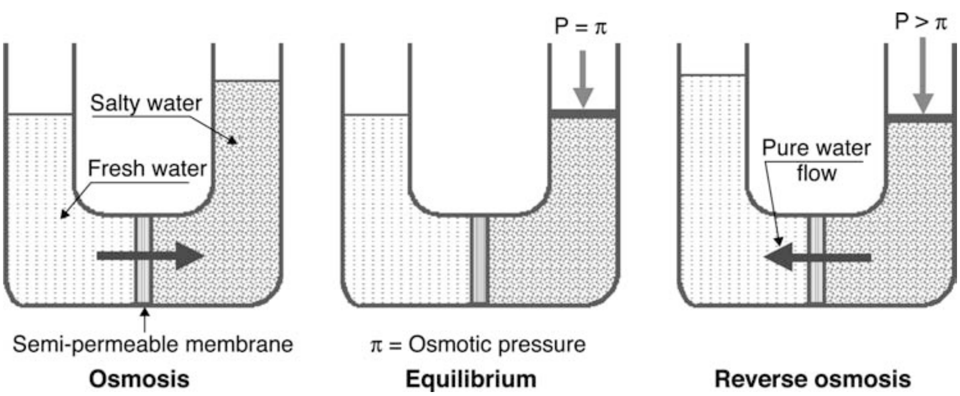

Fig. 4 Osmosis and reverse osmosis concepts.

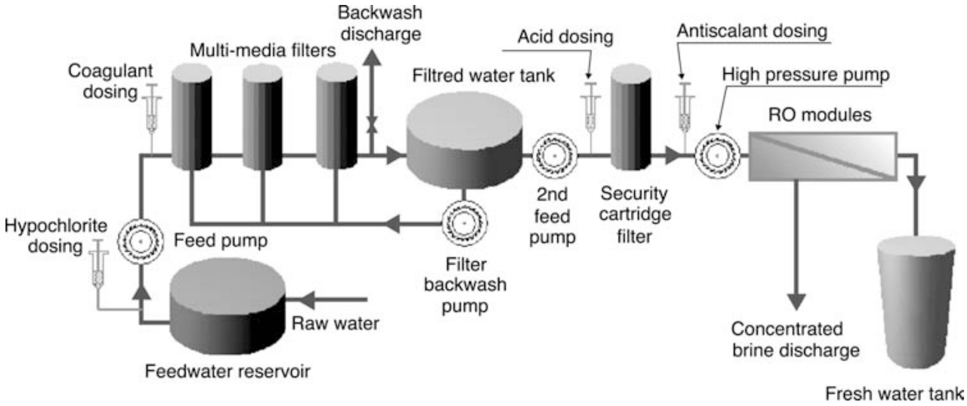

Fig. 5 Basic components of a reverse osmosis desalination plant.

(e.g., overdraft and seawater intrusion). Some of the concerns and impacts associated with feedwater intake and brine discharge may be offset by colocating desalination plants with power plants so as to take advantage of existing intake and outfall structures and to dilute the brine discharge. Discharge to a wastewater treatment plant or mixing the brine with the treated wastewater effluent will also contribute to its dilution.

CONCLUSION

As more and more stress is exerted on conventional water sources worldwide and given the rising cost of developing new water supply sources, desalination of seawater, brackish, and impaired waters is becoming a viable alternative for meeting the ever-growing demand for fresh water. Various processes have been proven to successfully produce potable water from saline sources; and recent technological improvements, especially in the domain of membrane technology, have made desalination more affordable and, in some instances, competitive with other water supply options. A desalination process that is well disposed toward the environment can play an important role as part of a diversified water supply portfolio to meet current and future water needs for many arid and water-stressed regions. Although many of the desalination processes

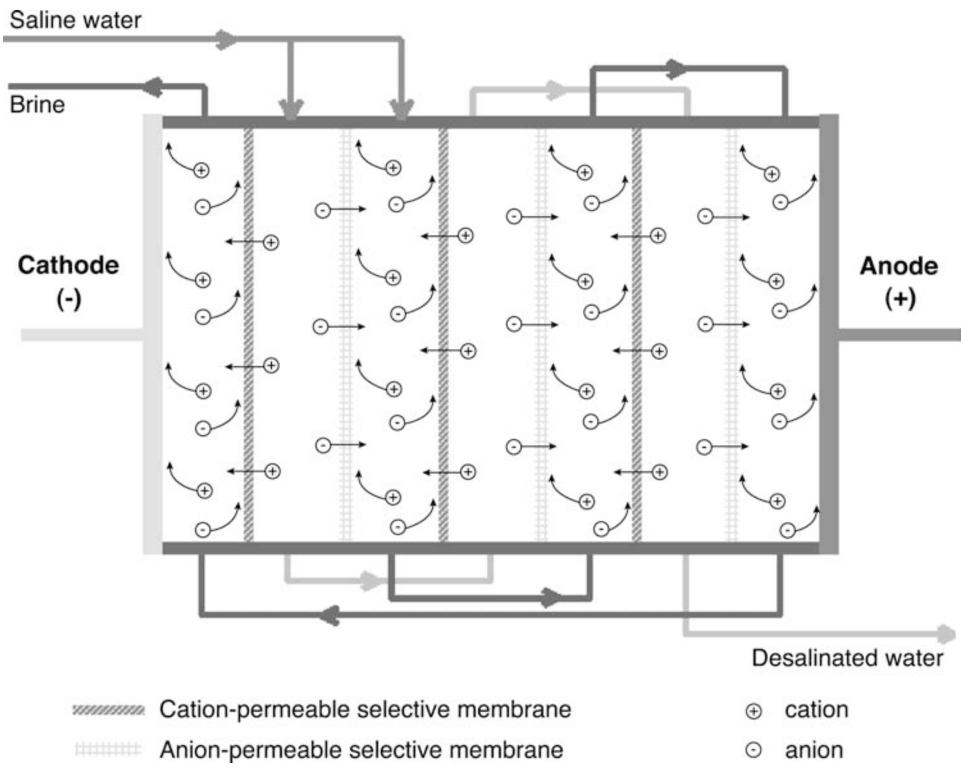

Fig. 6 Electrodialysis process.

currently in use have reached maturity, there is still room for improvement and perfection. Research needs deemed crucial in advancing desalination use include the following factors: more efficient pretreatment and posttreatment methods, improved process designs and the development of cheaper corrosion-resistant materials, improved membranes with higher salt rejection rates, improved scaling and fouling prevention techniques, environmentally acceptable strategies for brine disposal and concentrate management, advanced technologies that reduce entrainment and impingement of aquatic organisms at the feedwater intake, and opportunities for energy efficiencies, energy recovery methods, cogeneration, and the use of renewable energies.

Drainage and Water Quality

James L. Baker
Department of Agricultural and Biosystems Engineering, Iowa State University, Ames, Iowa, U.S.A.

INTRODUCTION

Artificial subsurface drainage is required on many agricultural lands to remove excess precipitation and/or irrigation water in order to provide a suitable soil environment for plant growth and a soil surface capable of physically supporting necessary traffic, e.g., for tillage, planting, and harvesting. Although this drainage makes otherwise wet soils very productive, subsurface drainage alters the time and route by which excess water reaches surface waters and can carry nutrients, pesticides, bacteria, and suspended solids to surface waters and cause nonpoint source pollution problems. The net water quality impact of subsurface drainage considered here is determined by comparison to the same cropping system not having subsurface drainage (not on the fact that the existence of adequate drainage will affect land use). The degree of pollutant transport with surface runoff and subsurface drainage is determined by the product of the volumes of water and the pollutant concentrations in the water. These are both influenced by environmental conditions, pollutant properties, and management factors, and their interactions with subsurface drainage are discussed.

ENVIRONMENTAL CONDITIONS

Soils/Hydrology

Whether water added to the soil surface as precipitation or irrigation infiltrates or becomes surface runoff is critical to water quality. Topography/slope, soil moisture content, texture, and soil structure, including the existence of preferential flow paths or ''macropores,'' can affect both the rate and route of water infiltration (as shown in Fig. 1). While different drain spacings are used to provide a desired ''drainage coefficient'' (e.g., 0.5 in./day) based on the internal drainage characteristics of the subsoils, the conditions of the surface soil will determine what percentage of applied water (rain or irrigation) will infiltrate. In general, the existence of subsurface drainage increases the volume of infiltration and thus decreases the volume of surface runoff (and pollutant loss with that runoff), increases shallow percolation, and lowers water tables. This effect will be more pronounced for ''lighter'' soils that have higher infiltration rates and lower water holding capacities. These changes affect the final quality of cropland drainage because of differences in time and type of soil-water–chemical interactions. Surface runoff allows water to come in contact only with the surface soil and materials such as crop residue and surface-applied fertilizers, manures, and pesticides present on it for short periods of time. On the other hand, water that infiltrates and percolates through the soil comes in intimate contact with all the soils in the profile to at least the depth of the tile drain, and generally, for much longer periods of time. The soil residence time is shorter for that portion of infiltrated water intercepted by the tile drains than for water that must flow through the underground strata to appear as base flow.

Climate/Precipitation

The timing, amount, and intensity of water inputs, including precipitation and irrigation, relative to evapotranspiration (ET) determines the timing and amount of excess water that will leave agricultural land as surface runoff and subsurface drainage. Inputs at low intensities generally will totally infiltrate, but as intensities increase past the rate of infiltration, surface runoff begins. As just discussed, because decreased antecedent soil moisture contents, which result from the existence of artificial subsurface drainage, increase infiltration rates, the volume of surface runoff generally is decreased when subsurface drainage exists. This effect will be more pronounced for areas where input intensities often exceed the rates of infiltration.

For a given crop and climatic region, the amount of ET is relatively constant, so the volume of subsurface drainage is very much dependent on the amount of input water above that value. As an example, in a 4-yr Iowa tile drainage experiment,[1] during a low rainfall year, only a trace of subsurface flow occurred; in a wet year (116 cm of precipitation vs the average of 80 cm), there was 29 cm of flow; and the overall average flow for the four yr was 15 cm.

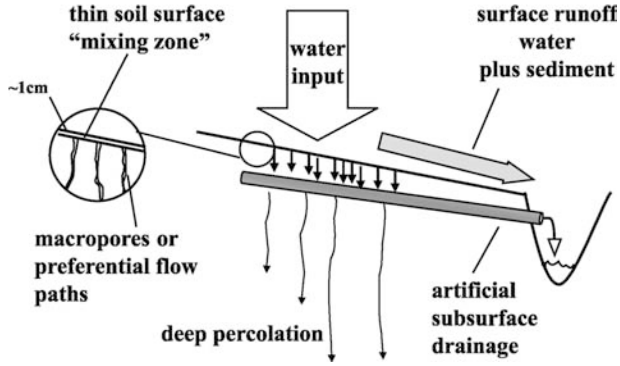

Fig. 1 Schematic of transport processes.

POLLUTANT PROPERTIES

Persistence

Pollutants that have a limited existence in agricultural lands because of plant uptake/chemical transformation (i.e., nutrients), degradation (i.e., pesticides), and die-off (i.e., micro–organisms) have different potentials for off-site transport with water based on their persistence. Because surface runoff is much more of an immediate process than subsurface drainage, concentrations of nonpersistent pollutants in subsurface drainage are usually lower than in surface runoff. This effect will be more pronounced, the lesser the persistence is. However, the "route" of infiltration, where in some cases the drainage water moves quickly through the soil profile because of macropores (see Fig. 1), plays a role and can somewhat negate the expected dissipation effect.

Adsorption/Filtration

Based on their chemical properties and/or their physical size, some pollutants transported down into and through the soil with subsurface drainage are removed from the flow stream by the soil. In particular, pollutants that are positively charged (e.g., ammonium-nitrogen (NH_4-N)) and larger, less soluble, organic compounds (e.g., some pesticides) can be attenuated by adsorption to soil clay and organic matter. Inorganic P ions can be removed by complexation or precipitation with soil cations. Microorganisms and sediment can be filtered out by small soil pores. Thus, in general, with the exception of soluble salts of nitrate-nitrogen (NO_3-N), sulfate (SO_4), and chloride (Cl) anions, pollutant concentrations in subsurface drainage are lower than in surface runoff. This effect will be more pronounced, the greater the interaction between the pollutant and soil is.[2]

For sediment itself, because soil erosion is dependent on the erosive ability and transport capacity of surface runoff, reducing the runoff flow rate and volume with subsurface drainage reduces sediment loss. For example, in a 6-yr study in the lower Mississippi Valley, surface runoff volumes from plots on a clay loam soil with subsurface drainage were 34% less than for plots without subsurface drainage, and the corresponding soil loss of 3500 kg/ha/yr represented a decrease of 30%. For the plots with subsurface drainage, both sediment concentrations and losses in subsurface drainage were about one-tenth those in surface runoff.[3]

For nitrogen (N), loss from poorly drained soils is usually much less than that from soils with improved drainage systems.[4] While significant N can be transported with sediment (often sediment has at least 1000 ppm N), land needing subsurface drainage is usually not highly susceptible to erosion, and N loss is dominated by soluble inorganic-N loss. In a 3-yr tile-drained watershed study in northeast Iowa,[5] NO_3-N losses in solution represented over 85% of the total N losses, including NH_4-N, organic-N in solution, and N associated with sediment. In a 5-yr study in east-central Iowa,[6,7] where nutrient concentrations in both surface runoff and subsurface drainage from cropland were monitored, NO_3-N concentrations in subsurface drainage averaged about 12 mg/L and 2–3 times those in surface runoff. While NH_4-N concentrations were usually 2–10 times higher in surface runoff, on an absolute scale, the concentrations were overall much lower than those for NO_3-N and constituted only a fraction of the total N loss.

For phosphorus (P), transport is primarily in surface runoff with sediment (often sediment has at least 500 ppm P) and dissolved in surface runoff. For conventionally tilled cropland, about 75–90% of P transported in surface runoff is with sediment. In areas where soil erosion is minimal, soluble P in surface runoff water can dominate transport. The soluble P in surface runoff (and subsurface drainage) is regulated by adsorption/desorption characteristics of soil. Therefore, with P in surface soils generally much higher than in subsoils, subsurface drainage usually has much lower soluble P concentrations than in surface runoff.

For pesticides, because of their adsorption characteristics, like with P, concentrations in surface runoff water are usually much greater than in subsurface drainage. However, this effect is even more dramatic for pesticides because unlike P, pesticides have a limited persistence, which decreases their potential for movement with subsurface flows with long travel times. In a series of studies on herbicides in surface and subsurface drainage,[8–10] atrazine concentrations in May (the period of application) were 75 μg/L in

Drainage–Dust

surface runoff for plots with surface drainage only, and were 51 μg/L and 1 μg/L in surface runoff and subsurface drainage, respectively, for plots that also had subsurface drainage. Not only were there much lower atrazine concentrations in subsurface drainage water, but the presence of the subsurface drains delayed and reduced surface runoff such that concentrations in surface runoff from the plots with subsurface drainage were reduced about one-third.

For bacteria, a review by Crane et al.[11] showed that fecal coliform counts in surface runoff from manured lands often were greater than 10,000/100 mL. In a comparison of surface runoff and subsurface drainage, Culley and Phillips[12] found similar counts (>10,000/100 mL) for fecal coliform in surface runoff from both manured and fertilized plots, but with much, much lower counts (<5/100 mL) in subsurface drainage.

MANAGEMENT PRACTICES

Tillage Systems

The hydrologic interactions between tillage systems and subsurface drainage that affects water quality involves how tillage affects the timing, route, and volume of infiltration (and hence the relative volumes of subsurface drainage and surface runoff). In a review of the hydrologic effects of conservation tillage, Baker[13] noted that changing the relative volumes of subsurface drainage and surface runoff also can affect chemical concentrations in those carriers. In general, increasing infiltration increases the time for beginning of surface runoff, which in turn reduces the concentrations of chemicals at the soil surface (shown as a thin mixing zone in Fig. 1) and therefore in surface runoff. However, the effect of conservation tillage on infiltration is time-dependent. For the first storm after any tillage there is usually less runoff from the tilled soil, although on an annual basis, conservation (or less) tillage often results in lower total surface runoff volumes.

Cropping

As with tillage, the hydrologic interactions between cropping systems and subsurface drainage that affects water quality involves how cropping affects the timing, route, and volume of infiltration (and hence the relative volumes of subsurface drainage and surface runoff). A major difference between perennial crops such as forages, and row-crops such as corn and soybeans, is the volume and timing of ET demands. In general, with higher, more consistent ET, perennial crops would have lower total drainage volumes. A bigger effect of cropping would be the effect of needed chemical applications and their potential losses. For example, the large amounts of N needed (added, recycled, and/or fixed) in a continuous corn or corn–soybean rotation means there is usually high NO_3-N concentrations in the soil profile, and hence in subsurface drainage when it occurs. However, for grasses and alfalfa. NO_3-N concentrations in subsurface drainage are much lower.[14,15]

Controlled Drainage

In areas where subsurface drainage exists, controlling the timing of outflows has been suggested as one method to reduce chemical losses. This controlled drainage could reduce losses by reducing both subsurface volumes and chemical concentrations. The potential for reduced concentrations is probably the greatest for NO_3-N, where the process of denitrification would reduce NO_3 to N gases in the soil profile where high water tables and the presence of organic matter drives the system anaerobic. The results summarized from 125 site-years of data from North Carolina[16] showed that controlled drainage reduced subsurface drainage volumes an average of 30% compared to uncontrolled drainage systems. Reductions in N and P lost with subsurface drainage were 45% and 35%, respectively. While almost all the reduction of P loss was due to decrease in drainage volume; for N, reductions in NO_3-N concentrations also contributed to the reduction.

CONCLUSION

The total effect of surface drainage on surface water resources receiving drainage from agricultural lands involves the relative volumes of surface runoff and subsurface drainage, and the relative concentrations of sediment, nutrients, pesticides, and bacteria. In general, the existence of subsurface drainage increases infiltration rates which delays and reduces the volume of surface runoff. For pollutants lost mostly with surface runoff, which include sediment, NH_4-N, P, pesticides, and bacteria, not only is the volume of the carrier reduced, but also the concentrations. This is because delayed runoff and more water moving through the surface-mixing zone reduce the amounts of contaminants at the soil surface available to interact with added water and overland flow. Thus the only real water quality negative to subsurface drainage is the increased volume of water moving thorough the soil profile carrying the soluble unadsorbed NO_3-N anion. The use of improved in-field N management in the way of rate, method, and timing of N applications has some potential to reduce this problem.[17] However, other practices such as controlled drainage or construction/reconstruction of wetlands may be needed to provide some NO_3-N reduction treatment. Alternatively, reducing the amount of row-crops grown on subsurface-drained lands could have a large impact although the current economics of doing that would be quite negative.

Drainage Coefficient

Gary Sands
Department of Biosystems and Agricultural Engineering, University of Minnesota,
St. Paul, Minnesota, U.S.A.

INTRODUCTION

Artificial (surface and subsurface) drainage systems are designed for the timely removal of excess water from land to reduce the risk of water damage to crops, soils, or structures. The term drainage coefficient represents the quantity or rate at which water is removed by the drainage system to either lower a water table (saturated portion of the soil profile) or accommodate surface runoff. For subsurface drainage systems, drainage coefficients are usually expressed as a depth of water removed per 24 hr over the drained area (mm/day), and for surface drainage systems, as a rate of flow per unit area drained. Drainage practitioners—farmers, contractors, engineers—routinely use the term drainage coefficient as an important criterion in design, operation, and management of drainage systems.

ESTIMATION AND SELECTION OF DRAINAGE COEFFICIENTS

The estimation and selection of drainage coefficients for a drainage project require an understanding of soil properties, surface and subsurface hydrology, and involve economic and risk decision-making. Estimation of soil drainage rates involves the process of determining the nature and extent of excess water, and how soil and drainage design factors influence the water removal rate for the soil of interest. Knowledge of the hydrology of the area to be drained (field, farm, building site, watershed) such as, the amount of excess water that occurs in response to various rainfall events and the drainage characteristics of the soil, is very important. Because drainage coefficients depend on both climatic and soil/watershed characteristics, they should be regarded as site/region specific values.

The rate at which water can be drained from the soil depends on soil hydraulic properties (e.g., hydraulic conductivity or the ability to transmit water), various drainage design parameters, and water table depth. Table 1 shows the effect that some of these parameters have on drainage rate.

The rate at which water can be removed from the field depends not only on the previous factors, but also the size and slope of the drains. Some practitioners consider the term drainage coefficient to indicate the maximum capacity of the drainage system, in mm/day. The capacity of the drainage pipe network may in fact, exceed the rate at which water can move through the soil to the drains. Hence, the actual drainage coefficient is typically less than the capacity of the drainage pipe network.

It is through the judicious selection of the design parameters that the drainage practitioner influences the rate at which water is removed from the drainage area. For drainage in irrigated regions, additional water for irrigation leaching requirements (application of excess water to ''flush'' the rooting zone) must also be factored into drainage coefficients and system capacities.

The *selection* of the appropriate design drainage coefficient from a set of possible values comprises elements of both economics and risk. The appropriate coefficient depends not only on the estimated cost of drainage measures or techniques, but also on the relative value of that which is to be protected from water damage. In the case of agricultural crops and other plants, the relationship of plant growth and performance to excess water stress is

Table 1 Effect of various drainage parameters on drainage rate

Parameter	Change in parameter	Effect on drainage rate (all other factors unchanged)
Drain spacing (for systems with parallel drains)	Increase	Decrease
Drain depth	Increase	Increase
Soil texture	Lighter	Increase
Soil hydraulic conductivity	Increase	Increase
Water table depth (over the drains)	Increase	Increase

paramount to selecting appropriate drainage coefficients. Plants that are more sensitive to excess water stress or are of higher value may justify the selection of higher drainage coefficients. The effects of inadequate drainage on crop growth and yield were recently summarized by Evans and Fausey.[1]

As a design criterion, the drainage coefficient plays the primary role in the size and extent (capacity), and ultimately, the cost of a drainage system. For a given area of interest, use of a larger drainage coefficient typically results in a more extensive drainage system, greater system capacity, and cost. These costs must be considered together with the expected benefits of the system to produce a design as close to the economic optimum (maximum net return) as possible. Fig. 1 shows the concept of balancing increased drainage system cost with increased levels of excess water control. The selection of drainage coefficients must also incorporate risk because, as a precipitation-driven process, drainage needs from year-to-year are uncertain. Thus, risk and economics are inherent elements in the selection of drainage coefficients, implying that the design of a drainage system that reduces the risk of damage to zero can rarely, if ever, be justified.

A number of different approaches to estimating and selecting drainage coefficients have been taken over the years. These approaches can be generalized into the following categories: 1) mathematical models; 2) field experimentation/measurement; and 3) computer modeling. Mathematical models and field experiments focus on estimating drainage rates based on soil, rainfall, and drainage design parameters. Computer models such as DRAINMOD[2] have been used to bothestimate drainage coefficients and select optimal design parameters for drainage systems based on

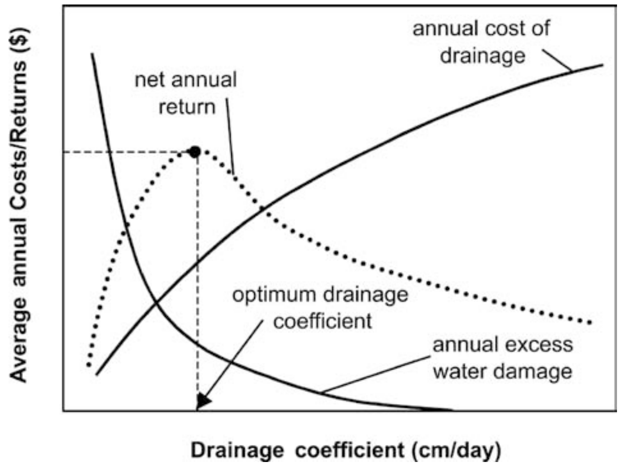

Fig. 1 Economic consequences of drainage coefficient (system capacity) selection.

Drainage–Dust

Table 2 Criteria for water table depth and drainage coefficients for various countries

Country	Water table depth (m)	Drainage coefficient (mm/day)
Humid regions		
South China (Jiangsu province)	Concentrated root system layer plus the height of the capillary moisture saturation of the soil	
	wheat 0.5–1.2	
	cotton 0.5–1.5	
Germany		7–18
Hungary	0.5–1.2	3.5–5.2
Ireland	0.4–0.6	10–15
Netherlands	0.3–0.5	7–10 (in greenhouses, 20–30)
Poland	Planting season 0.4–0.6	5–8
	Growing season 0.45–0.8	
Portugal		9–18
France	Drawdown from 0.20 to 0.45–0.5 within one day for intensive arable land, 3–5 days for grassland or less intensive arable land	10–20 (in mountainous areas up to 50)
Japan	Paddy monoculture 0.3–0.4 after 2–3 days of rainfall and 0.4–0.5 after 7 days of rainfall	10–50
	Permanent crops 0.5–0.6 after 2–3 days, and 0.6–1.0 after 7 days of rainfall	
U.S.A.		10–38

(Continued)

Table 2 Criteria for water table depth and drainage coefficients for various countries *(Continued)*

Country	Water table depth (m)	Drainage coefficient (mm/day)
Semiarid and arid regions		
India	1.2	2.5
Iraq	1.2	2.5–3.0
Pakistan	Cultivated land 1.0	2.5–3.5
	Fallow land 1.5	
Romania	Sandy soils 0.6–0.8	3.5
	Intermediate soils 1.0–1.2	
	Heavy soils 1.3–1.2	
USSR		0.8–3.5
Australia	For moderately saline groundwater (2.0 ds/m)	0.8–3.5 horticultural crops
	One week after irrigation 0.8–1.1	2.5–5.0
	Horticulture 0.45–0.75

Drainage: Controlled

Robert O. Evans
Department of Biological and Agricultural Engineering, North Carolina State University, Raleigh, North Carolina, U.S.A.

INTRODUCTION

Excessive soil water is a major concern on soils with seasonally shallow water tables. Drainage is the practice of removing excess water from land in order to facilitate seedbed preparation and planting and to provide adequate aeration following excessive rainfall. Several techniques are available to improve drainage and reduce excess water-related crop stress. These include both surface practices[1] and subsurface practices.[2–4] While wetness is the major concern, soil moisture under rainfed conditions varies such that crops periodically suffer from drought stresses even on traditionally shallow water table soils. Intensive drainage systems that are often necessary to remove excess water during extreme wet periods, tend to remove more water than necessary during drier periods, a condition referred to as temporary overdrainage.[5] To reduce the occurrence of overdrainage and improve crop utilization of rainfall, a water control structure may be installed in the drainage outlet to regulate or "control" the rate and amount of drainage, Fig. 1. The decline in the drainage volume often results in a reduction in the nutrient load being discharged with the drainage water.[7,8] While recent growth in the use of controlled drainage has been to conserve water and enhance drainage water quality, controlled drainage has been used historically to reduce subsidence in drained organic soil.[9] This application continues in places such as the Everglades agricultural area in Florida, the Wester Johor area in Malaysia, and several other locations around the world.[10]

HOW CONTROLLED DRAINAGE WORKS

Controlled drainage involves the use of some type of adjustable, flow-retarding structure placed in the drainage outlet that allows the water level in the outlet to be artificially set. Many types of structures can be used depending on the layout of the drainage system. Controlled drainage may be practiced with either surface or subsurface drainage systems, although the benefits of drainage control are closely correlated to subsurface drainage intensity. In other words, controlled drainage effectiveness increases as the subsurface drainage intensity increases. Where drain tubing or field ditches outlet directly to an open channel such as a canal or stream, the system is referred to as an open system. Water control structures for open systems may range from simple, stop-log, weir type structures often referred to as flashboard risers,[11] Fig. 2, to automated inflatable dam type structures.[5] Where drain tubes outlet to main drains rather than open channels, the system is referred to as a closed system.[12] Several tubing manufacturers have designed and marketed barrel type structures for use in closed systems that function as a weir in the main drain line and allow the water level to be controlled.

When operated in the controlled drainage mode, drainage occurs as long as the water table in the field is at a higher elevation than the weir elevation at the control structure. As the water table in the field recedes, the rate of drainage decreases. Once the water table drops below the weir setting, drainage stops; however, the water table will continue to recede as the crop removes water by evapotranspiration. Once the field water table drops below the water level in the outlet, the process may reverse and water stored in the outlet ditch flows back through the drains into the soil profile. The amount of water stored in the outlet depends on the dimensions of the outlet. Large canals may supply the equivalent of 5–10 mm while tubing outlets store very little water. In either case, water stored in the soil profile that would otherwise drain is typically of greater magnitude than the amount of water stored in the outlet. In the controlled drainage mode, the water level in the outlet typically fluctuates several times during the growing season between the weir setting and the bottom of the outlet, Fig. 3, in response to daily fluctuation in rainfall and evapotranspiration.

The control structure is normally sized to convey the full capacity of the ditch or waterway during high flow periods. For a flashboard riser type structure, the flashboards function as a rectangular weir, Fig. 4, and the flow over the weir is computed by the equation:

$$Q = CH^{3/2}(L - 0.2H) \quad (1)$$

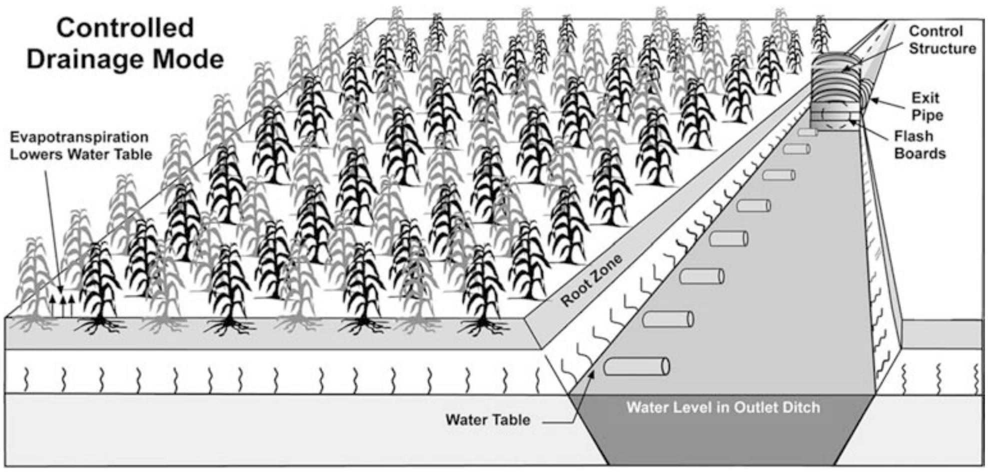

Fig. 1 Schematic of the controlled drainage operational mode. Drainage stops when the water table drops to the same level as the top of the control structure (weir). The water table may continue to drop due to evapotranspiration. *Source*: From Ref.[6].

where Q is the discharge in cubic meters per second neglecting velocity of approach, L the length of weir in meters, H the head on the weir in meters measured at a point no less than $4H$ upstream from the weir, and C is 3.33 for rectangular weir.

The weir design is normally based on fully contracted flow, which means that the weir crest and sides are far enough removed from the bottom and sides of the weir box or channel that "fully contracted" flow is developed. The discharge pipe for a flashboard riser structure is sized as a culvert (i.e., boards are out and ditch is flowing full), although the weir is normally sized as though boards are in place. This usually eliminates the need for the farmer to rush out to the structure and remove boards each time a high flow event occurs (flash flood type event). The design head on the weir is typically assumed to be between 150 mm and 300 mm. These design constraints result in a weir length that is about 1.5 times the diameter of the culvert or outlet pipe. Similar design guidelines are used for barrel type structures.[15] The backfill over the outlet pipe must be of suitable texture and compaction to function as a dam. The outlet pipe often serves as a road crossing so the pipe length typically varies from 6 m to 12 m depending on depth of the ditch and whether or not head walls are constructed. Water pressure acting against the upstream side of the flashboard riser results in uplift, which tends to cause the structure to "float up." For small structures, typically structures with weir lengths less than 0.5 m, the weight of the soil over the outlet pipe is adequate to counteract the buoyancy of the water being held by the structure. For structures larger than 0.5 m, concrete should be poured around the base of the structure to offset the buoyancy of the upstream water.

Fig. 2 Flashboard riser type water control structure used to manage the outlet water level in an open ditch system.

PRODUCTION BENEFITS OF CONTROLLED DRAINAGE

In shallow water table soils, crop yield is roughly related to water table depth as shown in Fig. 5. Under highly controlled environmental conditions with a static water table, there is an optimum water table depth, typically 0.6–1 m deep, where yield will be maximized. This optimum depth is associated primarily with the type of crop and the soil physical properties affecting soil-water and aeration. Under field conditions, the water table position is constantly fluctuating such that an absolute optimum rarely exists. When the water table is close to the soil surface, conditions are typically too wet for optimum crop growth and yields are often suppressed due to wet stress. Holding the water table too high can result in root pruning and nitrogen deficiency as high water levels promote rapid loss of

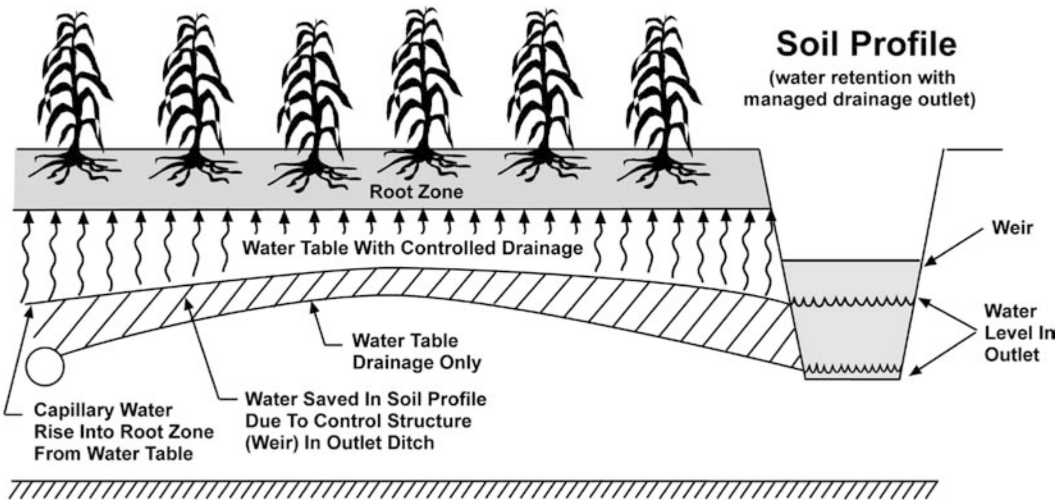

Fig. 3 Water level fluctuation with a controlled drainage system. The cross hatched area represents the amount of water saved during one cycle. Once the water table drops below the weir, it does not rise again until the next rainfall event large enough to cause percolation below the root zone. *Source*: From Ref.[13].

nitrogen through denitrification. Similarly, when the water table drops ''too low'' below the root zone, capillary rise (as was shown in Fig. 3) is not adequate to supply evapotranspiration requirements leading to crop yield reduction due to drought stress. The objective and challenge with controlled drainage is to manage the water table within these two extremes.

Controlled drainage has the greatest production benefit where drought conditions are intermittent and of short duration. For a single event, controlled drainage may retain up to 25 mm of water in a sandy soil profile that would otherwise drain from the system. The water saved could delay drought stress for a period of 3–7 days depending on evapotranspiration. Over the course of a growing season, drainage control may conserve upwards of 75 mm that would otherwise drain from the soil.[13] Actual storage depends on the drainage intensity, drainage system layout, and soil drainable porosity. The benefit of the water saved depends on the rainfall amount and distribution during the growing season coupled with the water requirements of the crop.

Crop yield response to water table depth and subirrigation has been studied extensively.[17] Although controlled drainage has been practiced with a variety of crops, there are only a few field studies documenting yield response. Most studies have involved corn, soybean, or wheat. In a watershed scale study in North Carolina, Parsons and Evans[18] reported a 15–25% yield increase with water level control on corn, Table 1. In a 10-yr study, Cozier et al. (unpublished data, N.C. State University, Department of Soil Science) observed yield responses ranging from −16 to 13% for corn and 5–21% for soybean with controlled drainage compared to conventional drainage. They observed considerable year to year variation

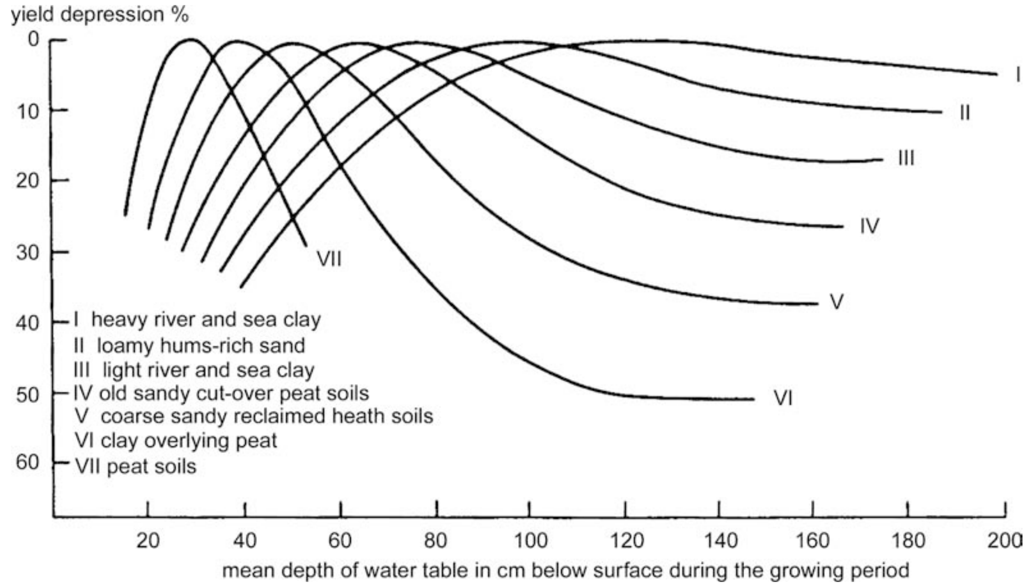

Fig. 5 Yield depression as a function of the mean depth of the water table during the growing season for various soil types. *Source*: From Ref.[16].

that was closely correlated to rainfall with controlled drainage being most beneficial in dry years. Winter wheat yield was generally suppressed by controlled drainage, a result they concluded was due to periods of excess moisture occurring during the winter and early spring. While yield increases have been observed, results demonstrate that controlled drainage must be closely managed to obtain consistent yield benefits.

WATER QUALITY BENEFITS OF CONTROLLED DRAINAGE

Fertilized cropland is a potential source of nitrogen and phosphorus, which can contribute to the nutrient enrichment of surface water ecosystems.

Table 1 Summary of corn yields at the Mitchel Creek Stream Control Project, 1981–1985

	Corn yield, kg/ha			
	No stream control		Stream water control	
Year	Non-irrigated	Irrigated	Non-irrigated	Irrigated
1981	6,460	10,662	—	—
1982	6,899	8,279	8,279	10,286
1983	3,199	7,840	5,394	9,784
1984	7,401	9,533	7,338	10,411
1985	6,899	8,844	9,847	11,038
Mean	6,147	9,032	7,715	10,412

Many artificially drained soils are adjacent to environmentally sensitive and ecologically important surface water resources. Often natural streams and surface water bodies provide the outlet for artificial drainage systems. Research has shown that agricultural drainage water may contain fertilizer nutrients. In many of the surface water bodies, nutrient levels, particularly nitrogen and phosphorus, have become high enough that a very delicate balance exists between undesirable species such as blue-green algae and other desirable flora.[19] Controlled drainage has been recognized in some states as a best management practice (BMP) to reduce the transport and delivery of nitrogen and phosphorus to surface waters.[7]

The first suggested use of controlled drainage for the purpose of reducing nitrate-nitrogen losses in drainage water came from experiments on drainage from irrigated land.[20,21] Both groups of researchers were successful but the practice apparently was not adopted in either location.[22] Research on the water quality benefits of controlled drainage was begun in North Carolina in 1974 and have continued since that time. Evans, Gilliam, and Skaggs[23] summarized drainage water quality studies representing approximately 125 site years of drainage and controlled drainage water quality data collected at 14 locations in North Carolina. Skaggs, Breve, and Gilliam[24] presented a comprehensive review of research on hydrology and water quality effects of agricultural drainage, citing studies from several countries. Gilliam, Baker, and Reddy[22] explained the processes by which nutrients are transported in drainage waters and how drainage control could be utilized to reduce drainage losses.

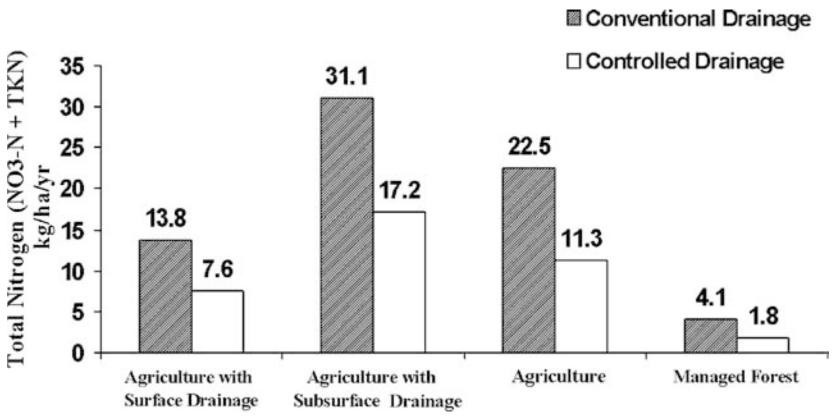

Fig. 6 Average annual total nitrogen transport in drainage outflow as measured at the field edge of 14 sites in eastern North Carolina. Controlled drainage resulted in a net 45% reduction compared to conventional drainage. *Source*: From Ref.[25].

Collectively, these reviews represent more than 200 published articles on the hydrology and water quality of drainage and controlled drainage practices. General conclusions derived from these reviews are summarized later. The reader is encouraged to refer to the earlier reviews for details and citations from the original work.

The original idea of using controlled drainage to reduce nitrate-nitrogen transport was that holding the water table closer to the soil surface would encourage more rapid and complete denitrification. Several studies have documented modest decreases (typically less than 15%) in nitrate-nitrogen concentration resulting from controlled drainage. However, the most dominant factor affecting the reduction in nitrate effluxes appears to be associated with the reduction in drainage volume sometimes on the order of 30% per year. The combined effect of concentration and outflow reduction resulted in a net decrease in nitrogen efflux of 45% in the North Carolina studies, Fig. 6. The reduction in outflow also resulted in a reduction in phosphorus efflux, Fig. 7, although controlled drainage did not cause a change in P concentration.

APPLICATION AND MANAGEMENT CONSIDERATIONS

The successful management of controlled drainage systems rests on two important objectives. The first is achieving optimum production efficiency and maximum nutrient utilization by the crop. The second is attaining maximum water quality benefits. A major challenge for controlled drainage is determination of the optimum water control level and then maintenance of the water table within that range. Typically, the costs of additional structures needed to maintain a suitable water level becomes prohibitive when the land slope exceeds 0.5%. Thus, controlled drainage is most practical on relatively flat fields. As noted earlier, potential production benefits are greatest in coarse textured drained soils sometimes prone to overdrainage and drought. Several studies have documented that the nitrogen reduction benefits increase at higher control levels up to about 300 mm from the soil surface. Ideal yields result when water levels are in the range 600–1000 mm. Under some conditions, productivity,

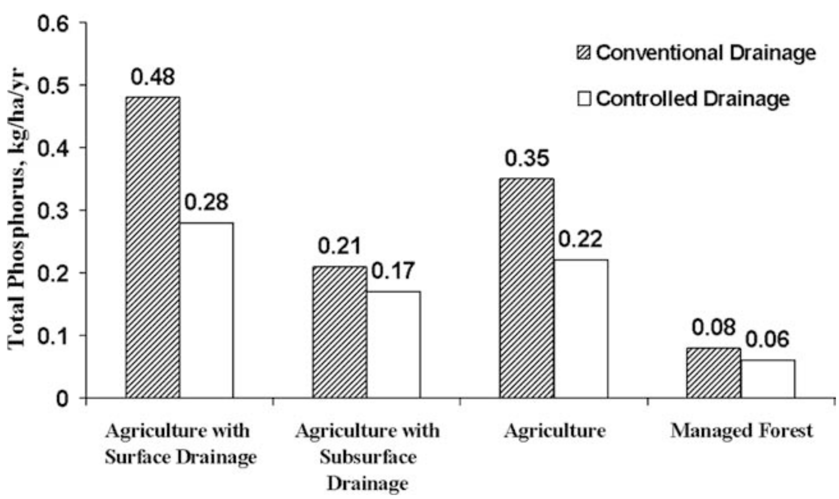

Fig. 7 Average annual total phosphorus transport in drainage outflow as measured at the field edge of 12 sites in eastern North Carolina. Controlled drainage resulted in a net 35% reduction compared to conventional drainage. *Source*: From Ref.[25].

water quality, or both goals may need to be mutually compromised for the benefit of the other. At other times, productivity and water quality goals may be compatible at least seasonally. Gilliam, Osmond, and Evans[26] present general management recommendations that attempt to achieve a balance between production and water quality goals. They suggest that for most mineral soils, the water table should be maintained between 300 mm and 1000 mm, depending on the crop and its stage of development, the need to access fields with equipment, and prevailing weather conditions. As a guide, crop production goals can be satisfied during the growing season with only modest compromise to water quality. They suggest that some water quality benefit will be realized, although not necessarily optimized, whenever the water level is maintained within 1 m of the soil surface. Water levels in the range 500–750 mm will satisfy crop requirements for most crops grown on most mineral soils during non-extreme wet periods. Water control levels should be lowered to 1000 mm to accommodate field operations involving heavy equipment. By holding the water table high (within 300 mm of the surface) during non-cropping periods, water quality goals can be optimized with no adverse production impacts. It should be noted that many of the management indicators are hidden from view and the response to adjustments is not always immediate. Thus, intensive management with long-term monitoring is necessary to develop a site-specific understanding of the system.

SUMMARY

The technical feasibility of controlled drainage is well documented. Controlled drainage can increase crop yields, reduce overdrainage, reduce the transport of fertilizer nutrients and other potential pollutants, and improve water use efficiency. The magnitude of the benefits vary among fields and watersheds as well as from year to year. The success of controlled drainage at any scale is influenced by soils, crops, topography, seasonal rainfall, hydraulic properties within the controlled area, and overall management of the system. While research over the past 30 yr has lead to significant improvements in design and operational methods, there still remains a need to improve and fine tune management strategies to optimize the net benefits of controlled drainage.

Drainage: Hydrologic Impacts

INTRODUCTION

Land drainage is the practice of removing excess water from the land, and it is one of the most important land management tools for improving crop production in many parts of the world. Drainage systems may be broadly divided into surface drainage (comprising land grading and open ditches), shallow drainage (such as subsoiling to mechanically loosen the upper layer of soil), subsurface or groundwater drainage (buried perforated pipes or deep ditches), and the main drainage systems (commonly open channels) used to convey the drain water away.[1] Drainage will inevitably affect the pattern of water flows from the land and into the receiving watercourses. It is these downstream impacts of farmland drainage on the timing and magnitude of peak flows which are considered here, using the results of experimental studies and computer simulations, to present a coherent picture, and to answer most of the apparent anomalies and conflicts.

HYDROLOGIC IMPACTS

Concern about the possible downstream effects of drainage is shown by many published papers worldwide, in North America,[2,3] Great Britain,[4,5] and continental Europe, including France,[6] Netherlands,[7] Ireland,[8,9] Finland,[10] and Germany.[11]The role of drainage has been highlighted by recent flood events—for example in the Midwest of the United States in 1993, and across Europe in 1997—which reawakened concerns that drainage could aggravate flooding downstream.

There has been a debate about the effects of drainage on streamflow for well over a century, but until recently due to the lack of appropriate data, the debate has been largely speculation. Too often, the absence of evidence has erroneously been taken as evidence of an absence of effect. The earliest published account[12] was a report of a 4-day meeting held at the Institution of Civil Engineers in London in 1861. Many of the arguments and opinions expressed have resonance today, but due to the absence of objective measurements the participants were unable to reach any conclusions and the meeting was inconclusive.

These conflicting opinions resulted from differences in the emphasis given to the two processes of water storage and routing. Considering the former, it may be argued that because drainage lowers the water table, the available storage capacity in the soil is enlarged and able to absorb more storm rainfall, thereby reducing peak flow rates. In contrast, according to the routing argument, the purpose of drainage is to "remove water from the land more quickly" than under natural conditions, so peak outflows must necessarily increase.

Probably more work has been carried out in Britain upon the effects of agricultural drainage upon streamflow than in any other country. Britain was the originator of modern field drainage[13] and so became the first country where concern arose about its downstream effects, it is also one of the most extensively drained countries in the world.

It is only in the last few years that it has been possible to obtain a coherent picture based on observations of field processes, and supported and extended by computer modeling. This has shown that general statements that drainage "causes" or "reduces" flood risk downstream are oversimplifications of the complex processes involved, and that any consideration of the impact of drainage on streamflow must identify the point of interest, whether at the outfall from the field, along the main channel, or a combination of both at the catchment scale.

Experimental studies indicate that the provision of surface drainage will result in higher peak flows downstream. This was shown by a long-term experiment at Sandusky in Northern Ohio,[14] and is a result of the reduction/elimination of surface storage capacity, as well as the provision of more efficient faster flow routes. This has been demonstrated conclusively both by experimental studies and by computer simulations.

In contrast, there seems to be general agreement from experimental studies that subsurface drainage of waterlogged, poorly permeable clay soils reduces peak outflows.[15–17] Since this is one of the most common situations where artificial drainage is used, it might be considered to represent the most general result of field drainage.

There are, however, instances where even on heavy soils this result may not apply. Due to their low hydraulic conductivity, most water movement in clay soils is confined to flow through macropores, such as cracks. As a result of clay shrinkage and cracking in warm, dry summers, rapid macropore flow can result in larger peak flows from the drained land than from the undrained land. The role of macropores on the seasonality of peak flows from drained land was demonstrated in detail.[18]

More permeable, drier soils may also be drained where there is an economic justification—for example, drainage of land producing high value crops. In contrast to clay soils, relatively few scientific field studies have investigated the impact of draining lighter, more permeable soils. This may be partly due to the emphasis on draining clay soils, but also, no doubt, results from the greater practical difficulty encountered in plot definition where the soils are more permeable. Nevertheless, data are available from several drainage experiments on permeable soils. At Withernwick[19] flow peaks were increased in the first year after drainage and there was then a reduction in the following years due to the progressive deterioration of the secondary system of subsoiling designed to improve the soil structure. Supporting evidence of increased peak flows following the drainage of more permeable soils also comes from studies at Cockle Park in northern Britain[20] and Ellingen in central Germany.[21]

To identify factors influencing drainage response, the results of field drainage experiments under temperate northern European climates were analyzed in terms of their site characteristics.[22,23] This included topography, precipitation, drainage depth and spacing, natural (i.e., predrainage) soil water regime, and the soil properties. The only characteristics distinguishing sites, where drainage increased peak flows from those where they were reduced, were those relating to the soil water regime before drainage. The experimental sites all had similar land practices on the drained and the undrained land.

Drainage reduced peak flows on sites, which had wetter soils, with poor natural drainage, and significant amounts of storm runoff were generated as overland flow and near-surface flow in the thin upper layers of the soil. These sites had higher topsoil clay contents, and shallower depths to a poorly permeable subsoil horizon. When artificially drained, the surface saturation was largely eliminated, greatly increasing the soil water storage capacity.

In contrast, at sites with more permeable, loamy soils which were not routinely saturated before drainage, natural stormflow occurred predominantly by slower subsurface flow, the artificial drainage pipes provided more rapid flow routes leading to increases in peak outflows.

The findings are summarized in Fig. 1. This shows the topsoil texture, together with the effect of drainage on peak flows, and provides the engineer or conservationist with an initial guide to predict the effect on flows of the drainage of a site, based on a knowledge of the predrainage site characteristics.

Further insights into the factors controlling the impact of drainage may be obtained by the application of modeling techniques to investigate the important interaction between soil properties and climate in determining soil water regimes. DRAINMOD[24] was applied to two of the field sites with similar climates: a heavy clay soil at Grendon and a more permeable loam at Withernwick. The model was applied to each site using actual field values of drain and soil parameters, and the simulated peak flows from drained and undrained land were compared for similar rainfall inputs. The results showed a 70% lower median peak flow after drainage of clay soil and an increase of 40% in the median peak flow from the more permeable land.[23]

The modeled fluxes and water stores confirmed that the reduction in peaks from the clay soil after drainage was achieved by a change in storm runoff generation from overland flow (caused by soil saturation) to subsurface drainflow. For the loamy soil, the model indicates that the increase in peak subsurface flow rates was due to the steeper hydraulic gradients created by the closer spaced artificial drains.

The model also demonstrated the effect of different climatic conditions. If the loam soil site at Withernwick had double the normal rainfall (1200 mm yr^{-1} instead

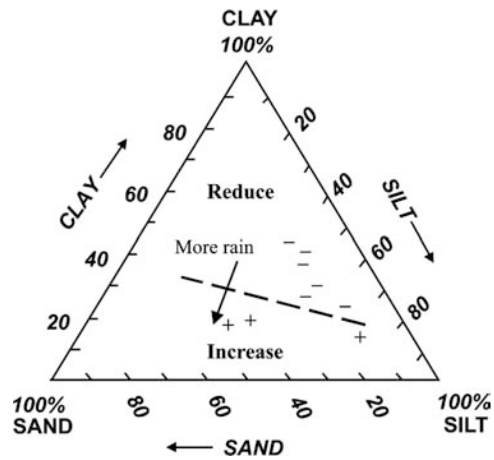

Fig. 1 Observed impact of pipe drainage on downstream peak flows (increase/reduce), showing the importance of soil texture. Model simulations of climate changes indicate that higher rainfall and wetter ground conditions will shift the balance towards drainage schemes reducing peak flows. See text for details.

of 600 mm yr^{-1}) the resulting increase in ground wetness would be sufficient to generate substantial amounts of overland flow on the undrained land. Artificial drainage in this case would then reduce peak flows—exactly as happens for a clay soil (where in contrast the ground wetness is caused by the low soil permeability). Using the model in this way enables these effects of site characteristics to be explored in an objective manner. The overall dominant criterion—the amount and frequency of surface runoff from undrained land—can be assessed in terms of both soil properties and climatic characteristics.

CONCLUSIONS

The effect of subsurface drainage on peak flows depends upon site wetness. If the water table is close to the surface (due to high rainfall or poor permeability), natural flows occur either over the surface or through the upper, more permeable layers of the soil. Drainage will increase soil water storage capacity and hence the amount of water that can infiltrate, thereby reducing surface runoff and peak storm flows. If the water table is deeper, due to a dry climate or due to more permeable soils, natural flows will occur through the body of the soil. In this case, artificial drainage will increase peak flows as a result of the shorter flow paths and steeper hydraulic gradients.

It must be noted that these conclusions depend upon the scale of the drainage considered. At the river catchment scale, main channel improvements will undoubtedly increase the speed of flow routing, and the timing of arrival of flows from different subcatchments will influence the peak discharge at the point of interest. The relative importance of field drainage and main drainage channels will vary with storm size: field drainage being dominant for small and medium storms, but main channel improvements becoming dominant for large events. In extreme situations where the rainfall intensity exceeds the infiltration capacity of the soil, the effects of the subsurface drains will be minimal but the associated improved watercourses will rapidly carry away the surface runoff.

Overall, it seems likely that in large catchments, drainage schemes with substantial associated surface drainage and main channel improvements will lead to higher flow peaks downstream, even though locally the effect of drainage may be to lower the peak flows.

Drainage: Inadequacy and Crop Response

Norman R. Fausey
Soil Drainage Research Unit, Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Ohio State University, Columbus, Ohio, U.S.A.

INTRODUCTION

Drainage is an agricultural water management practice that has been used for many centuries.[1] In early times, development of cities and commerce was dependent upon stable and bountiful agriculture requiring fertile soils and adequate rainfall or irrigation water. There is evidence of failure of early irrigation-based agriculture due to salt accumulation in the soils because of not understanding how to use drainage to leach the salt from the soil.[2] Areas with adequate rainfall to support permanent agriculture frequently also need drainage to manage excess water in the soil. Soils in low-lying areas were recognized by early farmers as the more fertile and productive soils, but these soils were also subject to periodic flooding and crop loss or damage. The goals for early drainage works seem to be centered on removing standing water from crops. Archeological evidence from the Mayan culture in Central America indicates that ridges or raised beds were constructed and used as planting zones to avoid inundation of crops, a very early form of surface drainage. Ancient Greek and Roman writings included instructions for construction of both surface and subsurface drains.[1] Agriculture has evolved to a highly mechanized industry, and this has intensified the demands on drainage. Modern goals for drainage include a trafficable soil surface for timely planting and harvesting of crops using large machines; an aerated root zone that promotes good crop nutrition and minimizes disease organisms; sustained high crop yields; and an ability to maintain the salt balance within the soil profile.

INADEQUATE DRAINAGE

Inadequate drainage results when excess water (or salt) in or on the soil causes economic impairment to the present or intended use of the soil. For agriculture, this definition allows for excess water (or salt) in the soil during times when crop yield is not reduced or reduced by an amount less than the cost of improving the drainage. Some factors that affect the adequacy of drainage at any given time are the type of crop and its stage of growth, the type of soil, the current weather pattern, and the time required to complete field activities (including salt leaching). The adequacy of drainage involves a complex interdependence among soil, climate, crop, and economic factors.

TRAFFICABILITY

Excess soil water causes loss of soil strength leading to an inability to support and to provide traction for the equipment used to plant, tend, and harvest the crop. Poor trafficability may cause delays at critical times for planting, applying fertilizers and pesticides, and harvesting. Timeliness is important to both the quantity and quality of crops.

Delays in planting shorten the growing season, alter the plants' responses to rainfall and temperature patterns and day-length changes, and affect the plants' ability to compete with weeds and resist attack by insects and disease. For most spring-seeded crops, there is a critical or threshold date after which yield is reduced by delay of planting. Evans and Fausey[3] have given a very good recent review.

Delays in applying fertilizers and pesticides can cause serious economic effects. Lack of nutritional requirements in readily available form and sufficient quantity can severely reduce biomass accumulation and the harvestable yield. Disease, insects, and weeds can totally overwhelm a crop if not managed or controlled in a timely manner. Delays in harvesting can lead to loss of quality and value for most products and missed windows of economic opportunity for niche market crops.

Crop response to trafficability and timely fieldwork, made possible with drainage, could be very significant in terms of the quantity and quality of yield and also economically important.

ROOT ZONE AERATION

While water by itself is not harmful to plants, excess water interferes with soil aeration, especially the adequate supply of oxygen for root growth and respiration and for beneficial soil microbial and biological activity. Gaseous byproducts of root respiration and organic matter decomposition by microorganisms accumulate, sometimes to toxic levels, when excess water is present. The excess water fills the pores spaces in the soil and blocks the pathways for the exchange or equilibration of gases between the soil and the atmosphere. When these pathways are blocked, diffusion of gases between the soil and the above-ground atmosphere declines or ceases completely and oxygen in the soil can be depleted rapidly. The rate of decline in soil oxygen content is dependent upon the metabolic activity of the microorganisms and plant roots and the soil temperature.

Poor soil aeration can suppress or prevent seed germination; slow or terminate root growth; and, depending on the duration, cause wilting, poor growth, early maturation, or even death of the above-ground plant parts. The impact on the above-ground plant parts is a direct result of the effects on the roots.

Seed germination requires both water and oxygen. Water imbibition through the seed coat initiates germination, after which both water and oxygen are necessary to sustain the process. An excess of water in the soil surrounding the seed can cause an insufficient supply of oxygen reaching the rapidly dividing and growing cells. Cell division and growth rate are reduced when the supply of oxygen is inadequate, even for a few hours. If no oxygen can reach the seed, germination cannot continue, and, once terminated, will not resume.

Root elongation is slowed or terminated by an inadequate supply of oxygen. Low oxygen concentrations reduce the rate of root elongation, but do not result in root death. Total lack of oxygen for as little as a few hours can kill roots. Root elongation is vital to bring roots to the vicinity of nutrients and water that are needed to sustain plant growth and development. Under low oxygen conditions, increased resistance at the root impedes water movement into roots. McDaniel[4] reported the recovery of corn roots to normal growth rates if the duration of excess water was less than three days; otherwise the total root mass, maximum root depth, and seasonal consumptive water use were significantly reduced.

These observations lead to establishing drainage system design and performance criteria that are intended to avoid prolonged periods of excess water in the vicinity of germinating seeds and within the root zone of plants. Generally, under rain-fed agriculture, it is recommended that the drainage system has the capacity to lower the water table from the soil surface to a depth of 30 cm within 24 hr in order to adequately aerate the root zone.

SALT LEACHING

Drainage is required in irrigated agriculture to provide a means to manage the salt balance in the soil. Irrigation waters, whether from surface of subsurface sources, contain salts such as sodium, chlorine, and bromine. These salts originate from rock during the ongoing process of weathering, and are transported by water to streams and groundwater. Irrigation water, after being applied to the soil, is taken up by the plants largely to transport nutrients into the plant and to cool the plants during transpiration, or is evaporated directly from the soil into the atmosphere. In either case, the salts are left behind in the soil and accumulate over time as more irrigation water is added to the soil.

In order to manage the salt balance in the soil, subsurface drainage is necessary and additional water is required to dissolve the salt and transport it out of the root zone. This additional water is known as the leaching requirement. In some cases, natural drainage rates are sufficient; in others, subsurface drainage must be installed to provide the drainage requirements. Hoffman and Durnford[5] discuss the design of drainage systems for salinity control in detail.

CROP RESPONSE

The response of plants to excess water stress resulting from inadequate drainage varies greatly with the stage of plant development and growth. Plants are very fragile during the germination stage. Once water has been imbibed through the seed coat and the germination process has been initiated, even 2 hr to 3 hr of flooding are enough to interrupt the process and kill the developing embryos.[6] As plants grow, specialized tissues and structures develop that help the plants cope with their environment. Once the shoots emerge from the soil and photosynthesis begins, the plants are no longer dependent solely on stored energy and have a direct connection with the above-ground atmosphere. At this stage, the plant is a much more complex system that is capable of tolerating extended periods of root zone flooding without death. Vegetative growth and yield are affected by the duration of flooding, the stage of growth at the time of flooding, and the prevailing temperature during the flooding. Depending upon the plant species, physiological adaptations may occur that allow the plant to survive prolonged flooding; however, significant reductions in growth and yield typically accrue. Plants tolerate flooding stress better under cool and cloudy conditions than under hot and sunny conditions. Tolerance to flooding tends to increase with plant age.

Flooding is a result of inadequate drainage and can cause a decrease in photosynthesis,[7] in biomass accumulation,[8] and in seed yield.[9] Damaged and dead roots in flooded plants[10] have been attributed to the lack of oxygen to support root respiration.[11,12] Flooding causes premature senescence, which results in leaf chlorosis, necrosis, defoliation, cessation of growth, and reduced yield.[13] While the lack of oxygen has been proposed as the main problem associated with flooding,[14] growth reduction and yield loss during and after flooding could also arise from root rot diseases,[15] nitrogen deficiency,[16] or nutrient imbalance.[17,18]

The common plant response to excess salt is a general stunting of growth. As salt concentrations increase above a threshold level, both the growth rate and ultimate size of the plants progressively decrease.[19] The threshold and rate of growth reduction vary widely among crop species. Some begin to exhibit injury symptoms and growth reductions at salt concentrations only twice that are present in non-saline soil. Others actually grow better in moderately saline environments.

CONCLUSION

Yield reductions may occur as a result of excess water (or salt) on undrained or inadequately drained soils. These yield reductions may be due to factors related to trafficability or root zone aeration in the case of excess water, or inadequate leaching in the case of salt. Drainage is an effective management tool for minimizing these reductions.

Drainage: Irrigated Land

James E. Ayars
U.S. Department of Agriculture (USDA), Parlier, California, U.S.A.

INTRODUCTION

Food production statistics indicate that approximately 30% of the world's food supply is produced by irrigated agriculture and that this percentage will increase in future. As such, irrigated agriculture has an important role to play in meeting the world's future food demand. Irrigated agriculture is practiced in humid areas to supplement rainfall, particularly during droughts, and in arid and semi-arid areas of the world as the sole water supply during crop production. Recent statistics compiled by the International Commission on Irrigation and Drainage (ICID) for 97 member countries of the Commission show there are approximately 271.1 Mha of irrigated land.[1]

However, there are no statistics to indicate what percentage of this irrigated area requires drainage. The most recent statistics on irrigation methods show that about 6% (15 Mha) of this irrigated area is irrigated by either sprinkler or micro-irrigation implying that the remainder of the area is irrigated with some other method, most probably using surface irrigation techniques. This is significant, since surface irrigation methods used on 94% of the world's irrigated area are generally considered to be less efficient than sprinkler or micro-irrigation. Areas where inefficient irrigation takes place are more likely to require artificial drainage to sustain crop production.

The classic example of the need for drainage is the decline of Mesopotamia in the area between the Tigris and Euphrates Rivers. This was a rich agricultural area that relied on irrigation to sustain itself. However, the area had no drainage other than the existing natural drainage capacity of the soil. As a result of poor irrigation practice, the water table rose and the soil gradually salinized resulting in poorer yields and ultimately no production and considerable desertification. Several things were attempted to stave off the inevitable but nothing was successful and villages were abandoned and agriculture ended because of the lack of drainage.[2]

Irrigation is the application of water to meet the crop water requirement. The systems used include sprinklers, micro-irrigation systems, and surface methods such as furrows, level basins, flood, and combinations of these. No irrigation system is 100% efficient in the application of water, so there are losses resulting from soil variations and man's inability to meet crop water requirements and maintain salt balance in the crop root zone. These losses have been termed deep percolation and have been defined as the water that moves past the root zone into the groundwater. The magnitude of the loss will be determined by the selected irrigation system, its design and management, and the soil and crop being irrigated. Irrigation efficiencies are in the range of 70–85% for surface systems, 80–90% for sprinkler systems, and in excess of 90% for micro-irrigation systems for reasonably well-managed systems. The consequence of poor efficiency is that more water has been applied to meet the crop water requirement than has been determined as being needed. This excess water then becomes deep percolation and has to be removed or the soil will become water logged and aeration will be a problem.

NEED FOR DRAINAGE

Soil drainage is needed to provide adequate aeration and salinity control for agricultural production in areas where crops are grown under conditions of natural precipitation or artificial irrigation.

Aeration

Growing crops need a well-aerated root zone to survive and meet yield potential. If the natural drainage capacity of the soil is inadequate to remove the excess water, then the soil will eventually become saturated, either from precipitation and/or irrigation, and artificial subsurface drainage will be required to provide a well-aerated soil. Soils that have low saturated hydraulic conductivities or impeding layers that are either compacted or contain soil with low hydraulic conductivity will have limited natural drainage capacity. Investigations that are needed as part of the design process for irrigation systems are generally required to determine the need for artificial drainage.

Salinity Control

Maintaining an aerated root zone is a problem that is common to both arid and semi-arid areas and to humid areas, while salinity control is generally a problem only in arid and semi-arid areas. Salinity is found in both the soil and irrigation water in arid and semi-arid areas and has to be controlled to prevent salination of the soil and the eventual loss of production. Salt accumulates in the soil as crops use pure water leaving behind salts that are in the water. Also, when crops use water from shallow groundwater, the salt is left behind in the crop root zone.

Another chapter discusses the use of drainage in the management of soil salinity. It is important to note that the design of both irrigation and drainage systems includes consideration of the leaching fraction for salinity control. The leaching fraction is a component of the deep percolation loss from irrigation inefficiency. A separate leaching fraction may or may not be required, depending on the quality of the irrigation water and the efficiency of the irrigation practices.

DRAINAGE SYSTEM DESIGN

Drainage systems can be characterized as either horizontal or vertical. The horizontal systems are made up of clay or concrete tile or plastic pipes that are installed parallel to the soil surface to collect water and let it flow by gravity to an outlet. A vertical system is a pumped well that is used for drainage. Vertical drainage is discussed in another section. In arid areas, deep open ditches are often used as drains to collect subsurface drainage water as well as surface water losses and then discharge this water to a surface water body. Economics is often the consideration involved in which method is selected as best to use for the conditions involved.

The design objective for a good drainage system is to remove water from the soil; that is to either lower the water table to specific depth in a given period of time or to prevent the water from rising in the soil above a specified depth. A well-designed horizontal drainage system results in a specification of the drain lateral size, depth, and spacing to provide adequate aeration for the crop and to control the salinity in the crop root zone. The two basic design methods that are currently applied in irrigated areas are labeled transient and steady state.

Transient Design

The transient method was developed by the U.S. Bureau of Reclamation[3] and accounts for the soil type, crop, and uses intermittent application of irrigation water and rainfall. The design is an iterative process, where a drain lateral, depth, and spacing are specified, then the deep percolation calculated from the irrigation and rainfall sequence is applied to the existing water table. Each application of water results in the water table rising closer to the soil surface. A drain out period following the application removes water from the soil and lowers the water table. The yearly water table response is then calculated as a succession of drain out periods following the addition of the deep percolation. The drain spacing is adjusted for a given depth until the depth to the water table at the mid-point between the drains meets the design criteria specified to occur at the end of the irrigation season. For a crop rotation, the deep percolation used in the analysis is based on the crop with the largest water requirement and deep percolation losses.

Steady State

The steady state method has been adapted from procedures used in humid areas. The deep percolation losses are calculated based on the crop water requirement and rainfall and are distributed uniformly throughout the year with the lateral spacing being based on this average rate. The criteria are set to remove a specified volume of water and to lower the water table to a given depth in a specified number of days. This is called the drainage coefficient and is discussed in more detail in another article. A mid-point water table depth is specified in the design and assumed to remain relatively constant at this depth throughout the year. This is significantly different from the transient design where the depth to water table varies over a wide range during the year.

In recent years, environmental concerns over the disposal of drainage water from agricultural land have had impacts on the design criteria for drainage systems. The designs have changed to account for crop water use from shallow groundwater and to consider water quality.[4,5] The new design recommendations result in the installation of drain laterals at shallower depths than used in the past with either the transient or the steady state design criteria. The shallower placement of the drain lines allows the water table to become closer to the soil surface, makes the shallow groundwater available for plant use, and reduces the depth of the flow lines to the laterals. A reduction in the depth of the flow lines reduces the salt concentration of the drainage water in arid areas where there is increasing soil salinity with depth in the profile.

DRAINAGE SYSTEM MANAGEMENT

Active management of subsurface drainage systems is a relatively new concept for drains installed in irrigated agricultural areas. Managed drains are contrasted with free flowing drains. Controlled drainage has been used extensively in humid areas, but concerns over salinity management have limited the application of this concept in arid areas.

Free Flowing

In the past, the management of horizontal subsurface drains and open drains has assumed that the drains would be free flowing and that all water removed from the soil would be discharged and disposed of to either a stream or river or an evaporation basin. However, environmental concerns related to water quality issues have resulted in significant changes in the way drainage water is managed. In many areas, surface and subsurface drainage are not mixed and surface water that runs off the field is mixed back into the irrigation supply. Subsurface drainage water is either used as a supplemental source of irrigation water or discharged into an evaporation basin. Reuse of drainage water on progressively more salt tolerant crops or other vegetation is used to increase the salt concentration and reduce the drainage volume prior to discharging the drainage water into an evaporation basin for disposal.

Controlled

This is a relatively new option for managing drainage water in irrigated agriculture and is only suitable for application when the drain laterals are installed perpendicular to the grade of the soil surface. This permits adequate control of the groundwater depth over a significant portion of the field similar to the conditions found in humid areas. The depth to water table is controlled by installing a control structure at the outlet of the drainage system or strategically in the field. The height of the control structure can be varied to regulate the water table depth in the field. Adoption of controlled drainage will increase crop water uptake from shallow groundwater in cases where the crop salt tolerance and groundwater salinity are compatible. It will also alter flow patterns and reduce water discharge and salt load from the system.

WATER QUALITY IMPACTS

Irrigation and drainage in arid and semi-arid areas has a dual impact on water quality in surface water. The diversion of irrigation water from a stream or river reduces the total flow of that watercourse thus decreasing the dilution potential of the stream. When drainage water is returned to the stream it may have been degraded by salt, fertilizers, pesticides, herbicides, and other elements that are in solution. Fertilizers, particularly nitrate fertilizer, which is very soluble and mobile in water, and phosphorus, contribute to the growth of aquatic vegetation. Nitrate is a problem when considering drinking water standards. Depending on the parent material of the soil and the level of leaching trace elements such as selenium, boron, arsenic, and molybdenum are problems in addition to the sodium, calcium, bicarbonate, and sulfate routinely found in drainage water.

Because of the potential for transport of fertilizers, salts, trace elements, pesticides, and herbicides, it is important that the drainage system is designed and managed with the irrigation system to improve the total water management and reduce drainage flow. This is also a change in the way drainage design and management has been approached in irrigated agriculture.

Drainage: Land Shaping

Rodney L. Huffman
Department Biological and Agricultural Engineering, North Carolina State University, Raleigh, North Carolina, U.S.A.

Drainage–Dust

INTRODUCTION

The natural drainage network does not always provide adequate outlets for runoff. Land shaping can alter the surface configuration to permit surface water to flow easily by gravity to outlets, usually ditches or natural streams.[1] Sumps and pumping stations may be required to lift drainage water into a ditch or stream if the drained area is either lower than the outlet or so flat that the natural gradient is inadequate to achieve the required discharge.[2] Land shaping speeds removal of surface water, thereby improving access for field operations and promoting healthier crops and higher yields.

Poor surface drainage is common in landscapes such as glaciated areas, coastal plains, floodplains, deltas, and old lake beds. Problem areas are typically flat to gently rolling and may contain numerous small depressions. Slowly permeable soils and relatively large distances to discharge areas reduce internal drainage rates, exacerbating the problem of excess water. With clayey soils, surface drainage usually provides a better cost–benefit ratio than subsurface drainage[3] and may eliminate the need for subsurface drains in some cases.

Land shaping for drainage entails modification of the surface of the land to facilitate the flow of water. In some cases, only a small percentage of the land surface must be modified. In others, the entire land surface must be reshaped. Factors that must be considered include: existing topography, intended use of the land, characteristics of the soil profile, local climate, and the intended outlet for the drainage water.

METHODS

Any but the most minor land shaping operation may remove all of the topsoil from a cut (borrow) area. To maintain productivity, it may be necessary to remove and stockpile topsoil for redistribution over the project area after the primary shaping work is completed.

Grading and Smoothing

Land grading is the shaping of the land surface to predetermined grades. (*Land leveling* is a special case where the final grade is a level surface.) *Land smoothing* is the removal of irregular, uneven, broken, mounded, and jagged surfaces without the use of survey information.[4] Very shallow and/or small depressions may be filled by minor scraping and smoothing if there is no need to have specific final grades.

Entire fields or portions of fields can be graded to facilitate water movement. Utilization of any of the following practices must consider soil erodibility, slope steepness, slope length, adjacent land surfaces, outlet location and capacity, and volumes of earthwork required.

Uniform Slopes

A field can be graded to a planar surface with a uniform slope (Fig. 1). This may include major and minor slopes, i.e., along the crop rows and across the crop rows. The slope may be zero to permit uniform flooding, e.g., where rice (*Oryza sativa* L.) is grown. In other cases, a slope of about 0.1–0.5% is desirable.[5,6] Maximum recommended slopes depend on the soils, slope lengths, and location.

Non-uniform Slopes

Where planar surfaces are desired but uniform slopes would require excessive earthwork, non-uniform slopes are employed. Non-uniform slopes are composed of two or more piece-wise uniform sections (Fig. 2). The upslope sections are generally steeper than the downslope sections. Where long slopes would permit excessive soil loss, erosion control measures such as terraces should be considered.

Warped Surfaces

Warped surfaces are non-planar surfaces with smoothly varying slopes (Fig. 3). They range from relatively simple to very complex. Warped surfaces may be designed where planar surfaces are unnecessary and would require excessive earthwork. Warped surfaces take advantage of the existing topography and tend to follow existing grades fairly closely to minimize cut and fill volumes.[7]

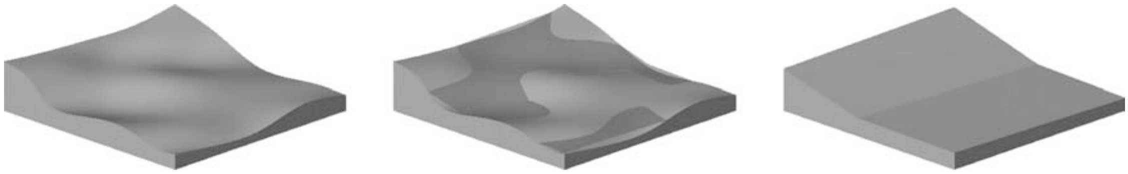

Fig. 2 Land grading to non-uniform slopes. Left: existing grade. Center: existing grade with final grade superimposed. Right: final grade.

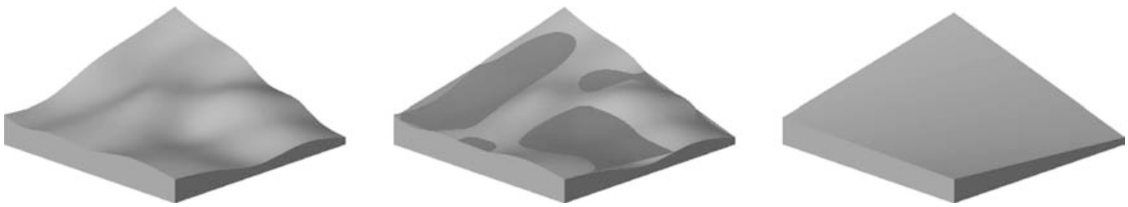

Fig. 3 Land grading to warped surfaces. Left: existing grade. Center: existing grade with final grade superimposed. Right: final grade.

Crowned Surfaces

Bedding and *crowning* (Fig. 4) are very similar in concept, differing mainly in scale and sophistication. Bedding is the practice of using the deadfurrows between lands (resulting from moldboard or turn plowing) as small field drains. With bedding, field operations are typically parallel to the deadfurrows, which must be oriented somewhat up-down slope to facilitate drainage. The only equipment needed for construction and maintenance is a plow. The elevation difference between the top of the bed and the bottom of the deadfurrow is typically 15–45 cm. In the Corn Belt region of the United States, the width of beds ranges from 7 m for very slow internal drainage to 28 m for fair internal drainage.[8]

Crowning is the practice of grading land between parallel drains to an approximately parabolic convex shape. If the drains have side slopes of 8 : 1 or flatter, planting, cultivating, and harvesting operations may run perpendicular to the drains, which allows runoff to flow easily toward the drains between the rows.

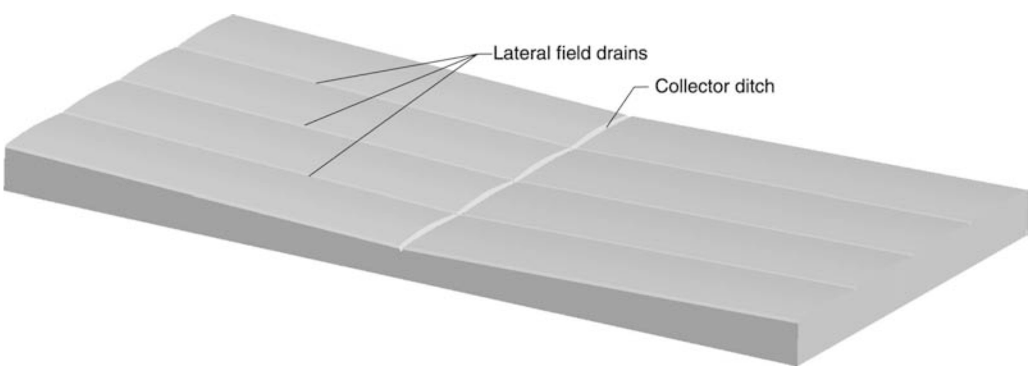

Fig. 4 Bedding and crowning. Land surfaces between parallel field drains or deadfurrows are sloped slightly toward the drains.

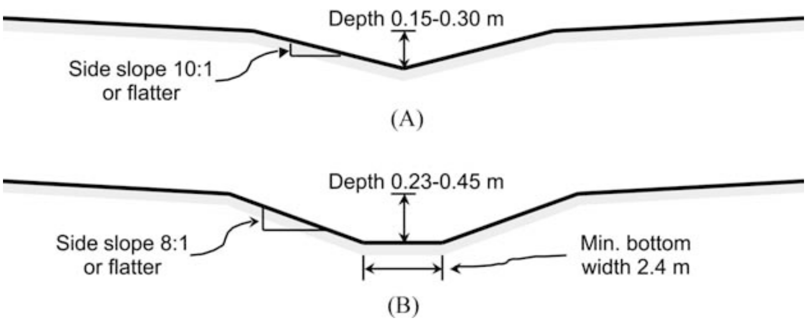

Fig. 5 Cross-sections of field drains: (A) triangular or ‘‘vee’’ cross-section; (B) trapezoidal cross-section.

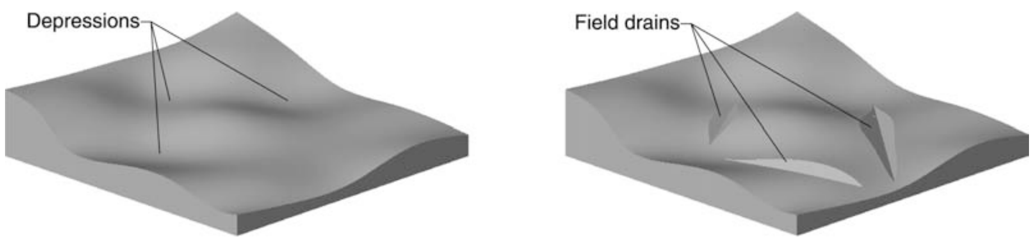

Fig. 6 Random field drains. Left: existing land with undrained depressions. Right: final configuration with field drains providing outlets for occasional depressions.

Plowing should be done parallel to the drains. The spacing between drains may be as much as 360 m if rows drain in both directions and the soils are erosion resistant. On highly erodible soils, it is recommended that slopes not exceed 90 m in length.[8] The slope of the land should generally not exceed 0.3% but may be up to 0.5% on erosion-resistant soils.[7]

Surface Drains

Surface drainage can be improved by creating shallow channels to collect and/or convey water across the surface toward an outlet. Field drains are typically constructed with either triangular (vee) or trapezoidal cross-sections (Fig. 5). The side slopes of the drains should be 10 : 1 or flatter for triangular and 8 : 1 or flatter for trapezoidal cross-sections. The minimum recommended bottom width for trapezoidal field drains is 2.4 m. Typical depths are 0.15–0.3 m for triangular and 0.23–0.45 m for trapezoidal drains.[6]

Field drains may be constructed individually as needed to drain occasional depressions or in parallel systems to drain entire fields.

Random Field Drains

Where depressional areas are too large or deep to simply fill, random field drains can be installed to provide outlets as needed (Fig. 6). Side slopes of 10 : 1 or flatter are recommended to permit normal field traffic. Discharge capacity is not considered in design of random field drains unless the drained area exceeds 2 ha. Grades should not be less than 0.05%[6] and should not exceed 0.2% for sandy soils or 0.5% for clay soils.[8]

Random field drains are often constructed such that a depression drains through one or more other depressions along the way toward an outlet.

Parallel Field Drains

On flat to very gently sloping terrains, a system of parallel field drains may be installed. The land between drains is often crowned (see ‘‘Crowned Surfaces’’ above) to aid water movement toward the drains (Fig. 4).

CONCLUSION

Land shaping is a cost-effective way to improve surface drainage. Properly designed grading, smoothing, and/or field drains can enhance productivity while requiring minimal maintenance.

Drainage: Materials

James L. Fouss
Soil and Water Research Unit, Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Baton Rouge, Louisiana, U.S.A.

INTRODUCTION

Subsurface drainage technology changed and modernized more during the 1965–1980 period than in the previous 100 yr. The inefficient and slow installation of heavy rigid drainage conduit materials (clay and concrete draintile) gave way by the early 1970s to lightweight flexible corrugated plastic drain tubing installed with laser-beam-controlled high-speed trenchers and plow-type equipment. In fact, the developments of the modern drainage plow equipment and the laser-beam automatic grade control were a direct result of the technological developments for corrugated plastic drainage tubing, and the need for a rapid and accurate method to install the new drainage material.[a]

BACKGROUND

The development of a rapid and low-cost technique for subsurface drainage had challenged engineers and inventors for centuries. Many ideas emerged over time, but very few found widespread use or application. With the development of the power trenching machine in 1875, the goal of mechanized drain installation seemed to have been reached—and it lasted around 100 yr. However, the extraordinarily large amount of drainage work that was needed around the world required even less labor, more speed, and lower costs. Efforts to modify the mole drainage concept and installation methods were particularly important. The goal was to use the inherent high speed of installation of mole drainage and its elimination of relatively slow ditching and backfilling operations associated with conventional drainage methods. Because the mole drain collapsed after a short time in many soils, most of the research focused on stabilizing the mole channel with structural support, using a tube or mole-liner; this approach, although showing some promise, was not satisfactory for adoption or use.[1] This investigative work with the mole plow did lead, however, to the eventual development of the drain-tube plow equipment for installing subsurface plastic drains that is in common use today throughout the world.

Corrugated-wall polyethylene plastic tubing, originally developed and used in the United States in the mid-1960s for underground electrical and telephone line conduit applications, was modified and perforated to serve as a subsurface drainage tube in early experiments.[1] By the latter half of the 1960s almost all the research and development on drainage materials and methods of materials handling and installation for agricultural drainage applications had begun to focus on corrugated-wall plastic tubing, primarily because of the advantages of low material requirement vs. high-strength ratio and flexibility for ease of coiling and handling. Continuous extrusion and molding machinery for manufacturing the new plastic tubing, with primarily polyethylene and polyvinyl chloride resins, had been perfected earlier in Germany for small diameter drain tubing. Underground drainage with the new conduit (about 50 mm in diameter) caught on rapidly in Germany and soon spread to other regions of Europe.

Research in the United States on developing polyethylene corrugated-wall plastic tubing, of 100 mm diameter, for agricultural subsurface drainage began in 1965.[1,2] The corrugated-wall tube structure developed for polyethylene plastic (Fig. 1) provided high strength to resist deflection by radial type loads from over-burden soil, but with a considerably reduced requirement for wall thickness as compared with smooth-wall tubing. Both tubing unit weight and unit cost are reduced significantly by pipe-wall corrugations.

By 1967, corrugated plastic drainage tubing was being manufactured commercially in the United States for the agricultural market, and the new industry grew rapidly.[3,4] By the mid-1970s, corrugated plastic drainage tubing had wide acceptance for agricultural drainage, highway berm drainage, septic tank leach field, and construction site applications. By 1983, 95% of all agricultural subsurface drains installed annually in the United States, and more than 80% of Canada, were corrugated plastic tubing.[5,6]

[a]Detailed reports on the innovations in drainage technology are given by: Fouss,[3] Fouss and Reeve,[10] and Schwab and Fouss.[6]

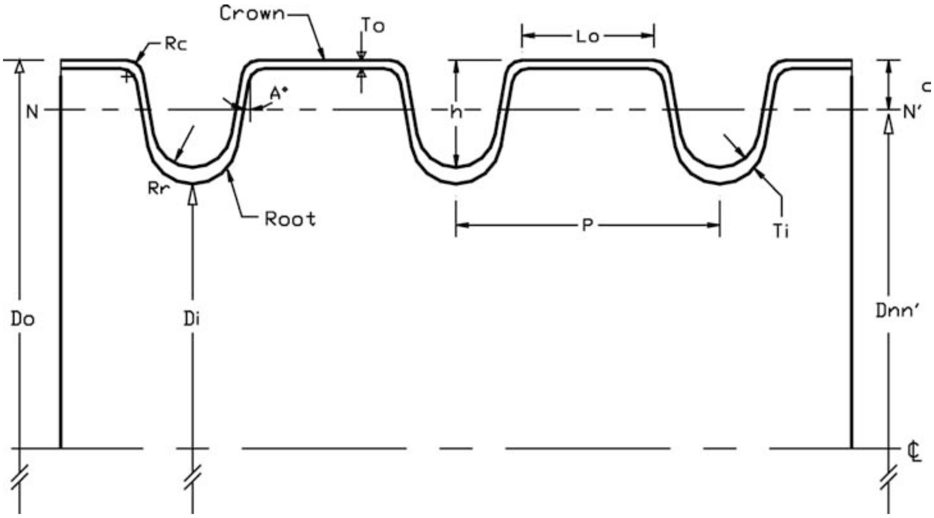

Fig. 1 Cross-section of corrugated-wall polyethylene plastic drain tubing.

CORRUGATED PLASTIC TUBING

The structural strength of a plastic pipe can be expressed as a function of its deflection resistance when loaded between parallel plates (see Fig. 2). The parallel-plate test method is required in ASTM Standard Specifications F-405 and F-667 for corrugated-polyethylene tubing. The strength-deflection characteristic determined for a conduit tested by this method and defined as the "pipe stiffness," is expressed in units of applied load per unit length of pipe sample per unit of vertical deflection (flattening) of the pipe (i.e., F/L/L or F/L^2). The parallel-plate pipe stiffness is expressed mathematically in terms of the geometrical, physical, and pipe-wall material properties of the conduit structure, given as:

$$\textit{Pipe Stiffness} = (W/\Delta Y) = 53.6EI/(D_{\mathrm{NN}})^3 \qquad (1)$$

where, W = parallel-plate load on a sample length of pipe (F/L); Y = vertical pipe deflection under parallel-plate load (L); E = modulus of elasticity for pipe-wall material (F/L^2); I = moment of inertia of pipe-wall cross-section (L^4/L; i.e., per unit of pipe length); D_{NN} = diameter of pipe to the neutral axis (NN) of pipe-wall cross-section (L); and 53.6 = dimensionless constant related to angular position of parallel-plate loads on pipe circumference and to convert from pipe radius to pipe diameter.

Eq. (1) applies to the linear range of deflection between parallel-plates for plastic corrugated-wall pipe, which typically occurs from 0 to between 5% and 10% deflection of the inside pipe diameter.[7] At a specified pipe stiffness (W/Y) for a regular corrugated-wall or smooth-core corrugated plastic pipe of given inside diameter (D_i) and assumed neutral axis diameter (D_{NN}), and for a given plastic resin material of known modulus of elasticity (E), the only term unknown in Eq. (1) is I, which represents the moment of inertia of the pipe-wall cross-section. Corrugation shape and smooth interior wall features govern the magnitude of I, the major structural parameter of the plastic pipe determined or controlled through product design and fabrication.

The cost of corrugated tubing is almost directly proportional to tubing weight. The longitudinal flexibility of the corrugated-wall tubing makes it coilable for ease of handling, but the coilability characteristic also makes it stretchable. Thus, a compromise in design of corrugation shape has been necessary, and special materials handling procedures and equipment have been developed to prevent stretch during handling and installation.[b]

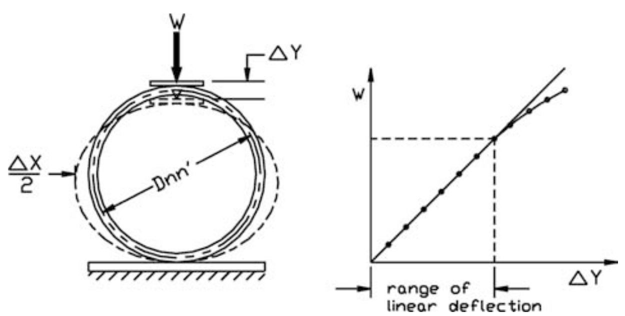

Fig. 2 Parallel-plate load/deflection method of measuring drainpipe stiffness.

[b]The reader is referred to Fouss,[3,7] and Schwab and Fouss,[6] for detailed discussions on optimal design procedures for corrugated-wall plastic drainage tubing for resistance to both deflection and stretch.

TUBING STANDARDS

Specifications and performance standards were developed during the early 1970s for these new corrugated plastic drainage products under the auspices of ASTM, which involves voluntary and cooperative efforts among industry, government, and public groups. This resulted in an ASTM Standard Designation F405 entitled "Standardization Specification for Corrugated Polyethylene Tubing."[8] A major step in the development of this standard was the recognition by the cooperating groups that corrugated plastic tubing is a flexible-type conduit with properties substantially different from the classical rigid draintile such as clay, shale, or concrete.

Under field conditions, a flexible conduit gains most of its vertical soil load-carrying capacity from the support provided by the soil compressed at the sides of the conduit. The density of this sidefill material is the key element in load-carrying capability of the pipe–soil composite structure. The sidefill material provides lateral support to the conduit to give it more rigidity and acts in combination with the conduit to form a vertical load-carrying arch (Ref.[6]).

The parallel-plate method for measuring the deflection resistance of the corrugated plastic tube was adopted as an integral part of the ASTM F405 Standard Specification. This standard was developed to provide minimum values for physical and chemical properties as related to product performance, including handling and installation. Minimum deflection resistance is specified for 5%–10% deflection of tubing diameter. The standard also included a requirement on elongation (stretch) resistance, which limited elongation to 5% when a specified tensile load is applied. Table 1 gives the ASTM recommended minimum values for pipe stiffness and elongation for various drain diameters. In 1978, a revision of the standard specified a falling "Tup" impact test, conducted at a cold temperature to detect brittle or poor-quality plastic resin.

Table 1 Physical test requirements for corrugated plastic tubing

Physical requirement	Standard quality[a] MPa (psi)	Heavy duty[b] MPa (psi)
Pipe stiffness at 5% deflection, minimum	0.17 (24)	0.21 (30)
Pipe stiffness at 10% deflection, minimum	0.13 (19)	0.175 (25)
Elongation, maximum %	10	5

[a]ASTM F405-97 (75 mm–200 mm diameter). Ref.[8].
[b]ASTM F667-97 (250 mm, 300 mm, and 380 mm diameters). Ref.[12].

FABRICATION AND MARKETING

Water entry openings are made in the corrugated-wall drain tube wall during the manufacturing operation by punching or drilling holes, sawing short narrow slots, or other means of perforation. Typically, the openings are formed in the corrugation roots (valleys) rather than on the crowns (outside diameter), and are positioned in three or more rows along the length of the tubing. The cross-sectional area of openings for water entry to the drain varies among manufacturers, but ranges from 21 to more than 148 square centimeters per linear meter of drain. ASTM Standard F405 requires a minimum of 21 square centimeters per linear meter of pipe. Because the drainwall openings are controlled in the manufacturing operation, the quality of installation improved significantly with corrugated tubing compared with ceramic tile. The crack spacing between ceramic draintile sections had to be controlled during installation, thus giving rise to great variability in drain quality among contractors.

Most of the early corrugated plastic drainage tubing was black, but by the mid-1970s, tubing was produced in lighter colors such as white, yellow, gray, and red. Ultraviolet stabilizers and antioxidants were incorporated in the plastic resin to increase its resistance to weathering when tubing was stored outside and exposed to sunlight. The lighter color tubing was developed partially for marketing purposes, but improved performance during handling and installation was also realized because strength and stretch resistance were maintained, even when exposed to the hot sun. The darker tubing was more prone to absorbing the sunlight, which elevated the tube-wall temperature, thus reducing the tubing's stretch resistance during handling and installation.

Corrugated plastic tubing larger than 300 mm in diameter is generally more expensive than the same-size clay or concrete tile, but the market demand and use for the lighter and easier to handle corrugated plastic is increasing significantly. These large-size corrugated conduits (300 mm–600 mm) are also used extensively for culvert applications (Watkins and Colleagues[13]) which was an area formerly thought to be reserved for concrete and steel pipe. The noncorrosive nature of the product and the advances in the structural performance of plastics for this use are milestones in the drainage industry.

MATERIALS HANDLING

The use of corrugated tubing greatly reduced labor and energy requirements in drainage materials handling. Initially, the typical 100-mm diameter tubing used for laterals was supplied in 76-m coiled lengths and weighed about 36 kg. This compared with a weight of about 900 kg for clay or concrete tile of the same diameter and total length.

As the demand of, and use for, corrugated plastic drainage tubing grew in the United States, contractors desired larger and larger coils to make the materials handling operation even more efficient. In 1984, typical coil sizes available for 100-mm diameter tubing were 915-m "maxi-coils" and 1525-m "jumbo coils." The 76-m coil is still commonly used for many small agricultural jobs, for industrial installations, and around housing projects. Several types of self-loading trailers and wagons became available to string tubing in the field. Special reels were developed for mounting directly onboard the drainage equipment to uncoil the tubing as it was installed.[c]

Use of the maxi-coils and special reels for stringing tubing reduced tubing stretch problems during installation, even for black tubing on hot, sunny days. The 2% carbon-black used as the ultraviolet light inhibitor in black tubing is superior in performance and lower in cost than the light pigments, permitting outdoor storage of the product. The power tubing feeder designed to eliminate the natural stretch-producing drag at the top of the tubing chute was one of the most significant developments in minimizing the adverse effects of stretch.[9]

Diameters of corrugated plastic pipe increased from the original 100 mm in the mid-1960s to 600 mm by 1982. Sizes up through 254 mm are commonly coiled for shipment and handling. Drain sizes larger than 300 mm are typically manufactured and shipped in 20-ft lengths. There is a noteworthy market for 76-mm corrugated tubing, which is typically shipped in 105-m standard coils, or 1525-m coils. The 100-mm tubing is considered the minimum tube size for lateral drains in most areas of the United States and Canada. A 127-mm diameter is specified as the minimum-size lateral drain in Iowa, and in Minnesota, a 150-mm drain is the preferred minimum diameter.

SYNTHETIC DRAIN ENVELOPE MATERIALS

Although graded sand and gravel envelopes have distinct performance advantages, the cost is generally prohibitive in areas where natural sands and gravels are not readily available. For this reason and because thin-membrane fabrics are easily handled and installed, especially in conjunction with corrugated plastic pipe, synthetic envelopes have become widely used throughout the major drainage areas of the United States and Canada. With the rapid adoption and widespread use of corrugated plastic drainage tubing, the development of synthetic fabrics as envelopes to protect these drains against sedimentation advanced rapidly. Because subsurface drain envelopes are used primarily to protect the drain from the inflow of sediment and still maintain free open flow of gravity water from the soil profile into the drain, the development of envelopes has been mostly centered around the performance of thin membranes with fine sand and coarse silt-size particles (0.005 mm–0.125 mm). Understanding of the basics and development of improved practices in the use of drain-synthetic envelopes have both advanced significantly in the past two decades.

Fabrics that were developed by major chemical and oil companies for other engineering applications were readily available from the 1960s to the 1980s and thus were quickly adopted for use as materials for subsurface drain envelopes. Many of these materials have been tested for use as drain envelopes, including polyester, nylon, and polypropylene, which were commercially available in North America. While woven, knitted, and spun-bonded productions of the above materials have been used, the most commonly used products from among these are knitted polyester (sock), spin-bonded nylon (Cerex™, Drainguard™), and spun-bonded polypropylene (Typar™, Remay™).[d]

By the early 1980s, as much as 8% of the corrugated plastic drainage tubing installed had a synthetic fabric envelope. These synthetic envelopes are light in weight and compact for ease of handling during transportation and installation. They are also relatively low cost compared with sand or gravel envelopes. The synthetic fabrics may be placed directly onto the tubing during manufacturing, or the envelope is placed on the tubing during installation.

Standards and specifications for synthetic fabric envelopes or drainpipe filter materials were still not developed by the early 2000s, even though various commercial products had been available and in use for nearly 30 yr. Developing performance standards for these products was complicated by the many variables involved in installation and hydraulic variables encountered in the field. Research had been conducted to determine why fabric materials plug up in some soil types, particularly in clays and silty clay loams, but results were not definitive. In other cases where the fabric mesh size was too large and the sediments were extremely fine, such as in very fine sand and/or silt loams, envelopes failed by allowing excess sediment to pass through the fabric and into the drain tubing.

[c]The reader is referred to Broughton and Fouss[9] for detailed discussions on modernized materials handling and installation equipment.

[d]Trade and company names are included in this article for the benefit of the reader and do not imply endorsement or preferential treatment of the product listed by USDA.

Fortunately, technical information about the past research efforts and their applications are available in the literature in a suitable form to permit the proper selection or design of envelopes for subsurface drains installed in various type of soils.[e]

The performance of a thin-membrane envelope depends primarily on the conditions of the soil at the time of installation, the imposed hydraulics on the system, and the method of installation. Failures are more common when the drain is installed under extremely wet conditions, where the soils are unstable and subject to ''quick'' conditions, and where the initial hydraulic head imposed on the drain during water table draw down is much higher at or soon after installation than that likely to occur once the soil surrounding the drainpipe has settled and stabilized. Drains installed with envelopes, even in very fine sandy or silty soils, have performed satisfactorily when installed where the water table had been low, the surface soil had been dry for better machine operation, and excessive hydraulic heads were not imposed on the system during installation. After the drain is installed and functioning, the soil near the drain stabilizes and the hydraulic head at the drain then becomes a function of head conditions as modified by the head loss of resistance to flow in the soil.

Experience and research have shown that favorable installation conditions and extreme care on the part of the contractor are both very important to obtaining trouble-free performance of subsurface drains with thin-membrane envelopes.

Drainage: Modeling

George M. Chescheir
North Carolina State University, Raleigh, North Carolina, U.S.A.

INTRODUCTION

Methods have been used over the centuries to guide the design and installation of drainage systems. These methods range from simple guidelines that relate drainage requirements to soil types, to computer programs that simulate long-term day-to-day performance of drainage systems in response to weather conditions and management practices. Our discussion here will be limited to groundwater equations that are applied to drainage and to the computer models that use these equations to simulate drainage systems. More detailed reviews of drainage models and their applications are available to the reader.[1–3]

The primary objective of drainage is to provide a favorable environment for crop production; therefore, development of drainage models has depended on formulations of equations to describe movement of shallow groundwater. Models have progressed with advances in math, science, and computer technology toward more accurate solutions of increasingly complex equations and boundary conditions. Technological advances have also made possible more rigorous treatment of other important processes such as crop growth, evapotranspiration, and rainfall that vary with time. The resulting models can simulate the performance of various drainage system designs over long periods of time and evaluate system performance in terms of specified objective functions, such as crop yield and profit.

Drainage models have also evolved in response to changing needs and concerns of the communities affected by drainage. The primary objective of drainage during early model development was to enable land development and increase crop production. Since the 1970s, communities in the United States and Europe have been concerned about the impact of agriculture and drainage on the quality of water draining to sensitive environments. Recent developments in drainage models have therefore focused on the fate and transport of nutrients and pesticides in drainage systems. The resulting computer programs integrate routines for groundwater flow, solute transport, crop response, and climatological processes into comprehensive simulation models.

EQUATIONS FOR DRAINAGE MODELING

Simple Analytic Equations

The simplest models are the analytic equations that relate steady state flow to drain depth, hydraulic conductivity, and drain spacing. The ellipse equation is commonly used for the case of parallel drainage ditches (Fig. 1).

$$R = \frac{4K}{L^2}(b^2 - D^2)$$

where R is the steady recharge rate (often defined as the drainage coefficient), K, the effective lateral hydraulic conductivity, b, the water table height above the impermeable layer, D, the water level in the ditches above the impermeable layer, and L, the spacing between the ditches.

The ellipse equation was derived assuming that all flow lines are horizontal (Dupuit–Forschheimer assumptions), which is reasonable for most cases of flow to ditches. These assumptions, however, do not apply for the flow lines as they converge to a drain tile. Methods have been developed that account for the convergence of flow near the drain by calculating an effective depth (d_e) from the drain tile to the impermeable layer and replacing D with d_e in the ellipse equation. Discussion of steady state drainage equations and their derivations can be found in Ritzema,[4] and van der Ploeg Harton and Kirkham.[5]

Non-steady drainage equations have been developed to determine the time required for the water table drawdown from an initial elevation to a lower elevation. Development and applications of drawdown equations are discussed by Ritzema,[4] and Youngs.[6] These equations, however, have not been as widely used as the steady state equations.

Boussinesq Equation

The simple analytic equations are limited to specific cases for parallel drains at normal spacings and where

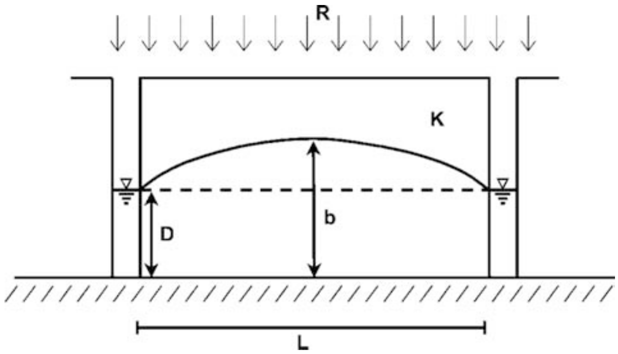

Fig. 1 Schematic of steady state drainage to parallel ditches. The ellipse equation would be used to describe saturated flow in these conditions.

site and boundary conditions are relatively uniform. There are, however, many situations in which soils, crops, and topography vary in the horizontal direction or in which quantifying the horizontal variation of the water table is important. An example of this type of situation is shown in Fig. 2. For this example, one would need to determine the depth to the water table at any horizontal point along the soil profile, which varies in thickness and hydraulic conductivity in addition to having non-uniform boundary conditions.

The simplest and most common approach is the use of the Boussinesq equation to characterize flow in the saturated zone only (see Ref.[6]). The Boussinesq equation is based on the DF assumptions and the principle of continuity. Referring to Fig. 2, the Boussinesq equation may be written as,

$$f(h)\frac{\partial h}{\partial t} = \frac{\partial}{\partial x}\left[K(h)\frac{\partial h}{\partial x}\right] + R(x,t)$$

where h is the water table height above the impermeable layer, $f(h)$ is the drainable porosity and $K(h)$

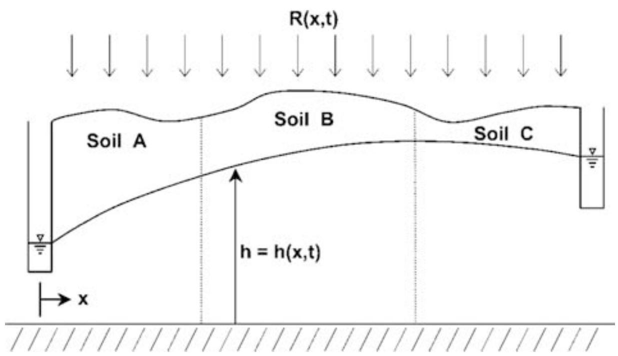

Fig. 2 Schematic of a drainage case where there is non-uniform variations in the horizontal direction. The Boussinesq equation would be used to describe saturated flow in these conditions.

is the effective lateral hydraulic conductivity, both written as a function of h, $R(x,t)$ is the vertical recharge rate, x is the horizontal position, and t is the time.

Many of the simple analytical equations were derived from the Boussinesq equation for uniform boundary conditions. For non-uniform conditions, the Boussinesq equation is solved numerically using finite element or finite difference methods.

Richards' Equation

The Boussinesq equation describes groundwater flow only in horizontal directions and only in the saturated zone, with the vertical recharge rate term, $R(x,t)$, being a lumped term representing the net effect of vertical movement in the unsaturated zone. The Richards' equation is a more exact description of water movement and storage in the unsaturated zone. This adds levels of complexity since both hydraulic conductivity and soil water content are related to soil water pressure head. The Richards' equation is presented in a separate entry in this Encyclopedia (see the entry *Richards' Equation*). Most drainage conditions of interest can be described by solving the Richards' equation subject to appropriate boundary and initial conditions. Solutions provide soil water contents and pressure heads as functions of time and space as well as the position of the water table and flux rates due to drainage, subirrigation, infiltration, and evapotranspiration.

SIMULATION MODELS

Solutions to the equations discussed thus far assume some idealized conditions driving the system such as steady rainfall, evapotranspiration, or an initial condition for transient drainage. In reality, drainage systems are subject to many perturbations that occur randomly though time. The most notable random perturbation is precipitation. Although processes involving plant root growth, evaporation, and transpiration also have very important random impacts on drainage systems. With increased speed and power of computers, the performance of drainage system designs for longer and more representative conditions can be simulated. The resulting simulation models are therefore multiple solutions to groundwater equations in response to variable temporal and boundary conditions. Simulation models can be combined with methods to predict crop yield and solute transport to evaluate system designs in terms of multiple objective functions such as crop yield, profit, or drainage water quality.

Two-Dimensional Richards' Equation

General simulation models for solving the 2-D Richards' equation subject to changing boundary conditions are available. The integrated program, HYDRUS-2D[7,8] was developed at the U.S. Salinity Laboratory to simulate water flow, heat transfer, and solute movement in variably saturated soils. HYDRUS-2D is a combination of the SWMS_2D and CHAIN_2D models that use finite element methods to solve the Richards' equation and the convective–dispersion equations. The flow equation incorporates a sink value to account for water uptake by plant roots. The models can handle a wide range of boundary conditions, including ditches and drain tubes, as well as boundaries controlled by atmospheric conditions. HYDRUS-2D also includes programs for generating finite element grids, for organizing input, and displaying output. The U.S. Geological Survey has also developed an integrated program, VS2DI[9,10] to simulate water flow, heat transfer, and solute movement in variably saturated soils. VS2DI is an integration of the VS2DT and VS2DH models based on finite difference solutions to the Richards' equation with pre and post processing programs.

One-Dimensional Richards' Equation

Drainage simulation models have been developed that use the 1-D Richards' equation to describe vertical water movement in a soil column subject to variable surface boundary conditions such as atmospheric and crop uptake conditions. Lateral flow to the drains is usually calculated with simple analytic equations for saturated flow or with tabular flux–groundwater relationships. The widely used model, SWATRE,[11] has been combined with other models and routines for describing plant growth, solute transport, and soil heat flux to create the comprehensive model, SWAP.[12,13] Vertical water flow calculations can consider the effect of hysteresis and preferential flow due to soil cracking or water repellent soil. Solute transport calculations consider convection, diffusion and dispersion, nonlinear adsorption, first-order decomposition, and root uptake. A soil heat flow equation is solved analytically assuming uniform thermal conductivity and soil heat capacity, or solved numerically from soil composition and moisture content. Plant growth is simulated based on the calculated radiation energy absorbed by the plant canopy.

Several other drainage simulation models (see Ref.[1]) have been developed based on the 1-D Richards' equation. The Root Zone Water Quality Model (RZWQM) uses a mass-conservation technique[14] to solve the Richards' equation. Like the SWAP model, the RZWQM[15] has become an integrated model that simulates major physical, chemical, and biological processes in an agricultural crop production system. The Root Zone Water Quality Model considers water and solute movement through the soil profile including macropores, soil heat flux, crop growth, nutrient and pesticide transformations, and agricultural management practices.

Water Balance Models

The water balance models discussed in this section perform water balances at one or two points in the soil profile using analytically or numerically calculated values for saturated flow, ET, infiltration, seepage, and other inflows or outflows. The widely used water balance model, DRAINMOD[16,17] was developed for the design and evaluation of multicomponent drainage and related water management systems. The model conducts a water balance on an hour-by-hour, day-by-day basis and calculates infiltration, ET, drainage, surface runoff, subirrigation, deep seepage, water table depth, and soil water status at each time step. Lateral saturated flow to and from the drains is calculated by simple analytic equations. Soil water is distributed vertically assuming a drained-to-equilibrium profile above the water table. Water content can be as low as the wilting point in a separate dry zone that can form in the crop root zone. As with other currently available drainage models, DRAINMOD is now an integrated model that considers the major processes occurring in a drained crop production system. Routines have been added to the model to predict crop yield and to calculate heat flux. Additional routines have been added to consider the effects of drainage and water management on losses of nitrogen and on soil salinity.

Several models that were originally developed to predict losses of sediment, nutrients, and pesticides from sloping upland soils have been modified for use on more poorly drained flatland soils. These models include EPIC-WT,[18] WEPP,[19] ADAPT,[20] and GLEAMS-WT.[21] The modifications to these models usually involved addition of algorithms similar to those used in DRAINMOD to predict drainage rates, infiltration, and water table response. In other cases, the output calculated by DRAINMOD were used as input to other models such as CREAMS.[22]

Boussinesq Equation

Drainage simulation models based on the 1-D Richards' equation and water balance methods examine the soil column at the midpoint between parallel drains or ditches. This is due to the use of analytic equations for calculating saturated flow to the drains.

Drainage–Dust

For evaluations of most drainage designs, these models are very practical; however, there are situations where boundary conditions or flow domains are complex and models based on parallel drainage equations will not suffice. Possible scenarios may be similar to the case shown in Fig. 2, or may be best represented in 3-D such as when ditches are perpendicular or serpentine.

Parsons, Skaggs, and Doty.[23] developed the simulation model, WATRCOM, using finite element solutions to the Boussinesq equation. Solutions to the 1-D form facilitated a quasi 2-D model while solutions to the 2-D form facilitated a quasi 3-D model. A water balance similar to the one in DRAINMOD was conducted at each node and coupled to the finite element solutions. Other routines were added to route surface water, to determine ditch water levels for controlled drainage situations and to calculate crop yield. A similar approach was used by De Laat et al.[24] to develop GELGAM, which was used for regional water resource planning.

CONCLUSION

Drainage models have been developed in response to advances in math, science and technology, and to the changing needs and concerns of society. Many drainage models have integrated routines for describing plant growth, solute transport, and soil heat flux to create comprehensive models able to predict crop yield and the quantity and quality of drainage water for a wide range of field and climatological conditions. Consequently, a wide variety of drainage models are now available to design and evaluate drainage and water management systems for agriculture and other purposes. The potential user is faced with the challenge of selecting which model to use for their particular situation. Obviously, the most complex model could be used for almost any situation; however, many expenses come with the most complex model. Most notably are the expenses required to gather and process large amounts of detailed input data and the expenses required for training the model user or hiring a qualified expert user. In many cases, a simpler and less expensive model can be used to obtain satisfactory designs. The wise project manager and model user will clearly define the objectives of their system, assess the capabilities and limitations of the available models, and select a drainage model that is suitable for their needs.

Drainage: Soil Salinity Management

Glenn J. Hoffman
Biological Systems Engineering, University of Nebraska, Lincoln, Nebraska, U.S.A.

INTRODUCTION

Soil water must drain through the crop root zone when salinity is a hazard to prevent salts from increasing to levels detrimental to crop production. Drainage occurs whenever irrigation and rainfall provide soil water in excess of the soil's storage capacity. In humid regions, rainfall normally satisfies crop water requirements and precipitation infiltrating into the soil in excess of this requirement leaches (drains) salts present below the crop root zone. In subhumid areas, rainfall is often inadequate in amount or temporal distribution to satisfy crop needs and irrigation is implemented. For arid regions, rainfall is never abundant and the preponderance of the crop water requirement must be provided by irrigation. Regardless of the climate, if soluble salts are present, water in excess of that needed to satisfy the crop water requirement must be provided to leach excess salts. Leaching may be accomplished continuously or at intervals, depending on the degree of salinity control required. It may take decades or as little as one season, depending on the hydrogeology of the area, but without drainage, agricultural productivity cannot be sustained where salinity is a threat. For a more complete discussion on drainage design for salinity control, the reader is referred to Hoffman and Durnford.[1]

DRAINAGE CONDITIONS

All soils have an inherent ability to transmit soil water provided a hydraulic gradient exists. If the hydraulic gradient is positive downward, drainage occurs. Soils with compacted layers, fine texture, or layers of low hydraulic conductivity may be so restrictive to downward water movement that drainage is insufficient to remove excess salts. In some areas, the hydrogeology may be such that the hydraulic gradients are predominantly upward. This leads to water logging and salination.

Before designing a man-made drainage system, the natural drainage rate should be determined. If the natural hydraulic gradient causes soil water to drain out of the crop root zone, the capacity of the artificial system can be reduced, thereby decreasing the cost for drainage. In some situations, upward flow into the crop root zone from a shallow aquifer can significantly increase the drainage requirement. The upward movement of groundwater leads to salination as the water evaporates at the soil surface, leaving salts behind. If upward flow is ignored, the drainage system may be inadequate. Regardless of the source, an artificial drainage system will not function unless it is below the surface of the water table.

DRAINAGE REQUIREMENT

Saline Soils

The amount of drainage required to maintain a viable irrigated agriculture depends on the salt content of the irrigation water, soil, and groundwater; crop salt tolerance; climate; soil properties; and management. At present, the only economical means of controlling soil salinity is to ensure an adequate net downward flow of water through the crop root zone to a suitable disposal site. If drainage is inadequate, harmful amounts of salt can accumulate.

In irrigated agriculture, water is supplied to the crop from irrigation, rainfall, snow melt, and upward flow from groundwater. Water is lost through evaporation, transpiration, and drainage. The difference between water inflows and outflows is the change in soil water storage. A water balance, expressed in terms of equivalent depths (D) of water, can be written as

$$D_s = D_i + D_r + D_g - D_e - D_t - D_d \qquad (1)$$

where the subscripts s, i, r, g, e, t, and d designate storage, irrigation, rainfall and snow melt, groundwater, evaporation, transpiration, and drainage, respectively. The corresponding salt balance, where S is the amount of salt and C is salt concentration, can be expressed as

$$S_s = D_iC_i + D_rC_r + D_gC_g + S_m + S_F - D_dC_d - S_p - S_c \qquad (2)$$

with S_s being salt storage, S_m is the salt dissolved from minerals in the soil, S_f indicates salt added as fertilizer or amendment, S_p is precipitated salts, and S_c is the salt removed in the harvested crop.

Rarely do conditions prevail long enough for steady state to exist in the crop root zone. However, it is instructive to assume steady state to understand the relationship between drainage and salinity. If upward movement of salt, the term ($S_m + S_f - S_p - S_c$), and the change in salt storage are all essentially zero, then the salt balance Eq. (2) can be reduced to

$$D_d C_d = D_i C_i + D_r C_r \quad (3)$$

The leaching fraction, L, is the ratio of the amount of water draining below the crop root zone, D_d, and the amount applied, $D_i + D_r$. The ratio of the salt concentration entering and leaving the root zone can also be used to estimate L. Since C_r is essentially zero.

$$L = C_i/C_d = D_d/D_i + D_r \quad (4)$$

The concept in Eq. (4) is important because it illustrates the relationship between leaching fraction and salinity.

The minimum leaching fraction that a crop can endure without yield reduction is termed the leaching requirement, L_r. The leaching requirement is the minimum amount of drainage required to prevent excess accumulations of salt that result in loss of crop yield. Several models have been proposed to estimate the drainage (leaching) requirement. Of the four models tested,[2] the one presented in Fig. 1 agrees well with measured values of the drainage requirement through the range of agricultural interest. The drainage requirement given in Fig. 1 is the fraction of the volume of applied water that must pass through the crop root zone as a function of the salinity of the applied water and the salt tolerance of the crop.

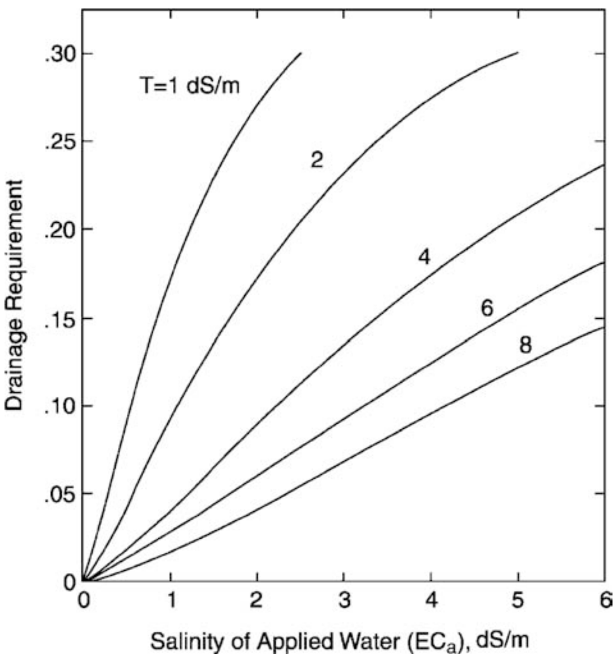

Fig. 1 Drainage requirement as a function of the salinity of the applied water (reported as the volume weighted electrical conductivity) and the salt tolerance threshold value for the crop (T). *Source*: Adapted from Ref.[15].

Sodic Soils

A soil is said to be sodic if an excessive concentration of sodium causes a deterioration of soil structure. The impact of excess sodium is a reduction in hydraulic conductivity and crust formation. Sodic conditions decrease the rate of drainage. Before a sodic soil can be restored to full productivity the excess sodium in the soil must be replaced with calcium or magnesium. This process frequently requires copious amounts of leaching to reclaim the soil. The design of an artificial drainage system that may be required, however, is based upon the long-term requirement for drainage as estimated in Fig. 1 rather than the anticipated high drainage requirements for reclaiming a sodic soil.

DRAINAGE SYSTEM DESIGN

There are three types of subsurface systems used to control soil salinity: relief drains, shallow wells, and interceptor drains. Relief drains, usually consisting of perforated corrugated plastic tubes buried in a regularly spaced pattern, is the most common subsurface system. Laterals for relief drains are typically placed 2.0–3.5 m deep and are spaced horizontally ten to hundreds of meters apart where salinity is a hazard. Shallow wells, called tube wells in some regions, can also be used to lower the water table by allowing pumping from shallow, unconfined aquifers. Tube wells are spaced at distances of a few hundred meters to several kilometers and may be a few meters to a hundred meters deep. Interceptor drains are used to remove excess soil water from saline seeps. Frequently, one subsurface drain, properly located at the upslope side of the seep, is sufficient. Regardless of the type of drainage system, the depth of the water table must be maintained low enough that (1), salts in the soil profile move to the water table (2), the rate of water movement by capillary flow to the soil surface because of evaporation is minimal, and (3), upflow of saline groundwater into the root zone is prevented.

Relief Drains

A relief drainage system consists of a main drain, collector drains, and field drains (laterals). The main drain is frequently a surface stream or an open drainage canal. Collectors and laterals are usually buried in a regular parallel pattern. Either open ditches or perforated pipes can serve as collectors and laterals. Open ditches are not normally installed now because they occupy land, are difficult to maintain, and are only capable of shallow drainage. Laterals are up to 300 m long and terminate in a collector drain. Both single- and double-sided entries by laterals into a collector are common.

Drain Depth

Subsurface drains are installed much deeper for salinity control in arid regions than drains for water table control in humid regions. The goal for salinity control is to place the drains deep to limit salination of the root zone by capillary upflow. Drains are placed at depths of 2.0–3.5 m in arid regions.[3] The appropriate drain depth depends upon the depth capacity of the installation machinery, the location of a shallow soil layer that impedes water movement, and anticipated benefits compared to additional costs of deeper installation.

Drain Spacing

The spacing between laterals is often estimated using simple drainage design equations. Drain spacing determinations can be based on criteria of steady-state, falling-water-table, or fluctuating-water-table conditions.[4] For large drainage projects or where more accurate values are desired, computerized drainage design models are available. An early computer model developed by Skaggs[5] has been altered by several for irrigated conditions.[6,7] Other models present drainage designs for irrigated areas based on optimization,[8] decision support systems,[9] or reuse of drainage water.[10]

Drainage Wells

Shallow or tube wells offer a viable alternative to relief drains when the aquifer has sufficient transmissivity to provide a significant yield of drain water and the vertical permeability between the crop root zone and the aquifer is adequate. Under these conditions, tube wells have the advantages of being able to lower the water table to greater depths than relief drains and also provide supplemental water for irrigation if the quality is appropriate.

Because drainage wells can be installed at convenient locations within the area to be drained and can be operated either continuously or intermittently, the management of a system of drainage wells is more versatile than relief drains. Relief drains are typically a passive drainage system relying on gravity and designed to operate continuously.

Economic comparisons between the costs of drainage wells and relief drains vary. It is generally found that relief drains have lower construction and operation costs.[11] However, Mohtadullah[12] showed tube wells were a better economic choice than relief drains for the Indus Basin.

Saline Seeps

The occurrence of saline water at the soil surface downslope from a recharge area is referred to as a saline seep. Saline seeps can occur because of the reduction of evapotranspiration that occurs when grasses or forests are converted to cropland in the upland (recharge) areas of a watershed. Dryland farming practices that include fallow periods tend to aggravate the seepage problem. Salination occurs as water infiltrating in the upper elevations of the watershed moves through salt-laden substrate on its path to a discharge site at a lower elevation. In the discharge area of the seep, crop growth is reduced or the plants killed by an intolerable level of salinity. Saline seeps can be distinguished from other saline soil conditions by their recent origin, relatively local extent, saturated soil profile, and sensitivity to precipitation and cropping systems.[13] Saline seeps occur throughout the Great Plains of North American and in Australia, India, Iran, Turkey, and Latin America.[14]

Planting crops in the recharge area that consume soil water before it percolates below the crop root zone will prevent saline seeps. Failing this, improved drainage may provide a solution. Installing an interceptor subsurface drain immediately upslope from the saline seep is frequently a successful solution. Interceptor drains to control seepage should be installed as deep as practical. If the layer restricting soil water flow is not too deep, placing the interceptor drain just above this layer is the most effective location.

Drinking Water Supply Distribution Systems

Laura J Ehlers
Water Science and Technology Board, National Research Council, Washington, District of Columbia, U.S.A.

INTRODUCTION

Water distribution systems consist of the pipes, pumps, valves, storage tanks, reservoirs, meters, fittings, and other hydraulic appurtenances that carry drinking water from a centralized treatment plant or well supply to consumers' taps. Because distribution systems represent the vast majority of physical infrastructure for water supplies (they span almost 1 million miles in the United States), they constitute the utility's primary management challenge from both an operational and public health standpoint.

The issues and concerns surrounding distribution systems are many. First, the type and age of the pipes, which make up distribution systems, range from cast and ductile iron pipe to plastic pipe. Most distribution pipes will be reaching the end of their expected life spans in the next 30 yr. Thus, the water industry is entering an era where it will have to make substantial investments in pipe repair and replacement. Second, of the 34 billion gallons of water produced daily by public water supplies in the United States, approximately 63% is used by residential customers, and more than 80% of the water supplied to residences is used for activities other than human consumption.[1] Nonetheless, distribution systems are designed and operated to provide water of a quality acceptable for human consumption. Finally, in addition to providing drinking water, a major function of most distribution systems is to provide adequate standby fire-flow, which requires that distribution systems have standpipes, elevated tanks, storage reservoirs, and larger sized pipes than would otherwise be needed. The net effect is that transit times between the treatment plant and the consumer are longer, allowing for water quality degradation.

Most regulatory mandates regarding drinking water focus on enforcing water quality standards at the treatment plant and not within the distribution system. Ideally, there should be no change in the quality of treated water from the time it leaves the treatment plant until the time it is consumed. However, in reality substantial changes can occur to finished water as a result of complex physical, chemical, and biological reactions. Indeed, waterborne disease outbreaks, both microbial and chemical, are more and more likely to be caused by problems within distribution systems, although the total number of reported waterborne disease outbreaks has decreased since 1980 (see Fig. 1).

Two reports of the National Academies' Water Science and Technology Board[2,3] recently identified and prioritized issues of greatest concern for distribution systems, evaluated different approaches for characterizing the public health risks of distribution systems, evaluated the effectiveness of relevant existing codes and regulations, and identified general practices and policies that could be considered by water utilities and others to reduce the risks posed by water-quality deteriorating events in distribution systems. Although a host of contamination events can lead to water quality degradation in distribution systems, a select few are considered of highest priority given available epidemiological data[2] and are the focus of this entry. These include backflow events through cross connections; contamination during installation, repair, and replacement activities; contamination of finished storage facilities; and events occurring to and within premise plumbing. Other contamination events that are generally less troublesome but may be significant in certain distribution systems include intrusion, the growth of biofilms, nitrification, loss of disinfectant residual owing to increased water age, permeation, leaching, and post-precipitation.

BACKFLOW AND CROSS-CONNECTION CONTROL

One of the most common means of contaminating distribution systems is through a cross connection, which is a location where contaminated water from a non-potable source has the potential to flow back into the distribution system. Backflow can occur when the pressure in the distribution system is less than the pressure in the non-potable source, such as during water main breaks, firefighting, and pump failures. Backflow can also occur when there is increased pressure from the non-potable source that exceeds the pressure in the distribution system, which can occur when industrial operations or irrigation systems connected to the potable source are exerting high internal pressure. In a study of 188 households, the University

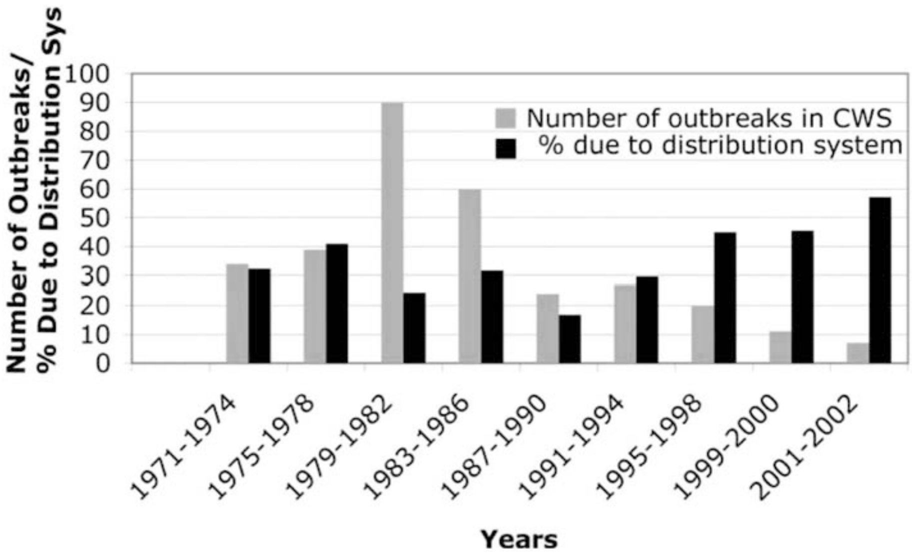

Fig. 1 Waterborne disease outbreaks in community water systems (CWS) associated with distribution system deficiencies. Note that the majority of the reported outbreaks have been in small community systems and that the absolute numbers of outbreaks have decreased since 1982. *Source*: Data from Refs.[14–16].

of Southern California's Foundation for Cross Connection Control and Hydraulic Research reported that 9.6% of the homes had a direct cross connection that constituted a health hazard, and more than 95% had either direct or indirect cross connections.[4]

The vast majority of states require some sort of cross connection control program, either through regulations or guidelines, although the requirements and the authority to implement them vary considerably in terms of how detailed a water system's program must be, the types of water systems required to have a program, and the role the states play in implementing and maintaining a program. Some states rely solely on plumbing codes to address cross connections and backflow, which may not require testing and follow-up inspections of backflow prevention devices. A number of states do not go beyond minimum requirements or require public water systems to administer any type of cross connection control program at the local level.

There are five primary elements of an effective cross connection control program, the first of which is *authority*. Effective cross connection control programs must have the legal authority to (1) enter premises and inspect facilities to determine hazards; (2) install, repair, and test backflow devices; (3) license inspectors to test assemblies; and (4) terminate water service in case of non-compliance. The second requirement is to *inspect facilities and test devices*. A testing program must identify the appropriate standards that a backflow prevention device must meet, and assemblies must be tested by a certified backflow assembly tester. A third issue is *training and certification*. The testing of backflow prevention assemblies by a certified tester is necessary to ensure that the assembly is functioning properly and will prevent backflow. The fourth and fifth elements, which are generally not found in cross-connection control programs, are *record keeping* following inspections and testing and *public education*.

At present, there is no unified basis from which cross connection control programs are designed, adopted, and implemented, although EPA has provided guidance for approximately two decades through its Cross Connection Control Manual.[5] Those states with cross connection control programs that are lacking could benefit greatly from EPA directives.

NEW AND REPAIRED WATER MAINS

Construction activities such as laying new pipes, engaging in pipe repairs, and rehabilitating sites are a major cause of distribution system contamination. Contamination incidents are not uncommon, as revealed by Pierson, Burlingame, and Martin[6] who pointed out that pipe repair and installation have not been accomplished using the best available sanitary practices. This is captured in Table 1, which summarizes a survey of distribution system workers at three different utilities (eastern and western United States and western Canada) on the potential for external contamination to occur during water main repair and replacement activities. Sanitary practices vary widely, with even well-run utilities experiencing a 30% failure rate in the approval of new mains based on water quality testing.[7] In addition, the storage of pipe, pipe fittings, and valves along roadways or in pipe yards prior to installation can expose them to contamination from soil, stormwater runoff, and animals. Damage to pipes prior to their installation is also possible, such as during pipe storage and handling or actual manufacturing defects such as surface impurities or nicks.

Table 1 Potential for contaminant entry during water main activities

	Percent of Responses from Workers at Three Different Utilities (A, B, C)					
	Occurs Often			*Occurs Sometimes*		
Activity	**A**	**B**	**C**	**A**	**B**	**C**
Broken service line fills trench during installation	46	75	56	39	25	33
Pipe gets dirty during storage before installation	53	75	22	43	25	33
Trench dirt gets into pipe during installation	24	100	39	37	0	44
Rainwater fills trench during installation	20	25	5	60	75	83
Street runoff gets into pipe before installation	30	0	11	61	38	67
Pipe is delivered dirty	4	25	17	33	63	22
Trash gets into pipe before installation	24	0	0	56	50	11
Vandalism occurs at the site	15	0	0	35	0	5
Animals get into pipe before installation	0	0	0	11	0	11

There are practices that can minimize the contamination potential of repair and installation activities, such as maintaining a positive pressure until the repair site is unearthed and cleared. Trench water should be removed before work is done, and street drainage should be provided to keep water and runoff out of the trench. New and repaired materials can be sprayed or swabbed with chlorine or appropriate sanitizing agents. During these activities, inspectors or engineers managing the site need to be aware of water quality issues, including the type of pipe that can be laid in soils suspected of contamination (to predict the potential for permeation), the means by which to protect materials during storage, and what to do if materials do become contaminated.

Non-technical solutions are also needed. Pipe design and construction need to better incorporate sanitary practices and permeation concerns. There are standards that attempt to address installation or construction practices, but there is a general lack of training and use of sanitary practices. This could be addressed in part by requiring foremen or managers of construction sites to be certified on a regular basis, as it is for the certification of backflow installers and testers. Not only would foremen or managers have to know the engineering requirements, but they would also have to record and understand the issues related to protecting the sanitary condition of the materials and the water supply.

FINISHED WATER STORAGE

There are 154,000 treated water storage facilities in the United States[8] that are designed and operated to provide reserve capacity for firefighting and other emergencies, to equalize system pressure, and to balance water use throughout the day. To meet these goals, large volumes of reserve storage are usually incorporated into system operation and design, resulting in long water detention times. Long detention times and improper mixing within such facilities provide an opportunity for both chemical and biological changes in the water. One of the most important manifestations of water quality degradation during water storage is a loss of disinfectant residual, which can be further compromised by temperature increases in storage facilities under warm weather conditions. Internal chemical contamination can also occur owing to leaching from coatings used in the storage facility or solvents, adhesives, and other chemicals used to fabricate or repair floating covers.

Storage facilities are also susceptible to external contamination from birds, animals, wind, rain, and algae. This is most true for uncovered storage facilities, although storage facilities with floating covers are susceptible to bacterial contamination owing to rips in the cover from ice, vandalism, or normal operation, or via improperly sealed access openings and hatches or faulty screening of vents and overflows.

One of the difficulties with storage facility management is that water quantity and quality requirements are frequently in conflict. While water quantity objectives promote excessive storage, water quality objectives are geared toward minimizing residence times and frequent exercising of facilities to maximize the disinfectant residual. Appropriate balancing is therefore required to ensure disinfection effectiveness and a sufficient level of service. This involves adequate turnover of the water in the facility to eliminate dead zones and prevent the short-circuiting of the water entering and leaving the facility.

A disciplined storage facility management program includes developing an inventory and background profile on all tanks, developing an evaluation and rehabilitation schedule, developing a detailed tank evaluation process, performing tank evaluations, making rehabilitations and replacements when needed, and performing a 1-yr warranty inspection for all tanks.[9] Depending on the nature of the water supply chemistry, such detailed inspections should be made every 3–5 yr, and consist of tanks needing to be drained, sediment removed, and appropriate rust-proofing applied to the metal surfaces.[10] These inspections are in addition to daily or weekly inspections for vandalism, security, and water quality purposes (such as identifying missing vents, open hatches, and leaks).

PREMISE PLUMBING

Premise plumbing includes the portion of the distribution system associated with homes, schools, hospitals, public housing, and other buildings. It is connected to the main distribution system via the service line. Virtually every problem identified in the main distribution system can also occur in premise plumbing. However, unique characteristics of premise plumbing relative to the main distribution system can magnify the potential public health risk and complicate management strategies. These characteristics include:

- *a high surface area to volume ratio*, which can lead to more severe leaching and permeation;
- variable, often *advanced water age*, especially in buildings that are irregularly occupied;
- more *extreme temperatures* than those experienced in the main distribution system;
- *low or no disinfectant residual*, because buildings are unavoidable "dead ends" in a distribution system and because of advanced water age;
- potentially *higher bacteria levels and regrowth* owing to the lack of persistent disinfectant residuals, high surface area, advanced water age, and warmer temperatures;
- *exposure routes through vapor and bioaerosols* in relatively confined spaces such as home showers;
- *proximity to service lines*, which have been shown to provide the greatest number of potential entry points for pathogen intrusion;
- *higher prevalence of cross connections*, since it is relatively common for untrained and unlicensed individuals to do repair work in premise plumbing;
- *variable responsible party*, resulting in considerable confusion over who should maintain water quality in premise plumbing.

Premise plumbing is a contributor to the degradation of water quality, particularly owing to microbial regrowth, backflow events, and contaminant intrusion, although additional research is needed to better understand their magnitude. In particular, colonization of premise plumbing (particularly hot water heaters) by *Legionella* accounts for a significant proportion of reported waterborne disease outbreaks attributable to distribution systems. Changes to plumbing codes and new technology hold promise for controlling *Legionella* growth and subsequent health risks. For example, mandated mixing valves can prevent both scalding and microbial regrowth in premise plumbing water systems. On-demand water heating systems may have benefits worthy of consideration versus traditional large hot water storage tanks. Although preliminary results suggest that chloraminated water systems have a lower incidence of *Legionella*,[11–13] the possible effects of chloramination and other treatments need to be quantified to a higher degree of certainty.

To better assess cross connections in the premise plumbing of privately owned buildings, inspections for cross connections and other code violations at the time of property sale could be required. Such inspection of privately owned plumbing for obvious defects could be conducted during inspection upon sale of buildings, thereby alerting future occupants to existing hazards and highlighting the need for repair. Finally, a homeowner's guide that highlights the nature of the health threat associated with premise plumbing and mitigation strategies that can be implemented to reduce the magnitude of the risk would be helpful. As part of this guide, it should be made clear that water quality is regulated only to the property line, and beyond that point responsibility falls mainly on consumers.

CONCLUSIONS

This entry summarizes the work of two recent NRC reports[2,3] on the public health risks of contaminated distribution systems and how they should be managed to reduce risk. The highest priority issues, which have a recognized health risk based on clear epidemiological and surveillance data, include cross connections and backflow; contamination during installation, rehabilitation, and repair of water mains and appurtenances; improperly maintained and operated storage facilities; and water quality in premise plumbing. The NRC reports contain a comprehensive discussion of other issues of importance, including distribution system operator training, biofilm growth, effects of increased water age, intrusion, nitrification, permeation, leaching, and post-precipitation.

Drip Lines and Emitters: Acidification for Prevention of Clogging

Andrew C. Chang
Department of Environmental Sciences, University of California–Riverside, Riverside, California, U.S.A.

INTRODUCTION

Water from both surface and underground sources pick up particulate matter during conveyance—sands, silts, plant fragments, algae, diatoms, larvae, snails, fishes, etc. While the majority of the suspended solids may be removed in preirrigation treatments such as sedimentation and filtration, some of the fine silts and colloidal clay particles inadvertently remain and settle inside the lateral lines or emitters impeding the water flow. As the flow slows down and/or the chemical background of the water changes, chemical precipitates and/or microbial flocs and slimes begin to form and grow, thus microirrigation emitter clogging occurs. This section delineates the occurrences of chemical precipitates and the chemistry of acidification that is employed to mitigate clogging caused by chemical precipitates. Clogging resulting from formation of microbial flocs and slimes is controllable by acidification as well as chlorination.

OVERVIEW

Within the extensive network of a drip irrigation system, it is difficult to predict where or when clogging will take place. The hydraulic characteristics such as flow velocity, path length, orifice diameter, and pressure compensation all affect the flow rate and thus the clogging. The lower end of an operating irrigation system (laterals and emitters) should be visually inspected for build-up of deposits, and the flow rates and pressures of the systems should be regularly tested. Routine examinations will identify segments of the network that are potentially problematic and isolate them for corrective measures. The clogging, once formed in the distribution system, is difficult to mitigate. Prevention is by far the preferred measure.

Clogging caused by the deposition of inorganic suspended substances may be overcome by regular flushing of the system and by employment of self-cleaning emitters. High-dosage, short-duration shock treatment with acidification and chlorination may be necessary to dissolve the chemical precipitates and to inactivate the microorganisms. Many publications outlined the practical and operational aspects of acidification and chlorination processes for drip irrigation.[1–4]

CHEMICAL PRECIPITATION

Calcium (Ca^{2+}) and bicarbonate (HCO_3^-) ions in water have a tendency to form calcium carbonate precipitates when the temperature and pH rise and CO_2 partial pressure changes. As the pH rises, the HCO_3^- ion in the bicarbonate–carbonate equilibrium shifts toward the CO_3^{2-} ion. The HCO_3^- ion in water is also in equilibrium with CO_2 in the atmosphere. When the temperature of water rises, the dissolved CO_2 escapes and again the equilibrium shifts toward the CO_3^{2-} ion. The reactions result in the precipitation of calcium carbonate:

$$Ca(HCO_3)_{2(aq)} \rightarrow CaCo_{3(s)} + H_2O + CO_{2(g)}$$

Water, high in hardness, is especially susceptible to the precipitation reaction.

After an irrigation event, water left behind in the emitter and the laterals will evaporate. The evaporation leaves behind mineral deposits that are carbonate as well as chloride and sulfate salts of calcium, magnesium, sodium, and potassium near an emitter outlet, or orifice. The chloride and sulfate salts may be dissolved in subsequent irrigation. Because of their low solubility, minerals such as calcite (calcium carbonate), gypsum (calcium sulfate), and magnesium hydroxide are likely to accumulate over time on and around the emitter openings. For saline water, the deposits will build up rapidly. Ground water may also contain reduced forms of iron and manganese. Upon exposure to oxygen in the atmosphere, they are oxidized and the oxidized iron and manganese ions form precipitates with hydroxide, carbonate, and phosphate in water. The deposits accumulate in and around the microirrigation line, and emitters invariably are mixtures of precipitates of different chemical nature.

ACIDIFICATION

Calcium carbonate is by far the most common chemical precipitate causing clogging in drip irrigation systems.[5] Acids are frequently added to irrigation water to prevent formation of precipitates or to dissolve precipitates when they form in the drip irrigation lines and emitters.

In water, the solubility of calcium carbonate is a function of the Ca^{2+} concentration, alkalinity, and pH of the water.[6] The pH at which the calcium carbonate solubility in the water reaches saturation is designated as the saturation pH, pH_s, and it may be calculated as:[7]

$$\mathrm{pH_s} = \mathrm{p}K_2 + \mathrm{p}[\mathrm{Ca}^{2+}] - \mathrm{p}K_{\mathrm{sp}} - \log(2[\mathrm{Alkalinity}]) - \log\gamma_{\mathrm{m}}$$

where p denotes −log operator, [ ] denotes molar concentration of the chemical species specified inside the brackets, K_2 is the dissociation constant of HCO_3^- to CO_3^{2-}, K_{sp} is the solubility product of calcium carbonate, and γ_m is the activity coefficient of monovalent ion. Alkalinity refers to the ability of the water to resist the change of pH when acid or base is added. It is measured as moles of H^+ required for reducing the pH of 1 L of water to 4.5. If the pH of the water is maintained at less than the calculated pH_s, calcium carbonate precipitation will not take place in the water.

To dissolve precipitates in and weaken the attachments on drip lines and emitters, acids are added to reduce the pH of water to approximately 2, and they should remain in the affected sections for at least 24 hr. Any strong acid such as sulfuric, hydrochloric, or nitric acid will serve the purpose. Afterwards, the treated section of the drip lines is flushed to remove the dissolved and loosened deposits.

When acid is added into water, the pH does not change at a constant rate with the addition. The volume of acid required to lower the pH to a given level is dependent on the alkalinity of the water. It may be necessary to perform a titration trial on a water sample to determine the acid addition required for achieving the desired pH level.

Drip Lines and Emitters: Chlorination for Disinfection and Prevention of Clogging

Andrew C. Chang
Department of Environmental Sciences, University of California–Riverside, Riverside, California, U.S.A.

INTRODUCTION

Water from both surface and underground sources picks up particulate matter during conveyance—sands, silts, plant fragments, algae, diatoms, larvae, snails, fishes, etc. While the majority of the suspended solids may be removed in preirrigation treatments such as sedimentation and filtration, some of the fine silts and colloidal clay particles inadvertently remain and settle inside the lateral lines or emitters impeding the water flow. As the flow slows down and/or the chemical background of the water changes, chemical precipitates and/or microbial flocs and slimes begin to form and grow, thus microirrigation emitter clogging occurs. This section delineates the occurrences of chemical precipitates and the chemistry of acidification that is employed to mitigate clogging caused by chemical precipitates. Clogging resulting from formation of microbial flocs and slimes is controllable by acidification as well as chlorination.

OVERVIEW

Within the extensive network of a drip irrigation system, it is difficult to predict where or when clogging will take place. The hydraulic characteristics such as flow velocity, path length, orifice diameter, and pressure compensation all affect the flow rate and thus the clogging. The lower end of an operating irrigation system (laterals and emitters) should be visually inspected for build-up of deposits, and the flow rates and pressures of the systems should be regularly tested. Routine examinations will identify segments of the network that are potentially problematic and isolate them for corrective measures. The clogging, once formed in the distribution system is difficult to mitigate. Prevention is by far the preferred measure.

Clogging caused by the deposition of inorganic suspended substances may be overcome by regular flushing of the system and by employment of self-cleaning emitters. High-dosage, short-duration shock treatment with acidification and chlorination may be necessary to dissolve the chemical precipitates and to inactivate the microorganisms. Many publications have outlined the practical and operational aspects of acidification and chlorination processes for drip irrigation.[1–4]

BIOLOGICAL GROWTH AND BIOLOGICAL GROWTH INDUCED CHEMICAL PRECIPITATION

Many microorganisms may grow within the water delivery network in the absence of light producing slime and causing iron and sulfur to precipitate in the water. Organic substrates and nutrients will enhance bacterial growth. The aggregates resulting from microbial slimes adhering to the suspended solids in the water are the primary causes of clogging.

When the iron present in water is in the ferrous form (Fe^{2+}), it may be oxidized to the ferric iron (Fe^{3+}) that in turn form precipitates. The oxidation reactions are often mediated by filamentous (*Gallionella*, *Leptothrix*, *Toxothrix*, *Crenothrix,* and *Sphaerotilus* spp.) and non-filamentous (*Psedomonas* and *Enterobactor* spp.) bacteria.[1] In the presence of dissolved oxygen, Fe^{2+} is oxidized to (Fe^{3+}) according to the reaction

$$Fe^{2+} + \frac{1}{4}O_2 + H^+ = Fe^{3+} + \frac{1}{2}H_2O$$

At pH 7, the solubility of Fe^{3+} is approximately 6 orders of magnitude lower than that of the ferrous iron Fe^{2+}. Solution Fe concentrations as low as $0.1\,mg\,L^{-1}$ may result in significant deposition of Fe precipitates in the distribution systems.

When hydrogen sulfite is present in the water, *Thiothrix* spp. bacteria oxidize the S^{2-} in H_2S to insoluble elemental sulfur, S^0, in the presence of dissolved oxygen:

$$H_2S + \frac{1}{2}O_2 = H_2O + S^0$$

The potential for clogging is related to the quality of irrigation water. Based on field experience, concentrations that exceed the levels labeled as low given in

Table 1 Water quality criteria for drip irrigation

	Clogging potential		
Parameter	**Low**	**Moderate**	**High**
Suspended solids ($mg\,L^{-1}$)	<50	50–100	>100
pH	<7	7–8	>8
Dissolved solids ($mg\,L^{-1}$)	<500	500–2000	>2000
Manganese ($mg\,L^{-1}$)	<0.1	0.1–1.5	>1.5
Iron ($mg\,L^{-1}$)	<0.1	0.1–1.5	>1.5
Calcium and magnesium ($mg\,L^{-1}$)	<20	20–50	>50
Hydrogen sulfite ($mg\,L^{-1}$)	<0.5	0.5–2	>2
Bacterial population (count mL^{-1})	$<10^5$	10^5–5×10^5	$>5 \times 10^5$

Table 1 can cause clogging; the more the parameters exceed the limits, the higher the clogging potential.

CHLORINATION

Chlorination is by far the most common method used to disinfect water. It involves the addition of chlorine or chlorine compounds to produce chemical species that have ability to inactivate microorganisms present in water. The method was first introduced over 100 yr ago and has remained as an effective, cost-effective, and easy to operate process.

When chlorine is dissolved in water, it hydrolyzes to hypochlorous acid (HOCl) that subsequently ionizes to hypochlorite (OCl^-).

$$Cl_{2(g)} + H_2O \rightarrow HOCl_{(aq)} + H^+ + Cl^-$$

$$HOCl_{(aq)} \rightarrow H^+ + OCl^-$$

For other chlorine chemicals (such as the active ingredients found in household bleach), the reactions are similar:

$$Ca(OCl)_2 + 2H_2O \rightarrow 2HOCl + Ca(OH)_2$$

$$NaOCl + H_2O \rightarrow HOCl + NaOH$$

$$CaClOCl + 2H_2O \rightarrow HOCl + H^+ + Cl^- + Ca(OH)_2$$

HOCl and OCl^- are the chlorine species active in the disinfection actions. The ratio of HOCl and OCl^- species in water is dependent on pH (Fig. 1). This relationship is significant, as $HOCl_{(aq)}$ is a far more effective chemical species for disinfection than OCl^-.

HOCl and OCl^- are strong oxidants and may be dissipated before significant disinfection occurs because of their reactions with various impurities in water. Chemical species such as H_2S, SO_3^{2-}, NO_2^-, Fe^{2+}, and Mn^{2+} react rapidly with HOCl according to the following reactions:

$$H_2S + 4HOCl \rightarrow H_2SO_4 + 4HCl$$

$$2Fe^{2+} + Cl_{2(g)} + 6H_2O \rightarrow 2Fe(OH)_3 + 2Cl^- + 6H^+$$

$$Mn^{2+} + Cl_{2(g)} + 2H_2O \rightarrow MnO_2 + 2Cl^- + 4H^+$$

In these reactions, the disinfecting power of the added chlorine (i.e., Cl_2, HOCl, and OCl^-) is spent in

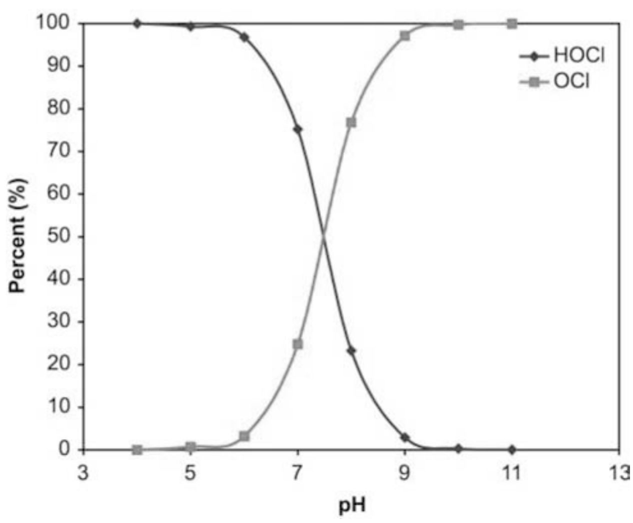

Fig. 1 Distribution of HOCl and OCl^{-1} in water.

oxidizing the reduced forms of sulfur (S^{2-}), iron (Fe^{2+}), and manganese (Mn^{2+}) present in the water. If Fe^{2+} and Mn^{2+} are present in water, as in some ground waters, they will be oxidized through the chlorination process and the oxidized Fe and Mn species are considerably less soluble in the water. It is preferable that the reduced Fe and Mn species are oxidized at the pre-irrigation treatment to prevent the formation of precipitates in the distribution system.

If ammonia is present in the water it will also react with $HOCl_{(aq)}$ and result in the formation of chloroamines:

$$NH_3 + HOCl \rightarrow NH_2Cl + H_2O$$

$$NH_2Cl + HOCl \rightarrow NHCl_2 + H_2O$$

$$NHCl_2 + HOCl \rightarrow NCl_3 + H_2O$$

These combined chlorine species are considerably less efficient in inactivating microorganisms than $HOCl_{(aq)}$. If the addition of chlorine continues after the conversions, combined chlorines will be further oxidized to form gaseous nitrogen species and chloride:

$$NH_2Cl + NHCl_2 + HOCl \rightarrow N_2O + 4HCl$$

$$HN_2Cl + NCl_3 + HOCl \rightarrow N_2 + 4HCl$$

In addition, organic reducing agents such as phenols and unsaturated organic compounds also react with free chlorine. Notably, $HOCl_{(aq)}$ reacts with dissolved organic matter in water to form trihalomethanes. Trihalomethanes are chemical species that have the structure of a methane molecule in which three of the hydrogens are substituted by permutations of halogens (I, Cl, and Br). Because of their similarity in chemical structure, trihalomethanes are categorized along with chloroform ($CHCl_3$), the most common trihalomethane species among them, as potential carcinogens. Some irrigation waters, such as those obtained from the Sacramento Delta in California, can contain significant amounts of humic and fulvic acids, which are precursors of trihalomethanes. Unlike in drinking water through which consumers may be exposed to potentially harmful chemicals, the chlorination-induced trihalomethanes are not expected to be absorbed by plants. However, additional chlorine must be spent to satisfy the reactions before the sufficient concentrations of effective chlorine species are present in the treated water to satisfy the disinfection needs.

The disinfecting potential of the water may be represented by the chlorine residue that sums up the free and combined chlorine species present in the water (Fig. 2). In this diagram, the added chlorine at first does not result in any chlorine residue as it reacts with

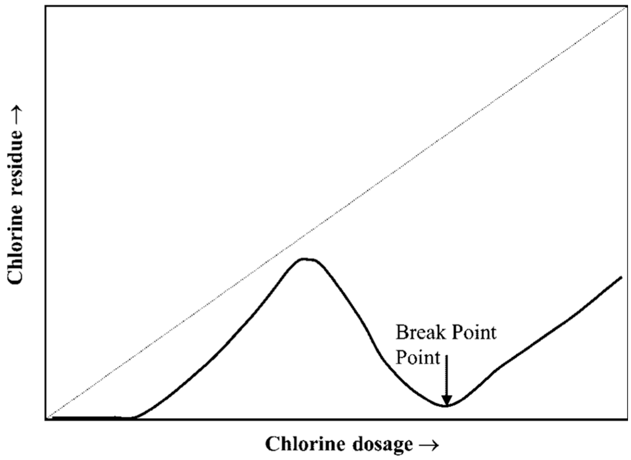

Fig. 2 A schematic depiction on the chemical reactions of chlorination and the formation of chlorine residues for disinfections.

the reducible substances in the water. Subsequently, the chlorine residue rises as the added chlorine reacts with ammonia in water to form the combined chlorine species and then falls as these compounds decompose to chloride and gaseous nitrogen. The most effective disinfecting chlorine species will not be present in the water until all reactions are completed and the dosage reaches beyond the break point marked in Fig. 2.

The amount of chlorine required to reach the break point is dependent on the amounts of reducible substances and ammonia present in the water. This dosage is empirically determined for each water.

In chlorination, the effectiveness of microbial kill is in proportion to the concentration of disinfectant and time of contact. Low-chlorine dosages may be compensated by longer time of contact and vice versa. In practical applications, the microbial growth in drip-irrigation lines may be controlled by continuous chlorination at rates that result a chlorine residue concentration of 1–2 $mg\,L^{-1}$, or at intermittent basis with a chlorine residue concentration of 10–20 $mg\,L^{-1}$ for 30–60 min once each day of irrigation. When severe blockages caused by microbial growth occur, super-chlorination at chlorine residue concentrations of 500–1000 $mg\,L^{-1}$ may be necessary until the blockage is removed.

INTRODUCTION

Drought differs from other natural hazards in several ways.[1] First, drought is a slow-onset, creeping natural hazard. Its effects often accumulate slowly over a considerable period of time and may linger for years after the termination of the event. Therefore, the onset and end of drought is difficult to determine. Second, the absence of a precise and universally accepted definition of drought adds to the confusion about whether or not a drought exists and, if it does, its degree of severity. Realistically, definitions of drought must be region and application (or impact) specific. This is one explanation for the scores of definitions that have been developed. Third, drought impacts are non-structural and spread over a larger geographical area than are damages that result from other natural hazards. Because drought can affect such large areas, it is far more difficult to quantify impacts and respond effectively.

Although many people consider drought a natural or physical event, it has both a natural and social component. The risk associated with drought for any region is a product of both the region's exposure to the event (i.e., probability of occurrence at various severity levels) and the vulnerability of that area or region to the event. The natural event (i.e., meteorological drought) is a result of the occurrence of persistent large-scale disruptions in the global circulation pattern of the atmosphere. Exposure to drought varies spatially, and we can do little to alter drought occurrence. Vulnerability, on the other hand, is determined by social factors such as population growth, population shifts (regional and rural to urban), demographic characteristics, technology, policy, environmental awareness, and social behavior. These factors change over time and thus vulnerability will increase or decrease in response to these changes.

DROUGHT DEFINITION AND TYPES

Drought is an insidious natural hazard that results from a departure of precipitation from expected or "normal" that, when extended over a season or longer period of time, is insufficient to meet the demands of human activities. Drought is normally grouped by type as follows: meteorological, hydrological, agricultural, and socioeconomic.[1] Fig. 1 explains the relationship between these various types of drought and the duration of the event. Meteorological drought is commonly defined on the basis of the degree of precipitation deficiency, compared to "normal" or average, and the duration of the dry period. Thus, intensity and duration are the key characteristics of these definitions. Agriculture is usually the first economic sector affected by drought because soil moisture supplies are often quickly depleted. Agricultural drought links various characteristics of meteorological drought to agricultural impacts, focusing on precipitation shortages, differences between actual and potential evapotranspiration, and soil water deficits. Agricultural drought would develop more quickly on sandy soils because of lower soil water-holding capacity. A plant's demand for water depends on prevailing weather conditions, biological characteristics of the specific plant, its stage of growth, and the physical and biological properties of the soil. A definition of agricultural drought should account for the variable susceptibility of crops at different stages of crop development.

Hydrological droughts are associated with the effects of periods of precipitation deficits on surface or subsurface water supply (i.e., streamflow, reservoir and lake levels, groundwater). Extended drought periods may result in serious depletion of these components of the hydrological system. Hydrological droughts are usually out of phase or lag the occurrence of meteorological and agricultural droughts. More time elapses before precipitation deficiencies are detected in surface and subsurface water supplies. As a result, impacts are out of phase with those in other economic sectors. Also, water in hydrological storage systems is often used for multiple and competing purposes (e.g., power generation, flood control, irrigation, recreation), further complicating the sequence and quantification of impacts. Competition for water in these storage systems escalates during drought, and conflicts between water users increase significantly. Hydrological drought is also likely to continue long after the end of meteorological drought because of the time necessary to recharge surface and subsurface water supplies.

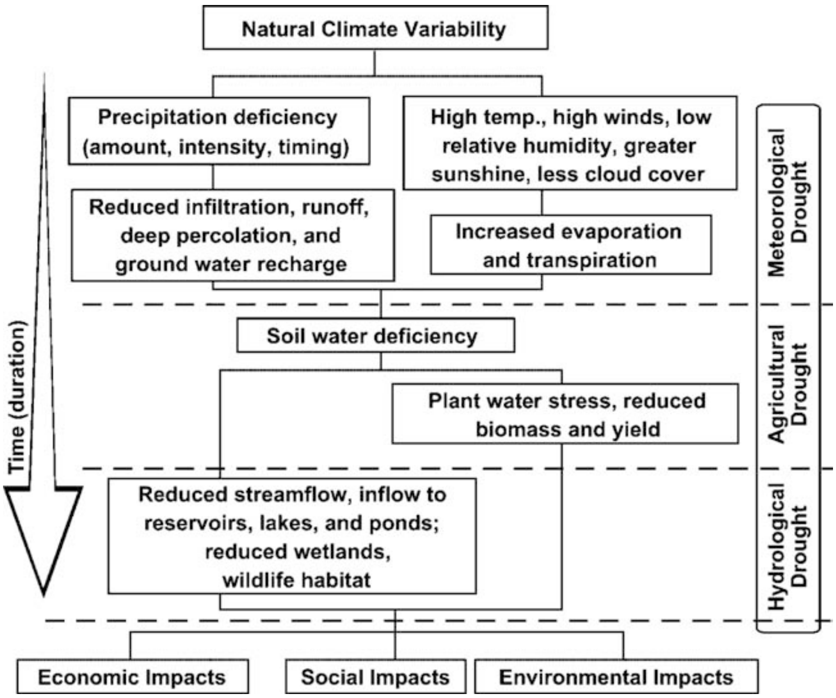

Fig. 1 Relationship between various types of drought and duration of drought events. *Source*: From Ref.[1].

Finally, socioeconomic drought is associated directly with the supply of some commodity or economic good (e.g., hay, hydroelectric power) and that supply is related directly to precipitation levels. Increases in population can substantially alter the demand for these economic goods over time. Thus, the incidence of drought could increase because of a change in the frequency of meteorological drought, a change in societal vulnerability to water shortages, or both. For example, poor land-use practices such as overgrazing can decrease animal carrying capacity and increase soil erosion, which exacerbates the impacts of and vulnerability to future droughts.

DROUGHT CHARACTERISTICS

Droughts differ from one another in three essential characteristics: intensity, duration, and spatial coverage. Intensity refers to the degree of the precipitation shortfall and/or the severity of impacts associated with the shortfall. It is generally measured by the departure of some climatic index from normal and is closely linked to duration in the determination of impact. Many indices exist and are used to detect the onset and severity of drought conditions. One of the principal difficulties with any index is the determination of the threshold between non-drought and drought conditions or levels of severity (i.e., moderate, severe, extreme). These thresholds are important because they are used to determine when emergency response or mitigation actions are triggered.

Another distinguishing feature of drought is its duration. Droughts usually require a minimum of two to three months to become established but then can continue for months or years. Drought impacts are magnified as dry conditions extend through multiple seasons or years.

Droughts also differ in terms of their spatial characteristics. The areas affected by severe drought evolve gradually, and regions of maximum intensity shift from season to season. As drought emerges and intensifies, its core area or epicenter shifts and its spatial extent expands and contracts throughout the duration of the event.

THE IMPACTS OF DROUGHT

The impacts of drought are diverse and often ripple through the economy. Impacts are often referred to as direct or indirect. Because of the number of affected groups and sectors associated with drought, its spatial extent, and the difficulties connected with quantifying environmental damages and personal hardships, the precise determination of the financial costs of drought is an arduous task.

The impacts of drought can be classified into three principal areas: economic, environmental, and social.[2] Economic impacts range from direct losses in the broad agricultural and agriculturally related sectors, including forestry and fishing, to losses in recreation, transportation, banking, and energy. Other economic impacts would include added unemployment and loss of revenue to local, state, and federal government.

Environmental losses are the result of damages to plant and animal species, wildlife habitat, and air and water quality; forest and range fires; degradation of landscape quality; and soil erosion. Although these losses are difficult to quantify, growing public awareness and concern for environmental quality has forced public officials to focus greater attention on these effects. Social impacts mainly involve public safety, health, conflicts between water users, and inequities in the distribution of impacts and disaster relief programs. As with all natural hazards, the economic impacts of drought are highly variable within and between economic sectors and geographic regions, producing a complex assortment of winners and losers with the occurrence of each disaster.

DROUGHT PLANNING AND MITIGATION

Drought planning is defined as actions taken by individual citizens, industry, government, and others in advance of drought for the purpose of mitigating some of the impacts and conflicts associated with its occurrence.[3] Because drought is a normal part of climate variability for virtually all regions, it is important to develop plans to deal with these extended periods of water shortage in a timely, systematic manner. This planning process needs to occur at various levels of government and be integrated between levels of government.

The purpose of a drought plan is to reduce the impacts of drought by identifying the principal sectors, groups, or regions most at risk and developing mitigation actions and programs that can reduce these risks in advance.[3] Plans will also improve coordination within and between levels of government. Generally, drought plans have three basic components: monitoring and early warning; risk and impact assessment; and response and mitigation.[4] Substantial progress in state-level drought planning has been made in the United States in recent years. States with drought plans have increased from 3 in 1982 to 31 in 2001. Drought plans are at the foundation of improved drought management, but only if they emphasize risk assessment and mitigation programs and actions.

CONCLUSION

Drought is an insidious natural hazard that is a normal part of the climate of virtually all regions. It should not be viewed as merely a physical phenomenon. Rather, drought is the result of an interplay between a natural event and the demand placed on water supply by human-use systems.

Many definitions of drought exist; it is unrealistic to expect a universal definition to be derived. The three characteristics that differentiate one drought from another are intensity, duration, and spatial extent. The impacts of drought are diverse and generally classified as economic, social, and environmental. Impacts ripple through the economy and may linger for years after the termination of the drought episode. It appears that societal vulnerability to drought is escalating in both developing and developed countries, and at a significant rate. It is imperative that increased emphasis be placed on mitigation, preparedness, and prediction and early warning if society is to reduce the economic and environmental damages associated with drought and its personal hardships. This will require improved coordination within and between levels of government and the active participation of stakeholders.

Drought Hardening and Pre-Sowing Seed Hardening

Neil C. Turner
Centre for Mediterranean Agricultural Research, Plant Industry, Commonwealth Scientific and Industrial Research Organization (CSIRO), Wembley, Western Australia, Australia

INTRODUCTION

Drought hardening is the process whereby a plant is subjected to partial drying so that when it is exposed to a subsequent drought event, the plant is able to withstand a greater severity of drought. During drought hardening, morphological, physiological, and chemical changes are induced within the plant as a result of phytohormone activity that enable the cells to withstand greater dehydration. Drought hardening also confers greater cold tolerance to the plant. Drought hardening is widely used in seedlings to increase their survival rate when transplanted. The wetting and drying of seed, known as presowing seed hardening, is also used to increase the germination, emergence, and drought tolerance of seedlings.

The acclimation of plants is the *non-heritable* modification by the plant in response to exposure to new climatic conditions such as drought.[1] It relies on the occurrence of temporary phenotypic modifications induced by the change in environment. Acclimation differs from adaptation in that the latter refers to the *heritable* modifications in structure or function that increase the probability of a plant surviving and reproducing in a particular environment.[1] Hardening is the equivalent of acclimation,[1] that is, it depends on phenotypic modifications. Seedlings are ''hardened'' prior to transplanting by exposure to full sunlight and transient water stress to ensure greater survival.

EFFECTS OF DROUGHT HARDENING

The changes that take place during drought hardening are several. First, drought hardening induces morphological and anatomical changes in the plant. In wheat, exposure to water stress during the growth of the flag leaf resulted in a reduction in leaf area and thickness, smaller cells with thicker walls, and an increased stomatal frequency.[2] Similarly, in cotton a reduced frequency of irrigation resulted in smaller leaves with smaller cells and thicker cell walls.[3] These morphological changes resulting from drought preconditioning make the plant more xeromorphic and less sensitive to subsequent drought.[4,5] Drought hardening also influences the physiological responses of plants. In cotton, drought hardening made leaf expansion and stomatal conductance less sensitive to a subsequent water deficit.[4] Also, the proportion of root dry weight to shoot dry weight shifts in favor of the root during drought hardening,[4] thereby enabling increased water uptake during subsequent water shortage.

Additionally, drought hardening induces a lowering of the osmotic potential and turgor maintenance.[6] This is illustrated, for cotton, in Fig. 1. The turgor pressure was higher and osmotic pressure was lower at a particular leaf relative water content in drought-hardened cotton plants exposed to three cycles of water stress, compared to continuously well-watered cotton plants.[5] The lower osmotic potential in the hardened plants may arise from solute accumulation by osmotic adjustment or by changes in tissue elasticity.[5,6] In cotton, while solutes increased during a subsequent stress, solute accumulation was similar in drought hardened and non-hardened plants suggesting that it was the change in cell size and tissue elasticity that resulted in the changes observed in Fig. 1.[5] Certainly, the accumulation of solutes by osmotic adjustment[6,7] during drought hardening can play a role in maintenance of turgor and physiological activity in a subsequent cycle of drought.[8] One consequence of osmotic adjustment is the continued growth of roots and deeper extraction of water from the soil,[9] thereby maintaining the water status of the plant high during a subsequent drying cycle and delaying the onset of plant dehydration, a mechanism recognized as drought avoidance. The solutes that accumulate during drought hardening are soluble sugars and amino acids, especially proline.[7,10] Table 1 gives the relative concentrations of amino acids and soluble sugars in the phyllodes (leaves) of *Acacia cyanophylla* seedlings during drought hardening for periods up to 13 mo. Reducing the water available to one-sixth in the well-watered tree seedlings induced, after the first month, a gradual increase in the concentration of aspartic acid, glutamine acid, proline, and soluble sugars.

When soils dry, it is now recognized that the leaves and roots synthesize the phytohormone, abscisic acid (ABA). Root-synthesized ABA is quickly transferred to the leaves in the xylem sap.[11] ABA closes stomata, reduces leaf growth, increases leaf senescence and abscission, and promotes root growth.[11,12] Thus,

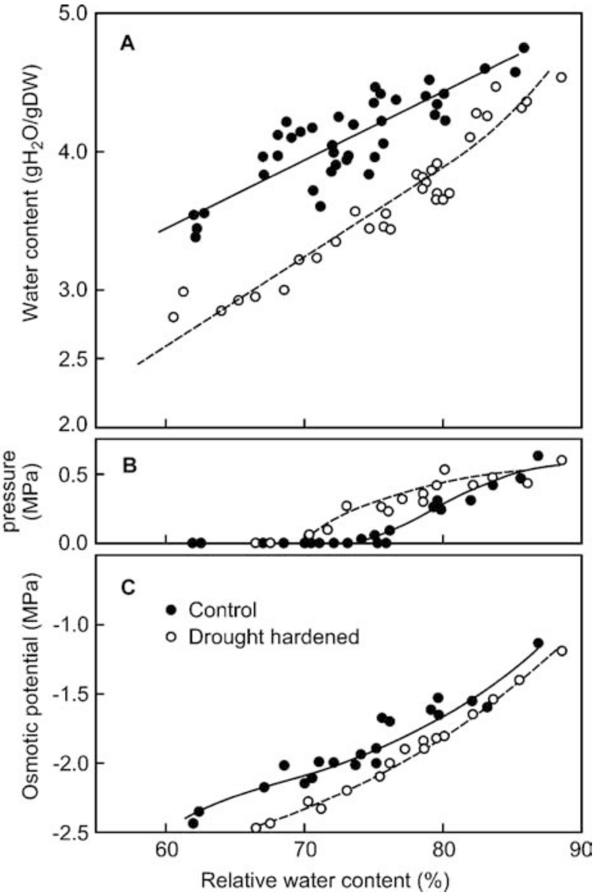

Fig. 1 The water content (A), turgor pressure (B), and osmotic potential (C), of cotton leaves subjected to drought hardening or kept well watered. Drought hardening was induced by three cycles of withdrawing water until the stomata closed during the day. *Source*: Adapted from Ref.[5].

ABA acting alone or possibly in concert with other phytohormones such as cytokinins, sap pH, and sap mineral composition,[13] induces changes in the plant's water loss and water harvesting capabilities that enable it to withstand subsequent drought better. This suggests that ABA plays an important role in the induction of drought hardening.

ABA is also known to induce production of specific proteins, dehydrins, which are part of the late embryogenesis abundant (LEA) class of proteins that are also stimulated by dehydration in a wide range of plants.[14–16] However, the role of these proteins in drought hardening is still unclear since the overexpression and downregulation of the genes had no influence on a plants' abilities to withstand subsequent water deficits.

Water deficits also induce accumulation of compatible solutes such as glycine betaine, proline betaine, and other quaternary ammonium compounds that may play a role in drought hardening by acting as osmoprotectants and to store energy for use when stress is relieved.[17] Genes for their overproduction have been identified and genetic modification to increase the content of compatible solutes has been shown to increase salinity tolerance.[18]

The changes induced by drought hardening also reduce the chilling injury of plants. The morphological, physiological, and chemical changes induced during drought hardening such as smaller cells, thicker cell walls, lower stomatal conductances and transpiration, high soluble sugar, and amino acid levels appear to confer greater chilling resistance to the plant. However, chilling resistance and drought hardening appear to be induced by separate mechanisms. Chilling of the roots does induce water deficits in the leaves because of the decreased hydraulic conductance of roots at low temperature, provided shoot transpiration is high.[19] ABA increased when plants were chilled[20] at high relative humidities that induced a water deficit in the chilled plants, but not in plants chilled at high relative humidities designed to minimize transpiration.[21] Indeed, low temperature appeared to minimize ABA production even in water-stressed plants[21] suggesting that ABA does not induce chilling resistance like it induces drought hardening.

Table 1 Influence of drought hardening for various periods of time on the composition of the phyllodes (leaves) of *Acacia cyanophylla* Lindl. The results are presented as drought hardened as a fraction of the unhardened plant. Drought hardening was induced by providing one-sixth the water of that given to the unhardened well-watered plants

	Duration of hardening (mo)			
Phyllode composition	**1**	**3**	**5**	**13**
Free amino acids	0.63	1.60	2.53	5.73
Aspartic acid	0.44	1.55	5.53	5.00
Glutamic acid	0.46	1.49	1.29	2.69
Proline	0.53	2.00	3.31	9.00
Soluble sugars	1.00	1.13	1.39	1.94

PRESOWING HARDENING

Henckel and his coworkers concluded that presowing hardening of seeds conferred greater drought resistance on a plant after germination.[22] Presowing hardening is achieved by soaking the seed in water for a period of about 2 days so that imbibition of water occurs and then slowly air drying the seed until it reaches the initial water content.[22] Henckel[22] suggested that the presowing hardening induced a number of physicochemical changes to the cytoplasm, including greater hydration of colloids, higher viscosity and elasticity, increased bound water, increased hydrophilic and decreased lipophilic colloids, and an increased temperature for protein coagulation. Other studies showed that presowing hardening of carrot increased the embryo size by about 50%[23] and increased the speed of germination and emergence of seedlings[23,24] such that in a drying soil a greater proportion of seeds germinated and emerged.[25] The benefits that the presowing hardening had on the drought resistance of the plant have been disputed.[26] Both benefits[23] and lack of benefit[25] have been reported. Presowing hardening of rice seed was shown to increase the percentage emergence of the seed in three of eight cultivars of rice, but not in another five.[27] The increased emergence was associated with longer coleoptiles and greater root length, suggesting that in the cultivars in which presowing hardening had a beneficial effect it was from the faster initial growth, as in previous studies.[23,25]

CONCLUSION

Drought hardening is a recognized method that is widely used when transplanting seedlings into the field and also provides widespread benefit to crops grown under dryland conditions or with limited irrigation. Presowing hardening of seed, on the other hand, has had mixed results and has not been widely adopted, particularly as soaking and drying the seed is a costly and exacting practice.

Drought: Avoidance and Adaptation

J. W. Chandler
Department of Developmental Biology, University of Cologne, Cologne, Germany

Dorothea Bartels
Botanisches Institut der Universitat, University of Bonn, Bonn, Germany

INTRODUCTION

Surviving periods without water is one of the greatest challenges faced by many plants. To cope with this challenge, plants have developed several strategies: either adaptation mechanisms which allow them to survive the adverse drought conditions, or the possession of particular growth habits to circumvent or avoid drought. Both mechanisms must have arisen under the same evolutionary constraints to enable plants to cope with low water availability. Plants avoid drought by completing their life cycle during the wet season when sufficient water is available. This strategy has been adopted by many flowering annuals. Another drought-avoidance mechanism is the formation of deep roots which allows better access to groundwater resources. The development of deep roots is an example where it is difficult to distinguish between avoidance and adaptation mechanisms. Most adaptation mechanisms are constitutive and are also present during non-stressful conditions. The objective of drought-adaptation mechanisms is to decrease transpiration and to improve water up-take. The development of succulence in leaves and roots, sunken stomata, reduction of transpiring surfaces even by the shedding of leaves or the presence of specialized photosynthetic pathways (C_4 and CAM plants) are examples of drought-avoidance mechanisms. In summary, adaptation includes modifications of a plant on the morphological, anatomical and/or biochemical level to cope better with water-deficit.

Acclimation is a third mechanism, different from avoidance and adaptation. Acclimation is a response of plants to changing water conditions, and it is generally associated with the synthesis of a specific set of transcripts. During acclimation, plants acquire resistance to stress conditions which may otherwise be lethal. This review will focus on avoidance and adaptation mechanisms.

MECHANISMS OF DROUGHT AVOIDANCE AND ADAPTATION

Anatomical Mechanisms

Most anatomical adaptations to drought conditions contribute to the maintenance of a positive water balance, either by maximizing water up-take, or minimizing water loss. To maximize water absorption from the soil, desert plants often have well-developed xylem tissue, which helps rapid water conduction in times of water supply. For example, in the case of *Lygeum spartam*, the roots are extremely hygroscopic to maximize water absorption. At the level of minimizing water loss, roots of plants from arid environments often develop thick bark, show sclerification of the cortical cells or ensure that the vascular cylinder is protected by periderm formation or necrosis of the cortical parenchyma. In addition, a feature mainly specific to desert grasses is the production of sheath roots which exude a mucilage to cement particles around the root and protect against dehydration. In aerial parts of the plant, transpiration is the major process through which water is lost. Structural characteristics specific to desert plants, which contribute to reducing water loss, logically include a reduction in total leaf surface area and a concomitantly low surface area/volume ratio. This tendency towards succulence often reflects a reduction in leaf cell size.[1] Many diverse mechanisms have evolved to reduce water loss in plants where the vapor-pressure gradient between vegetative organs and the air is extreme. One common mechanism is the development of either a thick waxy epidermis or a multiple epidermis in leaves. Equally important is the chemical composition of the epidermis, which will regulate how effective water loss is minimized. Many desert plants have a thick covering of hairs or trichomes on the leaves, which in the same way as cuticular wax or resin, serves to reduce solar radiation to the leaves and increase solar reflectance.[2] In addition to creating a boundary layer of still air close to the leaf surface, this traps moisture and reduces evapotranspiration. In the same way, sunken stomata also minimize transpiration through the creation of a pocket of moist still air above the stomatal pore. A more specialized characteristic of some xerophytes, e.g., *Achillea fragrantissima* is to produce annual interxylary cork rings. This helps to reduce water loss and limits water flow to a narrow zone of xylem.[2]

Morphological Characteristics

The major ways plants avoid drought stress is to alter their whole morphology to minimize transpirational water loss. Plants growing in arid environments have a low shoot/root ratio, which means that each unit of aerial transpiring surface is provided with water by many more roots than is the case for mesophytes, thereby increasing the potential for a positive water balance. Individual plants may show a remarkable ability to modulate leaf area, depending on environmental conditions. For example, the desert shrub *Lycium shawii* can produce broad thin leaves in wet conditions, or small leaves in progressively drier habitats, or even no leaves at all. Many desert plants avoid desiccation by shedding their leaves during the dry season, such as broom-like xerophytes. Under extreme conditions, leaf shedding may also be accompanied by branch shedding in some species. Other plants shed large winter leaves at the start of the dry season and form increasingly smaller leaves throughout the dry season, such as *Artemisia herba-alba*. *Zygophyllum dumosum* reduces its transpiring surface up to 96% by shedding its leaf blades to leave only the petioles. The ability of a plant to orientate its aerial parts to minimize the effect of sunlight on transpiration include epinastic or hyponastic growth responses, or nyctinasty, the endogenously-controlled circadian rhythm of leaf movement. Another mechanism to reduce water loss from exposed surfaces is that of leaf rolling, shown by many desert grasses, such as *Sporobolus arabicus*. This ensures that the adaxial side of the leaf, containing the stomata faces inwards and is protected from the direct impact of the climate and reduces transpiration loss. Although plants in arid environments have a high root/shoot ratio, it is hard to generalize about the nature of the root systems of plants adapted to drought. Root depth is often significantly increased in response to drought[3] and phraeatophytes have extremely deep tap root systems. However, some plants (e.g., cacti) have superficial root systems. It is at least accepted that the capacity of the root system to develop early and rapidly in the life cycle is an important factor in drought resistance.[4] Some xerophytes and geophytes produce ephemeral roots or fine rootlets in response to rain very rapidly, even within a few hours for some cacti,[5] just below the soil surface, which absorb dew as well as ground water.

Physiological Mechanisms

Xerophytes usually have higher osmotic pressures in their roots and shoots than mesophytes, which increases the efficiency of water absorption. Maintaining osmotic pressure in drought conditions may be achieved by adjusting the cytoplasmic content of either organic acids (malate), inorganic cations (K^+), carbohydrates (glucose, fructose, sugar alcohols) or amino acids (proline). This osmotic adjustment, together with cell wall elasticity, can maintain osmotic pressure and appropriate cell volume as cellular water is lost. The ability to osmoregulate not only serves to prevent further water loss in dry environments, but allows for the continued uptake of water against large negative water potentials.

C_4 and CAM pathways of photosynthesis are usually found in plants growing in environments where high temperatures predominate, and are both considered as physiological mechanisms to avoid water loss. This is a result for CAM plants of the bulk of carbon being fixed during the night, when leaf temperatures and water vapor-pressure differences are low, so that stomatal opening minimizes transpirational water loss and maintains a high water use efficiency. In C_4 species, the biochemical steps of CO_2 assimilation are spatially separated: CO_2 is first fixed into oxaloacetic acid in the mesophyll cells and is then transferred to the bundle sheath cells for entry into the Calvin cycle. The morphologically distinct bundle sheath and mesophyll cells represent a Krantz anatomy and C_4 photosynthesis is associated with a higher photosynthetic efficiency and a higher water use efficiency than for C_3 plants.

Growth Habits

Many angiosperms have evolved a drought-avoidance strategy by altering their life cycles to evade potential dry seasons. These winter annuals and ephemerals are therefore abundant in arid environments with seasonal droughts, since they have very short life cycles, as rapid as 2–3 weeks (e.g., *Linaria haelava*) and can successfully reproduce and die before the onset of drought and leave a reserve of viable dormant seeds in the soil. Perennials, as already mentioned, evade desiccation by partly or completely (as in geophytes having corms or bulbs) losing the vegetative structures at the onset of drought. Ephemerals and winter annuals have been shown to have much higher values of reproductive resource allocation than other plants,[6] since they need not retain reserves for perennation. In general, most plants avoid drought by accelerating the transition from vegetative to reproductive growth or at least reducing reproductive growth in general, so that resource allocation does not outstrip resource availability.

Many aspects of growth form contribute to the avoidance of desiccation; an increase in bushiness to minimize water loss and increase shading of leaves. The tree *Ocotea foetens*, which grows in areas of low rainfall, shows a spectacular adaptation to drought by forming a very dense canopy which aids the condensation of water from fog, which then runs to the tree base to irrigate itself and other species.[7] Otherwise, direct water absorption from the air is limited to lichen and algae, which can obtain water from air with a relative humidity of more than 70%.[8] Foliar uptake of precipitation, dew or water vapor by vascular plants is an extremely debatable phenomenon according to strict defining criteria. Many poikilohydric plants, including some ferns and ‘‘resurrection’’ plants[9] may equilibrate their water content with the relative humidity of the air during drought periods, and fully rehydrate in plentiful water supply.

FUTURE PERSPECTIVES

Further study of the molecular biology underlying many of the adaptation and avoidance responses will contribute to our understanding of the genetic bases of these processes. If traits contributing to drought tolerance are determined by a single gene, the possibility is raised that biotechnology and gene transfer techniques may be able to engineer plants better adjusted or better able to respond to water-deficit conditions. Some preliminary successes towards obtaining plants genetically enhanced for coping with drought stress are emerging. For example, manipulating the expression of the transcription factor cbf from *Arabidopsis* results in the alteration of a drought-stress pathway and results in *Arabidopsis* plants with an improved drought tolerance.[10] The identification of quantitative trait loci involved in heightened drought tolerance may also facilitate the introduction of loci from one species into another and improve more complex traits.

Drought: Management

Donald A. Wilhite
Michael J. Hayes
National Drought Mitigation Center, University of Nebraska, Lincoln, Nebraska, U.S.A.

INTRODUCTION

Some would argue that drought cannot be "managed." Yes, it is true droughts are a normal part of climate for virtually all areas of the world (e.g., Fig. 1), and that droughts affect more people worldwide than any other natural hazard.[1] It is also true that officials from both developing and developed nations struggle to deal with the wide range of economic, environmental, and social impacts related to droughts. However, these officials are not powerless to reduce the impacts of drought. Rather, there are important management actions that officials at local, regional, and national levels can take to reduce the impacts from droughts. The approach taken to address drought impacts and reduce their effects is called drought management, or perhaps more appropriately, drought risk management. The long-term goal is to reduce the impacts of drought through the adoption of drought preparedness plans.

SHIFTING THE EMPHASIS FROM CRISIS TO DROUGHT RISK MANAGEMENT

Traditionally, droughts have been viewed as unusual occurrences that creep up on officials who are typically unprepared to deal with the impacts droughts create. This is why drought has been called the "creeping phenomenon."[1] In reality, drought is a normal feature for virtually all climates. Officials often react to the occurrence of drought through "crisis management." After a drought is over, officials turn their attention to the next crisis, and any lessons learned about responding to the drought are most likely lost and forgotten. This crisis management approach is illustrated in the "Hydro-Illogical Cycle" (Fig. 2). Crisis management approaches to dealing with droughts are reactive, poorly coordinated and targeted, untimely, and generally too late. As a result, they are largely ineffective.

In order to break the Hydro-Illogical Cycle, officials around the world at local, regional, and national scales need to adopt a drought risk management approach. Drought risk management involves taking actions before droughts occur in order to reduce the drought impacts. It has three main components: 1) a comprehensive drought monitoring and early warning system; 2) planning and building the institutional capacity to respond to droughts; and 3) identification and implementation of mitigation actions and policies that can be taken before the next drought. These components will be discussed in greater detail.

A comprehensive drought monitoring and early warning system is a critical component of drought risk management because effective, timely decisions related to droughts can only be made if officials have an accurate assessment of the potential or developing drought event. This early warning system must incorporate all of the critical components of the hydrologic system (e.g., precipitation, streamflow, groundwater, snowpack, soil moisture, and reservoir and lake levels) because drought severity cannot be defined by precipitation deficiencies alone. A comprehensive system will assist officials by providing appropriate "triggers" for actions that the officials need to take, or by identifying when particular impacts are going to occur. An effective drought monitoring and early warning system requires synthesis and analysis of timely data and an efficient dissemination system to communicate this information (e.g., the media, extension services, or the World Wide Web).

Drought planning is a very important component of drought risk management because it establishes and preserves the institutional capacity with which officials can respond to droughts and reduce drought impacts. There are many benefits of a drought plan. A drought plan serves as the organizational framework for dealing with droughts and improving the coordination between and within levels of government. In addition, drought plans enable proactive mitigation and response to droughts; enhance early warning through integrated monitoring efforts; involve stakeholders, which are necessary for successful programs; identify areas, groups, and sectors particularly at risk; improve information dissemination by outlining the information delivery systems and strategies; and build public awareness of the need for improved drought and water management.

Several methodologies exist for assisting officials with the development of drought plans. One of these

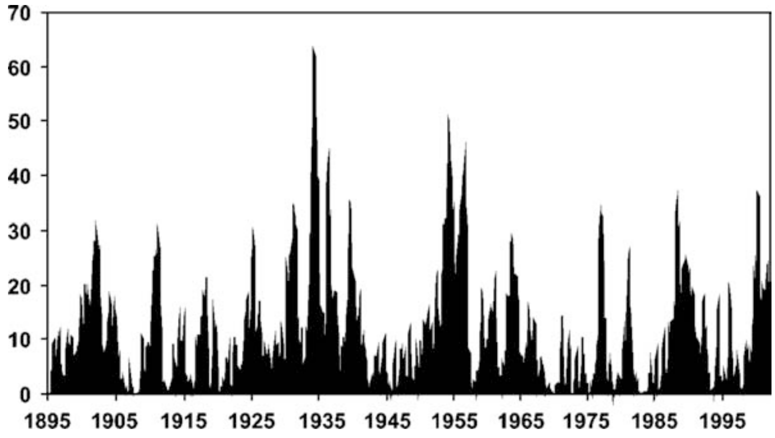

Fig. 1 The percent area of the United States in severe to extreme drought by month from 1895 through March 2002. Similar periodic patterns appear on graphs depicting regional hydrological basins in the United States, and would likely appear for most regions in the world. *Source*: From: National Climatic Data Center, Asheville, North Carolina, U.S.A.

methodologies, described by Wilhite et al.,[2] is a 10-step drought planning process that targets drought planners in the United States and elsewhere (http://drought.unl.edu/center/pdfpubs/10step.pdf) (accessed April 2002). The process was designed to be generic and adaptable because it is important for planners to develop a plan appropriate for their regional and governmental structures. These plans must be dynamic, reflecting changing government policies, technologies, personnel, and natural resources management practices.

The third important component of drought risk management is mitigation. Mitigation is defined as the policies and actions taken before a drought that will reduce drought impacts. Sometimes, if officials are alert enough and can see the development of drought in its early stages, mitigation can take place during the drought's early stages and may be very effective in reducing impacts as the drought becomes more severe. Otherwise, actions taken during a drought are generally responses directly related to the drought's severity and impacts. These responses are important, of course, and need to be well documented ahead of time within a drought plan. But it is important to keep in mind that mitigation is most effective if it takes place during times when drought is not occurring and officials are not responding to drought during a crisis. Mitigation actions should address vulnerabilities associated with drought with the goal of reducing impacts in future events.

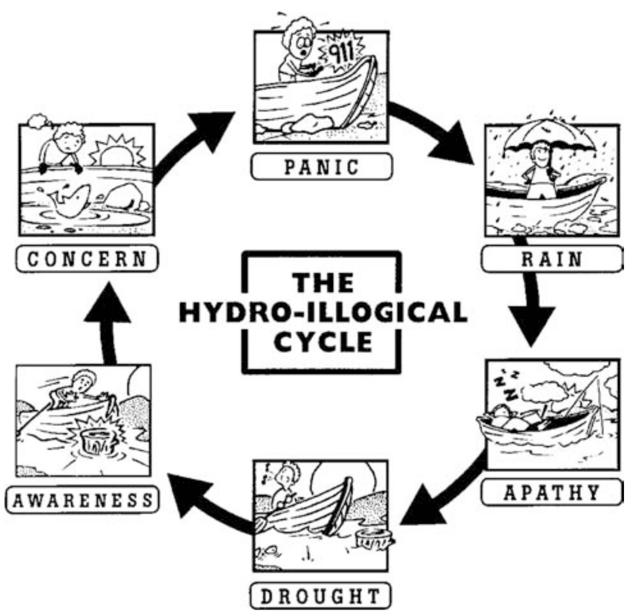

Fig. 2 The Hydro-Illogical Cycle. (Source and copyright: National Drought Mitigation Center, University of Nebraska, Lincoln, Nebraska, U.S.A.)

What are some examples of drought mitigation? Certainly the development of a comprehensive drought monitoring and early warning system and the development of a drought plan, as described above, are two examples of mitigation. Both of these actions should be taken before a region is experiencing drought. Other broad categories for potential drought mitigation actions include revising or developing legislation or public policies related to drought and water supplies; water supply augmentation and the development of new supplies; demand reduction and the development of water conservation programs; public education and awareness programs; specific priorities for water allocations; and water use conflict resolution.[3]

As with drought planning, there are several methodologies for identifying the appropriate mitigation actions to take in a region. In 1998, as part of the activities of the Western Drought Coordination Council (WDCC), a methodology was developed to look at drought risk. An important part of this methodology was the identification of mitigation actions and how these actions would be implemented.[4] The methodology also involves identifying and understanding the people and sectors that are vulnerable to droughts and why, allowing officials to target their mitigation efforts more effectively.

DROUGHT RISK CHALLENGES AND OPPORTUNITIES

Serious challenges still remain in drought risk management. One of these challenges is the acceptance of drought as a natural hazard, and a hazard that needs to be prepared for. Fragmented resource management and numerous federal programs present challenges, as do the declining financial and human resources. Confusion over the difference between mitigation and response is a challenge, and many times officials have a difficult time identifying innovative mitigation actions and implementing new policies and programs. Stakeholder involvement and acceptance still needs improvement. Perhaps one of the biggest challenges is to maintain the momentum for risk management in a changing political climate.

Some progress toward drought risk management is being made around the world. Australia and New Zealand, for example, have had national drought policies and strategies to reduce drought impacts.[5,6] Other nations are looking at establishing national drought policies. A global drought preparedness network is in the development stages; this network would assist nations by promoting drought risk management and sharing lessons learned about drought monitoring, planning, and mitigation. The network, based at the National Drought Mitigation Center/International Drought Information Center at the University of Nebraska, would be made up of regional networks coordinated by institutions around the world. Collectively this network of regional networks may enhance the drought management capability of many nations.

In the United States, three states had drought plans in 1982. As of 2002, 33 states have drought plans, and 6 of those states incorporate mitigation actions into their plans. In 1998, New Mexico became the first state to develop drought plan that emphasizes mitigation. Five states are currently in the process of developing drought plans, and it is hoped that mitigation will be a major component of each of these new plans. A number of Native American nations in the southwestern United States have developed drought mitigation plans recently as well. In addition, improved coordination has occurred within federal agencies and between federal and state governments.

New drought monitoring efforts and products have been developed in recent years. One of the best examples of progress in this area is the Drought Monitor product, developed to assess current drought conditions in the United States. The first Drought Monitor map was issued in August 1999, and a weekly update is posted every Thursday morning (http://drought.unl.edu/dm/) (accessed April 2002). The unique feature of this product is that four agencies rotate creating the map: the National Drought Mitigation Center, the United States Department of Agriculture, the Climate Prediction Center, and National Climatic Data Center of the National Oceanic and Atmospheric Administration. In addition, a feedback network of more than 160 local experts provides input about the map's portrayal of drought conditions before the map is released each week.

CONCLUSION

Clearly, there is reason for optimism about drought risk management and reducing drought impacts in the future. But it is also clear that officials around the world need to take proactive steps to develop comprehensive and integrated drought monitoring and early warning systems, determine who and what is at risk to droughts and why, and create drought mitigation plans with specific actions that address these risks with the goal of reducing the impacts of future drought events. There is a growing recognition that drought risk management is a critical ingredient of sustainable development planning and must be addressed systematically through risk-based policies and plans.

Drought: Resistance

M. B. Kirkham
Department of Agronomy, Kansas State University, Manhattan, Kansas, U.S.A.

INTRODUCTION

Agricultural drought is defined as "a climatic excursion involving a shortage of precipitation sufficient to adversely affect crop production or range productivity."[1,p.2] For centuries, plants have been classified based on their response to drought. Theophrastus, the Greek philosopher and botanist (371/370–288/287 B.C.), divided plants into groups according to their need for water. He said, "For there are some plants which cannot live except in wet; and again these are distinguished from one another by their fondness for different kinds of wetness . . . Others . . . seek out dry places."[2,p.31–33] In the early 1900s, researchers tried to define "drought resistance" exactly. Maximov[3] followed the definition of Kearney and Shantz[4] and Shantz,[5] and defined drought-resisting plants as those that "resist drought by storing up a supply of water in their fleshy bodies, to be used when none can be obtained from the soil . . . To this type belong succulents, such as cacti and *Agave*, and many epiphytes. Plants of a non-succulent type, but with large water reservoirs in their stems or in their underground organs, e.g., many trees of the African grasslands, which spring into bloom before the rains, are also included by Shantz in this group."[3,p.309] Levitt's[6] definition of drought-resisting plants is widely taught today. He divided them into two groups: drought-avoiding and drought-tolerating plants.[6,p.355] Drought avoidance can be achieved through restriction of water loss or by expansion of the root system to reach a greater supply of water.[7,p.3] Tolerance is the ability of an organism to perform well, or survive, despite the existence of a stressed condition within its tissues.[7,p.35] The distinction between drought-avoiding and drought-tolerant plants is not always clear, and Levitt, [6,p.418] added groups such as "tolerant avoiders" to cover "more complicated" situations.

NEED FOR QUANTITATIVE DEFINITION

These definitions are not quantitative. Since the work of Philip,[8] who pioneered the concept of the soil, plant, and atmosphere as a thermodynamic continuum for water transfer, we know that water moves in soil and plants along a potential energy gradient. The potential energy can be measured and compared between drought-resistant and drought-sensitive plants. Such measurements, because they are quantitative, can be replicated by others, negating the need for vague terminology.

DEFINITION OF WATER POTENTIAL AND ITS COMPONENTS

Under equilibrium conditions, the state of water at a particular point in a plant or in soil can be written in terms of the various components of the potential energy, as follows:[9]

$$\psi = \psi_s + \psi_p + \psi_m + \psi_g, \tag{1}$$

where ψ is the water potential, ψ_s the osmotic (solute)-potential component, ψ_p the pressure (turgor)-potential component, ψ_m the matric component due to capillary or adsorption forces such as those in the cell wall, and ψ_g is the component due to gravity. For plants, the matric potential and the gravitational potential usually are neglected, and Eq. (1) reduces to

$$\psi = \psi_s + \psi_p \tag{2}$$

We now have a relationship that can define the state of water at any point in a plant and that can be compared and provide a value that can be compared with values for other plants. Descriptive terminology, like drought tolerance and drought avoidance, is no longer necessary because we can quantify drought resistance by measuring water potential and its components.

MEASUREMENT OF WATER POTENTIAL AND ITS COMPONENTS

The most accurate way to measure water potential is by using thermocouple psychrometers, because they measure relative humidity in soil or plants, from which water potential energy can be related by using the Kelvin equation:[10]

$$\psi = (RT/V_w^o)\ln(e/e_o), \tag{3}$$

Contribution No. 01-235-B from the Kansas Agricultural Experiment Station

where ψ is water potential, R the ideal gas constant, T the absolute temperature, V_w^o the molar volume of pure water, e the partial pressure of water vapor in air, e_o the saturated vapor pressure, and e/e_o is the relative humidity. Thermocouple psychrometers were not used routinely to measure plant water potential until 1960s, because microvoltmeters were not on the market until then. They enabled measurement of the small voltages necessary in the technique. Osmotic pressure can be measured using thermocouple psychrometers after breaking cell membranes, for example, by freezing. Turgor potential is obtained by subtracting osmotic potential from water potential. However, pressure chambers are used more frequently to measure water potential, because they are easier to use and do not require careful temperature control. Boyer[11] showed that the amount of pressure necessary to force water out of the leaf cells into the xylem tissue is a function of the water potential of the leaf cells.

DROUGHT RESISTANCE OF C_3 AND C_4 PLANTS

Crops vary in drought resistance. In particular, plants with C_4 type of photosynthesis have a lower transpiration ratio (250–350 g H_2O/g dry weight) than those with C_3 type of photosynthesis (450–950 g H_2O/g dry weight).[12,p.165] That is, C_4 plants use less water to produce a certain amount of dry matter or grain than C_3 plants. The difference in water requirements of plants was noted almost 100 yr ago by Briggs and Shantz,[13] even though the photosynthetic pathways had not been discovered then.

In a study of six row crops grown in Kansas (corn, *Zea mays* L.; millet, *Pennisetum americanum* L.; sorghum, *Sorghum bicolor* (L.) Moench; pinto bean, *Phaseolus vulgaris* L.; soybean, *Glycine max* (L.) Merr.; and sunflower, *Helianthus annuus* L.), sunflower had the highest evapotranspiration, and sorghum generally had the lowest water use.[14] Despite sunflower's high use of water, it is considered a drought-resistant crop because it has a deep root system that can use water at depths that are unavailable to crops like sorghum.[15] However, in comparison to sorghum, sunflower has: 1) a higher transpiration rate; 2) a lower stomatal resistance; and 3) a lower hydraulic resistance, all of which are non-water-conserving characteristics.

Even though elevated levels of carbon dioxide close stomata (it is an excellent antitranspirant), studies show that high concentrations of carbon dioxide in the air, which occur now and are predicted to get even higher, do not save water used by plants. Leaves become larger with higher amounts of carbon dioxide (because of a higher rate of photosynthesis for growth), so they have a greater number of stomata through which water is lost. But water-use efficiency increases with elevated carbon dioxide.[16] That is, less water is needed to produce a certain amount of grain with elevated carbon dioxide than with an ambient level of carbon dioxide. For example, elevated carbon dioxide (about two times the ambient concentration) reduced the water requirement (reciprocal of water-use efficiency) of C_4 plants (big bluestem; *Andropogon gerardii* Vitman) by about 35%[17] and reduced the water requirement of C_3 plants (winter wheat; *Triticum aestivum* L.) by about 30%[16] under both well-watered and dry conditions. The increased water-use efficiency is of great importance in a semi-arid region. Research also has shown that augmented levels of carbon dioxide compensate for reductions in growth by drought both in a C_3 species (winter wheat)[16] and in a C_4 species (big bluestem).[17]

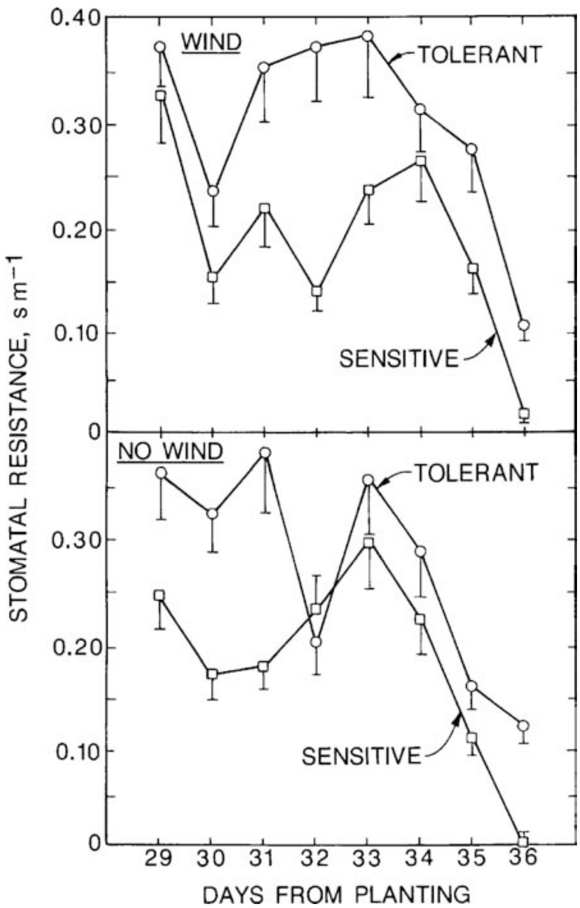

Fig. 1 Stomatal resistance of a drought-resistant (tolerant, 'KanKing') and drought-sensitive ('Ponca') cultivar of winter wheat grown in wind or still air. Vertical lines show standard deviations. Only half the bar has been shown to avoid cluttering the figure. *Source*: Adapted from Ref.[18], with permission.

DROUGHT RESISTANCE OF DIFFERENT CULTIVARS

Not only do different crops vary in drought resistance, but also cultivars (cultivated varieties) of the same crop vary. Intensive work comparing two cultivars of winter wheat—one known to be drought resistant (‘KanKing’) and the other known to be drought sensitive (‘Ponca’)—has shown that the drought-resistant cultivar has a higher stomatal resistance (Fig. 1),[18] usually has a lower water potential and turgor potential (Fig. 2),[18] is more efficient in utilization of mineral elements in the soil, more salt tolerant, has a different hormonal regulation (e.g., is insensitive to abscisic acid), has a higher hydraulic resistance, and is better able to extract water from drying soil than the drought-sensitive cultivar. Studies with drought-resistant cultivars of corn and sorghum have substantiated those results with winter wheat. A drought-resistant genotype of sorghum (‘IA 28’) produced more ethylene, a gaseous hormone, than a drought-sensitive genotype (‘Redlan’) (Fig. 3).[19]

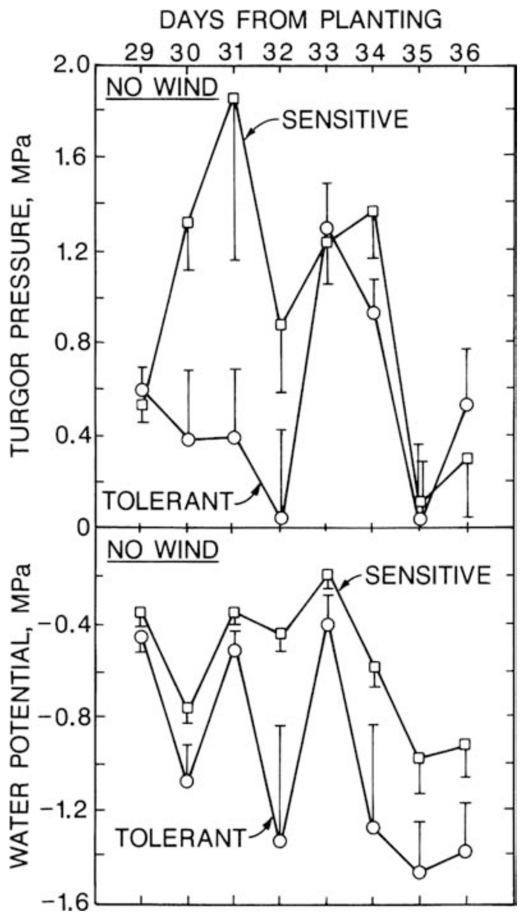

Fig. 2 Water potential and turgor potential (pressure) of a drought-resistant (tolerant, ‘KanKing’) and drought-sensitive (‘Ponca’) cultivar of winter wheat grown in still air. For vertical lines, see legend to Fig. 1. *Source*: Adapted from Ref.[18], with permission.

GROWTH OF DROUGHT-RESISTANT PLANTS

Drought-resistant varieties usually do not grow as well and yield as much as drought-sensitive varieties under well-watered conditions (Fig. 4), because the stomata of the drought-resistant varieties are more closed (Fig. 1). If less carbon dioxide is taken up, then growth is reduced. Stomatal conductance is related directly to growth.[20] To achieve a high yield under optimal conditions, a variety with a high stomatal conductance (a drought-sensitive cultivar) should be planted.

Planting a drought-resistant and a drought-sensitive variety of a crop together might be advantageous in a sustainable farming system to assure some yield under drought. In dry years, the drought-resistant variety should survive and produce some grain. In wet years, the drought-sensitive variety should yield well. However, when a drought-sensitive (Ponca) and a drought-resistant (KanKing) cultivar of winter wheat were

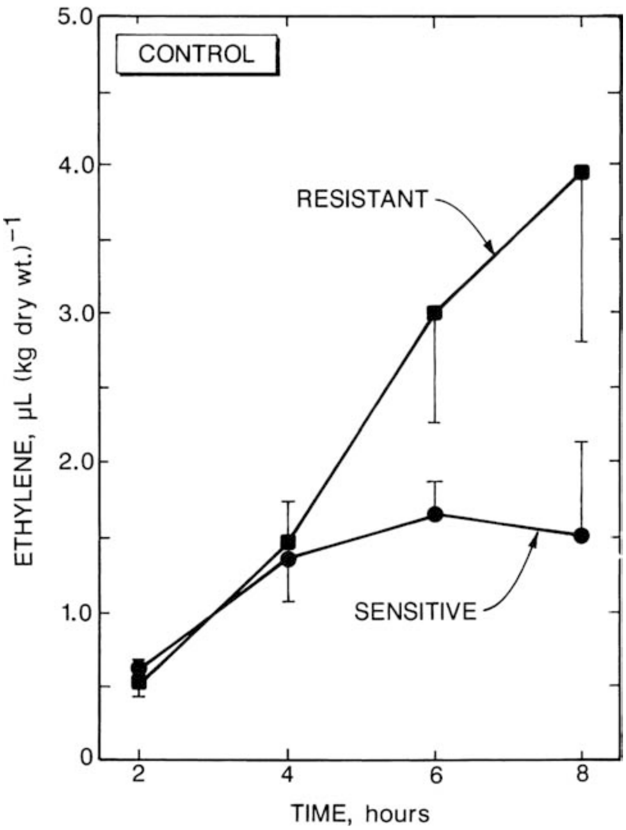

Fig. 3 Ethylene production by drought-resistant (‘IA 28’) and drought-sensitive (‘Redlan’) genotypes of sorghum. Plants were grown in sand culture and watered with nutrient solution. For vertical lines, see legend of Fig. 1. *Source*: Adapted from Ref.[19], with permission.

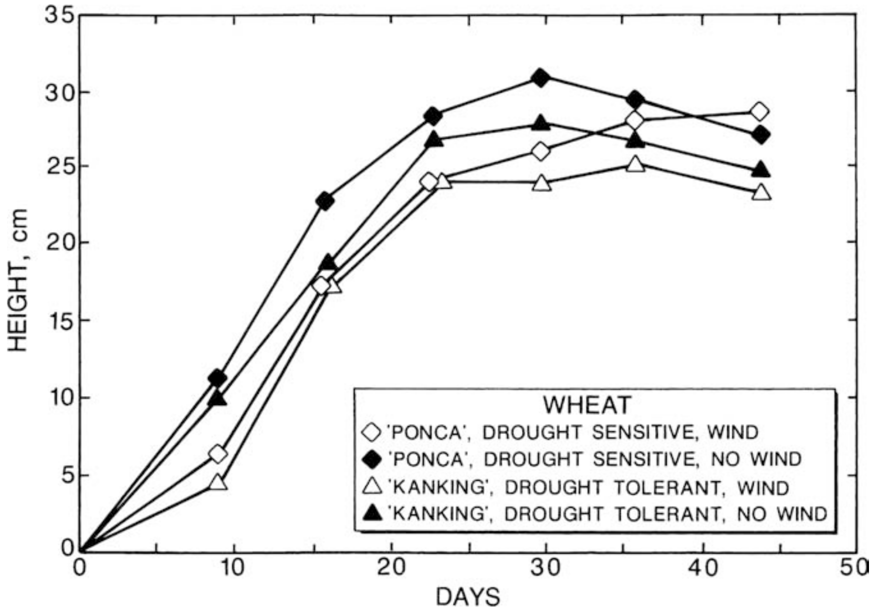

Fig. 4 Height of a drought-resistant ('KanKing') and a drought-sensitive ('Ponca') cultivar of winter wheat grown in wind or still air. Same study as shown in Figs. 1 and 2. *Source*: From author's files; never published.

grown together, the drought-sensitive cultivar used up water, causing the drought-resistant cultivar to die. When the drought-resistant cultivar was grown alone, it was able to survive drought.[21]

Dryland and Semiarid Regions: Research Centers

John Ryan
Natural Resource Management Program, International Center for Agricultural Research in the Dry Areas (ICARDA), Aleppo, Syria

INTRODUCTION

The history of civilization, and its evolution, has been inextricably linked to agriculture. Where the natural resources—land and water—were abundant and climatic conditions favorable, societies flourished, often leading to great empires. With colonization of new lands, the well-watered fertile areas were first to come under man's sway. Not surprisingly, many of today's strong world economies, mainly in temperate regions, have a strong agricultural base. However, dry areas of the world, where rainfall is low and erratic and drought is an invariable constraint to agriculture, have always languished. Only where irrigation water was available, whether from rivers or groundwater, has it been possible for such areas to advance. While much research has been focused on development of agriculture in favorable areas—and with astounding success—drier regions were the "poor relation" in terms of research investment. Following a description of the essential features and the intractable nature of dryland farming, a brief overview is presented on the types of research institutes worldwide that service dryland or rainfed agriculture.

ARID AND SEMIARID REGIONS

Any definition of arid or semiarid hinges around the soil water balance; such regions are those where potential evapotranspiration exceeds precipitation. Semiarid zones are those where precipitation is insufficient or erratic so that soil moisture is the principal limitation for crop production.[1] Arid regions are too dry for normal crop production, which is only possible with irrigation. The FAO classification is based on length of the growing season, semiarid being 75–119 day and arid being 1–74 day.[2] Arid environments only permit sparse growth of drought-tolerant shrubs and range grasses and forage species. However, there can be exceptions to these generalities; in humid and subhumid climates, drought that limits crop production can also occur periodically. Conversely, arid and semiarid regions may experience unusually high seasonal rainfall; depending on topography, arid regions may have microenvironments where reasonable cropping can occur in normally dry years.

As temperature controls evapotranspiration, the distinction between arid and semiarid can vary depending on the region and the environment. For instance, in Mediterranean-type climates, rainfall in semiarid zones ranges from 200–600 mm/yr; above that range is subhumid and below that is arid.[3] Rainfall in such a climatic region is seasonal, usually in cooler winter/spring months when evapotranspiration is relatively low and rainfall is erratically distributed in time and space; variability increases as precipitation decreases.

DRYLAND AGRICULTURE

Crop production practiced under the limited rainfall conditions of semiarid climates is termed dryland or rainfed cropping, and is dependent on the capture and efficient use of limited rainfall, and thus dependent on the vagaries of the weather.[4] Such conditions exist in about 40% of the world's land surface, most of which is in the lesser-developed world. The drylands of Africa, the Middle East, Latin America, and South Asia are inhabited by about a billion people—most of whom are poor and eke out an existence in resource-poor environments. Population growth and increased food demand are the driving force behind land-use intensity in the world's drylands.

In comparison with humid regions or where irrigated agriculture is practiced, research into dryland farming systems has been modest. Stimulated by the "Dust Bowl" era in the United States—the result of land mismanagement—dryland research gathered momentum and was again brought to the public consciousness with land-degradation-induced famine in Africa in the latter part of the 20th century. While the early successes of irrigated agriculture initially detracted from dryland farming research, factors such as disenchantment with the "downside" of irrigation schemes—the exorbitant costs involved, the negative impact on the environment, and declining water supplies—served to provide a renewed focus on drylands, in particular the sustainable use of such fragile resources. Though potential crop yields from dryland agriculture are lower than irrigated agriculture, the relatively modest yield increases per hectare can translate into a substantial impact on national food production in view of the large areas associated with drylands.

DRYLAND RESEARCH AGENDA

Today, dryland research has an identity of its own, with common research themes that vary depending on the biophysical and socioeconomic conditions of the target eco-region: local conditions, institutional factors, and community involvement. An understanding of the development constraints in such circumstances is fundamental for designing appropriate research strategies and implementing solutions. Notwithstanding the achievements made in dryland research in the past century and the basic principles elucidated,[5,6] research activities in most institutions center around water conservation and use efficiency, combating soil erosion by wind and water, and devising management strategies, including tillage and fertilization, to implement these objectives. A major component is adaptation of the principles of crop physiology and breeding crop varieties to accommodate moisture-stressed environments. Given the complex nature of dryland farming, a multi-disciplinary approach is vital for success. The socio-economic context is of greater relevance for traditional societies in developing countries.

ARID LAND RESEARCH INSTITUTIONS

The list of research institutions that deal with semiarid and arid agriculture is extensive,[7] ranging from pioneering centers in the heart of the U.S. dryland region to an international network of research centers around the world. What follows is a sampling of such centers and their areas of concern—a complete listing is beyond the scope of this article.

Conservation and Production Research Laboratory, Bushland, Texas, U.S.A.

While the U.S.A. is home to several USDA-ARS dryland research stations of world renown, e.g., Akron, Colorado; Mandan, North Dakota; Pullman, Washington; and Pendleton, Oregon, it is fitting that of all the dryland research centers the Bushland station should be singled out for special mention. Created in the late 1930s to combat wind erosion that had devastated the drylands of Oklahoma and Texas, it was a cooperative effort between the United States Department of Agriculture (Agricultural Research Service) and the Texas Agricultural Experiment Station. The scientific achievements of Bushland are legion; to it can be attributed the large-scale reversal of land degradation in the United States and the establishment of sound management practices. It was appropriate that the 50th anniversary of this center was marked by a world conference that highlighted progress in soil and water conservation and the challenges that lay ahead for U.S. and international agriculture.

Much of what we know today can be linked to research at Bushland; the mechanics of wind erosion, and tillage systems to conserve moisture, and thus mitigate the effects of drought, are some of the many examples. The proceedings of this milestone meeting in the history of dryland agriculture[8] established research themes for the future. Recognizing the increasing role of dryland farming in world food production, there is need for continued international dialogue of establishing networks among institutions for coordinating research and technology transfer. The resource base must be protected by sustainable soil and cropping systems. Greater attention will need to be given to the socio-economic dimension and for policies that reduce human and animal pressure on the fragile resource base.

Other North American Semiarid and Arid Institutions

The Office of Arid Lands of the University of Arizona focuses on academic research and serves as a clearing house of published works related to arid regions—social, cultural, ethnographic, economic, flora and fauna. Its world directory of "Arid Lands Research Institutions"[7] provides basic information on institutions in most countries of the world that deal with arid and semiarid areas, in addition to United Nations and other international programs. Other Arizona institutions related to arid land research include: 1) the University of Arizona's various departments in the College of Agriculture; 2) Environmental Research Laboratory focusing on protected cropping in arid environments; 3) Arid Lands Watershed Management Research Center; 4) Desert Laboratory; 5) Desert Botanical Garden; 6) Boyce Thompson Southwestern Arboretum; 7) Water Resources Research Center; and 8) USDA Agriculture Water Conservation Laboratory.

In addition to most Land Grant Colleges of Agriculture in the West and Mid West, a major listing includes: Desert Research Institute (Nevada); East–West Environment and Policy Institute (Hawaii); Plant Genetic Engineering Laboratory for Desert Adaptation (New Mexico); Dry Lands Research Institute and the U.S. Salinity Laboratory (California); and

International Center for Arid and Semi-Arid Land Studies, Chihuahan Desert Research Institute, and Drylands Agriculture Institute (Texas).

While Canada is not perceived as a dry country, there are regions of dryland agriculture, e.g., southern Alberta and Saskatchewan with Agriculture Canada dryland research institutes at Lethbridge and Swift Current. In addition, Canada's International Development Research Center (IDRC) supports a wide range of programs overseas, including arid land-related concerns.

U.S. Overseas Development

At the global level, the United States Agency for International Development (USAID) had promoted extensive programs in the areas of health and population, agriculture, and environment. Dryland agriculture was not neglected. One major example of such an effort was the Dryland Agriculture Project in Morocco (1979–1994) in collaboration with the National Institute of Agronomy (INA) and executed by the Mid-America International Agricultural Consortium (MIAC), spearheaded by the University of Nebraska. During the lifetime of the project, the main station in Settat was developed, along with substations, staffs were trained at Ph.D., M.S., and technical level in U.S. universities, and research and technology programs were developed. Among the many achievements of the project were the development of Hessian fly-resistant cereals, fertilizer application criteria, and conservation tillage. Today, the Center is the lead institution in dryland agriculture in North Africa. Another Moroccan institution, the Institut Agronomic et Veterinaire Hassan II, a university which is involved in teaching and research in arid agriculture, was similarly established and funded through a USAID collaborative program with the University of Minnesota.

Throughout its history, USAID has been actively involved with many other development efforts in arid areas of the world, providing US-based technical expertise and training national scientists, e.g., Northeastern Brazil (University of Arizona), Ethiopia (Oklahoma State University), Pakistan (Colorado State University)—the list is a long one. Other international research/development agencies that deal with dryland areas of the world include Windrock International Institute for Agricultural Development, and the Washington-based World Resources Institute.

Australia

A major part of this great landmass is arid desert, merging into semiarid conditions where rainfed agriculture is possible; a significant part has a Mediterranean climate. As in the United States, research in such environments is well developed. The major organizations involved are: Commonwealth Scientific and Industrial Research Organizations (CSIRO): Division of Soils, Center for Irrigation and Freshwater Research, and Division of Wildlife and Rangelands Research; various State Government Organizations, e.g., Department of Primary Industries (Queensland); Fowlers Gap Arid Zone Research Station, Soil Conservation Service, Water Resources Division (New South Wales); Arid Zone Research Institute, and Water Resources Division (Northern Territory); and the Victorian Department of Natural Resources and Environment Stations-Rutherglen Research Institute and the Victorian Institute of Dryland Agriculture at Horsham. Much of the expertise and technology related to dryland farming has been exported to other regions of the world through government development programs.

Africa

Nowhere in the world is the need for research in dry regions more needed than in Africa; however, there, institutional strength varies from country to country. The strongest institutes are in Southern Africa, in particular South Africa, mostly in universities and government departments. In other parts of Africa, war and economic stagnation have taken their toll on previously active research institutes, e.g., Agricultural Research Corporation, and Soil Conservation, Land Use and Water Administration in Sudan. Most countries of North Africa have national institutions dealing with arid lands, e.g., Institut des Regions Arides and Institut National de la Recherches Agronomique de Tunisie (INRA). Dryland and arid region research organizations are poorly developed in West Africa, a region plagued by drought. Examples include Institut National de la Recherches Agronomique du Niger (INRAN), Institute for Agricultural Research, and Almadu Bello University (Nigeria), and Comite Permanent Interetats de Lutte Contre la Secheresse dans le Sahel (Burkina Faso).

Middle East and Asia

As a region with a high proportion of extremely arid land, especially in Arabian Gulf, and also large areas of semiarid rainfed land, the Middle East–West Asia area is relatively well endowed with research support of arid and dryland research centers, e.g., Bio-Saline Center (Abu Dhabi); Desert Research Center, North Khorosan Dryland Research Center, Dryland Research Center, Maragheh (Iran); Desert Research Institute, Desert Development Center (Egypt); Applied Agricultural Research Center (Iraq); Field Crops

Department, and Soil and Fertilizer Institute (Turkey); Center for Desert Studies, Water Studies Center (Saudi Arabia); and National Center for Agricultural Research and Technology Transfer (Jordan). Arid land research centers in Israel includes The Jacob Blaustein Institute for Desert Research and the Center for Agricultural Research in Arid and Semi-Arid Lands. Regional conferences[9] have highlighted the unique concerns regarding Mediterranean drylands.

The Indian sub-continent has many dryland and arid research institutes. In Pakistan, these include: Cholistan Institute of Desert Studies, Arid Zone Research Institute (AZRI), Semi Arid Zone Development Authority, Tarnab Agricultural Station and Atomic Energy Agency in Peshawar, and the University of Agriculture in Faisalabad; India hosts many such institutions: Central Arid Zone Research Institutes and Desert Studies in Rajasthan.

In the former Soviet Union, many arid and semiarid land research institutes existed such as Desert Institute (Turkmenistan) and the Dochuchaev Soil Institute in Moscow. With the collapse of the USSR and the emergence of separate Central Asian republics, most institutes are poorly funded and staffed. Considerable efforts and funding are needed to address the widespread soil degradation and land mismanagement that is occurring. However, China with its huge area of arid and semiarid land has many well-known research institutes such as Institute of Desert Research, Lanzhou and the Research Center for Arid and Semi-Arid Areas, Shaanxi.

International Agricultural Research Centers

The Worldwide network of 16 research centers of the Consultative Group on International Agricultural Research (CGIAR) address agricultural production, poverty and malnutrition, capacity building and environment in resource-poor, food-deficit countries through research and technology transfer. Chief among dryland centers is the International Center for Agricultural Research in the Dry Areas (ICARDA) whose mandate covers North Africa and West Asia and Central Asia—a vast area dominated by deserts, range and scrubland, and semiarid rainfed agriculture. The center focuses on erosion control and land management to enhance water-use efficiency and on drought mitigation through breeding programs, including molecular markers and other biotechnological approaches.

Another major arid to semiarid institution is the International Center for Research in the semiarid Tropics (ICRISAT). Headquartered in India, it addresses all aspects of cropping systems in the subcontinent and in countries of the region. Its major substation is in Niamey in Niger, West Africa, a harsh zone of arid–semiarid cropping, pastoral systems, with acid sandy soils. A second substation is in Southern Africa in Bulawayo, Zimbabwe.

Other centers that deal with dry areas are: 1) the International Center for Research in Forestry (ICRAF) in Nairobi, which focuses on forest trees and shrubs in association with cropping systems in Africa; 2) The International Institute for Tropical Agriculture (IITA) in Nigeria; and 3) Centre Internacional de Agricultura Tropical (CIAT) which deals with some dryland areas in Latin America, in addition to humid areas. While the centers mentioned above have an active research agenda in dryland agriculture, they work in collaboration with the national research systems in their mandate regions.

Other non-CGIAR regional and international centers are active in arid land research. An example is the Syrian-based Arab Center for Studies in Agricultural Development (ACSAD), which focuses on the Arab region. Other international agencies that sponsor research related to dry areas include the Food and Agricultural Organization (FAO) of the United Nations, and the International Atomic Energy Agency (IAEA), Vienna.

Though not characterized by an arid climate, some countries such as the United Kingdom have international institutions that deal with research in dry regions, e.g., Center for Overseas Research and Development and the Center for Arid Zone Studies at the University of North Wales, while Germany's University of Stuttgart has a "Working Group on Desert Research."

CONCLUSION

While much is known about the biophysical processes and constraints related to arid and semiarid research, the major bottleneck is implementation at the user's level. That calls for a greater understanding of the social and cultural factors associated with dry areas. Major conferences on semiarid dryland farming[8] and on desert development in Lubbock (1996) and Cairo (1999) indicate that research momentum is gathering. Knowledge gained has to be translated into public practices that promote community action. Despite the large number and diversity of arid/semiarid research institutions worldwide, there is need for networks among institutions for information sharing. The problems of dry regions will not disappear, but, given the scenario of exacerbated drought in many parts of the world due to global warning, will be more urgent than ever. As vast areas of arid regions are categorized as rangelands, concerted international efforts are needed to tackle problems in such fragile areas.[2]

The United Nations Convention to Combat Desertification and other coordinated international efforts in support of arid and semiarid lands are a major step in that direction. Success in these endeavors is dependent on the global awareness of political leaders and the consequent creation of enabling environments for policy implementation.

Dryland Cropping Systems

William A. Payne
Crop Stress Physiology, Texas A&M System Agriculture Research and Extension Center, Amarillo, Texas, U.S.A.

INTRODUCTION

Agriculture involves the management of land, water, energy, labor, and other resources by humans for the purpose of producing food and fiber. An *agricultural system* refers to the regional classification of a particular type of *farming system*, which is a combination of crops, animals, and management practices. The fundamental social, ecological, and economic unit of a farming system is the *farm*, which is of course managed by farmers.

Farmers manage their pastures and fields according to a *cropping system*, which is characterized by specific management practices, e.g., for soil tillage, rotation of field crops within a field from one season to the next, or maintenance of soil fertility. In developed countries, farmers tend to manage cropping systems with a view towards generating profit and, to a certain extent, maintaining a lifestyle. In developing countries, the majority of farmers tend to be small landholders who manage cropping systems more to avoid risk of crop failure and hunger. There are of course exceptions to these general tendencies. Relationships among agricultural systems, farming systems, cropping systems, and farms are explored in greater detail by Loomis and Connor.[1]

In *dryland cropping systems*, crops depend upon rainfall for water supply rather than upon irrigation. Dryland cropping systems may therefore be viewed as a subset of rainfed systems. They are commonly found in semi-arid environments, where precipitation tends to be low and erratic, and other environmental stresses, such as high temperature, are common. In dryland cropping systems, water supply is usually the factor that limits crop production most. For this reason, whether for profit or subsistence, farmers must use water supply efficiently for crop production. Some illustrative dryland cropping systems of the world are summarized in Tables 1–3. Pearson et al.[2] give a more detailed discussion of dryland cropping systems of the world.

FUTURE PERSPECTIVE

In the coming decades, dryland cropping systems will play an increasingly important role in maintaining global food security, because of dwindling land and especially water resources.[3] It follows that the challenge of meeting growing food demand, while protecting environmentally sensitive lands from agricultural expansion, will fall increasingly upon dryland cropping systems. Efficient water use in dryland cropping systems should therefore be of interest to society as a whole, and not merely to the farmer.

EFFICIENT WATER USE AND CROP PRODUCTION

The amount of water required to produce a crop has always interested farmers, and has occupied scientists for much of the last century. However, as Tanner and Sinclair[4] pointed out, the description of this relationship with such terms as "efficient water use" and "water-use efficiency," (WUE) can be ambiguous. There exist different perspectives on what constitutes yield (e.g., marketable yield, total biomass, aboveground biomass, or photosynthate) and "used" water. Because of these different perspectives, there are different definitions of efficiency. Indeed, it has been held that, strictly speaking, the ratio of growth to water use is not an efficiency at all, since it lacks a theoretical maximum value.

To the farmer managing an irrigated cropping system, any measure that reduces the amount of water for which he has to pay has achieved increased WUE. However, an irrigation engineer might define WUE as the ratio of yield increase from irrigation to the amount of water applied. An agronomist might define it as the ratio of crop yield to the sum of water transpired by the plant plus that which evaporates from the soil surface (termed "evapotranspiration" or "total evaporation"). To a plant scientist, it may refer to the ratio of yield to plant transpiration over part or all of the growth cycle, whereas a more basic physiologist might define it in terms of diffusion of CO_2 and H_2O molecules during a period of a few seconds.

Here, we adopt the convention used by Tanner and Sinclair.[4] Any management practice that conserves soil water to increase crop production, such as runoff capture or storage of rainfall for eventual crop use, constitutes an *efficient use of water*. On the other

Table 1 Major crop components of dryland cropping systems of Africa, Southern Asia and Australia, and eastern Oregon and Washington (U.S.)

Location	Crops
West Africa	Millet/sorghum, maize, groundnuts, cowpea, sesame, cassava, yams, and tree legumes
East Africa	Maize/barley, sorghum, millet, and teff (Ethiopia)
Southern Asia	Sorghum/millet (India), maize/rice (other); cassava; kenaf, wheat, groundnut, soybean, and chickpea
S. Australia, East WA, and OR (U.S.)	Wheat/barley; lupins, peas, mustard, and improved pastures

Source: Adapted from Ref.[2].

Table 2 Distribution of major dryland cropping systems in Mediterranean countries

Country	Main crop rotations
Italy	Cereal–hay crops–cereal Fallow–cereal–cereal–fallow (has grazing value) Cereal–tobacco, sugar beet, grain legumes
Greece	70% cereal–cereal 10% cereal–hay crops 2% cereal–grain legumes 18% with other alternatives (cotton, sugar beet, tobacco)
Algeria	80% fallow–cereal (fallow has grazing value) 15% cereal–hay crops 5% cereal–grain legumes
Morocco:	
Low rainfall zones	25% fallow (has grazing value) 75% continuous cereal
High rainfall zones	15% continuous cereal 70% grain legumes 15% fallow (grazed)
Lebanon	Little remaining fallow. Where it exists it has grazing value except in low rainfall zone Rotations are wheat–barley–wheat–alfalfa and wheat–lentils

Source: Adapted from Ref.[2].

hand, WUE is an index of crop or individual plant performance. The ratio of yield (Y) or biomass (DM) production to evapotranspiration (ET), or WUE_{ET}, may be viewed as an index of field performance of the crop with regard to water use, whereas the ratio of Y or DM to transpiration (T), or WUE_T, can be viewed as an index of plant performance. However, this is a simplified discussion. Readers are referred to Tanner and Sinclair[4] or a recent group of papers edited by Payne[5] for a more advanced presentation.

It is important to keep in mind that efficient water use and WUE are concepts mostly used by scientists. Most farmers have more practical goals, such as yield stability and sustainability, because these facilitate economic planning. However, there are many perspectives on what constitutes stability and sustainability.[6]

WATER USE AND CROP YIELD

Plants grow by using solar energy intercepted by leaves to fix atmospheric CO_2 as part of the process of photosynthesis. When CO_2 diffuses into the leaf through open stomata to be fixed by specialized enzymes, there is a simultaneous export of water vapor (transpiration) in response to a concentration gradient of H_2O, caused by high humidity within the leaf and lower humidity in the atmosphere. Because of this simultaneous import of CO_2 and export of H_2O, crop growth, biomass production, and yield are roughly proportional to transpiration.

A plant's environment affects WUE_T for a number of reasons. Atmospheric humidity, e.g., determines the size of the concentration gradient that drives H_2O export from the leaf. If atmospheric humidity decreases, then the gradient increases, causing the plant to expend more water to fix the same amount of carbon. It thereby also affects the ratio between biomass production and transpiration. Other environmental factors, such as nutrient and water availability, can also affect WUE_T.

Importantly, WUE_T is also under genetic influence. To a large extent, this is governed by the photosynthetic pathway of the particular crop species; "C_3" species (e.g., wheat, beans, or rice) generally have lower WUE_T than "C_4" species (e.g., maize or sorghum), particularly in warm climates. However, within species, there is also considerable genetic variability for WUE_T.[7] There is, therefore, scope for modest increases in WUE_T through modern plant breeding methods.

Because of the same proportionality between biomass accumulation, or growth, and T, farmers and agriculturalists increase yield by increasing T. Under irrigated conditions, T is increased because of greater total amount of water available to the cropping system, which translates into greater yield. Under dryland conditions, however, the total amount of water available to the cropping system is limited by precipitation. Increasing T, therefore, requires that as much precipitation as possible becomes available for use by the crop. An understanding of how this is done requires a basic understanding of the soil water balance.

Table 3 Change of dryland cropping systems with rainfall amount, growing season length, soil type, and local preferences in India

Environment	Intercrop system	Sequential system
Jodhpur 380 mm rainfall, 11 week growing season, Cambisol soil	Green gram or cluster bean grown with pearl millet	Pearl millet followed by fallow
Hisar 400 mm rainfall, 13 week growing season, and Cambisol soil	Pearl millet/mung bean or Pearl millet/cowpea (for animal fodder)	Pearl millet followed by chickpea or Mung bean followed by mustard
Hyderabad 770 mm rainfall, 25 week growing season, and deep vertisol soil	Sorghum/pigeonpea	Sorghum followed by safflower, sorghum followed by chickpea, or maize followed by chickpea
Bangalore 890 mm rainfall, 32 weeks growing season, and deep luvisol soil	Finger millet/soybean, groundnut/pigeonpea, or finger millet/maize	Cowpea followed by finger millet

THE SOIL WATER BALANCE

When precipitation falls upon the soil surface, it remains there ponded, evaporates, runs off, or infiltrates into the soil. Because soils are porous, water can be stored and transmitted within a given volume of soil, much as it can within a sponge. Water is extracted from soil pores by plant roots, and then conducted through the stems to leaves through specialized conducting tissue. As described in the previous section, water is then transmitted via transpiration into the atmosphere through leaf stomata. Water moves through the soil, plant, and atmosphere continuum in response to energy gradients, much as it runs down hill in response to potential energy gradients imposed by gravity. This thermodynamic process is described in more detail by Nobel.[8]

To understand how precipitation can be managed such that transpiration is maximal, we use the soil water balance, which is a restatement of the fundamental principle of conservation of mass. Any change in the amount of water stored within a specified soil volume (usually the crop root zone) must be equal to the difference between any inputs and outputs. That is,

$$\Delta S = \text{Inputs} - \text{Outputs}, \tag{1}$$

where ΔS represents the change in the amount of water storage (S) in the root zone of the plant. Hillel[9] gives a much more thorough description of the soil water balance and related subjects.

Water inputs and outputs of a dryland agricultural field are generally restricted to precipitation (P) and run-on (R_{on}), while outputs include drainage from the root zone (D), evaporation from the soil surface (E), run-off (R_{off}) and plant transpiration (T). We can substitute these into Eq. (1) to get

$$\Delta S = (P + R_{on}) - (E + T + D + R_{off}) \tag{2}$$

Recalling that yield is proportional to T, we rearrange Eq. (2) to view the variables representing processes that determine T, and therefore yield:

$$T = (P + R_{on}) - \Delta S - (E + D + R_{off}) \tag{3}$$

The degree to which the terms on the right side of Eq. (3) can be managed varies with cropping system features, and depends upon such factors as soil physical and chemical properties, slope, weather patterns, water table depth, landscape position, crops grown, and availability of machinery and other inputs.

Four common means of managing the soil water balance terms to maximize T include 1) use of appropriate crops and crop sequence; 2) addition of soil amendments or other inputs; 3) soil surface management; and 4) water harvesting. Volumes have been written on each of these four subjects. A general review of the third topic can be found in Chan's review article, and of the fourth topic in the chapter by Frasier and Tanaka in this encyclopaedia. Here, therefore, an overview of the first two is given. More detailed discussions of all four topics are available from Hillel,[9] Unger and Stewart,[10] and Loomis and Connor.[1]

APPROPRIATE CROP AND CROP SEQUENCE

The daily water demand of a crop varies with its size and growth stage. As plants grow, so do the size and number of their leaves, which constitute assimilatory (for CO_2) and evaporative (for H_2O) surfaces. Generally speaking, the larger the total leaf area of a crop, the greater its water demand, until an approximately constant ratio of leaf area to water use (T or ET) is reached. For many crops, this constant ratio is reached at leaf area indices (LAI, i.e., leaf area divided by land area) greater than 3, but this is crop- and site-specific. Many dryland crops never reach an LAI value of 3, particularly where soil nutrient status is poor. For most agricultural plants, the largest LAI occurs near flowering which, for most crops, is also the growth stage during which yield is most sensitive to drought or high temperature.

Crop daily water demand also depends on the evaporative demand of the atmosphere, which is determined by temperature, humidity, windspeed, and solar radiation. The magnitude and annual patterns of evaporative demand change from region to region. Furthermore, the evaporative demand to which the crop canopy is subjected can be modified by canopy and soil properties, because these affect how radiation is intercepted and windspeed momentum is transferred, which in turn affect temperature and humidity profiles.

A fundamental strategy of efficient water use in dryland cropping systems is to match the pattern of crop water demand to that of soil water storage, or S of Eq. (1). In many environments, this simply means that plant growth and water demand should approximately match rainfall patterns. Short-duration crops, e.g., should be grown where rainy seasons are short, medium-duration crops should be grown where rainy seasons are of medium length, and so on. This principle is illustrated for the various cropping systems of India in Table 3. The use of crops with growth cycles that are too long in relation to rainfall patterns or seasonal patterns of S usually results in yield loss because of the onset of drought and unmet water demands of the crop toward the end of the growth cycle. On the other hand, the use of crops with growth cycles that are too short usually results in reduced yield loss because T is less than it potentially could be.

Unfortunately, in many semi-arid regions, rainfall is erratic as well as low. Indeed, rainfall variability often limits yield more than amount per se. Farmers use a number of strategies suited to their particular setting to cope with rainfall variability. In general, under variable rainfall environments, drought should be the least probable when crop demand and vulnerability are greatest.

In many tropical countries, multicropping systems, in which two or more crops with different flowering and maturity dates are grown together in the same season, are used as a method of reducing risk of total crop failure. Multicropping systems include "intercropping" systems, in which rows of one crop are alternated with those of another, "relay cropping" systems, in which an early-seeded crop is later inter-sown with a second, later-maturing crop, and "alley-cropping" or "agroforestry" systems, in which crop species are grown between woody or tree species. In addition to reducing risk, these cropping systems also improve use of sunlight, water, nutrients, and labor in low-input farming systems. Examples of risk averse, multicropping systems are given in Tables 1–3. Francis[11] explores multicropping more thoroughly.

Adjusting plant population, or spacing between plants, is another strategy by which farmers maximize crop T and, thereby, yield. By increasing plant population, E is reduced because more sunlight is intercepted by leaves rather than by the soil surface. Crops that have the ability to tiller profusely, such as wheat, tend to attain the same leaf area and yield over a range of plant population. Crops that do not tiller tend to have much lower plasticity, and therefore yield and WUE_{ET} are much more sensitive to plant population. In semi-arid environments in which the probability of rainfall is very low during the growing season, risk-averse farmers decrease plant population to reduce LAI, and therefore the rate of decrease in S. Optimal plant spacing therefore varies from region to region due to weather pattern, soil type, and farmers' perception of and tolerance to risk.

ADDITION OF SOIL AMENDMENTS AND OTHER INPUTS

Farmers apply a number of amendments to their fields in order to affect chemical, biotic, or physical soil properties, which in turn affect crop growth. Perhaps, the most important soil amendment is organic and mineral fertilizer, which is added to increase or maintain soil fertility. Fertilizer is added in many different ways, ranging from manure deposition by grazing animals, to rotation with leguminous crops that fix atmospheric nitrogen, to sophisticated precision mineral fertilizer applicators.

The importance of proper soil fertility to efficient water use, WUE_{ET} and, in some cases, WUE_T cannot be overemphasized. Among other things, it increases rooting depth and density, and the soil volume to which roots have access. Maintenance of soil fertility therefore can increase the amount of water to which plants have access (S), and decrease losses of water to drainage from the roots zone (D). Additionally, it increases WUE_{ET} by increasing plant growth and in particular crop leaf area, which shades the soil surface and thereby decreases E. Under highly infertile soil conditions, such as those found in many parts of Africa, addition of relatively small amounts of fertilizer can increase WUE_T as well.

Inputs other than fertilizer include insecticides, fungicides, and herbicides. Insects and disease must be controlled to efficiently use water in dryland cropping systems because they directly attack grain or reproductive organs of the plant, which obviously reduces yield, and therefore WUE_{ET}. Weeds compete for the same resources that crops use, including water, sunlight, and nutrients. Disease, insects, and some parasitic plants may also affect efficient use of water by damaging conductive tissue of the roots, stems, and leaves, thereby decreasing T and growth.

CONCLUSION

Farmers manage their fields and pastures according to a particular cropping system, which contributes to an overall farming and agricultural system. Dryland cropping systems tend to predominate in semi-arid systems with undependable rainfall. The sustained trends of continued global population growth, diminished land availability, and growing competition for fresh water will increasingly place the challenge of meeting food demands and protecting environmentally sensitive land upon dryland cropping systems. Since crop yield is proportional to T, this requires managing the soil water balance such that as much precipitation as possible is ultimately used as transpiration. Four basic methods of achieving this are the use of appropriate crops and crop sequence, soil surface management, addition of soil amendments, and water harvesting. The best method will depend upon specific characteristics of the particular cropping system. Finally, there is some potential for genetically increasing WUE_T.

Dryland Farming

Clay A. Robinson
Division of Agriculture, West Texas A&M University, Canyon, Texas, U.S.A.

INTRODUCTION

Dryland farming is the use of land for crop production in regions where growing season precipitation alone is usually inadequate to produce a summer grain crop. Droughts of varying intensity and duration are common in these regions. Dryland farming systems are dependent on natural precipitation, so the primary management concern in dryland farming systems is the capture and efficient use of water.[1]

Sometimes the term, dryland, is used in humid regions to mean "not irrigated." *Rainfed farming* or agriculture is the preferred term in regions where growing season precipitation alone is usually adequate to produce annual summer crops, and other management issues (fertility, pests, etc.) are more important than water conservation.

DRYLAND FARMING CHARACTERISTICS

Irrigation is practiced in many dryland regions when surface or groundwater is available to provide water for growing crops. Supplemental irrigation is also practiced in some humid regions to enhance production and limit losses due to drought. Irrigated land area will continue to decrease due to declining water levels, water quality and salinity problems, rising energy prices, and increased water demand for industrial, municipal, development, and other uses. As irrigated land area decreases, principles of dryland farming become more important.

Dryland farming is practiced worldwide with a diversity of mechanization and specific technologies. All dryland farming systems utilize some common principles:

- Using fallow (allowing land to lie idle during a growing season), tillage systems, residues, mulch, and/or structures to increase soil-water storage.
- Using tillage systems and mulch to limit evaporative water loss.
- Selecting shorter season, drought-resistant, and/or drought-tolerant crop genotypes.
- Selecting crops and rotations based on precipitation patterns and growing seasons.
- Manipulating plant density and geometry to optimize the evaporation (water lost from soil) to transpiration (water used by crops) ratio.
- Water harvesting.

Every dryland farming system does not incorporate all these principles, but all dryland farming systems use some combination of these principles. In addition to conserving water, many of these principles limit erosion by wind and water, and some enhance soil organic matter levels. These benefits are important since most dryland farming regions exist in fragile ecosystems. Long-term productivity in dryland regions depends on maintaining or enhancing the soil resource. Any management system that does not control erosion and limit soil degradation is not sustainable.

Every major continent has regions suitable for dryland crop production. Most dryland crop production occurs in areas classified as arid, semiarid, and subhumid. Though dryland cropping systems are diverse, they share one characteristic: Evapotranspiration (ET, combined water loss from crops and soil) exceeds precipitation during the growing season. In much of the North American Great Plains, monthly precipitation never exceeds one-half the ET.[2] Other dryland regions have some period during the year when soil-water storage is possible because monthly precipitation exceeds monthly ET.[2]

Fallow is used to store water from precipitation in the soil. Even in the Great Plains where monthly ET exceeds monthly precipitation, there are several days each year when precipitation exceeds ET and water can be stored in the soil. The efficiency of water storage during fallow depends on tillage choices and climate (Table 1). Tillage choices determine the intensity and depth of soil disturbance, and the quantity of residue remaining on the surface. Greater tillage intensity or tillage depth increases soil drying and decreases soil-water storage efficiency. Soil-water storage is directly related to residue quantities remaining on the surface.[3] Regional climate determines atmospheric demand for water and thus PET. In the central Great Plains, seasonal ET decreases with increasing latitude.

Using fallow to increase stored soil water decreases cropping intensity (number of crops per year). Increased soil-water storage has no economic benefit

Table 1 Tillage and water storage efficiency during fallow at Akron, Colorado and Bushland, Texas

unless that water can be used to produce a crop. Table 2 identifies some of the common cropping systems in the Great Plains. Research in the central Great Plains shows that less intensive tillage systems store more soil water and allow cropping intensity to increase. In the southern Great Plains, adoption of less intensive tillage systems has not altered cropping intensity, but yields have increased and crop failures due to drought are less common.

Many developing countries practice dryland cropping without large equipment. The principles of water conservation still work: disturb less soil (limit tillage), expose less soil surface (use mulch), and catch more water. Fig. 1 shows blade (sweep) plows used in the United States (Fig. 1A) and China (Fig. 1B). The same principle is at work, both limit soil disturbance and leave residues on the surface. Figure 2 shows wheat residue as a mulch in Texas (Fig. 2A) and a stone mulch in Gansu, China (Fig. 2B). Both mulches decrease evaporation, slow water movement across the surface, increase infiltration, and protect the soil from erosion. Fig. 3 shows the impact of furrow dykes (also called tied ridges) on precipitation capture and storage. The soil probe in Fig. 3A was inserted 30 cm into a furrow without dykes, but in the adjacent row with dykes (Fig. 3B), the soil probe was inserted to

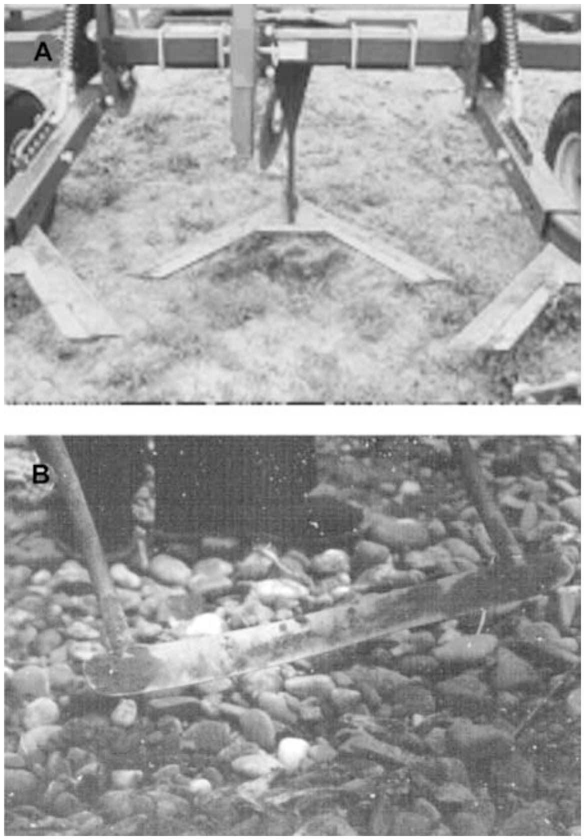

Fig. 1 Blade (sweep) plows used in the United States (A) and China (B).

120 cm, indicating an increase in plant-available water of about 12 cm. Furrow dykes capture precipitation, limit runoff, and increase infiltration into the soil.

A dust mulch may limit evaporation under certain conditions. Shallow tillage is practiced immediately following a rain, leaving the surface loose and unconsolidated. The loose soil limits upward capillary movement of water as the soil surface dries, thus limiting evaporation. Dust mulching probably works in developing countries where farmers use light equipment and draft animals, and tillage begins as soon as the rain stops. In mechanized systems, the field must be dry enough to support a tractor. Shallow tillage in these fields probably increases water loss because the evaporation that dust mulch can prevent has already occurred, and subsequent tillage further dries the soil.

Crop calendars are another important dryland-management tool. Winter wheat is common in the central and northern Great Plains, giving way to spring wheat in the Prairie Provinces of Canada. The winter wheat-growing season matches the precipitation and evaporative demand of the climate. There is usually fall precipitation to establish the crop. Wheat is dormant much of the winter, allowing some water storage from snow and precipitation events. Precipitation increases

Drainage–Dust

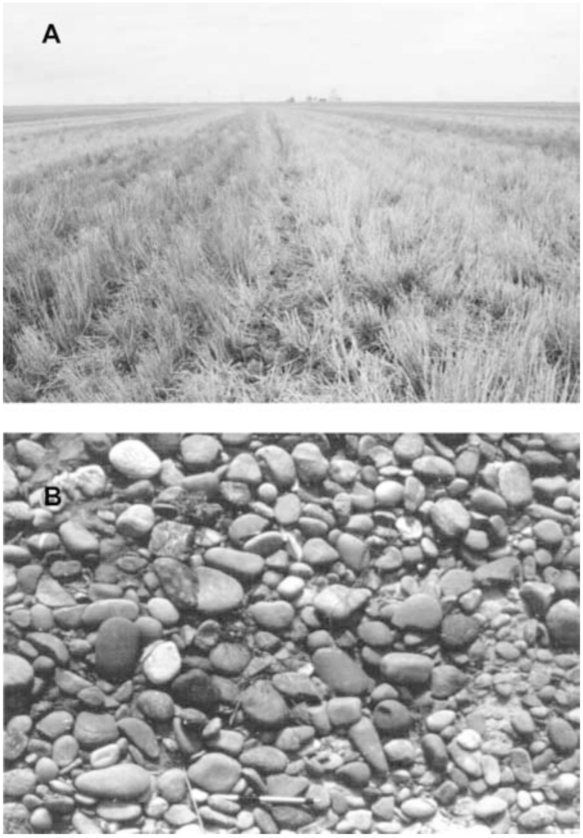

Fig. 2 Wheat residue mulch in Bushland, Texas (A) and stone mulch in Gansu, China (B).

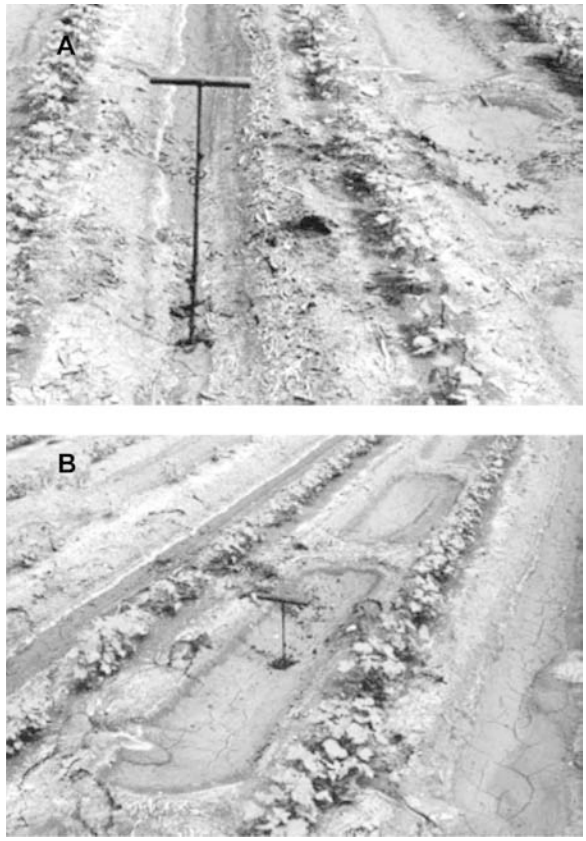

Fig. 3 Soil probe in furrows without (A) and with (B) furrow dykes.

in the spring as wheat breaks dormancy. In the central Great Plains, wheat is harvested before the highest summer temperatures. Dryland corn is becoming more common in the central Great Plains as reduced tillage practices increase the soil-water stored. The single precipitation peak matches the corn-growing season. Dryland corn in the southern Great Plains is not a viable option because the precipitation distribution is bimodal, and the valley occurs when corn reaches pollination and grain fill. Cotton has been historically limited to the southern Great Plains because the growing season is too short further north although shorter season varieties are being developed.

Another method to limit evaporation from soil is to achieve a closed plant canopy sooner. Recent research into planting geometries recommends using narrower row spacings, higher plant populations, and shorter season hybrids. This combination allows a more rapid canopy development, which decreases weed competition and evaporation. The result is that more water can be used by the plants, producing greater yields.[4] The higher plant populations induce more rapid development and maturity. Short-season hybrids are used so the crop does not deplete the soil water during vegetative growth.

Most crop varieties used in dryland production have a drought tolerance mechanism, enabling them to endure short droughts. Some crops slow metabolic activity and essentially go dormant to avoid the drought. Other crops reduce metabolic activity and water use during the drought. Both mechanisms allow the crop to resume normal growth when the water stress is alleviated.

The benefits of water harvesting are easily seen beside every road. The plants in the ditch are greener, taller, and lusher than those in nearby pastures. Many cultures have long used water-harvesting techniques to

Fig. 4 Water harvesting project in Gansu, China.

improve crop yields. Fig. 4 shows a water-harvesting system in Gansu, China, in which one-sixth of the land is covered with plastic and used as a watershed. The water collected from the plastic-covered watershed is stored in cisterns and used to irrigate the cropland on the remaining five-sixths of the land. Conservation bench terraces use a 2 or 3 to 1 watershed to bench ratio. This supplies enough water to the bench area to allow annual cropping. A wheat–sorghum-fallow system is used on the watershed, increasing the cropping intensity from 0.67 to 0.78.

CONCLUSION

Dryland farming systems are diverse, but all emphasize the capture and efficient use of precipitation through fallow, tillage, and residue management systems, crop selection, row spacing, plant populations, and/or water harvesting. Specific farming technologies are not universally applicable, but the basic principles of water conservation can be applied across all levels of technology.

Dust Bowl Era

R. Louis Baumhardt
U.S. Department of Agriculture (USDA), Bushland, Texas, U.S.A.

INTRODUCTION

The Dust Bowl era was the period of drought from 1931 to 1939 that was coupled with severe wind-driven soil erosion of overgrazed rangeland and soil exposed by the use of farming practices not adapted to the semiarid U.S. Great Plains. The eroding soil from once productive range and crop lands filled the air with billowing clouds of dust that subsequently buried farm equipment, buildings, and even barbed-wire fences (Fig. 1); thus, making the living conditions of many Great Plains inhabitants unbearable. On the Great Plains wind is common and drought recurrent; therefore, farm implements and management methods were developed for producing crops under these conditions. Likewise, farmers have evolved into innovative practitioners of soil and water conservation techniques that rely on residue management practices and crop rotations with fallow periods to store precipitation in the soil for later crop use.

HISTORY

During a sustained drought beginning in 1931 and continuing until 1939, wind erosion of range and farmlands filled the air with clouds of dust for days at a time. The Dust Bowl shifted annually over the Great Plains to affect different areas and grew with the expanding drought to damage an annual peak of about 20 million hectares.[1] However, the overall affected area (Fig. 2) encompassed almost 40 million hectares that extended from south of Lubbock, Texas (33° 34′ N, 101° 52′ W) to north of Colby, Kansas (39° 23′ N, 101° 3′ W) into Nebraska and from Great Bend, Kansas (38° 22′ N, 98° 50′ W) west to near Pueblo, Colorado (38° 16′ N, 104° 37′ W). The most severely affected farmland was located within a 160-km radius of Liberal, Kansas (37° 2′ N, 100° 55′ W), the center of the Dust Bowl.

The Dust Bowl land was native range for the North American bison and home to Native Americans prior to Euro-American settlement. It had been labeled the "Great American Desert" by explorer Stephen Long following his expedition to the area about 1820.[2] The challenges of this region, whether invoked by the perceptions of "Desert"-life or by Native Americans protecting their homes and hunting interests, limited cultivation. For example, in 1879 or about five years after the Red River Indian wars, only 264 ha were cultivated in all of the 26 counties that make up the Texas Panhandle,[2] but cultivation expanded with favorable rains during 1882–1887 and 1895–1906.[3] Native rangeland was typically cultivated by tillage methods adapted from the more humid U.S. regions, which buried most of the plant residues, e.g., a Lacrosse disc breaking plow that relied on as many as 12 horses and mules.[4] Draft animal requirements for forage crops and native range limited some soil disturbance and provided, incidental, residues that protected the land. These farming practices that indirectly conserved soil were replaced by agricultural mechanization, which expanded tillage and allowed a single farmer to manage increasingly more land.

Agricultural mechanization and increased demand for wheat by Europe during World War I nearly doubled the amount of land cultivated from 1910 to 1920.[1] However, mean annual rain during the period 1918–1929 averaged about 100 mm above the 515 mm norm[3] and promoted continued farm expansion to about 16 million hectares that were largely placed into a wheat monoculture. The booming wheat market, beneficial rains, and increasing agricultural mechanization placed in motion rapidly expanding cultivation that exposed millions of hectares of land with potentially erodible soil. It was the climatic conditions of drought from 1930 to 1940 (Fig. 3) that ultimately triggered wind erosion of excessively tilled land and the Dust Bowl.[3]

DUST BOWL LESSONS

In a 1936 report to President Roosevelt from the drought area committee, Morris Cooke and others outlined the nature, causes, and recommended lines of action to ameliorate factors resulting in the Dust Bowl.[5] They noted that Great Plains agriculture had developed a dependency on over grazing and excessive plowing, which exposed loose soil to the wind. These farming practices did not conform to natural conditions of the Great Plains and resulted in an unstable agriculture and unsafe economy. The basic problem causing the Dust Bowl was identified as the attempt

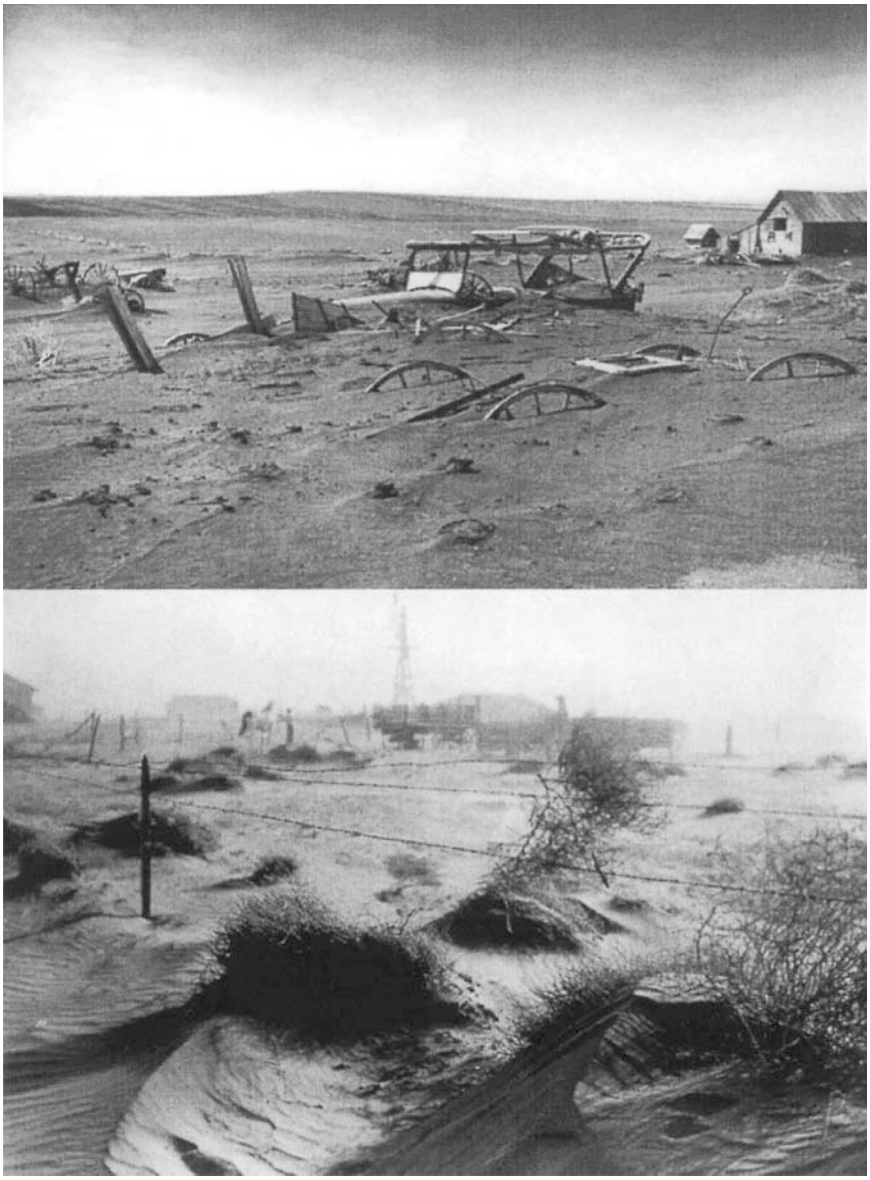

Fig. 1 The devastation imparted by dust storms to Great Plains farmsteads from Texas shown at the bottom (1938 USDA Photo by: B. C. McLean, Image # 01D11486) north to South Dakota (1936 USDA Photo by: Sloan, Image # 00D10971).

to impose farming practices suitable for humid regions on the semiarid Great Plains. The committee further recognized, as unrealistic, the expectations of climate changes toward improved temperature, precipitation, and wind conditions. Therefore, in a region of limited annual precipitation, farming practices to reduce run-off and increase water storage in the soil were critical to agricultural success.

The drought area committee further stated that the 1862 federal homesteading policy exacerbated land degradation by offering unrealistically small farm allotments for the semiarid Great Plains west of the 100th meridian.[5] That is, the government policy actually encouraged over utilization of pasture and cultivated land. Subsequent efforts to correct the homesteading policy by increasing land allotments as late as 1916[6] were heralded by the often-cited 1909 Bureau of Soils Bulletin 55 claim of an "indestructible and immutable soil resource."[7] The hazard of over cultivation and grazing was the exposure of loose soil to wind and erosion. This damage was aggravated further by volatile wheat markets that encouraged speculative production by absentee landowners relying on tenant farmers. In some cases, the tenants were transient farmers that only custom planted and harvested crops without remaining on the land. The proportion of land farmed by tenants increased from about 16% in 1880 to over 40% in 1935,[5] but the transient tenant farmers abandoned the land when commodity markets collapsed.

Agriculture capable of withstanding recurrent drought periods replaced the excessive tillage practices that incorporated crop residues and degraded the structure or natural cohesiveness of soil. Alternative

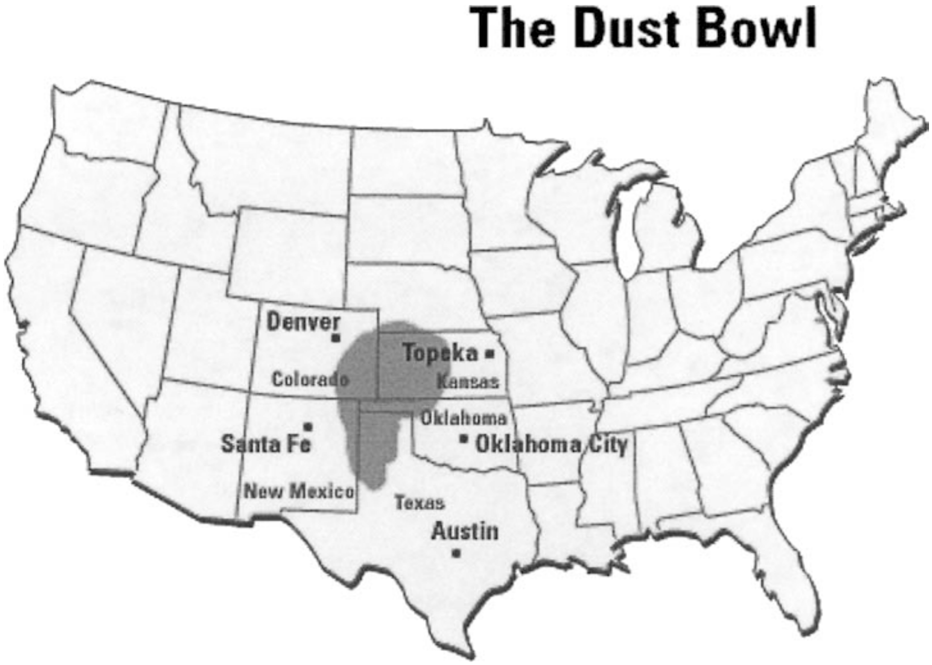

Fig. 2 The United States and the overall affected ''Dust Bowl'' area, from the ''American Experience.'' *Source*: From Ref.[13].

tillage practices were developed to control weeds and the use of precipitation stored as soil water. These tillage practices also undercut rather than inverted the soil, thus reducing soil disturbance and increasing crop residues retained at the surface to conserve soil and water.[8] Revised land policies promoted conservation practices by rewarding farmers for using contour plowing, listing, and strip cropping methods.[9] The Dust Bowl wheat monoculture required timely fall and winter precipitation for crop establishment and growth; however, in much of the southern Great Plains mean monthly precipitation is limited during this critical period (see example for Amarillo area, Fig. 4). In lieu of wheat monocultures, practical wheat and summer crop rotations with an intervening fallow (i.e., two crops in three years) were developed to take advantage of summer rain (Fig. 4) and to provide sufficient opportunity for storing precipitation as soil water during fallow and improve crop establishment.

The damaging effect of excessive tillage contributed significantly to soil erosion throughout the Dust Bowl, but it may have been overstated as in Rexford Tugwell's film *The Plow that Broke the Plains.*[1] Soil erosion was also triggered by overgrazing and drought conditions, which were reduced through improved cattle management and the use of irrigation. Depressed commodity prices, however, virtually eliminated irrigation of crops, e.g., the Texas Panhandle had some

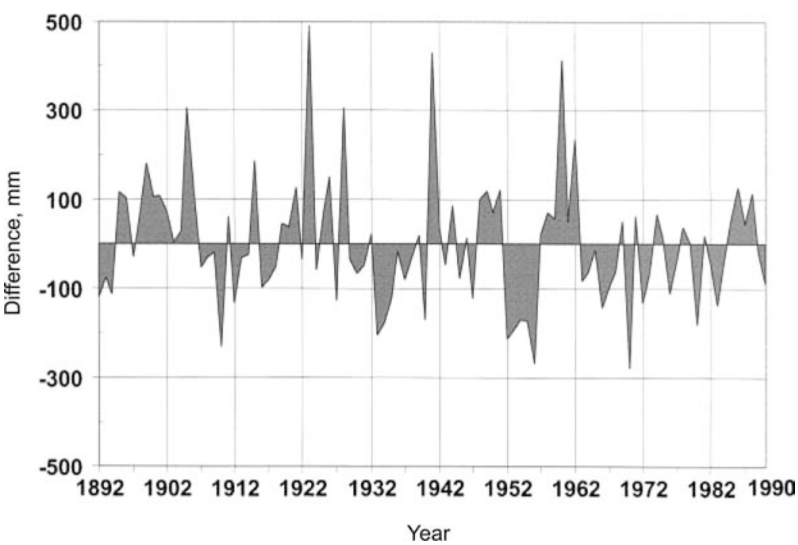

Fig. 3 Deviation from the mean annual precipitation (515 mm) at Amarillo plotted for the period 1892–1990.

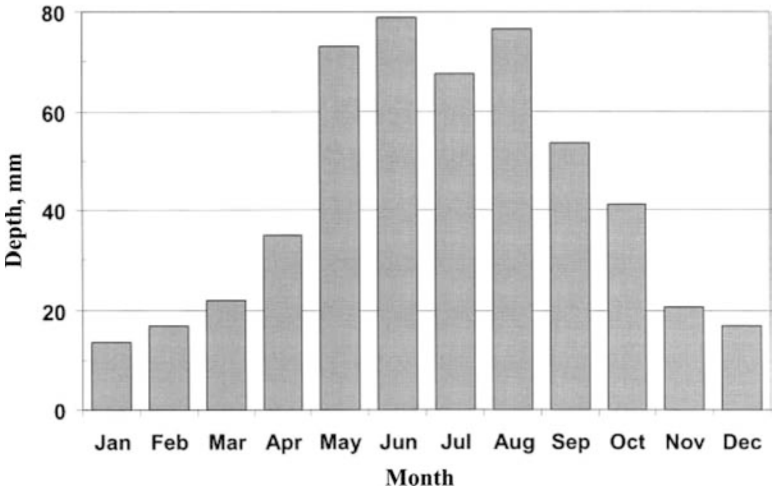

Fig. 4 Mean, 1892–1990, monthly precipitation at Amarillo.

170 irrigation wells in 1930 or 60 to 80 fewer wells than a decade earlier in 1920.[10] Irrigation expanded slowly until drought conditions of the 1950s promoted rapid growth from Texas to Kansas.[11,12] Irrigation as a solution to drought in the Dust Bowl region almost exclusively depends on the Ogallala aquifer,[12,7] which has now dramatically declined. If irrigation was the dominant factor preventing soil erosion during the 1950s by offsetting drought conditions, it would follow that the Dust Bowl miseries may eventually return when irrigation from the southern Ogallala becomes impractical.[7]

AGRICULTURE—DUST BOWL VICTIM OR VILLAIN

In 1933, the director of new Soil Erosion Service, Hugh H. Bennett, indicted Americans as great destroyers of land as substantiated by the Dust Bowl conditions and called for awakening to improved farming practices.[13] Farmers and their children likewise recognized the fragility of the land and the inappropriate nature of their farming practices in laments that ‘‘All the good soil will blow off this land if these sand storms continue’’[14] and ‘‘It would be better if the sod had never been broke . . . ’’[15] Many farmers expanded production to offset lower prices and passively relied on luck to ‘‘hit big’’ with a crop that would change their fortune even as the commodity market collapsed in the 1920s.[12] The resulting economy was unstable and led to a general depopulation trend and agricultural collapse that was squarely in line with the creation of a ‘‘Buffalo Commons’’[16] whereupon the government would step in to buy abandoned Great Plains farmland and restore it to an undisturbed range condition.

In response to the disastrous effects of the Dust Bowl, government programs were redesigned to encourage diversified agricultural crop production using tested practices and improved tools. That is, agriculture was empowered with new non-inverting tillage implements capable of penetrating the hard dry soils like the Graham-Hoeme plow for controlling weeds while retaining crop residue at the soil surface.[8] Innovative wheat-sorghum cropping sequences optimized soil water storage opportunities and increased the probability of capturing rain for crop use. A growing number of managers now farming the Great Plains minimize soil disturbance and protect their crop residues as vital resources to optimize the storage of precipitation as soil water.[17] The efficiency of precipitation storage in the soil has improved from about 20% during the Dust Bowl to more than 40% by using innovative crop sequences with fallow periods and no or reduced tillage.[18] Farmers now utilize preplanned alternative rotation sequences to optimize crop water use during periods of beneficial rain and include other production inputs like fertilizers in response to specific needs.[17] These innovations, in contrast to Dust Bowl soil management using inversion tillage and wheat monocultures, have resulted in substantially more stable economies and slowed the depopulation trend.

In contrast to the farmers of the Dust Bowl hoping to ‘‘hit-big’’ on a crop, many of today’s Great Plains farmers are more proactive managers that respond to adverse growing conditions with alternative technology.[12] For example, when drought conditions reappeared during the early 1950s, Kansas farmers widely adopted irrigation to stabilize production. Since that time fluctuating irrigation costs and the competition for and depletion of water resources have driven innovation in irrigation. These innovations include irrigation scheduling methods to meet plant demand and improved application technologies such as low-pressure center pivot systems. While these innovations will prolong the use of irrigation to offset recurrent drought conditions, the finite nature of Ogallala water supply[7,10–12] focuses concern on the potential of a recurrent Dust Bowl. The development and application of new soil and crop management practices not available during the 1930s will determine if the Dust Bowl is as recurrent as drought.

El Niño

David E. Stooksbury
Biological and Agricultural Engineering Department, University of Georgia, Athens, Georgia, U.S.A.

INTRODUCTION

The term El Niño refers to a number of related oceanic and atmospheric phenomena. A general definition of El Niño is a change in weather patterns associated with warmer than normal sea surface water temperatures in the central and eastern equatorial Pacific Ocean (see Fig. 1). El Niño is the best known example of inter-annual variation in the earth's weather and climate patterns.

Originally, El Niño referred to warmer than normal surface water temperatures off the coast of Peru. The name El Niño comes from the appearance of warm surface water temperatures around Christmas. This relationship between surface water warming and Christmas led the locals to call the phenomena El Niño, Spanish for boy, the Christ child. The appearance of an El Niño event inhibits the upwelling of cold and nutrient-rich water along the Ecuadorian and Peruvian coasts. Without the upwelling of cold, nutrient-rich waters, the fish migrate to more favorable locations and thus there are few fish for local communities.

El Niño changes the position of the subtropical jet stream, the steering current for weather systems. Changes in the subtropical jet stream cause changes in weather patterns. These weather pattern changes cause some regions of the earth to experience above-normal rainfall while other areas experience below-normal rainfall. El Niño weather patterns also cause some regions of the earth to be warmer than normal while other regions are cooler than normal. While the change in weather patterns associated with El Niño can be dramatic, most regions of the earth experience minimal to no direct impact from El Niño. El Niño events occur every three to seven years lasting from a few months to a year or more.

IMPACTS

In the United States, El Niño weather patterns usually mean a warm and wet fall in the central and northern plains while the Pacific Northwest and Middle Atlantic states experience drier than normal conditions. During winter, much-above normal rainfall usually occurs from southern California to the Gulf of Mexico and South Atlantic states. Across the northern two-thirds of the lower 48 states, El Niño winters are usually much warmer than normal. Across the Pacific Northwest states, winter precipitation is much below normal during El Niño winters making the region vulnerable to droughts. During an El Niño spring, the region east of the Mississippi River usually experiences below normal to much-below normal rainfall. The Pacific Northwest remains dry during the spring. Springtime temperatures are usually below to much below normal across the south while above normal to much-above normal temperatures are expected in the Pacific Northwest, the northern Rockies, and the northern plains making these regions vulnerable to drought. The southwestern United States usually experiences above-normal precipitation in an El Niño spring.

The impacts of El Niño weather patterns vary from one event to another. The impacts depend on the warmth of the surface water, the exact location of the warm surface water, the areal extent of the warm surface water, and other regional and global weather patterns. An ocean–atmosphere linkage that mitigates the impacts of El Niño is the Pacific Decadal Oscillation (PDO). The PDO has similar impacts as El Niño and can increase or decrease the impacts of El Niño. Unlike El Niño, the PDO cycle is decades long and not a few years.

During the summer monsoon season (late summer into early fall), the intermountain region of the western United States normally has above-normal rainfall during an El Niño weather pattern. The region has an increased probability of experiencing flash floods. The impacts of El Niño on the summer monsoon can be mitigated by the PDO.

From southern Mexico to northern South America, El Niño weather patterns normally increase rainfall and can lead to major flooding, especially in mountainous regions.

Not all regions impacted by El Niño have increased precipitation. The El Niño weather pattern usually brings drier than normal conditions to northern Australia, Indonesia, and the Philippines, often causing drought conditions.

Mechanism

It is now known that there is a linkage between the appearance of warm surface water temperatures and

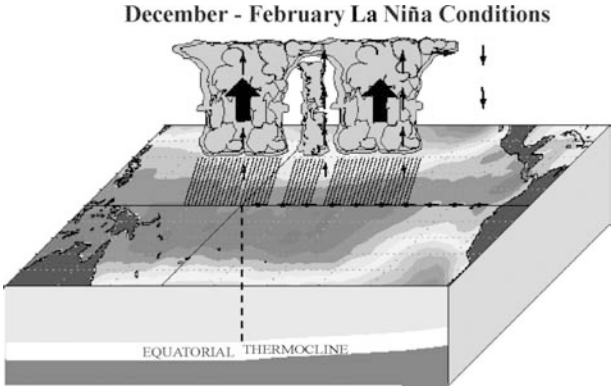

Fig. 1 Atmospheric and oceanic patterns during an El Niño www.cpc.ncep.noaa.gov/products/analysis_monitoring/ensocycle/enso_schem.html (From the National Weather Service Climate Prediction Center, Camp Springs, MD.)

atmospheric phenomena. For El Niño events, this means linking eastern and central equatorial Pacific Ocean surface temperatures with atmospheric pressure patterns across the Pacific Ocean (see Fig. 2). The atmospheric pressure patterns linked with El Niño is called the Southern Oscillation, SO. The combination of El Niño and SO is called ENSO (El Niño-Southern Oscillation). The term ENSO is often used interchangeably with the term El Niño.

The strength of SO is calculated by the surface atmospheric pressure anomaly differences between Tahiti and Darwin, Australia (Tahiti anomaly minus Darwin anomaly). This measure of SO strength is called the Southern Oscillation Index, SOI. A surface atmospheric pressure anomaly is calculated by subtracting the mean atmospheric surface pressure from the observed atmospheric surface pressure. Thus, if the observed atmospheric surface pressure is less than the mean, the anomaly has a negative value.

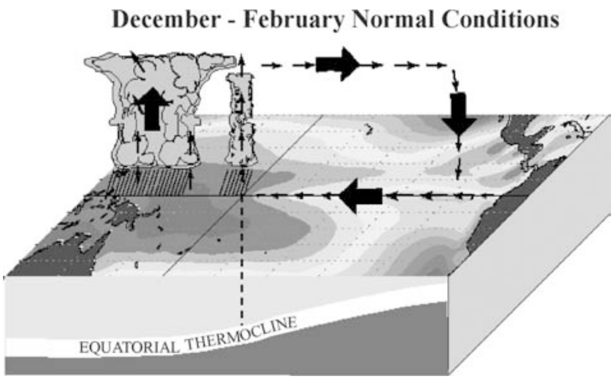

Fig. 2 Atmospheric and oceanic patterns during "neutral" or normal conditions www.cpc.ncep.noaa.gov/products/analysis_monitoring/ensocycle/meanrain.html (From the National Weather Service Climate Prediction Center, Camp Springs, MD.)

When the SOI has a negative value, it means that the surface atmospheric pressure is less than normal at Tahiti and above normal at Darwin (negative anomaly at Tahiti minus a positive anomaly at Darwin). A negative SOI is correlated with warming of the surface water in the eastern and central equatorial Pacific Ocean.

The linkage between SO and El Niño is complex. At the most basic level, sea surface temperature patterns influence atmospheric pressure patterns, and atmospheric pressure patterns influence wind speed and direction and thus the sea surface temperature patterns. Warm surface temperatures over the western Pacific Ocean lead to increased convection and lower surface pressure across the western Pacific Ocean. The normal cold surface water of the eastern Pacific Ocean is associated with relatively high surface atmospheric pressure. Air moves (wind) from areas of high atmospheric pressure to areas of low atmospheric pressure. The greater the pressure gradient (pressure difference between two locations divided by the distance between the two locations), the greater the wind speed. The moving air in contact with the ocean surface causes ocean surface currents, which redistribute the ocean surface temperature pattern. The stronger the wind, the more the occurrence of redistribution of surface water temperatures.

With ENSO, the linkage between the ocean and the atmosphere results in decreasing or increasing easterly trade-wind (wind from the east to the west) speeds over the equatorial Pacific Ocean. When the SOI is negative, the pressure gradient across the eastern and western Pacific Ocean is decreased. With a decreased pressure gradient, the speed of the easterly trade-winds decreases, and warm surface water from the western Pacific Ocean is able to "slosh back" over the colder surface water in the eastern Pacific Ocean. The decreased easterly winds also leads to a decreased upwelling of cold, nutrient-rich water along the coast of Ecuador and Peru. When the SOI is positive, the easterly trade-wind speed increases. The increased wind speed "piles-up" warm surface water in the western Pacific Ocean leading to below normal surface temperatures in the eastern and central equatorial Pacific Ocean due to strong upwelling.

Below normal surface temperatures in the eastern and central equatorial Pacific Ocean is the opposite of an El Niño event and is called either a La Niña (Spanish for girl) event or El Viejo (Spanish for old man) event.

Changes in the equatorial Pacific surface temperature patterns impact the weather patterns in other regions of the earth. During an El Niño pattern, sea surface temperature patterns change. These sea surface temperature pattern changes impact the locations of evaporative heat movement from the ocean surface to the atmosphere. With different evaporative heat patterns, there are changes in the locations of wintertime jet streams and thus the storm tracks. With changes in jet stream patterns and storm tracks, weather patterns across numerous regions can change. An example is the change in storm tracks that brings Pacific Ocean storms into southern California and across the southern-tier of states instead of the Pacific Northwest.

Since the 1990s scientists have used Pacific Ocean surface temperature data and computer models to predict the occurrence of an El Niño event months in advance. While these predictions are not perfect, they allow for planning to mitigate or take advantage of a shift in weather patterns. Thus regions that normally experience flooding during an El Niño event can plan to mitigate the impacts. For regions like Indonesia or the Pacific Northwest of the United States, drought mitigation plans can be activated months in advance.

For more detailed information about El Niño, see Ref.[1].

Energy Dissipation Structures

Iwao Ohtsu
Youichi Yasuda
Department of Civil Engineering, Nihon University College of Science and Technology, Tokyo, Japan

INTRODUCTION

Hydraulic structures such as dams, weirs, and drop structures have energy dissipators as a means of dissipating the excess energy of high-velocity flows, in order to protect the riverbed and banks downstream.

In energy-dissipation structures, there are stilling basins with horizontal or sloping aprons, stilling basins with baffles or sills, bucket-type stilling basins, and baffled or stepped chutes. The type of energy-dissipation structure to be selected depends on the kind of hydraulic structure, the discharge, the magnitude of the energy head upstream of the hydraulic structure, the tailwater conditions, and the topographical and geological characteristics of the river or channel.[1–3]

In order to properly complete the hydraulic design of an energy-dissipation structure, it is important to know the downstream flow conditions. In addition, information regarding flow conditions around the hydraulic structures might help in improving the landscape and other features of the river environment and in preserving the ecosystem for aquatic animals in the river.

OVERVIEW

The flow conditions that are used as energy dissipators introduced here are: hydraulic jumps on horizontal aprons, hydraulic jumps forced by a vertical sill, hydraulic jumps on sloping aprons, hydraulic jumps below abrupt expansions, transition flows over drop structures, and stepped-channel flows.

ENERGY DISSIPATORS IN STILLING BASINS

Hydraulic Jumps in Prismatic Horizontal Channels

In a stilling basin, the formation of a hydraulic jump is the most effective method of dissipating the kinetic energy of a high-velocity flow. A hydraulic jump is a transitional phenomenon from high velocity supercritical flow to lower velocity subcritical flow. The flow conditions of the hydraulic jump in a horizontal channel changes according to the inflow conditions and the shape of the channel. The formation of a symmetric jump with a surface roller is an effective energy dissipator.

A hydraulic jump in a horizontal smooth rectangular channel is referred to as a classical jump. Classical jumps have been classified into undular jumps, weak jumps, oscillating jumps, steady jumps, and strong jumps.[1,4] Steady and strong jumps can be utilized in a stilling basin. However, the position of a classical jump is very sensitive to changes in the downstream depth.[5] Some kind of elements are needed in order to stabilize the jump location (see the Section ‘‘Forced Hydraulic Jumps by a Vertical Sill’’).

In a trapezoidal horizontal channel, a submerged jump is recommended as an energy dissipator because a free jump becomes asymmetric for a mild side slope, and a submerged jump keeps a symmetric flow for any side slope (Fig. 1).

The sequent-depth ratio (ratio of downstream to upstream depth) and the energy loss of a free or submerged jump can be predicted theoretically. The jump length has been discussed by many researchers[1,6–8] and may be predicted for a free or submerged jump in a rectangular or trapezoidal channel.[9,10]

Forced Hydraulic Jumps by a Vertical Sill

When the downstream flow depth is less than the sequent depth required for a classical hydraulic jump, sills and blocks have been utilized in order to stabilize the jump location in a stilling basin. Standard designs for stilling basins employing sills and blocks have been published by the U.S.B.R.[1,8]

The flow conditions of a forced jump change according to the inflow Froude number, the sill height, the position of the sill, the boundary-layer development at the toe of jump, and the upstream and downstream depths. As illustrated in Fig. 2, the flow configuration upstream of the sill depends on the

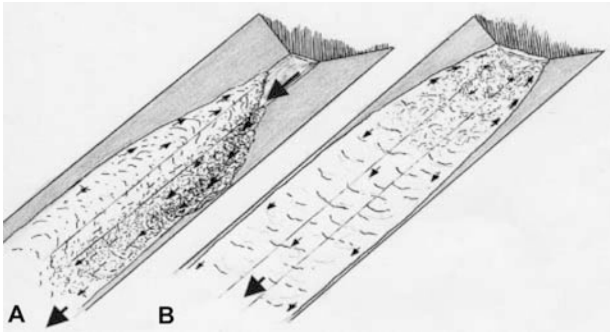

Fig. 1 Flow conditions of hydraulic jump in a trapezoidal channel with a mild side slope: (A) asymmetric flow; (B) symmetric flow.

downstream depth in some cases (Type-I jump). In other cases, the flow configuration upstream of the sill is independent of the downstream depth (Type-II jump). If a forced jump is not formed, the supercritical flow splashes over the sill (this is referred to as a splashing flow) (Fig. 2).

The hydraulic conditions required to form each type of flows have been documented.[11,12] When the discharge and the upstream and downstream depths are given, the height and position of the sill required to form a forced jump can be predicted. The drag force acting on the vertical sill in a forced jump has also been investigated.[12,13] An experimental equation for the length of a stilling basin required for the formation of a forced jump has been developed.[8,11]

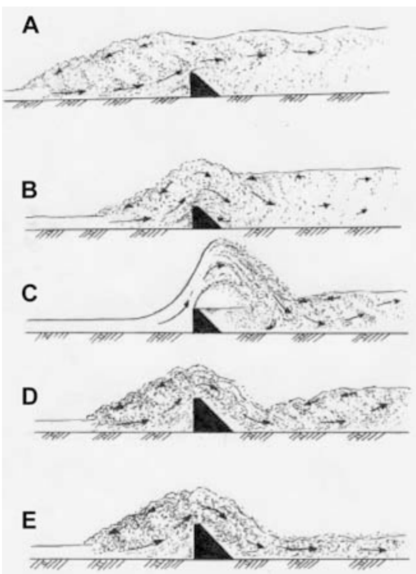

Fig. 2 Flow conditions of flow over a sill: (A) and (B) Type I forced hydraulic jumps; (C) splashing flow; and (D) and (E) Type II forced hydraulic jumps.

Hydraulic Jumps on Sloping Aprons

If the downstream depth is greater than the sequent depth of a classical hydraulic jump, control of the hydraulic jump by a sloping apron is effective as an energy dissipator.[1]

The flow conditions of the hydraulic jump change according to the inflow Froude number, the channel slope, and the upstream and downstream depths (Fig. 3). When the degree of channel slope is small, the jump occurs on the sloping channel apron, and the high velocity decays in a short distance (Fig. 3B). This flow condition is favorable as an energy dissipator.[1] If the degree of channel slope and the downstream depth become large, the flow becomes a plunging flow. For plunging flow, the high-velocity flow along the channel bed continues far downstream, and the effect of the surface eddy on velocity decay is negligibly small (Fig. 3D). This condition is less effective for energy dissipation.

The hydraulic conditions for the formation of various types of jumps and the length of the jumps have been documented and are predictable for a wide range of inflow Froude numbers, channel slopes, and downstream depths.[1,8,14]

Hydraulic Jumps Below Abrupt Expansions

Both symmetric and asymmetric flows can exist when an outlet conduit is connected to a wide open-channel (Fig. 4). An asymmetric flow is also observed in an open-channel having an abrupt expansion.[8] With asymmetric flow conditions, high-velocity flow may exist along one sidewall for a significant distance downstream. Maintenance of conditions suitable for the formation of a symmetrical jump is recommended for energy dissipation below an abrupt expansion.[3,15]

The minimum downstream depth required to form symmetric flow at an abrupt-symmetrical expansion

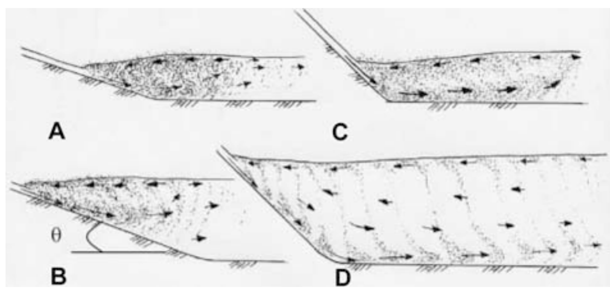

Fig. 3 Flow conditions in sloping channels with a horizontal channel portion: (A) and (B): degree of channel slope θ is smaller than 19° (A) B-type hydraulic jump; (B) D-type hydraulic jump, (C) and (D): degree of channel slope θ is larger than 40° (C) B-type hydraulic jump; (D) plunging flow.

El Niño–Evaporation

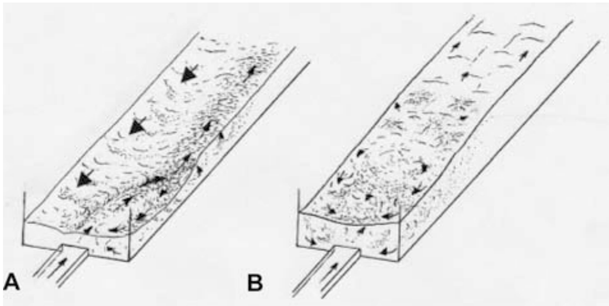

Fig. 4 Flow conditions of submerged hydraulic jump below an abrupt expansion: (A) asymmetric flow; (B) symmetric flow.

has been documented for a wide range of expansion ratios, aspect ratios, and inflow Froude numbers.[15] In addition, empirical equations for predicting the jump length for symmetric flow conditions have been developed. A flow chart for designing a stilling basin with an abrupt-symmetrical expansion is available.[15]

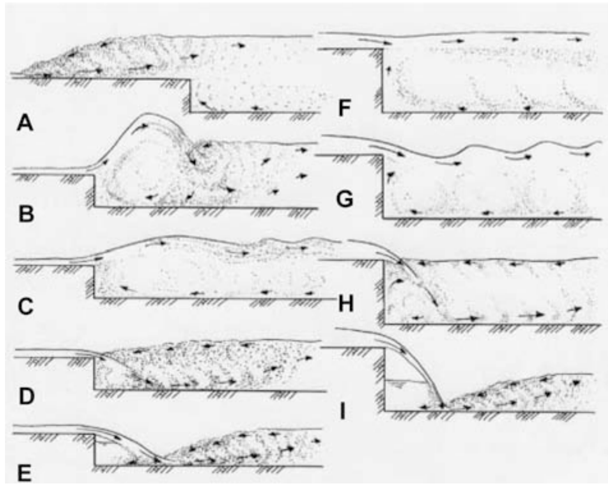

Fig. 5 Flow conditions at abrupt drops: (A)–(E): approaching flow on the step is supercritical (A) A-type hydraulic jump; (B) wave-type flow; (C) wave train; (D) B-type hydraulic jump; and (E) minimum B-type hydraulic jump (F)–(I): critical flow exists on the step (F) surface-jet flow; (G) wave train; (H) plunging condition; (I) limited jump.

Transitional Flows at Abrupt Drops

An abrupt drop in a channel may be used to stabilize the jump position effectively for a change of the flow depth.

A plunging flow with a surface roller is not always formed at the downstream region of drop structures. When the flow passing over a drop structure transits from supercritical flow to subcritical flow, various types of flow conditions are formed according to the inflow Froude number, the drop height, and the upstream and downstream depths.[8,16,17] For example, if the downstream depth is increased, the flow condition might change from a plunging flow to a wave train where the undular surface with a main flow propagates far downstream as illustrated in Fig. 5.

The hydraulic conditions required to form each type flow condition have been presented for a wide range of inflow Froude numbers, drop heights, and downstream depths.[17] Also, low-drop and high-drop structures have been defined according to the differences of flow patterns and design criteria for each type of drop developed.

ENERGY DISSIPATORS ON SPILLWAYS

A baffle chute that dissipates energy along the entire length of the channel is useful as an energy dissipator of high-velocity spillway flows.[1] Recently, stepped spillways have been utilized in connection with the roller-compacted concrete dam-construction method, and stepped-channel flows have been investigated by many researchers.[18,19]

The flow conditions on a stepped surface change according to the discharge, the step height, the slope angle of the stepped channel, and the total drop. Flow conditions have been classified as skimming flow (the main flow skims above a stepped channel, and a corner eddy is formed without an air-pocket in each step), nappe flow (an air-pocket is always formed in an aerated-flow region below the nappe), and transition flow (a transition between a skimming flow and a nappe flow with an air-pocket partly formed) (Fig. 6).

Experimental investigations have revealed the hydraulic conditions for the formation of each flow condition and the energy loss due to stepped flows.[20,21]

The utilization of stepped surface in approach channel is effective for the energy dissipation of plunging flow region. Especially, when a stepped channel is used for the steep section of a spillway, there is less tendency to develop plunging flow with a reverse-flow region

Fig. 6 Flow conditions on a stepped channel: (A) skimming flow; (B) transition flow; (C) nappe flow.

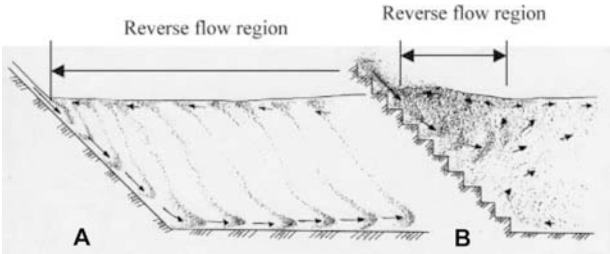

Fig. 7 Comparison of reverse flow region of plunging flows: (A) plunging flow on a smooth sloping channel; (B) plunging flow on a stepped channel.

on transition to the downstream channel[22] (Fig. 7). This increases the effectiveness of the energy dissipation in the transition region.

CONCLUSION

For design of an energy-dissipation structure, it is important to know the downstream flow conditions. A variety of flow conditions may be used for energy dissipation according to the type of the hydraulic structure, the discharge, and the downstream flow depth.

A stabilized jump with a surface roller is an effective energy dissipator in jump-type stilling basins. Baffle chutes and stepped spillways are effective in dissipating energy along the length of steep channels such as spillways.

Erosion and Precipitation

Bofu Yu
School of Environmental Engineering, Griffith University, Nathan, Queensland, Australia

INTRODUCTION

Erosion is a natural process to detach soil and rock fragments for subsequent removal, or transportation, of these materials to areas of lower elevation on the surface of the earth. In the context of agriculture, the primary agents for erosion are water and wind. Climate, precipitation in particular, plays a critical role in determining where and when erosion occurs and the magnitude of erosion rate. Rainfall erosivity, i.e., the ability of rain to cause erosion, is largely a function of rain amount and peak intensity. Rainfall erosivity and its seasonal variation in relation to the Universal Soil Loss Equation (USLE) and the revised USLE (RUSLE) can be estimated from mean annual rainfall and daily rain amount. Low rainfall, dry soil surface, and poor ground cover are the necessary conditions for wind erosion to prevail.

RAINFALL EROSIVITY

Rainfall erosivity is a measure of the climatic influence on water erosion. When other variables such as topography and vegetation cover are held constant, the rate of erosion is directly related to the level of rainfall erosivity. A number of rainfall erosivity indices have been proposed so that the amount of soil eroded is linearly proportional to the rainfall erosivity index *ceteris paribus*. The most commonly used rainfall erosivity index is EI_{30}, where E is the total kinetic energy per unit area for a storm (MJ ha^{-1}) and I_{30} is its peak 30-min intensity (mm h^{-1}). Wischmeier and Smith[1] found that the combination of kinetic energy and peak intensity is most closely related to the observed amount of soil loss. The R-factor in the USLE and RUSLE is the mean annual sum of these EI_{30} values.[2,3] Other measures of rainfall erosivity worthy of note include the modified Fournier Index,[4,5] KE $>$ 1 index,[6] and the so-called Universal Index of Onchev.[7] Numerous other attempts have been made to search for a rainfall-based estimator of the observed amount of erosion that is superior to EI_{30}. Most of these studies have relied on restricted databases that have limited their applicability. Most of these other indices or estimators are highly correlated with each other and with EI_{30}.

Although the definition of EI_{30} is straightforward, its calculation requires long-term rainfall data at short time intervals (<30 min) that are not widely available for most parts of the world. To develop a better understanding of what is exactly involved in EI_{30}, it is helpful to examine how this index is calculated. I_{30} is the maximum intensity for any 30-min interval in a storm, while the storm energy depends on how rainfall intensity varies during the event:

$$E = \int_T e(I) I dt \tag{1}$$

where I is the rainfall intensity, T the rain duration, and $e(I)$ a function of rain intensity called the unit energy equation. The consensus is that the unit energy as a function of rain intensity assumes the following functional form[3,8]

$$e(I) = e_{\max}(1 - \alpha e^{-I/I_o}) \tag{2}$$

For RUSLE, the following was recommended: $e_{\max} = 0.29$ MJ ha^{-1} mm^{-1}; $\alpha = 0.72$; $I_o = 20$ mm h^{-1}.[3] It can be shown from Eqs. (1) and (2) that the storm energy is bounded:

$$0.28 e_{\max} P < E < e_{\max} P \tag{3}$$

where P is the total rain (mm). The theoretical upper and lower bounds are related to zero and infinite intensity, respectively. Analyzing 6-min rain data for a number of sites around Australia shows that the ratio of storm energy to $e_{\max}P$ ranges mostly from 0.5 to 0.8, and the ratio is slightly higher in tropical/subtropical than in temperate regions (Table 1). From Table 1, it is also clear that the storm energy is always highly correlated with rain amount. Given that storm energy is primarily a function of rain total, it follows that rainfall erosivity, as defined in relation to USLE/RUSLE, depends mainly on rain total and peak intensity, and to a much lesser extent on rainduration.

For areas where long-term high-resolution rain data are unavailable, the simpler method to estimate rainfall erosivity in the context of USLE/RUSLE is to use the fairly consistent relationship between the mean annual

Table 1 Linear relationship between rain amount (P) and storm energy (E) as in $E = \alpha e_{\max}P$ for selected sites in Australia (n = number of storms analyzed; R^2—coefficient of determination, representing the fraction of the total variation in the observed E values that can be explained by rain amount)

Location	Climate	α	n	R^2
Perth	Temperate, winter rain	0.521	2354	0.96
Melbourne	Temperate, uniform rain	0.530	1800	0.93
Brisbane	Subtropical, summer rain	0.626	4088	0.96
Darwin	Tropical, summer rain	0.742	3701	0.98

rainfall and the R-factor:[9,10]

$$R\text{-factor} = 0.05(\mathrm{MAR})^{1.6} \quad R^2 = 0.82 \tag{4}$$

where MAR is the mean annual rainfall (mm). The regression [Eq. (4)] is based on a combined database for 161 sites (132 sites in the United States and 29 sites in Australia).[9,10] MAR ranges from 67 mm to 2060 mm for these sites. The non-linear relationship suggests that a 10% change to MAR would lead to 16% change to rainfall erosivity. This highly sensitive nature of rainfall erosivity to rainfall would have important implications for the impacts of climate change on soil erosion. Reasonably good relationships between the Modified Fournier Index and the R-factor have also been noted.[5,9] The difference between the two estimates, however, is small, and little is gained by using the Modified Fournier Index.[10] If we need to estimate the seasonal distribution of rainfall erosivity, daily rain data can be used, especially, in areas with a marked wet season in winter. Monthly and annual rain total are no longer adequate because summer rain with high peak intensity can lead to higher rainfall erosivity in the relatively drier months. Rainfall erosivity can be related to rain amount using a power function in the form:

$$EI_{30} = aP^{\beta} \tag{5}$$

The calibrated values of β for a number of sites around the world are summarized in Table 2. The β value mostly varies in the range from 1.5 to 1.8 with higher values found largely at higher latitudes. Such relationships for daily erosivity are sufficient for determining the seasonal variation of rainfall erosivity for USLE/RUSLE.

Rain total and peak rainfall intensity are also key precipitation variables for a physical description of water erosion processes.[22–24] Mass balance dictates that in an area of net erosion, the amount of soil loss, SL, is given by

$$SL = Qc \tag{6}$$

where Q is the runoff amount and c is the sediment concentration. In this context, the effects of rain on erosion manifest themselves in terms of the amount of surface runoff generated and the level of sediment concentration in the runoff water. With non-climatic variables held constant, the amount of runoff is largely determined by rainfall amount and to a lesser extent by the rainfall intensity. Sediment concentration is related to both rainfall intensity and runoff rate. Rainfall detachment is linearly related to rainfall intensity. Shear stress or stream power commonly used to quantify flow detachment is intrinsically related to the runoff rate. Thus, in this physical framework for soil erosion, rainfall intensity plays a direct role in rain detachment. Rain amount and intensity also play an indirect role in flow detachment and transport of eroded sediments by determining the magnitude of runoff amount and runoff rate.

Precipitation is important to water erosion because soil particles and aggregates are detached by raindrops and surface runoff. A lack of precipitation, on the other hand, leads to low moisture levels near the soil surface, and thus renders the soil particularly susceptible to wind erosion. Wind speed, precipitation, and potential evaporation were used to develop indices of wind erosivity.[25–27] For given wind speed and potential evaporation, wind erosivity is inversely related to precipitation. Fig. 1 shows schematic relationships between precipitation and vegetation cover, rainfall and wind erosivity, and predominant erosion processes. In high rainfall areas, the rate of actual erosion is not necessarily high in spite of high rainfall erosivity

Table 2 The average exponent and its one standard deviation in the power function relating daily rain (P) to rainfall erosivity (EI_{30}) as in $EI_{30} = aP^{\beta}$

unless the usually good vegetation cover is removed and the soil surface exposed. In arid and semiarid areas with low rainfall, the combined effects of poor ground cover and dry soil surface make the land particularly vulnerable to wind erosion.

CONCLUSION

Precipitation is a key climatic variable that determines the type and magnitude of erosion. In the context of water erosion, rain amount and peak intensity are the most important variables in determining the erosion rate. For areas without high-resolution rainfall intensity data, the *R*-factor and its seasonal variation for USLE/RUSLE can be estimated from mean annual rainfall and daily rain amount. Absence of rain, concomitant dry soil surface, and poor ground cover are the necessary conditions for wind to become the dominant erosion agent.

Erosion and Productivity

Francisco Arriaga
Birl Lowery
Department of Soil Science, University of Wisconsin–Madison, Madison, Wisconsin, U.S.A.

INTRODUCTION

Land productivity is influenced by many factors including sunlight and precipitation, but the most productive land can be altered by a simple process like erosion. Although soil erosion is a natural process, it creates serious problems, both environmental and economical, worldwide. Soil erosion and deposition of eroded material have a detrimental effect on soil and crop production and on surface water quality. Erosion causes soil degradation by removing topsoil, which is often rich in organic matter, and by reducing the total depth of the soil profile. Additionally, erosion causes off-site water contamination by transporting agricultural chemicals, such as pesticides, fertilizers, and naturally occurring minerals or biologically derived nutrients, to rivers and lakes. Therefore, it is essential that we reduce soil erosion and understand what effects it may have, so that to the extent possible we can minimize the harm caused by erosion.

The erosional process alters important soil physical, chemical, and biological properties necessary for optimal crop production.[1] It is often agreed that the main impact of erosion on soil productivity is caused by changes in soil chemical properties (i.e., fertility); however, soil physical (i.e., water holding capacity) properties undergo significant changes that are often overlooked. Fertilizers and manures have been used with varying levels of success to restore the fertility of eroded land, and manures might restore some physical properties such as water holding capacity and structure. However, the total soil depth is irreplaceable. It is universally accepted that the long-term productivity potential of an eroded soil is lower than that of an uneroded one. Simulation models of soil erosion and changes in long-term crop productivity for various regions of western Europe estimate that productivity could drop as much as 30% for soils with a shallow profile, less than 75 cm, by 2100.[2] However, these estimates are somewhat conservative since they only take into account soil depth, and not changes in soil organic matter and nutrient losses.[3]

EROSION AND CROP PRODUCTION: SOIL PHYSICAL PROPERTIES

Erosion is defined as the detachment and movement of soil by water, wind, or ice. Many factors affect the erosional process; however, the type of soil, ground cover, and landscape are considered the most important ones. One of the most noticeable effects of soil erosion is the reduction in organic matter of the surface soil layers.[4–8] Since organic matter plays a crucial role in soil structure and in the formation of soil aggregates,[9–12] it is not surprising that researchers have found a decrease in aggregation and aggregate stability in eroded soils.[5–7] A reduction in aggregate stability can result in decreased water infiltration rates, and thus reduced water recharge of the soil profile for plant use and groundwater recharge. Additionally, a decrease in aggregation can hamper crop-seedling emergence, root growth and development, and tillage operations through the formation of soil surface crusts and increases in soil bulk density.[13–17]

Scientists have found a correlation between reduced crop yields and decline in organic matter contents in eroded soils. 20 yr after soil desurfacing, Lindstrom et al.[4] found a decrease in organic matter levels in the Ap horizon (surface soil) with increasing depth of topsoil removal. This decrease in organic matter was accompanied by a decrease in corn grain and stover yields, as well as an increase in soil bulk density of surface and subsurface horizons. Similarly, Schumacher et al.[14] found a reduction in organic carbon, in the Ap horizon, of about 10% from moderate to severe erosion areas in a study conducted to examine properties of 11 soils in the North Central Region of the United States. However, scientists have also reported an increase in organic carbon from moderate to severe erosion in 2 of the 11 soils studied. Increases in organic carbon with increasing erosion level are infrequent, but can be attributed to increased clay contents in the surface of eroded soil (from the exposure of subsoil rich in clayey materials), and consequently to an increased interaction between soil particles and organic carbon, making organic carbon more stable in the soil.[18–20] Nevertheless, reductions in corn yields on eroded areas were observed for the 11 soils in the Schumacher et al.[14] study. Lowery et al.[16] found a significant increase in bulk density of the Ap horizon, as well as an increase in clay content, decreases in plant available water, and decrease in hydraulic conductivity of saturated soil for the same 11 soils investigated by Schumacher et al.[14] Corn grain yield decreased by 30% following removal of the surface 20 cm of a silty clay loam soil to simulate erosion.[7] Since fertilizer was applied at twice the rate in the desurfaced areas, reduction in grain production was attributed to decreased soil organic carbon, crack formation, drought stress, and corn disease.

Crop yield is generally related to the amount of water that is available to a crop from the soil. Greater capacity to hold water because of greater clay content can result in greater crop yields on eroded land in years when rainfall is less than normal.[21,22] Since the amount and time of precipitation have great effects on crop yield, the effects of erosion are more pronounced in some years than others.[23]

Because of the impact of soil water on yield, position in the landscape has an influence on productivity.[21–25] In general, linear slopes are more eroded than foot and head slopes. This relationship between landscape position and erosion adds to the difficulty of assessing the effects of erosion on crop productivity. On sloping terrain, landscape variations contribute to the many factors determining where water infiltrates and where it flows after a rainfall event. In general, water tends to run off steep sloping areas and infiltrate in lower landscape positions. Thus, lower landscape positions tend to be more productive than steeper slopes.[8,24]

In addition to landscape position, poor plant production can be attributed to changes in soil-water holding characteristics which can be altered by erosion.[26] Water is held in the soil under greater negative pressure, making it less available for crop use, with increasing level of erosion because of increases in clay content in the exposed lower horizons. Damage to soil physical properties caused by erosion has a significant negative impact on crop production.[6,13,27]

EROSION AND CROP PRODUCTION: SOIL CHEMICAL PROPERTIES

Organic matter not only plays an important role in shaping the soil physical characteristics, but also affects soil chemical properties. It serves as a source of plant nutrients and aids in the soil pH buffering capacity. Humus, or stable soil organic matter, is one of the most chemically active components in soil and serves as a major reservoir for charged molecules, reducing the loss of nutrients and pesticides by leaching.[18–20] When organic matter is reduced by erosion, there is a greater potential for leaching of nutrients which leads to a decline in soil productivity.

Lack of phosphorus (P) has been linked to reduced crop yields in eroded soils. Delays in emergence, plant development, and yield have been recorded in eroded areas.[4,28] This has been attributed to reduced P uptake by plants grown on eroded land.[29]

Nutrient loss from erosion has been described as one of the major causes of soil fertility depletion in Kenya[30] and in the Phillippines.[8] Soil-water erosion is associated with plant nutrient removal, especially P. Sediment collected from eroded areas is usually richer in P than the original soil. Changes in soil pH, organic carbon, and total nitrogen can also be correlated to soil loss by erosion. Thus, soil erosion removes necessary plant nutrients. However, when nutrients are lost by erosion, the loss can be compensated for by fertilizer application, but loss of soil organic matter is not easily replaceable and affects soil chemical and physical properties. As previously noted, organic matter improves soil-water holding capacity and aggregate stability.

CONCLUSIONS

Since important soil properties for plant production are degraded by soil erosional processes, crop productivity is often reduced in eroded soils. Even though intensive farming practices can mask some of the effects of erosion on crop production, erosion effects are still real and detrimental to long-term soil quality and production. Soil erosion mainly impacts and changes soil chemical and physical properties. Most of these changes are caused by the removal of surface soil layers and the subsequent exposure of lower soil horizons. Major changes in soil properties include soil particle size distribution and organic matter content. Changes in soil particle size distribution depend on the existing soil conditions, but in most cases, clay content increases with increasing erosion. Since surface soil rich in organic matter is removed during the erosional process, organic matter content is reduced in eroded soils. Changes in these two soil characteristics usually create changes in other important soil properties, such as bulk density, aggregation, water retention, hydraulic conductivity, CEC, pH, and nutrient availability, among others. Changes in soil particle size distribution are difficult, if not impossible, to reverse, and can be considered more or less permanent. However, organic matter contents can potentially be increased by applying organic matter sources. One such source is animal manure. Increases in organic matter can help to ameliorate the effects of erosion on soil properties, especially soil physical properties. Therefore, cattle manure has been proposed for use on eroded soil as an amendment to ameliorate the effects of erosion. Furthermore, as already discussed, aggregate formation and stability are aided by soil organic matter. Thus, organic matter can potentially increase a soil's resistance to erosion.

Erosion Control: Mechanical

Mark A. Nearing
Mary Nichols
Kenneth G. Renard
Jeffry Stone
Southwest Watershed Research Center, Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Tucson, Arizona, U.S.A.

INTRODUCTION

Soil erosion is a naturally occurring process. Accelerated erosion is a problem common to agriculture, mining, and construction wherever natural cover is reduced and soil is left unprotected. Mechanical erosion control measures are implemented to minimize onsite and offsite impacts of these activities, as well as to rehabilitate degraded lands. Often, mechanical erosion controls are applied in combination with vegetative erosion control techniques. The general goals of erosion control technologies are to alter runoff patterns and protect the soil surface, thereby reducing the erosive power of water. This article reviews mechanical erosion control technologies and the hydrologic and erosion processes they affect.

EROSION PROCESSES

Hillslope erosion caused by running water and the factors affecting soil loss are summarized in the Universal Soil Loss Equation (USLE).[1] The USLE is a model for predicting long-term average soil losses from fields based in part on the factors of slope length and steepness, and cover management. These are the primary factors that can be altered and improved through mechanical erosion control. Long, steep slopes with minimal protective cover are subject to high erosion rates. Decreased vegetative cover, often associated with land use, results in higher velocity runoff and increased concentrated flow. The primary approach to mechanically controlling soil erosion is to reduce the erosive power of flowing water by reducing the forces applied to the soil or by reducing the susceptibility of the soil to erosion. This is often accomplished by armoring surfaces, altering runoff patterns, and reducing sediment transport capacity.

In general, erosion includes the processes of soil detachment, transport, and deposition. Although the USLE does not address concentrated flow, channel processes, or deposition, the general principles of reducing or altering flow patterns, reducing velocity, and maintaining vegetative or rock cover also apply to controlling erosion in channels.

MECHANICAL EROSION CONTROL TECHNOLOGIES

Mechanical erosion control technologies can be grouped according to the hydrologic processes they impact. Technologies are available to alter overland flow, protect the soil surface, minimize channel scour, and induce deposition (Table 1). Decisions regarding which technology, or combination of technologies, to employ depend on several factors including safety (as in the case of a dam or the potential for downstream impacts), regulations, time frame of the project, cost, labor, local climate including rainfall and runoff patterns, drainage patterns, topography, and soils. In addition, site-specific erosion control needs, such as in response to construction where the source and extent of erosion are known, may require different technologies than landscape scale erosion control implemented to rehabilitate degraded watersheds. Erosion control structures are often specified based on a design storm. A design storm provides information on the amount of precipitation and runoff that the erosion control structure will accommodate. Design storms are often designated based on the anticipated storm volume for a specified return frequency at the location of interest.[2]

Technologies for Reducing Overland Flow Erosion

In the absence of concentrated flow paths, runoff travels across the landscape as shallow overland flow. The infiltration of overland flow provides soil moisture critical to vegetation. Over long distances of steep slope, runoff can reach velocities sufficient to detach and transport soil. Terraces intercept runoff and divert it from the field at reduced velocities. Water spreading berms reduce the overland flow slope and increase the

Table 1 Summary of mechanical erosion control technologies

Technology group	Structure
Overland runoff alteration	Terraces
	Water spreaders
	Berms

flow length, thereby increasing the residence time of runoff and reducing its erosive energy. Soil moisture and storage are increased thereby improving conditions for vegetation, which in turn acts to maintain soil onsite. Although diverting water at the top of steep slope sections can limit gullying and headcut advance, locating water diversions near the end of slopes is often more effective as the area contributing to flow and the amount of flow increases.

Technologies for Surface Protection

Several technologies are available to protect the soil surface. These materials act to mimic vegetative cover or create conditions for establishing vegetation. Hydraulically applied erosion control covers, such as wood fiber or straw, are often applied in combination with seed to protect exposed soil. Geotextiles, or high tech fabrics, for filtering sediment are commonly used on construction sites and to line eroding channels. The fabrics usually come on a roll and a variety of specifications are available depending on soil type and application. These fabrics may be treated to prevent degradation if the fabric is integral to a long-term stabilization project, or they may degrade as vegetation is established. The use of geotextiles may require technical consultation to ensure the characteristics of the fabric are best suited for the characteristics of the soil. Chemical amendments such as polyacrylimide (PAM)[3] can be added to soil to increase infiltration and reduce surface erosion. Wattles, or rolled straw, are effective for controlling erosion on roadsides and on slopes when anchored perpendicular to flow paths. Wattles are commonly used to protect areas where there is a need to reduce concentrated flow velocity and shear along the surface. Their placement reduces the flow length, slows the flow, and spreads the water.

Technologies for Concentrated Flow and Channels

Structures for controlling erosion in concentrated flow in channels are generally larger than those required for upland flow areas. Check dams and small water diversion dikes can be constructed with local materials and labor. These structures are often expected to both reduce erosion and retain sediment onsite. Check dams are built below small headcuts to trap eroded sediment and limit the headward migration of the channel. Water diversion dikes can alter the path of concentrated flow, increasing the travel length and thereby reducing the velocity.

Erosion control structures in large channels may require engineered designs and considerable expense. Wire baskets filled with rock, called gabions, can be used to build retaining walls and protect channel banks (Fig. 1). Porous structures that act to dissipate energy can be built across the channel to reduce flow velocity and induce deposition while allowing water to pass through. Geotextiles are often integral to porous structures to act as a filter for retaining small particles, improving seepage, and reducing scour.

If there is a substantial change in elevation along a channel course, a drop structure may be required to carry runoff to a lower elevation without causing erosion.[4] Drop structure are usually built of concrete or rock based on an engineered design with significant costs associated with both design and construction.

Technologies for Deposition

Increasingly, the potential for offsite impacts of sediment requires that onsite erosion control techniques be designed in the context of watershed scale processes. Sediment that travels within a watershed can be

Fig. 1 Stair stepped gabions, wire mesh, and concrete reinforced bank controlling erosion on the edge of an irrigated field in southern Arizona.

trapped at a downslope point. Small agricultural ponds are ubiquitous and serve a variety of purposes including water supply, recreation, and sediment detention. Effective sediment detention ponds must be designed to accommodate expected runoff and sediment loads while limiting maintenance required to maintain storage capacity.[5] Sediment detention basins and stilling ponds are often used in combination with erosion control technologies to improve onsite retention and to minimize the downstream impacts of sediment. The best sediment control is erosion control.

CONCLUSION

Mechanical erosion control technologies, methods, and practices evolve as new materials and applications are developed. Erosion control is critical for maintaining soil onsite and minimizing off site impacts. Erosion control practices are often implemented in response to laws and regulations, which may strongly influence their selection and design. Perhaps one of the most important aspects of erosion control is the fact that failure to control erosion can result in significant long-term damage that becomes increasingly expensive to repair.

Erosion Control: Tillage/Residue Methods

Jerry Neppel
Krisztina Eleki
John Kost
Department of Agronomy, Iowa State University, Ames, Iowa, U.S.A.

Richard Cruse
Iowa State University, Ames, Iowa, U.S.A.

INTRODUCTION

Historically, tillage has been used for seedbed preparation, weed control, residue burial, and fertilizer/manure incorporation. Modern technology, i.e., improved planters and pesticides, has reduced tillage requirements for crop production with equipment adapted to higher crop residue conditions. Tillage to improve the seedbed for planter performance and crop production also increases the soil susceptibility to erosion from both wind and water.

TILLAGE AND SOIL EROSION PROCESSES

The processes of soil detachment, transport, and deposition occur during erosion. Soil surface conditions created by tillage greatly influence these processes and therefore soil erosion losses. Tillage practices that increase (or at least do not decrease) soil structural stability, leave plant residues on the soil surface, slow surface-water flow velocity, and/or promote high infiltration rates favor soil conservation.

Surface residue cover greatly influences soil erosion. When 30% of the surface is covered, soil erosion losses are reduced by approximately 50% compared with a bare, tilled soil (Fig. 1). Conservation tillage is considered to be any tillage system that has at least 30% of the soil surface covered by plant residues after planting[1] (Fig. 1).

TILLAGE EFFECT ON SOIL PROPERTIES CRITICAL TO EROSION

Residues intercept raindrops and minimize soil detachment. This reduces soil available for transport and also limits surface seal development. This improves infiltration, which in turn reduces the amount of water runoff and transport potential. Residues also slow surface flow velocity, by acting like little dams on the surface. This causes soil deposition to occur on the upslope side of the residue pieces where water flow slows.[2]

Surface roughness and structural stability play dual roles. A rough surface stores water in the surface depressions between the clods or aggregates during heavy rainfall. This slows runoff and limits transport. The large pores of a rough surface also require more soil detachment to create a surface seal than a smooth surface, minimizing transport. Similarly, contour tillage, tillage occurring across the slope, reduces runoff by increasing surface water storage and slowing water runoff velocity.

Open pores from the subsurface to the soil surface are critical for high infiltration rates and therefore low transport potential. Tillage practices that promote stable structure and result in surface residues to intercept raindrop impact promote stable open pores. Most tillage practices, however, weaken structure and therefore promote soil detachment from raindrop impact. Tillage also disrupts earthworm activity. Earthworms can play a major role in producing large open pores on the soil surface and very high infiltration rates with selected management systems. Four basic tillage/management systems will be discussed. Many variations of each system exist. Also, other systems using the principles described in this paper have been developed and can be located in other literatures, for example see Ref.[3].

NO-TILL

No-till results in minor soil disturbance only during planting, leaving the greatest possible amount of surface residue after planting (Fig. 2).

Compared to cleanly tilled systems, no-till can reduce erosion by as much as 95%.[4] The accumulation of residue from season to season reduces erosion by protecting the soil surface from impacting raindrops, as well as improving structural stability, pore size,

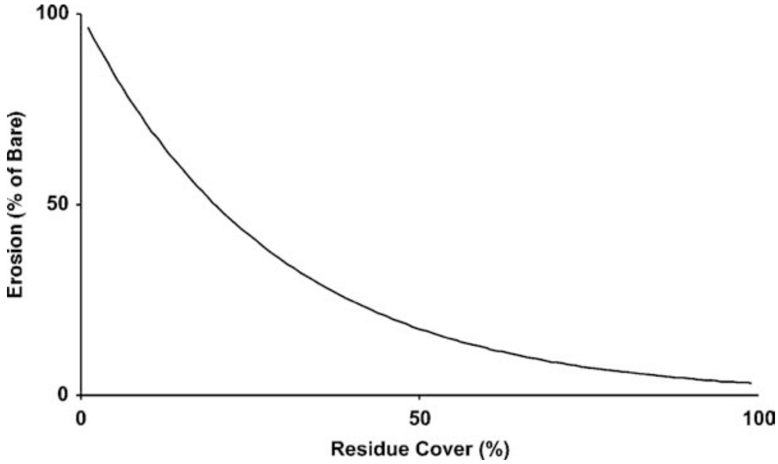

Fig. 1 Effect of surface residue cover on soil erosion by water, expressed as the percent of erosion observed for bare soil. *Source*: Adapted from Ref.[2].

and pore stability. Earthworm activity is promoted by no-till. Where large earthworm populations exist and the population is active on or near the surface, runoff can be very low or non-existent, even for large rainfall events.

No-till is best adapted for semiarid regions, sloping soils, and/or soils with good internal drainage. Low soil temperatures can be a problem in cooler climates, especially in early spring if soil is wet. One variation of no-till creates a residue-free band over the planted row with the planter. This helps the row zone warm and dry faster than if the soil is residue covered. In hotter climates, the reduced soil temperature caused by residue can be advantageous. In the absence of tillage, weed control is typically done through herbicide application. However, a combination of herbicide and cultivation for weed control can also be practiced.

Residue-covered surfaces also reduce soil water evaporation. No-till practices may conserve sufficient water under semiarid conditions (or on droughty soils) to significantly increase crop yield relative to that for other tillage methods (Fig. 3).

RIDGE TILLAGE

With ridge tillage the soil surface "is left undisturbed from harvest to planting" except for strips up to one-third of the row-width. Planting is completed on the ridge and usually involves removal of the ridge top. Planting is completed with sweeps, disk openers, coulters, or row cleaners. Residue is left on the surface between ridges. Weed control is accomplished with crop protection products (frequently banded) and/or cultivation. Ridges are rebuilt during row cultivation.[1]

Ridge tillage historically is practiced on wetter, poorly drained soils in northern climatic row cropping regions.[5] However, it is also a viable option in semiarid, rain-fed row cropping regions where soil moisture conservation is a necessity.

Fig. 3 No-till corn following wheat.

Fig. 4 Harvested corn on ridge-till soil.[6]

Selected aspects of ridge tillage systems protect the soil from soil erosion. Crop residues remain on the soil surface from harvest until planting of the succeeding crop. Only a portion of the soil surface is disturbed at planting. This leaves a high percentage of crop residues on the soil surface and maintains the large pores for rapid water infiltration. Crop residues from the row (ridge) are placed in the interrow (valley) area. This "extra" residue decreases detachment and slows water runoff, enhancing infiltration in the interrow area. Ridge tillage promotes controlled traffic, the practice of maintaining a fixed traffic pattern in the field, such that only certain interrow areas experience wheel-caused compaction. Controlled wheel traffic limits soil compaction to preselected interrows. The non-traffic areas maintain large pores and stable structure, enhancing infiltration. Ridge tillage is much more effective at conserving soil if ridging and planting are done on the contour than if up and down hill management is used.

Ridge till also offers opportunities to reduce weed control costs through banding of herbicides and row cultivation for weed management (Fig. 4). Nutrient losses may be reduced by injection and/or subsurface application of fertilizers.[7] Also, ridged soil warms quicker in the spring than no-till soil, permitting earlier planting in many situations.[8]

MULCH TILLAGE

Mulch tillage is a full width conservation tillage system involving one or more soil loosening operations prior to planting. Mulch tillage maintains a substantial amount of plant residue cover before and after crop establishment. Tillage tools such as chisel plows, field cultivators, disks, or blades are typically used for primary tillage. Secondary tillage is minimized to conserve surface residue.[9]

Mulch can be from any crop material. It is normally retained on the surface during harvest of the previous crop. The amount of mulch left on the surface depends on the sequence of the tillage, tool(s) used, and the mulch material of the previous crop. In general, the higher the crop yield, the more surface residue will exist.[10]

Surface mulch reduces the evaporation of soil water, increasing soil water content, relative to that occurring with a bare surface. Consequently soil warming can be slower in the spring, which can slow plant emergence and early development. The higher soil water content can also favorably affect crop yield under dry conditions. Mulch tillage increases soil organic matter content compared to more intensive tillage systems (Fig. 5). Weed control can be done mechanically, with herbicides, or with a combination of the two.

STRIP TILLAGE

Strip tillage involves tilling only in the crop row zone. The interrow area is untilled with surface residue left

Fig. 5 Mulch tillage procedure.

undisturbed. Tillage may be done in fall or spring. However, fall tillage is more commonly done. Typically a row cleaner, coulter, shank, and covering disks till each row area. This combination of components is equally spaced to match planter row-spacing so that the succeeding crop is planted in the tilled zones.[11] This system offers the combined advantages of no-till in the interrow zone and conventional tillage in the planted zone. The tilled zone is normally warmer and drier than if no tillage were performed.

Weed control can be through herbicide application, cultivation, or a combination of these methods. Fertilizer can be applied during the tillage operation at the base of the tilled depth and/or during the cropping season. Strip tillage is used only for row crop production. Strip tillage on the contour is much more effective at conserving soil than planting up and down hill.

SUMMARY

Tillage systems that leave residues on the surface, promote stable soil structure, and/or result in open pores to the soil surface favor water infiltration and soil conservation. Surface residue management is closely related to stable soil structure development and open surface pores. No-till, ridge tillage, mulch tillage, and strip tillage exemplify management systems that use these principles for favorable crop production and reduced soil erosion rates.

Erosion Control: Vegetative

Seth M. Dabney
National Sedimentation Laboratory, Upland Erosion Processes Research, Mid South Area, Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Oxford, Mississippi, U.S.A.

INTRODUCTION

Vegetation controls erosion by dissipating the erosive forces of rainfall and runoff (erosivity) and by reducing the susceptibility of soil to erosion (erodibility). Vegetation alters the partitioning of rainfall between infiltration, surface storage, and surface runoff. Erosivity is reduced because rainfall kinetic energy is absorbed, runoff volume is reduced due to increased infiltration, and runoff velocity is slowed through increased surface detention and reduced development of areas of concentrated flow. Vegetation reduces soil erodibility by increasing soil aggregation, binding aggregates together with roots, and lowering soil matric potential. Vegetation may cover the entire soil surface, as with crops, cover crops, or forests; or it may be limited to specific critical areas, as with various types of conservation buffers. This chapter reviews the mechanisms and processes by which vegetation reduces soil erosion by water, with emphasis on vegetative buffers. Crop residue effects are considered in another article.

GENERAL MECHANISMS

Slower Runoff

Theoretically, if runoff occurs uniformly over a plane, its depth increases in a predictable manner as slope length increases. In practice, the development of concentrated flow areas of high velocity limits the depth of sheet flows. By slowing runoff, vegetation can reduce or delay the development of rills and associated concentrated-flow erosion. Vegetation may increase runoff depth 10-fold compared to an equivalent discharge over a smooth surface or fivefold deeper than rainfall-impacted flow over a natural bare soil surface.[1] By increasing water depth fivefold, average velocity, V, is reduced fivefold. Since erosivity of runoff is proportional to V^2 and its sediment transport capacity is proportional to V^5, (see Ref.[2]) vegetation reduces concentrated-flow erosion.

The retardation of surface runoff is a critical aspect of the functioning of conservation buffers. Fig. 1 shows the situation where sediment-laden runoff encounters a vegetated buffer. Because of the additional hydraulic resistance of stems and leaves, flow depth within the buffer, D_2, is greater than upslope of the buffer's influence, D_0. The depth at the upslope edge of the buffer, D_1, however, is greater even than that within the buffer (D_2) because of: 1) enhanced vegetation growth at the buffer margin; 2) compression of stems into a denser barrier; and 3) loading of the buffer edge with trapped residues and thatch. In many studies, more than half of the sediment trapped by vegetated buffers is deposited in the ponded area upslope of the buffer. Where the ponded area is deep and slow-flowing, transport capacity is negligible and the water surface approaches horizontal. In these circumstances, the fraction of particles with fall velocity V_{si} that will be trapped (T_i) is given by Ref.[3]:

$$T_i = 1 - \exp[-V_{si}L/q] \tag{1}$$

where q is the specific discharge and L is the length of the pond (Fig. 1). When the ponded area retains significant transport capacity, trapping efficiency is reduced and a transport capacity or sediment re-entrainment term must be added.[4]

Increased Infiltration of Water into Soil

Vegetation increases infiltration by: 1) reducing the development of surface seals that limit infiltration rates; 2) increasing soil water storage capacity through evapotranspiration; and 3) developing soil macroporosity through root growth and enhanced activities mesofauna such as earthworms and ants. By covering the soil and absorbing the kinetic energy of raindrops, vegetation can prevent the detachment and rearrangement of soil particles that result in the creation of soil seals[5] and thus increases infiltration. Although water use varies with species and climate, vegetation transpires approximately 0.3 m^3 of water for each kg of above-ground dry matter produced.[6] This transpiration leaves more capacity in the soil for infiltration of subsequent rains and thus reduces runoff and erosion.[7] Vegetation increases soil macroporosity directly through root growth[8] and indirectly by improving the habitat and activity of mesofauna.[9] By slowing runoff,

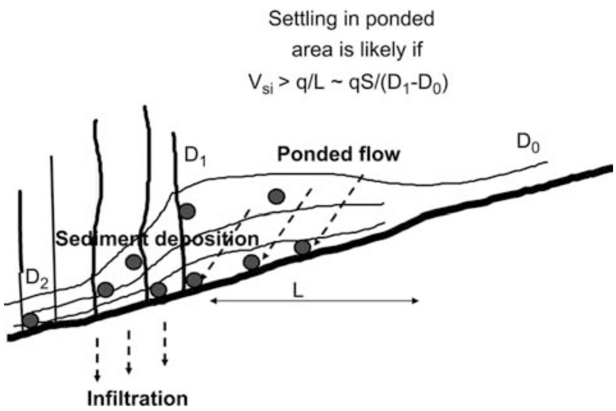

Fig. 1 Schematic illustration of how vegetative buffers slow runoff, increasing flow depth and trapping sediment.

vegetation increases the depth of ponded water and the area of soil that that is submerged, thus increasing opportunities for macropore flow.

Reduced Soil Erodibility

Soil erodibility refers to the ease with which soil particles (primary or aggregates) can be detached and transported by the shear forces associated with raindrop splash or flowing water. Soil with increased organic matter content has greater aggregate stability,[10] and hence greater resistance to detachment and transport. The effects of vegetation on reducing erodibility include consolidation of soil with time after tillage and binding together of soil particles by roots and by microorganisms that use plant biomass and exudates as a food source.[11]

VEGETATIVE BUFFERS

Buffer Types

Conservation buffers designed to reduce soil erosion and/or sediment delivery are usually areas of perennial vegetation placed at critical points in a landscape. These buffers may be located along stream banks, along the edges of fields, or may be placed within fields. To distinguish among these buffer types, the nomenclature of the U.S. Department of Agriculture—Natural Resources Conservation Service (NRCS) is adopted.

The seven conservation buffers types that reduce sediment delivery in runoff are summarized in Table 1. Practices normally located at the edges of fields are listed first, and those usually placed within fields are listed last. In addition to controlling erosion and/or reducing sediment delivery, many of these

Table 1 Comparison of water erosion control purposes and selected criteria of buffers types in the USDA-NRCS National Handbook of Conservation Practices that can be used to reduce sediment

		Erosion control purposes		Criteria					
Buffer type	NRCS code	Sheet-and-rill erosion	Concentrated flow erosion	Field slope (%)	Maximum strip gradient	Minimum strip width (SW) (m)	Strip spacing	Maximum field length	Minimum stem density
Riparian forest buffer	391		+		Along stream corridor	11			
Field border	386		+		Along field edge	6			
Filter strip	393			1–10	<0.5%	6		50 × SW	1500 m^{-2}
Grassed waterway	412		+		Along flow gradient		In concentrated flow areas		n-VR curve and permissible velocity
Alley cropping	311	+			Contour	6	Species light requirements		
Contour buffer strip	332	+		2–8	<2%	5 (Grass)	1/2 of RUSLE critical slope length (CSL)	RUSLE	540 m^{-2} (Grass)
						9 (Legume)		CSL	320 m^{-2} (Legume)
Vegetative barrier	601	+	+		<1%	1	1.3–2.0 m		Depends on stem diameter (Table)

Source: http://www.ftw.nrcs.usda.gov/nhcp_2.html.

Fig. 2 Vegetative barriers of vetiver grass (*Vetiveria zizanioides*) planted in rows on contour lines to hold the soil in St. Vincent, British West Indies, during the 1950s.[12]

buffers can also serve additional purposes such as improving water quality and providing wildlife habitat. Current national standards for these practices are given in the NRCS National Handbook of Conservation Practices, which is available on the internet: http://www.ftw.nrcs.usda.gov/nhcp_2.html. Descriptive information about each practice can be found in the CORE4 training materials: http://www.nhq.nrcs.usda.gov/technical/ECS/agronomy/core4.pdf. Local specifications criteria can be found in the local NRCS Field Office Technical Guide.

The edge-of-field buffers are: Riparian forest buffer (RFB), filter strip (FS), and field border (FB). An RFB is a forested area adjacent to a water body and is frequently combined with grass buffers. A field boarder is a grassed field margin. Because it may be used for parking and turning equipment, a FB is also usually wider than the minimum indicated in Table 1. In contrast to an FB, traffic is usually excluded from an FS and vegetation and slope requirements are far more stringent (Table 1). Generally, edge-of-field buffers are designed primarily to trap sediment and infiltrate water, not to control in-field erosion. The RFB is an exception in that it can control concentrated flow erosion caused by out-of-bank flood flows. The FB controls local scour on sloping head lands where concentrated water flows enter or exit a field. To properly function, these edge-of-field buffers require that runoff pass through them as diffuse, sheet flow.

The other four buffer types in Table 1 function within fields and are designed to control in-field erosion. Three of these buffers, alley cropping (AC), contour buffer strip (CBS), and vegetative barrier (VB) control sheet-and-rill erosion by interrupting hillslopes with strips of permanent vegetation aligned close to the contour (Fig. 2). The widths of these buffers are often varied so that the edges of each cropped zone stay parallel and within strip gradient specifications (Table 1). Alley cropping involves growing crops and forages between strips of trees. Vegetative barriers are usually narrow strips of large stiff-stemmed grasses (Fig. 2). Contour buffer strips are somewhat wider strips with less stringent vegetation and contour alignment requirements (Table 1).

Only two buffer practices, grassed waterway (GW) and VB, may be specifically designed to control in-field concentrated-flow erosion. Grassed waterways are oriented up-and-down the slope and are planted with vegetation that is intended to be submerged while functioning. In contrast, VB designed to controlling

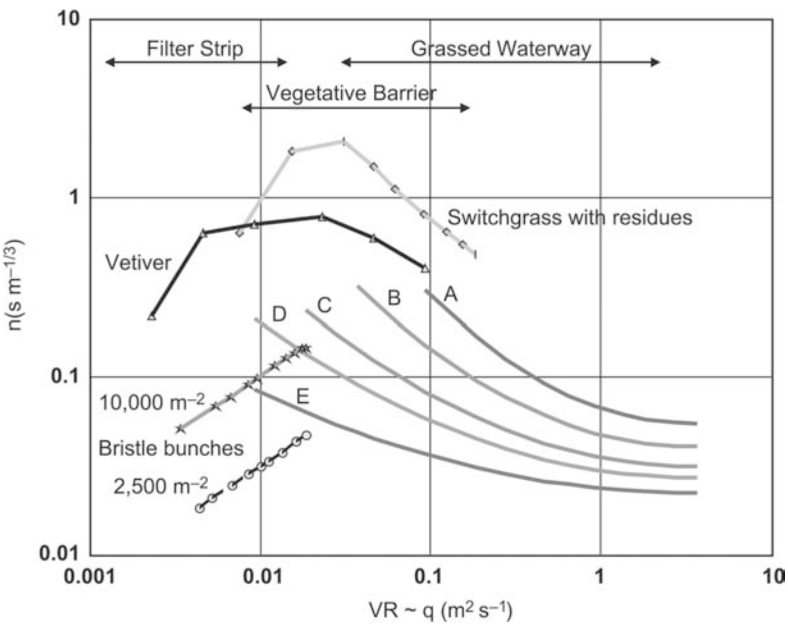

Fig. 3 Hydraulic roughness of vegetated areas first increases with increasing flow as more vegetation interacts with the flow, then decreases with increasing flow as flow approaches the height of the vegetation and submerges it. *Source*: Data for A–E from Ref.[15]; brush bristle data from Ref.[13]; switchgrass (*Panicum virgatum*) data from Ref.[16]; vetiver from Dabney (unpublished).

concentrated-flow erosion are planted perpendicular to the flow direction and are intended to remain unsubmerged while retarding runoff.

Buffer Hydraulic Resistance

The hydraulic resistance of vegetation frequently is parameterized with Manning's equation:

$$V = \frac{1}{n} R^{2/3} S^{1/2} \tag{2}$$

where V is the average flow velocity, R is the hydraulic radius (flow-area divided by wetted perimeter), S is the land slope gradient, and n is a hydraulic resistance parameter. Fig. 3 shows how Manning's n varies with the product V and R for three kinds of buffer vegetation. At low flows with unsubmerged vegetation, the hydraulic radius reduces to the flow depth, H, and VR equals the specific discharge. When the dominant component of hydraulic resistance is drag on emergent stems that are uniform with height, such as with the simulated FSs made of brush bristles (Fig. 3) in a flume with a smooth floor,[13] average velocity remains constant with increasing flow and n increases in proportion to the 2/3 power of discharge.[14]

At high flows, all of the vegetation is submerged and the main factor determining hydraulic resistance is the length of the stems that are dragging in the flow.[15] As discharge increases, more and more of the flow occurs in the zone above the submerged vegetation until eventually the hydraulic resistance of the vegetation becomes a constant. The vegetal retardance curve labeled "A" in Fig. 3 represents 0.9–1.0 m tall vegetation while "E" reflects vegetation that had been burned or mowed at about 4 cm height. In designing a GW, the erodibility of the underlying soil and the growth characteristics of the vegetal cover determine a maximum permissible velocity or the allowable hydraulic stress on the soil, and the channel is designed with dimensions great enough that, with expected vegetation, the permissible velocity or stress will not be exceeded at the design discharge.

Vegetative barriers have application at specific discharges that span the range between those of FS and GW (Fig. 3) and can thus be used to complement other buffer types by spreading out concentrated runoff. At low flows, the hydraulic resistance of VB increases more rapidly than the 2/3 power of discharge because stems and leaves become less clumped together, increasing projected area with increasing height in the lower canopy. At greater discharges, flow-depth increases to the point where stems begin to thin out or bend. Then average velocity increases, the flow resistance, expressed as Manning's n, ceases to increase and begins to decline, even while flow depth may continue to increase with increasing discharge.[16] The stiff grasses used to form VB remain erect and emergent at greater flows than other vegetation types in Fig. 3 because the large-diameter stems are stiffer and are on the order of 2 m tall. The enhanced growth and residue loading noted to occur at the edge of all buffers are also important factors that give VB greater hydraulic resistance than retardance class A vegetation. Riparian forest buffer vegetation, of course, remains erect at even greater flows than does VB vegetation, but usually offers less hydraulic resistance at low flows.

Erosion Problems: Historical Review

Andrew S. Goudie
St. Cross College, Oxford, U.K.

INTRODUCTION

Erosion is a process that has operated since the earth was created. Erosion of soil by water has likewise been a process that has been an entirely natural phenomenon ever since soils first appeared. However, during the last few millions of years that humans have inhabited the earth, their activities have caused spasms of accelerated soil erosion associated with land cover and land use changes. In classical times, it was noted that slopes in areas such as Greece, Turkey, and the Levant had been destabilized by deforestation and overgrazing. Undoubtedly, such actions as the deliberate setting of fire, adoption of pastoralism and agriculture, deforestation, urbanization, and use of machinery to move and disturb the soil have all contributed to accelerating rates. Appreciation of the nature, causes, and consequences of soil erosion has a long history, and during the 20th century, there were some notable studies of the phenomenon[1–3] stimulated by such events as The Dust Bowl in the United States and the menace of *donga* (gully) formation in Africa.[4]

However, it has never been easy to separate the role of climatic fluctuations in causing soil erosion from the role of human activities, and this has spawned long-running debates about the origin of phases of slope erosion, valley incision, and valley sedimentology in areas such as the Mediterranean basin[5,6] and the bottomlands of the western United States (see, for example, the discussion of *arroyos*[7]). Difficulties of determining how rates have been changed by human activities have also been bedeviled by an absence of direct long-term monitoring data. However, erosion leads to sedimentation, and so the study of rates of sediment accumulation in lakes, swamps, estuaries, reservoirs, and river floodplains provides a means of obtaining long-term data from which erosion rates can be inferred.

DEFORESTATION

Deforestation[8] has been a crucial cause of accelerated soil erosion in many areas (Fig. 1). Forests protect the underlying soil from the direct effects of rainfall, generating an environment in which erosion rates tend to be low. The canopy shortens the fall of raindrops, decreases their velocity, and thus reduces their kinetic energy. Most canopies reduce the erosion effects of rainfall. The presence of humus in forest soils[9] absorbs the impact of raindrops and gives them extremely high permeability. Thus forest soils have high infiltration capacities. Forest soils also transmit large quantities of water through their fabrics because they have many macropores produced by roots and their rich soil fauna. They are also well aggregated, making them resistant to both wetting and water drop impact. This superior aggregation is a result of the presence of considerable organic material, which is an important cementing agent in the formation of large water-stable aggregates. Furthermore, earthworms also help to produce large aggregates.

It is therefore to be expected that with forest removal, rates of soil loss will rise and mass movements will increase in magnitude and frequency. The rates of erosion will be high if the ground is left bare; under crops, the increase will be less marked. Furthermore, the method of plowing, the time of planting, the nature of the crop, and the size of the fields will influence the severity of erosion.

SEDIMENTATION RATES

A good example of using long-term sedimentation rates to infer long-term erosion rates is provided by a study[10] of the Kuk Swamp in Papua New Guinea. This identified low rates of erosion until 9000 BP, when, with the onset of the first phase of forest clearance, they increased from 0.15 to about 1.2 cm/1000 years. Rates remained relatively stable until the last few decades when, following European contact, the extension of anthropogenic grasslands, subsistence gardens, and coffee plantations produced a rate that is very markedly higher: 34 cm/1000 years.

A further long-term study of the response rates of erosion to land cover changes is provided by a study undertaken on the North Island of New Zealand.[11] During the last 2000 years of human settlement, catchments underwent a change from indigenous forest fern/scrub following Polynesian settlement (c. 560 years BP) and then a change to pasture following European settlement (AD 1878). Sedimentation rates under European pastoral land use were between 5 and 6 times the rates that occurred under fern/scrub and 8–17 times

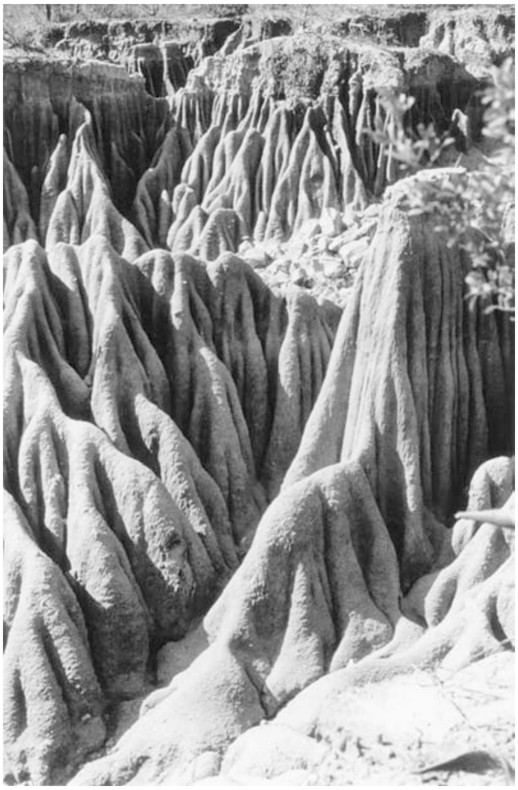

Fig. 1 An erosional badland (donga) in Swaziland, Southern Africa. It may date back to deforestation in Iron Age times.

the rates under indigenous forest. A broadly comparable study[12] looked at rates of infilling of an estuary fed by a steepland catchment in another part of New Zealand.

In pre-Polynesian times, rates of sedimentation were 0.1 mm year^{-1}, during Polynesian times, the rates climbed to 0.3 mm year^{-1}, while since European land clearance in the 1880s, the rates have shot up to 11 mm year^{-1}.

Major changes in rates of erosion have also taken place in Australia as a result of European settlement over the last two centuries.[13] Particularly important was the introduction of grazing stock.

There is increasing evidence to suggest that silty valley fills in Germany, France, and Britain, many of them dating back to the Bronze Age and the Iron Age, are the result of accelerated slope erosion produced by the activities of early farmers.[14] Indeed, in recent years, various studies have been undertaken with a view to assessing the importance of changes in sedimentation rate caused by humans at different times in the Holocene in Britain. Among the formative events that have been identified are initial land clearance by Mesolithic and Neolithic people; agricultural intensification and sedentarization in the late Bronze Age; the widespread adoption of the iron plow in the early Iron Age; settlement by the Vikings; and the introduction of sheep farming.

A core from Llangorse Lake (Brecon Beacons, Wales)[15] provides long-term data on changing rates of sedimentation. The 13-fold increase in rates after 5000 BP seems to have occurred rapidly and can be attributed to initial forest clearance. The second dramatic increase of more than 4-fold took place in the last 150 years and is a result of agricultural intensification.

The work on the lakes of the Peten region of northern Guatemala (Central America), an area of tropical lowland dry forest, is also instructive with respect to early agricultural colonization.[16] Combining archaeology and lake sediment stratigraphy, the diverse environmental consequences of the growth of Mayan civilization were reconstructed.

This showed a dramatic growth after 3000 years BP, but collapsed in the 9th century A.D.. The hypotheses put forward to explain this collapse include warfare, disease, earthquakes, and soil degradation. The population has remained relatively low ever since, and after the first European contact (A.D. 1525), the region was virtually depopulated. The period of Mayan success saw a marked reduction in vegetation cover, an increase in lake sedimentation rates and in catchment soil erosion, an increased supply of inorganic silts and clays to the lakes, a pulse of phosphorus derived from human wastes, and a decrease in lacustrine productivity caused by high levels of turbidity.

Serious sedimentation of bays and estuaries has been caused by human activity on the eastern coast of the United States. Gottschalk[17] calculated that at the head of the Chesapeake Bay, 65 million m^3 of sediment was deposited between 1846 and 1938. The average depth of water over an area of 83 km^2 was reduced by 0.76 m. New land comprising 318 ha was added to the state of Maryland and, as Gottschalk remarked, "the Susquehanna River is repeating the history of the Tigris and Euphrates." Much of the material entrained by erosion on upper slopes as a result of agriculture in Maryland, however, was not translocated as far as the coast. Only about one-third of the eroded material left the river valley.[18] The remainder accumulated on floodplains as alluvium and colluvium at rates of up to 1.6 cm/year. Similarly, an intensive augering survey of floodplain soils in Wisconsin established that, since the development of agriculture, floodplain aggradation had proceeded at a rate of approximately 0.85 cm/year.[19] Channel and floodplain aggradation caused the flooding of low alluvial terraces to be more frequent, extensive, and deeper. The rate of sedimentation has since declined[20] because of less intensive land use and the institution of effective erosion control measures on farmland.[21]

Various attempts have also been made to establish rates of accelerated erosion on the plainlands of Russia.[22] It has been calculated that during the period

1696–1796, a total of $19.5 \times 10^9\,m^3$ of soil was mobilized by sheet and rill erosion; for 1796–1887, it was $36.7 \times 10^9\,m^3$, and for 1887–1980, it was $42.5 \times 10^9\,m^3$. This increasing trend was a result of an increase in the area under cultivation and the assimilation of land more prone to erosion.

CONCLUSION

Accelerating rates of soil erosion are neither inevitable nor universal. In some parts of the world (e.g., New England or steep slopes in some of the Mediterranean countries[23]), the agricultural frontier has retreated and pressures on the soil have been reduced. Elsewhere, a whole range of soil conservation techniques has been introduced with some success. Nevertheless, accelerated soil erosion has a number of adverse consequences: loss of soil resource, sedimentation behind dams and in lakes, and a loss of water quality because of turbidity and other effects.

Erosion Research: History

Rattan Lal

Columbus, Ohio, U.S.A.

INTRODUCTION

Soil erosion implies detachment, transport, and deposition of soil by energy from water, wind, or gravity. Specific sources of energy to detach and transport soil are called ''agents'' of erosion. Soil erosion is a natural process and is responsible for formation of the most fertile soils, such as alluvial soils of the river valleys (e.g., Indus, Ganges, Euphrates, Yangtze, Nile) and loess soils of the savannas (e.g., Loess Plateau in China, the Palouse region of northwestern United States). The natural rate of erosion may be less than $0.5\,mm\,yr^{-1}$, and often as low as $0.1\,mm\,yr^{-1}$. The natural processes, however, can be accelerated by anthropogenic activities drastically exacerbating the rate of soil detachment, transport, and deposition. In contrast to the natural process, the accelerated soil erosion is an extremely destructive process leading to severe adverse effects on long-term productivity on-site, and pollution of natural waters and sedimentation of waterways and reservoirs off-site. Anthropogenic activities that accelerate the soil erosion process include deforestation, biomass burning, conversion of natural to agricultural ecosystems, and plowing especially up and down the slope for monoculture of open-canopy crops (e.g., corn) without protective ground cover of crop residue or a cover crop. The accelerated rate of erosion may be $0.5\,mm\,yr^{-1}$ to $10\,mm\,yr^{-1}$. For loess-derived soils, such as those in the Yangtze basin in China, the accelerated rate may be several cm yr^{-1} causing severe problems of sedimentation off-site.

On-site effects of accelerated erosion on reduction in long-term soil productivity are attributed to decline in effective rooting depth, reduction in plant available water capacity, depletion of soil organic matter content and the attendant adverse effects on soil structure, and loss of plant nutrients. Whereas the loss of plant nutrients (e.g., N, P, K) can be replenished by addition of fertilizers, that of the available water capacity is difficult to compensate. Thus, the problem of accelerated soil erosion is closely linked to the issue of sustainability. Some land uses and farming/cropping systems are not sustainable because of the severe problem of accelerated soil erosion.[1]

SOIL EROSION AND HUMAN CIVILIZATION

Settled agriculture originated some 10 to 13 millennia ago in major river valleys by the so-called hydric civilizations. Simple tools were developed between 5000 and 4000 BC to place and cover seed in the soil, to eradicate weeds, and bury the crop residue. A written record of plow (or ard) is found in Mesopotamia about 3000 BC.[2] Archaeological evidence shows the use of animal-driven plows dating back to 2500 BC in the Indus Valley.[3] Since their humble beginnings from 5000 to 4000 BC, the tools used to turn over, mix, and pulverize the soil, have been drastically transformed to suit the soil-specific needs for mechanized farm operations. Soil can now be plowed deeper, pulverized more, and disturbed more than ever before. In fact, plowing renders the soil in a state of an unstable equilibrium that exacerbates risks of soil erosion by water and wind.

Where the natural soil erosion created the most fertile soils in river valleys that were the cradle of modern civilization, the on-set of accelerated erosion by plowing toppled many of the same civilizations by washing/blowing away the mere foundation on which they developed. Accelerated erosion caused some of the thriving civilizations to vanish.[4] Indeed, it was the accelerated soil erosion in the Mediterranean Basin that destroyed the Roman Empire and toppled the Phoenicians.[5] Siltation of the irrigation systems in ancient Mesopotamia ruined the once thriving agriculture established since 10,000 BC.[6] The ancient kingdoms of Lydia and Sardis were ruined by severe soil erosion.[6] The demise of Harappan–Kalibangan culture in the Indus Valley[7] and that of Incas in Central America[4] has been attributed to soil erosion and the attendant degradation. This ''quiet crisis,'' analogous to ''cancer'' of the land, has ''plagued'' the earth and challenged farmers ever since the time they began to use the land for settled and intensive agriculture.[8]

SOIL EROSION RESEARCH

Managing and controlling soil erosion has been a challenge since the dawn of settled agriculture. An attempt to control erosion on sloping lands led to introduction of an innovative ‘‘terraced’ agriculture. ‘‘Terracing’’ has been a cultural tradition in many ancient civilizations around the world including the Middle East (The Phoenicians), East and Southeast Asia, West Asia (Yemen), and Central and South America. The Incas designed elaborate systems of stonewalled terraces in Peru.[9,10]

Modern research on soil erosion process and technologies to control it began in the United States during the 1930s. Since that time, both basic and applied aspects of soil erosion research have been conducted throughout the world.[11]

(1) *Soil Erosion Research in the CGIAR System*: Some applied issues of soil erosion research are addressed at several international agricultural research centers (IARCs) managed by the Consultative Group on International Agricultural Research (CGIAR). Relevant among these are four natural resources management centers including International Institute of Tropical Agriculture (IITA) in Ibadan, Nigeria, established in 1967; Centro Internacional de Agricultura Tropical (CIAT) in Cali, Colombia, also established in 1967; International Crops Research Institute for the Semi-Arid Tropics (ICRISAT) near Hyderabad, India, and the International Board for Soil Research and Management (IBSRAM) in Bangkok, Thailand, established in 1984. Extensive research on plot and watershed scales was done during the 1970s and 1980s at IITA.[12,13] Similar watershed management research was conducted at ICRISAT during the 1970s and 1980s.[14] Plot-scale experiments on erosional impacts on soil quality and productivity were conducted during the 1980s and 1990s at CIAT[15] and IBSRAM.[16] Soil erosion research at IBSRAM was sponsored by the Australian Center for International Agricultural Research (ACIAR). An important aspect of the erosion research at IARCs involves development of networks to establish cooperative programs with national agricultural research institutes (NARIs) in ecoregions of their mandate. An international conference on ‘‘Soil Conservation and Management in the Humid Tropics’’ held at IITA in 1975[17] brought together a group of scientists that eventually created a network that periodically organizes conferences around the world under the auspices of ‘‘International Soil Conservation Organization’’ (ISCO).[18] Closely related with ISCO is the World Association of Soil and Water Conservation (WASWC).[19]

(2) *United Nations and Related Organizations*: Other international organizations that have soil erosion research at international scales include the Food and Agricultural Organization (FAO) of the United Nations in Rome, Italy, and the United Nations Environment Program (UNEP) in Nairobi, Kenya. The FAO attempted to develop a methodology for assessment of soil degradation by erosion and other processes,[20] and organized a network to assess erosional effects on productivity.[21] Global research on desertification and its control has been organized by UNEP.[22]

In addition to ISCO and WASWC, there are other international professional societies whose members are involved in research on soil erosion. Two important organizations among these are the International Association of Hydrological Sciences (IAHS), and the International Soil Tillage Research Organization (ISTRO). Activities of IAHS have been sponsored by the United Nations Educational, Scientific and Cultural Organization (UNESCO).[23,24] Members of ISTRO are primarily involved in soil tillage research[25] but also address the problem of soil erosion. The International Union of Soil Sciences (IUSS) has established a special commission dealing with soil erosion and conservation.[26]

(3) *National Research Organization*: Soil erosion and its control is among priority research issues with most national research organizations in soil, agronomy, hydrology, and agricultural engineering. Many countries have special departments dealing with the issue of soil conservation such as the Soil Conservation Service (SCS) now Natural Resource Conservation Service (NRCS) in the United States. The SCS was established during the ‘‘dust bowl’’ era in the 1930s by H.H. Bennett. Accordingly, national societies have been established in several countries to address the issue. Some examples of such societies are Soil and Water Conservation Society (SWCS) of the United States and Canada; Australian Society of Soil and Water Conservation; Indian Society of soil and Water Conservation, etc. In addition to annual conferences, some of these societies also publish journals and books devoted to the relevant theme of soil erosion and its impact on productivity, water quality, and the greenhouse effect.

There are also national laboratories and institutions involved in both basic and applied research. Two examples of such institutions are the National Soil Erosion Research Laboratory, West Lafayette, Indiana, U.S.A.; and Central soil and Water Conservation Research and Training Institute, Dehra Dun, U.P., India.[27] Similar institutions exist in China and elsewhere. There are also regional organizations involved in soil and water conservation research. The East African Agricultural and Forestry Research Organization (EAFRO) established long-term experiments on watershed management in east Africa.[28] Similar, long-term experiments were established in Francophone Africa by ORSTOM and IRA.[29,30] Long-term experiments were also established in southern Africa by Hudson.[31] A regional project in the United States entitled "Soil Erosion and Productivity" (NC-174) was established in early 1980s to assess the impact of erosion on crop yields.[32]

FUTURE RESEARCH NEEDS

Soil erosion research is now at the crossroads. The focus during the 20th century has been on measurement and prediction of the rate of erosion and on-site effects of erosion on loss of agronomic productivity. Erosion effects on water quality, as affected by dissolved and suspended loads through non-point source pollution, have also been addressed. The emphasis has been on the study of erosional processes at the plot scale or landscape level. Soil erosion will continue to be an important and challenging process in relation to sustainable management of soil and water resources during the 21st century. However, there is a strong need for a paradigm shift. In addition to understanding basic processes at aggregate and soilscape level, it is also important to study processes at watershed and river basin scales.[33] There is a strong need to link erosional processes with water and energy balance, and cycling of elements with particular reference to C, N, and P. Linking erosional processes with C balance at the watershed scale is a high priority in order to assess the fate of C and N redistributed over the landscape and transported to the aquatic ecosystems. It is important to establish the cause–effect relationship between emissions of greenhouse gases (CO_2, CH_4, N_2O, NO_x) and erosional processes. The projected global warming has raised new issues related to soil erosion and emission of greenhouse gases. Do erosion and deposition cycles exacerbate emission of greenhouse gases from soil?[34] What is the fate of carbon in erosion-displaced sediments?[35] Does sedimentation and burial of C in depressional sites and aquatic ecosystems take C out of circulation and a long-term sequestration?[36] What may be the effects of predicted global warming, estimated to be 1–4°C by the end of the 21st century, on soil erodibility and soil's susceptibility to erosion at soilscape, landscape, and the watershed scales? These environmental concerns are over and above the on-site effects of erosion on decline in long-term productivity. A study of such processes necessitates establishment of long-term coordinated research at regional and international scales.

CONCLUSION

Soil erosion will remain a serious issue during the 21st century. Traditionally soil erosion research has been conducted by the CGIAR, FAO, UNEP, and national organizations. The empirical research conducted during the second half of he 20th century focused on measurement of erosion risks, and on the on-site loss in productivity. There is a need for a paradigm shift in conducting research at watershed scale and linking erosional processes to water and energy balance and cycling of C, N, P, and other elements. It is important to establish links between soil erosion and the emission of greenhouse gases into the atmosphere. The impact of projected global warming, and that of increase in atmospheric concentration of CO_2 and other greenhouse gases, on erosional processes need to be assessed. The much needed paradigm shift will necessitate establishment of regional and international networks to address issues of global importance including erosional effects on soil quality, water quality, and emission of greenhouse gases.

Erosion Research: Instrumentation

Gary D. Bubenzer
Department of Biological Systems Engineering, College of Agriculture and Life Sciences, University of Wisconsin–Madison, Madison, Wisconsin, U.S.A.

INTRODUCTION

Soil erosion and infiltration research may be enhanced by the use of simulated rainfall. Simulators make it possible to control rainfall characteristics such as intensity, duration, and energy levels. Storms may be duplicated at any time or location. Raindrops may be formed on the tips of drop formers or by nozzles. Except for specialized applications, simulators using nozzles to form drops are preferred because of the ability to produce high impact energy from relatively short fall heights.

OVERVIEW

Sediment laden runoff is often sampled by depth integrating or depth integrating samplers. Depth integrating samplers are preferred whenever there is a non-uniform distribution of sediment in the runoff; while flow with uniformly distributed sediment loads may be sampled form a single point. Samples may be collected in specified time increments or in constant runoff volume increments.

Rainfall Simulation

Early soil erosion researchers were dependent upon natural rainfall for their work. As a result, they had no control over the nature or timing of the rainfall event. Without this control it was impossible to predict accurately, soil conditions or crop stage at the time of the storm. It was impossible to duplicate storm events at various times and locations. Valuable data was often forgone simply because it did not rain at the desired time and location.

Approximately 70 yr ago, researchers began to use simulated rainfall on erosion plots. Earlier attempts consisted of covering the plots with water from sprinkling cans and other crude water application sprinklers. While these systems allowed researchers to apply given amounts of water to plots under controlled soil–plant conditions, the water applied had little similarity with naturally occurring rainfall.

Over time criteria were developed for improved rainfall simulators.[1] Among the criteria were:

- Drop size distribution near that of natural rainstorms of the geographical area.
- Drop impact velocities near those of natural raindrops.
- Intensities in the range of storm of interest.
- Plot area of sufficient size to satisfactorily represent the treatment and conditions being evaluated.
- Rainfall characteristics fairly uniform over the plot area.
- Rainfall application nearly continuous.
- Angle of impact nearly vertical.
- Capability of reproducing storm durations at selected intensities.
- Portability of movement from site to site.
- Satisfactory operation under a wide range of climatic conditions.

Two types of rainfall simulators were developed. The first were simulators that produced rainfall by forming drops on the tips of yarn, hollow glass tubes, hypodermic needles, or plastic tubing. Size and rate of drop formation (intensity) were controlled by the size and length of the dripper and the water head. Drops broke from the end of the tube when the weight of the drop was sufficient to overcome the surface tension. The primary advantage of the drip type simulators is the researchers' ability to accurately control drop sizes. Drop size was primarily a function of the tube material and diameter with little change in diameter over a relatively wide range of intensities. Drip simulators, however, had two serious limitations. Since the drops form on the tip of a dripper, they have no initial fall velocity. This means, they must fall from a considerable height in order to reach terminal velocity at the soil to simulate natural rainfall's droplet velocity. Such fall height are difficult to obtain, especially for field research and difficult to control under adverse climatic conditions. Secondly, a very large number of drippers per unit area are needed to provide uniform application. Therefore, drip simulators are very difficult to use in plots larger than a few square feet or under outdoor conditions.

The second general type of rainfall simulators uses spray nozzles to produce raindrops. Early nozzles, such as those used for watering gardens tended to produce large drops, high intensities, and low impact energies. Over time, these nozzles have been replaced by ones that produce drop size distributions, more similar to those of natural storms, at pressures that produce near terminal impact velocities. However, most of these nozzles produce intensities well above those found in natural storms of interest. To overcome these high intensities, intermittent rainfall is produced by intercepting a portion of the water before it strikes the soil surface. Mechanical systems for rainfall interception have been replaced by computer-controlled systems that make it possible to produce storms with varying intensity patterns.

Modern rainfall simulators can reproduce storms with desired rainfall characteristics on command. This means that soil conditions and cover conditions at the time of rainfall can be predetermined. Identical storms can be produced at different locations and at different times. Such simulators have provided researchers with a tool for greatly accelerating the knowledge of erosion processes.

Sampling Eroded Sediments

Sediment sampling is necessary to determine the concentration of sediment in the runoff water and the sediment load of a storm or series of storms. In erosion research the primary parameters of interest are the sediment load (total sediment lost per storm or series of storms) and the sedigraph (sediment eroded as a function of time). In order to determine these two parameters, it is necessary to measure both the flow and the sediment. Flow measurements are usually made through flumes, weirs, or other rated cross sections. Only instrumentation for the collection of sediment will be discussed in this article; for information on flow measurement the reader is referred to Dendy Allen, and Piest.[2]

Total flow samplers consist of a collection container large enough to collect all of the runoff and sediment from the design storm. Because of limitations on container size, use is limited to small plots. Such plots are usually not applicable to erosion studies because they are not large enough to allow the erosion process to develop. Therefore, most erosion studies use partial flow samplers where only a fraction of the total runoff is collected.

One of the simplest partial flow samplers is the Multislot divider.[2] A plate with multiple slots is inserted into the runoff stream. Flow through a portion of the slots, depending upon the fraction of the flow to be sampled, is diverted into the sampling container. The remainder of the flow is bypassed. The devices are simple to construct and install and require no power source. They may be used to determine sediment load, but do not provide data for the development of a sedigraph.

The Coshocton runoff sampler consists of a small flume and a slotted rotating disk.[2] As water exits the flume, the flow across the face of the disk causes the slotted disk to rotate. Only that portion of the water and sediment striking the slot is diverted into the sampling container. The remainder of the water and sediment is bypassed. The Coshocton samplers do not require an external power source. Like the slotted samplers, they are used primarily for determining total load.

Pump samplers are commonly used to collect sediment and runoff samples for modern erosion research. Major components of a pump sampler include:

- The intake that collects water from one or more points in the flow system.
- The pumping system to move the water from the intake to a series of collection containers.
- A flushing system to ensure that samples and successive samples are not contaminated by water remaining in the system from previous samplings.
- A collection system usually consisting of a series of jars for holding the samples.
- A control system for determining the sampling interval.
- A battery or a.c. current power supply.

Intake units may be either depth integrating or time integrating units. Depth integrating units consist of multiple inlets placed at various depths throughout the flow profile or of a single intake unit that is moved vertically during sampling. Such units are used to ensure accurate sampling when the sediment in the flow is stratified. Point integrating samplers consist of a single intake unit place in the flow stream. They provide satisfactory results when the sediment is well mixed in the runoff stream.

The control system is used to determine the sampling pattern. Two approaches are used. Samples may be collected at time intervals or at volumetric intervals. Samples may be collected at predetermined time intervals. Usually each sample is placed in a separate container. By combining the sediment concentration found in each sample with the hydrograph it is possible to determine not only the total load, but also the sedigraph for the storm event. Composing of sample for determination of sediment load or pollutant transport is not possible since each sample represents a different portion of the total flow.

Volumetric interval sampling is based upon flow volume rather than time. Samples are collected at predetermined flow volume intervals. Sediment load and the sedigraph are easily determined since each sample represents the same volume of flow. Volumetric sampling enables researchers to compose samples only when the total sediment load is needed.

INTRODUCTION

In 1997, the United States lost almost 970 million metric tons of soil through erosion by water.[1] Soil erosion has always taken place and always will. It is a natural process. The surface of the earth is continually undergoing what might be called a ''face lift in slow motion.'' Slowly, the coastline is receding, the hills and mountaintops are being carried down to the valleys, and the river deltas are being enlarged. The form of erosion that occurs naturally, without man's influence, is called geologic erosion. Some of the best examples of geologic erosion are the Grand Canyon, the Badlands of South Dakota, the canyons of Utah, and the great river valleys. Without human interference, geologic erosion would occur at a low rate on level land; and on gentle slopes, erosion would only be a minor problem. In humid areas there is an ideal environment for plant growth, and thus, there would be protective cover for the soil, thereby further slowing the rate of erosion.

Agriculture and urban development has replaced protective cover with plants that are of more value to man. However, such plants often do not cover the soil as effectively as the natural growth. Some farmers leave the soil totally bare through much of the year. The result is that accelerated erosion may increase to destructive proportions on some soils, carrying away topsoil and nutrients, washing pollutants into streams, filling waterways with sediment, and reducing the natural productivity of the land.

Compared with the magnitude of the problem, the basic cause (raindrops and resulting runoff) may seem insignificant. Yet, falling raindrops strike the ground with surprising force and the cumulative effect is immense. With no vegetative cover or mulch to absorb the impact, rain is especially erosive on cropland left bare between plantings. To understand the problem, let us look at some of the mechanisms of erosion.

RAINFALL

Soil erosion is the detachment of particles from the soil mass and their transport downstream. When it rains, drops up to 6 mm in diameter bombard the soil surface at impact velocities of up to 9 m/sec.[2] In general, the more intense the rainfall, the larger the drop size will be.[3]

The constantly pounding raindrops dislodge soil particles and aggregates and splash them up to 1 m away.[4] When rain hits vertically on a horizontal surface, the splash is equal in all directions. On a slope, more of the splash goes downhill than uphill[5] (Fig. 1). In wind-driven rainfall, splash movement depends on slope and wind direction.

To observe the effects of splash erosion, look at a white fence or building next to bare soil just after a rain. Most likely, rain will have splashed soil as high as 1 m on the fence or building. Other visual reminders of erosion's impact are soil pedestals, which can be created during a heavy rain when particles underneath a stone or piece of residue remain protected (Fig. 2). Meanwhile erosion batters and washes away unprotected soil from around the object, sculpting a soil pedestal that corresponds to the shape of the stone or residue.

A raindrop falling on a thin sheet of water detaches soil particles more readily than one falling on dry soil. Splash erosion increases with surface water depth, but only up to a depth about equal to the raindrop diameter. Once the water becomes deeper, the splash effect is reduced.[6]

Actually, if water did not accumulate on and run off the soil surface, the splashing of soil particles would not be a major concern. In most cases, splashed particles are not moved far enough to greatly disturb the soil surface. But water does accumulate on the soil surface. If rain falls hard enough and long enough, the soil eventually will become saturated and the surface will seal. The ground will have trouble absorbing more water; and in low spots, water will collect in small ponds. If rain continues, these ponds ultimately will overflow and water will move downhill.

TRANSPORT

The concern about splashed soil becomes clearer because of transport processes. Raindrops dislodge

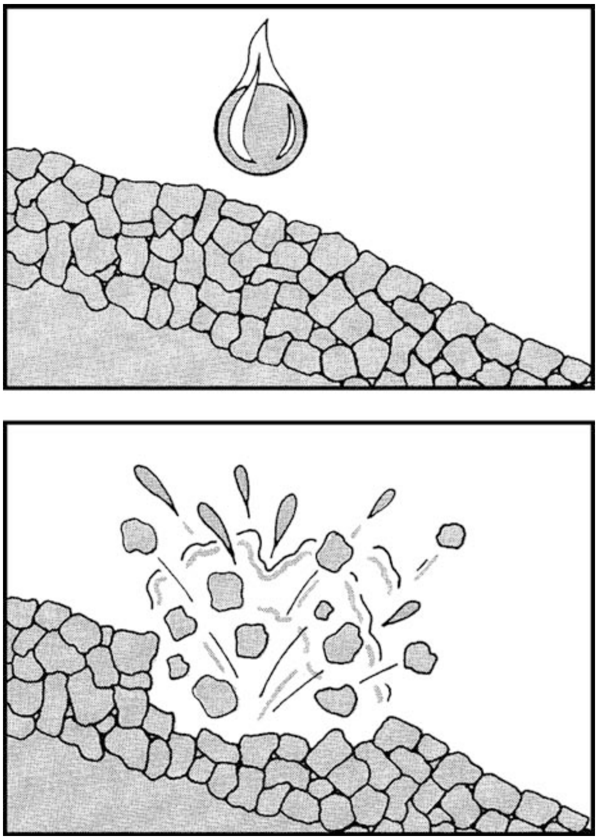

Fig. 1 Soil particles and aggregates are detached by raindrops.

particles from the soil mass and runoff water transports the eroded soil (Fig. 3). Unless there is runoff water, raindrops cannot do much damage. But by the same token, runoff water is dependent upon soil dislodged by raindrops for material to transport. An exception to this occurs when runoff moves as concentrated flow with sufficient energy to both dislodge and transport soil particles.

Fig. 2 Raindrop erosion has removed soil particles on all sides of this piece of crop residue creating a soil pedestal.

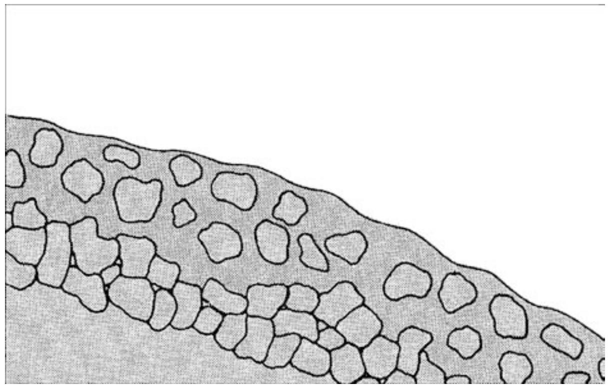

Fig. 3 Soil particles and aggregates are transported downslope with runoff water.

Water flowing off the soil surface (Fig. 3) provides the mechanism for transporting particles loosened by rainfall (Fig. 1). Although described as sheet flow, this type of flow seldom occurs in an uninterrupted sheet. Usually the water detours around clods, spills out of small depressions, and in general moves with sluggish irregularity. Even so, the water is able to carry soil particles. This type of erosion and transport is more properly called inter-rill erosion. The transport ability is influenced by the energy level of the flow, which in turn is dependent on the depth of flow and slope of the land. Flat areas have little or no runoff and low runoff velocities; consequently, little or no transport occurs. Runoff from steeper areas flows at greater velocities and may have considerable transport capability.

Sheet or inter-rill erosion is difficult to see, but its damage can be extensive. The destruction is more obvious when a plow turns up light colored subsoil on sloping land; which indicates that much of the topsoil has been eroded. A typical soil is made up of clay, silt, and sand particles. Erosion has a greater tendency to remove the finest material, the clay, than it does the coarsest material, the sand particles; however, most plant nutrients are attached to the fine, clay particles. So erosion, a selective process, steals the most valuable part of the soil, as well as important organic matter.

RILLS

When the thin layer of water moves downhill, it tends to concentrate in tiny channels called "rills." Rills look like miniature streams; bending and cutting through the soil. Raindrops continue to break apart the soil, but runoff also has built up enough momentum to break loose particles. More importantly, rills have an excellent ability to transport soil particles. This type of flow usually occurs on only a small percentage of a field, but because the flow is concentrated, it can

Fig. 4 An example of rill erosion.

cause erosion. The rills thus created leave small channels that can be obliterated by normal tillage operations (Fig. 4). Energy levels of water flowing in rills vary somewhat, depending on the depth of flow and slope of the channel. Long, steep slopes allow rivulets with considerable erosive power to develop.

In many situations, rill flow detaches less material than does splash erosion. However, while a rill is forming, raindrops continue to detach soil within shallow rills and from the surrounding soil surface. Eroded material is transported to the rills by sheet or inter-rill flow. Rill flow has an exceptional capacity to transport the detached particles. Because the flow is concentrated, material can be transported within these small channels. A few soils are very susceptible to rill erosion; thus any rill flow that develops can easily detach soil particles or aggregates.

GULLIES

Eventually, the rills in a field will merge to form larger channels. These may form even larger channels and can become deep enough to be labeled "gullies." Channels are defined as gullies when they cannot be obliterated with normal tillage operations. They are large, noticeable scars on the land. In many areas of the Midwest, gully erosion has divided fields into small parcels that are inefficient to farm (Fig. 5). Deep gullies with vertical side walls are a phenomenon found in the deep loess soils along the bluffs of the Illinois and Mississippi Rivers. Some can reach depths of 9 m (30 ft or more). Rills and gullies often progress upstream at a headcut or overfall (small waterfall). As the pool below the overfall enlarges, the turbulent water undercuts the overfall; eventually the soil sloughs off and is transported downstream.

Gully erosion can be deceiving. Although it is the most obvious form of erosion, it usually does not remove as much soil as the other, less visible forms

Fig. 5 Gully erosion on sloped land.

of erosion. Gully erosion has been shown to provide from 0% to 89% of the sediment yield to streams.[7] Thus, gully erosion may be a significant problem depending upon the soil and topography. Data from Illinois taken in 2000 indicates that 22% of the fields are affected by various degrees of gully erosion.[8]

A very wide rill that has eroded soil through the tilled layer has been termed an "ephemeral gully." Although an ephemeral gully can be obliterated with modern tillage equipment, such a rill has been named a gully because of the great mass of material removed (Fig. 6). Ephemeral gullies are somewhat transitory rather than permanent like classical gullies.

Streambank erosion is a process similar to rill and gully erosion that occurs along the edge of perennial and ephemeral streams. Undercutting and sloughing are the primary agents of detachment, with sediment falling directly into the flowing water that transports the sediment downstream.

DEPOSITION

Sedimentation from soil or other materials carried by moving water may occur with sheet, rill, gully, and stream flow. Natural or artificial dams are a prime

Fig. 6 An ephemeral gully with sheet or interrill erosion deposition at the edges.

place for runoff to collect. Large particles settle in quiet pools formed at these sites. When the water is slowly released, much of the material is deposited as sediment (Figs. 7 and 8).

Ponding is apt to occur in small depressions or above contour furrows in inter-rill areas. It may also occur above small debris dams formed from residue in rills and gullies, terrace channels, or reservoirs in large streams. In addition, dense vegetation can reduce the flow velocity, thereby allowing soil material to be deposited. Effects of this process are sometimes seen in grassed waterways where the center gradually fills with sediment.

Fig. 8 An example of sediment deposition near the edge of a field.

EROSION PROCESSES

All three processes of detachment, transport, and deposition occur during an erosive rainfall event. The extent that these processes occur are determined by the amount and intensity of rainfall, topography of the land surface, vegetative cover, and character of soil.

Each type of soil has its own inherent susceptibility to the forces of erosion; in large part because of chemical composition and organic matter content. Large-grained materials are easily detached by raindrop splash or flowing water, however, they are not easily transported. On the other hand, fine soils such as clays and mixtures of clays and silts that bond together tightly are not easily detached, but once free, they are transported with little difficulty. For this reason, fine materials can be carried considerable distances, whereas larger particles are deposited somewhere along the flow path.

Mulch and vegetative covers play an important role in hindering the erosion process. Without protective ground cover, raindrops may splash soil particles up to 1 m (Fig. 9). However, when mulch lays directly on the ground and completely covers the soil surface, the force from falling raindrops is absorbed and, thus, eliminates or reduces splash erosion (Fig. 10).

Canopy cover will also reduce drop erosion to a great extent. Close growing crops such as corn and soybeans catch raindrops and keep them from hitting the soil directly. Much of the water runs down the plant stem, although some runs off the leaves. Falling on bare soil, these drops cause a small amount of detachment, but since they have fallen from a lesser height, detachment is less than with no canopy cover (Fig. 11). Trees provide less protection for bare soil because of the greater height from which the drops fall. However, forests usually contain protective ground cover in the form of leaf or needle mulch.

Not only do ground covers intercept raindrops and keep them from detaching soil particles, but these

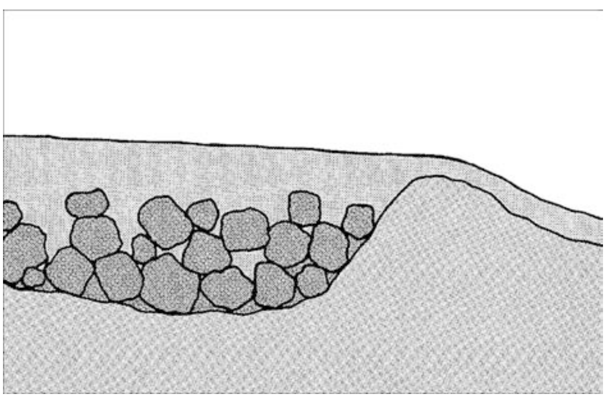

Fig. 7 Small irregularities in the soil surface, acting as small dams, cause ponding of runoff; then, some of the soil aggregates and particles are deposited as sediment and remain after flow ends.

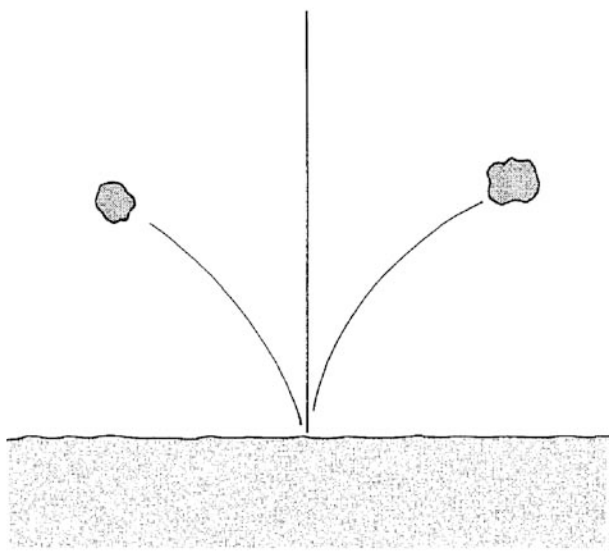

Fig. 9 With no protective ground cover, raindrops splash soil particles up to 1 m.

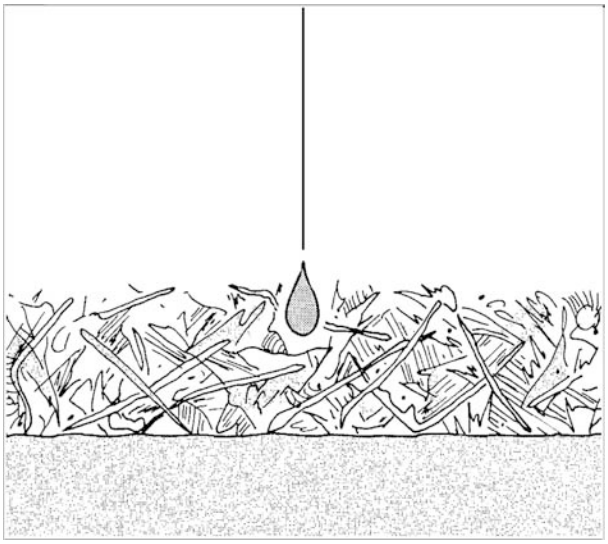

Fig. 10 Mulch cover dissipates the raindrop energy and hinders or eliminates splash erosion.

covers also prevent soil compaction which restricts infiltration of water into the soil. With greater infiltration, there is less runoff. However, some runoff with transport capacity will occur.

Even when no particles are detached by raindrop splash, the flow itself, forming larger and larger rivulets, can eventually loosen particles. By slowing down the velocity of flowing water, vegetation is helpful in reducing flow erosion. In a highly susceptible soil, some rill erosion may occur beneath the mulch cover, but the flow is impeded and the degree of erosion reduced.

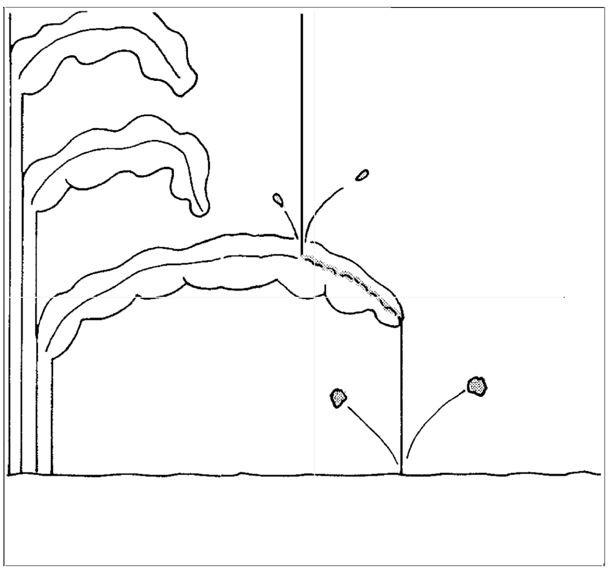

Fig. 11 The leaves of close-growing crops absorb the force of falling raindrops, thus minimizing the splash.

EROSION MODELING

Many factors, among them rainfall, soil, topography, and vegetative cover, affect the erosion process. Although many of these processes are recognized and understood, scientists do not yet have enough detail for developing complete physically based mathematical models. Some investigations have advanced more rapidly than others. For example, U.S. Department of Agriculture scientists at Purdue University and at Oxford, Mississippi, have made considerable progress in defining splash detachment and inter-rill transport mechanisms. Work in defining rill flow detachment and transport mechanisms continues, and progress is being made.

At present, the Universal Soil Loss Equation (USLE)[9] and the Revised Universal Soil Loss Equation (RUSLE)[10] are the most widely accepted methods of estimating soil loss from land surfaces. The equations include the effects of rainfall erosivity, soil erodibility, slope gradient and length, ground cover management, and erosion control practices. Although empirical, the equations provide the best estimates available for these complex phenomena. Using either equation, conservationists can estimate soil loss from a field and recommend alternative cultural practices for bringing excessive erosion to within tolerable limits. Many researchers are working on ways to improve estimates of the various parameters in this equation. A more advanced model, the Water Erosion Prediction Project (WEPP) equation,[11] has been developed. It is currently being validated by erosion scientists and used by researchers. It will become available for use by practitioners in the field.

We still need models that describe the erosion process in precise physical terms, but this is a long-range project. We also need to evaluate parameters for methods now used for estimating erosion. Both types of studies must continue concurrently. The new knowledge gained will help researchers develop exact descriptions for clearly defining erosion and sediment transport. The evaluation of parameters for current prediction methods enable conservationists to define causes and suggest cures for erosion problems.

Erosion: Bank

Steven B. Mitchell
School of the Environment, University of Brighton, Brighton, U.K.

INTRODUCTION

Factors affecting the erosion of sediment from channel banks vary widely depending on bank material, erosion mechanism, flow regime, vegetation cover, and land use. The processes may broadly be classified into hydraulic (erosion related to the passage of water past the bank), mass failure (erosion that occurs by bank collapse or slumping), and subaerial (erosion that occurs above the waterline). While the frequency, timing, and magnitude of bank erosion events may still be largely unpredictable for most natural systems, some consensus has been reached on the relative significance of the controlling mechanisms. Subaerial processes are rarely as important as hydraulic processes, for example. Estimation of bank erosion has benefits both in terms of predicting the possible loss of land and infrastructure[1] as well as in estimating the fate of sediments and nutrients from a river basin.[2,3] This short review summarizes the state of knowledge concerning these principles and points the reader to sources of further information on the subject.

FACTORS AFFECTING BANK EROSION

Hydraulic Entrainment

One of the primary factors controlling bank erosion is the hydraulic regime of the channel under consideration. In particular, high flow events can lead to significant bank erosion by the process of fluvial entrainment of material, but the relationship is highly non-linear. Precise data on the relationship between stream power and rate of bank erosion are rare. Hooke[4] provides an exhaustive review of bank erosion data. Shields, Simon, and Steffen[5] review lateral migration studies. Bank migration rates (in m/yr) when viewed across a wide range of fluvial systems appear to correlate only with channel width. Lawler[6] points to the importance of stream power Ω in determining the erosional ability of the hydraulic forces in the channel at any time. This is defined for the bankfull condition as a function of the flow rate and the channel geometry:

$$\Omega = \rho g Q S$$

where ρ is the water density, g is the acceleration due to gravity, Q is the flow rate, and S is the longitudinal channel slope. Furthermore, since for most natural channels Q increases and S decreases with distance downstream, it can be shown that Ω reaches a maximum value somewhere near the midpoint along the length of the channel.[6] Results from a 14.5-mo study of erosion rates in the Swale-Ouse system, U.K.,[2] point to a maximum erosion rate in mid-basin, but also point toward an extension in the length of the erosion "season" toward the downstream end. In this case, these authors point to a larger variety of erosion mechanisms taking place over different time domains.

Mass Failure

While there is a clear interaction between hydraulic entrainment and the propensity for mass failure,[7] many formulae are available for predicting a critical height, or angle, of a bank that triggers collapse by sudden mass failure of blocks material (Fig. 1). Often brought about by high fluvial flow events, these processes tend to dominate in deeper water found at the downstream ends of natural channels. Bank collapse is also very important in incised channel systems, which may be found in the smallest catchments, even in ephemeral channels.[8] The Culmann formula may be used[9] to predict the critical bank height H_c, above which mass failure may be triggered:

$$H_c = \frac{4c}{\gamma} \frac{\sin\alpha \cos\phi}{[1 - \cos(\alpha - \phi)]}$$

where c is the cohesion of the material (kN/m^2), γ is the specific weight of the material (kN/m^3), α is the slope angle (°), and φ is the friction angle (°). For a conservative approach, it is suggested that estimates of c should be taken from undrained shear testing,[9] or by borehole shear testing, where all testing is carried out in situ. Simon et al.[10] emphasize the role of soil science moisture and matric suction.

Subaerial Processes

Subaerial processes[1,11] include the action of cycles of freezing–thawing and wetting–drying on bank

Fig. 1 Bank mass failure in Bangladesh. (Photo courtesy of Phil Ashworth.)

material. Such processes, which act to weaken the cohesiveness of the bank material, have been commonly considered as preparatory to any significant erosion by fluvial entrainment or mass failure.[12] However, the difficulty of separating the effects of subaerial weakening from the other two bank erosion mechanisms means that it is not clear whether subaerial processes may themselves be partly responsible for bank erosion.[11] In any case, the effectiveness of moisture on moderating soil properties either through freeze–thaw action or wetting–drying is well known,[1] and may also be linked with silt-clay content.[13]

Other Factors

Other factors may be important in determining the resistance of bank material to erosion; for example, the silt-clay content of the bank and the length of time for which the material is submerged during a given flood event. A higher silt-clay content has been shown[13] to increase susceptibility to erosion by subaerial processes but decrease erosion due to fluvial entrainment, thus adding further complexity to predictions of bank erosion rates. The time of submergence of a bank has been observed as significant[1,2] as borne out by the occurrence of erosion events during prolonged periods of high flow. This may be particularly significant in the downstream end of a river basin where attenuation of flood waves may occur.

VESSEL WAKE

For the specific case of erosion due to the action of vessel wake published data are scarce, although in a detailed study on the Sacramento-San Joachim river[14] rates of 0.01–0.22 mm per boat passage were observed for this case. Macfarlane and Cox[15] have proposed that the use of multiple criteria to describe wave conditions provide better indicators of bank erosion potential rather than single indicators such as wave height.

VEGETATION

The prediction of the effects of vegetation on the erodibility of channel banks is problematic. Thorne[16] and Simon and Collison[17] state that the presence of significant vegetation can be considered neither as a benefit (reducing bank erosion) nor as a liability (increasing bank erosion) without further information about site-specific characteristics, such as the bank material properties, bank geometry, and the type, age, density, and health of the vegetation. Trimble[18] noted that banks vegetated with grass tend to be more resistant that those vegetated with trees. On the Latrobe river, in SE Australia, Abernethy and Rutherfurd[19] were able to identify a critical zone along the length of the river in which re-vegetation would be most effective, taking into account its role in moderating subaerial preparation, fluvial entrainment, and mass failure.

TIDAL BANK CHANNEL EROSION

Processes of bank erosion on predominantly muddy, estuarine tidal channels have historically received less attention that the equivalent processes in fluvial systems. Studies on the Trent-Ouse system in Northern England[20] have shown that erosion events are linked to hydraulic entrainment and mass failure, but that this is also heavily influenced by the degree of consolidation of bank material, which is generally much lower than for rivers. Furthermore, cycles of erosion are strongly linked for this system with spring–neap–spring tidal cycles, with significant deposition of new (and weakly consolidated) sediment during spring tides.

METHODS OF MEASURING BANK EROSION

A variety of methods have been developed to try to quantify the frequency, rate, and magnitude of bank erosion. In addition to traditional cross-section surveys, erosion pins may be inserted at intervals in the bank, either vertically or horizontally, and measurements made at intervals of the degree of exposure of the pins. The effectiveness of this method is generally limited by the frequency of field visits. Lawler[6] proposed the photo-electronic erosion pin (PEEP) that has successfully been used to monitor bank erosion

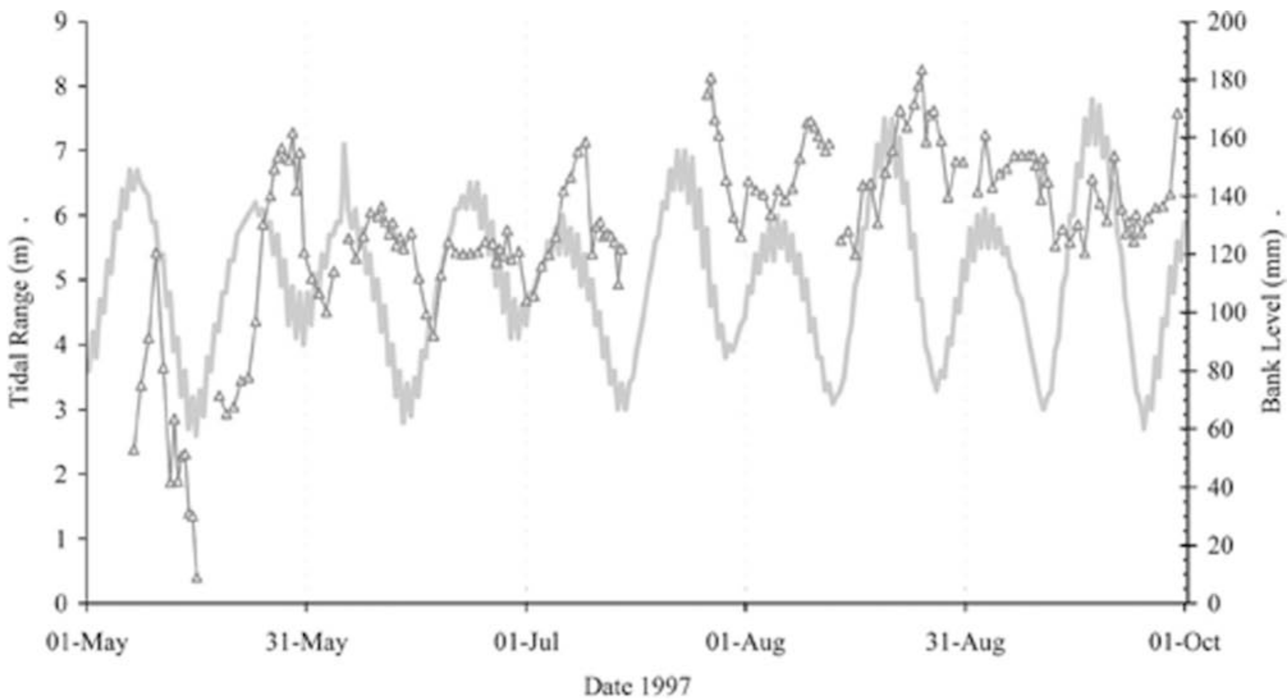

Fig. 2 Mean daily bank level measured by PEEP sensor (thin line, right axis), Blacktoft, River Ouse. Tidal range (thick line, left axis) as predicted for Immingham. *Source*: Adapted from Ref.[20].

remotely at a number of tidal[20] and non-tidal[12] sites, although one drawback is that these devices require good ambient light conditions to function properly. An example of PEEP for the (tidal) Ouse, U.K., is shown in Fig. 2, where bank levels increase (by erosion) or decrease (by deposition of fresh sediment) at a similar frequency to tidal range. For all bank erosion studies, it is useful also to record water level and turbidity,[12] in order that changes in bank position may be linked with specific fluvial or tidal events and with the release of sediment. Aerial photography has been used[3] to monitor large-scale bank erosion over long timescales.

CONCLUSIONS

Considerable uncertainty still exists about the relative influence of hydraulic entrainment, mass failure, or subaerial processes on bank erosion, although in general subaerial processes are less significant than hydraulic processes. Some agreement has, however, now been reached as to the erodibility of bank material as a function of seasonal vegetation growth, freeze–thaw activity, bank moisture status, and, in the case of tidal systems, tidal range. Numerical models of bank erosion point to the possibility of predicting the risk of bank erosion given sufficient data.[21] Most researchers agree that further work is needed to obtain more and better field data to quantify the mechanisms at work in specific systems.

INTRODUCTION

Soil erosion prediction models play an important role both in meeting practical needs of soil conservation goals and in advancing the scientific understanding of soil erosion processes. They are used to help land managers choose practices to reduce erosion rates. Erosion prediction models are used for erosion assessment and inventory work to track temporal changes in erosion rates over large areas. Erosion models are also used for engineering purposes, such as predicting rates of sediment loading to reservoirs. Increasingly, governments are using erosion models and their results as a basis for regulating conservation programs. Models are used wherever the costs or time involved in making soil erosion measurements are prohibitive.

In selecting or designing an erosion model, a decision must be made as to whether the model is to be used for on-site concerns, off-site concerns, or both. On-site concerns are generally associated with degradation or thinning of the soil profile in the field, which may reduce crop productivity. Conservationists refer to this process as ‘‘soil loss,’’ referring to the net loss of soil over only the portion of the field that experiences net loss over the long term (excluding deposition areas). Off-site concerns, on the other hand, are associated with the sediment that leaves the field, which we term here ‘‘sediment yield.’’

CHOOSING AND USING AN APPROPRIATE EROSION PREDICTION MODEL

Models fall into two broad categories: material and mathematical (also know as ‘‘formal’’) (Fig. 1).[1] Material models are physical representations of the system being modeled, and may be either iconic or analog. Iconic models are physical models that are composed of the same types of materials as the system that is being modeled, but simpler in form. In the case of soil erosion, a rainfall simulator applied to a field or laboratory plot of soil is an example of an iconic model. Analog models are also physical models, but are composed of substances other than those of the system being modeled. A classic example is the use of electrical current for modeling water flow. Analog models are not commonly used for soil erosion studies.

Mathematical models of soil erosion by water are usually either empirical or process based (Fig. 1). The first models of soil erosion were empirical, which means that they were developed primarily from statistical analysis of erosion data. The prime example of the empirical model is the Universal Soil Loss Equation (USLE).[2–4] More recent models have been based on equations that describe the physical, biological, and chemical processes that cause or affect soil erosion.[5] It is important to understand that process-based models also possess a major empirical component, in the sense that the constitutive equations use parameters based on experimental data.

Choosing how to manage land, from the practical perspective, is often a matter of choosing between an array of potential management options. Often, therefore, what we need to know is not necessarily the exact erosion rate for a particular management option to a high level of accuracy, but rather we want to know how the various options stack up against one another. Choosing which model to use then becomes a matter of 1) what type of information we would like to know and 2) what information (data) we have for the particular site of application. If we have an interest in off-site impacts, then we probably want to choose a process-based model that will provide estimates of the sediment leaving the hillslope or watershed. If we have an interest in obtaining auxiliary information about our choice of management strategy, such as soil moisture or crop yields, we might also decide to use a process-based model that provides such information. On the other hand, if data are limited for the situation to be modeled, then a simple empirical model might be the best option.

THE UNIVERSAL SOIL LOSS EQUATION

The prime example of an empirically based model is the USLE, which was developed in the United States

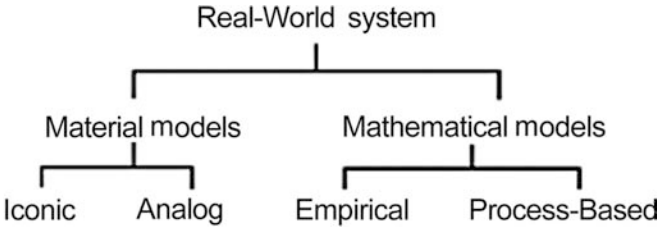

Fig. 1 Model classification. *Source*: Adapted from Ref.[1].

during the 1950s and 1960s.[2,3] This equation has been adapted, modified, expanded, and used for conservation purposes throughout the world.[6–8]

The USLE was originally based on statistical analyses of more than 10,000 plot-years of data collected from natural runoff plots located at 49 erosion research stations in the United States, with data from additional runoff plots and experimental rainfall simulator studies incorporated into the final version published in 1978.[4] The large database upon which the model is based is certainly the principal reason for its success as the most used erosion model in the world, but its simplicity of form is also important:

$$A = RKLSCP \tag{1}$$

where A (tons/ha/yr) is the average annual soil loss over the area of a hillslope that experiences net loss, R (MJ mm/hr/ha/yr) is the rainfall erosivity, K (tons hr/MJ/mm) is the soil erodibility, L (unitless ratio) is the slope length factor, S (unitless ratio) is the slope steepness factor, C (unitless ratio) is the cropping factor, and P (unitless ratio) is the conservation practices factor. The USLE predicts soil loss and not sediment yield. The word erosivity is used to denote the driving force in the erosion process (i.e., rainfall in this case) while the term erodibility[9] is used to note the soil resistance term.[9] These two terms are not interchangeable. The model predicts the ''average annual soil loss:'' it was not intended to predict soil loss for storms or for individual years.

The key to understanding the dimensional units for the USLE lies with the definition of rainfall erosivity and the concept of the ''unit plot.'' Wischmeier[10] found for the plot data that the erosive power of the rain was statistically best related to the total storm energy multiplied by the maximum 30-min storm intensity. Thus, we have the energy term (MJ) multiplied by the intensity term (mm/hr) in the units of R, both of which are calculated as tons per hectare and per year. The unit plot was defined as a standard of 9% slope, 22.13 m length, tilled and left fallow (cultivated for weed control). Most of the early erosion plots were 1.83 m (6 ft) wide. A length of 22.13 m (72.6 ft) and a width of 1.83 m (6 ft) resulted in a total area of 1/100 of an acre. Prior to the days of calculators and computers this was obviously a convenient value for computational purposes. The K value was defined as A/R for the unit plot. In other words, erodibility was the soil loss per unit value of erosivity on the standard plot. The remaining terms, L, S, C, and P, are ratios of soil loss for the experimental plot to that of the unit plot. For example, the C value for a particular cropped plot is the ratio of soil loss on the cropped plot to the value for the fallow plot, other factors held constant.

The USLE reduced a complex system to a quite simple one for purposes of erosion prediction. There are many complex interactions within the erosional system that are not, and cannot be, represented within the USLE. On the other hand, for the purposes of general conservation planning and assessment, the USLE has been, and still can be, used with success.

THE REVISED USLE: RUSLE1 AND RUSLE2

The USLE was upgraded to the revised universal soil loss equation (RUSLE1) during the 1990s[11] and evolved to the current RUSLE1.06c released in mid-2003.[12] RUSLE1 is land-use independent and applies to any land use having exposed mineral soil and Hortonian overland flow; RUSLE2 was also released in mid-2003, and is also land-use independent.[12]

Both RUSLE1 and RUSLE2 are hybrid models that combine the existing index with equations process-based equations. RUSLE2 expands on the hybrid model structure and uses a different mathematical integration than does the USLE and RUSLE1. Both RUSLE1 and RUSLE2 are computer based, and have routines for calculating time-variable soil erodibility, plant growth, residue management, residue decomposition, and soil surface roughness as a function of physical and biological processes.

PROCESS-BASED MODELS

Various process-based erosion models have been developed in the last 10 yr including EUROSEM in Europe,[13] the GUEST model in Australia,[14] and the WEPP model in the United States.[15,16]

Process-based (also termed physically based) erosion models attempt to address soil erosion on a relatively fundamental level using mass balance differential equations for describing sediment continuity on a land surface. The fundamental equation for mass balance of sediment in one dimension on a hillslope profile is given as:

$$\partial(cq)/\partial x + \partial(ch)/\partial t + S = 0$$

where c (kg/m^3) is the sediment concentration, q (m^2/sec) is the unit discharge of runoff, h (m) is the depth of flow, x (m) is the distance in the direction of flow, t (sec) is time, and S [kg/(m^2 sec)] is the source/sink term for sediment generation. Eq. (2) is exact. It is the starting point for development of physically based models. The differences in various erosion models are primarily: 1) whether the partial differential with respect to time is included and 2) differing representations of the source/sink term, S. If the partial differential term with respect to time is dropped, then the equation is solved for the steady state, whereas the representation of the full partial equation represents a fully dynamic model. The source/sink term for sediment, S, is generally the greatest source of differences in soil erosion models. It is this term that may contain elements for soil detachment, transport capacity terms, and sediment deposition functions. It is through the source/sink term of the equation that empirical relationships and parameters are introduced.

The disadvantage of the process-based model is complexity. Data requirements are greater, and every new data element provides the opportunity to introduce uncertainty. Model structure interactions are also large.

Erosion: Process Modeling

John M. Laflen
Purdue University, Buffalo Center, Iowa, U.S.A.

INTRODUCTION

Erosion is the removal (detachment) of a mass of soil from one part of the earth and its relocation (transport and deposition) to other parts of the earth. Water erosion is that portion of erosion caused by water.

Modeling of water erosion includes modeling the state of the soil and biomass system on and below the land surface in addition to modeling the detachment, transport, and deposition of eroded material. The state of the system when rainfall/snowmelt/irrigation occurs determines the reaction to the forces applied by rainfall; the magnitude of and reaction to the forces applied by surface runoff; and to a great degree, the total detachment, transport, and deposition of soil during rainfall events.

Modeling the state of the system involves modeling of many processes. These would include hydrologic processes—including those related to water movement, use, and storage above and below ground; those related to the accumulation, decomposition, and use of biomass-plant growth, root growth, biomass decomposition, grazing, and addition or removal of biomass. While such modeling is critical to accurately model soil loss from most lands, it is a comprehensive subject beyond the scope of this chapter.

A model is defined[1] as "a system of postulates, data, and inferences presented as a mathematical description of an entity or state of affairs.'' The objective here is to describe these processes and how they might be mathematically described and modeled. The processes described are those that occur on source areas on relatively small tracts of land.

MODELING THE EROSION PROCESS

The erosion process is usually visualized as detachment and transport by rainfall and detachment, transport, and deposition by flowing water. The detachment and transport by rainfall is usually termed interrill erosion. The detachment, transport, and deposition by flowing water, depending on scale, is referred to as rill erosion, channel erosion, ephemeral gully erosion, or gully erosion—in this chapter they are lumped appropriately as channel erosion.

Interrill Erosion

Interrill erosion is the detachment and transport of soil by raindrops and very shallow flow. It is constant down a slope as long as soil and surface properties remain constant.[2] Interrill processes generally occur within a meter or so of the point of impact of a water drop, and deliver the detached material to nearby channels called rills. If there is no flow in a channel, the detached interrill material stays close to the point of detachment. Interrill erosion is usually most apparent on row sideslopes.

The forces and energies in interrill processes are derived from waterdrops (rainfall and irrigation) and the shallow flows near where these drops impact the soil surface. Interrill erosion is not positionally sensitive, being relatively constant over an entire surface where cover, microtopography, soil, and waterdrops remain constant.

Interrill erosion has been modeled a number of ways. The detachment of soil due to individual raindrops has been mathematically modeled.[3,4] Numerous equations, empirical in nature, have been developed that express the detachment and transport of raindrops as a function of slope steepness, and raindrop and runoff characteristics. In the development of the Universal Soil Loss Equation, soil erosion for a rainfall event was expressed as a function of rainfall energy and a maximum 30-min rainfall intensity.[5] In a classic modeling of the erosion process[6] interrill detachment (D_i) was expressed as a function of the intensity (I) squared:

$$D_i = \alpha I^2 \tag{1}$$

Recently,[7] interrill erosion detachment rate was related to interrill slope and the intensity squared as:

$$D_i = K_i I^2 (1.05 - 0.85\, e^{-4 \sin \Phi}) \tag{2}$$

where K_i is the interrill soil erodibility and Φ is the slope angle.

In the Water Erosion Prediction Project (WEPP) model[8] interrill erosion is modeled as the product of intensity and flow rate. Interrill detachment is written as

$$D_i = K_i I q \mathrm{adj} \tag{3}$$

where q is the flow rate and adj is a series of adjustment factors including adjustments for slope [as given in Eq. (2)], sealing and crusting, residue cover, canopy cover, and canopy height. The major difference between Eqs. (2) and (3), in addition to the expansion of adjustment factors beyond the slope, is the use of an Iq term rather than the I^2 term in Eq. (2). This change was based on Australian research[9,10] and on the observation that interrill detachment was low for soils that had low runoff rates.

The energy of raindrops does the greatest damage in interrill areas, causing crusts on the soil surface that greatly increase surface runoff on interrill areas.[11] This runoff then drives the erosion and sediment transport process in channels. Thus, soil erosion control must begin in interrill areas in the control of rates and volumes of surface runoff.

Interrill erosion occurs at the soil surface—the region of the soil that is most biologically and chemically active. Interrill soil erosion removes a disproportionate amount of the soil's fertility, chemicals for the control of weeds, insects and diseases, and organic matter. These losses can eventually have serious consequences for the soil, and for receiving waters. The loss of fertility was the basis for establishing soil tolerance values in the United States,[12] and interrill erosion rates under clean tillage are often near the allowable soil loss.

Channel Erosion

Channel erosion is distinctly and visibly different than interrill erosion. Because they are distinctly different processes, they are modeled separately from interrill erosion. Channels are the visible erosion process that points to the existence of a threat to the sustainability of a land resource. Interrill erosion scarcely leaves a visible mark on the land, channel erosion causes ditches, gullies, and serious impediments to farming. Channel processes are positionally sensitive. Until the hydraulic forces that detach channel material exceed a limiting value, channel erosion does not occur, an important element in stable channel design.

Channel erosion takes many forms. First, it may take the form of rill erosion—the channel that interrill material is usually delivered to. Rill erosion is viewed as a channel that receives only interrill material. In rills, a common expression for representing the detachment due to flowing water is in an excess hydraulic shear model (Fig. 1) with adjustment for sediment in transport as shown in Eq. (4)

$$D_r = K_r(\tau - \tau_c)(1 - g/T_c) \quad (4)$$

where D_r is the rill detachment, K_r, the rill erodibility, τ, the hydraulic shear, τ_c, the critical hydraulic shear, g, the sediment load, and T_c, the sediment transport capacity. There has been much discussion in the literature about whether or not hydraulic shear is the detaching mechanism, and whether or not the sediment in transport affects sediment detachment. Rill erosion and rill initiation is apparently greatly influenced by seepage forces.[13]

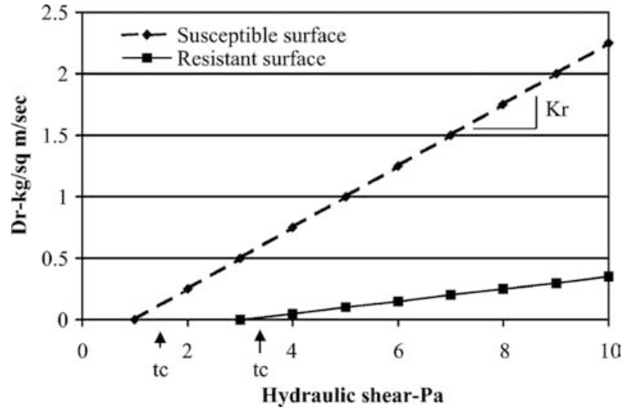

Fig. 1 Visual representation of an excess hydraulic shear model. The slope of the line is the rill erodibility, and the intercept with the x axis is the critical hydraulic shear. Soil differences and management differences may drastically change both rill erodibility and critical hydraulic shear.

Larger channels are formed where more than one rill intersect, or where flow concentrates. Some of these channels may be called ephemeral gullies, such gullies can be obliterated by tillage implements, hence the term ‘‘ephemeral.’’ The process in these channels and gullies are mathematically described in CREAMS,[14] and are represented in a model for estimating erosion in ephemeral gullies.[15,16] They are modeled similarly in the WEPP model.[8] In these models, erosion occurred over some width (computed or input) with material removed until a soil layer was reached that would not erode (usually the bottom of the latest tillage depth), then the channel would widen until it had reached an ultimate width where the flow depth was so low that the hydraulic shear was less than the critical shear. In studies of ephemeral gullies in the United States, the ratio of erosion from these small channels to sheet and rill erosion ranged from 0.24 to 1.47.

Gully erosion is found on many lands. Gullies may destroy the land, making it unusable for intense agricultural production. In the 1930s, it was reported that 20 million ha of former U.S. cropland was useless for further production because it had been stripped of topsoil or riddled with gullies and that most of this land had been abandoned.[17] Much of the Southern Piedmont has been stripped of its topsoil, and dissected and gullied so badly that the land is unsuitable for agriculture, with the entire area having lost an average of

0.17 m of topsoil[18] in the 270 yr of settlement—about 800 t/km^2/yr. The erosion was attributed to the use of clean-cultivated cash crops, and the exploitative nature of the land clearing and farming methods, quite similar in effect to those of Africa.[19]

The failure sequence for gully formation begins with a channel deepening when the force of flowing water exceeds the channels resisting force.[20] Then banks fail, and material is deposited in the gully and is carried away by subsequent flows. When a headcut occurs, material is deposited in the gully, and is carried away by subsequent flows. The location of gullies and the rate of gully formation is difficult to predict and model.

The failure sequence of gullies in the western Iowa loessial soil area begins with a weakening of the soil material at the base of the gully wall[21] attributable to wetting of the soil at the base of the gully wall. Once the base failed, overhanging material sloughed and then eroded material was transported downstream. The depth to water table in relation to the geometry of the gully bank played an important role in gully head and gully bank failure. It was observed that soil strength decreases with increasing moisture content, that seepage forces might be important, and that the increased unit weight of the soil mass with greater water content exerts more force.

A good gully erosion model has not been developed and accepted by the modeling community.

Deposition

Only a small portion of material detached and transported by interrill and channel processes reach major water bodies. Much of the detached and transported material deposits within a short distance from where it was detached. Major deposition sites are where slopes flatten, where flow velocities are reduced, or where temporary pondage occurs. Footslopes, culverts, fence lines, and small impoundments are major deposition sites near sources of eroded material.

Deposition is a very selective process, with larger, denser particles depositing more readily than smaller, less dense particles. Usually Stokes law is used to estimate fall velocities of sediments based on eroded sediment sizes and densities.[21] This approach has been used in modeling impoundments.[22,23]

Deposition in channels is generally modeled when the sediment transport capacity is less than the sediment load in suspension. It has been modeled similarly to settling tanks in water treatment plants, with sediment fall velocity being modeled based on sediment size and density, and deposition based on these fall velocities and the channel flow velocity

$$\text{Deposition} = \beta(V_f/q)(T_c - g) \tag{5}$$

where β is a rain induced turbulence coefficient (0.5 when runoff due to rainfall or sprinkler irrigation, otherwise 1.0 for snowmelt and furrow irrigation), V_f, the fall velocity of sediment (m/sec), q, the flow rate per unit width (m^2/sec), T_c, the transport capacity (kg/sec/m), and g, the sediment load (kg/sec/m).[24] According to Eq. (5), when transport and sediment load are equal, there is no deposition computed. When the fall velocity is small, and rain is occurring on the channel, deposition rates would be expected to be small. Deposition rates are calculated for individual sediment sizes and densities, then deposition rates can be integrated across the sediment sizes to estimate total deposition amounts within a channel reach.

CONCLUSION

Erosion processes are usually visualized as interrill and channel processes, although channel processes include an extremely broad range of channels—including small rills, larger channels, ephemeral gullies, and classical gullies. The processes described herein have been represented mathematically in a number of different ways. In this paper, we have limited the discussion to those that occur on smaller tracts of land, choosing to avoid continuously flowing streams on large areas.

The erosion processes are driven by both rainfall and runoff. Interrill processes are due almost entirely to rainfall and shallow runoff while channel processes are driven by runoff. Hence, control practices must be tailored to meet the conditions for controlling detachment in both areas, and to induce deposition in selected areas.

Eutrophication

Kyle D. Hoagland
School of Natural Resources, University of Nebraska, Lincoln, Nebraska, U.S.A.

Thomas G. Franti
Department of Biological Systems Engineering, University of Nebraska, Lincoln, Nebraska, U.S.A.

INTRODUCTION

Eutrophication is the nutrient enrichment of surface water and the subsequent impacts on water quality and the aquatic ecosystem. The over abundance of plant nutrients, usually nitrogen and phosphorus—but sometimes silicon, potassium, calcium, iron, or manganese—creates the conditions for excessive plant growth.[1] Algal blooms are an example of excessive growth caused by over supply of nutrients. A body of water is classified by its trophic state based on the amount of nutrients supplied to it. An oligotrophic state is low in nutrients, a mesotrophic state is intermediate, and a eutrophic or hypereutrophic state is high in nutrients.[2] Eutrophication is a natural process. However, as a natural process it takes generations, or even thousands of years, for eutrophication to cause significant changes. It is the acceleration of the process, known as cultural eutrophication, that is of the greatest concern to water quality and the health of aquatic systems.

CULTURAL EUTROPHICATION

Cultural eutrophication is the result of excess nutrients—primarily nitrogen and phosphorus—delivered to rivers, lakes, and estuaries by the activities of humans. Nutrient loading can come from both point sources and diffuse sources. Point sources of nutrients are generally urban sewage treatment or industrial water treatment. Diffuse sources (or non-point sources) of nutrients include agriculture, deforestation, and urban lawn runoff. The use of commercial fertilizer in crop production can lead to losses of nutrients to surface water. Concentrated animal feeding operations are also a potential source of excess nutrients.[2,3] Finally, deforestation and subsequent soil erosion, can deliver excess nutrients, sediment, and organic matter to surface water, creating the conditions for eutrophication.

The natural aging process of lakes in some climates can lead from an oligotrophic state, with clean open water supporting usually cold water fish species, to a eutrophic state of warmer, shallow water supporting different species of plants and fish, and ultimately, to a filled lake closed over by a bog or fen. This process usually takes thousands of years. In contrast, cultural eutrophication can occur in a matter of one or two generations.

The last 50 years of the Twentieth Century saw the greatest impact of eutrophication on the world's waters. Cultural eutrophication has accelerated the lake aging process, reduced water quality, and impacted aquatic plant and animal populations, at economic costs. These impacts are being felt worldwide.[1]

Modern society's use of phosphorus additives in detergents has lead to excessive phosphorus loading to surface waters.[1] Modern agriculture's use of commercial fertilizer and fertilizer's relative abundance, low cost, and over use, has lead to excessive nitrogen loading to surface water. Agriculture also contributes excessive phosphorus from fertilizer and from intensive livestock operations and land application of manure.[3,4] Urban sources, such as sewage treatment plants, storm water runoff, industrial water treatment facilities, and food processing contribute excess nutrients. Sewage treatment loading to waters, including treated gray water, is generally considered the greater source of phosphorus. The greater contributor of nitrogen is agricultural crop production. Other significant agricultural sources are animal confinement operations, forestry, and atmospheric inputs.

RATE OF EUTROPHICATION

The rate of eutrophication is controlled by the rate at which nitrogen and phosphorus are delivered to a body of water. It is generally accepted that phosphorous is the limiting nutrient for algal growth in lakes.[1,5] Another limiting factor for algal growth is light. As excess phosphorus enters a lake it can trigger high levels of algal growth. Excessive growth, or blooms, can reduce water clarity. Aquatic macrophytes may also thrive under these conditions. This process can increase the productivity of a lake to an extent. When it becomes excessive, the process of cultural eutrophication has begun.

The nutrients supplied to an aquatic system is the most important factor that determines the species and amount of plant material, which in turn controls available oxygen and the animal species that thrive.[1] As plants and macrophytes grow and die, organic matter accumulates on the lake bottom. Decomposition of excessive amounts of organic matter can consume available oxygen and create anoxic conditions. An anoxic condition drives away plant and animal species dependent on oxygen. Slowly a lake's original community changes.

This anoxic state creates another problem if a lake becomes stratified. Temperature differences in the water at the lake's surface and at depth can create thermal stratification. In this condition the cold, low oxygen water in the hypolimnion, or lower layer, does not mix with the epilimnion, the warmer surface water. In this condition the anoxic conditions in the hypolimnion creates a condition where the sediment releases phosphorus, which is transported upward to the epilimnion and contributes to increased algal growth. This internal cycling of phosphorus continues the eutrophication process even if no additional phosphorus enters the lake.[5,6]

EFFECTS OF EUTROPHICATION

There are various biological effects of eutrophication. Besides the problems of algal blooms and anoxic conditions previously described, there are changes in water temperature, reduction in water clarity, increased macrophyte production, population shifts in both plants and animals, and accelerated aging of lakes. Fish kills and the coastal ''red tides'' and ''brown tides'' are also potential environmental impacts from eutrophication.[5,7]

There are many impacts on human use of water from eutrophication. Potable water—water used for human consumption—can be significantly degraded by eutrophication. Besides the excess nutrients themselves, there is excess algae and other plant growth which can contribute to unwanted odors and tastes. Thus, additional water treatment is needed to make the water drinkable.[1,4]

The decline of commercial and recreational fisheries is also an indirect result of eutrophication. Fish populations may move away, or over time shift to less desirable fish species as water temperature, clarity, and quality change.[1] There are also negative impacts on recreational use of surface waters such as boating and swimming as a result of floating plant growth, smell, and the overall loss of aesthetic quality.[4] Finally, the general decline of an aquatic ecosystem and the loss of biodiversity are impacts of eutrophication.[1,3,7]

Some of these impacts can cause significant economic losses as well. Water treatment costs rise as water quality decreases. Algal blooms can contribute to shutting down water treatment plants. Advanced water treatment of municipal water to remove nutrients (such as alum addition)—hence removing a contributing factor to eutrophication—adds another expense to water treatment. Loss of commercial fisheries is an economic impact to a region. Finally, loss of recreation income from tourists, boaters, and recreational fisherman can have significant impacts on a local economy.[4,7]

REDUCTION AND MANAGEMENT

Two approaches can be taken to the reduction and management of eutrophication: 1) reduction of nutrient loads; and 2) managing the existing high-nutrient state.[1] Reduction of loading is clearly the more robust approach. Reduced loads are necessary if long-term improvement is expected. However, because of the ecosystem changes brought on by eutrophication and the potential problem of phosphorus cycling previously described, water quality and ecosystem improvements may not respond quickly to reduced loading.[3] A combination of reduced loads and in-lake controls may be needed.

Reducing nutrient loads requires reduction of both point and diffuse sources. To reduce point sources, sewage and industrial water treatment plants need advanced water treatment to remove nutrients.[1,7] Advanced water treatment is expensive, but is the only way to reduce these point source nutrients. Most diffuse sources contributing nutrients to surface water come from agricultural operations. Loading is dependent upon the type of crops grown, soil type, climate, cultural practices, fertilizer use, and whether animal waste management practices are sufficient to reduce loading. Nutrient reduction from these sources will require improved management of fertilizer and animal waste, and continued reduction of soil erosion throughout the watershed.[1]

There are several methods used to manage nutrient levels in lakes. These fall into two categories: those that 1) remove nutrients; or 2) manage nutrient levels without nutrient removal. Methods to remove nutrients include: 1) lake flushing; 2) hypolimnetic water withdrawal; 3) sediment removal (e.g., dredging); and 4) nutrient inactivation by precipitation (e.g., alum treatment). Methods to manage nutrients without removing them include: 1) artificial mixing and/or aeration; 2) dilution by the addition of water lower in nutrients; 3) bottom sealing to prevent internal nutrient cycling; 4) manipulation of lake biological communities (e.g., selective fish harvesting or the introduction of fish predators such as largemouth bass, walleye, or brown trout); 5) introduction of biological controls for unwanted macrophyte growth (e.g., weevils or grass carp); and 6) herbicide or other chemical treatments (e.g., copper sulfate) of excessive algal or macrophyte growth.[1,6]

Clearly the best way to reduce or reverse eutrophication is to reduce nutrient loading, that is, targeting the source of the problem.[1] This long-term solution involves participation and management by people throughout the entire watershed. In-lake nutrient management can be done, but may require annual inputs and regular management.

INTRODUCTION

Evaporation results from complex energy and mass exchanges and can occur on any humid surfaces in contact with air. The change of liquid water to vapor consumes energy (latent heat of vaporization $2.46 \times 10^6\,\mathrm{J\ kg^{-1}}$). The water vapor diffuses in the air and is taken away by air convection. This process cools the surface heated by radiation (net radiation) or eventually by convection mostly during the day. Then evaporation increases with surface availability of water and energy. The reverse of this process is called condensation (water and energy gain). Unit used for evaporation flux density (or condensation) is mass of water by unit of surface and unit of time (mass flux: $\mathrm{kg^{-1}\,m^{-2}\,sec^{-1}}$ or $\mathrm{mm\ day^{-1}}$; or energy flux $\mathrm{W\,m^{-2}}$).

HISTORICAL APPROACH

Since the sixth century BC, Greek antiquity has recognized evaporation as a main basic process of all meteorological knowledge: "rains are generated from evaporation that is sent up from the earth toward under the sun" according to Anaximander of Miletos.[1] Among the first direct measurements, Perrault (1670) and Sedileau (1730) analyze water balance between evaporation ($825\,\mathrm{mm\ yr^{-1}}$) and rain ($515\,\mathrm{mm\ yr^{-1}}$) to supply Versailles's ornamental lakes and fountains. This observation raises for the first time the question: "how with such water deficit, most of the rivers continue to flow in summer and plant canopies maintain transpiration and growth?" The given explanation arrived later and was that evaporation is a process under control of regional water balance. This water balance must include deep water flows, soil water content changes, and plant evapotranspiration widely reduced compared to free water evaporation (development of hydrology with Darcy's law 1880 and later of soil physics, then soil–plant–atmosphere continuum).

HYDROLOGIC CYCLE

At earth's global scale and with interannual mean, the water cycle dominates climates and influences meteorology. The radiative energy budget of earth (incoming solar radiation and outgoing infrared radiation with all their complex radiative interactions between earth surface and atmosphere such as the greenhouse effect, etc.) must balance to zero. The resulting radiative energy supply at the earth surface (from long-wave and short-wave radiation balance) amounts to 30% of the mean extraterrestrial solar irradiance (the mean extraterrestrial irradiance is equal to one-fourth of solar constant$\approx 1380/4\,\mathrm{W m^{-2}}$). Furthermore, the mean energy radiative budget of the atmosphere leads to a same energy loss (30% of the mean extraterrestrial irradiance). Then, convective fluxes (sensible heat flux, 6%, latent heat flux or water evaporation, 24%) restored the equilibrium between the heating earth surface and the cooling atmosphere. The energy consumed at the surface by latent heat flux can be released in the atmosphere through the reverse process of vapor condensation. Then, the processes of evaporation and condensation of the water cycle are the main energy exchanges in earth surface energy budget.[2]

The volume of water exchange between the earth and the atmosphere is so huge ($420 \times 10^{12}\,\mathrm{m^3\,yr^{-1}}$) compared with the atmosphere reservoir ($13 \times 10^{12}\,\mathrm{m^3\,yr^{-1}}$) that the time period in the atmosphere for water vapor is no more than 12 days. As a consequence, rains appear more on oceans where there is a constant total water availability than on continents where most of the time there is only more or less bound water ($P_c = 0.6\,P_o$ and $E_c = 0.4\,E_o$ by unit of surface). Furthermore, the water balance of oceans is negative and that of continents is positive. The reverse occurs in the atmosphere (above oceans and continents) that leads to an atmospheric water advection from oceans to continents (one-third of continental rains originates from oceanic advection and two-third from continental evaporation).

As continental evaporation supplies a significant proportion of atmospheric water vapor, anthropogenic activity that reduces evaporation (deforestation for example) tends to diminish rain. This activity initiates a positive feedback loop that lowers evaporation, and further desiccation leading to aridification and/or desertification. Other meteorological and pedological processes, like increase of drying surface albedo, lowered surface roughness, elevated surface temperature, soil crusting and erosion, accelerate the degradation.

EVAPORATION UNDER SURFACE ENERGY BALANCE

For any component of a physical or biological system, the balance of all energy fluxes is achieved by adjustments of temperature. The equation describing this energy balance is based on the principle of energy conservation, meaning that in-and-out flux of all energy fluxes are equal with no sink or source of energy at the surface. For deriving a simplified equation for the energy balance near the surface, we assume the surface to be a finite-depth interfacial layer, which must have finite mass and heat capacity. Depending on the nature of the surface, this layer may consist of soil, canopy, or some other substrate like water or snow.

Energy Balance

Then, a 1-D energy balance equation for this layer can be expressed as:

$$R_N = H + \mathrm{LE} + G \tag{1}$$

where R_N is the net radiation flux, H and LE are the sensible and latent heat fluxes to or from the air, and G is the ground heat flux to or from the subsurface medium (all fluxes in $\mathrm{W\,m^{-2}}$). Here we used the sign convention that all the radiative fluxes directed towards the surface are positive, while other energy fluxes (convective or conductive) directed away from the surface are positive and vice versa.

1. The net radiation flux R_N is a result of radiation balance between short-wave and long-wave radiation received at or emitted by the surface which can be written as:

$$R_N = (1 - a)R_g + \varepsilon(R_a - \sigma T_S^4) \tag{2}$$

where R_g, global solar radiation, and R_a, long-wave atmospheric radiation, are the two terms of incident radiation ($\mathrm{W\,m^{-2}}$); a is albedo (proportion of solar radiation reflected by surface) and ε is emissivity defining the radiative properties of the subsurface (proportion of long-wave radiation emitted compared to a black body emission); so that εR_a is the absorbed downward long-wave radiation ($\mathrm{W\,m^{-2}}$) and $\varepsilon\sigma T_S^4$ is the emitted long-wave radiation ($\mathrm{W\,m^{-2}}$) with T_S the subsurface temperature (K).

2. The conductive ground heat flux G to or from the subsurface medium depends on physical properties of the soil and other factors including surface temperature (hence time of day) and soil moisture content, which, in turn, depend on whether it is a bare or vegetated surface.
3. The balance of energy fluxes at the surface places a constraint upon the sum of the convective fluxes, (H + LE), thus emphasizing the importance of partitioning the available energy ($R_N - G$) between the sensible and latent heat fluxes. These convective fluxes depend on surface characteristics, wind speed, and temperature or vapor pressure gradients.

$$H = \rho c_p \frac{T_S - T_a}{r_a}$$

$$\mathrm{LE} = \frac{\rho c_p}{\gamma} \frac{P(T_{dS}) - P(T_d)}{r_a} \tag{3}$$

where ρ is the volumetric mass of air (kg $\mathrm{m^{-3}}$); c_p, the heat capacity of air (J $\mathrm{kg^{-3}}$ $\mathrm{K^{-1}}$); r_a, aerodynamic resistance to diffusion between the surface z_s, and the reference height, z_r, (s $\mathrm{m^{-1}}$); T_a and T_d, the air temperature and dew point temperature at level z_r (K); T_{dS}, the dew point temperature at the surface (K); γ, psychometric constant (P $\mathrm{K^{-1}}$); $P(T_d)$, saturation vapor pressure at T_d (P).[3]

Evaporation

Eqs. (1) and (3) can be combined to yield the combination equation:

$$E, \mathrm{LE} = \frac{\Delta}{\Delta + \gamma}\left[(R_N - G) + \rho c_p \frac{\Theta_r - \Theta_S}{r_a}\right] \tag{4}$$

where Δ is the slope of the saturation vapor pressure (P $\mathrm{K^{-1}}$), and Θ_z, the air hygrometry temperature deficit (K) at level z [$\Theta_z = T(z) - T_d(z)$].

The combination equation neatly displays the two essential physical controls on evaporation: the supply of energy and the diffusion of water vapor from the surface. Depending on the value of the relevant parameters five different cases may occur:[4]

1. $\Theta_S = 0$ defines potential evaporation (EP): evaporation from any large uniform moist or wet (after rain) area so that the surface vapor pressure is saturated. This potential value mostly under climatic forcing is called climatic demand. The resulting surface temperature is always the lowest (near air temperature or even lower) for given air temperature, humidity, wind speed, and incoming radiation.
2. $\Theta_S = \Theta_r$ is a situation corresponding to a long exchange over an extended area; that is known as "equilibrium evaporation, E_o." In this case, wind speed and consequently convection have no effects and limit evaporation to a proportion of the radiant (R_N) and conductive (G) energy supply to the surface ($R_N - G$). This "equilibrium evaporation" is also an asymptotic regional value when air characteristics (the air hygrometry temperature deficit, Θ_z) tend towards surface characteristics (Θ_S) and may be considered as the climatic evaporation.
3. $\Theta_{S\max} = \Theta_r + (R_N - G)r_a/\rho c_p$ occurs on a dry surface where the evaporation is equal to 0. In these conditions, the surface temperature is maximum ($T_{S\max} = T_a + (R_N - G)r_a/\rho c_p$).
4. $0 < \Theta_S < \Theta_r$ is referred to as "oasis effect"; the air is drier at the reference level z_r than it is at the surface. In this situation, the strong availability of water at the surface allows relatively high evaporation ($E_o < E <$ EP). Sometimes, in this case, energy consumed by evaporation exceeds energy supplied by radiation; that implies a surface temperature cooler than the surrounding air and the atmosphere supplies sensible heat to the surface. The actual value of evaporation, E, is the real offer.
5. $\Theta_r < \Theta_S < \Theta_{S\max}$ is referred to as "island effect"; the air is wetter at the reference level z_r than it is at the surface, and evaporation is low ($0 < E < E_o$), decreasing the real offer. In this case, surface temperature increases to the maximum value ($\Theta_{S\max}$) as evaporation decreases to zero.

REGIONAL EVAPORATION

At the regional scale following several days of stable conditions, air boundary layer conditions characteristics control surface convective exchanges. These fluxes modify energy and mass budget of the planetary boundary layer. Most often, sensible heat flux releases energy to the boundary layer increasing air temperature and simultaneously evaporation adds water vapor. So, under wind direction according to distance or on a same point according to time, mean air and dew point temperature of boundary layer are changing. These time and space modifications induce evaporation changes by feedback. As a result, at regional scale under given net radiation (R_N) and soil water storage available for water flux, ΔQ, this mean air and dew point temperature difference ($\bar{\Theta}_Z$) of the boundary layer moves in few days toward a limit; this limit is the equilibrium value, Θ_S.[5] The analytical solution for this limit shows a value directly proportional to net radiation and to the soil water storage deficit [difference between maximum possible storage and actual storage, ($\Delta Q_{\mathrm{Max}} - \Delta Q$)]. With high irradiance and low rainfall, the unavailability of soil moisture limits evaporation but induces dry air conditions in the boundary layer (high level of the limit, $\bar{\Theta}_Z$) that enhances potential demand (EP). In a first approximation, this approach describes how regional evaporation decreases and how climatic demand simultaneously increases (giving the relation EP + $E = 2E_o$) and how local vegetation faces higher temperature and greater water stress (high demand EP and low offer ET). These conditions of aridification reduce plant cover and consequently evaporation enhancing aridification by positive feedback toward desert conditions.

CANOPY AND SOIL EVAPORATION

When local conditions allow the existence of a full vegetation cover, equilibrium evaporation (with $\Theta_S \approx \Theta_r$) provides an acceptable estimate of the vapor phase of the hydrological cycle. It depends on net radiation (mostly solar radiation), ground heat flux, and slightly on air temperature through the slope of saturation vapor function (Δ), as quoted in many scientific publications $\{E_o = [\Delta/(\Delta + \gamma)](R_N - G)\}$.[6] It is always convenient to analyze or to calculate evaporation for a given surface under given climatic conditions as a proportion of this equilibrium value $\{E = (1 + \beta)E_o\}$ introducing a discrepancy term β. As shown in Eq. (4), this coefficient is widely dependent on the difference between the air water hygrometry deficit, Θ_r, and Θ_s, that of the surface. With abundant water supply, discrepancy coefficient β may reach values around 0.3–0.4 due to effective water uptake by the plant roots.[7] For vegetation submitted to water shortage this coefficient may decrease to -0.4. When the surface is completely dry, usually bare soil, the coefficient drops more till -1. In fact with bare soil, in response to strong climatic demand, only water diffusion from deeper soil (slow process of diffusion) can supply water for evaporation and the soil surface dries quickly building a growing dry layer called "mulch," which reduces strongly evaporation.[8]

According to seasons, the water balance is positive or negative. Generally, vegetation grows when the balance is positive. Its increasing leaf area index allows evaporation to pass climatic equilibrium and to go beyond (β varying from -0.1 to 0.3). Later in the season, lack of available water in soil appears, accelerating vegetation senescence and hamper evaporation (β dropping from 0.3 to -0.2 or less as -0.6, then reaches -1 as stored soil moisture falls to zero).

ANIMAL TRANSPIRATION

Animals need to be fed with water in order to supply their excretion and evaporation (transpiration). Most of them have developed very impermeable skin to fight water losses (Θ_s, near $\Theta_{s\,max}$), but respiration may remain a main loss of water (internal evaporation). Even if an acceleration of blood circulation carrying energy to the surface of bodies occurs, homeotherms may have difficulties to regulate their internal temperature without substantial evaporation when ambient temperature exceeds the survival limit (between 37 and 43°C). In this case, because evaporation is an effective mean to consume energy, sweat from glands wets the skin surface, which returns to a small Θ_s inducing strong evaporation. Animals can also accelerate their respiration rhythm and evaporation from lungs, or animals without sweat like pachyderm can wet their skin with water or fresh mud.

CONCLUSION

With radiative balance, evaporation is the main term of any system energy budget in the biosphere and the main cooling process for ecosystem. Furthermore evaporation (or condensation) is also the fundamental phenomenon into water cycle. So, plant plays a particular part as component of water cycle and benefits from these efficient processes. Although plants evaporate less efficiently than free water, they are more efficient than bare soil through their ability to extract water from the deep layers of soil; some trees can reach down to several meters, even decameters. Animals have to protect themselves against excess loss, and respiration as well as sweat and blood circulation tends to cool instead of surface skin evaporation.

Evaporation and Eddy Correlation

Roger Shaw
University of California–Davis, Davis, California, U.S.A.

Richard L. Snyder
Department of Land, Air and Water Resources (LAWR), and Atmospheric Sciences, University of California–Davis, Davis, California, U.S.A.

INTRODUCTION

Except within the first few millimeters of the surface, turbulence in the atmospheric boundary layer greatly dominates molecular diffusion with respect to the mixing of the variety of materials that are exchanged with the underlying surface. To a large extent, and using appropriate instrumentation, these turbulent "eddy flux" motions are measurable with a high level of precision and with a high degree of spatial and temporal resolution. If the property being transported is also measured with equivalent precision and spatial and temporal resolution, it is possible to monitor the flux density of the property continuously across any plane of interest.

EDDY FLUX

Consider the measurement of this eddy flux across a plane parallel to and a few meters above a flat horizontal surface. It is only the vertical component of the fluctuating wind velocity that is responsible for the flux across the plane. The fact that there is a net transport of some specific entity across that plane implies a correlation between the vertical wind component and that entity. For example, if water vapor is released into the atmosphere from the surface beneath, updrafts will generally contain higher vapor content than will downdrafts, and vertical velocity (positive upwards) will be positively correlated with vapor content. Fig. 1 illustrates this with data collected above a deciduous forest. The origin of the term *eddy correlation* is thus quite apparent, although *eddy covariance* is becoming more popular because it is the covariance of the velocity and scalar that is actually used. Since short-period fluxes are not a concern, a suitable averaging period between, say, 10 min and 30 min is typically selected. The averaging period is constrained to substantially exceed the duration of the largest eddy involved in the transport process, and yet be short enough to be unaffected by any lack of stationarity in the environmental conditions.

It is normal to separate the perturbation and the time-averaged components of the quantity of interest. For example, $\rho_v = \bar{\rho}_v + \rho'_v$ is an expression for absolute humidity (water vapor density, $\mathrm{kg\,m^{-3}}$), where the overbar signifies a time average over a specified interval of time and the prime indicates a departure from the mean. The vertical velocity component w ($\mathrm{m\,s^{-1}}$) can be treated similarly, such that $w = \bar{w} + w'$. This separation into mean and perturbation parts is referred to as Reynolds notation. By definition, means of the fluctuating parts are equal to zero (e.g., $\bar{w}' = 0, \bar{\rho}'_v = 0$). If the mean flow is horizontal, $\bar{w} = 0$.

Using Reynolds decomposition, the flux density for water vapor E ($\mathrm{kg\,m^{-2}\,s^{-1}}$) is written as

$$E = \bar{w}\bar{\rho}_v + \overline{w'\rho'_v}$$

However, if there is no convergence or divergence of air due to sloping surface, the mean vertical velocity ($\bar{w}$) and hence the first term on the right equals zero. This simplifies the equation to $E = \overline{w'\rho'_v}$. The term on the right hand side contains the covariance of vertical velocity and absolute humidity fluctuations, and is an unambiguous expression for the flux of water vapor that does not depend on any assumptions about the mixing properties of atmospheric turbulence.

The eddy covariance technique is direct to the extent that it requires no assumptions about the mixing properties of the air. It is assumed that the measurement made at a small distance above the surface (one to several meters) is representative of the underlying surface. Because the airflow is mainly horizontal, with imposed 3-D perturbations, the signals from which the covariance is derived are representative of an area upwind of the measurement point. This is best defined in terms of the *footprint* of the source distribution,[1] which describes in a statistical manner the source probability distribution. The footprint depends on instrument height, becoming more distant as the instrument height increases. It is also dependent on surface roughness and atmospheric stability. Under nocturnal or otherwise stable conditions, the footprint might be far removed from the measurement point, whereas nearby footprints are expected under unstable conditions. Another common descriptor of the source

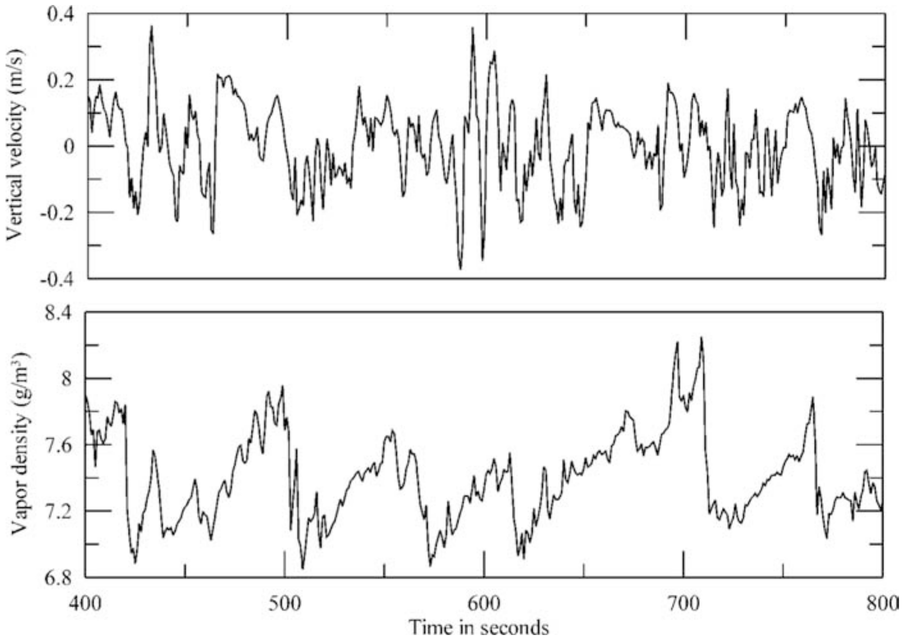

Fig. 1 Time traces of vertical velocity and humidity fluctuations above a deciduous forest showing positive correlation during a period when the foliage was actively transpiring.

region uses the term *fetch* to describe the upwind distance of uniform features required to ensure that the measurement is representative of the underlying surface and not contaminated by the flux from a distant surface. A general rule-of-thumb is that a uniform fetch is required that equals at least 100 times the height of the instrument above the effective surface. Such a fetch may be more than sufficient under unstable conditions but is likely to be inadequate when the atmosphere is very stable.

CORRECTIONS TO FLUX MEASUREMENT

Corrections are needed to the eddy covariance flux of a minor constituent in the presence of a flux of sensible heat and/or of a more major gaseous flux.[2] This arises because of density perturbations in the minor constituent imposed by the presence of the major flux. (No correction is needed if the mixing ratio of the constituent is measured instead of its density.) In a relative sense, the flux of a trace gas may require a large correction, and it may also be necessary to adjust a calculation of the flux density of water vapor in the presence of a considerable sensible heat flux. Webb, Pearman, and Leuning[2] estimated that corrections to the vapor flux vary from a few percent to more than 10% on occasion. They proposed the expression $E = 1.010\,(1 + 0.051\beta_r)E_r$, where β_r is the uncorrected Bowen ratio ($\beta_r = H/\lambda E_r$) and E_r is the uncorrected vapor flux density. H is the sensible heat flux density ($\mathrm{W\,m^{-2}}$) and λ is the latent heat of evaporation ($\mathrm{J\,kg^{-1}}$).

Often, eddy covariance measurements are made over surfaces that are not horizontal or over tall forests where variations in tree height create local departures from horizontal mean flow. Additional problems arise if the sensor is misaligned or if the tower or mast that supports the sensors create aerodynamic interference, or, indeed, if the sensors themselves distort the flow. Common practice is to perform coordinate rotations in a two-pass operation to force the mean lateral and vertical component velocities to zero ($\bar{v} = \bar{w} = 0$). A sensor misalignment of one degree can cause errors on the order of 3–4% for water vapor flux. Rotating the coordinates of the wind velocity vectors so that the vertical axis is orthogonal to the mean wind streamline will minimize tilt errors but procedures such as this are not without their problems and the reader is referred to the text by Kaimal and Finnigan[3] for further discussion.

EDDY COVARIANCE SENSORS

Sensors must measure vertical velocity and water vapor concentration with sufficient frequency response to record the most rapid fluctuations important to the diffusion process. Typically, a frequency response of the order of 10–20 Hz is sufficient, but the response-time requirement depends on wind speed, atmospheric stability, and on the height of the instrumentation.

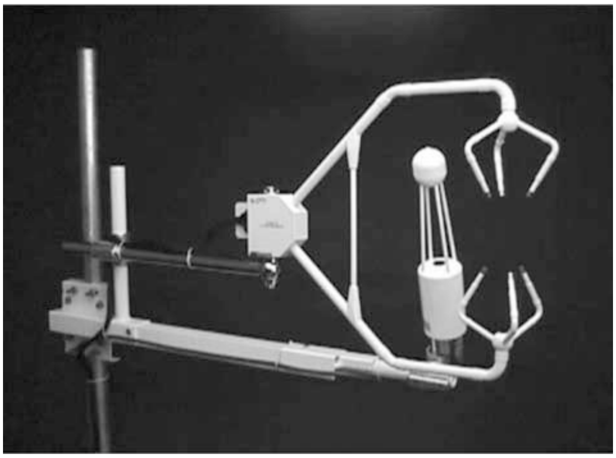

Fig. 2 Photograph of a triaxial sonic anemometer and an open-path IR hygrometer. (Photo courtesy of Campbell Scientific, Inc.)

The outputs are sampled digitally at a sufficient rate to obtain a statistically stable value for the covariance; typically, this rate is several samples per second.

Because collocation of sensors is usually not practical, instruments are placed apart but as close to each other as possible without unnecessary interference. Physical separation can lead to an underestimate of the flux. For example, Lee and Black[4] calculated an underestimate in the flux density of 3% when the ratio of the sensor separation distance to the difference between the measurement height and the zero plane displacement (effective level of momentum sink inside the canopy) was about 5%.

High-frequency wind vector data are usually obtained with tri-axial sonic anemometer (Fig. 2) in which ultrasound pulses ($\geq$40 kHz) are transmitted between an array of transducer pairs. The axial wind velocity (V_d) over the transducer separation distance (d) is given by $V_d = d/2(1/t_1 - 1/t_2)$, where t_1 and t_2 are pulse transit times in each of the two directions. The instrument performs an internal coordinate rotation to provide signals of three orthogonal velocities from a non-orthogonal transducer path array. Since the pulse transit time is usually only a fraction of a millisecond, the procedure of sending pulses back and forth is typically repeated up to 200 times per second and an output presented 10 to 20 times per second.

A range of humidity sensors has been employed for eddy covariance measurements of evaporation, including thermocouple psychrometry in some of the very earliest devices. In modern applications, high-frequency measurements of water vapor density are most commonly made with optical absorption devices operating in either ultraviolet (UV) or infrared (IR) wavelengths. The former utilize water vapor absorption in the spectral region of about 0.12 μm and open path commercial units are available as Lyman-alpha and krypton hygrometers. Lyman-alpha hygrometers use an excited hydrogen source, magnesium fluoride windows, and a nitric oxide detector. Strong absorption by water vapor allows for short paths ($\sim$1 cm) but the source ages, and the surfaces of the windows are subject to etching by water, and degrade with time. Such degradation is reversible, however, with appropriate cleaning. The krypton hygrometer uses a krypton glow tube as source. It operates much the same as the Lyman-alpha hygrometer and has the advantage of a more stable source but suffers to some degree from greater sensitivity to the gases: oxygen and ozone.

IR hygrometers generally operate in a differential mode at two nearby wavelengths: one with strong water vapor absorption and the other where absorption is weak. Longer optical paths are needed than in the case of UV-wavelength sensors and folding of the path is common. IR hygrometers are either closed or open path. In the case of the former, air is sampled by a tube at the site of the velocity measurement and drawn at high speed to a chamber of the hygrometer. A mechanical chopper switches the optics between the sample and the reference cells to allow amplification of the signal.

CONCLUSION

Eddy covariance is commonly used to determine sensible and latent heat fluxes from crop canopies, from rangeland, and from forests. Measurements of evapotranspiration are used to estimate crop coefficients, and are used in irrigation management and planning. In addition, eddy covariance is used to calibrate other less costly and more robust methods such as the surface renewal method for estimating energy and scalar fluxes.

Evaporation and Energy Balance

Matthias Langensiepen
Department of Modeling Plant Systems, Institute of Crop Science,
Humboldt University of Berlin, Berlin, Germany

INTRODUCTION

Various forms of energy drive water transport through the hydrological cycle. Radiant energy, originating from the sun, provides the input energy for the cycle. Once matter absorbs this energy, it is converted into sensible heat that elevates the temperature of the air and the ground, and latent heat that causes evaporation, driving thereby the cycle against the pull of gravity. Further transport is generated by kinetic energy and pressure energy of the moving air masses. Translocation of vapor is accompanied by continuous interchanges among radiant, thermal, kinetic, and pressure energy. Large amounts of latent heat are released when water condenses in the clouds and falls as precipitation on the earth surface. It carries kinetic energy while flowing through watersheds. Vertical movement and percolation through the earth's crust finally causes changes in potential and pressure energies.

The first law of thermodynamics states that energy is neither created nor destroyed, only converted from one form into another. This effectively means that the input and output energies of a completely defined system must balance. Storage effects may temporarily disturb this equilibrium condition. The energy balance must thus be expressed in its most general form as:

$$\textit{Energy Input} = \textit{Energy Output} + \textit{Energy Storage}$$

The water balance of the earth–atmosphere system can be treated analogically as the mass of water is conserved at all times. Evaporation is the connecting link between the system's water and energy balances. It is a surface process, which takes place at the lower boundary of the atmosphere and is an important component of the surface energy balance (see Fig. 1):

$$R_n = LE + H + G - A + S - L_p F_p$$

where R_n is the flux of net allwave-radiation, L the latent heat, E the evaporation rate, H the flux of sensible heat, G the heat flux at the lower boundary of the surface, and A the energy advected to the surface when the ground properties have horizontal discontinuities. The energy balance is sometimes parameterized for a volume of surface material (for example water body, soil, or canopy volume). As the solar energy input undergoes diurnal and annual fluctuations, heat storage S may become an important component of the balance when it is applied at time intervals shorter than the fluctuation period. When the layer includes vegetation, biochemical energy storage due to photosynthesis can also be considered. L_p is then the thermal conversion factor of carbon dioxide, and F_p is the flux of CO_2.

Shortwave radiation from the sun is the sole energy input of the earth–atmosphere system. Its net amount available for heat conversion is related to geographical location, time, atmospheric transparency, atmospheric path length, geometrical distribution of the surface elements, and their optical properties. Complementary longwave radiation exchange is governed by surface to air temperature differences and cloudiness. Net shortwave and longwave radiation form the net allwave radiation R_n.

The partitioning of R_n into the remaining terms of the surface energy balance determines the rate of surface evaporation and depends on the availability of surface water.

ENERGY BALANCE AND WATER AVAILABILITY

Unlimited Water Availability

When water availability is unlimited on a large scale, such as in oceans, vertical temperature gradients within the atmosphere tend to be very close to the adiabatic value, and most of the available energy (R_n) is diverted to latent heat (L_vE) from moisture flux at the surface. Wind gradients near the surface are typically very steep under such conditions and quickly approach values that remain nearly constant throughout the convective boundary layer. Vertical motion is damped out by strong subsidence inversion at the upper boundary of this well mixed layer. Heat Storage (S) has a dominant effect on the diurnal course of the ocean's energy balance leaving only little energy for transport ($L_vE + H$) into the air until late in the afternoon. This situation is reversed during the night, where heat released from

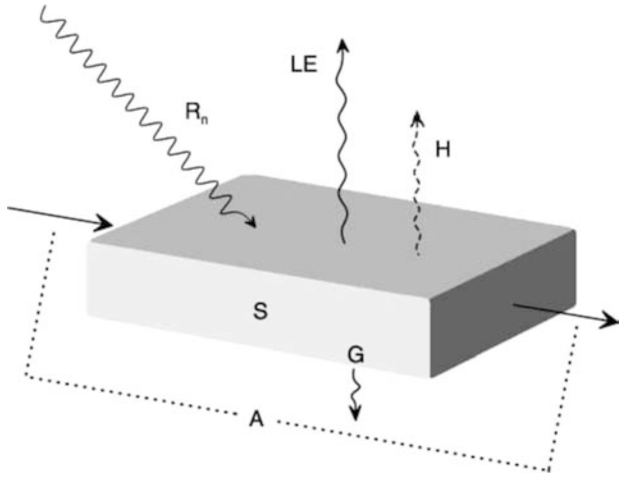

Fig. 1 Schematic illustration of the surface energy balance. (R_n = net radiation, LE = latent heat flux, H = sensible heat flux, G = ground heat flux, S = heat storage, A = advection. All symbols are expressed in $\mathrm{W\,m^{-2}}$.)

the ocean surface becomes the major source of energy. Large-scale advection (A) partly disturbs the thermal inertia of oceans, which has considerable effects on the global weather systems (Gulfstream, Humboldt-Stream, El-Nino). The smaller the water volume becomes the more it is likely that its thermal inertia is disturbed by local advection due to horizontal discontinuities of thermal surface properties. Since radiation can penetrate into water bodies it is also possible that the underlying floor becomes a source of heat.

Snow Covered and Frozen Surface Layers

When water is bound in snow covered or frozen surface layers, energy partitioning is affected by the penetration of shortwave radiation, phase changes, and internal distribution of water. Net radiation gain (R_n) is commonly restricted by a high surface albedo. The optical depth of snow and ice also affect radiation absorption and penetration. The available energy is mainly partitioned between storage energy (S) and energy required to allow water to change between frozen and liquid states (L_f). Only little energy is consumed by atmospheric transport ($LE + H$). Phase changes of water within the layer (freezing, melting, condensation, evaporation, sublimation) are accompanied by the continuous consumption or liberation of energy. The internal partitioning of available energy is thus influenced by the physical states of water: Water has a high specific heat of $4216\,\mathrm{J\,kg^{-1}\,K^{-1}}$ at 0°C due to a strong intermolecular bonding force. Fifteen percent of the hydrogen bonds break when water changes from a solid to liquid state. The energy required to effect this change is $0.334\,\mathrm{MJ\,kg^{-1}}$ and is called the latent heat of fusion L_f. Nearly 7.5 times as much energy is required at this temperature level to cause water to further change from a liquid to a gaseous state. The corresponding energy is called latent heat of vaporization L_v and is temperature dependant ($2.5\,\mathrm{MJ\,kg^{-1}}$ at 0°C, $2.45\,\mathrm{MJ\,kg^{-1}}$ at 20°C, and $2.41\,\mathrm{MJ\,kg^{-1}}$ at 40°C). In the event that water changes directly from a solid to a gaseous state (sublimation) the required latent heat of sublimation L_s is the algebraic sum of L_f and L_v. Freezing or condensation liberates energy, the amount depending on the corresponding phase shift. When the surface layer is below the freezing point and the sky is clear, net radiation can become negative under conditions of decreased radiation availability (high latitudes). It becomes positive, however, when the sky window is obstructed by clouds or surface emission is exceeded by incoming radiation. When the surface melts, both, radiation and convection act as energy sources, sometimes accompanied by additional heat input from rainfall. Surface temperatures change only little during this process, because most energy is stored as latent heat of fusion.

Water Scarcity

When water is scarce, as is the case in deserts, most of the available energy (R_n) is consumed by surface heating, which can be sensed as a rise in surface temperature. Sensible heat (H) dissipation from dry surfaces lowers the density of air increasing its instability and tendency to rise. The instable air parcels form plumes (thermals) that progressively cool down as they mix with the surrounding air and are finally capped off by the inversion layer. Additional air is entrained from the top of the capping inversion layer and dragged to the ground by sinking motion of the cooling air masses. The height of the inversion layer is dependant on the amount of energy available for surface heating. At night and during early morning, winds in deserts are light, turbulence is low, air is stable or neutral, and the inversion layer is close to the ground. Net radiation (R_n) is partitioned into surface heat-flux (G) and heat storage (S) under such conditions. However, low thermal admittance of the barren dry soil diverts a major portion of the available energy to sensible heat (H), increasing air instability and turbulence. They promote the build up of miniature whirlwinds known as dust devils. The situation is reversed during afternoons, where sinking radiation energy input stabilizes air masses. High differences between day and night temperatures are a consequence of lacking water, the magnitude depending on the diurnal evolution of net radiation (R_n). Sloping terrain and thermal surface heterogeneities induce horizontal heat transport, known as advection (A). It causes the buildup of wind gusts and turbulence, which act as kinetic energy sources in soil erosion. Advection also plays a significant role in the energy balance of wet surface islands in dry areas (Oasis effect). The evaporative demand of the atmosphere is generally high under conditions of elevated air temperature and limited water availability.

Vegetation Control of Water Availability

When vegetation cover controls water availability, energy partitioning is affected by the physiological state of the plants. The sites of regulation are *stomata* (from Greek ''mouth''), tiny pores serving as pathways between the plant interior and the atmosphere. Each pore is surrounded by a pair of specialized cells (guard cells), which control its aperture and respond to plant internal and external signals. Light, vapor pressure deficit, and water potential are the principal controlling signals. Carbon dioxide, hormones (abscisic acid and cytokinins), and photosynthetic assimilation capacity have so far been detected as additional regulating factors. Signals and plant responses are acting in an integrated manner and form the canopy resistance against water loss. Development and growth determine the evolution of plant stand architecture and hence the spatial distribution of exchange surfaces. The more the surfaces are vertically exposed against airflow, the higher is their capacity to absorb momentum. In neutral transport conditions, the logarithmic portion of the wind-profile above a canopy extrapolates downward to a height where wind speed becomes zero. This level is called *zero plane displacement* and is defined as the average height of mass and heat exchange within a canopy volume. This height changes in accordance with foliage density distribution, form drag, and wind speed. The type of surface vegetation cover thus influences the magnitude of heat and mass exchange. When determining the energy balance of a plant stand, two sources of water have to be considered, canopy and soil. If the vegetation cover is sparse or is at an early development stage, significant portions of the available energy (R_n) can reach the soil level. In this case, the availability of water depends on biological factors and the soil hydraulic properties (water retention, hydraulic conductivity, and soil water diffusivity). The partitioning of available energy (R_n) into the heat terms of the energy balance is largely determined by the water status of the soil–plant system. Latent heat (L_vE) from transpiration is the major energy sink when soil water is abundantly available. In case radiation reaches the canopy floor, latent heat (L_vE) from soil evaporation as well as soil heat flux (G) are additional sinks of energy. Advection (A) may become an additional source of energy in hot climates. Energy storage due to photosynthesis (L_pF_p) is very small in comparison with the other components of the energy balance and is therefore often neglected. Heat storage (S) becomes important in massive canopies like forests. When water becomes limited, surface regulation restricts latent heat loss (L_vE) and sensible heat (H) becomes the principal sink of energy causing rises in surface temperature. Plants have flexible capabilities to optimize production in response to such conditions.

DETERMINATION OF THE SURFACE ENERGY BALANCE

Model determinations of the surface energy balance are commonly carried out with the combination equation, which emphasizes the mutual relation between latent and sensible heat fluxes. Practical methods assume equality, either between scalars and momentum (aerodynamic method) or between the eddy diffusivities for heat and vapor. The ratio of sensible to latent heat is then proportional to the ratio of air temperature over vapor concentration (Bowen ratio $\beta = H/L_vE$). Instrumentation can be categorized in accordance to their application. Surface parameters are commonly measured with net-radiometers (R_n), heat flow sensors (G), and lysimeters (L_vE). Gradient measurements above exchange surfaces involve determinations of wind speed (anemometers), air temperature (thermometers), air humidity (hygrometers, psychrometers), and CO_2 (infrared gas analyzers). Sonic anemometers, quartz thermometers, Lyman-alpha, and Krypton hygrometers are applied with the eddy correlation method. Remote sensors can be used to deduce turbulence parameters, heat and momentum fluxes from backscattered or forward-propagated signals (sodars, radars, and lidars).

CONCLUSION

The first law of thermodynamics states that the input and output energies of any given system must balance. Solar radiation is the sole energy input of the earth–atmosphere system. Its partitioning into surface fluxes of latent and sensible heat is determined by the physical properties and availability of surface water, the ''evaporative demand'' of the atmosphere, and the nature of the surface. Evaporation is the connecting link between the system's energy and water balances. The quantification of a system's energy balance requires a definition of its boundary conditions. They consist of the spatial and temporal dimensions of the system and its exchange surfaces, their physical transport properties, the energy states across the system boundaries, and possible modes of energy transfer.

Evaporation from Lakes and Large Bodies of Water

John Borrelli
Department of Civil Engineering, Texas Tech University, Lubbock, Texas, U.S.A.

El Niño–
Evaporation

INTRODUCTION

The conversion of water from liquid state to vapor state is called evaporation. Evaporation requires energy—approximately $540\,\text{cal/cm}^3$ of water ($\approx 2.45\,\text{MJ/kg}$). Research has shown that the rate of evaporation is primarily a function of temperature, solar energy, wind velocity, vapor pressure deficit, and advected energy. The energy for evaporation comes predominately from solar radiation and wind. Evaporation is a major component of the hydrologic cycle, second only to precipitation. As such, precise documentation of evaporation from lakes and other water bodies is required for wise management of our water resources.

Annual lake evaporation across the United States has been estimated to range from 60 cm/yr to over 200 cm/yr.[1] The annual evaporation rates for several typical lakes vary from 51 cm/yr for Hungary Horse Reservoir (cool northern climate) to 223 cm/yr for Lake Mead (desert southwest) (Table 1). Consequently, there is a necessity to accurately measure evaporation rates and provide numerical models for estimating evaporation from numerous lakes and reservoirs where direct measurement is too costly to undertake.

TECHNIQUES FOR MEASURING LAKE EVAPORATION

There are three widely accepted methods for measuring the evaporation rates of lakes: a water budget, an energy budget, and the eddy correlation method. The water budget and the energy budget require a considerable amount of investment in personnel, instruments, and time. As a result, these methods are applied sparingly to calibrate numerical models.[2] With today's dependable computer technology, the eddy correlation method has become widely used in recent years. Most studies will employ two or all of the methods.

Water Budget

If all components of the water budget could be measured accurately, it is the only method that directly measures evaporation. The water budget for a lake is as follows:

$$\begin{aligned} Evap = {} & [(SW_{\text{in}} - SW_{\text{out}} + GW_{\text{in}} - GW_{\text{out}} \\ & + S_{\text{b}} - S_{\text{e}})/\text{Area} + \text{PPT}]/\text{Time} \end{aligned}$$

where $Evap$ [LT^{-1}] is evaporation, SW_{in} [L^3] is surface water inflow, SW_{out} [L^3] is surface water outflow, GW_{in} [L^3] is groundwater inflow, GW_{out} [L^3] is groundwater outflow, S_{b} [L^3] is lake storage at the beginning of the time period, S_{e} [L^3] is the lake storage at the end of the time period, Area [L^2] is the surface area of the lake, PPT [L] is precipitation, and Time [T] is the time period over which the measurements are made.[3] Evaporation is the residual of several measured terms and contains the errors included in the measurement of all those terms. Precipitation, for example, can have a bias error of up to 20% due to wind currents around the orifice of a rain gauge.[4] To use the water budget to measure evaporation, the inflow and outflow from the lake must be relatively small compared to the storage; otherwise, the errors in measurement will dominate the determination of evaporation. Overall, the error of measurement is $\pm$ 5–10%.

Energy Budget

The energy budget uses the conservation of energy principle to determine net transfer of energy into and out of a lake. Like the water budget, the evaporation rate is computed as the residual of all other terms; thus, it will contain residual measurement errors. Sturrock, Winter, and Rosenberry[5] used the following energy budget equation in the study of Williams Lake:

$$\begin{aligned} Q_{\text{x}} = {} & Q_{\text{s}} - Q_{\text{r}} + Q_{\text{a}} - Q_{\text{ar}} - Q_{\text{bs}} + Q_{\text{v}} \\ & - Q_{\text{e}} - Q_{\text{h}} - Q_{\text{w}} + Q_{\text{b}} \end{aligned}$$

where Q_{x} is the change in energy content of the body of water, Q_{s} is incoming short-wave radiation, Q_{r} is reflected short-wave radiation, Q_{a} is incoming long-wave radiation, Q_{ar} is reflected long-wave radiation, Q_{bs} is long-wave radiation emitted from the body of water, Q_{v} is net energy advected to the body of water, Q_{e} is energy used for evaporation, Q_{h} is energy

Table 1 Annual evaporation from lakes

Lake	Annual evaporation (cm)	Longitude	Latitude	Area (ha)	Average depth (m)
Pyramid Lake[2]	128	119°40′	40°00′	46,640	61
Salton Sea[2]	179	116°10′	33°05′	88,100	8
Lake Ontario[2]	73	77°00′	44°00′	1,940,000	86
Hyco Lake[2]	94	79°05′	36°15′	1,760	6
Hungary Horse Reservoir[2]	51	113°55′	46°00′	9,700	15
Lake Kerr[2]	118	81°50′	29°20′	1,040	5
Lake Mead[2]	223	114°30′	36°05′	51,400	54
Lake Okeechobee[9]	147	80°55′	27°00′	182,130	3
Amistad Reservoir[2]	203	101°20′	29°20′	27,900	16
Great Salt Lake[2]	101	112°30′	41°00′	388,900	10

conducted from the water as sensible heat, Q_w is energy advected from the body of water by the evaporated water, and Q_b is heat transfer to the water from the bottom sediments. All terms are expressed in W/m^2.

Eddy Correlation

At the surface of the water, the water vapor in the air is nearly saturated. As air moves across the surface, small eddies transport the water vapor vertically at a net air movement of zero in the vertical direction. With current instrumentation, it is now possible to measure the vertical flux of water vapor or evaporation above the surface of a lake. The eddy correlation method directly measures the evaporative flux as presented by Shuttleworth[6] in the following formula:

$$E = 86.4\overline{\rho_a w' q'}$$

where E is the evaporation rate (mm/day), ρ_a is the air density (g/m^3), w' is the vertical wind velocity (m/sec^1), and q' is the specific humidity (g of water/g of air). The overbar denotes a mean value over a specific interval and the prime denotes an instantaneous deviation from the mean. Kizer and Elliot[7] provide a complete procedure to measure and calculate all terms needed to use the eddy correlation method. The accuracy for the eddy correlation measurements is 5–10%.[6] This compares favorably with the energy and water budget methods, which have the same range of accuracy. Measurements are taken at a point but are used to represent a large area of a lake. This causes some error because there are different microclimates over a large lake.

ESTIMATION OF EVAPORATION

Evaporation cannot be measured at all lakes and reservoirs by using the methods described above. Thus, researchers have developed several equations that use climatological data for estimating evaporation. The most widely used equation is the modified Penman equation that was originally developed for evaporation as well as to estimate evapotranspiration from vegetation.[8] The modified Penman equation requires data on wind, net solar radiation, humidity, and temperature. There are many equations called modified Penman. The following is a good example of a modified Penman equation:[6]

$$E_p = \frac{\Delta}{\Delta + \gamma}(R_n + A_h) + \frac{\gamma}{\Delta + \gamma}\frac{6.43(1 + 0.536U_2)D}{\lambda}$$

where E_p is estimated potential evaporation (mm/d), R_n is net radiation exchange for the free water surface (mm/d), A_h is significant energy advected to the water body (mm/d), U_2 is wind speed at 2 m (m/sec), D is vapor pressure deficit (kPa), λ is latent heat of vaporization (MJ/kg), Δ the gradient of the saturation vapor–temperature curve (kPa/°C), and γ is the psychrometric constant (kPa/°C). Please refer to Shuttleworth[6] for details on the calculation of different variables.

Investigators have found that the modified Penman equation (not necessarily the same modifications as above) has estimated evaporation within the accuracy of measured evaporation rates.[9–11] The modified Penman equation does not take into account the heat stored in a lake, which can be significant. The Penman equation will overpredict evaporation during warmer months and underpredict evaporation during the colder months.[11] On an annual basis, the modified Penman has proven reliable over a wide range of locations and climatic conditions.

Pan evaporation rates have been widely used to estimate lake evaporation. Kohler, Nordenson, and Fox[12] reported on an extensive study at Lake Hefner in Oklahoma comparing lake evaporation and pan evaporation. They reported that the annual ratio for a U.S. Weather Bureau Class A pan evaporation to lake evaporation was 0.7. This proportional constant is called the pan coefficient. The USGS[13] reported that monthly pan coefficients varied from 0.13 in February to 1.32 in November. Annual pan coefficients have been reported as low as 0.51 at Lake Mead[14] to 0.75 at Lake Okeechobee.[9] Evaporation pans provide reliable results if several stations are used. However, pan evaporation records are often erratic and often trend downward with time because of environmental changes of surroundings and poor maintenance of the pan.

There are many other equations that have been developed to estimate evaporation. They include mass-transfer equations,[5] radiation equation,[9] temperature equations,[10] etc. The applicability of these equations is generally limited to their use in environments similar to those in which the equations were calibrated.

Evaporation from Soils

Andre Chanzy
Unité de Recherche Climat, Sol et Environnement, Institut National de la Recherche Agronomique (INRA), Avignon, France

INTRODUCTION

Evaporation is defined as the water-vapor flux from a surface towards the atmosphere. Evaporation from soil is an important component in soil water and energy balances. The rate of the soil evaporation flux varies commonly from $0\,\mathrm{kg/m^2}$ day to $15\,\mathrm{kg/m^2}$ day (also expressed as the equivalent depth of a water layer covering the surface from 0 mm/day to 15 mm/day).

Soil evaporation presents a strong variability depending on the climate conditions, the surface, and soil hydraulic properties. Fig. 1 represents evaporation sequences of two different soils under the same climate. The cases wet and dry differ by the strategy to maintain or not the soil water. When the soil is well watered, variations of the evaporation follow roughly those of the climatic demand characterized by reference evapotranspiration corresponding to a well-watered short grass surface. The differences between two wet soils or between the wet soils and the reference evapotranspiration are caused by surface properties. As soil dries evaporation decreases at rates depending on soil hydraulic characteristics.

Fig. 1 also shows the three evaporation phases. During phase I, the surface is wet enough to maintain an evaporation similar to that of a permanently watered soil (in Fig. 1 see the first day for the silty clay loam and the four first days for the loam). Phase II corresponds to the period of decreasing evaporation which does not depend on the climatic demand. Phase III occurs at the end of an evaporation period and is characterized by low and almost constant evaporation (in Fig. 1 see the silty clay loam after day 15).

WHY WATER EVAPORATES FROM SOILS

Evaporation occurs when the vapor concentration in equilibrium with the soil surface (C_s, kg m^{-3}) is higher than that of the air (C_a) above the soil (see A in Fig. 2). The vapor-flux intensity that results from this difference depends on the vapor-transport processes in the lower part of the atmosphere. The transport mechanisms are vapor diffusion and turbulence generated by the airflow over a rough surface (here the soil) and/or the air temperature differences between the soil and the air. In most cases turbulence is the dominant transport mechanism. Thus, when the soil surface is wet, evaporation increases with the wind velocity, the temperature difference between the soil surface and the air, and the surface roughness. At the surface, when vapor moves towards the atmosphere, water vaporization occurred to maintain a water-vapor concentration that respect the thermodynamic equilibrium of the water between the liquid and vapor phases. As soil looses water vapor, its surface cools to supply the heat required for the liquid to vapor phase change.

HOW SOIL CONTROLS EVAPORATION

Soil controls the vapor concentration (C_s) at the surface level (see B in Fig. 2).

The water thermodynamic equilibrium at a liquid–vapor interface is described by the Gibbs relationship that relates the water chemical potential to the temperature and C_s. From this relationship one can demonstrate that:

$$\psi = (RT/M) \cdot \rho_w \cdot \mathrm{Log}(C_s/C_{sat}(T)) \qquad (1)$$

where ψ is the soil-water surface potential (Pa), T the surface temperature (K), R the ideal gas constant, M (kg) the water molar mass, ρ_w (kg m^{-3}) the volumetric mass of liquid water, and C_{sat} the saturated vapor concentration which depends on the temperature. The soil potential ψ is linked to the soil moisture by a soil dependant relationship (commonly named retention curve). In wet condition ($\psi > -1$ MPa), $C_s/C_{sat}(T) > 0.99$ and thus C_s is controlled by the surface temperature ($C_s \cong C_{sat}(T)$). For dry soils ($\psi < -1$ MPa) C_s is controlled by both surface moisture and temperature.

Soil controls the water supply of the evaporative surface (see C in Fig. 2).

As a consequence of the water vaporization, the soil surface dries. So, the water-potential gradient increases near the surface and an upward water flux tends to homogenize the water potential between the surface and the upper soil layers. Such an upward water flux partly balances the water loss and thus contributes to maintain a wetness at the soil surface. The flux

El Niño–Evaporation

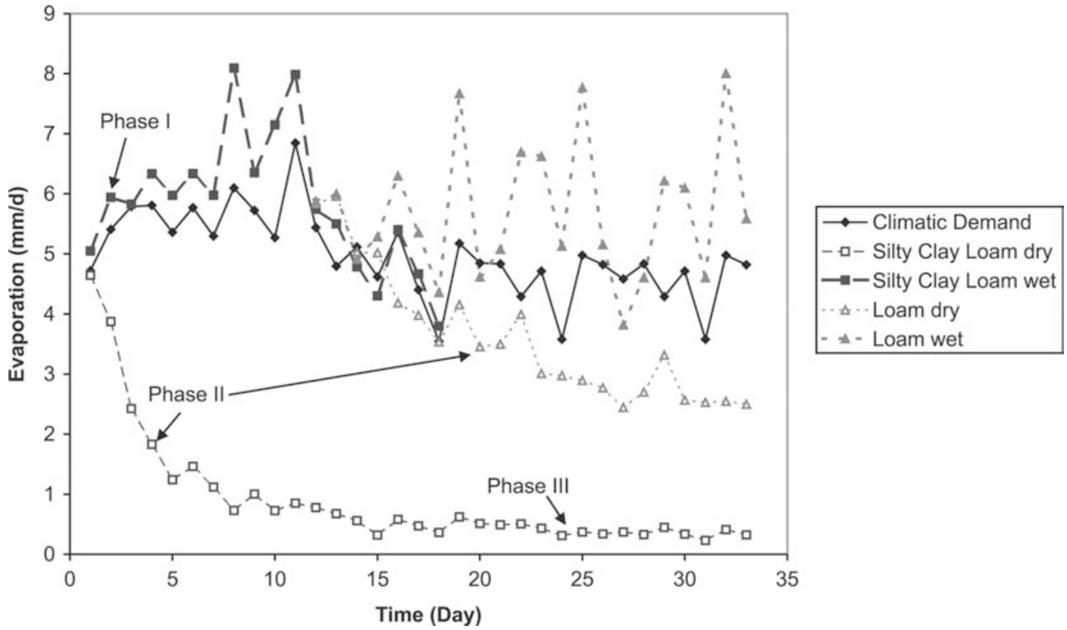

Fig. 1 Daily evaporation sequences for two different soils. For the dry condition no water supply was provided during the sequence whereas the wet conditions correspond to an irrigated surface where the wetness was maintained at saturation.

intensity depends on soil characteristics such as the retention curve and the hydraulic conductivity. When hydraulic conductivity is high (i.e., a wet and/or conductive soil) the upward flux is sufficient to maintain wet conditions (i.e., $\psi > -1$ MPa) at the surface. This situation corresponds typically to the evaporation phase I. When the soil conductivity is low, the upward flux does not balance the water loss and then surface

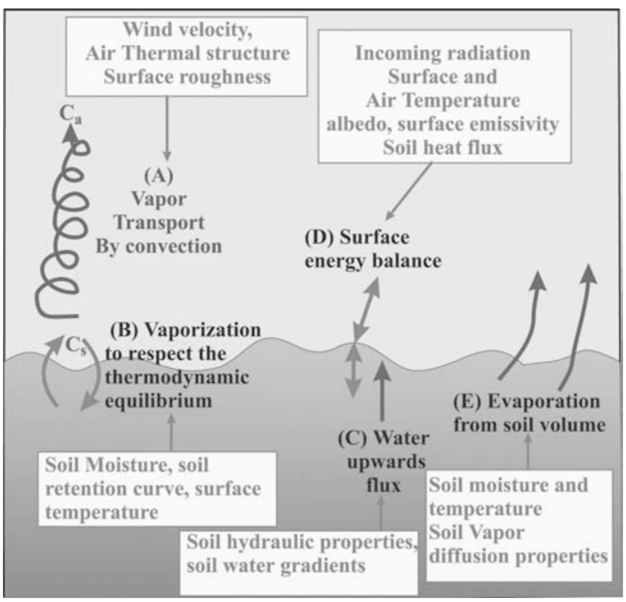

Fig. 2 Main physical processes involved in soil evaporation.

layers dries. Such a drying explains the evaporation decrease observed during the evaporation phase II.

Vaporization occurs within soil (see E in Fig. 2). There are soil/air interfaces within the soil when it is not saturated with liquid water. Vapor-concentration gradients can produce vapor fluxes by diffusion and convection. It is then possible that the soil volume contributes to the evaporation. In very dry condition corresponding to phase III, evaporation from the soil volume is the dominant contribution.[1] The soil heating by external sources and the soil vapor diffusive characteristics are the main factors affecting the vapor flux whereas atmospheric convection has little influence.[1] The soil thickness that contributes to evaporation is variable. It can reach several meters in case of desert areas where the water table is the main source of evaporation.[2]

ENERGY PROCESSES DURING EVAPORATION

As the soil provides the energy required for converting liquid water into vapor, evaporation lowers soil temperature. As a consequence, C_s decreases since $C_{sat}(T)$ monotonously increases with temperature. Without an external source of energy, C_s decreases until equilibrating with C_a, at which point evaporation stops. Therefore, the energy supply is a key factor for the evaporation (see D in Fig. 2). The energy fluxes at the soil surface are linked by the surface energy conservation law:

$$R_n + H + LE + G = 0 \quad (2)$$

where R_n (W m^{-2}) is the net radiation, H (W m^{-2}) the sensible heat flux, E (kg m^{-2} sec^{-1}) the evaporation flux, L (J kg^{-1}) the water vaporization latent heat, and G (W m^{-2}) the soil energy flux including both conductive and latent heat fluxes. The net radiation term is quantitatively the most important term. It can be written by the following equation:

$$R_n = (1 - a)R_s + \varepsilon R_a - \varepsilon\sigma T_s^4 \quad (3)$$

where R_s is the incoming solar radiation (W m^{-2}), R_a the atmospheric radiation (W m^{-2}), ε the soil emissivity, a the surface albedo, and T_s the surface temperature. The two last terms of the Eq. (3) right side generally balances each other and thus, solar radiation is the main source of energy. Soil albedo, a, defined as the fraction of reflected solar radiation has a determinant effect on the surface energy balance. It varies from 0.1 to 0.4 according to the soil (soil chemical composition and roughness) and decreases when soil moisture increases.[3]

MEASUREMENTS OF SOIL EVAPORATION

Evaporation can be measured either by a soil-water balance or by micrometeorological observations. The soil-water balance approach consists in monitoring the water storage from the surface to a given depth and the water flux at that depth. This can be implemented by in situ soil moisture measurements or by using weighing lysimeters.[4] These methods are appropriate to assess the evaporation at a local scale.

With the micrometeorological approach the evaporation turbulent flux above the surface is inferred directly or as a residual term of the surface energy balance equation [Eq. (1) by measuring the three other terms].[5] Measurements of turbulent fluxes (H, LE) have to be achieved over homogeneous plots and at a distance of about 50 m to 100 m from the plot boundary. Micrometeorological methods are then suitable to assess the fluxes at a field scale with a time resolution of approximately 10 min to 30 min.

SOIL EVAPORATION MODELING

Evaporation can be physically represented in mechanistic models that couple the soil heat and water flows with atmospheric fluxes.[2] Simpler approaches are available. Evaporation during phase I (also called potential evaporation PE) can be assessed using the Penman Equation:[6]

$$LPE = \frac{\gamma}{\gamma + \Delta} f(U)(C_{sat}(T_a) - C_a) + \frac{\Delta}{\gamma + \Delta}(R_n + G) \quad (4)$$

where γ is psychrometric constant ($\cong$ 67 Pa K^{-1}), Δ is the slope of the "saturation vapor pressure–air temperature (T_a)" relation and f is the turbulent vapor exchange coefficient which depends on the wind velocity (U). At a daily time step empirical relationships are given for the $f(U)$ and ($R_n + G$) terms[7] allowing an estimation of L PE from standard climatic measurements (T_a, U, C_a, and incoming radiation).

For evaporation phase II and III numerous models are available. However, all of these models link the actual evaporation to the PE with a parameterization that involves the soil surface moisture. This quantity is either explicitly introduced in the evaporation models [Eq. (1)] or estimated by a cumulative time or PE[8,9] from the beginning of the phase II period.

HOW CAN WE ACT ON SOIL EVAPORATION?

By modifying the soil properties and surface properties, it is possible to act on the rate of evaporation. Covering the soil surface with a plastic film or crop residues (mulch) suppresses or limits the vapor flux from the surface to atmosphere. This is a very efficient way to limit soil-water loss by evaporation. Soil tillage practices modify the surface roughness, the albedo, and the hydraulic conductivity. These modifications act on evaporation in different ways but it is difficult to foresee the resulting impact. Tillage is often used to break the porosity continuity. The unsaturated conductivity is then reduced accelerating drying of the soil surface layers that act like a mulch reducing further evaporation.

Evapotranspiration: Canopy Architecture and Climate Effects

Delphis F. Levia
Department of Geography and Center for Climatic Research, University of Delaware, Newark, Delaware, U.S.A.

INTRODUCTION

Evapotranspirational losses from plant canopies are significant, accounting for >50% of the incident gross precipitation (P_g) for some forests.[1] A wide range of biotic and abiotic factors regulate evapotranspiration. Biotic factors include species composition and plant physiological properties, plant nutritional status, and canopy architecture, whereas abiotic factors include seasonality, exposure to pollution, precipitation inputs, and soil water-holding capacity. Evapotranspirational losses are highly variable over space and through time. This article explores two of the primary factors affecting evapotranspiration: plant canopy architecture and climate–vegetation dynamics.

Temporal and spatial heterogeneity of evapotranspirational losses are partly attributable to plant canopy architecture and climate. The effect of plant canopy architecture on temporal variation of evapotranspiration differs among and within plant species. Inherent differences in crown form and architecture between coniferous and deciduous tree species, such as the presence or absence of foliage during winter, have a distinct impact on both interception and transpiration. Intraspecific variation in evapotranspiration may be explained by factors such as differences in plant age and life history. Climatic factors that affect evapotranspirational losses over varying time scales include the intensity of solar radiation receipt and precipitation amount.

Plant canopy architecture and climate also vary at the scale of a whole plant or leaf, differentially affecting evapotranspiration. On the scale of whole plants, for example, tree health and the degree of herbivory will impact plant canopy form and architecture, which, in turn, will impact water consumption by the plant. Differences in leaf shape with depth into the canopy, for any given tree, will also impact plant water use by altering boundary layer conditions and stomatal conductance. Thus, the configuration (i.e., three-dimensional geometry) of the plant canopy has a distinct and distinguishable effect on plant water consumption. Climatic factors, such as exposure to wind between trees of the forest interior and edge, also change from tree to tree and impact evapotranspiration. Shading and differences in light availability throughout the vertical profile of an individual plant influences evapotranspiration as well. Hence, water consumption by plants is impacted by both plant canopy architectural and climatic factors.

The first section of this article will describe the magnitude of evapotranspirational losses from wooded ecosystems and explain its effect on water yield to give readers a sense of its importance within the hydrologic cycle. Focusing on the interplay between plant canopy architecture, climate, and evapotranspiration, the remainder of this article will feature specific sections devoted to a description of canopy structure and its key components, the effect of canopy architecture on interception of precipitation, the interaction between canopy architecture and transpiration, and the effect of climate–vegetation dynamics on evapotranspiration. Each section, with the exception of the first, will examine the effects of canopy architecture or climate on evapotranspiration at the whole plant and leaf scales. Together, these sections will give insight into the influence of plant canopy architecture and climate on evapotranspirational losses.

VEGETATION AND WATER CONSUMPTION

Water balance calculations in forests and plantations have demonstrated that evapotranspirational losses are considerable, measuring approximately 400 mm/yr for deciduous forests (67% of incident P_g) and nearly 1500 mm/yr for tropical rainforests (35% of P_g).[2] In semiarid ecosystems, evapotranspiration has been found to reach 190 mm/yr, constituting 95% of P_g.[2] Evapotranspiration in deserts can exceed 100% of P_g where plants have access to groundwater resources.[2] Evapotranspiration varies seasonally, partly as a function of meteorological conditions, and is usually temporally mismatched with precipitation inputs (Fig. 1A), causing seasonal water deficits in which actual evapotranspiration is less than

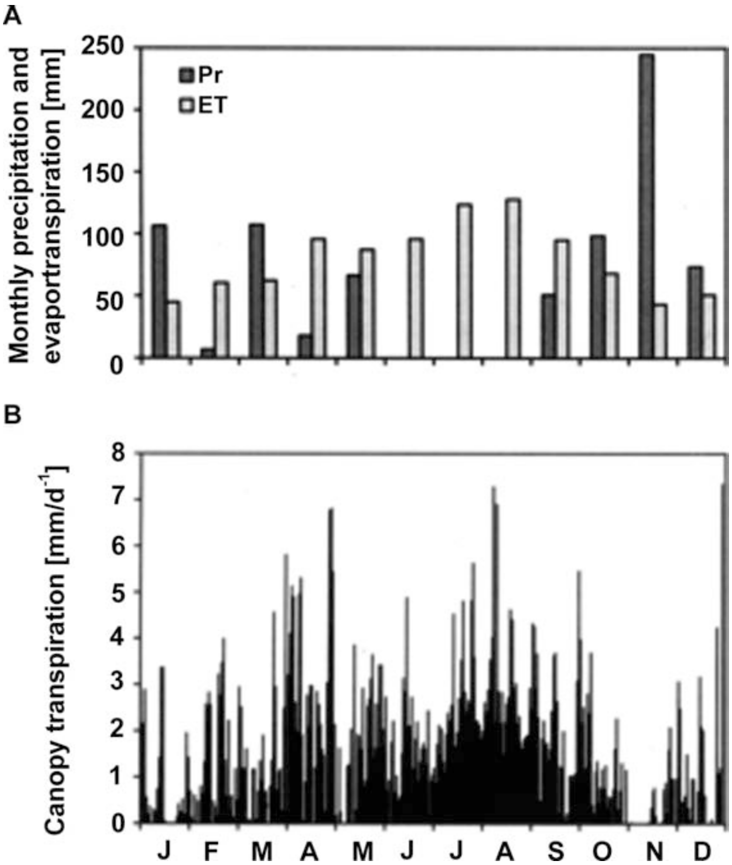

Fig. 1 Water–vegetation dynamics in a laurel forest in Tenerife (Canary Islands). (A) Total monthly precipitation (Pr, dark gray bars) and potential evapotranspiration (ET, light gray bars). (B) Daily water consumption totals (mm/day) by a *L. azorica* stand based on a continuous record of trunk sap flow. *Source:* From Ref.[2], translated from Ökophysiologie der Pflanzen, 6. Auflage. potential evapotranspiration. Fig. 1B depicts the overall decline in canopy transpiration from a laurel [*Laurus azorica* (Seub.) Franco] forest during the winter months in the Canary Islands and underscores the importance of changes in air temperature, air humidity deficit and stomatal resistance, day length and light availability, and net radiation receipt on transpiration losses.

Streamflow and water yield from catchments are affected by evapotranspirational losses.[3] Fifteen years following the conversion of a hardwood forest to eastern white pine (*Pinus strobus* L.), annual streamflow was found to decrease by 20% (20 cm) in western North Carolina.[4] The decrease in annual streamflow was attributed to larger interception and transpiration losses because of: 1) the larger total foliar surface area of pine compared to hardwoods and 2) the evergreen condition of pine.[4] Based on a review of 94 catchment experiments, Bosch and Hewlett[5] found that decreases in vegetative cover resulted in increased annual streamflow, with average increases being 40 mm in water yield per 10% reduction in vegetative cover for pine and eucalypt forests. The corresponding increase in water yield for deciduous forests with a 10% reduction in vegetative cover was approximately 25 mm.[5] In a real-world study of water yield–vegetation cover relationships, employing rigorous statistical models in 10 contiguous river basins (as opposed to an experimental catchment) of the Southern Piedmont region of the U.S.A., relatively minor increases in forest cover (10–28% of total area) were found to significantly decrease water yield.[6]

CANOPY STRUCTURE

Parker[7] defined canopy structure as "the organization in space and time, including the position, extent, quantity, type, and connectivity, of aboveground components of vegetation." Some common metrics of canopy structure that relate to plant water use are plant area index (PAI, m^2/m^2), leaf area index (LAI, m^2/m^2), woody area index (WAI, m^2/m^2), and leaf area density (LAD, m^2/m^3). The sum of LAI and WAI is equal to PAI. Leaf area and woody area indices are expressed as the amount of leaf or woody surface area per unit ground area. LAI and LAD are foliar metrics and include foliage in leaf and needle form. LAI generally ranges from 4 to 6 m^2/m^2 for a broad-leaved deciduous forest and from 15 to 20 m^2/m^2 for an evergreen coniferous forest (Table 1). LAI of agricultural crops ranges between 4 and 12 m^2/m^2.[2]

Table 1 LAI and mean LAD for selected forest types

	LAI (m^2/m^2)	LAD (m^2/m^3)
Deciduous broadleaf	4–6	0.1–0.3
Evergreen broadleaf	7–12	0.2–0.5
Deciduous conifer	5–7	0.1–0.4
Pinus	7–12	0.2–0.5
Evergreen conifer	15–20	0.3–0.7

Source: Adapted from Ref.[7].

LAD also tends to be larger for evergreen forests than for deciduous forests (Table 1). Fewer researchers have quantified WAI. Stand level WAI values for cypress (*Taxodium ascendens* Brongn.) wetlands and slash pine (*Pinus elliotti* Engelm.) uplands in north central Florida were around $1.0\,m^2/m^2$,[8] whereas WAI of selectively sampled tropical rainforest trees was found to range from 2 to $10\,m^2/m^2$.[9]

Plant canopy architecture can change dramatically over time and through space. Leaf drop in deciduous forests greatly alters canopy structure, catalyzing a number of changes that impact water use and consumption. Evaporation of intercepted precipitation, for instance, is reduced during the leafless period, which increases net precipitation inputs to the forest soil. Coniferous canopies also experience seasonal needle fall. The reduction in needle area and decreased air temperatures, coinciding with the onset of autumn, lead to a reduction in transpiration and initiation of soil moisture recharge.

The distribution of canopy leaf area as a function of tree height and age in a yellow poplar (*Liriodendron tulipifera* L.) stand of the mid-Atlantic U.S.A. is considerable (Fig. 2). Total leaf area reaches a steady state after approximately 15 years in a yellow poplar forest, but the vertical and horizontal distribution of leaf area continues to change as the forest progresses through succession and achieves crown closure (Fig. 2).[7] Hence, plant canopy water use will change throughout the vertical profile of the canopy, because leaf morphology and anatomy change with height and as the forest ages.[10]

CANOPY ARCHITECTURE AND PRECIPITATION INTERCEPTION

Incident P_g is partitioned into throughfall and stemflow upon impact with a plant canopy. Free throughfall is transmitted through the canopy without contact with any aboveground vegetative surface, whereas release throughfall is intercepted by the plant canopy and subsequently drips to the forest floor.[11] Stemflow is the water that drains on the surface of inclined branches converging on the tree trunk along channelized flow paths. The difference between P_g and net precipitation is interception. Intercepted precipitation evaporated from plant canopies is unavailable for plant use.

Canopy structure and architecture have been documented to affect the partitioning of P_g into throughfall and stemflow.[12] The partitioning of P_g is important because it dictates the amount of water intercepted and subject to evaporative loss. Interception storage capacity (I_s) is the amount of water stored on vegetative surfaces per unit area. I_s varies between foliar and woody surfaces as well as the three-dimensional presentation of those surfaces and is a key factor governing throughfall and stemflow yields. Bark has

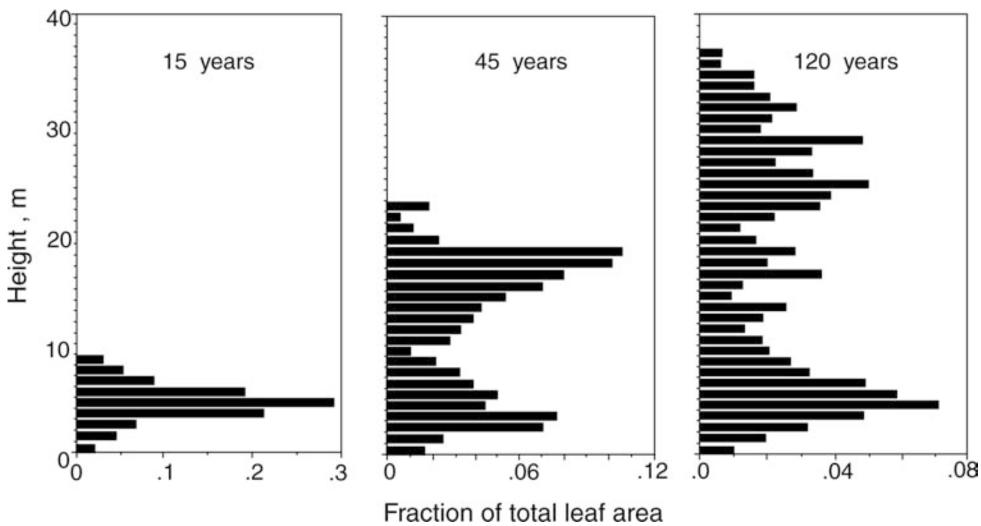

Fig. 2 Vertical canopy structures in different-aged stands of yellow poplar in the mid-Atlantic region, U.S.A. *Source:* Reprinted from Ref.[7], with permission from Elsevier.

a larger interception storage capacity than foliar surfaces,[8] reaching approximately 450 L for a northern red oak (*Quercus rubra* L.) with a trunk diameter of 40 cm.[13] Foliar interception storage capacities reported for tropical rainforest tree species ranged from 38 to 183 L under calm conditions, equating to 112–161 ml/m^2 leaf area and decreasing drastically under windy conditions.[9]

Another factor affecting the volume of throughfall and stemflow generated is branch inclination angle.[14] Level branches are more conducive to the generation of throughfall than stemflow, whereas more steeply inclined branches have a greater probability of producing stemflow. There is, however, a tradeoff between orthogonally projected area capable of intercepting precipitation and branch inclination angle. Orthogonally projected branch area (P_a) varies as a function of branch inclination angle (α) according to the following equation:

$$P_a = [\cos(\alpha)]A$$

where A is the projected branch area at 0° above the horizontal.[14] Upon impact with the bark surface, a raindrop drains to the underside of the branch and becomes entrained as throughfall or stemflow.[14] Once the underside of a branch is wet, it becomes quite effective at retaining the water and generating stemflow.[14] Other tree characteristics that have been noted to influence stemflow production are crown size, leaf shape and orientation, bark thickness and morphology, and flow obstructions.[15] Larger diameter trees tend to generate larger stemflow yields than the smaller diameter trees.[15] Whereas, vertically oriented leaves tend to promote throughfall generation, and concave leaves, with their tips above the leafstalk, tend to favor drainage to the branch and stemflow.[15] Detaching bark on tree trunks of some species generally causes stemflow to become throughfall unless the throughfall is intercepted by a lower branch.[15]

Water storage varies as a function of canopy height, corresponding with changes to the vertical distribution of aboveground vegetative surfaces[16] and impacting throughfall and stemflow generation. Along an altitudinal transect of black spruce [*Picea mariana* (Mill.) B.S.P.], forests that stand with higher LAI and foliar biomasses tended to have lower throughfall volumes than that stand with lower LAI values.[17] Forest canopy architecture also can effect precipitation interception and partitioning of wind-driven rainfall. Trees overshadowed by taller neighbors can be sheltered from wind-driven rain and generate much less stemflow and throughfall than more prominent trees intercepting the majority of the wind-driven rainfall.[18]

CANOPY ARCHITECTURE AND TRANSPIRATION

Transpiration is affected by many factors (biotic and abiotic), including LAI and tree vigor as well as soil moisture levels and meteorological conditions. Variation in evapotranspirational loss with forest age for cypress and cedar forests in Japan has been attributed to changes in transpiration corresponding to fluctuations in LAI.[19] For blue oak (*Quercus douglasii* Hook. & Arn.) woodlands in California, stomatal conductance and water use differed considerably between adult trees and saplings and seedlings, with seedlings exhibiting lower water use efficiencies than either adult trees or saplings.[20] Broadly defined as the amount of carbon gain per unit water lost, water use efficiency (WUE) can serve as an indicator of plant water consumption. It is important to note, however, that the

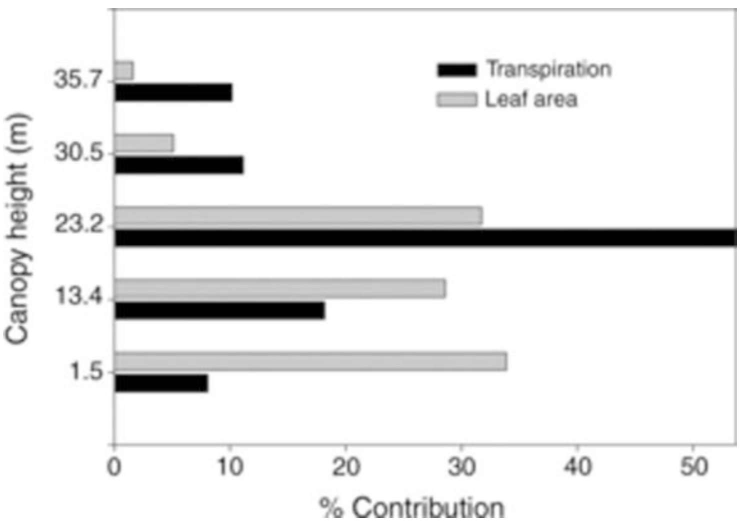

Fig. 3 Vertical variation of canopy leaf area and transpiration expressed as percentages of total leaf area and total transpiration, respectively, for five layers within the canopy of a virgin forest located in the Reserva Florestal Ducke, Manaus, Brazil. *Source:* From Ref.[22], copyright 2000, © John Wiley & Sons Limited, reproduced with permission. definition of WUE is usually contextual and that the time scale over which the efficiency is measured and the precise measure of carbon gain (e.g., biomass accumulation, economic yield) be specified.[21]

As demonstrated earlier, LAI varies within the vertical profile of a plant canopy. The change in LAI within a plant canopy alters wind speed, light and radiation inputs, air temperature, and humidity. Not surprisingly, then, transpiration varies as a function of height within a forest canopy but is not proportional to the amount of leaf area (Fig. 3). Transpiration is disproportionately higher in the upper portion of the canopy with lesser amounts of leaf area than increasingly shaded lower parts of the forest canopy (Fig. 3). This pattern is partly the result of lower light levels in the lower part of the canopy, which inhibit stomatal conductance as well as reductions in wind speed, radiation, and air temperature, which decrease transpiration. The change in leaf morphology and anatomy with height of the canopy is less important for transpiration loss in forests with canopy closure, because the cooler leaf temperatures of the more deeply lobed leaves near the canopy top tend to be counterbalanced by the lower boundary layer resistance. Research from France has found that transpiration does not rise with increases in LAI with the emergence of the second and third flushes of leaves in sessile oak [*Quercus petraea* (Mattuschka) Liebl.] because new leaves have low stomatal conductance and appear when potential evapotranspiration rates are high (i.e., when stomatal closure is likely).[23] Domingo, van Gardingen, and Brenner[24] discuss the interactions between the plant canopy and boundary layer conductance for two semi-arid native species in southeastern Spain, concluding that canopy structure does affect water use.

The internal architecture of canopy trees, specifically, sapwood thickness, also impacts transpiration.[25] Ewers et al.[25] found that sapwood thickness was independent of tree diameter for two wetland species, white cedar (*Thuja occidentalis* L.) and speckled alder [*Alnus regosa* (Du Roi) K. Spreng.], but not for other species growing beyond wetlands, such as red pine (*Pinus resinosa* Ait.) and quaking aspen (*Populus tremuloides* Michx.). Stand transpiration was found to be determined by the sapwood area per unit ground area, indicating that the internal structure of the tree impacts water use.[25]

CLIMATE–VEGETATION DYNAMICS AND EVAPOTRANSPIRATION

Bonan[26] argued that ‘‘ecological climatology is an interdisciplinary framework to understand the functioning of terrestrial landscapes in the climate system.’’ Ecological climatology provides a useful context to examine climate–vegetation interrelationships that regulate evapotranspiration. Most have observed dramatic differences in vegetation as a result of climatic setting. In fact, plant species adapt to different climatic settings to control evapotranspirational losses. Sclerophyllous vegetation, adapted to regions with hot dry seasons, tend to have small leaves and thick, waxy cuticles that limit evapotranspirational losses. These plants also are able to bear much lower soil water potentials than temperate tree species. Eucalypts, for example, have been found to be able to tolerate water potentials as low as of -10 MPa (-100 bars), whereas water potentials of -5 MPa (-50 bars) are lethal for many temperate tree species.[27] Climate–vegetation interactions are also critical in areas with high fog incidence and those under irrigation.

In areas where fog is prevalent, such as coastal regions and montane cloud forests, the immersion of trees in fog results in fog drip and a net increase of precipitation to the forest floor (i.e., precipitation augmentation).[28] Fog interception inputs represent a considerable proportion of the annual precipitation inputs in coastal northern California where redwood trees (*Sequoia sempervirens* Lamb. ex D. Don) Endl. receive an average of 34% of their total input from fog drip.[29] In tropical montane cloud forests of Panama, fog interception inputs were found to range between 2% (142 mm) and 60% (2295 mm) of total water inputs, varying as a function altitude and extent of crown exposure to prevailing winds.[30] Thinning of a Canary Island pine (*Pinus canariensis* Chr. Sm. ex DC.) plantation has been demonstrated to reduce throughfall inputs by reducing the amount of aboveground surface area available to intercept fog and route subsequent drip to the forest floor as throughfall.[31] Basal area, surface roughness, and LAI demonstrated a positive relationship with throughfall volume yields in the Canary Island pine plantations.[31]

Climate–vegetation dynamics in drylands also have a profound effect on evapotranspirational losses as native vegetation is replaced by irrigated crops. Although irrigation of crops in drylands has undoubtedly boosted agricultural production and provided food and materials necessary to sustain a growing world population, the cultivation of non-indigenous crops in drylands exacts a significant toll on the environment. The Aral Sea catastrophe is a prime example illustrating the extent to which poor management decisions in marginal climatic settings result in severe land degradation. Diversion of water from the Amudarya and Syrdarya Rivers for irrigated cotton production in the drylands of the former USSR has starved the Aral Sea of its water supply, decimating the fisheries industry and local economy.[26] Moreover, increased evapotranspiration from the irrigated cotton plants (vis-à-vis the non-irrigated sparse natural vegetal cover) has accelerated soil salinization in the Aral Sea region.[26] To mitigate future problems associated with dryland agriculture and irrigation, the role of climate–vegetation interactions and its effects on the lithosphere, hydrosphere, atmosphere, and biosphere should be considered.

CONCLUSIONS

Spatial and temporal changes in plant canopy architecture and climate engender concomitant modifications in evapotranspirational losses. The form and architecture of forest trees and agricultural crops impacts the process of precipitation interception which dictates how much water evaporates from aboveground vegetative surfaces and the amount that eventually infiltrates into the soil. Stomatal conductance and transpiration are affected, in part, by plant canopy architecture and climate, governing the amount of water vapor returned to the atmosphere. While water use efficiencies undoubtedly differ among and within plant species and are a function of many interacting factors, including climate–vegetation interrelationships, it should be acknowledged that plant canopy architecture and climate are key because of their detectable and notable effects on evapotranspirational losses that impact infiltration, percolation, runoff, and streamflow in wooded ecosystems.

Evapotranspiration: Formulas

Robert D. Burman
Department of Agricultural Engineering, University of Wyoming, Laramie, Wyoming, U.S.A.

Evapotrans–Giant

INTRODUCTION

An agricultural scientist or hydrologist often needs to be able to calculate numerical values of evapotranspiration, ET, in equivalent depth per time units. ET is commonly defined as the transfer of water vapor to the atmosphere through evaporation from the earth's surface and transpiration from plants. This article is intended to be useful to both the engineering disciplines and the general area described by the words agricultural sciences.

The measurement of ET is both complex and expensive. First there is the requirement that much climatic data must be collected so that measurements can be associated with climatic data useful in predicting ET. Then usually measurements are taken using sensitive lysimeters. It is very possible to use simpler approaches such as non-weighing lysimeters or neutron meters but these require careful management. Study sites must have proper fetch. Water table conditions are technically difficult to properly include. The necessary calculations can usually be made using spreadsheets though often computations require computer programming using advanced programming languages. Originally measurements of ET were made on simple monocultures involving commercial crops. The need for ET measurements on more complex plant communities such as native vegetation or greenhouse plants has added complexity to ET measurements. To summarize the ET measurements are expensive, difficult, and proper data analysis is difficult.

The calculation of ET involves the process of evaporation and is obviously related to climatic variables such as solar radiation, humidity, wind movement, and temperature. ET also involves plants, which have growth cycles and may involve a single plant in the case of monocultures such as a commercial crop such as corn or maize but may also involve many kinds of plants in the case of pastures.

BACKGROUND INFORMATION

Many formulas have been developed that can be used to compute ET using climatic data. The formulas range from computation using supple correlations usually for monthly calculations to much more complex formulas for calculating ET for daily time periods or even shorter periods as short as hourly calculations. Climatic data come from existing data in databases or climatic data can be collected using automated electronic systems that are very flexible and may be programmed to collect very specific data. The automated systems can be programmed to do a considerable amount of summaries and data processing. Often the climatic data needs to be extrapolated a considerable distance. When using historic climatic data it must be analyzed for equipment operation, placement, and other things involving data suitability.

The determination of ET is a very complex process. Early methods of estimating ET involved empirical but intuitively logical correlations such as those using day length. Later the combination approach, which has an easy to understand theoretical basis was developed. Still many parts of calculating ET involve a great many empirical correlations.

The professional who needs to determine evapotranspiration can easily find a large number of formulas that are available. It is assumed here that virtually all professionals have computer skills and that a reasonable computer is available. The choice of an ET formula is difficult involving several factors. The first is consideration of good professional practice. The question of acceptance of a method is very important. Then available or collectable climatic data is also very important.

The question of consistency may be impartment. When possible it is desirable to estimate ET, net radiation, crop coefficients, and corrections for limited soil water using the same methods used by the primary reference. The final ET estimates usually involve ET calculations, various radiation components, and existing plant factors. Then to properly apply a method it is necessary to answer several questions. First, is the resulting ET calculation for the direct calculation, potential, or reference definitions? Next the professional must know the time period for the resulting ET estimates. Are estimates suitable for monthly, daily, or short-term estimates such as hourly time periods? It is necessary to properly classify and identify the purposes of calculations.

Formulas for only a few selected methods of estimating ET are shown in detail because of space limitations. For historical reasons, the Blaney Criddle, BC, method is shown in detail.[1] Three versions of the

Penman method are shown. One is an early version of the Penman method[2] and the later addition to the Penman method identified as the Penman–Monteith, PM, method.[3,4] The version of the PM method as described in FAO 56[5] will be discussed in more detail.

SI units are used exclusively except for the very limited use of English units used for historic reasons. When each method is discussed the recommended use of the method will be shown including limitations.

DIRECT, POTENTIAL OR REFERENCE DEFINITIONS IN ET

Early formulas for estimating ET were intended for specific crops at a given time, thus the definition ET_d is used to represent this quantity. A crop coefficient, K_c is not used in the estimation. An example of this is the BC method, which involved simple empirical terms.

The Penman method then followed using a more fundamental application of physics through the radiation and energy balance concepts of the evaporative process. The concept of potential evapotranspiration, ET_p, was developed from this concept. The definition of ET_p has been changeable over time. For example a water surface was used by Penman.[2] Then ET_p was defined as ET from various crops whose growth was not limited by reduced soil water amounts in the root zone. ET_p has largely been replaced by the concept of reference ET, ET_r, following the concepts now used in FAO 56.[5]

The defined quantity ET_r is now widely used. The vegetative surfaces that define ET_r are often hypothetically based on physical characteristics of grass or alfalfa.[3] The current reference definition is a combination of the definitions for ET_p and ET_r plus calculation details often describing specific methods of calculating various parameters. Reference ET is currently based on either a short, smooth crop like grass or a more aerodynamically rougher crop like alfalfa.[3] ET_o is used in FAO 56 for ET_r which form a short (0.12 m tall), cool-season grass.

N FUNDAMENTAL EQUATION

The following equation illustrates the overall methods of calculating ET. The form of the equation is intended to illustrate direct estimation or those using crop coefficients. Detailed methods of determining "crop coefficients" appear in a separate article in this encyclopedia (see the article *Crop Coefficients*).

$$\begin{aligned} \mathrm{ET} &= (\mathrm{ET_r})^{\text{uses meas or est}}_{\text{climatic data}} K_c K_{sw} \\ &= (\mathrm{ET_d})^{\text{uses meas or est}}_{\text{climatic data}} K_{sw} \qquad (1) \end{aligned}$$

where K_{sw} is a correction for dry soil water amounts, K_c if used is a crop coefficient, and ET_d is ET calculated without the use of crop coefficients using a method like the earlier versions of the BC method or using the PM method as used by the extensive British MORECS system.[1]

SPECIFIC FORMULAS

Detailed discussions of specific methods of estimating ET follow. Often calculating methods are complicated and good backgrounds in thermodynamics and meteorology are helpful to follow their developments. Some classifications of ET formulas follow even though any classification scheme is by nature somewhat arbitrary.

Temperature Methods

Air temperature is intuitively related to the evaporation process. Most of us assume that evaporation is greater when air temperature is greater than when the air temperature is lower. Many ET formulas use air temperature as a major input data.

Blaney–Criddle method

The BC method[2] became widely accepted in the 1950s and marked the start of widespread evapotranspiration calculations. Due to its simplicity and easily understood concepts, it was often adopted in the western United States for legal water rights determinations. The following is intended to estimate ET by direct calculations only. The suitable time period is for monthly calculations.

$$U = \sum k_{BC} f \qquad (2)$$

$$T_F = 1.8 T_C + 32 \qquad (3)$$

$$f = T_F p / 100 \qquad (4)$$ [3]

where U is defined as the consumptive use of water for the growing season in inches, T_F is mean monthly air temperature in Fahrenheit, p is the monthly percent of daylight hours in the year, and k_{BC} is the monthly BC consumptive use coefficient (not the same as a crop coefficient as now used).

Hargreaves method

The Hargreaves method is described in various publications involving Hargreaves and is described in detail in Ref.[3]. The method is said to be suitable for

Evapotrans–Giant

computing ET_r for 10-day periods for a grass reference crop.

$$ET_o = 0.0023\, R_A TD^{1/2}(T + 17.8) \quad (5)$$

where TD is the mean monthly maximum air temperature – the mean monthly minimum air temperature in °C and R_A is extraterrestrial radiation $\mathrm{MJ\,m^{-2}\,day^{-1}}$.

Turc method

The Turc Method is from France and is thoroughly discussed in Ref.[2]. The method was originated in the humid parts of Europe and earlier versions have a correction for dry conditions where the relative humidity is less than 50%.

$$\lambda ET_p = 0.013 \frac{T}{T + 15}(R_s + 50) \quad (6)$$

where T is the average daily air temperature in °C and R_s is solar radiation in $\mathrm{cal\,cm^{-2}\,day^{-1}}$. Calculations are suitable for 10-day periods.

Combination Methods

The use of the word combination arises from the use of an energy balance and an evaporation function to derive the basic Penman ET formula. Three variations of the Penman method follow.

Penman method

The Penman method, which also is known as a combination method, was first introduced in 1948[2] and later simplified by Penman in 1963. The original version used sunshine duration to estimate radiation. A detailed discussion of the Penman method and many of its variations is found in Ref.[3]. The origin and development of the combination equation represented a major step forward in the science of predicting ET. Many derivations exist, and it is easy to see the assumptions made in the derivations. The method has been widely used for monthly or daily calculations. Determinations have been for direct, potential, or reference crops. Most of the calculations using the Penman method have utilized monthly or daily time periods.

Many empirical wind functions have been used, and the Penman method has been used with both grass and alfalfa reference crops. The reader is urged to look for locally calibrated versions that may be applicable for the area in question. The version explained in detail here is credited to Jensen and Wright, 1972.[3] The equation follows:

$$DET = \frac{\Delta}{\Delta + \delta}(R_n - G) + \frac{\delta}{\Delta + \delta}6.43(e_s - e_a) \times (0.75 + 0.00115u_2) \quad (7)$$

where u_2 is wind movement in $\mathrm{km\,day^{-1}}$ at a height of 2 m.

Priestley–Taylor method

The Priestley–Taylor Method was developed in 1972 and is a truncated version of the Penman combination ET equation. The wind term was dropped and the radiation term multiplied by a constant α, which is greater than 1. The value of the constant determines the type of ET calculated. The Priestley–Taylor Method has often been used to calculate potential ET.

$$\lambda E_p \quad \text{or} \quad \lambda ET = \alpha \frac{\Delta}{\Delta + \gamma}(R_n - G) \quad (8)$$

where α is an empirical constant ($\alpha = 1.26$ is common and represents wet or humid conditions) and the remainder of the variables are defined elsewhere. The value of the constant α determines the kind of output from the equation.

Penman–Monteith method

The PM method[4] is a major addition to the Penman method, which was not originally developed for reference crop ET calculations. The use of this refinement of the PM method is discussed in many places including Refs.[3,5,6].

Historically determinations using the PM equation have been for direct ET estimates and for reference crop ET estimates. The following equation has been adapted and used for grass referable crops and is described by Allen et al.[6] Suitable time periods are monthly, daily, or even hourly calculations.

$$\lambda ET = \frac{\Delta(R_n - G) + \rho_a C_p \frac{(e_s - e_a)}{r_a}}{\Delta + \gamma\left(1 + \frac{r_s}{r_a}\right)} \quad (9)$$

The following equations are used in Ref.[6] and in FAO 56.[5] Many different equations can be used to compute

Evapotrans–Giant

r_a, the canopy aerodynamic surface resistance. Different formulas and approaches are used in MORECS.[7]

$$r_a = \frac{\ln\left[\frac{z_m - d}{z_{om}}\right] \ln\left[\frac{z_h - d}{z_{oh}}\right]}{k^2 u_z} \quad (10)$$

$$d = 2/3h \quad (11)$$

$$z_{om} = 0.123h \quad (12)$$

$$z_{oh} = 0.1 z_{om} \quad (13)$$

where h is the height of vegetation in m, k is von Karman's constant (commonly taken as 0.41), u_z is wind velocity in m sec^{-1} at a height of z meters. The bulk surface and canopy surface resistance are calculated by the following

$$r_s = \frac{r_l}{0.5 \text{ LIA}} \quad (14)$$

from FAO 56[5] defines a grass reference as a hypothetical crop with a height $h = 0.12$ m, a constant leaf surface resistance, r_l, of 70 sec m^{-1} and with an albedo of 0.23. At this point different assumptions will result in an alfalfa reference crop or direct calculations of ET. The definition of grass reference ET[6] results in the following equation.

$$\text{ET} = \frac{0.408\Delta(R_n - G) - \gamma \frac{C_{int}}{T + 273} u_2 (e_s - e_a)}{\Delta + \gamma(1 + 0.34 u_2)} \quad (15)$$

For daily calculations

$$C_{int(daily)} = 900 \quad (16)$$

and for hourly calculations

$$C_{int(hourly)} = 37 \quad (17)$$

Parameters, Combination Methods

The following parameters apply to various versions of combination methods. For example the version of the PM method used in MORECS is very different.

General

λ is latent heat of vaporization in MJ kg^{-1}, Δ is the slope of the vapor pressure temperature relationship in kPa °C^{-1}, R_n is net radiation in MJ m^{-2} day^{-1}, and G is soil heat flux in MJ m^{-2} day^{-1}, ρ_a is air density in kg m^{-3}, C_p is the specific heat of dry air (1.013 MJ kg^{-1} °C^{-1}), e_s is saturation vapor pressure in kPa, e_a is actual vapor pressure of the air in kPa, r_a is aerodynamic resistance in sec m^{-1}, r_s is bulk surface resistance in sec m^{-1}, and γ is the psychomotor constant kPa °C^{-1}.

R_n and G should be estimated by the best available methods. For detailed descriptions and examples see Refs.[3,5].

Vapor pressure

Standard values of saturation vapor pressure appear in thermodynamic steam tables. Many empirical equations have been developed to predict saturation vapor pressure. The following equation has been adopted as a standard equation for ET estimation.[5,6]

$$e^o = 0.6018 \exp\left[\frac{17.27T}{T + 237.3}\right] \quad (18)$$

where e^o is the saturation vapor pressure of the air in kPa and T is temperature in centigrade units.

Vapor pressure deficit (VPD)

$$VPD = e^s - e^a \quad (19)$$

where VPD is defined as the vapor pressure gradient, e^s is the saturation vapor pressure, and e^a is the actual vapor pressure of the air. All vapor pressures are in kPa.

The calculation of VPD appears to be quite simple because of its relatively simple definition. However, actual calculations involve many assumptions depending upon the data available. For example available data may include average, maximum, or minimum relative humidifies. For these data limitations the estimator of ET should carefully follow the recommendations of the principal reference used.

CORRECTIONS DUE TO LIMITED SOIL WATER

A very intuitive notion is the idea that actual crop ET, ET_a, is reduced by limited soil water. Corrections of

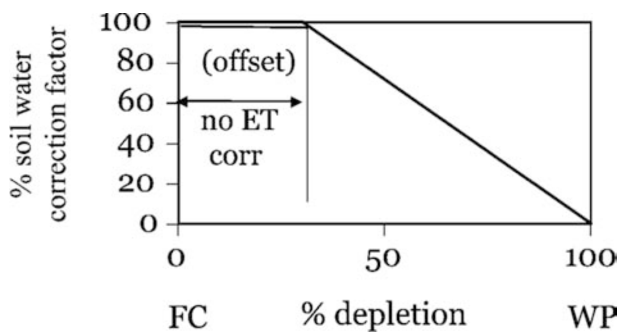

Fig. 1 Soil water correction vs. depletion.

Evapotrans–Giant

many kinds have been used. Where crop coefficients are used the corrections are usually incorporated into the K_c values. Functions leading to a great many types of functions or relationships have been used. At times corrections have been incorporated into ET calculations yielding relationships that are often difficult to predict. Burman and Pochop[8] discuss the many limited soil water corrections that are available and widely used. Only relationships using segments of straight lines are discussed here (Fig. 1).

Evapotranspiration: Greenhouses

Thierry Boulard
Unit Plante et Systemes Horticoles, Institut National de la Recherche Agronomique (INRA), Avignon, France

INTRODUCTION

Crop transpiration is the most important energy dissipation mechanism determining the thermal environment of the protected crops. Through the transpiration mechanism, the crop builds its own climate that in turn influences the transpiration.[1] As already noted by different authors,[2–4] protected crop transpiration analysis is coupled to the energy balance of the whole system and depends strongly on the greenhouse characteristics (cladding material) and on the climate control equipment (shading screen, fog system, heating, and ventilation). Therefore, reliable estimations for plant requirements must take these factors into account and conversely we must consider the mechanisms of coupling between crop transpiration and the greenhouse climate.

THEORY

Crop Transpiration Estimation from Inside Climate

Water vapor conductance (or resistance) between the leaves and the bulk of inside air, regulated by physical and physiological processes, governs greenhouse crop transpiration. With a leaf-air saturation vapor pressure deficit D_l (Pa), the transpiration Φ ($\mathrm{W\,m^{-2}}$) of a crop characterized by a leaf area index LAI and a total resistance r_t ($\mathrm{m\,sec^{-1}}$) to water vapor transfer is given by:

$$\Phi = \frac{\rho C_p}{\gamma} LAI \frac{D_l}{r_t} \tag{1}$$

In Eq. (1): ρ ($\mathrm{kg\,m^{-3}}$) is the density of air, C_p($\mathrm{J\,kg^{-1}\,°C^{-1}}$) its specific heat, and γ ($\mathrm{Pa\,K^{-1}}$) is the psychrometric constant. This simple formulation requires the leaf temperature measurement (T_l) for the determination of the leaf air saturation vapor pressure deficit D_l ($D_l = w^*(T_l) - w_i$), where w_i is inside air humidity and $w^*(T_l)$ the saturation pressure at leaf temperature. Difficulties with surface temperature measurements make Eq. (1) inconvenient for practical use. The Penman–Monteith equation or big leaf equation[5] eliminates crop surface temperature:

$$\Phi = \frac{\delta(R_n - S_h) + \rho C_p(D_i/r_a)}{\delta + \gamma(r_c/r_a)} \tag{2}$$

Here δ is the slope of the saturated vapor pressure curve at the mean air temperature, R_n is the net radiation, S_h is the soil heat flux, r_a is the aerodynamic resistance, r_c is the total canopy resistance ($r_c = r_t/\mathrm{LAI}$), and D_i is the inside air water vapor deficit ($w_i^* - w_i$).

As net radiation and soil heat flux are seldom measured in greenhouses, ($R_n - S_h$) can be replaced by G_a, the radiation absorbed by the crop, which can be estimated from the incident global radiation G_i and the crop leaf area index LAI.[6,7] If r'_a is the aerodynamic resistance of only one face of a leaf ($r'_a = 2r_a$), Eq. (2) can be rearranged as follows:

$$\Phi = \frac{\delta(r'_a/2)}{\delta(r'_a/2) + \gamma r_t} G_a + \frac{\rho C_p \mathrm{LAI}}{\delta(r'_a/2) + \gamma r_t} D_i \tag{3}$$

In this equation, the transpiration rate (Φ) is the sum of a radiative component proportional to the radiation (G_a) and an advective component, proportional to the inside air vapor pressure deficit (D_i). This model was first applied to compute greenhouse tomato crop transpiration,[7] but pertains also to other greenhouse crops.

Water Vapor Transfers Between Leaf Surface and Greenhouse Air

The resistance to water vapor flow transfers between the leaf stomatal chambers and the air is a critical parameter of the model. The total canopy resistance r_t is the sum of the aerodynamic resistance between leaf surface and bulk greenhouse air r'_a, plus the leaf resistance r_s, which is the parallel connection of stomatal and cuticular resistances. Water vapor transfer through the stomata occurs mainly under the leaf surface but also partly at the upper leaf surface for amphistomatic leaves (tomato leaves for example).

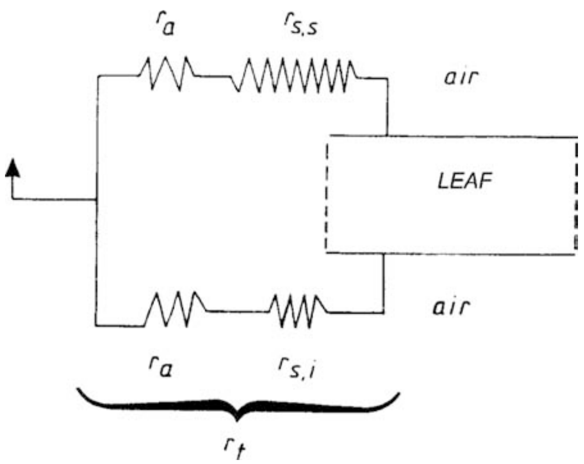

Fig. 1 Scheme of the resistances to water vapor transfers between leaf and air: r'_a: aerodynamic resistance of one face of the leaf, r_{ss}: "stomatal" resistance of the upper leaf surface, r_{si}: "stomatal" resistance of the lower leaf surface, r_t: "total" air leaf resistance.

In this case (Fig. 1), the ratio A of the upper to under leaf surface stomatal resistance ($A = r_{ss}/r_{si}$) allows the determination of the total leaf resistance:

$$r_t = \frac{r'_a + Ar_{si}^2 + (1 + A)r'_a r_{si}}{2r'_a + (1 + A)r_{si}} \tag{4}$$

As the stomatal density is higher on the lower side of the leaves, A value can vary with the stomata opening, depending on light intensity. For a tomato crop in greenhouse conditions, Boulard et al.[8] found the following relation between A and the inside global radiation G_i ($W\,m^{-2}$), over the crop cover:

$$A = \log(2.7 + 0.057G_i) \tag{5}$$

Climate dependence of the stomatal resistance

As the crop water demand can generally be satisfied in greenhouse conditions, leaf stomatal resistance mainly depends on climate conditions, including solar radiation, G_i,[9] leaf air saturation deficit, D_i,[10] and temperature, T_i.[11] Following Jarvis,[12] many authors[7,8] have expressed the stomatal resistance of greenhouse crops as a function of the greenhouse air climate parameters following a general form of multiplicative models:

$$r_s = r_{smin} f_1(G_i) f_2(D_i) f_3(T_i) \tag{6}$$

where r_{smin} is the minimum stomatal resistance of the leaf (for tomato leaves, $r_{smin} \approx 100\,s\,m^{-1}$), and f_{1-3}, the response functions.

For describing the response functions to the different environmental variables, three main types of relations have already been used:

- Exponential relation,[13] as for the dependence of r_s on global radiation:[8]

$$r_s = r_{smin}\left(1 + \frac{1}{\exp(0.05(G_i - 50))}\right) \tag{7}$$

- Polynomial models,[7]
- Homographic functions.[14]

With the exception of a few plants (lettuce for example), the Penman–Monteith formulation applies to most greenhouse crops with specific parameters and functions for the climate dependence of the stomatal resistance: cucumbers,[15] ornamental species,[16] or roses.[17]

Determination of the aerodynamic resistance

The aerodynamic resistance of the leaf, r'_a, depends on the aerodynamic regime prevailing in the greenhouse. Pieters, Deltour, and Debruyckere[18] summarized these different regimes according to the Reynolds (ul/ν) and Grasshof ($g\beta\Delta Tl^3/\nu^2$) numbers (Fig. 2), where u and l are the characteristic air speed and leaf length, respectively, β the coefficient of thermal expansion, g the gravity constant, ΔT the leaf air temperature gap, and ν the kinematic viscosity of air.

Air speed $<0.2\,m\,sec^{-1}$[19] in Venlo type greenhouses and $<0.3\,m\,sec^{-1}$ in multispan plastic houses with roof openings[20] justifies the laminar flow assumptions of many authors.[7,21] For wind force only, r'_a relates to

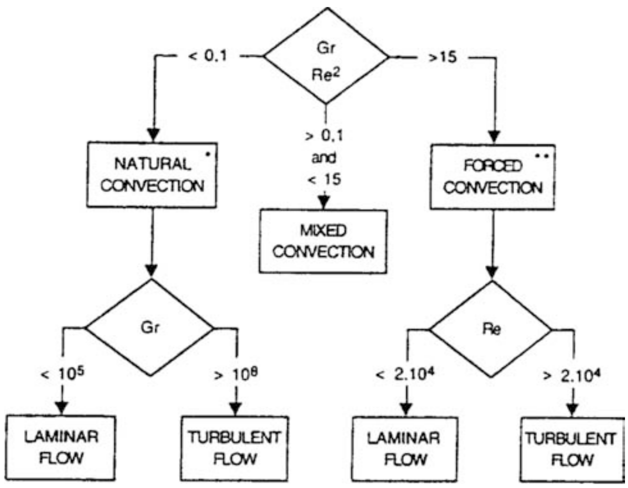

Fig. 2 Convective transfer regimes in greenhouse with respect to the Reynolds and Grashoff numbers. *Source:* After Pieters, Deltour, and Debruyckere.[18]

Evapotrans–Giant

average interior air speed following the classical relation:

$$r'_a = \rho C_p l/(0664 \lambda Pr^{1/3} Re^{1/2}) = 305(l/u)^{1/2} \quad (8)$$

where λ is the air thermal conductivity and Pr the Prandl number of air.

Following Wang, Boulard, and Haxaire[20] u the characteristic interior air speed ($\mathrm{m\,sec^{-1}}$), is proportional to the ventilation flux ϕ_v ($\mathrm{m^3\,sec^{-1}}$) divided by A_c ($\mathrm{m^2}$), the vertical cross section area perpendicular to the average direction of the inside air flux:

$$u = \frac{\phi_v}{A_c} \quad (9)$$

With thermal stratification, transport must combine forced and free convection as discussed in details by numerous authors, various formula based on the combination of forced and free convection being proposed by Seginer,[22] Stanghellini,[7] Yang et al.,[23] and Zhang and Lemeur.[21]

Simplified Penman–Monteith Formulation

As several parameters are needed for the application of the complete model (relations 1–9), one can consider that the leaf stomatal and aerodynamics resistances can be considered as roughly constants in greenhouse conditions. Consequently Eq. (3) can be expressed in a much simpler form:

$$\Phi = AG_a + BD_i \quad (10)$$

where A and B are constant values for a given greenhouse crop stage (Table 1).

Crop Transpiration Estimation from Outside Climate Parameters

For ventilated greenhouses used in Mediterranean regions, crop transpiration can derive directly from outside climate[30] and greenhouse ventilation characteristics by solving the energy balance:

$$\lambda\Phi + H = \Pi G + Q_h - S_h - K_S \Delta T \quad (11)$$

where Φ is the latent heat of canopy transpiration ($\mathrm{W\,m^{-2}}$), H the sensible heat exchange by ventilation ($\mathrm{W\,m^{-2}}$), G($\mathrm{W\,m^{-2}}$) the outside global solar radiation, Π the solar absorption by the greenhouse-crop system, Q_h ($\mathrm{W\,m^{-2}}$) the heating flux density provided by the heating system, S_h ($\mathrm{W\,m^{-2}}$) the heat storage or retrieval rate of the greenhouse-soil system, K_S the overall heat transfer coefficient through the cover between inside and outside and ΔT (K) the air temperature difference between inside and outside.

At the equilibrium, if we neglect the other evapo-condensative phenomena, the latent heat exchange due to canopy transpiration is proportional to the difference of air humidity between indoors and outdoors:

$$\Phi = K_v \Delta e \quad (12)$$

where Δe is the water vapor pressure gap between the interior and exterior air (Pa). K_v ($\mathrm{W\,m^{-2}\,Pa^{-1}}$) is the latent heat transfer coefficient proportional to the ventilation flux V_f ($\mathrm{m^3\,sec^{-1}}$):

$$K_v = \lambda \xi \rho V_f / A_g \quad (13)$$

λ ($\mathrm{J\,kg^{-1}}$) is the latent heat of water vaporization; ξ ($6.25 \times 10^{-6}\,\mathrm{kg_w}\,kg_a^{-1}\,\mathrm{Pa^{-1}}$) the conversion factor between the air water vapor content and the air water vapor pressure, and A_g ($\mathrm{m^2}$) the greenhouse area.

Table 1 Identified values of the PM coefficients [Eq. (10)] from different sources for different crops and stages

Source	Crop	A	B ($\mathrm{W\,kg_a/kg_w m^2}$)
Jolliet and Bailey[2]	Tomato	0.34	45
Doorenbos and Pruitt[24]	Tomato	0.54	20
Jemaa[25]	Tomato ($L = 1.33$)	0.32	11
—	Tomato ($L = 3.5$)	0.36	8
—	Tomato ($L = 3.8$)	0.37	15
Pollet[26]	Lettuce	0.28	35
Stanghellini[7]	Tomato ($LAI = 1$)	0.30	72
Jolliet[27]	Tomato ($LAI = 1$)	0.28	40
Kittas, Katsoulas, and Baille[28]	Rose	0.24	29
Lorenzo, Medrano, and Sanchez-Guerrero[29]	Cucumber ($LAI = 1$)	0.23	90

Evapotrans–Giant

The sensible heat exchange by ventilation can also be expressed with respect to the difference of air temperature between indoors and outdoors ΔT:

$$H = K_H \Delta T \tag{14}$$

K_H ($\mathrm{W\,m^{-2}\,K^{-1}}$) the sensible heat transfer coefficient is proportional to the ventilation flux V_f ($\mathrm{m^3\,sec^{-1}}$):

$$K_H = \rho C_p V_f / A_g \tag{15}$$

The water vapor pressure deficit of the interior air (D_i) is a linear function of the water vapor pressure deficit and temperature of exterior air, D_o and T_o:

$$D_i = \delta(T_o)(\Delta T) - \Delta e + D_o \tag{16}$$

where $\delta(T_o)$ is the slope of the water vapor saturation curve at T_o ($\mathrm{Pa\,K^{-1}}$).

The system composed of Eq. (2) and Eqs. (11)–(16) constitutes a linear system of five equations with five unknowns (Φ, H, D_i, ΔT, and Δe), which can be solved analytically and Φ can be deduced from both outside climate and greenhouse-crop:

$$\Phi = \frac{\Pi G + Q_h - S_h + \frac{(K_S + K_H)K_2}{K_1 K_H + \delta K_2} D_o}{1 + \frac{(K_S + K_H)(1 - K_1 + K_2/K_v)}{K_1 K_H + \delta K_2}} \tag{17}$$

with K_S the overall energy loss coefficient can be considered as dependent on external wind speed V ($\mathrm{m\,sec^{-1}}$) following the simple relation:[31]

$$K_S = C + DV \tag{18}$$

where C and D depend on the greenhouse design (ratio of the soil surface- to the greenhouse cover: S_s/S_c), on the type of the cover material (glass, polyethylene, PVC) and on the presence of a single or double cover.

K_1 and K_2 are combinations of crop characteristic parameters:

$$K_1 = \frac{\delta}{\delta + \gamma(r_t/r_a)} \tag{19}$$

$$K_2 = \frac{\mathrm{LAI}\rho C_p}{\delta r_a + \gamma r_t} \tag{20}$$

K_v and K_h given, respectively, by Eqs. (13) and (15), are the most crucial parameters of this model because they describe the coupling of the crop with the atmosphere through the ventilation flux V_f.

THE COUPLING BETWEEN THE CROP AND THE ATMOSPHERE

As indicated by relations 11–15, greenhouse air temperature and humidity depend on solar absorption and on the balance between crop transpiration (main source of water vapor) and the losses of sensible heat and water vapor by ventilation. Eq. (17) suggests a strong coupling between the crop and the outside atmosphere when the ventilation flux is important as confirmed by Boulard, Baille, and Le Gall[32] who studied the dependence of a mature greenhouse tomato crop transpiration on outside climate when using natural ventilation, evaporative cooling, and a shading screen (Fig. 3).

This coupling between greenhouse crop transpiration and the environmental control was analyzed both for Northern Europe climate conditions[2,3] and Mediterranean conditions.[32,33] Environmental control models and strategies were derived from these studies, pertaining both for irrigation and for climate control in

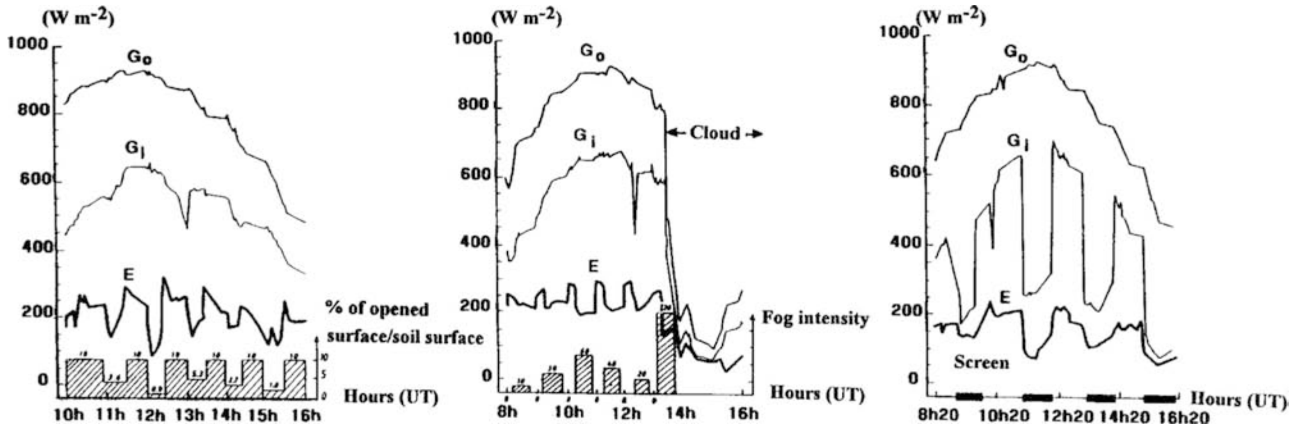

Fig. 3 Effect of ventilation, fog system, and shading screens on the transpiration rate of a tomato greenhouse crop in summer. *Source*: After Boulard, Baille, and Le Gall.[32]

hot and dry conditions[34] and winter conditions.[35] For a mature greenhouse crop and buoyancy driven ventilation in hot and arid conditions, Arbel, Shlykar, and Barak[36] have performed a similar study and proposed a numerical treatment of the interactions between cooling, ventilation and crop transpiration.

When modeling the case of sparsely planted seedlings in greenhouses, Seginer[37] shows that sparse plants transpire more per unit surface, due to micro-advection of energy ‘‘surplus’’ from the surrounding dry soil. He determined that, if water supply to the stomata is not limiting, the canopy temperature of a sparse crop is normally similar to that of a dense crop. However, high foliar potential transpiration may lead to water stress to be corrected by artificial evaporative cooling and increased ground albedo.

CONCLUSIONS

The Penman-Monteith model provides accurate estimates of crop transpiration in greenhouses. Proper evaluation of radiation balance, heat, and water vapor transfer allows to link the rate of transpiration with climate control operations to improve crop-growing conditions. As water availability becomes an increasing constraint on horticultural production, the refined tuning of irrigation based on development of the transpiration models opens perspectives for the improved efficiency of water use.

Evapotranspiration: Reference and Potential

Marcel Fuchs
Environmental Physics and Irrigation, Volcani Center, Institute of Soil, Water and Environmental Sciences, Agricultural Research Organization (ARO), Bet-Dagan, Israel

INTRODUCTION

Water vapor loss from land surfaces depends on meteorological factors that provide the energy required to transform liquid into vapor and disperse the free water molecules into the atmosphere. The process can occur only if continuity in the gaseous phase between the liquid water and the atmosphere is established. More specifically, it depends also on the availability of liquid water in the vegetation and in the soil. The purpose of the *potential* and *reference evapotranspiration* concepts is to standardize liquid water availability.

DEFINITIONS

Potential evapotranspiration is the rate of water vapor loss from vegetation-covered ground when its entire surface in contact with the atmosphere is wet. Maintaining a continuous and persistent presence of liquid water the interface between the plants and the atmosphere is not feasible in real situations. Therefore, potential evapotranspiration is a theoretical concept specifying an asymptotic upper limit of actual evapotranspiration.

Reference evapotranspiration is the rate of water vapor loss from ground fully covered with actively growing short grass of uniform height whose root system is unrestrictedly supplied with water. This quantity can be determined by measuring the water vapor loss from vegetation growing on a soil that is frequently and uniformly wetted by natural rainfall or irrigation. The frequency of wetting should be such that the soil moisture content remains in the range for which the flow of water towards the roots is unimpeded, a condition characterized by the occurrence of gravitational drainage. This evapotranspiration rate can be measured with weighing lysimeters.

OVERVIEW

The evaporation of liquid water from plant communities involves both supply and demand controlled processes: supply as the flow of water to the plant organs and soil pores where the liquid to vapor transformation occurs and demand as the weather driven delivery of heat that converts liquid into vapor. This link to the heat balance of the surface sets the process in the realm of meteorology. As open water surfaces have infinite supply, meteorologists initially considered that evaporation from free water could provide a measure of the demand. However, evaporation from free water surfaces does not provide universal relationships with soil moisture withdrawal by vegetation because the energy and mass exchanges of water surfaces and vegetation or soil respond differently to radiation, wind, air humidity, and temperature.[1]

In search of a more appropriate measure of atmospheric evaporative demand, Thornthwaite[2] introduced the concept of *potential evapotranspiration* to classify climates according to their effect on the water balance of vegetation. He used the terms *evapotranspiration* to include water vapor sources in the plants and in the soil and *potential* to indicate unlimited liquid flow toward the surface. He formulated a temperature-based empirical estimate of the water vapor loss, but results did not relate correctly with measured evapotranspiration. Consequently, the conceptual impact of Thornthwaite's method surpassed its practical significance on hydrology, climatology, and irrigation science. Penman[3] developed a similar concept, based on an approximate linear solution of the energy balance for a short green lawn fully shading the ground and never lacking water. Setting the water vapor pressure of the vegetation to its saturated value at the vegetation surface temperature fulfilled the condition of unlimited water supply. The resulting formula was a linear combination of a radiation term and a wind function with empirical coefficients fitting estimated evaporation of open water to the evapotranspiration of well-watered lawn. Penman's approach elegantly eliminated explicit reference to surface temperature and surface water vapor pressure from the energy balance solution, enabling potential evapotranspiration to be calculated from standard data measured in meteorological stations.

The method became the standard for determining potential evapotranspiration and found numerous applications in irrigated agriculture. However, measured evapotranspiration occasionally exceeded the calculated potential value. Reasons for these apparent anomalies were easily identified. As liquid to vapor conversion occurs below the epidermis of transpiring organs, fitted parameters included implicitly the diffusive resistance of stomatal pores in the epidermis. Some plants have lower stomatal resistance than the lawn for which the parameters of Penman's formula were derived. Many vegetation canopies have higher radiation absorption and stronger aerodynamic exchanges, and therefore, are capable of higher evapotranspiration rates than grass.

The need to invoke an additional resistance in the pathway between the source of the vapor and the free atmosphere prevented the definition of the unambiguous upper bound implied in the original potential evapotranspiration concept. Still, the calculated values provided a *reference* for comparing water use by plants growing under widely diverse climatic conditions. Irrigation oriented scientists introduced the term *reference evapotranspiration* to reflect the conceptual change in the meaning of potential evapotranspiration.[4,5] Initially, alfalfa served as the reference surface, but irregular growth following repeated mowing and the limited range of climates where it could be grown favored the use of ubiquitous grass kept at a height between 0.08 m and 0.15 m. Lysimeter measurements of grass evapotranspiration served to recalibrate Penman's formula to determine reference evapotranspiration.[5] Thus, reference evapotranspiration became the water vapor loss of a well-watered grass surface, as in Penman's original operational definition of potential evapotranspiration.

The convergence of definitions led to the interchangeable use potential and reference evapotranspiration, confusing novices and generating futile controversy among experts. The term potential evapotranspiration should be kept for the theoretical upper limit of water vapor loss from a given vegetation-type when resistance of the vapor pathway in the plant tissues approaches zero. Reference evapotranspiration should designate the water vapor loss of an extended, actively growing, well-watered grass, fully covering the ground and mown to remain between 0.08 m and 0.15 m high. The resistance of vapor pathway inside the plants assumes the minimum value experimentally determined for what is believed to be unrestricted water supply to the roots. This experimental minimum resistance used to define reference evapotranspiration replaces the theoretical condition of unlimited liquid flow to the surface in the definition of potential evapotranspiration. Therefore, reference evapotranspiration represents the closest experimental realization of potential evapotranspiration.

ADDITIONAL INSIGHT

Potential and reference conditions imply evapotranspiration rates higher than those from vegetation without free water on its surface and undergoing periodic water shortage between watering events. The difference increases with the aridity of the climate and the moisture deficit in the soil. The larger latent heat dissipation increases the water vapor content of the air and reduces the energy available for air and soil heating, leading to a wetter and cooler microclimate. Thus, creating the conditions for realizing potential or reference evapotranspiration decreases its value. This paradox is reminiscent of Schrödinger's cat in quantum mechanics. It led Bouchet[6] to formulate the concept of complementary evapotranspiration based on the hypothesis that the sum of potential evapotranspiration and actual evapotranspiration is a constant. The idea was adapted to derive climatological estimates of regional evapotranspiration,[7,8] without requiring values for soil moisture availability and stomatal resistance of plants. As regional evapotranspiration is extremely difficult to measure, applications deriving from the complementary evapotranspiration concept did not gain acceptance. Furthermore, the approach could not evaluate water use of agricultural fields at the spatial and temporal scale required to control soil moisture by irrigation. For these applications, the climatic factors determining evapotranspiration had to consider the specific radiometric, aerodynamic, and stomatal resistance properties of the crop surface.

The radiation balance and aerodynamic transport terms in Penman's original derivation of potential evapotranspiration assumes empirical functions adapted to the standard data recorded in meteorological stations: daily hours of sunshine, average air temperature and vapor pressure deficit, and wind run. The increased availability of pyranometers giving a direct measurement of incident solar energy improved the accuracy of the method. Net pyrradiometers measuring the total radiant energy absorbed by the vegetation surface constituted an important additional step to the accurate calculation of potential evapotranspiration for real vegetation surfaces. The calculation of potential evapotranspiration became even more specific when Businger[9] introduced turbulent transport characteristics of the air surface layer to parameterize explicitly the aerodynamic properties of the vegetation, using the roughness length to quantify the drag exerted by the vegetation. Adjustments accounting for buoyancy[10] and separation between the sink-source lengths dimensions for momentum and water vapor[11] further fine-tuned the aerodynamic function.

Monteith[12] realized the full potential of Penman's contribution by relating potential evapotranspiration to actual evapotranspiration in terms of a surface resistance that lumped the stomatal resistance of transpiring organs and the resistance of soil to water vapor diffusion. Surface resistance quantified field scale soil moisture availability and established a link with laboratory studies of physiological indicators of plant water stress. Setting the surface resistance to its minimum value allowed the calculation of reference evapotranspiration. However, selecting the value of minimum resistance proved to be difficult, because stomatal resistance varies with radiation, carbon dioxide concentration, air humidity, and temperature. Some of its variability is related to the physiology and biochemistry of plants. As mechanisms regulating stomatal resistance are still only partially understood its value remains unpredictable. This biological uncertainty affects reference evapotranspiration and weakens its reliability as an objective indicator of atmospheric evaporative demand. The widely accepted definition of plant surface characteristics for realizing reference evapotranspiration[13] has retained the fuzziness of a 1956 published statement about "extended surface of short green crop, actively growing, completely shading the ground, of uniform height and not short of water."[14] By contrast, potential evapotranspiration sets unequivocally the minimum resistance to zero. With proper modeling of radiation and momentum absorption, it can parameterize specifically any vegetation geometry. Therefore, despite the lack of experimental validation, it provides the most consistent climatic measure of evaporative conditions.

INTRODUCTION

For over two decades, approaches to sense evapotranspiration (ET) remotely have made use of radiometric surface temperatures [$T_R(\theta)$, where θ is the radiometer viewing angle] as a key surface boundary condition in the land–surface energy balance. Such methods include simple flux–profile (single-level) models of surface exchange, statistical/analytical schemes, and other techniques that are based on more complex physical models of the land surface, including the so-called soil–vegetation–atmosphere–transfer (SVAT) schemes.[1]

Typically, these methods estimate fluxes through the evaluation of a surface–air temperature gradient at a single time. The aerodynamic resistance to heat transfer is largely defined by the aerodynamic roughness length, and the land surface is treated as a single effective surface in contact with the atmosphere. Any factor that introduces errors into the evaluation of this gradient, as well as the simplifications of the model, may introduce significant errors in the resulting flux estimates.

This article gives a brief overview of some of the modeling schemes that have utilized remotely sensed surface temperature data. Some recent modeling efforts will be described that address the limitations described below. These include 1) uncertainty in T_R (θ); 2) observations of T_A at regional scales; and 3) nonuniqueness of the radiometric–aerodynamic temperature relationship. The resulting modeling framework leads to a more reliable scheme for quantifying ET at regional scales using satellite remote sensing.

SOURCES OF ERROR IN ET ESTIMATION

Even after performing the corrections for atmospheric attenuation and surface emissivity required to obtain a radiometric surface temperature from a satellite-measured brightness temperature, there remains 1–3° uncertainty in $T_R(\theta)$. Compounding this is the fact that vegetation density, architecture, and angle of view of the radiometer also have significant effects on brightness temperature observations (the angle-of-view ''effect'' being most pronounced for surfaces with partial canopy cover). As a result of these error sources, estimates of the surface–air temperature gradient and resulting fluxes are likely to have large uncertainties.[2]

An additional complication is the significant differences that exist between the radiative and the so-called ''aerodynamic'' (single level, ''effective'') surface temperature.[3] Unfortunately, this aerodynamic temperature is a construct that cannot be measured and many of the factors affecting the radiometric temperature are not well correlated to the aerodynamic roughness, making radiometric–aerodynamic temperature relationships somewhat ambiguous to begin with.

For applications over regional scales, deriving the required meteorological upper boundary conditions [i.e., shelter-or anemometer-level (2–10 m) air temperature and wind speed] for each satellite pixel may also lead to significant errors in flux evaluations. Typically, these meteorological quantities come from an analysis of hourly weather observations (observations typically spaced on the order of 100 km apart), and may not be representative of actual conditions at a given location.

OVERVIEW OF REMOTE SENSING METHODS

The most common way to estimate ET is to solve for the latent heat flux, LE, as a residual in the energy balance equation for the land surface:

$$\mathrm{LE} = R_N - G - H \tag{1}$$

where R_N is the net radiation, G, the soil heat flux, and H, the sensible heat flux all usually given in $\mathrm{W\,m^{-2}}$. The quantity $R_N - G$ is commonly called the "available energy"; remote sensing methods for estimating these components are described in Kustas and Norman.[1] Typically with reliable estimates of remotely sensed solar radiation (e.g., Ref.[4]), differences between remote sensing estimates and observed $R_N - G$ are within 10%.

The largest uncertainty in estimating LE comes from computing H. A simple form to express and examine the relationship between H and the surface–air temperature difference is via a resistance relationship (e.g., Ref.[5]),

$$H = \rho C_P \frac{T_R(\theta) - T_A}{R_A + R_{EX}} \tag{2}$$

In this equation, T_A is the near-surface air temperature, ρ, the air density, C_P, the specific heat of air, R_A, the aerodynamic resistance and R_{EX}, the so-called "excess resistance," which addresses the fact that momentum and heat transport from the roughness elements differ.[6] The method offers the possibility of mapping surface heat fluxes on a regional scale by using radiometric temperature observations, $T_R(\theta)$ (converted from satellite brightness temperatures) if R_A and R_{EX} can be estimated appropriately. R_{EX} has been related to the ratio of roughness lengths for momentum, z_{OM}, and heat, z_{OH}, and the friction velocity u^* having the form[5,6]

$$R_{EX} = k^{-1} \ln\left(\frac{z_{OM}}{z_{OH}}\right) u^{*-1} \tag{3}$$

where $k = 0.4$ is von Karman's constant. While addressing the well-known differences in efficiency between momentum and heat transport from natural surfaces, this model is just one of several that have been developed (e.g., Refs.[5,7]). There have been numerous efforts in recent years to apply Eq. (2) and hence determine the behavior of R_{EX} or z_{OH} for different surfaces, but no universal relation exists for land surfaces with large spatial and temporal variations in the magnitude of z_{OH} having been documented.[1] These results are due, in part, to the fact that this formulation lumps view angle dependency of $T_R(\theta)$ into the excess resistance, which makes the relation useless for any conditions except those similar to the training data.[8] Nevertheless, the method for estimating ET using the approach summarized in Eqs. (1)–(3) is still widely applied.

Satellite observations are essentially "instantaneous" or merely "snap shots" of the surface conditions. For many practical applications, LE estimates over longer time scales (daily values or longer) are needed. This was the impetuous for an empirical scheme for estimating daily LE, LE_D, suggested by Jackson, Reginato, and Idso[9] using observations of $T_R(\theta)$ and T_A near mid-day or maximum heating:

$$LE_D = R_{N,D} - B(T_{R,i}(\theta) - T_{A,i})^n \tag{4}$$

where the subscript i and D represent "instantaneous" and daily values, respectively. The coefficients B and n have been related to physical properties of the land surface and atmosphere, such as z_{OM} and stability, respectively.[10] Both theoretical and experimental studies have evaluated Eq. (4) lending further support for its utility as a simple technique for estimating LE_D.[11–13] In fact, studies have applied Eq. (4) to meteorological satellites for longer term regional ET monitoring.[14]

A major drawback with these approaches summarized above, however, is that there is no distinction made between soil and vegetation canopy contributions to land-surface fluxes or to satellite-measured brightness temperatures used to diagnose the fluxes. Hence, vegetation water use or stress cannot be evaluated. Furthermore, as evidence from many previous studies both the resistances in Eq. (2) and consequently the B parameter in Eq. (4) are not uniquely defined by surface roughness parameters. In addition to experimental evidence (e.g., Refs.[15,16], Kustas et al.[8] using SVAT simulations, have shown the lack of a unique relationship between $T_R(\theta)$ and the aerodynamic surface temperature, T_O, (satisfying the flux relationship in Eq. (2) when used with traditional expressions for the resistances; see Ref.[2]).

An alternative approach proposed recently considers the soil and vegetation contribution to the total or composite heat fluxes and soil and vegetation temperatures to the radiometric temperature measurements in the so-called "Two-Source" Modeling (TSM) scheme.[17] This allows for Eq. (2) to be recast into the following expression:

$$H = \rho C_P \frac{T_R(\theta) - T_A}{R_R} \tag{5}$$

where R_R is the radiometric–convective resistance given by[17]

$$R_R = \frac{T_R(\theta) - T_A}{\frac{T_C - T_A}{R_A} + \frac{T_S - T_A}{R_A + R_S}} \tag{6}$$

where T_C is the canopy temperature, T_S, the soil temperature, and R_S, the soil resistance to heat transfer. An estimate of leaf area index or fractional vegetation cover, f_C, is used to estimate T_C and T_S from $T_R(\theta)$:

$$T_R(\theta) \approx \left(f_C(\theta) T_C^4 + (1 - f_C(\theta)) T_S^4\right)^{1/4} \tag{7}$$

where $f_C(\theta)$ is the fractional vegetative cover at radiometer viewing angle θ, and R_S is computed from a relatively simple formulation predicting wind speed

Evapotrans–Giant

near the soil surface.[17] With some additional formulations for estimating canopy transpiration, and the dual requirement of energy, and radiative balance of the soil and vegetation components, closure in the set of equations is achieved. Through model validation studies, revisions to the original two-source formulations have been made improving its utility under a wider range of the environmental conditions.[8,18]

Several relatively early studies recognized the need to assess the impact of vegetation cover on remote methods for deriving ET. For example, Price[19] used information provided in the Vegetation Index–radiometric temperature, VI–$T_R(\theta)$, space. This work involved the use of an energy balance model for computing spatially distributed fluxes from the variability within the Normalized Difference Vegetation Index, NDVI–$T_R(\theta)$ space from a single satellite scene. NDVI was used to estimate the fraction of a pixel covered by vegetation and showed how one could derive bare soil and vegetation temperatures and, with enough spatial variation in surface moisture, estimate daily ET for the limits of full cover vegetation, dry and wet bare soils.

Following Price,[19] Carlson, Gillies, and Perry[20] combined an Atmospheric Boundary Layer (ABL) model with a SVAT for mapping surface soil moisture, vegetation cover, and surface fluxes. Model simulations are run for two conditions: 100% vegetative cover with the maximum NDVI being known a priori, and with bare soil conditions knowing the minimum NDVI. Using ancillary data, including a morning atmospheric sounding, vegetation and soil type information, root-zone and surface soil moisture are varied, respectively, until the modeled and measured $T_R(\theta)$ are closely matched for both cases so that fractional vegetated cover and surface soil moisture are derived. Comparisons between modeled–derived fluxes and observations have been made recently by Gillies et al.[21] indicating approximately 90% of the variance in the fluxes was captured by the model.

In a related approach, Moran et al.[22] defined theoretical boundaries in VI–($T_R(\theta)$–T_A) space using the Penman–Monteith equation. The boundaries define a trapezoid, which has at the upper two corners unstressed and stressed 100% vegetated cover and at the lower two corners, wet and dry bare soil conditions (Fig. 1). In order to calculate the vertices of the trapezoid, measurements of R_N, vapor pressure, T_A, and wind speed are required as well as vegetation specific parameters; these include maximum and minimum VI for the full-cover and bare soil case, maximum leaf area index, and maximum and minimum stomatal resistance. Moran et al.[22] analyze and discuss several of the assumptions underlying the model, especially those concerning the linearity between variations in canopy–air temperature and soil–air temperatures and transpiration and evaporation. Information about ET rates are derived from the location of the VI–[$T_R(\theta)$–T_A] measurements within the date and time-specific trapezoid. This approach permits the technique to be used for both heterogeneous and uniform areas and thus does not require having a range of NDVI and surface temperature in the scene of interest as required by Carlson, Gillies, and Perry[20] and Price.[19] Moran[23] compared the method for estimating relative rates of ET with observations over agricultural fields and showed it could be used for irrigation scheduling purposes.

These modeling schemes, however, are vulnerable to errors in the radiometric temperature observations and most require screen level meteorological inputs (primarily wind speed, u, and air temperature, T_A, observations) which at regional scales suffer from errors of representativeness (observation not taken at the same location where flux estimates are performed). Approaches using remotely sensed data for estimating

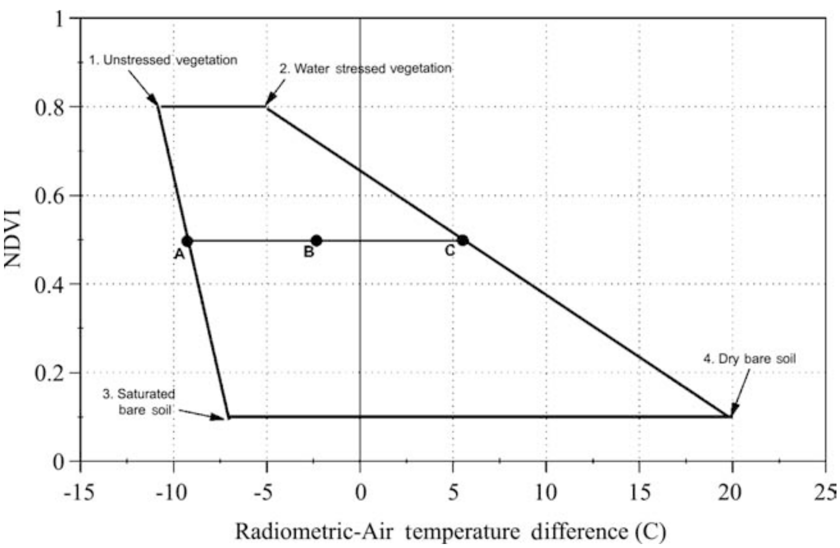

Fig. 1 The trapezoidal shape that results from the theoretical relation between radiative temperature minus air temperature [$T_R(\theta)$ – T_A] and the NDVI from Moran et al.[22] With a measurement of ($T_R(\theta)$ – T_A) at point C, it would be possible to equate the ratio of actual to potential LE with the ratio of distances CB and AB.

the variation of these quantities are being developed and tested.[24,25] How reliable the algorithms are for different climatic regimes needs to be evaluated.

A robust modeling framework to address some of these limitations was proposed early on in the application of satellite observations by Wetzel, Atlas, and Woodward[26] Strictly speaking, the Wetzel, Atlas, and Woodward study was aimed at the estimation of soil moisture from remotely sensed data, but an evaluation of surface fluxes is implicit in the scheme. The study recognized that using a time rate of change in $T_R(\theta)$ from a geostationary satellite such as from the Geosynchronous Operational Environmental Satellite (GOES) coupled to an ABL model could mitigate some of the inherent problems arising from the use of single-time-level data, such as atmospheric corrections, emissivity, and instrument calibration. By using time rate of change of $T_R(\theta)$, one reduces the need for absolute accuracy in satellite calibration, and atmospheric and emissivity corrections, all significant challenges (see Refs.[1,8]). Diak and Whipple[27] implemented this approach with a method for partitioning the available energy into LE and H by using the rate of rise of $T_R(\theta)$ from GOES and ABL growth and included a procedure to account for effects of horizontal and vertical temperature advection and vertical motions above the ABL.

Further refinements to these time-rate-of-change schemes have been recently developed[28,29] that use an energy closure scheme based on energy conservation within the ABL. The so-called Atmospheric–LandEXchange-Inverse (ALEXI) model uses a simple slab model of the time-development of the ABL in response to heat input to the lower atmosphere. A profile of atmospheric temperature at the initial time (usually from an analysis of synoptic data) serves as the upper boundary condition in atmospheric temperature. Through surface–ABL energy balance considerations and implementation of the TSM scheme for the land surface component of the model,[17] ALEXI couples ABL development to the temporal changes in surface radiometric temperature from GOES and fraction vegetation cover from Advanced Very High Resolution Radiometer, AVHRR–NDVI. The advantages of using temporal changes in brightness temperature measurements have been noted. With an energy balance method utilizing the temporal change of ABL structure, errors that arise in schemes utilizing shelter-level (~2 m above ground level) measurements of air temperature (to estimate the surface–air temperature gradient) for estimating the heat fluxes are also mitigated. Approaches that utilize this surface–air temperature gradient, typically evaluated within 10 m of the surface, are very sensitive to errors in the evaluation of the gradient arising from errors both in the representativeness of the air temperature measurements, and errors in evaluating radiometric temperatures.

Another much simpler scheme, which also uses the TSM framework, employs the time rate of change in radiometric temperature and air temperature observations from a nearby weather station in a simple formulation for computing regional heat fluxes, called the Dual-Temperature-Difference (DTD) approach.[30] Although this technique requires air temperature observations, by using a time difference in air temperature, errors caused by using local shelter level observations for representing a region are still reduced. Moreover, the scheme is simple, thus it is computationally efficient and does not require atmospheric sounding data for initialization.

APPLICATION OF ALEXI AND DTD METHODS

An example of the utility of the DTD approach is presented at the field scale using ground-based $T_R(\theta)$

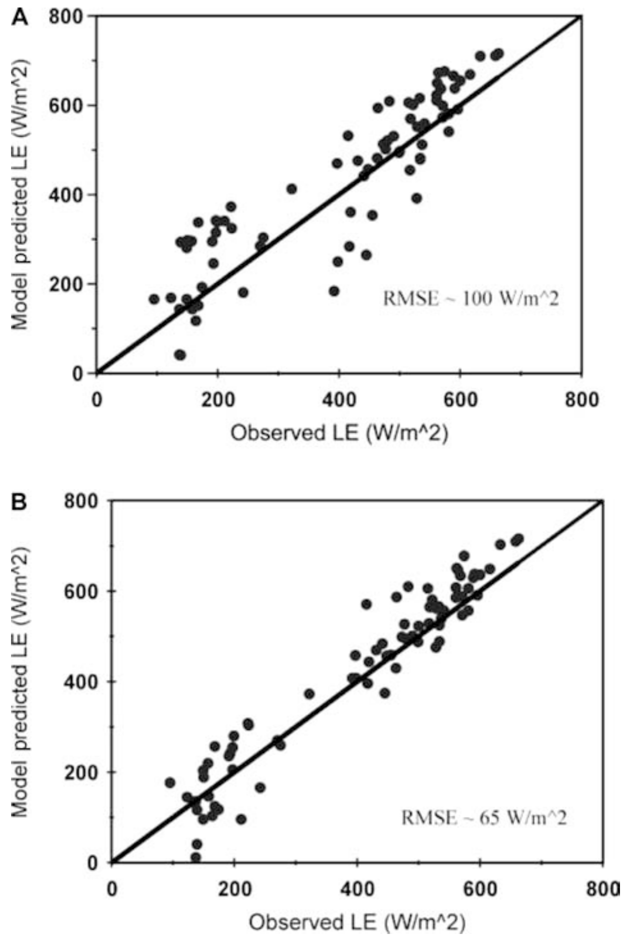

Fig. 2 Comparison between observed and modeled mid-day latent heat flux, LE, using (A) original TSM scheme and (B) DTD approach. Regional T_A and u observations are from weather stations ~50 km to ~100 km away from study site. Line represents perfect agreement with observations.

Evapotrans–Giant

observations and regional weather station data from sites in subhumid and semiarid climatic regions (i.e., Oklahoma and Arizona). In addition, a comparison of regional scale heat fluxes between the more rigorous ALEXI model and the simple DTD method using satellite data over the U.S. Great Plains is presented.

With the field scale $T_R(\theta)$ observations, the comparisons in Fig. 2 are LE estimates using the original TSM approach and the DTD scheme with regional weather station data (T_A and u) collected 50–100 km away from the site compared to on-site flux tower observations.[30] There is considerably more scatter using the TSM vs. the DTD approach with non-local meteorological inputs resulting in a Root Mean Square Error (RMSE) on the order of 100 W m^{-2}. Using the DTD scheme, there is a significant reduction in scatter with the flux observations yielding almost a 40% reduction in error with a RMSE $\sim$65 W m^{-2}.

To illustrate a regional application of the DTD and ALEXI approaches, GOES brightness temperature data and NOAA–AVHRR satellite observations were used with surface synoptic data for July 2, 1997 over the U.S. Great Plains, same case study used by Mecikalski et al.[29]. The domain investigated was divided into 10 km $\times$ 10 km grid cells, with 223 cells east-to-west and 201 in the meridional direction, a total of 44,823 cells. NOAA–AVHRR–NDVI product for the region was utilized to estimate fractional vegetation cover. Hourly GOES brightness temperature measurements for the region were cloud screened and subsequently linearly time-interpolated to 1.5 hr and 5.5 hr after local sunrise. These top-of-atmosphere brightness temperatures were then atmospherically corrected to estimate surface radiometric surface temperatures and corrected for emissivity using land surface classification data (for details, see Ref.[29]).

The estimates of LE for 5.5 hr after local sunrise for the domain are shown in Fig. 3 from the DTD and ALEXI schemes. Areas that are white in this figure were either those identified as cloudy by screening procedures, and thus were not evaluated in either method, or did not achieve model convergence (primarily ALEXI). The DTD method displays very similar spatial features as the ALEXI output, although, as shown, there is a systematic difference between the two, with the DTD method showing overall higher values of LE.

Unlike ALEXI, in which air temperature is dynamically determined within the scheme, in the DTD method, air temperature is a measured (from surface synoptic data) and invariant upper boundary condition for the model. The horizontal spacing of hourly synoptic air temperature measurements is roughly 100 km, while the satellite data and the DTD grid on which the $T_R(\theta)$ and NDVI data are applied have a significantly higher resolution. With fixed boundary conditions measured on the scale of 100 km, DTD cannot account for the sub-synoptic-scale interactions between surface radiometric temperatures and air temperature, as does ALEXI. Nevertheless, results from the DTD procedure are encouraging in their ability to duplicate the spatial patterns from ALEXI, a much more complicated and data-intensive parameterization. Computer processing time for the domain shown in Fig. 3 for the ALEXI model was about 35 min, while

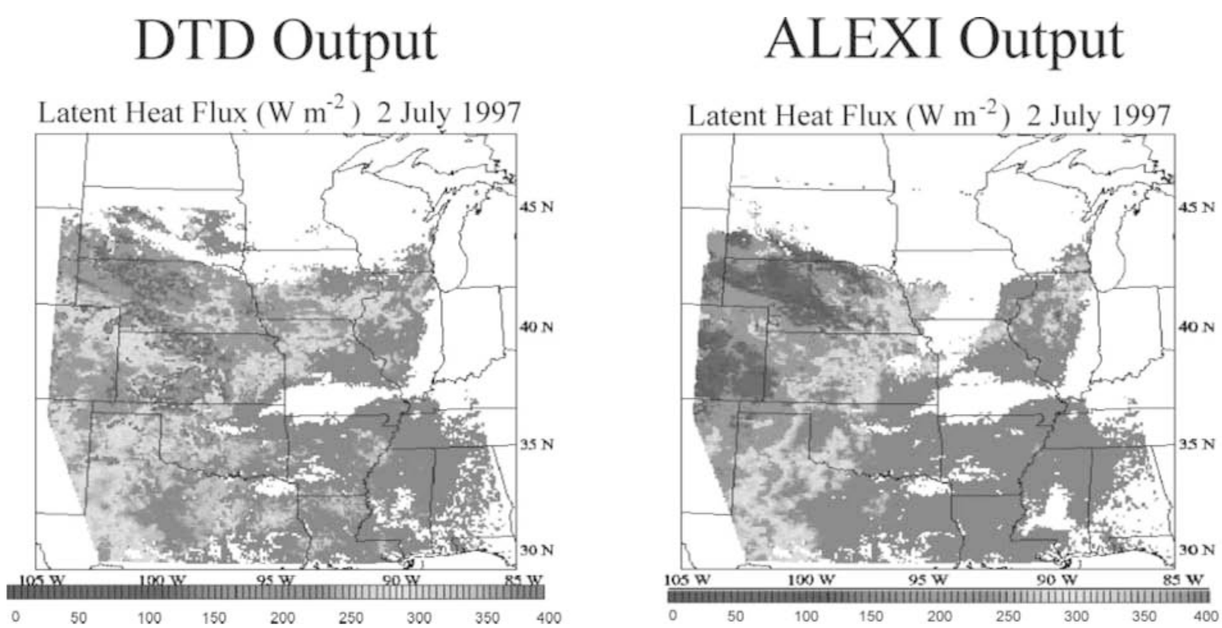

Fig. 3 Regional scale latent heat flux maps from DTD and ALEXI $\sim$5.5 hr after local sun rise for the U.S. Great Plains region on July 2, 1997.

the DTD scheme required less than 1 min of processing time on the same UNIX workstation.

CONCLUSION

Current efforts incorporating remote sensing data into SVAT modeling schemes that accommodate the fundamental differences between aerodynamic and radiometric temperatures and that are not sensitive to measurement errors should greatly enhance the prospect of quantifying ET at regional scales with remote sensing. The measurement errors with the largest impact on ET estimation are atmospheric and emissivity effects in converting satellite brightness temperatures to radiometric surface temperatures and assigning meteorological variables, primarily air temperature, for each satellite pixel from regional weather station observations.[28] Due to limited spatial observations of atmospheric properties, the uncertainty in the surface–air temperature difference is likely to be several degrees resulting in unreliable ET estimation, which have significantly hampered many past modeling approaches.

Although the current approaches described here, ALEXI and DTD, address most of these limitations, there is a drawback to these schemes in that the source of radiometric temperatures (GOES), and the atmospheric boundary layer closure and weather station network dictate an output resolution of 5–10 km. For many applications, particularly evaluating ET for individual fields, these 5–10 km estimates are at a much coarser spatial scale. Unfortunately, temporal changes (1/2-hourly) of satellite brightness temperatures are only available from GOES at a minimum resolution of ~5 km. Other satellites have much finer spatial resolution, such as the Land Remote-Sensing Satellite (Landsat) and the Advanced Spaceborne Thermal Emission Reflectance Radiometer (ASTER), but have much coarser temporal coverage (~16 days).

Kustas and Norman[31] found subpixel variability in surface properties can result in large errors in pixel-average heat flux estimation, using pixel-average inputs when there is a significant discontinuity in surface conditions, particularly under low winds. A solution to the problem of spatial resolution was introduced by Norman et al.,[32] who developed a scheme for "disaggregating" ALEXI 5 km flux estimates (called DisALEXI) to the 30 m scale using high-resolution NDVI and $T_R(\theta)$ data, and the local 50 m air temperature estimate provided by ALEXI as the important atmospheric boundary condition in temperature. Although, this scheme makes use of energy conservation principles applied to ABL dynamics to deduce air temperature via ALEXI, it still does not consider local variability in mean air properties. However, the preliminary results are encouraging, suggesting disaggregation of coarse spatial resolution ET output may be feasible periodically with high resolution data from Landsat or ASTER.

INTRODUCTION

Weather station data are increasingly being used to calculate reference evapotranspiration (ET_{ref}), for purposes of irrigation system planning, design, scheduling, and management. There is a range of methods used to calculate ET_{ref}. The Food and Agricultural Organization (FAO) of the United Nations, in collaboration with the International Commission for Irrigation and Drainage (ICID) and the World Meteorological Organization (WMO), has recommended the Penman–Monteith method (referred to as FAO56-PM) to calculate ET_{ref}.[1] Recently, the Environmental and Water Resources Institute (EWRI) of the American Society of Civil Engineers (ASCE) recommended a standardized ASCE - Penman–Monteith (ASCE-PM) equation.[2] The computation of parameters in the ASCE-PM incorporates the procedures described in FAO56-PM. The term "standardized" as used in the ASCE-PM equation infers that some computational procedures have been fixed. FAO and ASCE provide guidelines to assure that estimated ET_{ref} is relatively accurate.

The accuracy of estimated ET_{ref} depends on three important factors: weather station setting, station maintenance, and data quality control. Placement and the local environment of a weather station site can affect the accuracy and representativeness of ET_{ref}. A standardized regular maintenance program is essential. Furthermore, data quality control is a necessary component of any weather station network.[3–7] The absence of a quality control program can result in poor quality ET_{ref} data, which severely limits its usefulness for irrigation scheduling and can change to impair water resources planning and management. Weather station network operators or other agencies need to provide the information needed, such as crop coefficients, to allow users of ET_{ref} data to schedule irrigation.

In this article, we present the Penman–Monteith form of the combination equation and a description of the parameters, a brief description of station sitting criteria and maintenance, and quality control. Additionally, we enumerate what we think operators of network weather stations should provide to their customers.

REFERENCE EVAPOTRANSPIRATION

Reference evapotranspiration was defined by Doorenbos and Pruitt[8] as "the rate of evapotranspiration from an extensive surface of 0.08–0.15 m tall, green reference crop of uniform height, actively growing, completely shading the ground and not short of water". Using the same definition, while assuming the reference crop as hypothetical, ASCE defined evapotranspiration for a "short" reference similar to clipped, cool season grass as "the rate of evapotranspiration from a hypothetical reference crop with an assumed crop height, fixed surface resistance and surface reflectance (albedo), closely resembling the evapotranspiration from an extensive surface of green reference crop of uniform height, activity growing, completely shading the ground and with adequate water".[2,3] The reference crop selected to physically represent this hypothetical reference has historically been clipped, cool season grass having about 0.12 m height or an approximately 0.5 m tall, full-cover crop of alfalfa.

ET_{ref} can be calculated for different time steps; however, for irrigation scheduling, management and design in most climate regions, a 24-hr time-step calculation is adequate. The hourly Penman–Monteith equation[2] might be needed in coastal or mountainous regions. The 24-hr time-step Penman–Monteith equation as standardized by Ref.[2] is:

$$ET_{ref} = \frac{0.408\Delta(R_n - G) + \gamma\frac{C_n}{T + 273}u_2(e_s - e_a)}{\Delta + \gamma(1 + C_d u_2)}$$

where:

ET_{ref} = reference evapotranspiration ($\mathrm{mm\,d^{-1}}$)

R_n = net radiation ($\mathrm{MJ\,m^{-2}\,d^{-1}}$)

Evapotrans–Giant

G = soil heat flux density at the soil surface ($MJ\,m^{-2}\,d^{-1}$; small amount $\sim$ 0)

T = mean daily air temperature at 1.5–2.5 m height (°C)

u_2 = mean daily wind speed at 2 m height ($m\,s^{-1}$)

e_s = mean saturation vapor pressure at 1.5–2.5 m height (kPa)

e_a = mean actual vapor pressure at 1.5–2.5 m height (kPa)

Δ = slope of the saturation vapor pressure–temperature curve ($kPa\,°C^{-1}$)

γ = psychometric constant ($kPa\,°C^{-1}$)

C_n = numerator reference crop constant (grass = 900, alfalfa = 1600)

C_d = denominator reference crop constant (grass = 0.34, alfalfa = 0.38)

0.408 = reciprocal of latent heat of vaporization [$mm\,(MJ\,m^{-2})^{-1}$].

For hourly calculations, the values for C_n and C_d are different and depend on whether it is daytime or nighttime.[2] The estimation of R_n from solar radiation, temperature, and humidity, and on how to calculate G for 24-hr and hourly time steps is provided in Ref.[2].

WEATHER STATION SITING

The placement of a weather station and the local environment of a weather station can affect the accuracy of ET_{ref}. Buildings or trees close to a weather station can affect wind speed and solar radiation data, which in turn affect the estimated ET_{ref}. The recommended horizontal separation from obstacles should exceed 10 times the height of the obstacles. The absence of a healthy green reference crop under and upwind of a weather station affects humidity and air temperature, which will adversely affect ET_{ref}. Bare soil or dry vegetation instead of moist, cropped land around the weather station can increase advective energy, increasing temperatures and decreasing humidity, which tends to increase the ET_{ref} value. A station should be sited within the region it is meant to represent. Locating a station in a transition area between two regions of distinct climates should be avoided unless one is attempting to characterize the area. Topographic depressions should be avoided, as the temperature is frequently higher during the day and lower at night. High points should also be avoided. The ideal site for a weather station is a well-watered reference type of vegetation extending at least 100 m in all directions.[2] The vegetation should be properly irrigated, fertilized, and mowed frequently to maintain a proper height (averaging approximately 0.12 m for grass or 0.50 m for alfalfa). Fences used to protect the station from animals should be made of porous material and height should not obstruct wind movement. If the ideal site described above is not available, the station should be located in an area with a maximum fetch upwind of the station.

STATION MAINTENANCE

To assure the quality of ET_{ref}, a standardized maintenance program is essential.[9] It is recommended that a maintenance program includes monthly site visits, a record of prior maintenance, troubleshooting of problems, and sensor checks, replacements and calibrations. In most cases, the environment where the station is located will determine the maintenance schedule.

DATA QUALITY CONTROL

Data quality control (QC) should include a data processing operation in the form of a computer program that scans collected data for conformance with a list of data standards. Data processing procedures take different forms.[3–7] Common QC assessments include comparing incoming weather parameters against physical extremes, using statistical techniques to identify extreme or anomalous values, and comparing data with theoretical or expected norms and neighboring stations.[2] The QC assessment often depends on whether the station is a stand-alone or is part of a network.

INFORMATION DISSEMINATION

In addition to providing ET_{ref} information, operators of weather station networks should provide other information necessary for end users to plan, design, schedule, and manage an irrigation system. Operators should provide:

- A mechanism for disseminating up-to-date ET_{ref} data to the public, for example, via the World Wide Web.
- Crop coefficients for producing estimates of ET by crop or directing the public to where such data are available.
- Information on irrigation system evaluation, management, and performance.

- Information on training classes, seminars, and workshops on different aspects of irrigation scheduling that are offered by public and private agencies.

Dissemination of up-to-date ET_{ref} data is by itself not sufficient for successful water budget irrigation scheduling. The success of ET_{ref} based water budget irrigation scheduling hinges on the performance of an irrigation system and knowledge of this behavior by the scheduler. In particular, performance depends on the uniformity with which water is applied across the field, the distribution uniformity, and by extension the efficiency of the irrigation system. In addition, successful irrigation scheduling programs generally include some form of soil water monitoring and means of communication between the user and scheduler to communicate information on specific crop characteristics, actual irrigation events and amounts, and accuracy of the proposed schedule. Weather station operators can coordinate with organizations such as FAO, Irrigation Association (IA), cooperative extension services, and universities to organize training seminars and workshops for the public. Crop coefficient values are commonly supplied by universities and research institutions at no cost.

CONCLUSIONS

The information provided herein briefly summarizes the use of weather station networks to supply ET_{ref} information. It describes the ET_{ref} equation that is recommended; the importance of weather station siting, maintenance, and data quality control; and some of the information that weather station operators should provide to the public to assist them in effectively utilizing ET_{ref} data.

Weather station networks need to keep up with new emerging technologies. Future prospects include development of a methodology for short-term ET_{ref} forecasting; integration of wireless technology, remote sensing, GPS and real- or near real-time data dissemination. For example, a farmer using a hand-held PDA with GPS can transmit his location to a central computer, which then relays back information specific to that location. Along with crop coefficients and irrigation system efficiency stored in the hand-held device, the farmer can accurately calculate and determine a specific crop water requirement.

Evapotrans–Giant

INTRODUCTION

The Everglades of south Florida was originally a broad, shallow "River of Grass"[1] that extended from the south shore of Lake Okeechobee to Florida Bay at the southern tip of the state, east to the Coastal Ridge, and west to the Immokalee Ridge. Historically, the area was a vast sawgrass marsh, dotted with tree islands and interspersed with wet prairies and sloughs covering an area about 40 mi wide by 100 mi long. One of the unique regions of the world, it has steadily decreased in size and declined in health during the past century. Half its wetland area has been lost to agriculture and urban development and the remaining segments are impacted by lack of a clean, dependable water supply. Natural water flows have been diverted for irrigation, drinking water, and flood protection. The conveyance system of canals, levees, structures, and pumps developed for flood control has altered natural patterns of water flow and storage, adversely affecting food webs that supported a diverse ecosystem. Nutrient runoff from urban and agricultural sources is transported by the conveyance system to the remaining natural wetland areas, causing undesirable changes in flora and fauna. Hydroperiod changes have altered natural fire patterns and stimulated invasion of exotic species. A multi-agency state and federal task force has developed a Comprehensive Everglades Restoration Plan (CERP)[2] to address and reverse these major changes to this unique wetland ecosystem. The major hydrologic modifications to be addressed in the Everglades restoration include: 1) regain lost storage capacity; 2) restore more natural hydropatterns; 3) improve timing and quantities of fresh water deliveries to estuaries; and 4) restore water quality conditions. The Comprehensive Plan, considered the world's largest such project, includes more than 60 components proposed for implementation over a period of four decades with an estimated investment approaching $8 billion. State and federal legislation provides for a 50/50 cost share between the federal and state governments to implement the plan.

EVERGLADES WATER MANAGEMENT—PAST, PRESENT, AND FUTURE

History

Primitive canals were dug in portions of the Everglades as early as the late 1800s in attempts to reclaim fertile swampland for agriculture.[3] Early promoters and developers led people to believe that a productive subtropical agriculture was possible in the entire Everglades region. These early attempts at land reclamation were largely unsuccessful until the 1920s when a period of less than normal rainfall helped dry the region around Lake Okeechobee for farming. Following severe hurricane damage in the region in the late 1920s and again in 1947, the focus was shifted from land reclamation to flood protection and the Central and Southern Florida Flood Control Project was authorized and implemented beginning in 1948. Over the next 15 yr, this project resulted in a perimeter dike around Lake Okeechobee and the extensive conveyance system of canals, levees, structures, and pumps currently in place. It also allowed development of the Everglades Agricultural Area (EAA), a highly productive, 700,000-acre region of organic soils in the northern Everglades used primarily for sugar cane and winter vegetable production.[4]

Environmental Issues

By the mid-1960s, concerns were already growing about conservation issues and adverse environmental impacts. Additional areas along the eastern border of the Everglades have since experienced urban encroachment. A total of about 1 million acres, roughly 50% of the Everglades wetlands, have been transformed for human uses during the past half-century. The 1700 mi of canals and levees in the region have interrupted connections between the central Everglades and the adjacent wetlands, resulting in over-drainage in some areas and excessive flooding in others.

This system provides water supply, flood protection, water management, and other benefits to south Florida, but it must be modified to reduce the negative impacts on the environment. The current canal system works very effectively, discharging an average of 1.7 billion gal of water per day to the ocean and gulf. This discharge must be reduced if future urban, agricultural, and environmental demands for water are to be met.

Today's remaining Everglades have been significantly affected by the current water management system. Wading birds and other wildlife populations are greatly decreased. Tree islands, with their unique combination of wetland and terrestrial vegetation and wildlife, are considered to be an excellent indicator of the overall health of the Everglades. Many of these tree islands have disappeared from the northern Everglades over the past 50 yr, and many others have been taken over by exotic vegetation. These effects are mainly due to changes in the quantity, quality, timing, and distribution of water that have occurred over the years as a result of changed water management. Water depth, duration, and timing are important to both wildlife and vegetation. The sawgrass wetlands of the Everglades developed under very low nutrient conditions with rainfall as the main source of phosphorus. Nutrient inflows, especially phosphorus, as a result of development and modified water management have influenced changes in vegetation type.[5] Where phosphorus concentrations have increased, sawgrass and spike rush have been replaced by cattail causing undesirable changes in the ecosystem. Native vegetation remains healthy where phosphorus concentrations are low.

Restoration

Restoration of the remaining Everglades depends upon a knowledge and understanding of the original conditions. Efforts are focusing on improving upstream water quality and the distribution, timing, depth, and flow of surface water into and through the Everglades. Early historical information sources, combined with further interpretation and analysis, are being used to estimate original drainage patterns and soil, topographic and vegetation conditions before canal drainage began in the late 1800s. Results of these studies indicate that the predrainage landscape of the Everglades probably was configured in subtle ridges and sloughs with two major flow pathways: a flow path southeastward to the Atlantic Ocean, and a southwestward flow path along Shark Slough to the Gulf of Mexico.[6] These flow patterns may have influenced the ridge and slough landscape configuration that is important to the health of the ecosystem. Redevelopment of these flow patterns and landscape configuration will be important to the restoration process. About 70% less water flows through the Everglades today compared to the historic Everglades system.

The main goal of Everglades restoration is to deliver the correct amount of water, with the correct quality, to the correct locations, and at the correct time.[7] Most of the water currently lost to the ocean or gulf will be stored in surface and subsurface storage areas until needed, when 80% of it will be allocated to the environment and 20% to increase urban and agricultural water supplies. Water to be stored for future use will be routed through surface storage reservoirs and wetland-based stormwater treatment areas to improve its quality. Additional water quality improvements can be expected from comprehensive integrated water quality planning efforts currently in progress. To restore water flow paths, more than 240 mi of canals and levees will be removed in the Everglades. This will allow more natural overland water flow in the remaining natural areas of the Everglades. Water held and released will be managed to match natural discharge patterns more closely. Operational plans will be developed in some areas to simulate natural rainfall patterns with water releases to improve the timing of water flowing through the Everglades ecosystem. These strategies are all being designed to enhance not only ecosystem restoration, but also urban and agricultural water supply and flood protection as part of the process of moving toward a more sustainable south Florida.

CONCLUSION

The Everglades landscape is a unique combination of subtropical wetlands and uplands, including sawgrass marshes, sloughs, wet prairies, tree islands, tropical hardwood hammocks, pinelands, and mangroves. It provides important habitat for many threatened and endangered species. Water management for flood control and water supply purposes has caused some areas to become drier and others to become wetter than normal. More than half of the original wetland area has been lost to agricultural and urban development. The introduction of increased nutrients resulting from this development has caused undesirable shifts in vegetation communities. Hydrologic changes have altered the extent of naturally occurring fires and promoted the growth of exotic species. While the current water management system performs well for flood protection it must be modified to reduce adverse environmental impacts and conserve more fresh water to meet a variety of needs. A Comprehensive Everglades Restoration Plan received initial authorization in 2000 to begin the restoration of the south Florida ecosystem and provide for water-related needs of the region. This plan addresses the quantity, quality, distribution, and timing of water to the Everglades. A large amount of additional information regarding the Everglades is available on the web at http://www.sfwmd.gov/koe_section/2_everglades.html and http://www.evergladesplan.org/.

The following quote from the Comprehensive Everglades Restoration Plan web site[7] conveys the importance of the Everglades and the current restoration program.

> The significance of the remaining Everglades to the nation and the world has been affirmed time and again. Congress established Everglades National Park. The Everglades have also been designated an International Biosphere Reserve, a World Heritage Site, and a Wetland of International Significance. Identified as one of the world's major ecosystem types, the Everglades are home to 68 threatened or endangered plant and animal species. The benefits and functions of these plants and animals may never be known if we do not restore and protect their habitat. Saving the Everglades requires us to save the entire south Florida ecosystem. The ecological and cultural significance of the Everglades is equal to the Grand Canyon, the Rocky Mountains, or the Mississippi River. As responsible stewards of our natural and cultural resources, we cannot sit idly by and watch any of these disappear. The Everglades deserves the same recognition and support.

Farm Ponds

Ronald W. Tuttle
U.S. Department of Agriculture (USDA), Chantilly, Virginia, U.S.A.

INTRODUCTION

The rural American landscape is a rich tapestry of interdependent ecosystems. It is also a working landscape of over 900 million privately owned acres devoted to cropland, pastureland, or rangeland.[1] Scattered across this diverse matrix are countless farm ponds, reflecting the light of day and night (Fig. 1[2]). Although there is no accurate count of the total number of ponds in the United States, a conservative estimate is well over 2 million. The United States Department of Agriculture (USDA), Natural Resources Conservation Service (NRCS) reported more than 2.1 million ponds had been built on privately owned lands by 1980.[3] The Soil Conservation Service [SCS (now NRCS)] assisted in the planning and construction of approximately 2 million farm ponds during the 30-yr period between 1945 and 1975. According to SCS historical records, in 1974 the South region of the United States led in the cumulative number of ponds built with 1,108,959. The Midwest region was next with 450,847 ponds. The West and Northeast regions followed with 278,360 and 134,327 ponds respectively. Texas, Oklahoma, Mississippi, and Kentucky were the leading states in number of ponds built by SCS at that time.[4]

Farm ponds continue to be much in demand with many constructed each year in the United States. Iowa, for example, reports 87,000 farm ponds with an additional 1000 being added yearly.[5] A conservative estimate suggests over 50,000 ponds ranging in size from less than 1 acre to over 30 acre in Virginia.[6] The list goes on with Mississippi reporting more than 280,000 farm ponds ranging in size from 1/2 acre to 40 acre.[7]

POND CHARACTERISTICS

Farm ponds are commonly described as water impoundments used for agricultural or domestic farm uses and enjoyment. NRCS defines them as a water impoundments made by constructing a dam or by excavating a pit or dugout.[8] There are two general types of farm ponds, largely determined by topography. Embankment ponds are formed by impounding water behind a dam built across a watercourse. Good sites occur in gently sloping valleys with steep side slopes to provide adequate pond depth and discourage the establishment of aquatic vegetation. NRCS recommends dams that are less than 35-ft high and located where their failure will not result in loss of life; damage to buildings, highways, and other infrastructure elements; or in interrupted use of public utilities.[3] Excavated ponds, as the name implies, are constructed by removing soil to create a pond basin at an elevation below the surrounding ground level. Unlike embankment ponds, they are typically constructed on relatively level areas where a source of water may be more limited.

Water adds variety to a landscape, thereby enhancing its aesthetic quality. Many terrestrial species as well as fish, amphibians, and waterfowl are dependent upon the habitat offered by farm ponds. They attract songbirds, small and large mammals, osprey, heron, and other species in a linked web of life. In addition to their intrinsic value for wildlife and aesthetic quality, farm ponds are important for livestock, recreation, energy conservation, fish production, and water supply for irrigation or farmstead fire protection. Properly managed ponds also reduce storm runoff, aid in erosion control, and improve water quality (Fig. 2).

PLANNING AND DESIGN CONSIDERATIONS

Farm ponds should be properly planned, designed, and constructed if they are to function as intended. A basic problem-solving process involving inventory and analysis of prevailing natural resource conditions, identification of related problems and opportunities, and evaluation of alternatives will lead to appropriate decisions when planning and designing a pond.

There are many useful references on the subject of planning, designing, and constructing ponds. The NRCS publication *Ponds—Planning, Design, and Construction* (see Ref.[3] is available at NRCS offices and describes basic requirements for building a pond. The many details covered in this and other sources of information are beyond the scope of this publication; however, major considerations include location, water supply, and soil type.

Location

Site and watershed investigation will determine if an area is suitable for the type of pond desired.

Fig. 1 A typical farm pond in rural America.

The relationship of alternative pond sites to prevailing ecological structure and functions within the larger landscape or watershed is critical to achieving a properly functioning farm pond. Dams, for example, are proven to have significant detrimental impacts upon the equilibrium of stream corridors.[9] Therefore, it is generally not advisable to dam streams for the purpose of constructing an embankment pond. Locating them nearby will protect the stream and prevent damaging floodwaters and silt from entering the pond.

Farm ponds should be planned and designed to fulfill their intended use as an integral part of the surrounding landscape. This is achieved with minimum disturbance to existing landform, vegetation, water, and structures. The desired principal use(s) of a pond will determine its best location. A pond intended for aesthetic quality and fire protection, for example, should be sited near farmstead structures and easily visible from important viewpoints near the home or elsewhere.[10] This proximity to major viewpoints will also help to prevent misuse of the farm pond and ensure greater safety.

Water Supply

High quality water from either a surface or groundwater source is important to properly functioning farm ponds. Watersheds with good vegetative cover and conservation systems installed to protect the land are best suited for an appropriate supply of water.

The amount, intensity, and duration of surface runoff should be evaluated to determine if the watershed above the pond site is large enough to provide an adequate water supply. In place of local runoff information, NRCS offers a general guide for estimating the approximate size of drainage area needed based upon the desired capacity of an embankment or

Fig. 2 A farm pond managed to reduce storm runoff, aid in erosion control, and improve water quality.

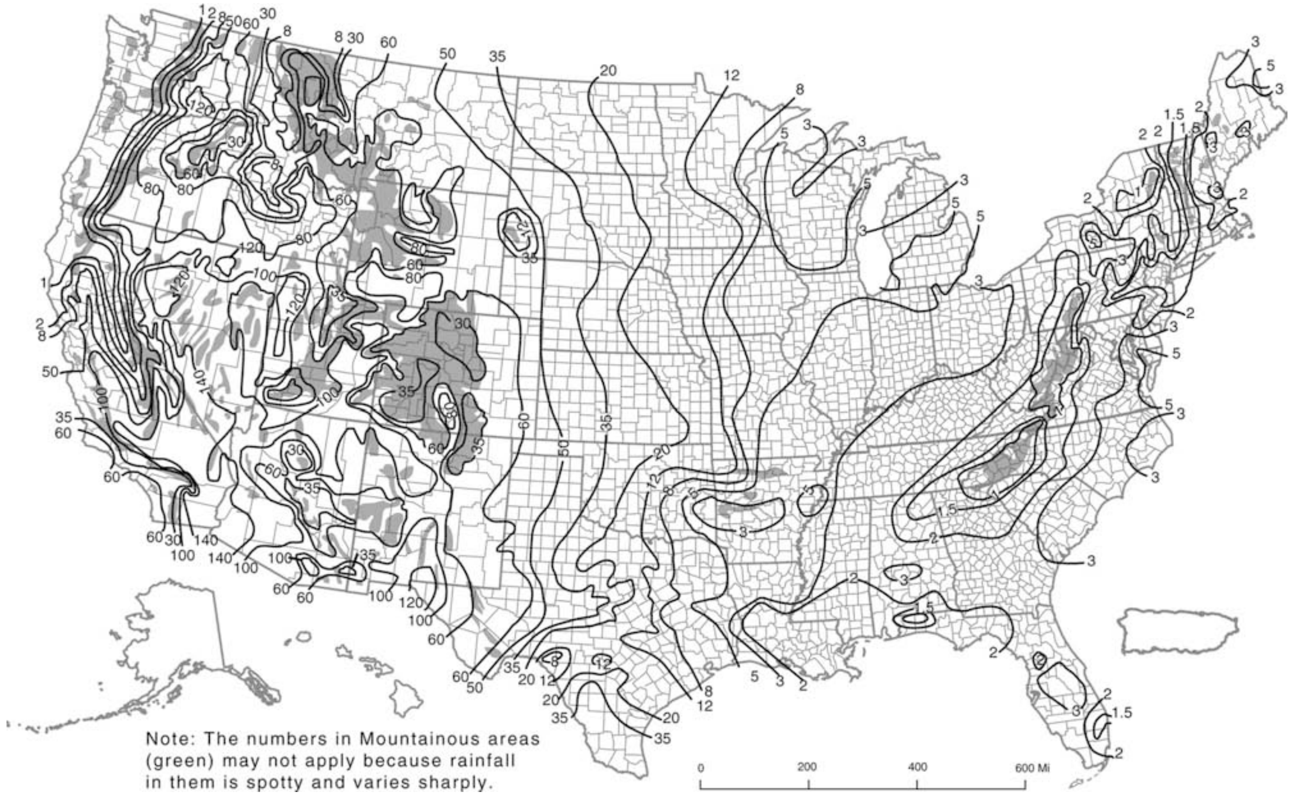

Fig. 3 A guide for estimating acres of drainage area required for an acre-foot of pond storage.

excavated pond (Fig. 3). The acreage needed in a drainage area for each acre-foot of pond storage can be determined by using this guide; however, some adjustments may be necessary to account for extremes in local runoff conditions. One acre-foot is equal to the amount of water to be stored to a depth of one foot over one acre (a total of 325,851 gal). Details for estimating storm runoff and recommended minimum depths of ponds to account for normal seepage and evaporation are also available.[3]

Soil Type

Many ponds fail because they are built in the wrong type of soil. A properly functioning pond must, by definition, hold water. The soil must be suitable for the pond bottom as well as for the dam in the case of embankment ponds. Deep soil that has slowly permeable subsoil containing lots of clay or silty clay is the best. Sites containing coarse-textured sand, gravel, sand–gravel mixtures are generally unsuitable unless an adequate clay content is present. Areas containing limestone or gypsum are especially hazardous due to crevices, sinkholes, or channels that can drain water from a pond very rapidly. A clue to suitability of the site is the degree of success of nearby ponds.[3]

POND MANAGEMENT

Management and maintenance are just as important to a properly functioning farm pond as good planning, design, and construction. Appropriate management prescriptions, which can be diverse in their nature, are often dictated by the principal use(s) of a pond. Fencing to exclude livestock from ponds and installing a gravity-fed watering trough nearby, for example, will often increase the value of ponds for multiple use and enjoyment.

A diverse plant community will also increase a pond's value for multiple uses. Trees, shrubs, herbs, and grasses established and maintained as a buffer will provide wildlife habitat, improve aesthetic quality, and increase the life expectancy of ponds by reducing erosion. However, deep-rooting trees or shrubs should be prevented from growing on dam embankments, where their roots can endanger the integrity of the structure.

Damage from erosion, burrowing animals, livestock, silting, aquatic vegetation, overflow, undercutting, and other sources can occur rapidly and should be corrected promptly. Occasionally, a pond will begin to leak water at an excessive rate and require corrective measures. Clay blankets, bentonite, chemical additives to reduce soil permeability, and waterproof linings are common alternatives for sealing ponds.[3] Excessive aquatic plant growth is another maintenance problem that will hasten eutrophication and seriously degrade conditions for use and enjoyment of the pond. Adequate pond depth will discourage undesired plants from becoming established; otherwise, mechanical removal or chemical methods may become necessary.

Owners have an obligation to ensure their farm ponds are as safe as possible. Signs warning of dangers should be installed and hazards to swimmers removed. Rules regulating recreational use of the pond and life-saving devices such as ring buoys and ropes or poles stationed at ponds will provide additional protection.

SOURCES OF ASSISTANCE

Most states and other governing entities have regulations pertaining to pond construction. Those planning and designing ponds must comply with these requirements by contacting the local planning board or other appropriate governing body before building a pond. Landowners are responsible for obtaining permits, performing necessary maintenance, and ensuring pond safety.

The local county Soil and Water Conservation District (SWCD) should be the first stop for those interested in planning and constructing a farm pond. The SWCD works closely with other local, state, and federal government entities, including State Departments of Natural Resources, Cooperative Extension Service, and the USDA, NRCS. Collectively, they can provide helpful technical and financial assistance.

Cost-share funds also may be available for the construction of ponds. The Environmental Quality Incentives Program administered by the NRCS is one of the several similar programs available to farmers and ranchers. It offers financial, educational, and technical assistance to install or implement conservation practices, including farm ponds.[11] Program managers indicate that over 8000 ponds were contracted from 1997 to 2000 under this program.

Fertilizer and Pesticide Leaching: Irrigation Management

Luciano Mateos
Instituto de Agricultura Sostenible, Consejo Superior de Investigaciones Científicas, Córdoba, Spain

INTRODUCTION

Good irrigation management begins by selecting the appropriate irrigation method and strategy according to the water availability, the characteristics of the climate, soil and crop, and to the economic and social circumstances. Good irrigation management continues with the actual application of the scheduled water, its even distribution over the field, and the storage in the root zone of as much of the applied water as possible. During the cropping season, the irrigation schedule must be adjusted to the weather variations and to other cropping practices such as fertilization and pesticides application.

Depending on the irrigation method, the water is distributed through pipes or overland channels. The water that is not stored in the root zone percolates or runs off the field. The percolated water can leach solutes; the water that runs off can carry away solutes or chemical components adsorbed in suspended soil aggregates.

Therefore, since irrigation water can be one mean by which fertilizers and pesticides are transported out of the root zone, good irrigation management must be integrated with the application and subsequent dynamic of the fertilizers and pesticides.

FACTORS AFFECTING LEACHING

The amount of percolation is determined by the average infiltrated depth in relation to the previous soil water content, by the spatial distribution of the infiltrated depth, the hydrologic characteristics of the soil, and the concentration, location, and chemical characteristics of the solutes. The potential for leaching is especially large on coarse-textured soils because of their low cation-exchange and water-holding capacity and their high water permeability.

Most of the water below field capacity is held in the soil, i.e., a uniform depth that refills a homogeneous root zone up to field capacity can be potentially consumed by the crop. On the contrary, if the average infiltrated depth is deeper than that require to take the root zone water content up to field capacity, the excess of water will percolate. Preferential flow through the soil macropores may cause drainage before the water content is risen up to field capacity. A non-uniform water infiltration and distribution within the soil profile can cause percolation at certain locations in the field while other locations may suffer water deficit.

The dynamics of water flow in soils influences the transport behavior of reactive and non-reactive solutes. The solute velocity for low-frequency intermittent flow may be larger than for continuous flow because the infiltration rate increases after the drying cycles. When the soil is initially wet, the leaching of a solute applied in a solution just before the irrigation is lower than when the soil is initially relatively dry. The reason for this behavior is that the large pressure gradients under dry conditions pull the solution into the small pores.[1] Preferential transport is more likely to occur under ponded conditions, where flow occurs under saturation, than under application intensities limiting the infiltration rate.[2] In addition, under ponded conditions, the natural spatial variation of soil infiltration characteristics should increase the field scale dispersion of a leaching chemical in comparison to transport under flux-controlled boundary conditions.[3]

IRRIGATION SCHEDULING AND LEACHING

Irrigation scheduling is the determination of the next irrigation date and the depth of water to apply. Proper irrigation scheduling controls drainage and thus leaching of fertilizers and pesticides. One accepted irrigation practice to reduce leaching of fertilizers and pesticides is to apply the water necessary to bring the soil to field capacity. Even with the right amount of water, significant leaching occurs if rainfall events come soon after irrigation. An option under these conditions is to allow the soil to become drier between irrigation events; thus the probability of rainfall on a water full soil decreases; but the chances of the crop running into water stress are higher. Alternatively, irrigation depths smaller than that required to fill the soil to field capacity leave soil storing capacity for unforeseen rains.

A reduction in fertilizer or pesticide input generally results in a leaching reduction of that agrochemical. However, a reduction in irrigation amount does not necessarily imply a reduction in leaching. It may be found that crop production is optimized and N losses to the environment are minimized when the crop is irrigated for full evapotranspiration replacement. Under conditions of deficit irrigation, water stress restricts crop growth; thus nutrients uptake and fertilizer recovery are lower. Nitrate leaching between the harvesting of one crop and the planting of the next may be more important than nitrate leaching induced directly by the irrigation water.

IRRIGATION UNIFORMITY AND LEACHING

The inherent and management-induced non-uniformity of the irrigation systems implies that some water deficit and/or drainage must occur after the irrigations. There is a trade-off between uniformity, water deficit, and percolation. To avoid water deficit at any point in the field, excess of water must be applied. The infiltrated water that is not used to refill the root zone will percolate. This amount must be larger as more non-uniform are the water application and infiltration and lesser the allowable crop water deficit.

The occurrence of drainage due to non-uniformity of the water application implies leaching. Experimentally quantifying the effect on leaching of irrigation scheduling and uniformity in relation to fertilization is very complex. Pang, Latey, and Wu[4] used a crop model to simulate the combined effects of these factors on crop yield and nitrogen leaching. These authors found that high corn yield under low nitrate leaching constraints is possible only with irrigation systems that have a Christiansen uniformity coefficient of 90 or greater. Vickner et al.[5] added an economic analysis to the yield and nitrate leaching responses to irrigation uniformity. They used a dynamic model to appraise policy options for regulating groundwater quality in the western region of United States of America, finding that a limit on leaching due to corn production is economically feasible by increasing the uniformity of center-pivot irrigation systems.

IRRIGATION METHOD AND LEACHING

The irrigation methods are classified under three major groups: surface, drip/micro, and sprinkler.

Surface Irrigation

The efficiency and uniformity of surface irrigation depends on the control of the relationship inflow-soil infiltration rate-application time, soil heterogeneity, and on land grading and field microtopography. The distinctive feature of surface irrigation is that the soil surface is the transportation medium. Therefore, field water distribution occurs simultaneously to and it is controlled by infiltration. Furthermore, the infiltration rate varies spatially and temporally.

Infiltration in a surface-irrigated field is usually higher at its upstream end, where water flows for longer time (i.e., has a greater opportunity time for infiltration). The risk for leaching is, thus, higher at the upper part of the field. For a target depth at a given location in the field, percolation can be reduced by increasing the inflow rate and decreasing the application time. Advance will be faster, thus opportunity time variability along the field will be less and so the infiltrated water at the field head.

Surge flow (the application of water in intermittent pulses) and compacted furrows—e.g., wheel furrows—also increase uniformity and decrease head percolation by reducing the infiltration rate. But if the field is open at the downstream end, the higher stream size can result in excessive run-off. In this case, inflow cutback after completion of the advance phase or tailwater recovery are options for restricting run-off.

Alternate-furrow irrigation combined with fertilizer placement in the non-irrigated furrow has the potential to reduce fertilizer leaching. However, adequate root development in the non-irrigated furrow is required to allow nutrients uptake, and avoid residual fertilizer that can be potentially leached.[6]

Microtopography also affects opportunity time variability in basin irrigation. Laser leveling reduces the soil surface microrelief, thus infiltration is more uniform and percolation and leaching can be better controlled.

In addition to the opportunity time non-uniformity, the natural heterogeneity of the soil infiltration characteristics enhances the infiltration variability and the risk of percolation below the root zone. Some authors claim that the variability of the soil infiltration characteristics is damped under surge flow.

The solute displacement under the continuous flow typical of paddy rice can be expected to be lower than under drying-irrigation cycles because of the larger infiltration rate in the later situation. Fertilization timing in relation to irrigation timing may also affect leaching. For instance, as it was pointed out earlier, a slug of liquid nitrogen fertilizer applied to a relatively dry topsoil will be less prone to subsequent leaching than if applied to wet soil. If the slug is applied to wet soil, delaying irrigation for several days will reduce leaching.[1] For similar reasons, preferential solute movement is more likely to occur under flood irrigation, where water ponds on the soil surface, than under sprinkler or drip/micro irrigation, where the application rate is usually lower than the soil infiltration rate.

Drip/Micro Irrigation

Under drip/micro irrigation, water is applied directly to small areas adjacent to the plants through emitters placed along a water delivery line. High application frequency and partial soil wetting distinguish drip/micro irrigation. The use of drip irrigation leaving dry part of the soil should be beneficial in reducing N leaching in regions where rain occurs during the crop growing season.

The hydraulic features of the drip/micro irrigation systems allow very uniform emitter flow and water application control. Relevant non-uniformity can only stem from poor system design and/or maintenance. Irrigation scheduling can be easily implemented if the crop water requirements are properly estimated. Therefore, percolation and leaching out of the root zone of drip/micro irrigated crops can be minimized.

Sprinkler Irrigation

In sprinkler irrigation, water is distributed using a pressurized system with nozzles or jets that apply the water through the air. The water distribution patterns of the sprinklers in a system can be slightly different due to pressure differences. The individual patterns are not uniform, neither compositions of arranged stationary or moving patterns. Moreover, the distribution patterns can be distorted by the effect of the wind. Therefore, certain non-uniformity is inherent to sprinkler irrigation and the risk of percolation exists under most of the irrigation management scenarios. The non-uniformity and percolation risk can be at different spatial scales. The redistribution of water within the soil and the extent of the crop roots can contribute to damp the small-scale variability and thus the reduction of the percolation risk. However, neither the soil nor the crop will be able to damp the part of the non-uniformity due to differences among laterals and along individual laterals.

CHEMIGATION

Chemigation can be an efficient way of applying pesticides and fertilizers. Best management practices endorse split applications of fertilizer to match nutrient supply and demand and to reduce the potential of leaching. Applying fertilizers with irrigation water (fertigation) expands opportunities for timed applications.

Chemigation in drip/micro irrigation is a well-developed practice.[7] Also sprinkler fertigation (chemigation) has technical basis. Recent modeling attempts have tried to develop scientific criteria for surface fertigation. Boldt et al.[8] used a surface irrigation model to simulate the distribution of N during surge irrigation—a promising means of furrow fertigation.

Despite the potential advantages of chemigation, experimental results indicate that flood chemigation or chemigation with high-rate sprinkler irrigation may actually increase rather than decrease deep leaching of agricultural chemicals. Jaynes, Rice, and Hunsaker[2] observed that a tracer applied with the irrigation water moves deeper into the soil than a tracer sprayed on the soil surface immediately before irrigation because the former is better able to use preferential pathways and move deeply into the soil. Therefore, caution on timing of the chemical application and flow regime are important aspects to consider when fertigation is practiced.

Field Water Supply and Balance

Jean L. Steiner
Grazinglands Research Laboratory, Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, El Reno, Oklahoma, U.S.A.

INTRODUCTION

Field water supply has been a major focus of agricultural research and management. The soil water balance is a widely used method of tracking soil water supply in a field. This approach provided some of the earliest information available about the amount of water required to produce a crop, the relationship between water use and plant production, and water stress impacts on plant water use, and remains an important approach to research and management today.

The soil water balance (Fig. 1) can be given as:

$$SW_t = SW_i + P + I - R - E - T - D \qquad (1)$$

where SW is soil water content within a defined root zone, t and i subscripts represent the end and beginning of a time period, respectively, P is precipitation, I is irrigation, R is runoff, D is drainage below the root zone, E is evaporation from the soil surface, and T is transpiration, with all terms in the same units and over the time period defined by the t and i subscripts. The R term might be modified to include any horizontal movement of surface water or shallow water table flow, which can be either imported to or exported from the defined soil volume. In most circumstances, the D term is downward flux below the root zone, but can be defined to include vertical flux across the bottom of the root zone that could include upward movement from a shallow water table to deep rooted plants. The E term can be considered to include water evaporated from any wetted surface (e.g., ponded water, wetted plants, evaporation or sublimation of accumulated snow), as well as evaporation of water from the soil profile. Frequently, the soil water balance is used to determine terms of Eq. (1) (e.g., $E + T$, $SW_t - SW_i$,) by measuring or estimating the remaining terms. Infiltration is often estimated by measuring P and R, if the other terms can be considered negligible during the precipitation event. Gardner[1] provides additional detail about the soil water balance.

WATER BALANCE COMPONENTS

Soil Water Content

Many different methods have been used to measure soil water content. A direct method that has been used since the early days of soil and agricultural research and remains common today is the gravimetric method. For the gravimetric method, soil samples, often cores, are collected and the water content is determined by weighing the sample before and after oven drying to determine the quantity of water lost by evaporation. Gravimetric sampling offers the benefit of providing a direct measurement of soil water content using simple equipment. However, it is time consuming and cannot be used to provide repeated measurement at the same location because it is destructive sampling. Given the high degree of spatial variability in most field soils, this limits the ability to determine temporal changes in soil moisture precisely, limiting the application of the soil water balance to relatively longer time periods. Methods that provide repeated measures of soil water content at the same location, such as using neutron probe or other technologies, reduce the problem of spatial variability and allow the soil water balance to be applied over shorter time periods.

Precipitation and Irrigation

Water is added to the system through precipitation or irrigation. Since precipitation is often highly variable, the rain gauge should be as near the site of the investigation as possible and should use standard weather gauges, properly sited away from tall buildings or vegetation that can distort rainfall catch. At field scales, irrigation applications are not totally uniform, so the gross irrigation amount may have to be adjusted by efficiency and uniformity factors to determine the net input to the soil water balance. However, well-managed, modern irrigation techniques such as low pressure applicators on center pivots and drip or subsurface irrigation methods, can provide very uniform distributions of water in a field with high efficiency.

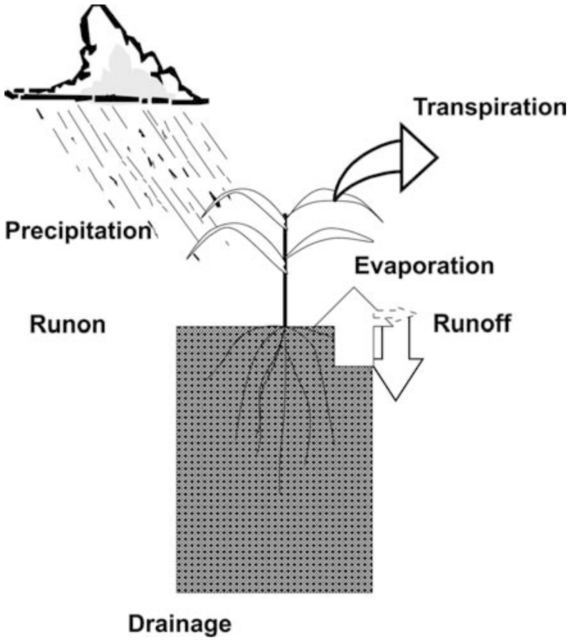

Fig. 1 Soil water balance for an agricultural plant.

Horizontal Movement of Water

The horizontal surface movement of water is largely runoff. In some situations, there may be a net gain through run-on of water from another portion of the landscape. However, there is normally a net loss to the water balance of a particular field when horizontal movement occurs. The proportion of precipitation that runs off depends on soil properties, vegetation, and topography, as well as the intensity and duration of rainfall. In some soil water balance calculations, runoff is assumed to be negligible because of level topography, or in some cases berms are constructed around small experimental areas to restrict horizontal movement. When a large amount of precipitation falls as snow, there can be considerable movement caused by the wind and drifting. In some field situations, there is a substantial horizontal movement of water below the surface, making it difficult to use the water balance method.

Evaporation and Transpiration

Because it is difficult in field studies to separate loss of water by evaporation from soil and transpiration from plants, these terms are often linked into a single term, usually called evapotranspiration, E_t. From a management perspective, options for influencing soil evaporation and transpiration are different, so the terms are presented separately in Eq. (1).

Energy Balance

The energy balance approach, often used to estimate E_t, was developed for a plant–soil system under conditions where transpiration dominated the total loss. This approach has been successful because a large portion of energy that enters the earth's atmosphere is required to transform water from liquid to vapor (the evaporation process). The combination evaporation equation derived by Penman[2] and Monteith[3] can be expressed as

$$E_t = \{\Delta(R_n + G) + [\rho C_p(e_s - e_a)/r_{av}]\} / L[\Delta + \gamma(1 + r_s/r_{av})] \quad (2)$$

where Δ is the slope of the saturation vapor pressure curve, R_n is net radiation, G is soil heat flux, ρ is air density, C_p is the specific heat of dry air, e_s and e_a are the vapor pressures at the evaporating surface (assumed to be the saturation vapor pressure at the surface temperature) and of the atmosphere, respectively; r_{av} is the aerodynamic resistance, L is the latent heat of vaporization, γ is the psychrometric constant, and r_s is surface resistance. Because it is difficult to measure some of these terms, particularly the surface resistance term, methods have been developed to evaluate the equation for potential evaporation conditions using standard weather data, applying assumptions about a well-watered, vegetated surface; and then relating the potential evaporation to actual evaporation for a particular vegetative surface (such as early or late in the season with low vegetative cover or under water-stressed conditions) using crop coefficients and other adjustments. These methods are discussed thoroughly in Allen et al.[4] and Allen.[5]

Radiation Balance and Soil Heat Flux

Net radiation is the balance resulting from the incoming and outgoing fluxes of short and long-wave radiation and is affected by several aspects of the soil and plant cover at the surface.[6] Short wave radiation is strongly affected by surface roughness, color, soil water content, and solar angle. For soils and plants, emitted long-wave radiation is largely determined by surface temperature, so wetter soils (which are generally cooler) have less outgoing long-wave radiation than drier, warmer soils. Incident long-wave radiation is influenced by sky conditions (cloudiness, cloud type, etc.), and it will generally decline with increased sky cover. As vegetative cover increases, the effect of soil conditions on net radiation decreases to negligible levels. For calculation of short-term evaporation, soil heat flux is sometimes taken as a fraction of net radiation (~10%). For bare soils, such as early or late in a growing season, the fraction can be much higher. For longer time periods, changes in air temperature can be used to estimate the flux of heat into or out of the soil over the period.[4] As vegetative cover or crop residue cover increases, the flow of heat in the soil is reduced because temperature gradients in the soil decrease as the soil is shaded.

Drainage of Water Across the Lower Boundary

In some cropping systems, the flux across the lower boundary of the root zone can be considered to be negligible. This is true primarily in semiarid or arid climatic regimes and in soils with a high water holding capacity and/or a low hydraulic conductivity, such as clay loams, silty clay loams, or in some cases silt loams and loams. It may also be true where there is a restrictive layer in the soil profile that prevents or slows the flow of water below the root zone. However, when considering year round water balances, soil water is often lost below the root zone during at least part of the annual cycle in periods of high precipitation or low evapotranspiration. Water losses below the root zone can be measured using lysimeters, or can be calculated using measurements of soil water tension or content over time along with knowledge of soil hydraulic properties. In some situations, water can move upward from a shallow water table into the root zone of deep rooted plants.

APPLICATIONS

Irrigation Scheduling

Irrigated agriculture is one of the most intensive forms of agriculture. Having control of the water supply to ensure adequate water for crop growth allows a producer to invest more in other inputs that ensure a high yield and quality of the crop. However, irrigation applications can be expensive and excessive water application can result in loss of nutrients and other production inputs as well as causing environmental problems. Therefore, it is important to apply enough, but not too much, irrigation water. One way to do this is to monitor soil water content during the growing season and apply knowledge of the soil water balance to guide timing and amount of irrigation applications. Some irrigation scheduling models use weather data to simulate the evapotranspiration and maintain a soil water budget to predict changes in the soil water content. Depending on the rate of water use by the crop and the amount of soil water storage capacity, the producer can project the upcoming needs for irrigation applications.

Rainfed Cropping

Rainfed cropping is subject to great risks because of the high variability of rainfall in most agricultural regions. In many regions, water stored in the soil at planting time is an important component of the seasonal water supply. If there is a large amount of water stored at planting time, that stored water provides a buffer against dry periods during the growing season, and the producer might plan for an average or good yield level and invest in inputs to support those yield levels. If the water storage at planting is low, then the risk of crop losses due to growing season drought is high and the producer may decide to reduce or delay investment in some inputs until later in the season when more is known about growing season precipitation and forecasts. Analysis of long-term climatological records using a soil water balance approach can be used to evaluate alternative crops or rotations for a region. In some cases, high soil water levels at the end of the growing season will result in a low faction of off-season precipitation being stored for the next crop with greater losses to percolation (with some possible nutrient leaching) or runoff (with possible greater erosion).

Plant Growth and Natural Resource Modeling

Soil water balance calculations are an integral part of plant growth and hydrologic models. Many of these models have been developed to operate at a daily time step and have been applied to a wide range of analyses. Some examples of such models that are available for downloading from the internet include crop growth, erosion, and hydrology models developed at the Grassland Soil and Water Research Laboratory at Temple, Texas, http://arsserv0.tamu.edu/intro.htm; the soil organic matter model, CENTURY, developed at the Natural Resource Ecology Laboratory at Colorado State University, http://www.nrel.colostate.edu/projects/century5/; water balance, irrigation management, and soils models developed by Dr. J. T. Ritchie and colleagues, http://nowlin.css.msu.edu/; the Decision Support System for Agrotechnology Transfer, DSSAT, which is a series of crop models and associated weather, crop, and soil data bases, http://icasanet.org/dssat/ and a suite of models, ranging from nutrient management and water quality models to an operational tool for whole farm/ranch strategic planning developed by the Great Plains System Research Unit at Fort Collins, Colorado, http://gpsr.ars.usda.gov/products/. These models, and many more, include a soil water balance as an integral part of the system.

CONCLUSION

The soil water balance approach has played an important role in improving our understanding and management of plant, water, and soil resources. The field soil water balance involves accounting for inputs of water to the system, such as precipitation and irrigation, as well as water leaving the system via evapotranspiration, runoff, and drainage below the root zone. The way a field is managed can have a large impact on the magnitude of the components of the water balance, such as runoff and drainage, as well as patterns of evapotranspiration and partitioning of the water loss into soil evaporation and transpiration. In agriculture, increasing the amount of transpiration increases productivity of the system. Soil water balance approaches can be applied to irrigated and rainfed agriculture and are an integral part of all plant growth and natural resource model, so understanding the basic concepts and principles is important for sound water management.

Filtration and Particulate Removal

Lawrence J. Schwankl
Department of Land, Air and Water Resources (LAWR), University of California–Davis, Davis, California, U.S.A.

INTRODUCTION

Filtration of water to remove particulate matter and biological contaminants is critical to the efficient operation of many pressurized irrigation systems. Filtration for sprinkler irrigation systems, where there are large-size water contaminants that can clog the sprinkler nozzles, is usually done with screen or disk filters. Microirrigation systems, with small flow passageways in the drip emitters and microsprinklers, may use screen, disk, or sand media filters to remove small particulates and organic contaminants to prevent clogging. The choice of which filter to use is often based on the water quality.

FILTRATION REQUIREMENTS

The degree of filtration for sprinkler and microirrigation systems is significantly different. Sprinkler irrigation, with its larger nozzle openings can pass all but the larger particulates. Thus, filtration treatment to remove the trash and larger sand particles is adequate. Unless heavy organic contaminant loadings occur, organic materials are passed through the sprinkler system with little clogging hazard. Microirrigation systems, with their small passageways, require more extensive filtration systems. The degree of filtration recommended for specific drip emitters and microsprinklers is available from the manufacturer and should be followed.

The degree of filtration of screen and disk filters is designated by their mesh size. The mesh size is the number of openings per inch of screen. The degree of filtration of sand media filters is determined by the size of the sand media particles with the sand media sizes referenced to equivalent mesh size (Table 1).

Mineral particulates in irrigation water range in size from sands to silts to clays. The equivalent mesh sizes for these mineral particles are given in Table 2. Few microirrigation systems require greater than 200-mesh filtration. Note that small sand particles, silts, and clays will pass through a 200-mesh screen. These very small particles can pass though drip emitters or microsprinklers, or they may settle out in the pipelines or lateral lines requiring flushing to be removed (discussed later).

TYPES OF FILTERS

Suction Screen Filters

Suction screens (Fig. 1)[3,4] are used on centrifugal pump intakes, where there is a significant problem with large particulates and trash in the water as can be the case from surface water sources such as rivers and streams. Used by themselves, they may provide adequate filtration for sprinkler irrigation systems, but not for microirrigation systems. Rather, they may be the first filtration step for microirrigation systems, removing the large particulates which would quickly overwhelm the screen, disk, or media filters also being used.

To be effective, suction screen filters should filter out the contaminants and keep themselves clean. Some suction screen filters continually rotate and use water jets to clean the contaminants off the screen. The water flowing by the intake screen carries the contaminant's downstream.

Centrifugal Sand Separators

Centrifugal sand separators (Fig. 2)[3,5] are well suited to removing larger sand particles which may be present in both surface water sources and in groundwater. They are designed to "swirl" the water passing through them, using centrifugal forces to remove the sand particles. While sand particles may not clog sprinkler systems, they may cause wear to the sprinkler nozzles and should be removed. In sprinkler irrigation systems, centrifugal sand separation may be the only filtration required, particularly when groundwater is used.

Larger sand particles must be removed from microirrigation systems since they will cause clogging. While screen, disk, or sand media filters can all remove sand particles, large volumes of sand may clog these filters quickly. In microirrigation systems, centrifugal sand

Table 1 Sand media size and screen mesh designation

Sand no.	Effective sand size (in.)	Screen mesh designation
8	0.059	70
11	0.031	140
16	0.026	170
20	0.018	230
30	0.011	400

Source: Adapted from Ref.[1].

separators are often used as the first stage filtration method, followed by screen, disk, or sand media filters.

Screen Filters

Two types of screen filters are common—pressurized screen filters (Fig. 3)[6–10] and gravity flow screen filters (Fig. 4).[3,8,10] In a gravity flow screen filter, water is allowed to run over the screen filter, open to the atmosphere, with the filtered water falling through the screen and being collected. The contaminants caught on the screen are either washed off the screen by the water flowing across the steeply inclined screen, or, in another design a slightly inclined screen is continually washed clean by a rotating jet which moves the contaminants into a collection trough. The use of a gravity screen filter requires the irrigation water to be pressurized following filtration.

A pressurized screen filter is plumbed into the irrigation system, and filtration is accomplished as the pressurized water passes through it. Pressurized screen filters are used in sprinkler irrigation to remove larger particles, which may clog the sprinkler nozzle or cause excessive wear. Screen filters are widely used in microirrigation systems, particularly where groundwater is used. Pressurized screen filters may not be appropriate for use with water high in organic matter. The organic contaminants may quickly clog the screen and be difficult to remove. Once the screen is clogged, there may be a significant pressure loss across the screen and

Table 2 Particle size classifications by mesh size

Particle size	Mesh equivalent
Very coarse sand	10–18 mesh
Coarse sand	18–35 mesh
Medium sand	35–60 mesh
Fine sand	60–160 mesh
Very fine sand	160–270 mesh
Silt	270–400 mesh
Clay	Smaller than 400 mesh

Source: Adapted from Ref.[2].

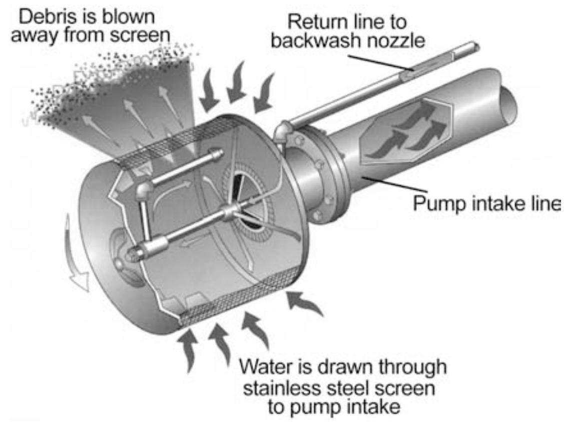

Fig. 1 Suction screen filter on the intake to a pump. (Courtesy of the Claude Laval Corporation.)

the flow rate through the screen may be substantially reduced. Installation of pressurized screen filters with upstream and downstream pressure gauges is recommended so that the manager can easily note when the screen needs cleaning.

Some pressurized screen filters require the screen element to be manually removed for cleaning. Others have a backwash system so that the screens can be cleaned without disassembling the filter. Some of these backwash systems are operated manually while others

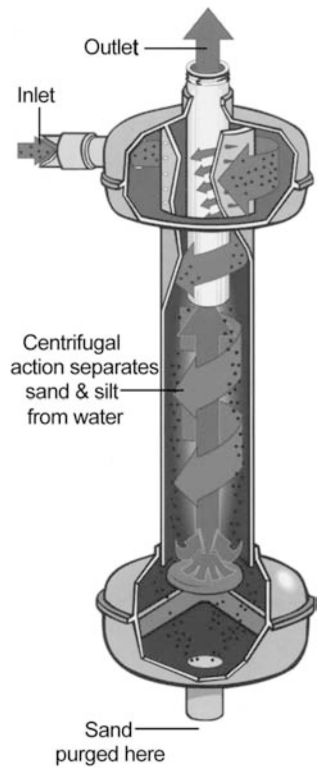

Fig. 2 Centrifugal sand separator. (Courtesy of the Claude Laval Corporation.)

Evapotrans–Giant

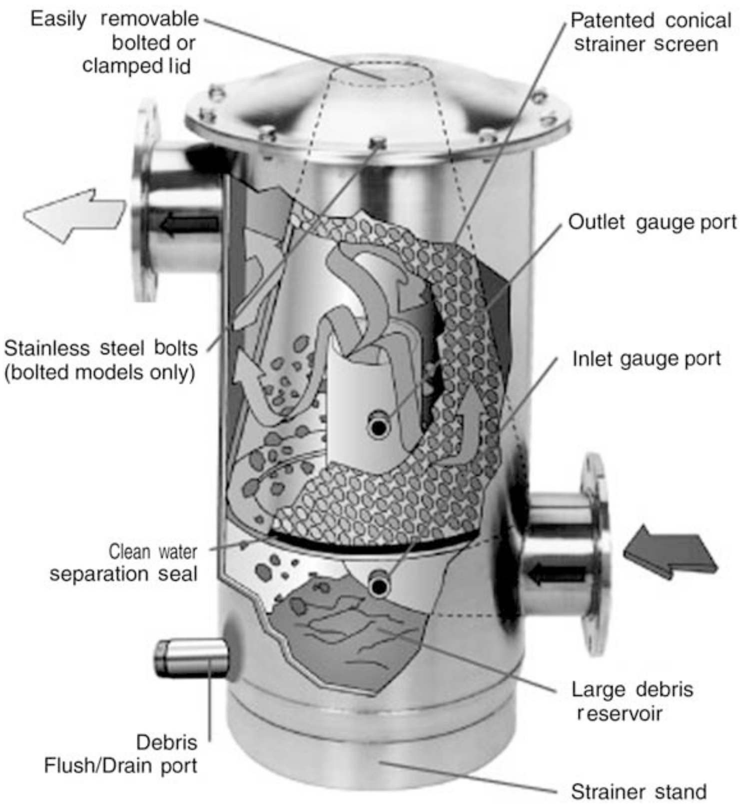

Fig. 3 Pressurized screen filter. (Courtesy of Miller-Leaman, Inc.)

allow the backwash to be done automatically, either on a set time interval and/or on a pressure loss across the screen, sensing system.

The recommended, maximum flow rate through the screen filter will be specified by its manufacturer. Waters high in contaminants will clog the filter more quickly. Automatic backwash filters may be advantageous under these conditions, or an alternative would be a larger filter element (or more filters

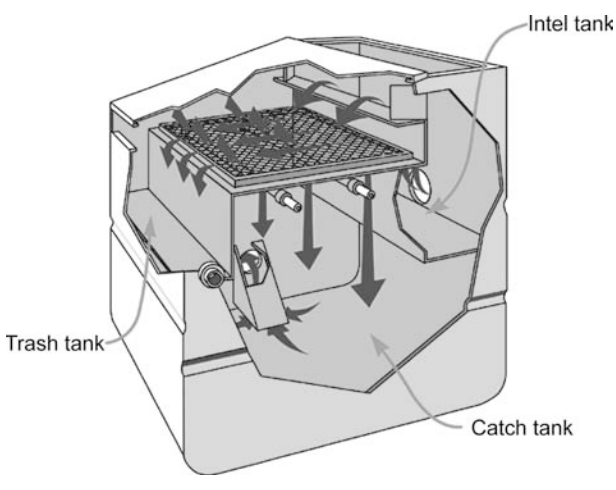

Fig. 4 Gravity flow screen filter. (Courtesy of Fresno Valves and Castings, Inc.)

plumbed in parallel) to increase the interval between manual cleanings.

Disk Filters

Disk filters (Fig. 5)[9–11] consist of a stack of thin disks, tightly held together, each having a series of very small grooves along their sides. Water is filtered as it flows through the grooves. The degree of filtration is measured as mesh size. Disk filters effectively filter particulate matter, and they will remove organic contaminants from the water but the organic contaminants tend to clog the disk filter quickly, necessitating frequent cleaning. Most disk filters must be disassembled and cleaned manually, but there are automatic backwash disk filters available. Where the water is high in organic matter, a disk filter with an automatic backwash system may be advantageous. The water required for backwashing disk filters is less than that for sand media filters.

Sand Media Filters

Sand media filters (Fig. 6)[5,6,9,10,12] are tanks made of epoxy-coated metal or stainless steel. They are filled with a filtering media, often silica sand. The particle size of the media is selected according to the desired

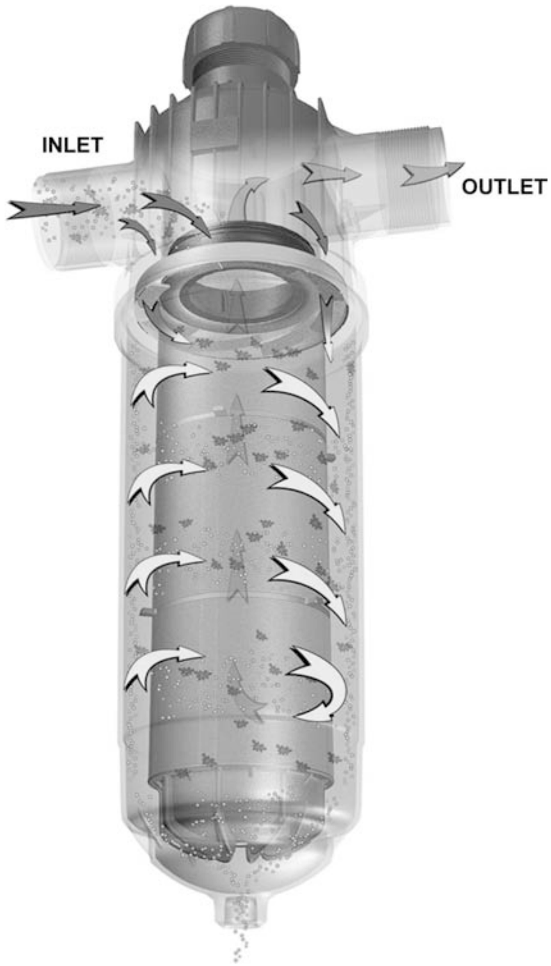

Fig. 5 Disk filter. (Courtesy of Miller-Leaman, Inc.)

degree of filtration (Table 1). Water contaminants are filtered from the water as the water flows down through the media. An under-drain, made from either an epoxy cake or perforated pipe at the bottom of the tank, collects the filtered water and retains the filtering media during filtration.

Sand media filters have a greater filtering capacity than screen or disk filters and can be used to remove both organic contaminants and particulate matter,[13,14] making them well suited for filtering surface waters. At least two media filter tanks, plumbed in parallel, are required at a site so that as one filter is being backwashed, the other filter(s) can continue to provide water for the backwashing and for irrigation. Additional sand media filter tanks can be added if increased filtration capacity is needed. Frequently, a backup screen filter is placed downstream of the sand media filters to catch any sand escaping the media filters, either from routine operation or from failure of the media filter's under-drain system.

The recommended flow rate for sand media filters is $35\,m^3\,hr^{-1}m^{-2}$–$60\,m^3\,hr^{-1}m^{-2}$ ($15\,gal\,min^{-1}\,ft^{-2}$–$25\,gal\,min^{-1}\,ft^{-2}$) of filter surface area. The higher flow rates can be used where the water contains less than 10 ppm of suspended material. If the water has 100 ppm or more of suspended material, the lower filter flow rates should be used to avoid the need for frequent backwashing. Manufacturers of sand media filters provide recommended filter flow rates both for filtration and for backwashing of filters. These recommendations should be followed.

Backwashing of sand media filters can either be done manually or automatically. When backwashing, a three-way valve at the top of the filter changes position, and clean water passes upward from the under-drain system. This suspends and agitates the filter media with contaminants being flushed out of the filter with the backwash water. Pressure gauges should be installed upstream and downstream of the filters and backwashing should be done when the pressure drop across the filters (approximately 70 kPa) indicates that they are dirty. Automatic backwashing systems allow

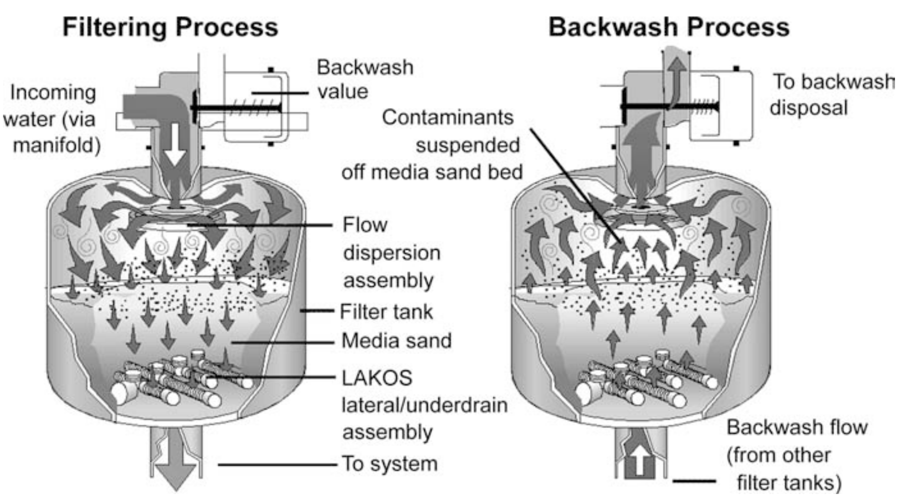

Fig. 6 Sand media filters. (Courtesy of the Claude Laval Corporation.)

the media filters to be cleaned on a desired time interval or when the pressure drop across the filter exceeds a selected value.

Disposal of backwash water can be a problem when using sand media filters. The backwash flow rate is nearly $45\,m^3\,hr^{-1}$ ($200\,gal\,min^{-1}$) for a typical 48-in. (1.2 m) sand media filter, so a substantial volume of backwash water is generated. Some microirrigation system managers are even constrained to disposing of backwash water by using reservoirs or tile drain systems.

FLUSHING

Small sand, silt, and clay particles pass through the filters used in microirrigation systems. These fine particles frequently settle in the pipelines and polyethylene lateral lines of microirrigation systems and, unless they are flushed out, can lead to clogging of drip emitters or microsprinklers.

Appropriately sized flush-out valves should be located at the end of pipelines. These valves can be opened and the particles that have settled in the pipelines flushed out. Following flushing of the pipelines, the ends of the lateral lines should be opened, a few at a time, and allowed to flush clear. In drip irrigation systems designed for row crops, the lateral lines may be manifolded together to allow more convenient flushing. An alternative to manual flushing of lateral lines is to use self-flushing end caps on the lateral lines. These end caps allow a short flush at the beginning and end of the irrigation event.

Floodplain Management

French Wetmore
French & Associates, Ltd., Park Forest, Illinois, U.S.A.

INTRODUCTION

Throughout time, floods have altered the landscape. Flooding is a natural process and floodplains are created and altered by that process. Floodplains have also been altered by human development, with consequences to those who live in them.

During the early settlement of the United States, locations near water provided required access to transportation, a water supply, and water power. These areas had fertile soils, making them prime agricultural lands. In recent decades, development along waterways and shorelines has been spurred by the recreational value of these sites.

The result has been an increasing level of damage and destruction wrought by the natural forces of flooding on human development. Flooding has become the nation's number one natural hazard. It affects more property each year and has accounted for over 70% of the Presidential disaster declarations since 1970.

HISTORICAL APPROACHES

During the 1920s, the insurance industry concluded that flood insurance could not be a profitable venture because the only people who would want flood coverage would be those who lived in floodplains. As they were sure to be flooded, the rates would be too high to attract customers. Unlike other hazards, such as wind and hail, where the risk can be spread, private industry opted out of playing a role in flood protection.

With the great Mississippi River flood of 1927, the federal government became a major player in flooding. As defined by several Flood Control Acts, the role of government agencies was to build massive flood control structures to control the great rivers, protect coastal areas, and prevent flash flooding.

Until the 1960s, such structural flood control projects were seen as the primary way to reduce flood losses. In some areas, they still are. However, starting in the 1960s, people questioned the effectiveness of this single solution. Disaster relief expenses were going up, making all taxpayers pay more to provide relief to those with property in floodplains. Studies during the 1960s concluded that flood losses were increasing, in spite of the number of flood control structures that had been built.

One of the main reasons structural flood control projects failed to reduce flood losses was that people continued to build in floodplains. In response, federal, state, and local agencies began to develop policies and programs with a "non-structural" emphasis, ones that did not prescribe projects to control or redirect the path of floods.

A milestone in this effort was the creation of the National Flood Insurance Program (NFIP) in 1968. The NFIP is based on a mutual agreement between the Federal government [represented by the Federal Emergency Management Agency (FEMA)] and local governments. Federally guaranteed flood insurance is made available in those communities that agree to regulate development in their mapped floodplains.

If the communities do their part in making sure future floodplain development meets certain criteria, FEMA will provide flood insurance for properties in the community. The Federal government is willing to support insurance because, over time, local practices will reduce the exposure to flood damage.

Also during the 1960s and 1970s, interest increased in protecting and restoring the environment, including the natural resources and functions of floodplains. Coordinating flood loss reduction programs with environmental protection and watershed management programs has since become a major goal of federal, state, and local programs. This evolution is shown graphically in Fig. 1. Now, we no longer depend solely on structural projects to control floodwater. Instead of "flood control," we now speak of "floodplain management."

FLOODPLAIN MANAGEMENT

Floodplain management is officially defined by the Federal Government's *Unified National Program for Floodplain Management* as "a decision-making process that aims to achieve the wise use of the nation's floodplains." (see Ref.[1], p. 8) "Wise use" means both reduced flood losses and protection of the natural resources and functions of floodplains. This is accomplished through different tools, including, but not limited to:

- Floodplain mapping.
- Land use regulations.

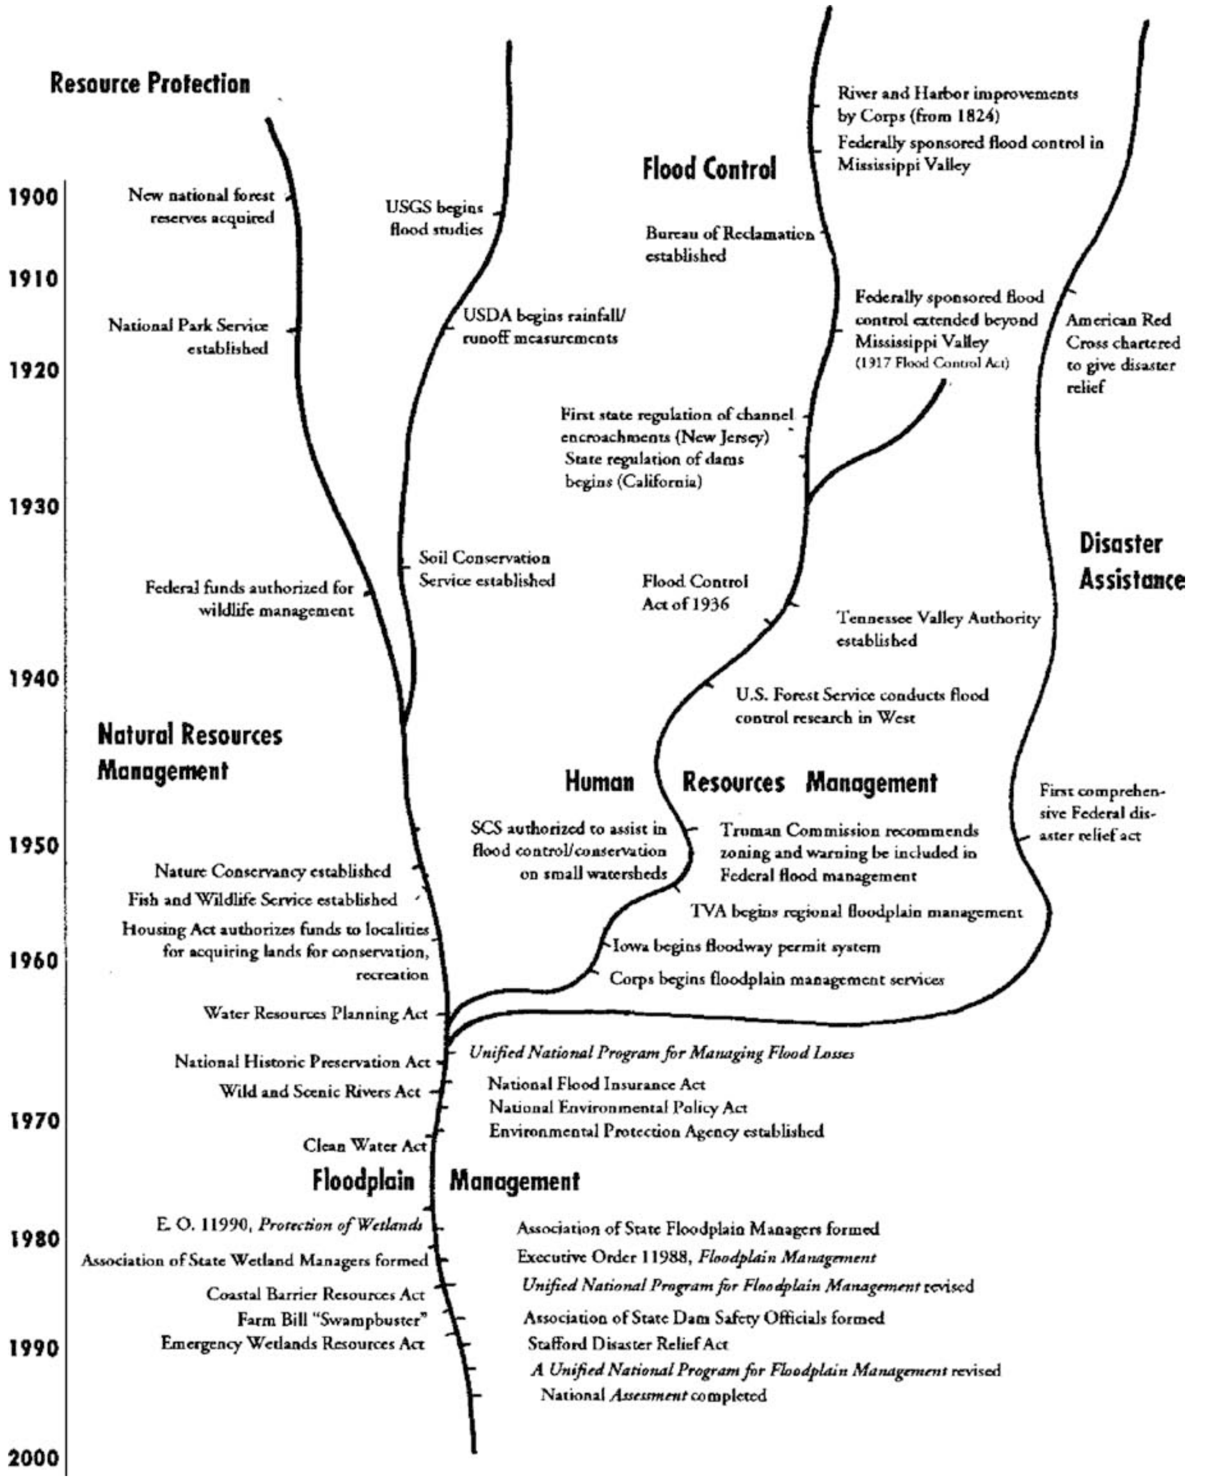

Fig. 1 Evolution of floodplain management in the United States.

- Preservation of floodprone open space.
- Flood control (levees, reservoirs, channel modifications, etc.)
- Acquiring and clearing damaged or damage-prone areas.
- Floodproofing buildings to reduce their susceptibility to damage by floodwaters.
- Flood insurance.
- Water quality best management practices.
- Flood warning and response.

- Wetland protection programs.
- Public information.

There are a variety of Federal, state, and local programs that administer these tools. Private organizations and property owners also have roles.

THE NATIONAL FLOOD INSURANCE PROGRAM

The nation's focal floodplain management program is the NFIP. It has prepared floodplain maps for 22,000 communities. FEMA sets the minimum land use development standards that participating communities must administer within the floodplains designated on their Flood Insurance Rate Maps. These standards are summarized in Fig. 2.

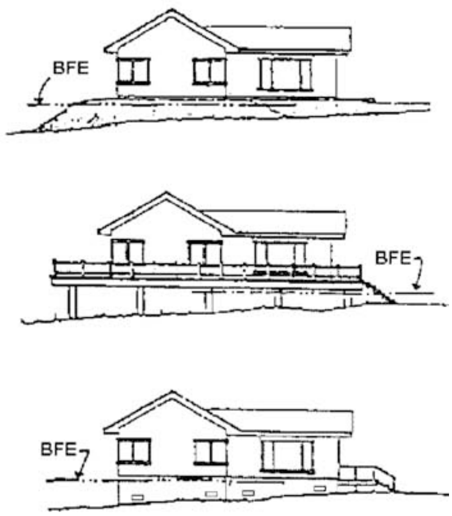
While participation is voluntary, communities that decide not to join or not to enforce those regulations do not receive Federal financial assistance for insurable buildings in their floodplains. Rather than face the loss of Federal aid (including VA home loans, HUD housing help, and disaster assistance), just about every community with a significant flood problem has joined. By 2002, 19,700 cities and counties were participating.

Within participating communities, Federal law requires the purchase of a flood insurance policy as a

The National Flood Insurance Program (NFIP) is administered by the Federal Emergency Management Agency (FEMA). As a condition of making flood insurance available for their residents, communities that participate in the NFIP agree to regulate new construction in the area subject to inundation by the 100-year (base) flood.

There are four major floodplain regulatory requirements. Additional floodplain regulatory requirements may be set by state and local law.

1. All development in the 100-year floodplain must have a permit from the community. The NFIP regulations define "development" as any manmade change to improved or unimproved real estate, including but not limited to buildings or other structures, mining, dredging, filling, grading, paving, excavation or drilling operations or storage of equipment or materials.
2. Development should not be allowed in the floodway. The NFIP regulations define the floodway as the channel of a river or other watercourse and the adjacent land areas that must be reserved in order to discharge the base flood without cumulatively increasing the water surface elevation more than one foot. The floodway is usually the most hazardous area of a riverine floodplain and the most sensitive to development. At a minimum, no development in the floodway may cause an obstruction to flood flows. Generally an engineering study must be performed to determine whether an obstruction will be created.
3. New buildings may be built in the floodplain, but they must be protected from damage by the base flood. In riverine floodplains, the lowest floor of residential buildings must be elevated to or above the base flood elevation (BFE). Nonresidential buildings must be either elevated or floodproofed.
4. Under the NFIP, a "substantially improved" building is treated as a new building. The NFIP regulations define "substantial improvement" as any reconstruction, rehabilitation, addition, or other improvement of a structure, the cost of which equals or exceeds 50 percent of the market value of the structure before the start of construction of the improvement. This requirement also applies to buildings that are substantially damaged.



Communities are encouraged to adopt local ordinances that are more comprehensive or provide more protection than the Federal criteria. This is especially important in areas with older Flood Insurance Rate Maps that may not reflect the current hazard. Such ordinances could include prohibiting certain types of highly damage-prone uses from the floodway or requiring that structures be elevated 1 or more feet above the BFE. The NFIP's Community Rating System provides insurance premium credits to recognize the additional flood protection benefit of higher regulatory standards.

Fig. 2 Minimum National Flood Insurance Program regulatory requirements.

condition of receiving Federal aid, including mortgages and home improvement loans from Federally regulated or insured lenders. This requirement, coupled with personal experiences with flooding, has convinced over four million property owners to buy flood insurance. Unfortunately, it is estimated that only half of the properties in the FEMA mapped floodplains are insured.

OTHER FEDERAL PROGRAMS

FEMA administers other floodplain management programs, including:

- Disaster assistance programs that help flooded communities and property owners recover after a flood.
- Mitigation assistance programs that fund local projects to acquire and clear floodprone properties.
- Research and technical assistance activities in the fields of mapping, planning, mitigation, and floodproofing.
- The National Dam Safety Program which assists state programs that regulate dams (dam failures were a factor in three of the four largest killer floods since 1970).

The U.S. Army Corps of Engineers is the second largest participant in Federal floodplain management programs. While it is best known as the builder of structural flood control projects, it has its own authority to regulate new development in navigable waterways and wetlands. It is also the leader in the technical aspects of floodproofing and river basin planning.

The U.S. Department of Agriculture's Natural Resources Conservation Service has a role in planning and building flood control projects, similar to the Corps,' but limited to smaller watersheds. Through local soil and water conservation districts, NRCS staff can be valuable advisors to local officials reviewing floodplain or watershed development proposals.

Just as rivers traverse many lands, floodplain management pervades many government programs. Other agencies with floodplain management responsibilities include:

- Tennessee Valley Authority (where floodplain management got its start)
- Bureau of Reclamation (water control projects in the west)
- U.S. Geological Survey (river data and mapping)
- Environmental Protection Agency (water quality programs)
- Small Business Administration (disaster assistance for private property owners)
- National Oceanic and Atmospheric Administration (coastal zone policies)
- National Weather Service (the lead in flood warning programs)

OTHER PROGRAMS

State and local agencies are also into a variety of floodplain management activities. Their regulatory programs often exceed the NFIP requirements. Many states set additional minimum standards for mapping, floodplain and wetland regulations and water quality. Some state agencies require their own permits, in addition to local permits, for new construction on waterways, lakes, shorelines, and floodplains.

In addition to being the lead regulators, most flood control projects are built and operated by local governments: cities, towns, counties, and special districts. The trend at the local level is toward special purpose authorities at the county or multicounty level to tackle problems holistically at the watershed level.

Private organizations have become more directly involved, too. Groups like the Nature Conservancy and land trusts work to preserve floodprone areas that have natural benefits. Others, like the National Wildlife Federation and American Rivers, are active on the political scene, reminding government agencies of their responsibilities and working to strengthen or expand their programs.

Over time, the distinction between what is done by what level of government has blurred. There are more and more cooperative and coordinated approaches, especially with increased non-federal cost sharing requirements and regional and river basin organizations. A recent example of this is FEMA's Cooperating Technical Partners program where a state or local government can contribute to the cost of floodplain mapping and have a say on the techniques and standards used to prepare their Flood Insurance Rate Maps.

Another reason for the blurring of the distinction is the increased professionalization of the field. Most people active in floodplain management are members of the Association of State Floodplain Managers. Private practitioners and staff from all levels of government work together on solving common problems, rather than debating authorities or funding. There is also a new program that certifies floodplain managers. In less than 3 years, over 1000 professionals have earned the right to put "CFM" after their names.

PROGRESS

The impact of these efforts can be measured in three ways: threat to life, property damage, and the

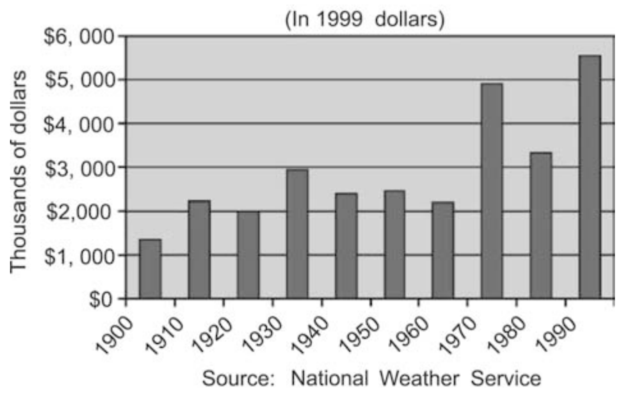


Fig. 3 Dollar damage caused by flooding.

environment. Statistics have shown that the loss of life due to floods decreased during the last century, primarily due to better warning and public information programs.

Progress in the other two fields has not been as encouraging. Property damage is still increasing, although at a slower rate than if there were no NFIP and other floodplain management efforts (Fig. 3). It is harder to see improvements in water quality and habitat protection, but it is generally concluded that while things are better than if there were no programs, we have a long way to go.

AGRICULTURAL CONCERNS

Farmers, ranchers, and other agricultural interests are likely to be involved in floodplain management in several different ways. First, as landowners, their freedom to develop the floodplain portions of their properties may be limited by floodplain management or wetland regulations.

Federal, state, and/or local regulations require permits for the following:

- Regrading in the floodway.
- Construction of a levee.
- Modifications to a channel.
- Filling in a wetland.
- Construction of a new building in the floodplain.

This is the controversial part of floodplain management: activities on one's own property are subject to government restrictions in order to prevent diverting flood flows to other properties or adversely affecting wetlands or habitat or to reduce government disaster response and assistance expenses. While many state laws exempt some agricultural activities from local zoning or building codes, FEMA has ensured that in every state, agricultural buildings will be regulated as a condition for a city or county to participate in the NFIP.

A loan or Federal financial assistance to purchase, improve or repair a building in the floodplain will likely be accompanied by a requirement to purchase a flood insurance policy on that building. However, by taking certain protection measures, such as elevating the building above flood levels, insurance premiums can be reduced.

Federal and state programs are not all about restrictive regulations. Federal disaster assistance, flood insurance and crop insurance can come to one's aid after a flood. After the Great Flood of 1993 in the Mississippi River basin, many farmers accepted Federal funds to set aside wetlands and marginal farmland as a start to allowing Mother Nature to reclaim the natural floodplains.

Hopefully, farmers, ranchers, and other agricultural interests will become involved in floodplain management activities voluntarily and in a broader extent. They can reduce their own exposure to flood losses, help their communities and neighbors protect themselves, and improve their environment. Good places to learn more are the following websites:

- FEMA—www.FEMA.gov
- Association of State Floodplain Managers—www.floods.org

Both have links to other agencies and organizations. The latter has links to state floodplain management associations.

Floods and Flooding

Steven Schultz
Department of Agribusiness and Applied Economics, North Dakota State University, Fargo, North Dakota, U.S.A.

Jay A. Leitch

INTRODUCTION

Floods and flooding—the temporary condition of too much water—continue to plague many parts of the earth. The Yangtze River in China, for example, has flooded more than 1000 times in the past 2000 yr.[1] Floods occur on a large portion of the earth's land mass, and affect a significant percentage of its human inhabitants, since flood plains attract human activity. For example, three floods (1987, 1931, 1938) along the Hwang Ho (Yellow) River in China resulted in nearly 7 million deaths[1] (Table 1). Just what constitutes a flood depends somewhat on the perspective. From a human perspective, a flood is the act of getting one's person or property inundated (wet) (Fig. 1). From a purely physical perspective, a flood is the naturally occurring, temporary inundation of normally dry land. From either perspective, floods are fairly easy to describe.

PHYSICAL ASPECTS OF FLOODS

Physically, a flood occurs when the land surface is temporarily covered with water. Types of flooding include *flash floods* that result from rapid accumulation of water usually due to an intense rain storm (infrequently due to dam failure); *channel flooding* that results when water flows exceed the capacity of a waterway; and *overland or sheet flooding* that can occur when snow melt, storm water, or tidal surges (e.g., a tsunami) inundate large areas of relatively flat land that is normally dry. Simply put, flooding results from intense or prolonged precipitation, from rapid snow melt, from coastal surges, or, rarely, from dam failure.[2]

Floods are commonly characterized by their frequency, or expected frequency, which is based on the record of past events and hydrologic modeling. For example, a flood that has occurred only once in 100 yr of record is a 100-yr flood and has an expected return frequency of every 100 yr. Unfortunately, current and future conditions do not always match past records. In fact, 100-yr floods could occur two or even three years in a row. The expected frequency of floods is also referred to as the recurrence interval. Likewise, a 10-yr flood is relatively common, expected to happen once every ten years, or have a 1 in 10 chance of happening in any one year. At the other extreme, 500-yr floods are rare, low frequency, high volume events. These frequency extremes are in large part related to the physical dimensions of floods, which can be explained by examining watershed maps, river cross-sections, and flood hydrographs.

Watersheds

A watershed (also known as a basin or catchment) is that portion of the earth's surface where runoff terminates or accumulates in a common hydrologic feature, such as a lake or river (Fig. 2). At a localized level, the watershed of a pond or stream includes all the land area that contributes runoff to the pond or stream. On a regional level, the watershed of a river includes all the land area that contributes runoff to the river or its tributaries. Examples of regional watersheds would be the Colorado River basin or the Ohio River basin. Finally, at the largest scale, the continental divide separates large, continental watersheds whose runoff ultimately flows to the oceans surrounding continents. Examples of some of the largest watersheds that drain significant portions of continents include the Amazon, Mississippi, and Nile River basins.

Watershed shape, drainage patterns, and runoff routing help to determine stream flow and flooding within the watershed. Shapes range from circular to elongated; drainage patterns range from dendritic (i.e., tree-like) to ditch;[3] and runoff routing ranges from natural flow to artificial flow and detention basins. A long, narrow watershed would be less likely to experience high peak flooding than a more circular watershed, all other things being equal, largely because water does not enter the main stem of the river at the same time.

Table 1 Examples of severe flooding worldwide

Date	Location	Impacts
1861	Sacramento River (California)	7,000 deaths, 300 villages destroyed, 2 million homeless
1887	Huang Ho (Yellow) River (China)	900,000 deaths
1889	Conemaugh River (Pennsylvania)	2,000 deaths, $10 million property damage
1900	Galveston, Texas	6,000 deaths, 3,000 buildings destroyed
1931	Huang Ho (Yellow) River (China)	3,700,000 deaths
1936–37	Mississippi River	800,000 injured, 500 deaths, $200 million property damage
1955	Atlantic Coast (hurricane Hasel)	$1.6 billion property damage
1960	Bangladesh	6,000 deaths
7/71–6/72	77 flood events in the United States	519 deaths, 141, 151 dwellings destroyed or damaged
1979	Zambezi River (Mozambique)	45 deaths, 250,000 homeless
1979	Morvi (India)	As many as 15,000 deaths
1981	Northern India	1,500 deaths, extensive crop losses
1982	El Salvador, Guatemala	More than 1,300 deaths
1985	Northern Italy	361 deaths
1993	Mississippi River	40 deaths, $10 billion property damage, 42,000 homes destroyed, 20 million acres of farm land disrupted
1997	Red River of the North (U.S.A.)	45,000 people evacuated, downtown Grand Forks burns

Sources: From Refs.[4,6].

Overall topographic relief within a watershed also affects the type of flooding. Relatively flat (i.e., low relief) watersheds may experience more sheetwater flooding, while steeper watersheds might experience more flash flooding. Proximity to oceans or seas is necessary for flooding to occur as a result of tsunamis and tropical storms.

Fig. 1 Urban flooding as a result of runoff.

A number of other factors affect flooding within watersheds including climate and geographic orientation, soil types and land use/cover, and man-made alterations.

Climate and Geographic Orientation

Watersheds at higher latitudes that slope generally toward the Equator flood less frequently during spring snow melt than watersheds that slope toward the earth's poles. The snow pack in high latitude watersheds that slope toward the poles usually melts first in the headwaters, causing ice jams and flooding as it flows downstream and coincides with the timing of local snow melt and runoff. This is the case with the Red River of the North in central North America and many other north-flowing rivers in North America and Asia.

Soil Types and Land Use/Cover

Watersheds consisting of more permeable soils are generally less prone to precipitation-based flooding than

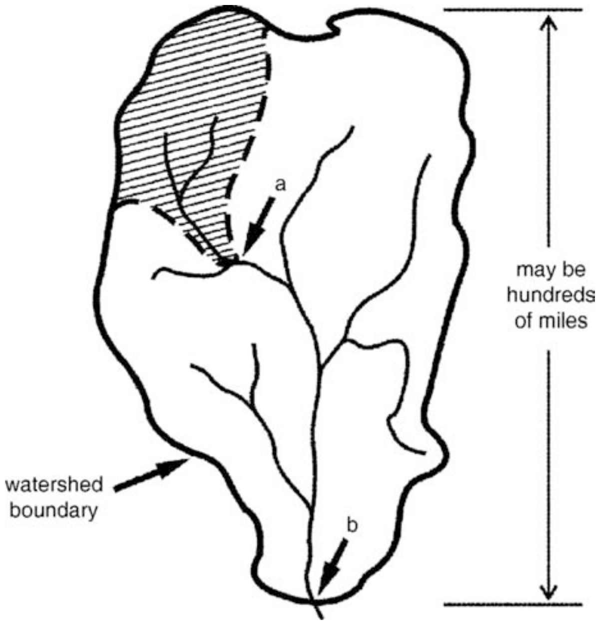

Fig. 2 Generalized watershed with subwatershed (shaded). Points a and b are watershed outlet locations for typical stream flow hydrographs (Fig. 3) and cross-sections (Fig. 4).

those with impervious soils. Watersheds with land uses or land cover that promote infiltration, evapotranspiration, or that simply impede runoff, are less prone to flooding. Conversely, watersheds with impervious soils and/or land uses and cover that accelerate runoff may be more prone to flooding. The role of soils in flooding is far more complicated than this, since soils play a major role in topographic relief, the development of drainage patterns, and water-borne deposition.

Man-Made Alterations

Both the frequency and the severity of floods are affected by man-made changes in land use, such as converting forested land to cultivated crop land. Clearly, urbanization, the process of converting areas that may have good potential for infiltration to impervious surfaces (such as roads, parking lots, or buildings), can increase the likelihood of flooding. Human alterations of drainage, such as channelization and retention basins, impact runoff and stream flows. Finally, human attempts to control floods (e.g., dams and dikes) may change flooding regimes; but this effect is far more pronounced on low volume, high frequency floods than it is on high volume, low frequency floods. In spite of all that humans have done to control flooding, it is widely accepted that there is no way to completely eradicate flooding or flood damages.[4]

Flood Hydrographs

A flood hydrograph is a two-dimensional graph depicting how much water flows by a given point during a certain time period (Fig. 3).[3] A hydrograph could be constructed for any point in a watershed with adequate data.

The vertical axis of a hydrograph depicts the volume of stream flow expressed as cubic feet per second, liters per second, cubic meters per day, or acre feet per day. The vertical axis may also depict the river stage at a certain point, i.e., feet/meters above "flood stage" or another benchmark. Flood stage is when stream flow is sufficient to exceed the normal channel and spill over to the flood way (Fig. 3).

Floods can occur in smaller watersheds with flows of only a few 100 m^3/sec, while the maximum flood

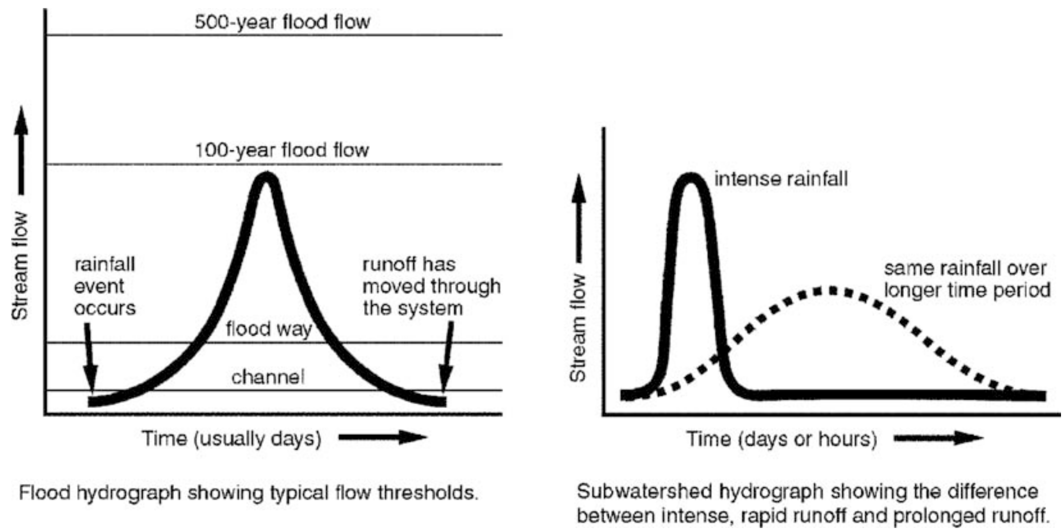

Fig. 3 Generalized stream flow hydrographs.

flow estimated in the Amazon Basin, one of the world's largest watersheds, is 370,000 m^3/sec.[4]

The horizontal axis of a hydrograph depicts time, usually in 24-hr increments or less, since floods generally occur over a period of several days. However, a spring snow melt flood at high latitudes may occur over weeks, while heavy rainfall in a mountainous region may result in a flash flood within hours.

River Cross-Section

A river cross-section is a profile of where the river flows at various river stages. As a river floods, more area is covered, and areas outside the main channel become part of the river. A cross-section depicts the "normal" channel, the flood way, and flood plains for several floods of various recurrence intervals (Fig. 4). The channel is where we would expect the river to be most of the time.

River cross-sections and their flood plain characteristics may be changed by structural measures such as dikes, levees, and dams. For example, there are 29 locks and dams, hundreds of runoff canals, and many miles of levees along the 2400 miles of the Mississippi River; each of which has an impact on downstream cross sections of the river and the associated hydrographs.[2] Prior to these control measures the Mississippi River typically flooded large areas every year.

Flood Way

The flood way is land immediately adjacent to rivers and streams that regularly (often annually) becomes inundated by channel overflow.

Flood Plain

The year-specific flood plain is the extent of land that is inundated with each frequency of flood. For example, the 10-yr flood plain, which we expect to be inundated about every ten years, is narrower than the 100-yr flood plain. The 500-yr flood plain, which represents extreme, highly unlikely events, stretches well beyond the 100-yr flood plain.

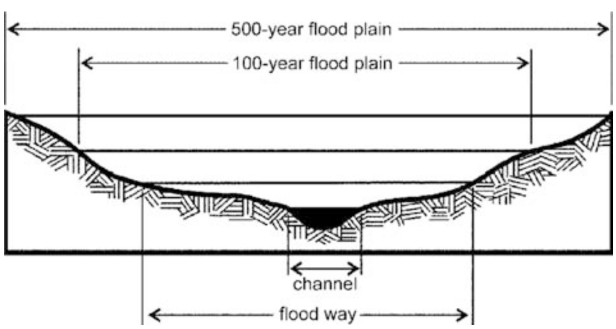

Fig. 4 River valley cross-section showing flood plains.

HUMAN ASPECTS OF FLOODS

Throughout history, floods have caused disruptions in human activity, from inconvenience to property damage to loss of life. In addition to the obvious direct impacts of high water, floods affect human activity by depositing sediments, changing stream channels, uprooting trees and moving boulders, and altering fish and wildlife habitats. Some of these impacts can be positive, as in the case of the Nile before it was dammed, where annual flooding was referred to as the "Gift of the Nile," because of the fertility it added to the soil.[2]

Some of the most severe floods rank high among the world's greatest natural disasters in terms of their impact on humans. For example, the Mississippi River flood of 1993 is considered by many to be the greatest natural disaster in the history of the United States with estimated loses of \$10 billion.[4] Flood flows at Hannibal, Missouri, were measured at 2 ft higher than the 500-yr flood mark. Virtually no region of the United States is immune from potential flooding[5] or, for that matter, in the world.

The greatest loss of human lives due to floods has occurred in China (Table 1). In 1931, 3.7 million people lost their lives when the Huang Ho (Yellow) River in China flooded, where only 44 yr earlier, nearly 1 million people perished in a flood. Flood prevention, flood warning, and flood fighting have greatly reduced the numbers of deaths due to flooding. However, over 500 people lost their lives in 77 separate flood events in the United States in 1971–72, the highest annual number of flood-related casualties in the past four decades.[6] Nearly half of those deaths occurred in one event near Rapid City, South Dakota, on June 9, 1972, when campers were caught in a flash flood. Overall, nearly three-fourths of the flood-related deaths in the United States involve automobiles.

While flood-related fatalities are decreasing on a per capita basis worldwide, flood-related property damage is increasing. The decrease in fatalities is due to better forecasting and warning, while the increase in property damage is largely due to increased density of urban development, much of which is subject to some degree of flooding risk. More than 2000 cities in the United States are located at least partially in a floodplain.[4] Flood damages in the United States have grown from an average of about \$2 billion/year in the first part of the 20th century to about \$4 billion/yr in the last quarter of the 20th century, with nearly \$20 billion in damages estimated for all U.S. floods in 1993.[3]

Over time, people have adapted to flooding with varying degrees of success. The first, and still the simplest, way for humans to avoid flood problems is to minimize their activity in flood plains. However, since some of the world's best land resources, busiest transportation corridors, and most populated built-up areas are adjacent to waterways, abandonment of flood plains is neither likely nor feasible. Other mechanisms for dealing with floods can be categorized as either structural or non-structural.

Structural Measures to Control Flooding

Structural measures for mitigating the adverse impacts of flooding on humans include dams, dikes, levees and flood walls, channel modifications, diversions, flood proofing, and pumping systems. These measures are intended to reduce the severity, frequency, duration, or geographic extent of flooding by physically altering the flow of water in space and time. Dams retain water for later release when it will not contribute to flood flows. Many of the world's largest dams have been built at least in part to control flooding. Dikes, levees, and flood walls protect property by blocking water from reaching structures (e.g., ring dikes) or raising the river bank to keep higher flows within the flood way. Channel modifications are used to straighten, shorten, or deepen channels to accelerate the flow of water. Flood water diversions or bypass channels may be used to route water around urban or built-up areas where it is not feasible to enlarge the existing channel,[3] for example the Red River flood water bypass around the city of Winnipeg, Manitoba. Flood proofing may involve waterproofing, de-watering, or elevating structures within a flood plain. Pumping systems may be used to remove excess water from low lying areas or from the "wrong side" of dikes and levees when water overtops them or excess runoff occurs.

The success, in physical or economic terms, of structural measures to control flooding has been mixed. Economic effectiveness of structural measures to control floods is most commonly assessed using benefit-cost analysis.[7] Criticisms of economic efficiency analysis include a failure to include all the costs or all the benefits, insufficient time-series data for predicting flood frequencies and severities, and not adequately accounting for the human pain, suffering, and anxiety involved with all types of floods. Nonetheless, benefit-cost analysis is a helpful tool to identify and quantify effects and to systematically evaluate a project's feasibility.

Fig. 5 Flooding.

Non-structural Measures to Control Flooding

Non-structural flood control measures include mechanisms to modify the severity of flooding through runoff retarding land stewardship practices, enhanced flood prediction and warning systems, disaster preparedness, and flood plain awareness and zoning. The human impact of flooding can be mitigated through flood insurance, tax adjustments, flood emergency measures, and post flood recovery assistance.[4]

Flood Fighting

Once a flood is imminent or occurring, various measures are taken to minimize the negative impacts. Flood fighting in larger events is usually led by government or domestic and international NGO relief agencies. Evacuation, rescue, and last minute measures to protect life and property are carried out under emergency conditions. The U.S. Federal Emergency Management Agency (FEMA) and the U.S. Army Corps of Engineers are the principal players in organized flood fighting efforts in the United States, working closely with state and substate government units and NGOs.

Flood Recovery

Disaster relief agencies-public, private, local or international-routinely provide assistance following major flood events by helping to get individuals, businesses, and infrastructure back to normal. However, the time immediately after a major flood is the best time to begin to prepare for the next major flood by providing incentives to discourage rebuilding or relocating in flood prone areas. In recent years, aggressive government buyout of flood prone structures usually followed major flood events in the United States.

CONCLUSIONS

The temporary inundation of normally dry land-flooding-is a natural phenomena that occurs worldwide in spite of ongoing efforts to control it. Floods of all sizes and types can be described in physical terms using flood hydrographs and other fairly basic tools. Flood characteristics are a function of watershed shape, weather and climate, land use and land cover, and man-made alterations.

The human dimensions of flooding—primarily preparation for floods, flood fighting, and flood recovery—have more qualitative aspects than the physical dimensions, which are more quantitative. Floods will never be completely controlled, especially the largest ones. However, the more that is known about floods, climate, and human behavior related to flooding (Fig. 5), the better prepared humans will be to minimize the damages caused by flooding.

Flouride

Judy A. Rogers
University of Arkansas, Fayetteville, Arkansas, U.S.A.

Evapotrans–Giant

INTRODUCTION

Fluoride is an ion of the element, fluorine and is found dissolved in natural waters, commonly in concentrations less than $1.0\,\mathrm{mg\,L^{-1}}$, and seldom outside the range from about $0.01\,\mathrm{mg\,L^{-1}}$ to $10.0\,\mathrm{mg\,L^{-1}}$. Fluoride is incorporated by humans into bone and tooth structure; public health attempts to add low concentrations (less than $1\,\mathrm{mg\,L^{-1}}$) of dissolved fluoride into drinking water to strengthen teeth and minimize cavities (dental caries) has been characterized by rancor and controversy. At fluoride concentrations of $2\text{–}4\,\mathrm{mg\,L^{-1}}$, mottling and otherwise aesthetically unappealing tooth discoloration may occur; at greater concentrations, fluoride poisoning, or fluorosis, can cause structural damage to teeth and bone.

SOURCES OF FLUORIDE IN WATER

The major source of fluoride in water is dissolution of minerals, including amphiboles, fluorite, apatite, and mica. Rocks rich in alkali metals, obsidian, volcanic condensates, and volcanic ash are generally higher in fluoride content than most other igneous rocks. Sources ascribe concentrations from $2\,\mathrm{mg\,L^{-1}}$ to $3\,\mathrm{mg\,L^{-1}}$ fluoride in ground water from coastal plain sediments in South Carolina to the dissolution of fluorapatite in fossil sharks' teeth in the aquifer material.

Geochemically, fluoride ions have the same charge and nearly the same radius as hydroxide ions, thereby facilitating the replacement of each other in mineral structures.

The form of fluoride that is most commonly added in water-treatment applications is hydrofluorosilicic acid (HSD), also referred to as fluorosilicic acid. In this aqueous form, the compound is a transparent, water-white to straw-yellow solution. At 60°F, a 25% solution of HSD typically possesses a specific gravity of 1.224 and weighs $10.2\,\mathrm{lb\,gal^{-1}}$.

HISTORY

Dr. H. Trendley Dean identified the beneficial dental health effects of adjusting the level of fluoride in drinking water in 1931. While researching the cause of tooth enamel mottling, Dean "discovered" that in those individuals exhibiting signs of mottling there tended to be a higher than normal background level of fluoride in their drinking water. Consequently, Dean termed this condition "fluorosis." Comparing the prevalence of fluorosis and the incidence of dental caries (cavities), Dean discovered a strong inverse relationship. The greater the level of fluoride in a community's water supply, the lower the incidence of dental caries in the children living there. Realizing the health benefits of fluoride, many public water agencies in the United States have included it as part of their water treatment through a process known as fluoridation.

However, fluoridation has not been accomplished without its fair share of controversy over the years. Since its adoption as a public health measure, fluoridation of U.S. water supplies has met opposition from various groups. As is the case in many controversies, fact and fiction sometimes becomes blurred. For example, since the "Red Scare" associated with the fear of communism in the 1950s and 1960s, there have been groups who have suggested that fluoridation of public water systems is a means of "mass medication." Conspiracy theorists have cited the fact that fluoride was an essential element found in Zyklon B, the infamous "gassing" agent used by the Nazis as a part of their horrific "Final Solution" measure in the Death Camps. While it is true the Zyklon B did contain a derivative of fluoride, there is no scientific evidence to substantiate the claim that HSD can affect any level of "mind control."

Today's opponents of public water fluoridation have also cited the case of unsolicited mass medication. However, mind control is rarely mentioned, especially when highly trained and educated scientists present the arguments. In June 2000, the National Treasury Employees Union, Chapter 280, voiced their opposition to the fluoridation of U.S. public drinking water supplies. This group asserted that the long-term effects of fluoride exposure needed to be further investigated in order to determine whether or not the possibility of toxicity is of issue.

Relying on data gathered over the last half of the 20th Century, the Center for Disease Control and Prevention (CDC) in Atlanta, Georgia has documented the overall decline in decayed, missing, and filled teeth in children who live in communities that fluoridate their drinking water supplies. During the first half of the 20th Century, American children were plagued by tooth loss due to dental caries. As Dental practices at that time were not as sophisticated as today, many people were beset with extensive tooth loss. Indeed, many young men were rejected for military service during both World Wars because they failed to meet the minimum standard of having six opposing teeth, a problem that is largely unheard of today. Leading dental organizations have attributed the decline in tooth loss due to caries to the fluoridation of public drinking water supplies. According to the latest figures released by the CDC, more than 144 million citizens in greater than 10,000 communities in the United States have access to fluoridated drinking water supplies.

As is the case in most chemicals used in the production of public drinking water, the Environmental Protection Agency (EPA) has assessed an optimal range for fluoride. This range has been set between 0.7 and 1.2 million parts per million (ppm) or milligrams per liter ($mg\,L^{-1}$). A level of 4 ppm of fluoride in public drinking water sources has been set as the Maximum Contaminant Level by the EPA. In an effort to minimize the possibility of any undesirable effects, the EPA has also established a Secondary Maximum Contaminant Level (SMCL) of 2 ppm. It should be noted that while this SMCL is a non-enforceable limit, suppliers of public drinking water are encouraged to notify the public should that level be exceeded. This is due to the fact that children are more susceptible to the negative effects of any chemical, including fluoride.

In those areas where higher levels of fluoride occur naturally, community water systems are not required to attempt to reduce those levels to what would be considered therapeutic. This is of particular importance in water consumption by infants, toddlers, and small children. Due to their smaller body mass, these individuals are more susceptible to any possible negative effects of fluoridation. The most common negative effect of higher levels of fluoride in drinking water is that of tooth mottling. Only in extremely rare cases have any cases of skeletal fluorosis been seen or reported. Therefore, in those communities where there is a naturally higher level of fluoride in the water, parents are encouraged to substitute bottled drinking water for tap water for infants and children less than ten years of age.

Flow Measurement: History

James F. Ruff
Engineering Research Center, Colorado State University, Fort Collins, Colorado, U.S.A.

INTRODUCTION

Hydraulic structures existed before recorded history. Archeologists have found irrigation systems in Mesopotamia and check and diversion dams on the Arabian Peninsula dating to about 5800 BC. The first water level records on the Nile River appeared about 3050 BC. The Romans, even though they did not fully comprehend hydraulic principles relating to discharge, devised a method based on pipe areas in order to charge for water supplied to baths and private residences. Hero, a Greek of the first century AD, was the first to express the basis for flow measurement as we know it today. This important finding went unnoticed, however, for about 1500 yr until Leonardo da Vinci extended the relationship to the continuity equation, but even da Vinci's work went unknown until his manuscripts were found in 1690. The German engineer, Reinhard Woltman, developed the spoke-vane current meter in 1790, a breakthrough for measuring velocities in rivers and canals. During the 18th and 19th centuries development and installation of weirs and flumes made flow measurements possible on irrigation canals, and gaging stations were constructed on many rivers to provide records of flows. New technology has provided various water measurement techniques, and stream flow data now can be accessed at over 4200 gaging stations in the United States.

ANCIENT HYDRAULIC STRUCTURES

Hydraulic structures such as diversion dams, irrigation canals, and ditches were conceived and built when humans began farming on arid lands and needed supplemental water to nourish their plants. They used crude implements or sticks to dig ditches, the intake being just a cut in a stream bank. As a stream level dropped and rose over the yearly cycle, stones probably were placed in the stream as a dike or dam to raise the water level. Construction method was trial and error. Early humans developed some intuitive understanding of construction techniques, and of water quantity and application rates, which was passed on generation to generation. This is evident from archaeological studies of Mesopotamian irrigation systems dating back to about 5800 BC.[1,2] On the southern tip of the Arabian peninsula[3] at about this same time, check dams were constructed in Wadi Shumlya to divert some of the river flow into canals, and these structures represent some of the oldest known water management structures.

Early water management also developed in Egypt. Water for the Nile River depends on runoff from the highlands of east central Africa. The flood reaches Egypt starting about July, peaks about mid September, and recedes until January, providing sufficient water in normal years to produce an ample harvest. Basin irrigation,[4] which evolved as a result of this cycle, is a process of building dikes around agricultural fields starting in January to allow rising floodwaters to flow into diked fields. When a flood reaches its peak and begins to recede, openings in the dike are closed and water remains on the fields from six to eight weeks. Since famines could result from improper water levels, timing of inundation of the fields had to be matched with the water level in the river. Basin irrigation was possible for small groups of farmers near the river, but about 3200 BC a strong unified government headed by King Menes expanded the cultivated area by making numerous larger basins between the river and the desert, thus expanding the scope of water management.

No records exist of any attempt to measure water levels, volumes, or flow in all of these early systems until about 3050 BC.[5,6] By then in Egypt, however, water levels were measured on gages (nilometers) at several sites along the Nile River between Nubia and the Nile delta. Rising water levels were observed at the nilometers, and runners carried the information north from station to station. Nilometers had a two-fold purpose: to predict the area of inundated fields, and, thus, a year's harvest; and to establish water level as a tax basis.

In Egypt, by 2600 BC, dams and embankments were constructed for river training, river diversion for land reclamation, flood protection, and irrigation. Evidence of Egyptian skill in rock-filled dam construction may be seen in the remains of the right abutment of the Al Kufra Dam[4] discovered on Wadi Algarawi near

Helwan about 30 km south of Cairo and constructed between 2700 and 2600 BC.

In 641 AD the Arabs conquered Egypt and ruled until 1250 AD. During this reign they reestablished nilometers between Aswan and Cairo, some on earlier nilometer sites. One nilometer on the southern tip of the Isle of Roda at Cairo is the best known of the Arab nilometers and was built in 715 AD. The Roda nilometer consists of a tower constructed with the foundation below the river and three openings in the walls to convey water from the Nile. A measurement pillar was placed in the center of the tower and is shown in Fig. 1. Maximum and minimum Nile water levels were recorded at the Roda nilometer for over 1000 yr until 1890.[7] No hydrologic records on other rivers are comparable. Many present day gaging station stilling wells, consisting of cased well or sump on the riverbank attached to the river with pipes and containing a permanently fixed staff gage to read the water level, are very similar to the Roda nilometer.

HYDRAULIC CONCEPTS RELATED TO FLOW MEASUREMENTS

The Romans devised an early method of flow measurement to be able to charge baths and private homes at a flat rate for a regulated water discharge. The flow from a standardized distributing pipe made of lead originally was taken as the discharge.[8,9] The Romans measured a cross-sectional area of such a pipe and referred to it as a *quinaria*. The quinaria was not a measure of volume but was the capacity of a lead pipe five-fourth digits in diameter flowing constantly under pressure. They believed that the sum of all pipe areas supplied from an aqueduct should equal the cross sectional area of the supply canal. The Romans compared streams of water merely by their cross sectional areas and did not comprehend that velocity of a stream had any part in the quantity of water supplied. It appears the Romans did not fully comprehend hydraulic principles relating discharge, area, velocity, and time, even though they made great advances in distributing water.

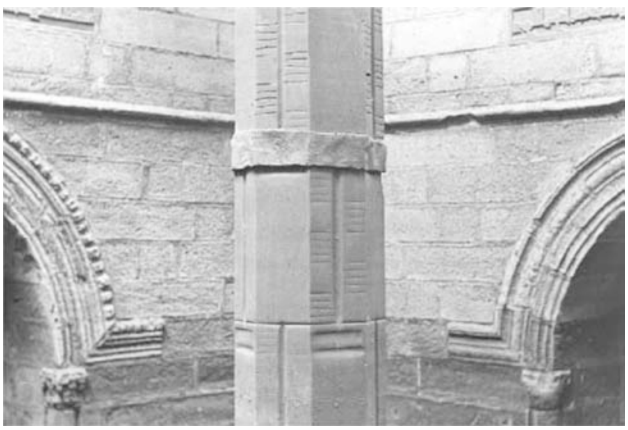

Fig. 1 Roda nilometer on the Nile River at Cairo. (From a lantern slide of T. H. McAllister, Manufacturing Optician, New York, c1900.)

Hero of Alexandria,[7,8,10,11] a Greek, lived sometime in the first or second century AD and was the first to express correctly the relationship for flow by using the time element along with cross-sectional area, velocity, and volume. His description of how to determine the quantity of water a spring can deliver, taken from his book *Dioptra*, became the basis for flow measurement as we know it today.

This important finding was ignored or went unnoticed for about 1500 yr until Leonardo da Vinci (1452–1519) and Castelli (c1577–1644) rediscovered the relationship and extended it to the continuity equation. Leonardo's treatment of hydraulics was almost completely unknown until after 1690, however, when his manuscript on hydraulics was found in a trunk in Rome.

Rouse[10] in *History of Hydraulics* describes many engineers and scientists in the hydraulics field who contributed to an understanding of flow and the need for measurement of discharge and velocity. Robert Hooke (1635–1703) presented a paper on feathering of windmill blades to the Royal Society of Britain and suggested that a similar machine could be used in water. The Italian Giovanni Poleni in 1717 analyzed flow through a rectangular opening extending to a free surface as a series of horizontal strips with the velocity of each assumed proportional to the square root of the distance of the strip from the original free surface. Later the same approach was used to derive the head-discharge relationship for sharp-crested weirs. The basic weir equation given below is often named after Poleni.

$$Q = (2/3)Cb(2g)^{1/2}h^{3/2}$$

In the weir equation, Q is the discharge; C, discharge coefficient; b, width of weir; g, acceleration of gravity; and h, head measured from the crest of the weir to the upstream water surface.

About 1768 the French engineer Antoine Chezy (1718–1798) developed the resistance formula for velocity in a stream, when he was required to determine the cross section and the discharge for a canal to be constructed from the Yvette River to Paris. This formula, widely used in Europe today, relates discharge, Q, to the hydraulic radius, R, the slope of the energy grade line, S, and a dimensional coefficient, C, that depends on the bed roughness or resistance.

The equation is:

$$Q = C(RS)^{1/2}$$

A German engineer, Reinhard Woltman (1757–1837), provided a significant contribution to flow measurement when he published a treatise in 1790 describing the application of the spoke-vane type of current meter with a revolution counter to the measurement of river flow. This was a major breakthrough in quantifying flow in rivers and canals and led to the use of stream velocity measurements to establish the relationship between head and discharge.

Robert Manning (1816–1897), an Irish engineer, presented a paper in 1889 to the Institution of Civil Engineers of Ireland on the resistance equation in the form given below that was in better agreement with available data than any relationship then in general use.

$$V = KR^{2/3}S^{1/2}$$

Although Manning did not realize it, this form of the equation was one of two equations Philippe Gaspard Gauckler (1826–1905), a French engineer, had proposed in 1868. In the above equation, K must have the dimension of length to the one-third power over time to be dimensionally homogeneous. Manning himself proposed use of another dimensionally correct equation in place of the previous equation, but it was not widely accepted. When K is replaced by the term $1/n$, the equation is now commonly referred to as the Manning equation and n is a roughness coefficient found empirically. The coefficient, n, is generally given only as a number without dimensional units.

FLOW MEASUREMENT DEVICES FOR DAMS AND HYDRAULIC STRUCTURES

By the end of the 19th century, many hydraulic engineers continued to work on ways to measure large flows more accurately. At this same time, the Western United States was being settled and developed with a great need for irrigation water. In the arid West water is scarce, and natural river flows vary greatly over the course of a year. Prior to 1900, there were only twenty-four large dams in the United States. By 1998, the United States had 75,000 dams over 2 m high with 6375 categorized as large dams (over 15 m high). The need existed for flow measurement structures ranging from those for small irrigation ditches to those for large rivers, and a variety of measurement devices have been developed. Orifices, venturi meters, and magnetic or sonic flow meters can be installed in smaller outlet pipes to measure small flows. These pressure conduit devices are part of the flow from a dam and will not be discussed here, but the flow measurement theory and operation can be found in many books.[12–14] Weirs, flumes, or gaging stations are frequently found downstream from dams where a measurement of all discharges passing over or through the dam can be made. Weirs and flumes have been installed for flow measurement in open channel situations, because they are relatively easy to construct and to maintain and provide a satisfactory degree of accuracy. To make discharge measurements using weirs and flumes requires a water depth or head relative to the crest at a point in the flow a short distance upstream from the crest.

Weirs and flumes have significant developmental histories. Weirs have been studied since the 18th century and many different shapes of broad and sharp-crested weirs were studied to determine discharge coefficients for many flow conditions. The entrance to most spillways on dams forms a weir. Most flumes evolved from broad-crested weirs. Flumes with different wall and floor constrictions also have received considerable attention as flow measuring structures. Many books describe weirs and flumes and provide flow equations, discharge coefficients, and/or rating tables relating upstream head to discharge.[14–16] Discharge coefficients[17] for uncontrolled and gate-controlled ogee crests and weirs at the entrance to spillways also have been determined so discharge passing through the spillway can be estimated.

A venturi flume[18,19] shown in Fig. 2, developed by Ralph Leroy Parshall (1881–1959) and named for him, became the standard of irrigation measurement in the 1930s, because it had been extensively tested and laboratory-calibrated for sizes of Parshall flumes with throat widths from 3 in. to 8 ft. No other flumes had been tested so extensively. Parshall flumes have been constructed with throat widths from 10 ft to 50 ft, and information on discharge characteristics can be found in the Water Measurement Manual published by the Bureau of Reclamation.[16] Parshall flumes were used extensively by the Bureau of Reclamation in canals supplied by diversion dams.

The long-throated flume or ramp flume[20,22] developed by John A. Replogle of the U.S. Department of Agriculture often provides economy of construction and more flexible capabilities for open-channel flow situations than other flume types. The simplest long-throated flume consists of a ramp constructed from the channel bed up to a horizontal broad-crested weir. Construction of concrete long-throated flumes requires less forming than for other types of flumes. When installed, these flumes can be computer calibrated within ±2%. The Bureau of Reclamation and Agricultural Research Service have developed a new computer program,[20,21] WinFlume,

to assist in retrofitting existing installations and designing new installations. The ramp flume is beginning to replace the Parshall flume for open channel flow measurements.

Gaging stations, as well, have a developmental history. A gaging station is a point in a canal, river, or stream where numerous current meter traverses have been made to develop a relationship between the measured head and the discharge. Fig. 3 shows a rating party in 1902 stream gaging the Cache la Poudre River. For more detailed information on measurement of stage, area, and velocity, and on equipment and gaging stations, refer to Chapter 1 in the National Handbook of Water Data Acquisitions.[14] The gaging station consists of a stilling well on the bank of the river. The water level in the river is measured in the

Fig. 3 Rating party stream-gaging on the Cache la Poudre River near Fort Collins, Colorado, 1902.

well that generally is connected to the water in the river by pipes. The station can be a recording or a non-recording station, and the water level is referenced to a specific datum. At a recording gaging station, a water-stage recorder produces a graphic, punched or printed record of the rise and fall of the water surface in an open channel with respect to time. By comparing the head with the rating curve, a discharge can be established. With the advent of the digital recorders and telemetry systems, stream flow data now can be accessed in real-time at over 4200 stations in the U.S. Geological Survey network.[22]

At non-recording gaging stations, the water level in a stilling well most often is measured by directly reading a staff gage, a rod or rigid board, precisely graduated and accurately located for scalar measurement. This is not too different than when the flood level of the Nile River was measured by the Egyptians five thousand years ago at the nilometer. Some progress has been made, because now we also can relate the water level to a discharge passing that point in the river.

As the history of water transport, diversion, storage, and measurement evolved, one of the most prominent conclusions to be made is that this evolution has occurred largely in places where water quantity is insufficient. From the aridity of Mesopotamia and Egypt, to the aridity of parts of the Roman Empire and the North American West, when water quantity is insufficient, inventors and engineers of their respective cultures undertake to manage water with great care. Need produces motivation which produces inspiration, a process continuing to this day.

Fluvial Islands

Waite R. Osterkamp
Desert Laboratory, National Research Program, Water Resources Discipline (WRD),
U.S. Geological Survey (USGS), Tucson, Arizona, U.S.A.

INTRODUCTION

Islands are familiar landforms surrounded by water. Fluvial islands, those in stream channels, are subject to change by water, especially overtopping floods, and most form and later are eroded by streamflow. The question arises, therefore, as to which processes result in fluvial islands rather than lower channel exposures such as bars. This question is largely answered by defining fluvial islands. Most importantly, fluvial islands are surrounded by channel. In perennial streams, they are higher than mean water level and persist long enough to have permanent vegetation. For intermittent and ephemeral streams, an island extends sufficiently above the channel to maintain well-defined banks, viability during most floods, and vegetation if moisture is adequate. Most fluvial islands are alluvial, formed of sediments deposited to flood-plain level, whereas others are results of incision or of rapid change in stream-channel position (avulsion). Some fluvial islands occur by erosion around a bedrock high, mass movement, glaciation, or eolian deposition. Regardless of the mode of formation, fluvial islands are channel features modified by streamflow. Thus, fluvial islands are unstable and transient over long periods, and although they rarely record long-term change, their shapes, sizes, and sediment may provide excellent information of recent stream processes and habitat.

OCCURRENCE

Alluvial islands, those formed by stream sedimentation, occur where stream networks have variable fluxes of water and sediment, regardless of whether the cause of variation is flood, climate, or vegetation change, or disturbance that alters runoff rates and sediment availability. Because alluvial fluvial islands result from flow dynamics, they are common near stream junctures and where streams meander freely across bottomlands. These optimal sites, down-valley, are areas of montane, piedmont-valley, and coastal flood plain.[1] Alluvial islands also occur where severe flooding has dramatically widened an alluvial channel, especially in reaches of expansion (Fig. 1). Other island varieties, those of bedrock incision, mass movement, glaciation, and eolian deposition, may occur anywhere in a stream system.

As products of sorting processes, alluvial islands are isolated areas of flood plain or terrace. They are common in streams with well-developed flood plain, and therefore are vulnerable to removal by normal stream dynamics. Islands formed by non-alluvial processes may maintain elevations unrelated to adjacent flood plain.

TYPES

Specific processes by which natural alluvial islands occur include avulsion, isolation of bars or similar channel prominences by progressive stream incision or lateral migration, stabilization of bars by fine sediment and vegetation during normal discharges, steady degradation around deposits of coarse or erosion-resistant alluvium thereby leaving a surface elevated between channel branches, rapid incision by channel branches following a flood that leaves a higher central surface, and lee deposition of bed sediment at a channel obstruction (Fig. 2) followed by overbank sedimentation. Fluvial islands forming at bars or similar channel sites may also receive deposits of air-borne sediment or various types of mass movement.[2]

Fluvial islands formed by avulsion generally consist of alluvium remaining following an abrupt change in channel position, whereas islands of gradual channel incision result from the steady evacuation of bed sediment after flood, debris flow, deposition of glacial outwash, or by disturbances causing accelerated upland erosion, bank failure, or an abundance of bed sediment. Closely related are islands formed first as sand or gravel bars by normal sorting of bed sediment followed by periodic overbank (flood) deposition of suspended sediment. These alluvial islands are typical of headwater streams and of larger flood-widened channels or those with large bed load fluxes.

Many fluvial islands, especially those of alluvial origin, assume a teardrop geometry that is described in Eq. (1) for a lemniscate loop,[3] in which R is the distance from the island tailpoint to any point on the perimeter, θ is the angle with the horizontal bisecting

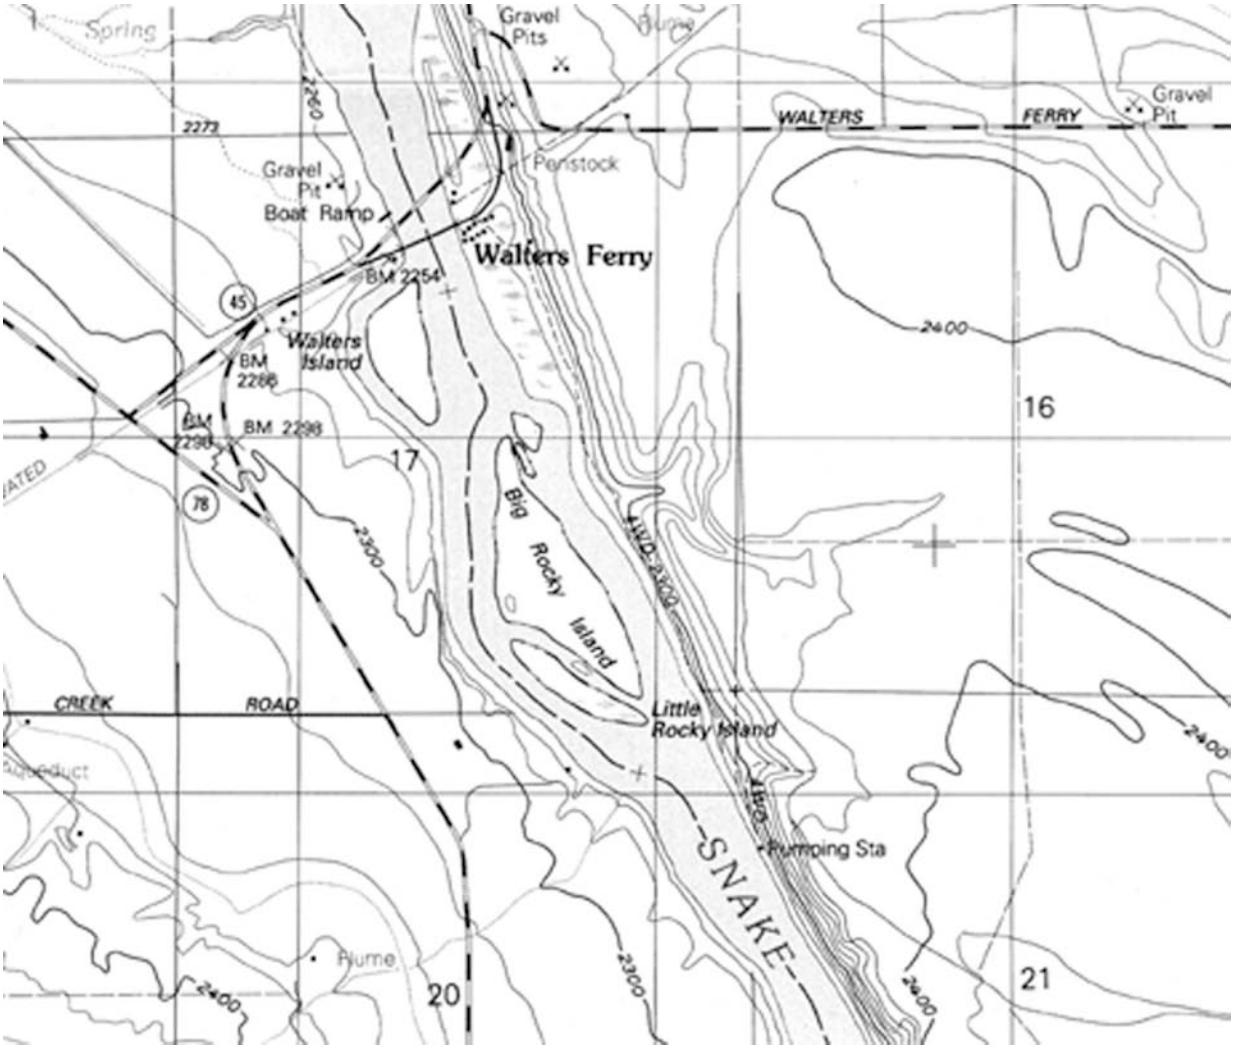

Fig. 1 Part of U.S. Geological Survey Walters Butte, Idaho, 7½′ quadrangle map, showing fluvial islands in an expansion reach of the Snake River, which was widened by the Late-Pleistocene Bonneville Flood. The islands extend 2 m above the flood-plain level owing to overbank and eolian deposition. Part of Big Rocky Island is coarse flood debris 5 m higher than flood-plain level.

Fig. 2 View of a teardrop-shaped island that formed by lee deposition behind an obstruction in Plum Creek, Colorado, following a channel-widening flood (photograph by W.R. Osterkamp).

Evapotrans–Giant

the island, and k is a function of island length and area. Teardrop-shaped islands often form in channels widened by flood or similar disturbances. Lee deposition of sediment behind a channel obstruction causes a shallow zone of reduced stream velocity that quickly accumulates sediment and vegetation. Incremental island growth may result in the coalescing of islands with each other and adjacent flood plain (Fig. 3), thereby effecting channel narrowing.[4]

$$R = L\cos(k\theta) \qquad (1)$$

Catastrophic flooding, mass movement, and pronounced landscape instability may cause extensive channel sedimentation. The deposits become susceptible to rapid incision and island formation through dewatering and accelerated evacuation, sometimes by headward migration of knickpoints during flood recession. This island variety occurs in channels of any size but is most common in small streams subject to short-term change. Channel landforms of this type formed in Plum Creek, near Denver, Colorado, following a major flood in 1965,[4] and persist in expansion reaches of the Snake River widened by the catastrophic Late-Pleistocene Bonneville Flood.[5]

Channel shifting and avulsion are prominent in coastal flood plains where large rivers meander, migrate, and often interact with tributary channels to isolate areas of overbank deposits as islands. Examples are low reaches of the Amazon and Mississippi Rivers. Slow base-level lowering and incision by streams into alluvium, bedrock, or other non-alluvial deposits cause islands whose surfaces may extend above flood-plain level. Examples are in rivers that flow on bedrock in eastern North America or on glacial deposits in Canada.

Atypical fluvial islands result from mass movements such as debris avalanche, rockfall, soil slump, or volcanic eruption. Also unusual are islands that form as typical flood-plain surfaces, in overly widened streams with stable discharges, but are not vulnerable to bank erosion. Where islands of this sort develop in arid or semiarid areas, such as in the Platte River, Nebraska, and the Snake River, Idaho, deposits of wind-entrained sediment may gradually raise the island surface substantially above flood-plain level.

IMPORTANCE

Fluvial islands and related landforms of unregulated streams record the magnitudes, frequencies, and durations of water and sediment fluxes. Where sediment from uplands is meager or channel change and sediment released by flooding have been limited, streams may lack islands. Thus, knowledge of the occurrence and characteristics of fluvial islands provides essential indicators of the biophysical condition of a river system. Where this knowledge is available, the effects of land-use change and streamflow regulation may be predictable.

As widespread landforms, fluvial islands generally indicate and nourish healthy, dynamic riparian-zone biotic communities because the processes that sculpt the islands likewise enhance habitat.[6] Some bottomland plants, insects, and other invertebrates tolerate widely ranging conditions, but others are sensitive to flood disturbance, inundation, gradients of water availability, particle sizes of substrate, and competition. Thus, sensitive plants may need ecologically constrained conditions to attain reproductive maturity,[7,8] and the occurrence of these species on fluvial islands helps document those conditions.

Information from fluvial islands is useful in recognizing interactions between fluvial landforms and habitat. Complex distributions of riparian-zone plants may be understandable if interpreted relative to island

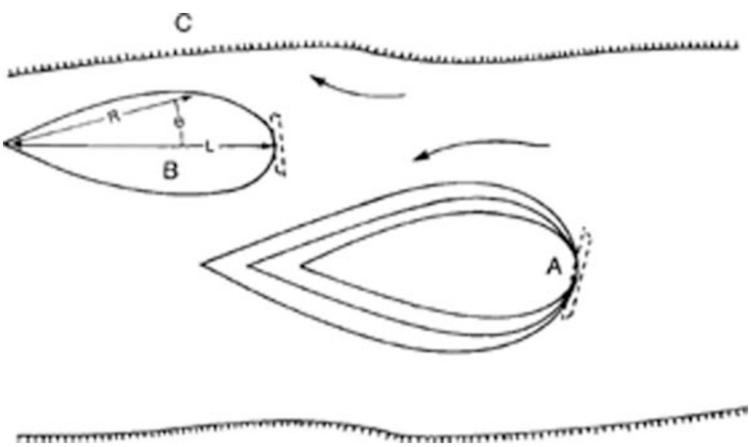

Fig. 3 Schematic of teardrop lee-deposition islands (A, B) that expand incrementally, coalesce with each other and the flood plain (C), and cause channel narrowing; symbols of island B refer to Eq. (1). *Source*: Modified from Ref.[4].

form, and may provide information on flow duration, flood frequency, channel stability, and habitat.[7–9] For example, the highest surface of many alluvial islands in perennial streams is dominated by mesophytes, but if the island top is above flood-plain level owing to channel incision or mass movement, xerophytes may dominate. Island enclosure by perennial streamflow shelters wildlife such as nesting waterfowl. As examples, fluvial islands of the American Great Plains provide stopover sites for migrating cranes and protection for ducks, geese, and numerous mammals.

CONCLUSION

A fluvial island is a landform that rises above and is surrounded by stream passageways and which persists a sufficient time so that permanent vegetation can develop. Most fluvial islands are caused either by high-energy processes such as avulsion, incision following flooding, and deposition of flood or mass-movement sediment, by sorting processes of stored channel sediment, or by accelerated sediment deposition due to drainage-basin disturbance. Fluvial islands are generally unstable landforms during periods of centuries or millennia, and are products of drainage-network dynamics, and thus yield information on bottomland processes, biota, and habitat.

Frozen Soil: Water Movement in

John M. Baker
Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, University of Minnesota, St. Paul, Minnesota, U.S.A.

Evapotrans–Giant

INTRODUCTION

Water movement in freezing and thawing soils can have important physical and physiological consequences. Water movement toward a freezing front can, under the proper circumstances, cause vertical displacement of the soil. This condition, known as frost heave, causes millions of dollars of damage to roads and structures. Water movement in frozen soil is also important during the thawing process; the impaired hydraulic conductivity of frozen soil sometimes causes catastrophic flooding when snow melts rapidly while the soil beneath is still frozen. An understanding of the principles of water movement in frozen soil is helpful in preventing or minimizing the damage associated with these hazards.

THEORY

The hydrodynamics of frozen soils differ from those of unfrozen soils primarily because the hydrostatic relationships are different. The most fundamental difference is that water and heat flow are much more strongly linked in frozen soils. Soil water does not freeze at a single temperature, but rather freezes incrementally over a temperature range. Within this range, water and ice coexist in thermodynamic equilibrium, the proportions of each dependent on temperature, solute content of the water, and retention properties of the medium. As the temperature decreases and more ice is formed, the water potential of the remaining liquid decreases as well. Once ice nucleation has occurred in a freezing soil, the pressure in the liquid phase and the temperature are related through the Clapeyron equation:

$$\frac{p_w - \pi}{\rho_w} - \frac{p_i}{\rho_i} = L_f \frac{T - T_0}{T_0}$$

where p_i and p_w are the gauge pressures within the ice and water phases, ρ_i and ρ_w are the densities of the respective phases, and π is the osmotic pressure of the soil solution. L_f is the latent heat of fusion ($334\,\mathrm{kJ\,kg^{-1}}$), T is the temperature, and T_0 is the temperature at which bulk water freezes, both in K.

Evaluation of this equation reveals that the quantity on the left side has a temperature dependence of approximately $1.2\,\mathrm{kJ\,kg^{-1}\,K^{-1}}$. The osmotic pressure depends on the solute concentration of the soil water, but its temperature dependence is quite small, on the order of π/T. In many cases, and particularly in unsaturated soil, the gauge pressure within the ice phase, p_i, should be negligible. Thus, the change in p_w (more commonly known as matric potential) with respect to T in a freezing soil will be about $1.2\,\mathrm{MPa\,K^{-1}}$. The relationship between the temperature of a frozen soil and its liquid water content is graphically expressed in a freezing characteristic curve, analogous to the moisture characteristic curve that describes water retention in unfrozen soil.[1,2] It has been shown that the moisture characteristic and the freezing characteristic are superimposable for porous media that are completely colloidal, i.e., clay suspensions, where surface tension effects are negligible. For such materials, the liquid water content corresponding to a specific gauge pressure should be the same whether its cause is drying or freezing (ignoring the issue of hysteresis). For media that are devoid of colloids, i.e., pure sands and silts, the rules for similarity are also clear, but different. Here, the ratio of the surface tensions of an air–water interface (σ_{aw}) and an ice–water interface (σ_{iw}) must be taken into account. For materials of this sort, it has been demonstrated that for similar water contents during drying and freezing the pore water pressure will be more negative in the drying soil by a factor of 2.2, the ratio of σ_{aw} to σ_{iw}. This means that at a specific pore water pressure, there will be less liquid water in the frozen soil than in the drying soil. Unfortunately, most soils contain both colloidal and non-colloidal particles, so direct scaling of a freezing characteristic curve from known moisture characteristic data is not possible, and the freezing characteristic must be determined empirically.

REDISTRIBUTION OF WATER DURING FREEZING

The decline in water potential during freezing creates a gradient favoring water flow toward the freezing front. The extent of freezing-induced water movement depends on the balance between heat flow and water flow. If the delivery of latent heat (the product of the water flow rate and the latent heat of fusion) to the freezing front matches the (sensible) heat flow rate away from it, the downward movement of the freezing front will stall as ice accumulates, filling available pore space. Under the proper circumstances ice can continue to form even after all the pore spaces are filled, resulting in the formation of lenses of pure ice and displacement of the soil above, a process known as frost heave.[3] Frost heave can cause tremendous structural damage to buildings and roadways, and can also harm plants and trees.

Since thermodynamic similarity exists between freezing and drying, i.e., both are functions of pore size, it is often assumed that for similar *liquid* water contents, the hydraulic conductivity of a frozen soil and an unfrozen soil will also be similar.[4] Models that employ this assumption sometimes overestimate water movement during freezing, leading some to posit additional, unspecified impedance to unsaturated flow in frozen soil.[5] Conclusive data remain elusive, due primarily to experimental difficulties, but some generalizations are possible. Coarse-textured, sandy soils, when unfrozen, generally have high saturated hydraulic conductivities, but since their pores drain at gauge pressures close to zero their conductivities decrease dramatically with desaturation. Finer textured soils generally have lower saturated hydraulic conductivities, but since the decrease in water content with declining pore water pressure is more gradual, their conductivities decrease more slowly, so that they can often sustain more water movement in the frozen state than sandy soils. For this reason, they are more prone to redistribution and frost heave during freezing.

Despite the substantial decrease in water potential during freezing, there often is minimal movement of water as the freezing front penetrates. Unless there is a ready supply of water close to the plane of freezing, the soil beneath will soon become desiccated, causing a sharp decrease in hydraulic conductivity, to the point that the delivery of latent heat cannot match the rate of sensible heat loss, so the freezing front moves downward. Thus, initially dry soils may freeze with little or no redistribution of moisture. Consistent with the Clapeyron equation, the largest water-filled pores freeze first, at temperatures closest to 0°C, and as the temperature decreases the water in progressively smaller pores freezes. Even in relatively moist soils, the hydraulic conductivity is often insufficient to support anything more than local redistribution of moisture. This is manifested in ice crystal formation in large pores and cracks, without significant change in water distribution profile at a scale detectable by traditional methods of soil moisture measurement.

INFILTRATION

Infiltration of water into frozen soil is a critical issue, due to the sometimes catastrophic flooding that can occur following snowmelt or rainfall on frozen soil. It is widely accepted that freezing dramatically lowers the infiltration capacity of a soil. This is generally, but not always, true, for reasons alluded to earlier. In wet soils, and soils with water tables near the surface, water movement during freezing fills large pores, and in extreme cases creates lenses of pure ice. Just as the largest water-filled pores are the first to freeze, they are also the last to melt, at temperatures closest to 0°C. These are the pores that are the most important in infiltration, so that infiltration rates are much lower if they are ice-filled. Even in well-drained, unsaturated soils, local redistribution during freezing is often sufficient to fill large pores at the soil surface with ice, retarding subsequent infiltration. However, in drier soils and in coarse textured soils, the large pores can remain air-filled and infiltration rates may approach those measured under unfrozen conditions.[6] Some evidence suggests that snowmelt infiltration in agricultural soils can be improved by the creation of large pores through tillage, either before or during freezing.[7,8]

CONCLUSION

Water movement in frozen soils remains rather less understood than the hydrology of unfrozen soil. A primary problem is the inability to separately measure water and ice contents at the spatial scales necessary to resolve water flow processes without inadvertently affecting them. This situation is exacerbated by the fact that water and heat flow are much more strongly coupled in frozen soil than in unfrozen soil. A clearer picture of the subject depends upon the development and application of innovative experimental methods.

Furrow Dikes

Ordie R. Jones
Amarillo, Texas, U.S.A.

R. Louis Baumhardt
U.S. Department of Agriculture (USDA), Bushland, Texas, U.S.A.

INTRODUCTION

Furrow dikes are small earthen dams formed periodically between the ridges of a ridge-furrow tillage system or, alternatively, small basins created in the loosened soil behind a ripper shank or chisel. The furrow diking practice is known by many names, including tied ridges, furrow damming, basin tillage, basin listing, and microbasin tillage.[1] The dikes or basins store potential runoff on the soil surface, allowing the water to infiltrate (Fig. 1) thus, decreasing storm or irrigation runoff and increasing storage and plant available water in the soil. Furrow diking is a soil and water conservation practice that is adaptable to both dryland and irrigated crop production. It is most often used on gently sloping terrain in arid and semiarid areas where crops are grown under water deficit conditions. This practice has become widely adopted due to new herbicide technologies to control weeds, herbicide tolerant crops, and improved mechanical equipment for constructing the dikes.

HISTORY

Furrow diking was first used on the Great Plains, U.S.A., in 1931 by C.T. Peacock, a wheat farmer at Arriba, Colorado.[1] By the late 1930s, commercial diking equipment was available and furrow diking was practiced extensively in the central Great Plains.[2] Research on the effectiveness of furrow diking for conserving soil and water and increasing crop yields was conducted at several central Great Plains sites, including Colby Kansas,[3] Hayes, Kansas,[4] Woodward, Oklahoma,[5] and at other locations. Most research involved the wheat–fallow rotation, and no consistent increases in yield due to diking were shown. Yield responses were more consistent for systems involving summer row crops.

Concurrent with development of furrow diking in the U.S. Great Plains, the practice was adapted for use in the arid and semiarid tropics, mostly in Africa. Farmers in the cotton (*Gossypium hirsutum* L.) growing regions of Tanzania used hand-tied basins in the 1940s to retain runoff. Research on tied ridges was conducted in Tanzania and Nigeria.[6–8] The U.K. National Institute of Agricultural Engineering (NIAE) pioneered the development of mechanized methods of constructing tied ridges in the tropics.[9]

By 1950, the practice of furrow diking on the Great Plains had been abandoned because of the slow operating speed of basin forming equipment, poor weed control, erratic yield responses, and difficulty with seedbed preparation and subsequent tillage.[1] Another factor in the demise of furrow diking was the rapid adoption of stubble-mulch tillage for wheat production in the 1940s and 1950s. Stubble-mulch tillage also leaves the surface flat with crop residues remaining to protect the soil against wind erosion, a prevalent problem in the Great Plains.[2]

A resurgence in furrow diking began in the 1970s and 1980s when diking equipment improved,[10] and herbicides achieved more effective weed control. Favorable responses to furrow diking were obtained with cotton grain sorghum [*Sorghum bicolor* L. (Moench)], and sunflower (*Helianthus annuus* L.).[1,11,12] The furrow diking practice was rapidly adopted by farmers of the Great Plains, and by 1984, an estimated 800,000 ha were being furrow diked, mostly on land cropped to cotton. The practice continues to be widely used with dryland cotton and sorghum, and is used extensively with center pivot irrigation systems to reduce irrigation runoff and to improve the efficiency of irrigation application.

EQUIPMENT

Equipment for constructing dikes or basins ranges from hand hoes and shovels to complex hydraulic motor-tripped mechanical units. Commercially available diking equipment includes the raising shovel, tripping shovel, basin implantation, and ‘‘chain’’ diker types.[13] Currently, the most commonly used equipment is the tripping shovel type, which has one, two, or three paddles that trip when filled with soil,

Fig. 1 Runoff of rain is retained by furrow dikes for continued infiltration (right), but this water is lost from undiked (left) fields.

Fig. 2 The most common type of furrow diker is the tripping paddle type, which is often used concurrently with cultivation of ridge till fields after planting.

thus depositing the soil and forming a small basin and dike between rows (Fig. 2). Most units trip independently due to the pressure of soil accumulating in front of the paddle and work well in loose, mellow, sandy, or loamy soils. Spacing between dikes within the row depends on soil conditions and tractor speed, but a 1–2 m spacing is common.

Furrow diking with the commonly used tripping shovel units is usually performed in conjunction with another tillage operation such as listing, planting, or cultivation in row crop production. Thus, a separate tillage operation is not required, and furrow diking can be performed very economically.[14] Some operators do not construct dikes in traffic furrows, thus facilitating cultivation, spraying, and other cultural operations.

Another type of basin forming equipment, applicable to row cropping with flat tillage, is the Dammer-diker,[a] which uses blades (shovels) mounted on spikes in a wheel-type arrangement to "implant" small reservoirs or basins in loose soil as they rotate behind a ripper or chisel shank. The action of the blades would be similar to inserting a hand shovel into the ground and pivoting the handle forward, thus forming a depression in the soil. This rather intense tillage operation increases infiltration, reduces runoff, and is particularly applicable to crop production on sloping land under sprinkler irrigation.[15]

Another type of basin tillage equipment, applicable to flat tillage for small grain production and to range seeding or renovation, in the "chain" diker has been developed in Australia.[16] This device, called the "Conservation King,"[a] forms basins by using special shaped metal paddles welded onto links of ship anchor chain, lengths of which rotate between bearings spaced about 5 m apart. In field tests of a 5-m wide unit, the authors found that the equipment performed well on a flat, sweep-plowed field, creating numerous small basins with an estimated surface depression storage capacity of 25 mm. On a no-till fallow field, with consolidated surface soil (clay loam), indentations formed with the chain diker were small and ineffective for water storage.

DRYLAND APPLICATIONS

Crop yield responses to furrow diking are highly variable under dryland crop conditions. When rain was not timely for crop use or was insufficient to produce runoff, the benefits of diking were masked.[17] Negative responses usually result from poor weed control or from poor aeration due to ponding of excess water. The need to reduce runoff must be balanced with the need for surface drainage during wet periods, especially on soils that have low intake or water holding capacity.[18] A possible solution to this problem is to dike alternate furrows. This method proved highly successful in increasing the yield of cotton in Africa.[7]

Cotton responds well to the additional water provided by furrow diking since it is a deep-rooted crop usually grown under water deficit conditions on dryland. In Texas, Gerard et al.[12] reported a 82 mm decrease in storm runoff and a cotton lint increase of 116 kg ha^{-1} (32%) due to furrow diking. Clark[19] reported a 36% increase in cotton lint yield, also in Texas. Increased cotton yield in response to furrow diking was also demonstrated in Tanzania and Nigeria.[7,20]

[a]The mention of trade or manufacturer names is made for information only and does not imply an endorsement, recommendation, or exclusion by USDA—Agricultural Research Service. Mention of a pesticide neither constitutes a recommendation for use nor it implies registration under FIFRA as amended.

Evapotrans–Giant

Grain sorghum also responds well to runoff conservation with furrow diking. In tests at Bushland, Texas, furrow diking and land leveling were equally effective in preventing runoff and increasing sorghum yield with an annual cropping system. The maximum yield increase due to furrow diking in this six-year study was 2460 kg ha^{-1} and averaged 760 kg ha^{-1}. The environmental and crop management factors that resulted in large sorghum yield responses to furrow diking were: 1) continual (annual) cropping that did not allow the soil water content of the root zone to be replenished during the non-crop period; 2) large rainfall/runoff events that occurred immediately before or early in the sorghum growing season with dikes in place to capture runoff; and 3) limited growing season precipitation that increased reliance on stored soil water.[1]

IRRIGATED APPLICATIONS

Furrow diking can be used with graded furrow and sprinkler irrigation systems. Operators often dike alternate furrows and irrigate the non-diked furrow, thus 50% of the land area can capture and store storm runoff. Stewart, Musick, and Dusek[21] developed a limited irrigated-dryland (LID) farming system for the conjunctive use of rainfall and irrigation on graded furrows. The LID system uses a limited water supply to irrigate the upper-half of the field fully, which is fully fertilized and seeded for maximum production. The next quarter of the field has reduced inputs and is managed as a tailwater runoff section, with the lower quarter of the field used as a ‘‘sink’’ to capture and utilize both rainfall and irrigation runoff from the wetter sections of the field. Furrow diking was used to capture precipitation on alternate (non-irrigated) furrows in the fully irrigated and tailwater runoff sections, and to capture and prevent rainfall and irrigation runoff from all furrows in the dryland section. The LID system was not widely adopted by farmers because of the different seeding rates and management requirements of the system, but it used both precipitation and a limited amount of irrigation water very effectively for increased sorghum yield.

The primary use of furrow dikes in irrigated agriculture is to improve water application efficiencies of sprinkler and low energy precision application (LEPA) irrigation systems by reducing or eliminating surface runoff. These irrigation systems are linear or center pivots that use drop tubes with low-pressure orifice-controlled emitters. Water is delivered on to the soil surface over a small area as the system moves through the field in a circular fashion. Required furrow dikes prevent LEPA applied irrigation water from moving down the furrow, thus increasing infiltration and distribution uniformity across the field. Irrigation water application efficiencies can exceed 95% with the LEPA system.[22] With center-pivot irrigation, an LEPA system requires the furrow diked rows to run in a circular pattern for all growing crops.

CONCLUSION

Furrow diking is a soil and water conservation practice that is versatile and can be adapted to dryland or irrigated crop production. Reasonably priced equipment is available so that furrow diking can be used on most soils and with many crops. Cotton, sorghum, sunflower, and corn have responded well to furrow diking in field tests. Conditions conducive to positive crop responses to furrow diking on dryland are: 1) annual or intensive cropping; 2) large rainfall/runoff events occurring before or early in the growing season; and 3) limited growing season precipitation. Negative crop responses to furrow diking are usually due to poor weed control or to retention of excessive water on the soil surface, which may cause aeration problems or restrict timely planting and tillage.

Ganges River

M. Monirul Qadar Mirza
Adaptation and Impacts Research Group (AIRG), University of Toronto, Toronto, Ontario, Canada

INTRODUCTION

The 2507 km-long Ganges (or 'Ganga') River originates near Gangotri, south of the main Himalayan divide at a height of 4500 m in the Uttaranchal region of India. It is distributed over China, Nepal, India, and Bangladesh. India has the largest (79%) share of the basin (or 1.1 million km^2) while Bangladesh's share is the smallest (4.6%) (Fig. 1). The river branches into two channels about 4 km below Farakka in the Indian State of West Bengal. The main left arm enters Bangladesh about 18 km below Farakka and joins the Brahmaputra River at Gualundo, while the right arm (known as Bhagirathi–Hooghly) continues to flow south in West Bengal as Bhagirathi.

Precipitation in the basin varies among regions. The average annual precipitation is about 1100 mm. In India, Bangladesh, and Nepal, the average annual precipitation in these areas is 908, 1860, and 1568 mm, respectively. The average temperature in the basin is estimated to be 25.1°C.[1] Mean annual runoff of the river at Farakka (India) and Hardinge Bridge (Bangladesh) is 415×10^3 million cubic meters (mcm) and 352×10^3 mcm, respectively.[2] However, seasonal variation in the flow of the river is very high. The ratio between dry season and monsoon flow is 1 : 6. The mean annual peak discharge of the Ganges at the Hardinge Bridge is 51,184 m^3/s.[3] The average yield of sediment is 520×10^6 tn/year and most of this is transported during the monsoon.[4] About 500 million people are directly or indirectly dependent on the water and ecosystem supported by the river. Today, over 29 cities, 70 towns, and thousands of villages extend along the Ganges' banks.[5] The population of the basin is projected to reach 750 million in 2020 and to almost a billion ten years later.[6]

CULTURAL IMPORTANCE

The Ganges River carries substantial cultural and religious meaning for people belonging to Hindu religion in every region. It is repeatedly invoked in the *Vedas*, the *Puranas*, and the two Indian epics, the *Ramayana* and the *Mahabharata*. The river is unique because it is considered holy by the people of India. Hindus personify it as a goddess, *Ganga Ma*, the Mother of India, because civilization evolved around it and the river supports the livelihoods of millions of people. People of the Hindu faith believe that the water of the Ganges heals them from sin and that the river provides a path to heaven if a body is cremated after death and thrown into the river.[5] Most of the religious places like Varanasi (Benares), Mathura, and Bodhgaya are located on the banks of the river. Every morning, thousands of Hindus make their way to bathe in the Ganges and to meditate on its banks. All of them face the rising sun with folded hands and prayers.

POLLUTION PROBLEM

The Ganges River is heavily polluted with waste from municipal and industrial sources. Municipal sewage constitutes 80% by volume of the total waste dumped into the Ganges, and industries contribute about 15%.[5] The majority of the Ganges' pollution is organic waste—sewage, food, and human and animal remains. Even though industrial pollutants account for a smaller proportion of contamination, their health and environmental effects can be even greater. Many metallurgical, chemical, pharmaceutical, electronic, textile, and paper plants, fertilizer manufacturers, and oil refineries discharge effluent into the river. Hydrochloric acid, polychlorinated biphenyls, mercury, and other heavy metals are major toxic pollutants. At an 8% annual growth rate, nearly 4 billion liters of industrial effluents would enter the river every day by the year 2030.[1] In addition to industrial pollution, runoff from farms in the Ganges basin adds chemical fertilizers and pesticides into the river, which have affected flora and fauna populations. Populations of the Ganges River dolphin, the smooth Indian otter, the gharial crocodile, and various species of turtles are declining.[7] Uses of polluted water often cause waterborne diseases including cholera, hepatitis, typhoid, and dysentery. It is estimated that 80% of all health problems and one-third of deaths in the countries of the Ganges basin result from waterborne diseases. To bring water quality of the Ganges and its tributaries to bathing levels, the government of India launched

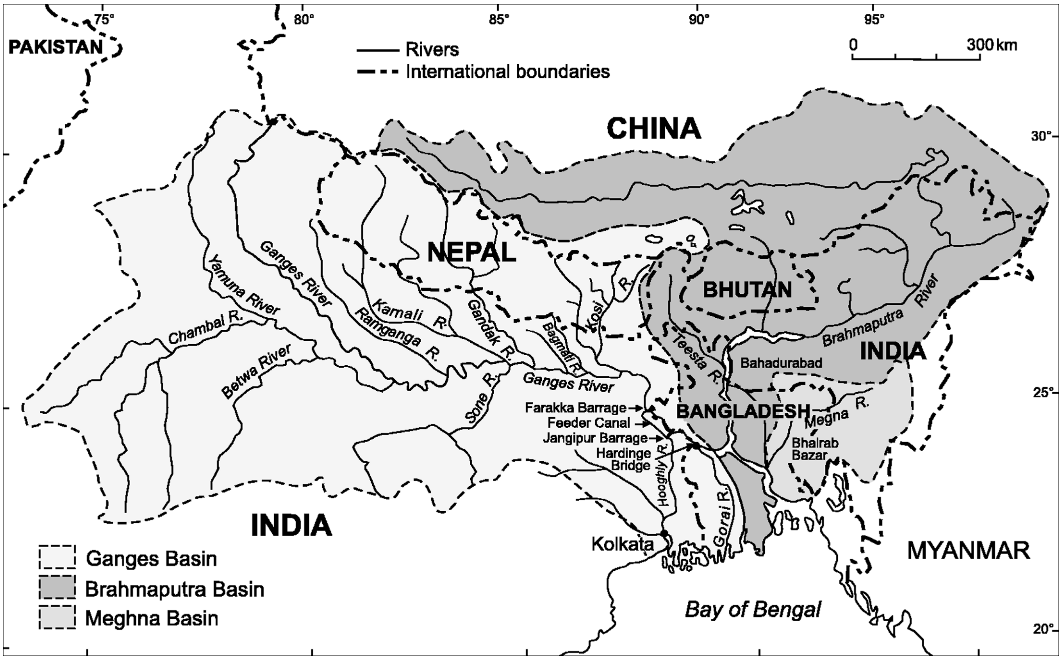

Fig. 1 The Ganges, Brahmaputra, and Meghna basins. *Source*: From University of Waikato (see Ref.[2]).

the Ganga Action Plan in 1985 but could not achieve its set objectives until 2000.[6]

WATER DIVERSION: POLITICAL ASPECT

India and Bangladesh became involved in a sharing dispute over the Ganges water in 1951 when India, the upper riparian country, decided to build a barrage across the river at Farakka. The purpose was to divert $1134\,m^3/s$ water to the Bhagirathi–Hooghly system to increase navigability of the Kolkata Port, which had gradually lost draft due to very high natural siltation that continued for centuries.[8] The Farakka Barrage was commissioned in April 1975. In addition, a substantial amount of the Ganges water is diverted through engineering structures at 34 locations. The total diversion capacity of these structures is $6832\,m^3/s$.[8] Negotiations regarding a permanent water sharing agreement have been continuing for more than five decades.

Bangladesh and India signed a 5-year water sharing agreement in November 1977 and a 30-year Treaty in December 1996. There are no indicators that a permanent solution to this problem will be reached in the near future. In order to resolve the problem, Bangladesh proposed to construct seven large dams in Nepal, which would increase water supply to the Ganges by storing monsoon runoff. India proposed to construct a 320 km-long canal to transfer water from the Brahmaputra River. Both countries rejected each other's proposals on technical grounds. India recently proposed a plan under India's National River Interlinking Plan to transfer water from several tributaries of the Brahmaputra River to the Ganges and to interlink the Ganges with the Mahanadi River in Orissa, eventually transferring water to South India. If implemented, further water diversion from the Ganges River may add a new techno-political dimension to the Ganges water sharing problem.

WATER DIVERSION: ENVIRONMENTAL IMPACTS

The diversion of water causes substantial environmental effects in India and Bangladesh.[8] Bangladesh is particularly affected because of its downstream location and sensitive ecosystems, which are dependent on regular water supplies from the Ganges. The most affected area is the southwest region of Bangladesh where Sundarbans, the largest patch of mangrove forest, is located. The Gorai River is the main distributary of the Ganges and supplies water to the Southwest region and the Sundarbans. This river almost disappears in the dry season. Agriculture, industry, navigation, and domestic and industrial water supplies have been severely affected by decreased water flow in the river. The diversion has substantially affected river morphology and increased erosion. In India, areas upstream of the Farakka Barrage have become increasingly vulnerable to flooding and erosion. However, diversion of water to the Bhagirathi–Hooghly system generated some positive benefits. For example, in the Hooghly River estuary, populations of flora and fauna have thrived.[8]

CLIMATE CHANGE, GLACIER MELT, AND FUTURE FLOW

Dry season water supply to the Ganges River may be threatened due to global climate change and its impact on the Himalayan glaciers. Many of the glaciers are shrinking at alarmingly fast rates compared to glaciers in any other parts of the world.[9] Between 1970 and 2000, the cumulative length of the glaciers in Himalaya decreased by about 18%. If this trend continues, the projected scenario of glacier wasting indicates a loss of 50% by the year 2035 in south Asian glaciers.[9] Global warming and glacier retreat in the Himalayas will have four broad implications. First, in the short-run, in the process of continued retreat, more water will be supplied to the glacier dependent rivers in the Himalayas. This may generate positive effects on dry season water availability. Second, chances of glacier lake outburst flood (GLOF) may increase.[10] Third, in the long-run, dry season flow in the glacier-fed rivers could be greatly reduced, posing serious environmental problems and water-related conflicts. Fourth, in the short run, with the increase in dry season flow, sediment supply in the rivers may increase.

CONCLUSIONS

The Ganges River has a profound importance in the lives of millions of people. Their livelihoods and culture are intertwined with this river. The Ganges is now unable to satisfy growing water demands in the summer months for agriculture, industrial, urban, and rural consumptions. However, there are potential opportunities within the Ganges basin to harness monsoon waters and utilize hydropower, which require concerted efforts under a realistic regional cooperation framework involving Bangladesh, India, and Nepal.

Giant Reed (*Arundo donax*): Effects on Streams and Water Resources

Gretchen C. Coffman
Department of Environmental Health Sciences, University of California–Los Angeles, Los Angeles, California, U.S.A.

Evapotrans–Giant

INTRODUCTION

Invasive, alien plant species have altered natural physical and biological processes of streams and water resources worldwide. Giant reed (*Arundo donax* L.), a large bamboo-like member of the grass family (Poaceae), is one of the greatest invasive species threats to streams in arid and Mediterranean-type climate regions. *A. donax* has successfully invaded rivers in these regions, forming extensive monotypic stands. Infestations of *A. donax* are known to increase risks of flooding, create unnatural fire hazards, compete with indigenous riparian species for scarce water resources, and reduce the value of riparian habitat for most wildlife. Both natural and anthropogenic disturbances along rivers in Mediterranean-type climates are thought to promote the spread of invasive plant species in natural as well as altered riparian ecosystems.[1–5] Although many organizations are actively removing small areas of *A. donax* from streams in California, larger watershed-scale removal is necessary to prevent further invasion and impacts to water resources.

BIOLOGY AND ECOLOGY

A. donax is one of the most successful weedy invaders in the highly dynamic, disturbance-defined rivers and riparian ecosystems of arid and Mediterranean climate regions[6,7] (Fig. 1). *A. donax* is a tall, erect perennial grass species with culms 1–4 cm in diameter, two ranked leaves 5–8 cm at the base tapering to a point, and tough fibrous roots emanating from a large creeping rhizome that penetrate more than 8 ft deep. Although the seeds of this reed-like grass species are mostly sterile outside its native range,[8,9] *A. donax* colonizes readily via vegetative propagation; it is dispersed downstream when small pieces of its culm or rhizome break off during flooding and land on bare, moist substrates.[1,6,7,10,11] Fragments of the rhizome or culm as small as 2 cm^2 sprout under most soil types, depths, and soil moisture conditions.[7,10,11] Growing at an extremely rapid rate (up to 6.25 cm per day under optimal conditions), *A. donax* quickly establishes on exposed or sparsely vegetated soil and grows to more than 8 m in height after only a few months.[12,13] Once established, *A. donax* clumps expand outward by clonal propagation (large rhizomes), crowding and displacing indigenous shrubs, herbs and grasses, and trees, especially under elevated soil moisture, nutrient, and light conditions.[8] In this manner, *A. donax* forms extensive stands, or monocultures, along floodplains and terraces of river and stream systems.

A. donax is thought to be indigenous to freshwaters of Eurasia,[14] extending from Southeast Asia to the Mediterranean Basin, although the precise extent of its native distribution is unclear. Herbivore diversity suggests that it is Mediterranean in origin, but its native range may extend much farther. Several thousand years ago, *A. donax* was thought to have been spread around the Mediterranean Basin for use in erosion control, production of reeds for wind instruments, and construction of roofs, ceilings, fences, and baskets.[15] It has been introduced to most tropical and warm, temperate regions worldwide, including North and South America, Southern Africa and Australia, and thrives below 350 m in elevation.[6,16] In North America, *A. donax* has become especially devastating to riparian habitats in California's Mediterranean climate region, creating significant impacts to natural river functioning and sustainability.[17] In Southern California, *A. donax* was originally planted along irrigation canals for erosion control and used as building materials and windbreaks.[18] Carried by floodwaters, *A. donax* eventually made its way to adjacent streams and rivers and by the 1820s, patches were commonly found along floodplains of many streams, including the Los Angeles River.[18] However, it appears that *A. donax* has only recently succeeded in invading (i.e., replacing native riparian vegetation) natural riparian ecosystems in Southern California.

Because of its clonal growth strategy, ability to colonize rapidly after disturbance, use of available resources, tolerance of stress, and high growth rate, *A. donax* is one of the most successful riparian weedy invaders in arid and Mediterranean-type climates.[12] Following an era of human alterations to river

Fig. 1 *A. donax* infestation along the Santa Clara River in Ventura County, California.

systems in Southern California, it was widely dispersed throughout riparian ecosystems in the floods of 1969, established in terrace and floodplain locations, and is now thriving in riparian ecosystems throughout this region.[19] Factors such as water, nutrients, light, and fire that are abundant in highly modified riparian ecosystems of arid and Mediterranean-climate regions increase the competitive ability of *A. donax*.[19] Although *A. donax* grows primarily in floodplains and terraces of low-gradient river and stream systems,[19,20] it may be found on beaches, around homes, in higher elevations, and next to hot springs where planted. *A. donax* forms huge infestations in open floodplains with high soil moisture and excess nutrients and in areas susceptible to wildfire.[19] *A. donax* successfully invades areas consisting of any soil type and once established can grow well in many soil moisture regimes.[7,19,21] Established stands recover readily after above-ground biomass is removed by wildfire, floods, frost, or mechanical means. In fact, the natural flood and wildfire regime characteristic of Mediterranean-type climates promotes growth and invasion of *A. donax*.[19]

From the time of early human settlement of these areas, humans have dammed, channelized, mined, diverted, and developed along rivers in arid and Mediterranean-type climates.[22,23] These alterations have magnified the susceptibility of streams in these regions to plant invasions by weedy species.[24,25] Human alterations associated with urbanization of watersheds in California in addition to the natural flood and wildfire processes have created ideal conditions for *A. donax* invasion. Increased water, nutrients and light availability, as well as occurrence of fire in riparian ecosystems in Southern California are thought to promote *A. donax* invasion.[6,19,26,27] Ever expanding residential and agricultural development in coastal Southern California has led to increased water availability and nutrient loading of riparian ecosystems. The once vast low-lying areas of riparian forest continue to be removed to make room for agriculture, golf courses, and residential and commercial development. Consequently, open areas along floodplains formed by floods and clearing of terraces for development create an ideal location for *A. donax* to establish and invade riparian ecosystems. Furthermore, fire is more frequent in riparian corridors owing to anthropogenic ignition during the dry summer and fall months when *A. donax* infested areas provide a large amount of dry fuel.[19,28] Because of its higher post-fire growth rate and immediate growth response when compared with natives, fire appears to contribute to the *A. donax* invasion process, especially in riparian terraces.[19,29]

EFFECTS ON STREAMS AND WATER RESOURCES

Infestations of *A. donax* have created serious physical and biological problems along streams in arid and Mediterranean-type climates.[6,13,20,27] Where it grows extensively along floodplains, *A. donax* physically obstructs natural water flow, thereby increasing the risk of flooding. *A. donax* uses more water than native plant species, outcompetes native riparian species, thus reducing the value of riparian habitats for wildlife, and creates unnatural fire hazards.[19]

Flooding

Large infestations of *A. donax* within the active floodplains increase stream roughness during moderate to large flood events, forcing flood stages to higher levels and flooding adjacent property. During very high winter flows in California, *A. donax* is removed from the floodplain, floats downstream and creates debris dams at bridges and culverts.[20] In addition, *A. donax* plant material collects in large piles along beaches after large flood events (Fig. 2). Although originally planted for erosion control, it now acts as an agent of erosion in California streams. The shallow rhizomes of the large, top-heavy plants growing along stream banks are undercut by high flows, causing bank erosion and instability. Economic losses due to effects of *A. donax* invasion include costs associated with repair of flood damage to property and bridges, beach clean up, and bank stabilization repair.

Water Use

Water loss due to high evapotranspiration (ET) of *A. donax* infestations is of increasing concern in arid and Mediterranean-type climates where water resources are scarce and the plant continues to invade. Using transpiration rates of rice (another C_3 species thought to have similar transpiration rates), estimates of *A. donax* water use suggest that it uses three times more water than native riparian species.[30] Other studies using a variety of methods indicate that ET of *A. donax* (1.2–7.5 m/yr) may be much higher than

Fig. 2 *A. donax* debris litters beaches in California after winter storms.

that of native riparian vegetation such as *Salix* spp., *Populus* spp. (1.0–3.3 m/yr), and mixed riparian communities of arid and Mediterreanen-type climates (0.11–1.6 m/yr).[31–34] On the Santa Ana River alone, *A. donax* was estimated to transpire 37,500 acre-feet more water per year than native plants worth approximately 12 million dollars at drinking water costs.[30] However, comprehensive studies are needed that compare water use efficiency of *A. donax* to various native species under different environmental conditions to determine exactly how much water is lost owing to this invasive plant. Excess water used in *A. donax* transpiration could be salvaged for groundwater recharge, drinking water supply, agricultural irrigation, and augmentation of in-stream flow for native vegetation and wildlife.

Wildfire

Wildfires ignited by humans at unnatural and dangerous times of the year burn rapidly through riparian corridors infested with *A. donax* and may help spread fires across watersheds and along riparian corridors.[19] Historically, dense biomass that accumulated over a period of 30–50 yr or more in chaparral communities of California and shrublands in other Mediterranean-type climate regions caused fires to ignite.[35–38] Although fire was once a natural part of shrubland ecosystems in many Mediterranean-type regions, large riparian ecosystems provided natural firebreaks because native vegetation retained foliar water that resisted ignition.[13] Lightning was the primary cause of wildfires, especially during July and August under dry, low humidity conditions, and would commonly burn slowly for months.[36] Currently, however, most wildfires in these areas are anthropogenic in origin, occur much more frequently, and during strong Santa Ana wind conditions starting in September. For example, all of the 14 concurrent fires in October 2003 (739,597 acres burned) resulted from human activities.[35]

Invasion of annual grass species has been linked to altered fire regimes in rangelands, deserts, and wildlands of California and the Western U.S.A.[35,39–43] However, giant reed may be an even bigger problem in riparian ecosystems of altered Southern California fire regimes because of its perennial growth form (the large volume of biomass produced) and rapid recovery after fire (Fig. 3A and B).[19] Several accounts suggest that infestations of giant reed have increased fuel load as well as fire frequency and intensity along riparian corridors.[12,13,28,44] Thus, *A. donax* invasion appears to have created a positive feedback cycle or an invasive plant-fire regime[19] similar to those presented by others.[39,40]

Biodiversity and Wildlife

A. donax has little habitat or food value for wildlife because of its dense growth structure and high content of noxious chemicals.[6,12,13] The federally endangered least Bell's vireo (*Vireo bellii pusillus*) and other riparian birds require structural diversity provided by riparian scrub and mature forest communities for breeding.[6,13,45] When naturally diverse riparian vegetation types are replaced by thick stands of *A. donax*, bird species abundance and other native wildlife have been found to decline.[6,13,46,47] Movement of medium to large mammals is most likely impaired by dense *A. donax* infestations. Herrera and Dudley[46] showed that arthropod abundance and diversity associated with native riparian vegetation was twice that associated with *A. donax* infestations. In addition, fish and aquatic invertebrates may be affected by increased stream temperature owing to lack of shading where *A. donax* has replaced mature riparian forests.[6]

Control Methods, Restoration and Revegetation

Over 25 million dollars have been spent in efforts to remove *A. donax* from riparian ecosystems in the Central Valley and coastal California. Although most attempts have been successful in removing small infestations on riparian terraces, *A. donax* continues to thrive in floodplains. An understanding of the ecological conditions that promote continued growth and invasion of *A. donax* is needed for its effective control. Management strategies for the control and removal of *A. donax* should be based on location and size of the infestation. Priority should be given to removal of *A. donax* from riparian terrace habitats where infested areas are easily accessible and require less maintenance than along floodplains, especially infestations located adjacent to fire-prone shrubland plant communities.[48] Removal of large *A. donax* infestations on riparian terraces with high soil moisture and nutrient availability will be most difficult, but is essential in removing the largest source of propagules to prevent future reinfestation. Active revegetation with native plants after *A. donax* removal is recommended to prevent reinfestation of *A. donax* or other weeds and restore functional riparian ecosystems. Unless *A. donax* is removed from floodplains on a watershed-scale working from the headwaters downstream, *A. donax* is likely to recolonize removal areas after flood events. Watershed removal planning is underway in several large streams in Southern California to eradicate *A. donax* from floodplains, including the Santa Clara and Santa Ana Rivers.

Both mechanical and hand clearing techniques may be used to remove *A. donax*. Mechanical clearing

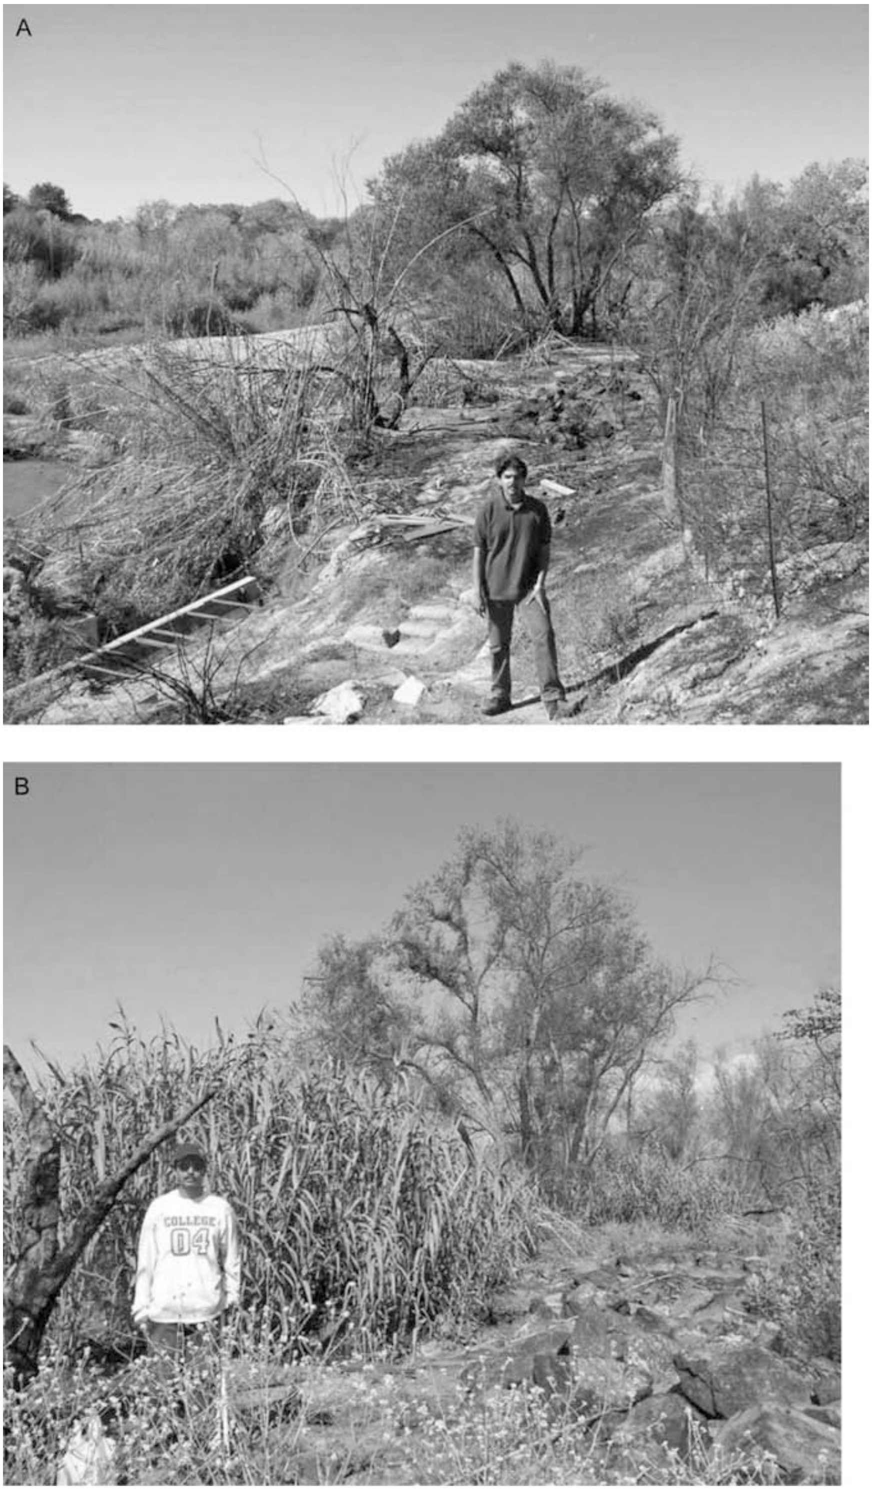

Fig. 3 Three weeks (A) and 6 months (B) after Verdale-Simi Fire, *A. donax* invades riparian terrace along Santa Clara River in Ventura County.

methods include mulching or total excavation of all above-ground and below-ground biomass. Hand clearing methods include either painting of *A. donax* stumps with herbicide after cutting or foliar applications of herbicide (glyphosate).[49] Research on biocontrol agents for *A. donax* is underway on the Santa Clara River, California and in Weslac, Texas.[50]

CONCLUSIONS

One of the biggest threats to streams and water resources in Mediterreanean-type climates is invasion of *A. donax*. Forming large monocultures under ideal resource conditions along streams, *A. donax* increases flooding, promotes the spread of wildfire, outcompetes natives for water resources, and decreases wildlife value of riparian habitat. Although millions of dollars are spent every year to remove *A. donax* in California, many rivers and streams are still heavily infested. Effective removal and control strategies must be based on an ecological understanding of the invasion process and removal areas prioritized based on gaining the greatest ecological benefit for the lowest effort. Control of *Arundo donax* from watersheds in Mediterreanean-type climates is an important initial step in restoration and long-term sustainability of riparian ecosystems.

Global Temperature Change and Terrestrial Ecology

Sherwood B. Idso
U.S. Department of Agriculture (USDA), Tempe, Arizona, U.S.A.

Keith E. Idso
Center for the Study of Carbon Dioxide and Global Change, Tempe, Arizona, U.S.A.

INTRODUCTION

Over the past two centuries, the earth has experienced significant increases in surface air temperature and atmospheric CO_2 concentration, as the planet has recovered from the global chill of the Little Ice Age, and the engines of the Industrial Revolution have burned ever greater quantities of coal, gas, and oil. Many people have imputed a number of negative biological consequences to these environmental changes. However, surveys of the shifting ranges of butterfly and bird species tell a vastly different story, while studies of the net effect of concomitant changes in the air's temperature and CO_2 concentration on plant physiological processes reveal positive consequences as well. In light of these observations, earth's terrestrial ecosystems appear destined to experience increases in stability and biodiversity in areas where they are not adversely affected by the local activities of man.

EARTH IN TRANSITION

Perceived Problems of Global Warming

It has been claimed that earth's temperature throughout the 1990s was higher than it had been at any other time in the past millennium, due largely to an enhancement of the atmosphere's greenhouse effect that is believed by many to have resulted from the historical increase in the air's carbon dioxide (CO_2) concentration.[1] Furthermore, it is repeatedly charged that this change in climate is causing many species of plants to migrate to higher latitudes and altitudes in search of cooler weather. It has also been claimed that the globe is warming at such a rapid rate that it will soon be impossible for much of the world's vegetation to migrate fast enough to avoid extinction; and it is warned that this phenomenon will raise havoc with the planet's ecology and lead to the destruction of much of its biodiversity.[2]

Climatic Complexities

On the surface, these contentions sound plausible. Digging a bit deeper, however, they are found to be highly debatable. With respect to the global warming aspect of the issue, most of the temperature increase the earth has experienced during what we could call the Age of Fossil Fuels did not occur over the past half-century or so, when atmospheric CO_2 concentrations rose most dramatically. Rather, it occurred in the latter part of the nineteenth century and the few decades that followed. Over this time period—which preceded humanity's most prodigious mining and burning of coal, gas, and oil—the earth, on its own, gradually recovered from the global chill of the Little Ice Age, which had not been produced by a decline in atmospheric CO_2 and, therefore, did not require an increase in atmospheric CO_2 to be ameliorated; and these facts suggest that the burning of fossil fuels may not have been the cause of any warming that is evident in the historical record, as has finally been acknowledged by the scientist who set in motion all the concern about the subject several years ago.[3]

There is also a considerable controversy about the precise nature of climate change over the past millennium. In contradiction of the claim that the last decade of the twentieth century was the warmest period of the last thousand years, numerous studies suggest that the Medieval Warm Period of the first part of the millennium—when there was much less CO_2 in the air than there is now—was the warmest,[4] while others contend that the alleged warming of the last two decades of the twentieth century was more virtual than real.[5] Hence, there is by no means any scientific consensus about the climatic significance of the ongoing rise in the air's CO_2 content.

Biological Complexities

Questions about the biological aspects of the issue are even more complex, though not as contentious, as direct experimentation can be employed to investigate most of the concerns that have been raised. One thing we have learned, e.g., is that it is not just the potential increase in air temperature that could influence the future ecology of the planet; there is also the ongoing rise in the air's CO_2 content, which exerts a number of important influences on the world's vegetation, not the least of which is the documented tendency for elevated levels of atmospheric CO_2 to change the many ways in which plants respond to rising temperatures.

THE MITIGATING ROLE OF CO_2

CO_2–Temperature Interactions

The story begins with the well-established fact that CO_2 is a powerful aerial fertilizer, which when added to the air can substantially increase the vegetative productivity of nearly all plants.[6,7] It continues with the fact that numerous studies have demonstrated that the percent increase in growth produced by an increase in the air's CO_2 content typically rises with an increase in air temperature.[8] In addition, at the species-specific upper-limiting air temperature at which plants typically die from thermal stress under current atmospheric CO_2 concentrations, higher CO_2 concentrations have been shown to protect plants and help them stave off thermal death.[9]

Another effect of atmospheric CO_2 enrichment that influences the biosphere's response to global warming is its ability to increase the species-specific temperature at which plants grow best.[10] Indeed, it has been experimentally demonstrated that the typical CO_2-induced increase in plant optimum temperature is as great as, if not greater than, the CO_2-induced global warming typically predicted by the state-of-the-art climate models.[10,11] Hence, an increase in the air's CO_2 concentration—even if it did have a tendency to warm the earth (which is hotly debated)—would not produce an impetus for plants to migrate to places of cooler air temperature, for they would grow equally well, if not better, in a warmer and CO_2-enriched environment. In seven different studies where this phenomenon was experimentally investigated, in fact, it was found that a 300 part-per-million increase in the air's CO_2 concentration resulted in the rate of net photosynthesis at the greater CO_2-induced optimum plant temperature, which was 5.9°C higher, being nearly twice as great as the rate that prevailed at the reduced CO_2 concentration and lower optimum plant temperature.[11]

Effects on Ecosystem Biodiversity

As a consequence of these observations, we would expect that if the air's temperature and CO_2 concentration rose in unison—as happened globally during the demise of the Little Ice Age and as is happening currently in specific regions of the world—there would be no major changes in the locations of the high-temperature boundaries of the geographical ranges of various plants. The locations of their low-temperature boundaries, however, would clearly be able to move towards higher latitudes and altitudes, which would expand the sizes of their ranges. Hence, with the greater overlapping of ranges that would result, ecosystem plant biodiversity would be expected to increase everywhere. Also, if the herbivores that feed on the plants—and the predators that feed on them—moved with the plants, we would expect to see an increase in the local biodiversity of animals as well, which is, in fact, exactly what is happening in various parts of the world.[12]

In a study of more than half a hundred European butterfly species, for example, Parmesan et al.[13] found that most of them moved northward in response to a regional warming of 0.8°C over the past century. However, in almost all of these northward "migrations," only the northern boundaries of the ranges moved. Furthermore, the northward range expansions did not displace other butterfly species residing in the newly acquired territories, for essentially none of the southern boundaries of any species shifted. Hence, because of the consequent increased overlapping of ranges, butterfly biodiversity must have increased in many areas of Europe over the past century in response to the warming and atmospheric CO_2 increase experienced there.

Moving another step up the trophic ladder of the food chain, Thomas and Lennon,[14] in a study of an equally large number of British bird species, found that from 1970 to 1990 the northern boundaries of species residing in the southern part of Britain shifted northward by an average of 19 km, while the southern boundaries of species residing in the northern part of the country shifted not at all. Consequently, there has been a measurable increase in the overlapping of British bird ranges over the latter part of the twentieth century, along with a concomitant increase in ecosystem biodiversity. Also, in a study of all the passerine (perching) bird species of North and South America, Manne, Brooks, and Pimm[15] determined that the fraction of endangered species, i.e., those threatened with extinction, drops off significantly as range size increases, which appears to be the result of simultaneous increases in air temperature and atmospheric CO_2 concentration.

CONCLUSION

In view of these real-world observations, there is a strong likelihood that if the air's CO_2 concentration

Global–Groundwater

continues to rise as it has in the past, and if air temperature also rises, both ecosystem biodiversity and stability will increase, in contradiction of many simplistic predictions. Perhaps that is why Cowling[16] has stated "we should be less concerned about rising CO_2 and rising temperatures and more worried about the possibility that future atmospheric CO_2 will suddenly stop increasing, while global temperatures continue rising.'' Clearly, these are areas of deep societal concern, where more research is needed to help clarify the issues for policymakers who are agonizing over what to do (or not do!) about the ongoing rise in the air's CO_2 content.

Groundwater: Contamination

Charles W. Fetter Jr.
C. W. Fetter, Jr. Associates, Oshkosh, Wisconsin, U.S.A.

INTRODUCTION

Contamination can be defined as the presence of a biological or chemical agent in groundwater in such a concentration that it renders water unfit for a particular use.[1] Agricultural uses of water include domestic drinking water, stock watering, and irrigation. Water that is contaminated for purposes of drinking might be perfectly suitable for use in irrigation.

Contaminants can be from both anthropogenic and natural sources, for example, arsenic. Arsenic found in groundwater in northeastern Wisconsin comes from a naturally occurring mineral, arsenopyrite, present in aquifer. Arsenic has also become a contaminant in groundwater due to use its use in agriculture as a pesticide as well as industrial sites where arsenic was used as a wood preservative.[1] The drinking water standard for arsenic in the United States for many years was $50\,\mu g/L$ (micrograms per liter). However, as of May 2000 the U.S. Environmental Protection Agency was reviewing the standard and it will most likely be lowered, possibly to as low as $10\,\mu g/L$.

TYPES OF CONTAMINANTS

Groundwater contaminants fall into two broad categories, biological and chemical. Biological contaminants include bacteria, viruses, and protozoa. Chemical contaminants can be classified as organic or inorganic. Organic chemicals are based on a framework of carbon and hydrogen atoms. Inorganic compounds include all other chemicals, although some will have carbon present in an inorganic form, such as carbonate (CO_3^{2-}) and bicarbonate (HCO_3^-).

Organic chemicals include fuels and most pesticides. Fuels such as gasoline and diesel are composed of hundreds of different organic chemicals in varying proportions depending upon the source, and their composition will vary depending upon the season. Fuels do not mix with groundwater, rather if present in the ground they will float on the water table. They are sometimes referred to as Light Non-Aqueous Phase Liquid (LNAPL) as they are less dense than water. However, some of the chemicals that comprise gasoline and diesel will separate from fuel into a dissolved form in the groundwater. The most soluble of these chemicals are benzene, toluene, ethylbenzene, and xylenes. They are referred to by acronym BTEX.[2] Some organic pesticides may be soluble in water as they may be mixed with water prior to application to a field.

Inorganic chemicals found in groundwater are salts that dissociate into cations and anions when in contact with water. The cations include heavy metals such as iron, lead, manganese, cadmium, chromium, zinc, and mercury. The anions include nitrate (NO_3^-), nitrite (NO_2^-), sulfate (SO_4^{2-}), fluoride (F^-), chloride (Cl^-), arsenate (AsO_4^{3-}) and arsenite (AsO_3^{3-}).

SOURCES OF CONTAMINATION

Sources of contamination can be divided into point sources and non-point sources. As the name implies, point sources can be traced to a very specific location. An example of a point source might be a septic tank, a landfill, or a pesticide mixing area. Non-point sources are dispersed across the landscape. Fertilizer and pesticides applied to fields are examples of non-point sources.

Human- and animal wastes are sources of potential groundwater contamination due to the presence of bacteria and viruses as well as nitrogen compounds. One chemical compound frequently found in groundwater in rural areas is nitrate. This can come from cesspools and septic tanks, barnyards, manure spread as fertilizer, and chemical fertilizers. Nitrate and nitrite in drinking water in excess of 10 mg/L (milligrams per liter) as nitrogen have been implicated in infant methamoglobanemia or "blue baby syndrome." Another salt found in animal waste is chloride. This will impart a salty taste in drinking water if present in amounts in excess of 250 mg/L.

Pesticides are also a potential source of groundwater contamination. They can be found concentrated in areas where pesticides are mixed or equipment is washed. Likewise pesticides can be a non-point source of contamination when they are spread on a field. For example, atrazine has been found in groundwater in Wisconsin as a result of use on corn crops. Not only can pesticides occur in the environment, but breakdown products called metabolites can also occur in groundwater.

When water is used for irrigation, some will evaporate. This will concentrate the soluble salts in the remaining water, which will drain down to the water table. As a result, toxic salts may build up in the soil and groundwater. This situation has developed in some areas of California with selenium.

Fuels used on the farm can leak from underground storage tanks resulting in the formation of a pool of LNAPL on the water table below the tank and dissolved BTEX chemicals in the groundwater. The federal drinking water standard for benzene in the United States is 5 μg/L. In some states the groundwater standard is even lower, 1 μg/L.

Chemicals used for degreasing equipment can also contaminate groundwater if improperly disposed.[3] Many degreasers contain chlorinated organic compounds such as trichloroethylene (TCE) and 1,1,1-trichlorethane (TCA). These liquids are denser than water and mix poorly with water. They are referred to by acronym DNAPL. If disposed into the environment, for example by spilling on soil, they can migrate vertically to the water table and then sink below the water table into the underlying aquifers. These compounds are sparingly soluble in water, but even small amounts are dangerous. The federal drinking water standard for trichloroethylene in the United States is 5 μg/L. In some states the groundwater standard is even lower, 1 μg/L.

Chemicals used in wood preservatives are also potential groundwater contaminants. These include creosote and CCA (copper, chromium, arsenic). Treated wood itself would most likely not contaminate groundwater, but spilled or improperly disposed wood-treating chemicals could contaminate the groundwater.

EFFECT OF CLIMATE

In humid climates, the water table may be close to the surface and frequent rains can leach contaminants from the soil and transport them down to the water table. If the climate is more arid, contaminants in the soil zone are less likely to be transported to the water table, which itself is likely to be deeper than in a corresponding area that is more humid. However, evaporation of irrigation water in arid climates may result in a build up of soluble salts in the soil and the excess irrigation water that may eventually reach the water table.

TRANSPORT OF CONTAMINANTS

Dissolved contaminants are carried by flowing groundwater through a process called *advection*. If the contaminant is *conservative*, it will move at the same rate as the groundwater in which it is dissolved. An example of a dissolved salt that is conservative is chloride. Water flowing through an aquifer will not all be moving at the same rate. Groundwater moves through pores and cracks in the ground. Some of these openings in the ground are larger than others, and water in the larger openings will be moving faster than water in the smaller openings. As a result, the faster moving water will spread out in front of the rest of the mass of the water. If a contaminant is present in a low concentration, the closer the contaminant gets to the moving front the faster moving water mixes with uncontaminated water. This process is called *longitudinal dispersion*. Through dispersion and diffusion a *plume* of groundwater contamination is formed. This plume is nothing more than a contiguous zone where the contaminant is present in the groundwater. If there is an ongoing source of contamination at the start of the plume, the greatest concentration of the contaminant will be found there and the concentration will decrease in the direction of the groundwater flow. The contaminant plume will extend along the direction of groundwater flow, but also spread sideways through a process called *lateral dispersion*. This is due to the flowing groundwater taking branching pathways.[4]

Non-aqueous phase liquids also have the potential to move through the soil and underlying aquifers. Their movement is dependent upon the ability of the non-aqueous phase liquid to overcome capillary forces and displace air in the pores above the water table and water in the pores of the earth below the water table.

FATE OF CONTAMINANTS

Biological agents are particles of protoplasm. As such they can travel through large pores and cracks in the earth, but not small ones. Fine-grained soils can remove bacteria and viruses by *filtration*, usually within a few hundred meters or less of the source. Some aquifers such as coarse gravel, fractured rock, and carbonate rock have larger openings. Bacteria and viruses can travel for significant distances in such aquifers.

Ionic substances can be removed from groundwater by *ion exchange*. In this phenomenon, ions such as sodium and calcium, which are loosely bound to clay particles can be exchanged for other cations, such as lead, mercury, cadmium, and manganese. The heavy metal contaminants will thus be removed from the groundwater. The ability of a soil to remove contaminants by ion exchange is measured as the ion-exchange capacity of the soil.

Dissolved organic compounds can be removed from groundwater by *adsorption* onto organic matter contained in the soil or rock. The rate of adsorption is inversely proportional to the water solubility of the organic compound. Those that have a low solubility are more tightly bound to the soil organic matter than those that are more soluble. This propensity to be absorbed is measured by a property known as the octanol–water partition coefficient. The other important factor is the percentage of organic matter in the soil. Obviously, the greater the percentage of organic matter, the more of dissolved organic compounds it can absorb.

Finally, many of the dissolved organic compounds can potentially be broken down into simpler compounds by the action of microbes in the soil and aquifer. This process is known as *biodegradation*. The components of petroleum based fuels can be degraded by soil bacteria. The end result is either carbon dioxide or methane, depending upon the presence or absence of dissolved oxygen in the aquifer. BTEX compounds are most readily degraded under aerobic conditions, i.e., with dissolved oxygen present. However, under certain geochemical conditions in the aquifer they can also be degraded in the absence of oxygen, but at a slower rate. Many other organic chemicals dissolved in groundwater, such as the chlorinated solvents, can be degraded either biologically or abiotically under the right geochemical conditions.[5]

INTRODUCTION

Arsenic is an element with atomic number 33 and atomic weight 74.92. It exists throughout the earth's crust and is the 20th abundant element in nature. For centuries, arsenic has been used as a drug and as a poison. Arsenic is thought to exert its toxicity by combining with certain enzymes and thereby interfering with cellular metabolism.

Groundwater arsenic contamination and sufferings of people have been reported in 20 countries in different parts of the world (Fig. 1). The magnitude is considered highest in four Asian countries, and the severity order is Bangladesh > West Bengal—India > P.R. China > Taiwan.

GROUNDWATER ARSENIC CONTAMINATION IN WEST BENGAL—INDIA

West Bengal—India's groundwater arsenic contamination in villages was first reported in 1982, and arsenical skin lesions were first detected in 1983. Twenty-two patients with arsenical skin lesions were known from five villages in four districts.

About 50% of the districts in West Bengal—India reported groundwater arsenic concentration above 50 μg/L. Six million people are drinking arsenic-contaminated water above 50 μg/L from 74 police stations/blocks in 9 arsenic affected districts including a part of Calcutta city in West Bengal (Fig. 2). In 2600 villages/wards, arsenic in groundwater has been found above 50 μg/L. In a preliminary study from 255 villages, 86,000 people were examined and 8500 people have been registered with arsenical skin lesions. Fig. 3 shows an arsenic patient with severe keratosis. In affected villages, the following skin manifestations and other symptoms of arsenic toxicity were detected—diffuse melanosis; mucous membrane pigmentation on tongue, gum, and lips; spotted melanosis; leuco-melanosis; spotted and diffuse keratosis; and dorsal and limb keratosis. The following non-dermatological complications were also observed in victims suffering from arsenic toxicity—weakness and anemia, muscle pain, non-petting oedema, conjunctival congestion, laryngitis, myopathy, neurological problem, chronic bronchitis, asthmatic bronchitis, hepatomegaly, splenomegaly, ascitis, and various types of external and internal cancer.

Arsenical skin lesions from nine affected districts of West Bengal affect an estimated 300,000 people.[1] From arsenic-affected areas of West Bengal, over 99,000 water samples from hand tubewells have been analyzed by flow injection hydride generation atomic absorption spectrometry. Fifty-five percent had arsenic concentrations above 10 μg/L and 25% above 50 μg/L. The highest concentration of arsenic found in a hand tubewell was 3880 μg/L. About 25,000 biological samples (hair, nail, urine, skin scale) have been analyzed from villagers living in arsenic-affected villages (about 40% samples of total 25,000 are from arsenic patients) and on average 80% of the biological samples had arsenic above normal arsenic level in human body. This indicates many more are subclinically affected.

GROUNDWATER ARSENIC CONTAMINATION IN BANGLADESH

Groundwater arsenic contamination and sufferings of people in Bangladesh surfaced in 1995. At that time, there was information about three affected villages in two police stations of two districts (Narayanganj and Faridpur). During the last 7 yr, a tremendous amount of survey work was done to determine the magnitude of the arsenic calamity in Bangladesh. Present survey reports indicate that 2000 villages in 178 police stations of 50 districts out of total 64 districts in Bangladesh, groundwater contains arsenic

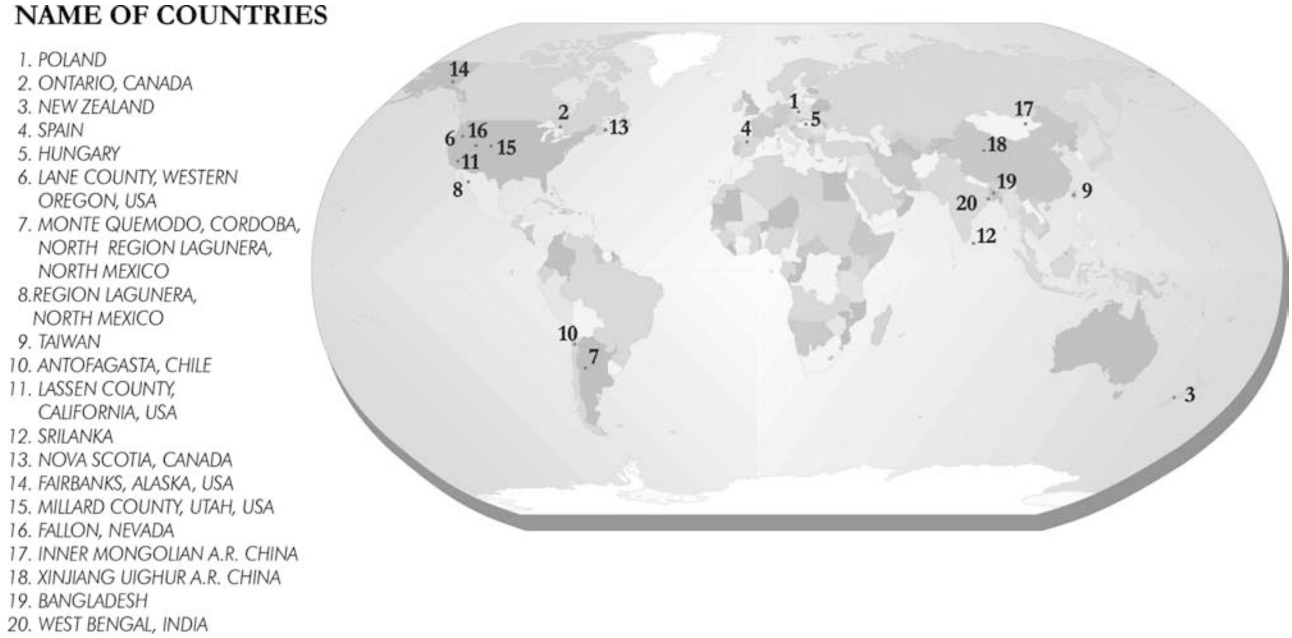

Fig. 1 Shows groundwater arsenic incidents round the world.

above 50 μg/L. Bangladesh comprises four existing geo-morphological regions: 1) Deltaic region (including coastal region); 2) Flood Plain; 3) Tableland; and 4) Hill Tract. Of these four regions, Hill Tract is free of arsenic contamination. Most of the Tableland region is also contamination-free (except Flood Plain deposition on the eroded surface of Tableland). The highly arsenic-contaminated areas of Bangladesh are Deltaic region followed by Flood Plain (Fig. 4). Huge arsenic-free groundwater aquifers remain in selected areas of Bangladesh.[2] Arsenic-contaminated areas of Bangladesh belong to arsenic-bearing holocene sediments. Bangladesh's arsenic calamity is considered the worst in the world. The World Bank and World Health Organization (WHO) described the magnitude of arsenic contamination in Bangladesh.[3] The World Bank's local chief stated that tens of millions of people are at risk from health effects, and that 43,000 of the 68,000 villages are presently at risk or could be at risk in future. According to the prediction of WHO, within a few years, death across much of southern Bangladesh (1 in 10 adults) could be from cancers triggered by arsenic.[3] The area and population of Bangladesh are 148,393 km^2 and 120 million, respectively. Thirty-four thousand hand tubewell water samples from 64 districts in Bangladesh have been analyzed and 56% contained arsenic above 10 μg/L, that the WHO recommended level of arsenic in drinking water with 37% contained more than 50 μg/L, the WHO maximum permissible limit. Maximum concentration of arsenic found in groundwater of Bangladesh was 4730 μg/L. Overall result shows only 25% and 37% of hand tubewells contain arsenic above 50 μg/L in arsenic-affected areas of West Bengal and Bangladesh, respectively, but there are many villages in West Bengal and Bangladesh where 80–90% of hand tubewells contain arsenic above 50 μg/L. It has been estimated that at the present time, more than 25 million people in Bangladesh are drinking arsenic-contaminated water above 50 μg/L, and 51 million people are drinking water above 10 μg/L. Analyses of more than 9900 biological samples from arsenic-affected villages of Bangladesh indicate that 95% of samples contain arsenic above normal level. So far in a preliminary survey, over 10,000 people have been identified with arsenical skin lesions from 222 out of 253 villages surveyed for patients. Fig. 5 shows an arsenic patient with squamous cell carcinoma.

SOCIAL PROBLEM AND IGNORANCE

Arsenic poisoning in villages of West Bengal and Bangladesh are causing social problems that are the biggest curse.

The prevailing social problems in the villages are as follows.

1. Due to ignorance, the villagers assume the arsenical skin lesions are a case of leprosy and force arsenic patients to maintain an isolated

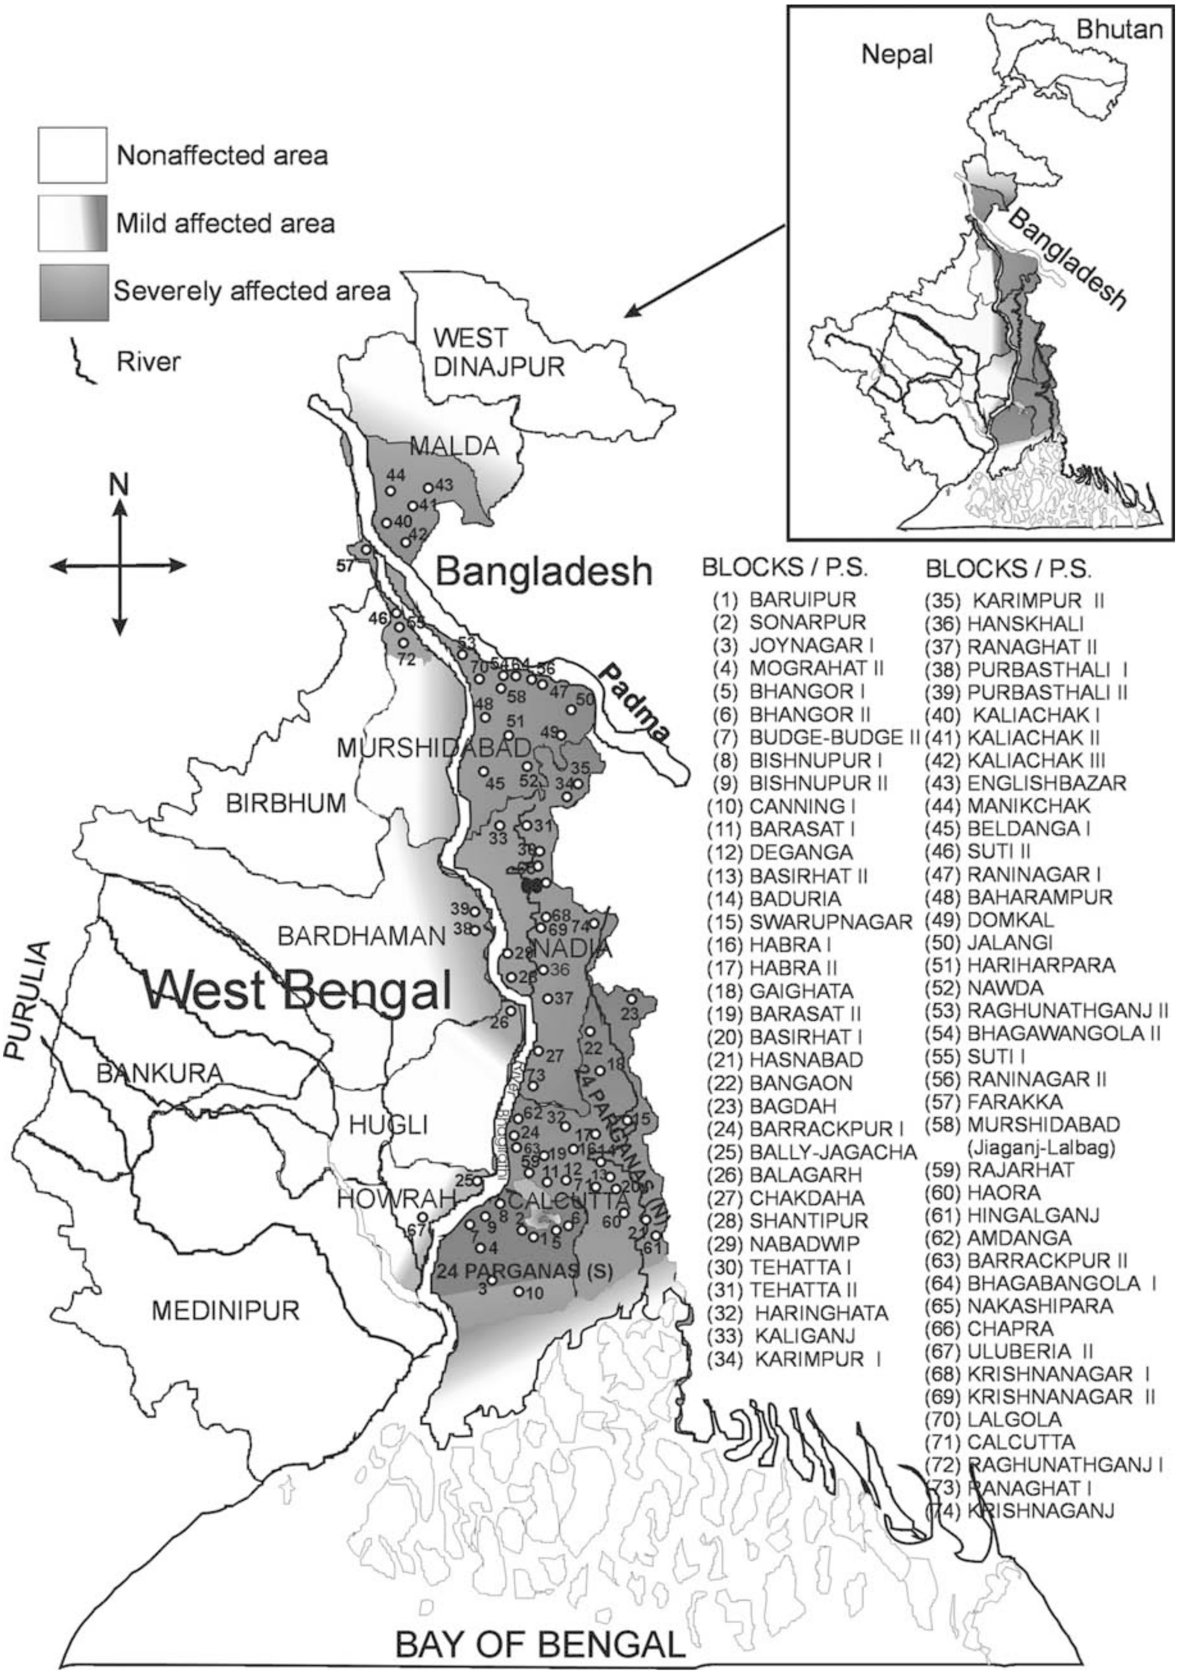

Fig. 2 Map shows the present arsenic affected areas and blocks of West Bengal—India.

Global–Groundwater

Fig. 3 Shows an arsenic patient with severe keratosis.

life or avoid them socially. It is a social curse and human tragedy.

2. Affected wives are sent back to their parents and often with their children.
3. Marriages in the affected villages have become a serious problem because of skin lesions.
4. Jobs/services have been denied/ignored to the arsenic-affected people.
5. When a husband or a wife has been singled out as an arsenic patient, the social problem has increased and destroyed the social fabric.

Most of the people in the affected villages are not aware of the serious consequence of arsenic toxicity. People think arsenical skin lesions are just a single skin disease and will be cured with ointment. Some of them also think the skin lesions are the ‘‘Wrath of God or Curse of God.’’ A group also think the skin manifestation is due to the sin committed in their last birth.

SOURCE OF ARSENIC

A single Rural Water Supply Scheme (RWSS) from Malda, one of the arsenic-affected districts of West Bengal—India, is withdrawing 147 kg of arsenic with groundwater in a year and 6.4 t of arsenic is being withdrawn in a year from 3000 shallow, large-diameter tubewells in use for agricultural irrigation in Deganga police station of North 24-Parganas district, West Bengal.[4] It indicates that the source of arsenic is not antropogenic and is geologic. Although the source of arsenic is believed to be aquifer sediments, the chemistry and mineralogy of the sediments of Ganges–Brahmaputra–Meghna (GBM) delta and arsenic leaching from the aquifer are not well understood. Reports[5,6] show existence of arsenic-rich pyrite in sediments of the delta region of Gangetic West Bengal. A probable explanation of arsenic contamination to the aquifer was predicted due to breakdown of arsenic-rich pyrite that occurred due to heavy groundwater withdrawal (i.e., underground aquifer is aerated and oxygen causes degradation of pyrite, the arsenic rich source). The cause of groundwater arsenic contamination in West Bengal and Bangladesh was also predicted due to reduction of arsenic-rich iron oxy-hydroxide in anoxic groundwater.[7,8,9]

Whatever may be the mechanism of arsenic leaching to the aquifer, in West Bengal—India 38,865 km^2 and in Bangladesh 118,849 km^2 are arsenic affected areas, and population in West Bengal—India living in arsenic affected areas is 42.7 million and 104.9 million in Bangladesh. This does not mean that the total population (147.6 million) is drinking arsenic-contaminated water in West Bengal and Bangladesh and will suffer from arsenic toxicity, but it does indicate the risk levels. Our knowledge about long-term effects on those who have stopped drinking arsenic-contaminated water, those drinking contaminated water, and those suffering from arsenical skin lesions is not complete. A limited follow-up study for the last 10 yr indicates that a percentage of those suffering from severe skin lesions are getting internal/external cancers. A future danger to those living in West Bengal—India and Bangladesh is that arsenic is entering the food chain. Of great concern is the huge amount of arsenic applied to agricultural land from contaminated water from hand tube-wells used for irrigation.

HOW TO COMBAT THE PRESENT ARSENIC CRISIS

The mistakes made in the past and that are persisting even today are due to the exploitation of groundwater for irrigation without even trying to adopt effective watershed management to harness the huge surface water resources and rain water. In West Bengal—India and Bangladesh, huge amounts of arsenic-free surface water is in ponds, canals, rivers, wetlands, flooded river basins, and ox-bow lakes. Per capita available surface water in Bangladesh is about 11,000 m^3. West Bengal—India and Bangladesh are known as the land of rivers and have approximately 2000 mm annual rainfall. Instead of using those resources, groundwater is being pumped without proper management. Proper watershed management and villager participation are needed to combat the present arsenic crisis.

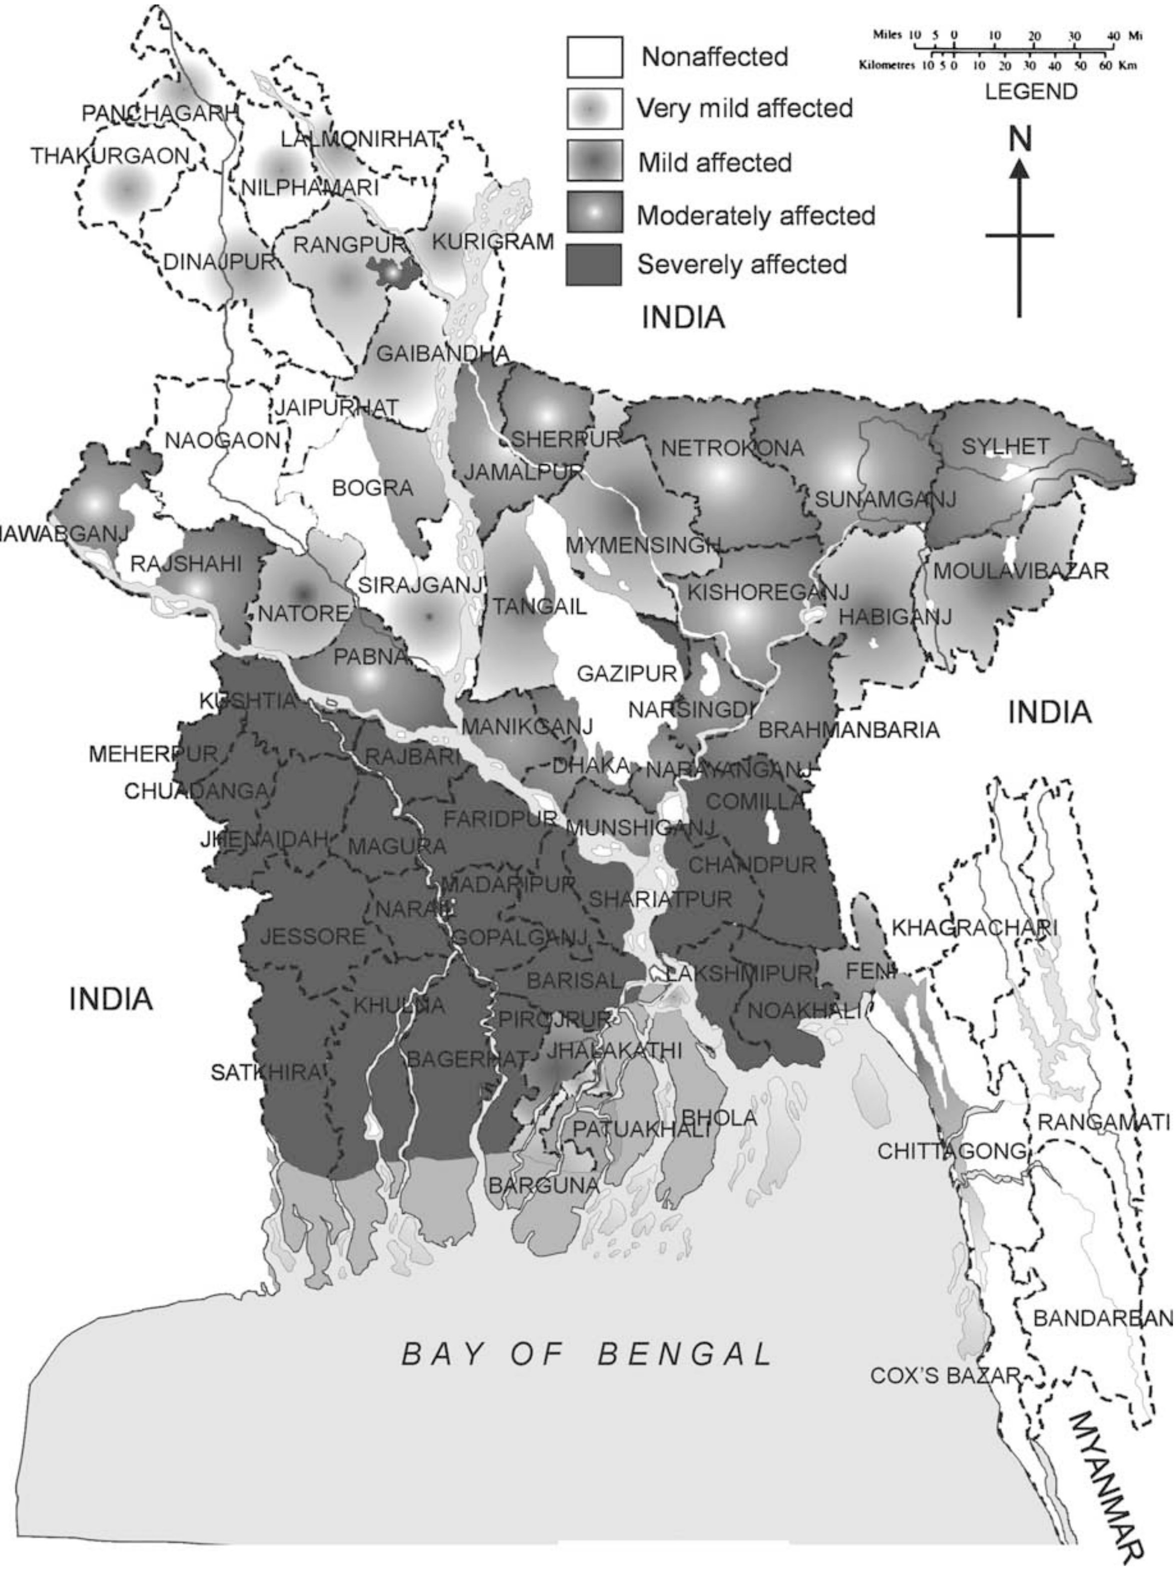

Fig. 4 Map shows the status of arsenic in groundwater in all 64 districts of Bangladesh and in four geo-morphological regions.

Fig. 5 Shows an arsenic patient with Squamous cell carcinoma on head.

Groundwater: Mapping Levels

Marios A. Sophocleous
*Kansas Geological Survey, University of Kansas,
Lawrence, Kansas, U.S.A.*

INTRODUCTION

Maps of groundwater levels are used to estimate groundwater flow direction and velocity, to assess groundwater vulnerability, to locate landfills and wastewater disposal sites, and as input to hydrologic and pollutant transport models. Because groundwater is hidden from view beneath the land surface, groundwater can only be directly observed through monitoring wells. However, because these observations are limited to specific points, mapping groundwater levels requires hydrogeologically appropriate techniques to generalize the point measurements. Rules or models for spatially and temporally generalizing monitoring (sample) data across the groundwater system are inherent and essential to hydrogeologic science. Our understanding of ground water is the product of a long history of hypothesis and model development, testing, and refinement.[1]

The position of the water table is the product of a wide range of static and dynamic environmental conditions and processes affecting the rate at which water enters and leaves the saturated zone of the aquifer. The water table rises if the rate of water added (recharge) exceeds the rate of water leaving (discharge); conversely, the water table falls if discharge exceeds recharge. The water-table surface is therefore not static, nor flat (as the name implies), but responsive to climatic, vegetative, geomorphic, and geologic conditions.

As Matson and Fels[1] also pointed out, traditional water-table mapping uses graphical methods to interpolate between water-table measurements and hydrogeologic boundaries, with professional judgment and experience filling the gaps in sampling. Computer assisted approaches may incorporate surface mapping methods such as trend surface interpolation and *kriging*;[2] many of these tools are currently provided in Geographic Information Systems (GIS) software. Other methods employ mathematical modeling to predict water-table elevation from hydrogeologic conditions and processes.

DESIGNING A MONITORING SYSTEM

Setting up a monitoring system requires careful consideration of both the hydrogeologic setting and the data needed. It is premature and wasteful to locate monitoring wells without first synthesizing what is known about the setting—in other words, without formulating a sound conceptual model of the system under study. For example, water-supply wells drilled without understanding area hydrogeology may be placed where 1) the aquifer is thin or missing altogether, 2) the aquifer is present but not very productive, or 3) the aquifer contains water of poor quality.[3]

Areas in which the geology is highly variable require more extensive (and costly) water-level monitoring systems than comparatively more homogeneous areas. The degree of geologic complexity is often not known or appreciated during the early phases of a testing program, and it may require several stages of drilling, well installation, water-level measurement, and analysis of hydrogeologic data before the required understanding is achieved. Due to space limitations, the design for an optimal spacing of groundwater-level monitoring wells cannot be covered in this article; however, the reader is referred to Refs.[4,5] for examples of such an observation well network design.

NATURAL PROCESSES CAUSING GROUNDWATER-LEVEL FLUCTUATIONS

To interpret the monitored water levels, one needs to understand the various processes causing fluctuations in groundwater level. These are the effects of hydrologic processes active in the atmosphere, land surface, and subsurface, the groundwater movement in hydrodynamic flow systems, groundwater recharge and discharge processes, atmospheric pressure changes, plant transpiration, aquifer compression and dilation, and others.

In addition to natural processes, human activities also cause groundwater-level fluctuations. Major among them are: 1) groundwater withdrawals from wells; 2) artificial recharge; 3) irrigation; 4) land clearing; 5) pumping of hydrocarbons and brine from reservoirs; 6) construction of water reservoirs; 7) mining; and 8) loading and unloading by heavy equipment, such as freight trains.

ANALYSIS, INTERPRETATION, AND PRESENTATION OF WATER-LEVEL DATA

Primary uses of groundwater-level data are to understand and predict water-level changes and to assess the direction of flow beneath an area. The usual procedure is to plot the location of wells on a base map, convert the depth-to-water measurements to elevations, plot the water-level elevations on the base map, and then construct a groundwater elevation contour map. Constructing a water-level change map, as will be explained later on (see section on ''Examples of Groundwater-level Data Interpretation''), will indicate the extent and severity of water-level declines resulting from a variety of factors, including human development and droughts. The direction of groundwater flow is estimated by drawing ground-water flow lines perpendicular to the ground-water elevation contours (Figs. 1 and 2) if the aquifer can be considered *homogeneous* and *isotropic*.

The relatively simple approach to estimating ground-water flow directions described above is suitable where wells are screened in the same zone and the flow of groundwater is predominantly horizontal. However, as attention has focused on detecting the subsurface position of contaminant plumes or predicting possible contaminant migration pathways, this simple approach has been shown to be not always valid.[6] Increasingly, flow lines shown on vertical sections are required to complement the planar maps showing horizontal flow directions to illustrate how groundwater is flowing either upward or downward beneath a site.

Groundwater flows in three dimensions, and as such can have both horizontal and vertical (either upward or downward) flow components. The magnitude of either the horizontal or the vertical flow component and the direction of groundwater flow are dependent on several factors: recharge and discharge conditions, aquifer heterogeneity, and aquifer anisotropy. Dalton, Huntsman, and Bradbury[6] summarized these factors, and the following draws on their summary.

In recharge areas, groundwater flows downward (or away from the water table), whereas in discharge areas groundwater flows upward (or toward the water table). Groundwater migrates nearly horizontally in areas where neither recharge nor discharge conditions prevail. For example, in Fig. 1 well cluster A is located in a recharge area, well cluster B is located in an area where flow is predominantly lateral, and well cluster C is located in a discharge area.[7] Note in Fig. 1 that wells located adjacent to one another, but finished at different depths, may display different water-level elevations.

In a heterogeneous aquifer, hydrogeologic properties are dependent on position within a geologic formation,[8] and thus the geology needs to be considered in evaluating water-level data. While recharge or discharge may cause vertical gradients to be present within a discrete geologic zone, vertical gradients may also be caused by the contrast in hydraulic conductivity between aquifer zones. This is especially evident where a deposit of low hydraulic conductivity overlies a deposit of relatively higher hydraulic conductivity.

Aquifer anisotropy refers to an aquifer condition in which aquifer properties vary with direction at a point within a geologic formation.[8] For example, many aquifer zones were deposited in more or less horizontal layers, causing the horizontal hydraulic conductivity

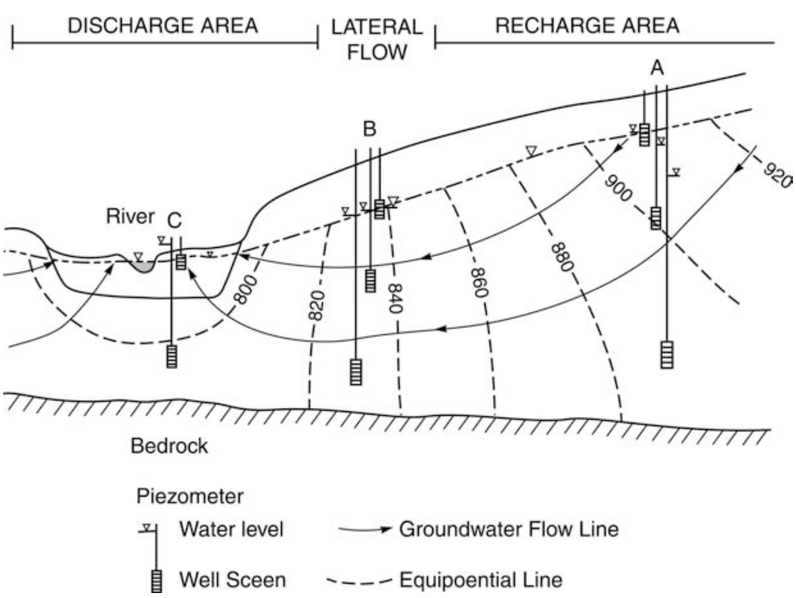

Fig. 1 Ideal flow system showing recharge and discharge relationships. *Source*: Adapted from Saines, 1981.[7].

Global–Groundwater

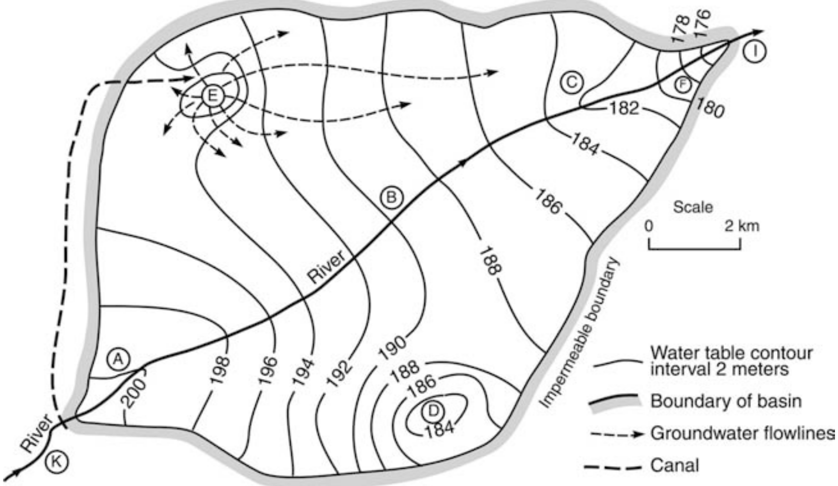

Fig. 2 Contour map of the water table in a small hypothetical groundwater basin. If the aquifer is homogeneous and isotropic and if the slope of the water table is not large, the map can be used to construct a flow net. A small number of flowlines (shown as dash lines) have been drawn on the map. Excessive convergence of the flow lines suggests a changing transmissivity of the aquifer. *Source*: From Ref.[9].

to be greater than the vertical hydraulic conductivity. In anisotropic zones, where the horizontal component of hydraulic conductivity is higher than the vertical one, flow will be restricted to higher elevations compared to an equivalent flow system in isotropic zones showing the same water-level conditions.

The practical significance of the three factors discussed earlier is that groundwater levels can be a function of either well-screen depth or of well position along a groundwater flow line or, more commonly, a combination of the two.[6] For these reasons, considerable care needs to be taken in evaluating water-level data.

Interpreting Water-Level Data

Dalton, Huntsman, and Bradbury[6] also summarized the various steps in groundwater-level data interpretation. The first step in interpreting groundwater-level data is to make a thorough assessment of the site geology. The vertical and horizontal extent and relative positions of aquifer zones and the hydrologic properties of each zone should be determined to the fullest extent possible. It is extremely important to have as detailed an understanding of the site geology as possible. Detailed surficial geologic maps and geologic sections should be constructed to provide the framework to interpret data on groundwater levels.

The next step in interpreting these data is to review monitoring wells with respect to screen elevations and the various zones in which the screens are situated. The objective of this review is to identify whether vertical hydraulic gradients are present beneath the site and to determine the probable cause of the gradients.

Once the presence and magnitude of vertical gradients and the distribution of data with respect to each zone are established, the direction of groundwater flow can be assessed. If the geologic system is relatively simple and substantial vertical gradients are not present, a planar groundwater elevation contour map can be prepared which shows the direction of groundwater flow. However, if multiple zones of differing hydraulic conductivity are present beneath the site, several planar maps may be required to show the horizontal component of flow within each zone (typically the zones of relatively higher hydraulic conductivity) and vertical sections are required to illustrate how groundwater flows between each zone.[6] The presence of vertical gradients can be anticipated in areas where sites are underlain by a layered (heterogeneous) geologic sequence, especially where deposits of lower hydraulic conductivity overlie deposits of substantially higher hydraulic conductivity; or are located within recharge or discharge areas.

Site activities can modify local conditions to such an extent that groundwater flows in directions contrary to what would be expected for ‘‘natural’’ conditions. For example, drainage ditches can modify flow within near-surface deposits, and facility-induced recharge can create local downward gradients in regional discharge areas.[6]

As mentioned previously, groundwater flow directions and water levels are not static and can change in response to a variety of factors, such as seasonal precipitation, irrigation, well pumping, changing river stage, and fluctuations caused by tides. Fluctuations caused by these factors can modify, or even reverse, horizontal and vertical flow gradients and thus alter groundwater flow directions.

Contouring of Water-Level Elevation Data

Typically, as Dalton, Huntsman, and Bradbury[6] also outlined, groundwater flow directions are assessed by preparing groundwater elevation contour maps. Water-level elevations are plotted on base maps and linear interpolations of data between measuring points are made to construct contours of equal elevation (Fig. 2). These maps should be prepared using data from wells screened in the same zone, where the horizontal component of the groundwater flow gradient is greater than the vertical gradient. The greatest amount of interpretation is typically required at the periphery of the data set. A reliable interpretation requires that at least a conceptual analysis of the hydrogeologic system be made. The probable effects of aquifer boundaries, such as valley walls or drainage features, need to be considered.

Computer contouring and statistical analysis (such as kriging) of water-level elevation data are becoming more popular. These tools offer several advantages, especially for large data sets. However, the approach and assumptions that underlie these methods should be thoroughly understood before they are applied, and the computer output should be critically reviewed. The most desirable approach would be to interpret the water-level data using both manual and computer techniques.[6] If different interpretations result, then the discrepancy between the interpretations should be resolved by further analysis of the geologic and water-level data.

Examples of Groundwater-Level Data Interpretation

Several common errors in interpreting and contouring groundwater-level data are summarized by Davis and DeWiest.[9] Fig. 2 presents a number of water-table configurations related to common geologic or hydrologic causes. Area A is an area of recharge within an alluvial fan where the surface is 24 m above the water table. Here the stream continually loses water to the permeable substrata. Streams with this relationship to the water table are called *influent* or *losing* streams. In such cases, ground-water contours form a V, pointing downstream when they cross a losing stream. At point B, the water in the stream is at the same elevation as the water table. The water-table contour is normal to the stream at this point because there is no flow from the stream and groundwater flowlines are therefore tangent to the direction of the stream. At C the surface of the stream is below the water table, and the stream receives groundwater discharge. At C the stream is called an *effluent* or *gaining* stream. Groundwater contours bend upstream when they cross a gaining stream. At F the stream is still an effluent stream, but most of the groundwater has already been discharged into the stream so the contours no longer bend sharply upstream.[9] Point D is an area of heavy pumping in which the water has been lowered to 6 m below the stream level at B. After a short period, the pumping at D should make the contours shift so the river will be influent at B. Area E is an area of recharge in which surplus irrigation water has produced a ground-water mound 3 m above the stream surface at B. The stream at K and I is flowing in an impervious channel. The difference between the discharges at K and I is equal to the water lost or gained within the ground-water basin.

Common mistakes in mapping groundwater levels are a failure to distinguish between the water levels of different aquifers and to identify wells that have contact with more than one aquifer (Fig. 3). If the area is one of complex stratigraphy or structure, the data should be interpreted with maximum use of geologic information. Similar problems occur if observation wells completed at different depths in recharge and/ or discharge areas are all combined to produce a

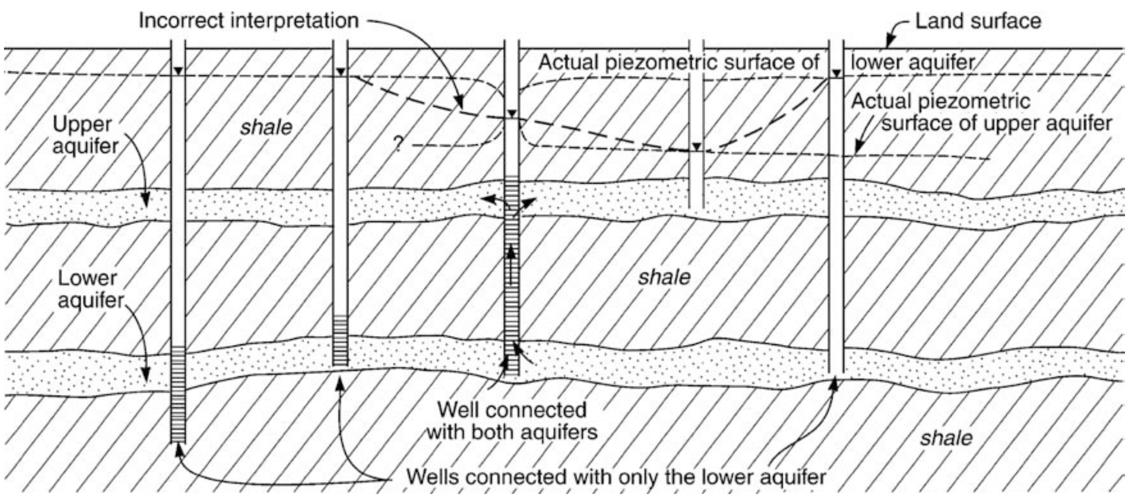

Fig. 3 Observation wells in a region having two confined aquifers under separate pressures. Correct interpretation of water levels is almost impossible unless details of well construction are known. *Source*: From Ref.[9].

groundwater elevation contour map. In such areas, vertical flow components are significant (Fig. 1) and water levels in wells completed at different depths will be at different elevations. In such cases, only shallow wells screened at or near the water table should be used for constructing water-table maps.

Surface-water features such as springs, ponds, lakes, streams, and rivers can interact with the water table. In addition, the water table is often a subdued reflection of the surface topography. All this must be taken into account when preparing a water-table map.[10] A base map showing the surface topography and the locations of surface-water features should be prepared. The elevations of lakes and ponds can be helpful information. The locations of the wells are then plotted on the base map, and the water-level elevations are noted. The datum for the water level in wells should be the same as the datum for the surface topography. Interpolation of contours between data points is strongly influenced by the surface topography and surface-water features. For example, groundwater contours cannot be higher than the surface topography. The depth to groundwater will typically be greater beneath hills than beneath valleys. If a lake is present, the lake surface is flat and the water table beneath it is also flat.[10] Hence, groundwater contours must go around it (Fig. 4A). The only exception to this rule is when the lake is perched on low-permeability sediments and has a surface elevation above the main water table.[10] Mistakes in constructing water-table maps are often associated with purely mechanical extrapolation of contours between measured water levels. The water table thus can be placed mistakenly above the land surface (Fig. 4A), or obvious geologic structures are ignored (Fig. 4B; Ref.[9]).

In areas where the groundwater levels exhibit a gentle gradient, the groundwater contours will be spaced well apart. If the gradient is steep, the groundwater contours will be closer together. Groundwater will flow in the general direction that the water-level surface is sloping.

Water-level change maps are constructed by plotting the change of water levels in wells during a given span of time. If the study is of a short span of time, data from the same wells can be used. If, however, the time span is long (of the order of 50 yr or more), it is impossible in some areas to measure the same wells, owing to their rather rapid destruction or failure.

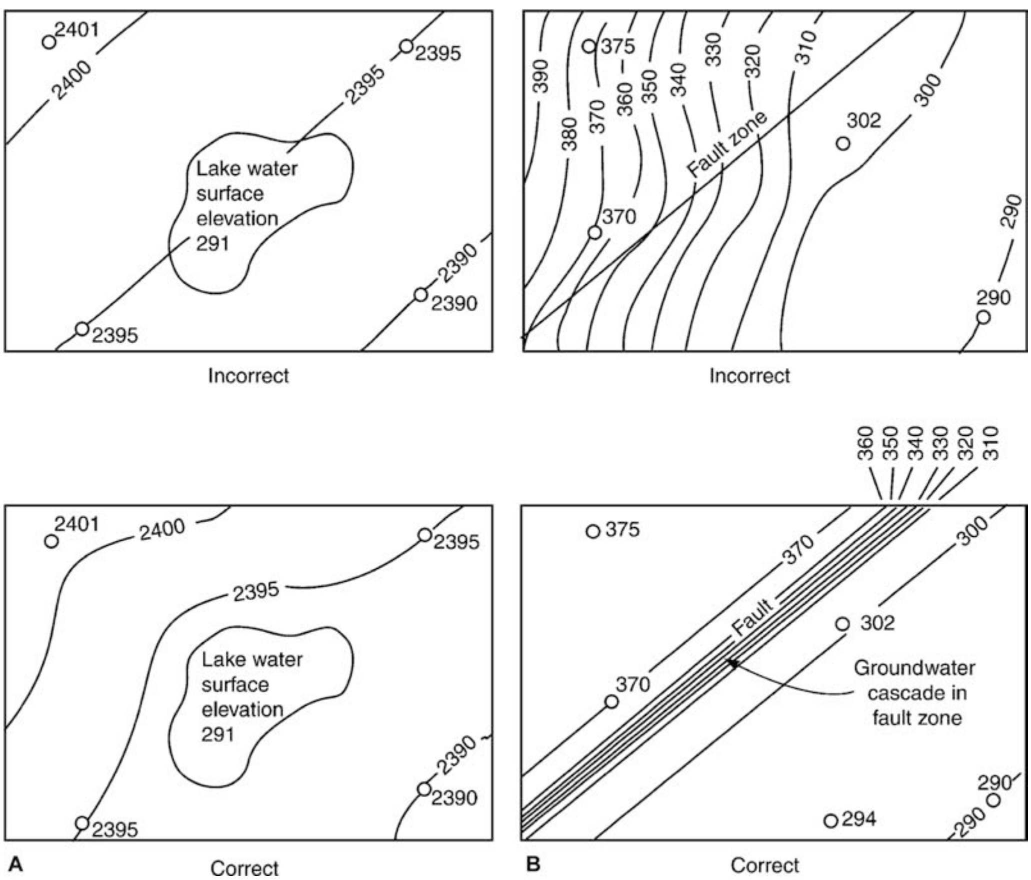

Fig. 4 Common errors encountered in contouring water-table maps in areas of (A) topographic depressions occupied by lakes, and (B) fault zones. *Source*: From Ref.[9].

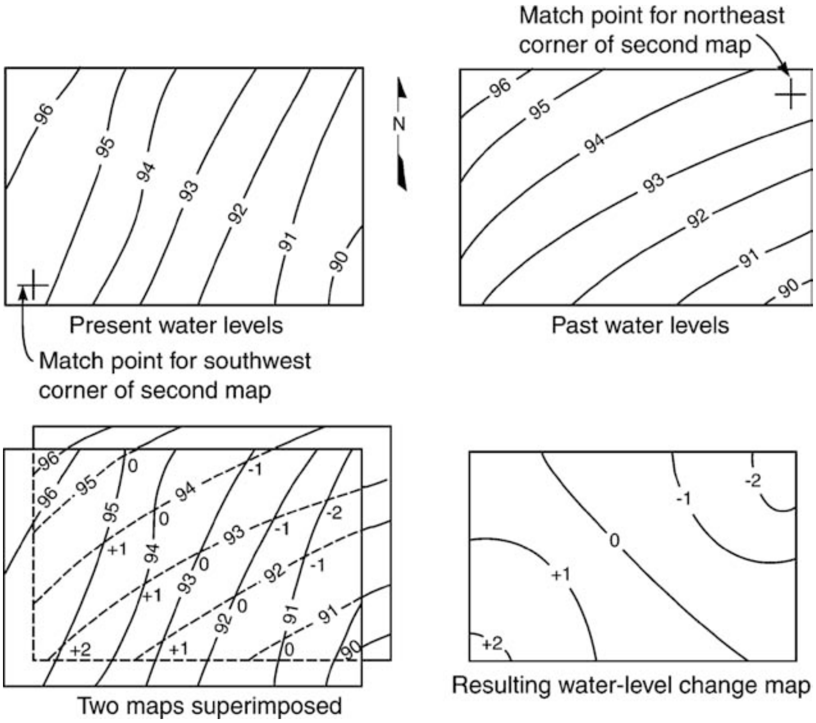

Fig. 5 Construction of a water-level change map by superimposing water-level contour maps. *Source*: From Ref.[9].

The best procedure in this case is to draw two water-table maps of the years of interest.[9] The maps are then superimposed and the water-level changes at contour intersections are recorded. The values can then be transferred to a separate map and lines of equal water-level change can be drawn (Fig. 5). Modern technology, especially the use of GIS, has made such procedures much easier and faster.

Groundwater: Measuring Levels

Paul F. Hudak
Department of Geography, University of North Texas, Denton, Texas, U.S.A.

INTRODUCTION

A "groundwater level" is the elevation of water in a well tapping an aquifer. Well construction in addition to hydraulic conditions in the aquifer influence measured groundwater levels. Hydraulic head, the mechanical energy per unit weight of water,[1] is equal to the elevation to which water rises in a cased well open to a "point" in an aquifer. The hydraulic head measurement pertains only to that point and is normally expressed in units of length above mean sea level. Groundwater levels from several cased wells, at several points in time, illustrate spatial and temporal patterns in hydraulic head within an aquifer.

WELL CASING AND SCREENED INTERVAL

For the purpose of monitoring hydraulic head, wells should have as short a screened interval (intake) as possible, generally less than 3 m long.[2] Short intakes are especially important if there are strong vertical flow components. Under these conditions, piezometers (wells with intakes less than 0.3 m long) provide more accurate hydraulic head data.[3]

A hydraulic head measurement can be obtained by subtracting the depth to water in a well from the elevation of a reference point at the top of the well casing. The well casing should be permanently marked at the reference point—depth to water measurements should always be made from that point. The reference point must be accurately surveyed, to within 0.01 ft (3 mm). It should be resurveyed every 5 years to account for settling. Unstable terrain, such as expansive clay soils or bogs, requires more frequent surveying. The initial survey should also establish *x*–*y* coordinates of each well. Each well at a field site should be permanently marked with a unique identifier (ID).

The water table represents the surface of an unconfined aquifer. Wells used to measure water table elevations should be screened across or just beneath the water table. In a well tapping a confined aquifer, groundwater levels will rise higher than the top of the aquifer (where it contacts an overlying confining layer). A flowing artesian condition exists if the water level rises above the land surface.

Measuring hydraulic head at flowing wells requires an extension pipe or pressure gage.[3] An extension pipe, tightly fitted to the top of a well casing, must be tall enough to contain the rising water. Alternatively, a pressure gage can be attached to the top of the well casing. The gage measures pressure head (height of water level above gage) or water pressure (pressure head times specific weight of water). The pressure head measurement should be added to the height of the gage above the reference point.

MEASURING DEVICES

Groundwater levels can be measured with several devices, including measuring tapes and poppers, chalk-coated tapes, acoustic probes, electrical sensors, pressure transducers, air lines, time domain reflectometry (TDR), floats and pulleys, and vibrating wire (VW) piezometers.

Poppers (Fig. 1) make an audible sound when dropped onto a water column.[4] The tape should be read at the reference point when the popper just reaches the water column. Length of the popper should be accounted for in the water depth measurement.

Weighted, chalk-coated tapes are similarly lowered down a well, but should penetrate the water column. The tape should be marked where it touches the reference point and then withdrawn from the well. Depth to water equals the distance from the marked point to the top of the wetted portion of the tape. Chalk-coated tapes are one of the most common and accurate methods for measuring groundwater levels.[5]

Acoustic probes transmit sound waves from the top of a well casing to the water level in the well. They measure sound-wave travel times and convert them to distance (depth to water). Electrical sensors (Fig. 1) transmit sound or light signals when a probe enters the water column. The measurement should be made as the probe enters the water column. Submerging and raising the probe, and taking a measurement as the signal stops, is less accurate because dripping water may prolong the signal. False signals from water condensed on the sides of a well should also be considered when using electrical sensors.

Pressure transducers (Fig. 1), air lines, and TDR measure the height of a water column above a

Global–Groundwater

Fig. 1 Pressure transducer (left), electrical sensor (middle), and vinyl tape and popper (right).

submerged probe or tube. They can be connected to data loggers that store water level measurements and corresponding times. Pressure transducers are often used to obtain frequent water level measurements in observation wells during pumping tests. Air lines are less accurate and used mainly in wells being pumped.[5] The TDR devices transmit pulses down a coaxial cable and analyze the reflected voltage signature.[6] A strong voltage drop at the air–water interface is produced by the difference in dielectric constant between air and water. Time domain reflectometry cables can be used in riser pipes as small as 12 mm in diameter.

Floats sit on the water column in a well. One end of a cable is attached to the float, and the other to a counter weight. The cable is draped over a pulley at ground level, and the pulley rotates as water levels in the well rise or fall. Water levels can be recorded with a pen-and-chart or digital system.

Vibrating wire piezometers can be lowered down wells, buried in boreholes, or pushed into unconsolidated sediment. One end of a stretched magnetic wire is anchored and the other attached to a diaphragm, which deflects in proportion to pore-water pressure. Any deflection of the diaphragm changes the tension in the wire, thus affecting the resonant frequency of the VW. Measured pore-water pressures can be converted to pressure head by dividing by the specific weight of water. Adding the pressure head measurement to the elevation of the sensor gives the hydraulic head at the sensor.

FIELD CONSIDERATIONS

Prior to measuring groundwater levels, they should be allowed to recover a minimum of 24 hr following any well construction, development, purging and sampling, or aquifer testing.[5] Recovery may take longer in aquifers with a low hydraulic conductivity.

Measuring devices should be inert and regularly calibrated, taking into account stretch of tapes, wires, or cables. Water level measurements should be made to the nearest 0.01 ft (3 mm) and repeated for accuracy. Well depths should also be measured during each field visit. These do not require as much accuracy as water level measurements and can be accomplished with a weighted tape measure.

Water levels should be measured before collecting water samples or performing aquifer tests, which disturb static water elevations. Ideally, the same device should be used to measure all wells (except in pumping tests requiring frequent or simultaneous measurements at different wells). In a contaminated aquifer, the first water level measurement should be made at the cleanest well, and subsequent measurements should be made at progressively more contaminated wells. The measuring device should be thoroughly cleaned between wells.

At wells with floating immiscible contaminants, both depth to the immiscible layer and depth to water should be measured. This can be done with interface probes or tapes coated with reactive paste, which transmit different signals or colors when contacting different fluids. An immiscible layer depresses the water column in a well—measured depth to water should be corrected by subtracting the product of immiscible layer thickness and specific gravity.

Unless a data logger is being used, each water level measurement should be recorded in a field book, along with the well ID, time of measurement, and device used. Weather conditions and the name of the person making the measurements should also be recorded in the field book.

MAPS AND GRADIENTS

When using water level measurements to construct a contour map of the water table (unconfined aquifer) or potentiometric surface (confined aquifer), the wells should be measured during the same time interval (typically less than 24 hr) and open to the same hydrostratigraphic interval.[2] As many wells as possible should be measured, without sacrificing the above considerations. Moreover, the wells should be spread throughout the study area to avoid inaccurate hydraulic head extrapolations.

Hydraulic gradient, change in hydraulic head with distance, should be calculated along a flow line in a water table or potentiometric surface map. Flow lines should be constructed perpendicular to hydraulic head contours (equipotential lines), unless the aquifer is anisotropic. A minimum of three wells defines a sloping plane and local flow direction. However, three wells allow for only a local, linear approximation of the groundwater flow direction.

Vertical gradients in groundwater can be computed from hydraulic head measurements at adjacent wells open at different depths. A vertical gradient can also indicate the gaining or losing status of a surface water body such as a lake or stream. This can be accomplished by driving a narrow steel pipe with a slotted conical tip about 0.5 m into the bottom of the water body. The vertical gradient is the difference between water levels in the piezometer and water body, divided by the distance between the bottom of the water body and bottom of the piezometer. A higher water level in the piezometer indicates an upward gradient and gaining condition, whereas a lower level in the piezometer indicates a downward gradient and that surface water is seeping into the ground.

Groundwater: Mining

Hugo A. Loáiciga
Department of Geography, University of California–Santa Barbara, Santa Barbara, California, U.S.A.

INTRODUCTION

Groundwater mining is defined as the extraction of ground water from aquifers by humans. This definition is analogous to that concerning the mining of mineral resources. There is, however, a fundamental difference between groundwater mining and the mining of minerals. Groundwater is, in most cases, a renewable resource. On the other hand, mineral resources, such as silver and gold ores, are non-renewable. Groundwater is a renewable resource because it is replenished naturally by fluxes that arise in the hydrologic cycle. The sum of the fluxes that replenish ground water is called recharge. During periods of plentiful precipitation, and in the absence of human intervention, aquifers are replenished by recharge. During droughts, groundwater storage and groundwater levels decline due to low levels of recharge. There are also groundwater deposits of ''fossil'' ground waters that have become isolated from the hydrologic cycle. These deposits resemble in many respects oil reservoirs. One important shared characteristic is that extraction of the resource, be it ground water or oil, produces an irreversible reduction in its stock. Continued mining of such fossil deposits leads to their eventual depletion.

This article is devoted to an analysis of the effects of groundwater mining on renewable ground water. The latter constitutes most of the ground water used by humans. Principles of sustainable groundwater mining are presented and illustrated with data from one of the most productive aquifers in the world.

GROUNDWATER MINING AND THE WATER BALANCE

Let us consider an aquifer that is subject to groundwater mining. Assume that the amount of groundwater storage is denoted by S, and that recharge (R), groundwater pumping (W), and outflow (G) affect the status of storage as shown in Fig. 1. Groundwater pumping is the means by which ground water is mined. The recharge is the net water flux into groundwater storage from surface water sources. It includes percolation, seepage (from rivers and lakes), and artificial recharge (by wells and spreading basins). Groundwater uptake by plants, baseflow, and spring flow abstractions from groundwater are also included in the calculation of aquifer recharge. The groundwater outflow (G) term is the net of subsurface fluxes in and out of groundwater storage across the (subsurface) aquifer boundaries. From water-balance considerations for a period of duration T, it is evident that the change in groundwater storage is given by the following equation:

$$S(T) - S(0) = \int_{t=0}^{t=T} [R(t) - W(t) - G(t)] \quad T \geq 0 \tag{1}$$

in which $S(0)$ and $S(T)$ are the storages at time zero (initial storage) and time T, respectively.

Pumping may be measured accurately with well meters. It commonly exhibits a strong seasonal pattern, rising during periods of low precipitation (i.e., during dry seasons) and subsiding during wet seasons. This is true for urban and agricultural groundwater uses. In addition, as a result of population growth, urban groundwater mining typically exhibits an increasing trend over time.[1] The recharge flux in Eq. (1) is, in general, difficult to estimate. Recharge depends strongly on the amount of precipitation, and, thus, it tends to replicate the seasonality and inter-annual variability observed in the climate specific to the region where the aquifer is found.[2] The groundwater outflow term (G) is not amenable to direct measurement. Instead, it must be estimated by indirect methods.[3] When the aquifer boundaries coincide with groundwater divides, the outflow term (G) is negligible.

Fig. 2 shows the evolution of annual groundwater recharge, pumping, and spring flow from 1934 to 1995 in the Edwards Aquifer of Texas, one of the most productive groundwater systems in the world.[1] The subsurface outflow term (G) in the Edwards aquifer is negligible.[4] In this instance, it is advantageous to treat separately the flux of water into the aquifer (i.e., recharge) from the discharge of ground water at several large springs (i.e., spring flow).

Recharge takes place primarily by means of stream seepage along aquifer outcrops. It is seen in Fig. 2 that recharge shows large inter-annual fluctuations, and that those fluctuations appear to become larger and larger over time. Groundwater pumping displays a

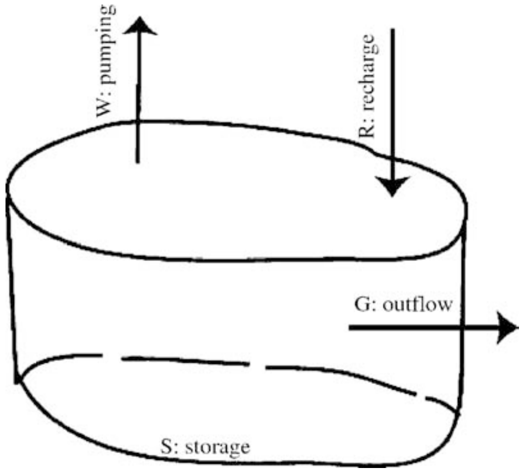

Fig. 1 Schematic of a mined aquifer.

long-term increasing trend until year 1985, even during the drought of 1936–1959. The intermittent lows in groundwater pumping after 1985 were caused by Court orders imposed on the mining of the Edwards Aquifer to protect aquatic habitats in the discharge zone near springs.[1]

Spring flow is concentrated along large fault springs that define the discharge zone of the Edwards aquifer.[1] As shown in Fig. 2, it is a smoothed-out and dampened replica of annual recharge. It lags recharge by a short period of time, typically less than 2 yr. The time series of spring flow shown in Fig. 2 does not represent natural groundwater discharge because of the effect that groundwater pumping had on spring flow. If the Edwards aquifer had not been mined in the period 1934–1995, the amount of spring flow would have been roughly equal to the amount of recharge. The latter is demonstrated in Fig. 3, where the cumulative recharge and the cumulative pumping plus spring flow time series are plotted. By adding pumping to spring flow, the latter is reconstructed to what would have been its natural value during the period of analysis. The differences between the two time series plotted in Fig. 3 arise from unequal beginning and ending aquifer storages.

Fig. 4 shows the change in storage, $S(T) - S(0)$, calculated from Eq. (1) for the Edwards Aquifer data shown in Fig. 2. It is seen there that during the drought period between 1936 (point 1) and 1956 (point 2) aquifer storage dropped by $3500 \times 10^6\,\mathrm{m}^3$ as a result of groundwater mining. Between 1956 and 1992 (point 3) ground water continued to be mined, yet, there was a recovery of aquifer storage equal to $5100 \times 10^6\,\mathrm{m}^3$. Since the Edwards Aquifer was severely de-watered in 1956—demonstrated by the drying of major springs—and in 1992 water levels rose to historically high levels after heavy El Niño rainfall, it can be concluded that the Edwards Aquifer extractable storage must be on the order of $5100 \times 10^6\,\mathrm{m}^3$. The evolution of storage $S(T)$ captures one important aspect of groundwater mining in any aquifer. For a full grasp of groundwater mining, however, one must broaden the scope of its analysis.

GROUNDWATER MINING AND SUSTAINABLE AQUIFER USE

The key question regarding groundwater mining is how to pump ground water from an aquifer without compromising the availability of ground water in storage, while maintaining its natural water quality and protecting water bodies that may depend on the status of groundwater storage (e.g., influent streams and lakes, springs, and wetlands). Groundwater mining concerns must go beyond the amount of ground water extracted or left in aquifer storage. Other environmental considerations must be taken into account in determining the best way to mine an aquifer. Groundwater mining that ensures a long-term supply of good-quality water while protecting the environment is what we call sustainable groundwater mining. Simplistic rules such

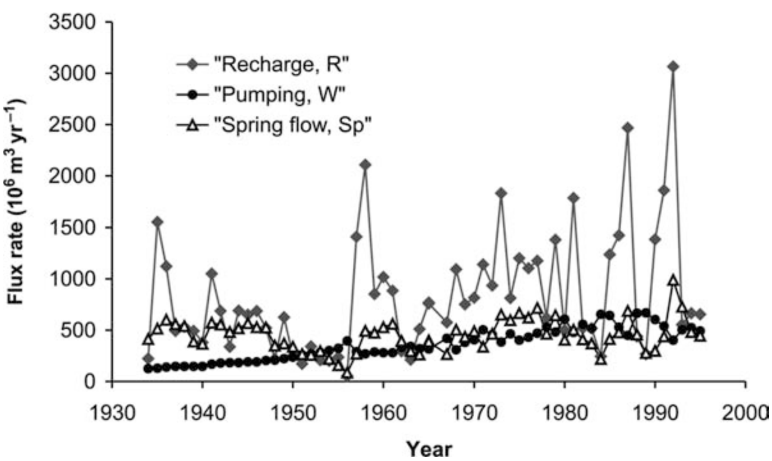

Fig. 2 Groundwater pumping (W), recharge (R), and spring flow (Sp) in the Edwards Aquifer.

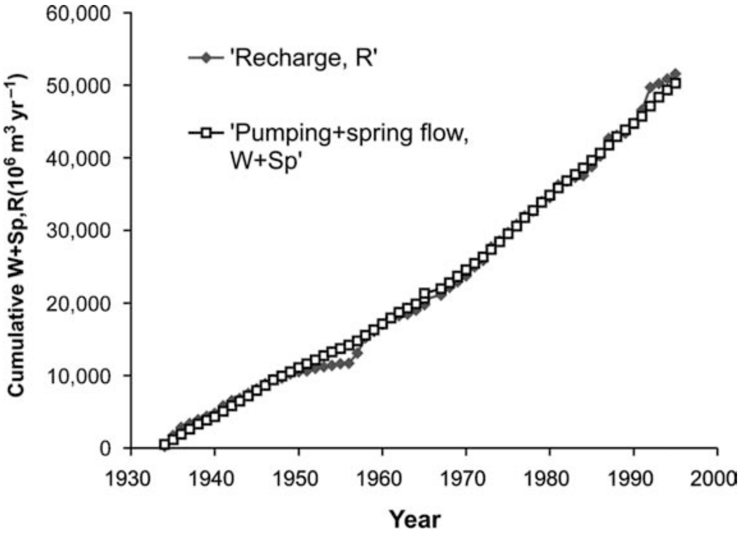

Fig. 3 Cumulative recharge and cumulative pumping plus spring flow from 1934 to 1995.

as ‘‘groundwater pumping shall not exceed the long-term average recharge’’ are inadequate to cope with the spectrum of impacts associated with groundwater mining. This is so because even if pumping does not exceed the long-term recharge (which, by the way, may be difficult to estimate accurately), groundwater storage may still reach levels that are detrimental from the perspective of water-quality protection and environmental conservation. The cyclic and variable nature of recharge, and the instinctive drive to intensify groundwater mining during periods of low precipitation (to irrigate crops for example, or to water lawns and gardens[5]) pose serious challenges to sustainable groundwater mining during periods of low precipitation, be they seasonal or associated with protracted drought.[6]

Fig. 5 shows a graph of the cumulative recharge in the Edwards Aquifer. The cumulative or mass recharge is expressed by:

$$\text{Mass recharge} = \sum_{t=0}^{T} \text{recharge}(t) \quad T \geq 0 \tag{2}$$

The curve shown in Fig. 5 is called a ‘‘mass curve’’ for the Edwards Aquifer. Mass curves are widely used in the analysis of stream flow time series for the purpose of sizing surface reservoirs or determining reservoir releases.[7] The mass curve is used herein to provide a first estimate of long-term groundwater pumping. Assume an extractable groundwater storage of $5100 \times 10^6\,\text{m}^3$, which was estimated from Fig. 4. One finds that the minimum-slope tangent to the mass curve (in this case drawn through point A in Fig. 5) that encompasses the estimated groundwater storage of $5100 \times 10^6\,\text{m}^3$ has a slope of $690 \times 10^6\,\text{m}^3\,\text{yr}^{-1}$

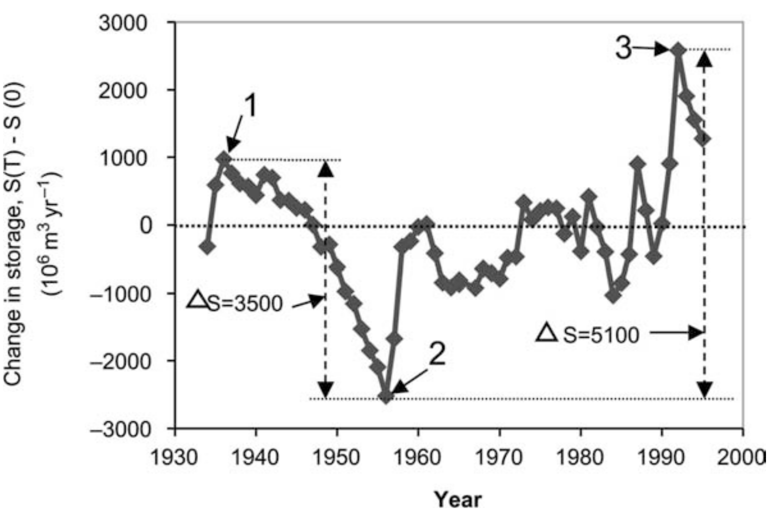

Fig. 4 Changes in aquifer storage as a result of groundwater mining and climate.

Global–Groundwater

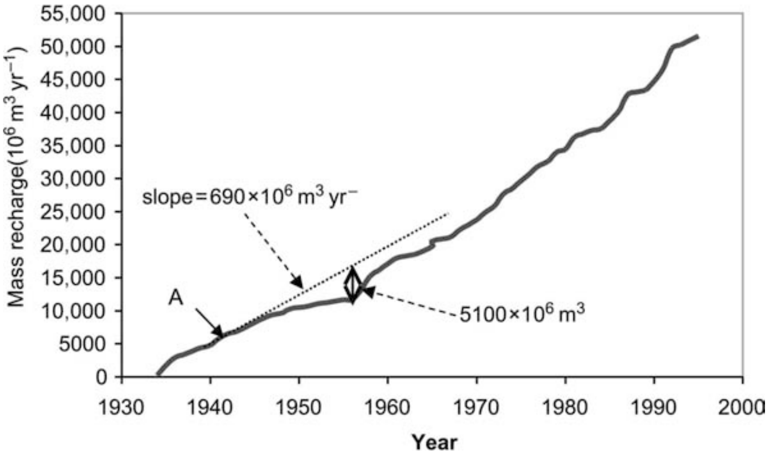

Fig. 5 Mass curve and the estimation of an average groundwater mining rate.

(see Fig. 5). Ignoring spring flow and related impacts associated with groundwater mining, the magnitude of that slope equals the average long-term groundwater pumping that would be consistent with an usable aquifer storage of $5100 \times 10^6 \, m^3$. It turns out, however, that a pumping rate of $690 \times 10^6 \times m^3 \times yr^{-1}$ would cause exceedingly low spring flow values during low-recharge years and adverse and irreversible impacts on aquatic ecosystems supported by the Edwards Aquifer springs.[1] More detailed simulations by the author, which were carried out with a specially calibrated numerical groundwater model for the Edwards Aquifer,[1] indicated that during low-recharge periods (1947–1956, for example) the aquifer may not be mined at a rate greater than $123 \times 10^6 \, m^3 \, yr^{-1}$ in order to protect minimum spring flow levels and aquatic habitats. For comparison, during the period 1934–1995, the average pumping in the Edwards Aquifer was on the order of $360 \times 10^6 \, m^3 \, yr^{-1}$, while during the high-growth period 1970–1995 pumping averaged $514 \times 10^6 \, m^3 \, yr^{-1}$, a mining strategy that has left a legacy of adverse ecological impacts.

CONCLUSIONS

The former example illustrates important factors that must be considered in the planning of sustainable groundwater mining. The first is the long-term behavior of aquifer recharge and aquifer discharge (besides artificial pumping). Secondly, one must have an in-depth understanding of the hydraulic and ecological linkages of aquifer storage and discharge to dependent ecosystems. The rate of pumping must be adjusted to the natural fluctuations of recharge. This requires detailed numerical simulations of aquifer response to pumping under specific recharge conditions. Although water-quality deterioration effected by groundwater mining was not specifically addressed in this work, it is another consideration that must be taken into account in planning sustainable groundwater mining strategies. The excessive lowering of aquifer storage may induce the upwelling of poor-quality groundwater and/or the intrusion of saltwater.

Groundwater: Modeling

Jesús Carrera
Technical University of Catalonia (UPC), Barcelona, Spain

INTRODUCTION

A model is an entity built to reproduce some aspect of the behavior of a natural system. In the context of groundwater, aspects to be reproduced may include: groundwater flow (heads, water velocities, etc.); solute transport (concentrations, solute fluxes, etc.); reactive transport (concentrations of chemical species reacting among themselves and with the solid matrix, minerals dissolving or precipitating, etc.); multiphase flow (fractions of water, air, non-aqueous phase liquids, etc.); energy (soil temperature, surface radiation, etc.); and so forth.

Depending on the type of description of reality that one is seeking (qualitative or quantitative), models can be classified as conceptual or mathematical. A conceptual model is a qualitative description of "some aspect of the behavior of a natural system." This description is usually verbal, but may also be accompanied by figures and graphs. In the groundwater flow context, a conceptual model involves defining the origin of water (areas and processes of recharge) and the way it flows through and exits the aquifer. In contrast, a mathematical model is an abstract description (abstract in the sense that it is based on variables, equations, and the like) of "some aspect of the behavior of a natural system." However, the motivation of mathematical models is not abstraction, but rather quantification. For example, a groundwater flow mathematical model should yield the time evolution of heads and fluxes (water movements) at every point in the aquifer.

Both conceptual and mathematical models seek understanding. Some would argue that understanding is not possible without quantification. Reversely, one cannot even think of writing equations without some sort of qualitative understanding. The methods of conceptual modeling are those of conventional hydrogeology (study geology, measure heads and hydraulic parameters, hydrochemistry, etc). On the other hand, the methods of mathematical modeling (discretization, calibration, etc.) are more specific. Yet, it should be clear from the outset that conceptualization is the first step in modeling and that mathematical modeling helps in building firm conceptual models.

Depending on the manner in which equations are solved, models can be classified as: analog, analytical, and numerical. Analog models are based on a physical simulation of a phenomenon governed by the same equation(s) as that of our natural system. For example, because of the equivalence between electrostatics and steady state flow, one may use conductive paper subject to an electrical current to solve the flow equation (a parallelism can be established between electric potential and hydraulic head). This kind of application, however, is restricted mainly to teaching. Boxes of resistances and condensators were used in the 1950s and 1960s as analog aquifer models, but they have become inefficient compared to computers. As a result, analog models are no longer used in practice.

Analytical models are based on closed-form solutions to the groundwater flow and transport equations. They are convenient in the sense that they are easy to evaluate and intuitive (visual inspection of the equation may yield an idea of the phenomenon). As a result, they are used very frequently. Examples include solutions of problems in well hydraulics, tracer movement, etc.

Numerical models are based on discretizing the partial differential equations governing flow and transport. This leads to linear systems of equations that can only be solved with the aid of computers. The advantage of numerical models lies in their generality. Analytical models are constrained to homogeneous domains and very simple geometry and boundary conditions. Numerical models, on the other hand, can handle spatially and temporally variable properties, arbitrary geometry and boundary conditions, and complex processes. The price to pay is methodological singularity. Analytical models are easy to use. Numerical models can be complex and, often, difficult.

Because of the methodological singularity mentioned above, this chapter concentrates on mathematical numerical models. Analytical solutions are not discussed. In addition, conceptual modeling will be discussed as the first step in modeling, but not by itself.

WHAT CAN BE MODELED AND WHAT FOR?

Modeled Phenomena

The most basic phenomenon is groundwater flow (Fig. 1) because of its intrinsic importance and because it is needed for subsequent processes. In essence, the flow equation expresses two things. First, groundwater

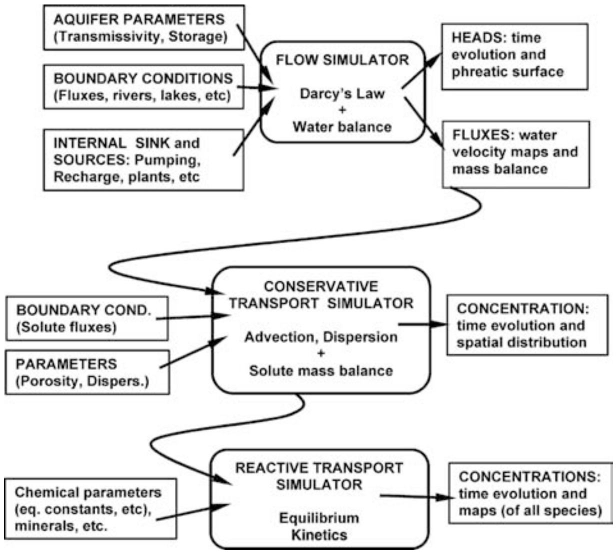

Fig. 1 A groundwater flow model involves using a flow simulator to take aquifer parameters, boundary conditions, and internal sink and sources as inputs and obtain heads and water fluxes as output. Water fluxes are used in conservative transport models, together with porosity, diffusivity, and solute mass inflows, to yield time evolution and spatial distribution of inert tracers.

moves according to Darcy's law. Second, a mass balance must be satisfied in the whole aquifer and in each of its parts. Therefore, the main output from flow models is a mass balance: classified inflows, outflows, and storage variations. The output also includes where water flows through the aquifer (water fluxes) and heads (water levels in the aquifer). In essence, input data are a thorough description of hydraulic conductivity (and/or transmissivity), storativity, recharge/discharge throughout the model domain, as well as conditions at the model boundaries. Obviously, these data are never available, and the modeler has to use a good deal of ingenuity to generate them. This is where the conceptual model becomes important.

Specific cases of flow phenomena are unsaturated and multiphase flow. In the first case, one models water flow in the vadose zone or, in general, in areas where water does not fill all the pores.[1] Therefore, besides heads and fluxes, one must work with water contents (volume of water per unit volume of aquifer), capillary pressures and suctions (difference between water and air pressure). From the input viewpoint, the main singularity of unsaturated flow is the need to specify the retention curve (water content vs. suction) and relative permeability (permeability vs. water content). The multiphase flow case is similar, but includes several fluids (phases). It is used to represent the flow of air or mixtures of liquids, singularly non-aqueous phase liquids (NAPLs), which have been the subject of much research in recent years.[2]

Conservative transport refers to the movement of inert substances dissolved in water. Solutes are affected by advection (displacement of the solute as linked to flowing water) and dispersion (dilution of contaminated water with clean water, which causes the size of the contaminated area to grow while reducing peak concentrations). The main input to a solute transport model is the output of a flow model (water fluxes). Additionally, porosity and dispersivity need to be specified (Fig. 1). The output is the time evolution and spatial distribution of concentrations. While the amount of data needed for solute transport modeling is relatively small, it must be stressed that solute transport is extremely sensitive to variability and errors in water fluxes. A flow model may be good enough for flow results (heads and water balances) but insufficiently detailed to yield water fluxes good enough for solute transport. Therefore, modeling solute transport ends up being rather difficult.

Reactive transport refers to the movement of solutes that react among themselves and with the soil phase. Reactions can be of many kinds, ranging from sorption of a contaminant onto a solid surface to redox phenomena controlling the degradation of an organic pollutant. Input for reactive transport modeling includes not only the output of flow and conservative transport models but also the equilibrium constants of the reactions (usually available from chemistry databases) and the parameters controlling reaction kinetics. However, the most difficult input is the proper identification of relevant chemical processes. Model output includes the concentrations of all chemical species, the reaction rates, etc.

Coupled models refer to models in which different phenomena are affected reciprocally. Density dependent flow is a typical example. Variations in density affect groundwater flow (e.g., dense sea water sinks under light fresh water), which in turn affects solute transport and, hence, density distribution. Other coupled phenomena are the non-isothermal flow of water (coupling flow and energy transport) and the mechanically driven flow of water (coupling flow and mechanical deformation equations).

What Are Models Built For?

While discussing the usage of models, it is convenient to distinguish between site-specific models and generic models. The former are aimed at describing a specific aquifer while the latter emphasize processes, regardless of where they take place.

Groundwater management is the ideal use of site-specific models. Management involves deciding where to extract and/or inject water to satisfy water needs while ensuring water quality and other constraints.

In this context, it is important to point out that a model is essentially a system for accounting water fluxes and stores (Fig. 2) in the same way that the accounting system of a company keeps track of money fluxes and reserves. No one would imagine a well-managed company without a proper accounting system. Aquifers will not be managed accurately until they have a model running on real time. Unfortunately, at present, this is still a dream. Because of the difficulties in building and maintaining models and because of legal and practical difficulties to manage aquifers in real time, models are rarely, if ever, used in this fashion.

Instead, models are often used as decision support tools. Building an accurate model is very difficult and time consuming. As a result, one can rarely expect models to yield exact predictions. However, approximate models are much easier to build. These do not result in precise forecasts but normally allow reasonable assessments of the outcome of different management alternatives, i.e., the relative advantages and disadvantages of each alternative can be evaluated and the options ranked. This is usually all one needs for decision making.

This type of use is very frequent in aquifer rehabilitation, where one has to choose among several alternatives, including the option of doing nothing.[3] Models are also used for supporting aquifer exploration policies, i.e., for answering questions such as ‘‘how much water can be extracted?,’’ ‘‘where should one pump to minimize environmental impact?,’’ etc. In fact, a large body of literature is devoted to this kind of questions in an optimal fashion.[4]

Site-specific models are most frequently used, however, as a tool to support aquifer characterization efforts. This is somewhat ironic because a model is

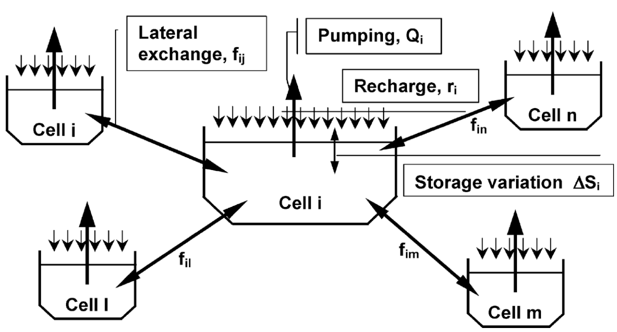

Fig. 2 A groundwater model is the accounting system of an aquifer. It keeps track of the balance of each section (cells or compartments in the groundwater language) by evaluating exchanges with the outside (pumping Q_i, recharge, r_i, etc.) and with the adjacent sections (f_{ij}). The difference between inflow and outflow is equal to the variation in reserves (storage variation, ΔS_i). A well-managed company needs an accounting system, and so does an aquifer.

an essentially quantitative tool while site characterization is rather qualitative. Yet, experience dictates that modeling is the only way to consistently integrate the kind of data available in site characterization. These data are very diverse and range from geologic maps to isotope concentrations. One can use vastly different models to verbally explain all observations. Quantitative consistency is not so easy to check and requires the use of a model. Because of the difficulties in fully describing all data, this kind of model use is rarely described in the scientific literature.

Models can also be used in generic fashion as teaching or research tools to gain understanding on physicochemical phenomena. In these cases, they do not aim at representing a specific aquifer, but at evaluating the role of some processes under idealized conditions. A classical example of this type of use is the analysis of flow on regional basins.[5] Models are used in this fashion to explain geological processes.[6,7] Much emphasis has been placed in recent years on the evaluation of the effects of spatial variability. This involves issues such as upscaling, i.e., finding the relationship between large-scale effective parameters and small-scale measurements;[8] or analysis of hydraulic tests.[9]

HOW ARE MODELS BUILT: THE MODELING PROCESS

The procedure to build a model is outlined in Fig. 3. First, one defines a conceptual model (i.e., zones of recharge, boundaries of aquifers, etc). Second, one discretizes the model domain into a finite element or finite difference grid. This can be entered as input data for a simulation code. Unfortunately, output data will rarely fit the observed aquifer heads and concentrations. This is what motivates calibration, i.e., the modification of model parameters to ensure that model output is indeed similar to what has been observed in reality. The model thus calibrated can be considered a ‘‘representation of the natural system’’ and can be used for management or simulation purposes.

The above procedure is formally described in Fig. 4. This section is devoted to discussing in detail the modeling steps as previously described.[10–12] In practice, the effort behind each of these tasks may be very sensitive to the objectives of the studies and model. For the time being, we will assume that one is building a model aimed at describing reality in detail for the purpose making predictions.

Conceptualization

Modeling starts by defining which processes are important and how they are represented in the model.

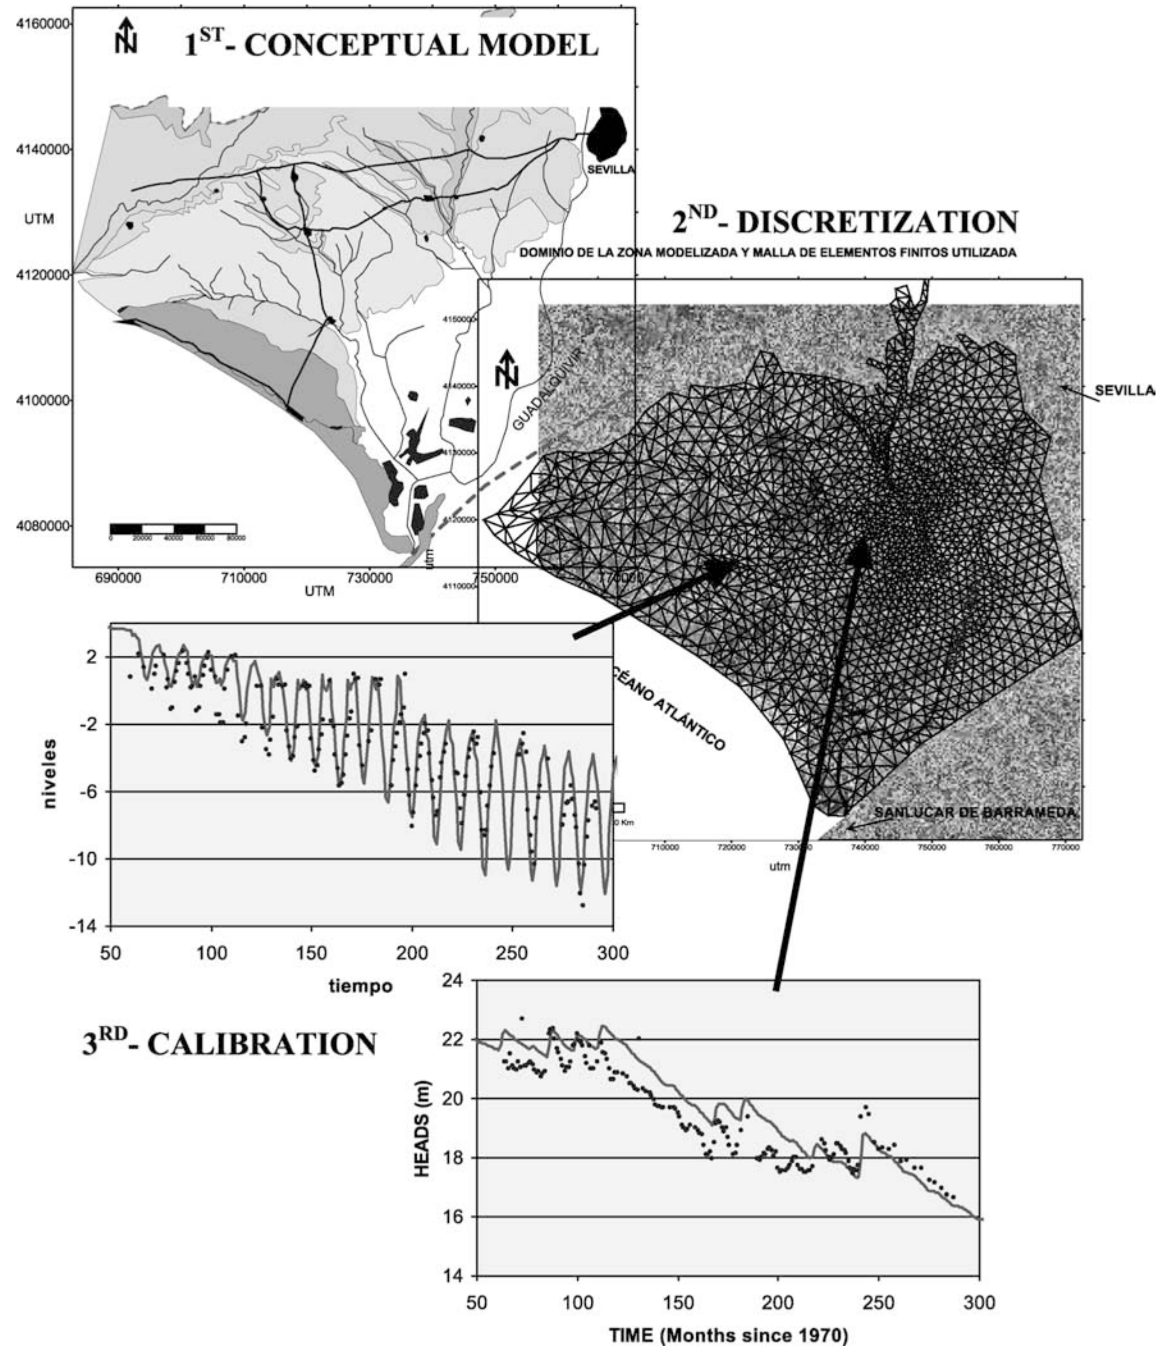

Fig. 3 Building a model involves three basic steps: conceptualization, discretization, and calibration. Example from the Almonte-Marismas aquifer.

Definition of the relevant processes is termed ''process identification'' and it is needed for several reasons. First, the number of processes that may affect flow and transport is very large. For practical reasons, the modeler is forced to select those that affect the phenomenon under study, most significantly. Second, not all processes are well understood and they have to be treated in a simplified manner. In short, process identification involves simplifications, both in the choice of the processes and in the way they are implemented in the model.

Model structure identification refers to the definition of parameter variability, boundary conditions, etc. In a somewhat narrower but more systematic sense, model structure identification implies expressing the model in terms of a finite number of unknowns called model parameters. Parameters controlling the above processes are variable in space. In some cases,

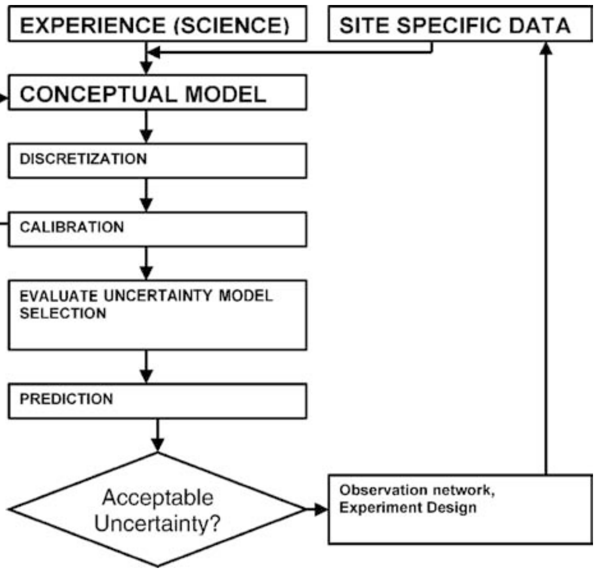

Fig. 4 A formal description of the modeling process. Modeling starts with an understanding of the natural system (conceptual model), which is based on experience about such kind of systems (science) and on data from the site. Writing the conceptual model in a manner adequate for computer solution requires discretization. The resulting model is still dependent on many parameters that are uncertain. During calibration, these parameters are adjusted so that model outputs are close to measurements (recall Fig. 3). Model predictions may be uncertain because so are the fitted parameters or because different models are consistent with observations. If uncertainty is unacceptably high, one should perform additional measurements or experiments and redo the whole process.

they also vary in time or depend on heads and/or concentrations. As discussed earlier, data are scarce so that such variability cannot be expressed accurately. Therefore, the modeler is also forced to make numerous simplifications to express the patterns of parameter variations, boundary conditions, etc. These assumptions are reflected on what is denoted as model structure.

The conceptualization step of any modeling effort is somewhat subjective and dependent on the modeler's ingenuity, experience, scientific background, and way of looking at the data. Selection of the physicochemical processes to be included in the model is only rarely the most difficult issue. The most important processes affecting the movement of water and solutes underground (advection, dispersion, sorption, etc.) are relatively well known. Ignoring a relevant process will only be caused by misjudgments and should be pointed out by reviewers, which illustrates why reviewing by others is important. Difficulties arise when trying to characterize those processes and, more specifically, the spatial variability of controlling parameters.

In spite of the large amount of data usually available, their qualitative nature prevents a detailed definition of the conceptual model. Thus, more than one description of the system may result from the conceptualization step. Selecting one conceptual model among several alternatives is sometimes performed during calibration, as discussed later.

Discretization

Strictly speaking, discretization consists of substituting a continuum by a discrete system. However, we are extending this term here to describe the whole process of going from mathematical equations, derived from the conceptual model, to numerical expressions that can be solved by a computer. Closely related is the issue of verification, which refers to ensuring that a code accurately solves the equations that it is claimed to solve. As such, verification is a code-dependent concept. However, using a verified code is not sufficient for mathematical correctness. One should also make sure that time and space discretization is adequate for the problem being addressed. Moreover, numerical implementation of a conceptual model is not always straightforward international code comparison projects; INTRANCOIN and HYDROCOIN have shown the need for sound conceptual models and independent checks of calculation results. Even well-posed mathematical problems lead to widely different solutions when solved by different people, because of slight variations in the solution methodology or misinterpretations in the formulation.[13] The reasons behind these differences and ways to solve them only become apparent after discussions among them.

The main concern during discretization is accuracy. In this sense, it is not conceptually difficult, although it can be complex. Accuracy is not only restricted to numerical errors (differences between numerical and exact solutions of the involved equations) but also refers to the precision with which the structure of spatial variability reproduces the natural system.

Calibration and Error Analysis

The choice of numerical values for model parameters is made during calibration, which consists of finding those values that grant a good reproduction of head and concentration data (Fig. 3) and are consistent with prior independent information.

Calibration is rarely straightforward. Data come from various sources, with varying degrees of accuracy and levels of representativeness. Some parameters can be measured directly in the field, but such measurements are usually scarce and prone to error. Furthermore, since measurements are most often performed on scales and under conditions different from those required for modeling purposes, they tend to be both numerically and conceptually different from model parameters. The most dramatic example of this is dispersivity, whose representative value increases with the scale of measurement so that dispersivities derived from tracer tests cannot be used directly in a large-scale model. As a result, model parameters are calibrated by ensuring that simulated heads and concentrations are close to the corresponding field measurements.

Calibration can be tedious and time consuming because many combinations of parameters have to be evaluated, which also makes it prone to be incomplete. This, coupled to difficulties in taking into account the reliability of different pieces of information, makes it very hard to evaluate the quality of results. Therefore, it is not surprising that significant efforts have been devoted to the development of automatic calibration methods.[14–16]

Model Selection

The first step in any modeling effort involves constructing a conceptual model, describing it by means of appropriate governing equations, and translating the latter into a computer code. Model selection involves the process of choosing between alternative model forms. Methods for model selection can be classified into three broad categories. The first category is based on a comparative analysis of residuals (differences between measured and computed system responses) using objective as well as subjective criteria. The second category is denoted parameter assessment and involves evaluating whether or not computed parameters can be considered as "reasonable." The third category relies on theoretical measures of model validity known as "identification criteria." In practice, all three categories will be needed: residual analysis and parameter assessment suggest ways to modify an existing model and the resulting improvement in model performance is evaluated on the basis of identification criteria. If the modified model is judged an improvement over the previous model, the former is accepted and the latter discarded.

The most widely used tool of model identification is residual analysis. In the groundwater context, the spatial and frequency distributions of head and concentration residuals are very useful in pointing towards aspects of the model that need to be modified. For example, a long tail in the breakthrough curve not properly simulated by a single porosity model may point to a need for incorporating matrix diffusion or a similar mechanism. These modifications should, whenever possible, be guided by independent information. Qualitative data such as lithology, geological structure, geomorphology, and hydrochemistry are often useful for this purpose. A particular behavioral pattern of the residuals may be the result of varied causes that are often difficult to isolate. Spatial and/or temporal correlation among residuals may be a consequence of not only improper conceptualization, but also measurement or numerical errors. Simplifications in simulating the stresses exerted over the system are always made and they lead to correlation among residuals. Distinguishing between correlations caused by improper conceptualization and measurement errors is not an easy matter. This makes analysis of residuals a limited tool for model selection.

An expedite way of evaluating a model concept is based on assessing whether or not the parameters representing physico-chemical properties can be considered "reasonable;" i.e., whether or not their values make sense and/or are consistent with those obtained elsewhere. Meaningless parameters can be a consequence of either poor conceptualization or instability. If a relevant process is ignored during conceptualization, the effect of such process may be reproduced by some other parameter. For example, the effect of sorption is to keep part of the solute attached to the solid phase, hence retarding the movement of the solute mass; in linear instantaneous sorption, this effect cannot be distinguished from standard storage in the pores. Therefore, if one needs an absent porosity (e.g., larger than one) to fit observation, one should consider the possibility of including sorption in the model. However, despite this example, parameter assessment tends to be more useful for ruling out some model concepts than for giving a hint on how to modify an inadequate model. Residual analysis is usually more helpful for this purpose.

Instability may also lead to unreasonable parameter estimates during automatic calibration, despite the validity of the conceptual model. When the number of data or their information content is low, small perturbations in the measurement or deviations in the model may lead to drastically different parameter estimates. When this happens, the model may obtain equally good fits with widely different parameter sets. Thus, one may converge to a senseless parameter set while missing other perfectly meaningful sets. This type of behavior can be easily identified by means of a thorough error analysis and corrected by fixing the values of one or several parameters.[14]

Predictions and Uncertainty

Formulation of predictions involves a conceptualization of its own. Quite often, the stresses, whose response is to be predicted, lead to significant changes in the natural system, so that the structure used for calibration is no longer valid for prediction. Changes in the hydrochemical conditions or in the flow geometry may have to be incorporated into the model. While numerical models can be used for network design or as investigation tools, most models are built in order to study the response of the medium to various scenario alternatives. Therefore, uncertainties on future natural and man-induced stresses also cause model predictions to be uncertain. Finally, even if future conditions and conceptual model are exactly known, errors in model parameters will still cause errors in the predictions. In summary, three types of prediction uncertainties can be identified: conceptual model uncertainties; stresses uncertainties; and parameters uncertainties.

The first group includes two types of problems. One is related to model selection during calibration. That is, more than one conceptual model may have been properly calibrated and data may not suffice to distinguish which one is the closest to reality. It is clear that such indetermination should be carried into the prediction stage because both models may lead to widely different results under future conditions. The second type of problems arise from improper extension of calibration to prediction conditions, i.e., from not taking into account changes in the natural system or in the scale of the problem. The only way we think about dealing with this problem consists of evaluating carefully whether or not the assumptions in which the calibration was based are still valid under future conditions. Indeed, model uncertainties can be very large.

We do not think that, strictly speaking, the second type of uncertainties, those associated with future stresses, falls in the realm of modeling. While future stresses may affect the validity of the model, they are external to it. In any case, this type of uncertainty is evaluated by carrying out simulations under a number of alternative scenarios, whose definition is an important subject in itself.

The last set of prediction uncertainties is the one associated with parameter uncertainties, which can be quantified quite well.

CONCLUSION

Groundwater modeling involves so many subjective decisions that it can be considered as an art. This is somewhat contrary to the widely accepted perception of models as something objective. The fact is that numerous assumptions need to be made both about the selection of relevant processes and about the manner of representing them in the computer. All these assumptions are specified in the conceptual model.

The result relies so heavily on conceptualization that models ought to be viewed as theories about the behavior of natural systems. Model predictions should rarely be viewed as firm statements about the future evolution of aquifers. Rather, they should be considered references against which actual data has to be compared. Codes do exist for modeling most processes affecting groundwater (flow, transport, reactions, thermomechanics, etc). It is lack of understanding and lack of data what limits the actual application of those codes.

Having specified a conceptual model, the remaining steps (discretization, calibration, uncertainty analysis, prediction) are relatively objective, in the sense that systematic procedures can be followed. This explains why conceptualization is so important. It also explains why modeling is the best way of integrating widely different data. Uncertain as it is, it may represent unambiguously the overall knowledge of the aquifer.

Models represent the water balance (or solute balance, or energy balance) at the overall aquifer and at each of its parts. Therefore, they can also be viewed as accounting systems. It is argued that well managed aquifers need real time models to help decision making, the same way that well managed companies need financial accounting systems. This is the challenge modelers must meet in the near future.

Groundwater: Modeling Using Numerical Methods

Jesús Carrera
Technical University of Catalonia (UPC), Barcelona, Spain

INTRODUCTION

Numerical methods are tools used by people who develop codes for solving equations governing groundwater problems. All problems that we are interested in are governed by partial differential equations. The computer cannot directly solve these and one needs numerical methods to transform them into a solvable form. In essence, all numerical methods are based on, first, discretizing (i.e., substituting the continuum by a discrete medium) and, second, approximating the differential equation by a system of equations. Numerical methods differ in the way discretization and approximations are performed. To illustrate these two steps, we will first develop them in detail for a generic numerical method.

We will, then, introduce the classical numerical methods (finite element, finite differences, etc.). This section ends with a discussion on specific methods for solute transport.

A GENERIC NUMERICAL METHOD FOR SOLVING GROUNDWATER FLOW

As mentioned earlier, all methods require, first, discretizing and, second, approximating the physical phenomenon. For the generic method we are going to present here, discretization will be performed as shown in Fig. 1. That is, the continuum aquifer domain will be substituted by a discrete number of cells. Furthermore, the continuum aquifer heads, $h(x,y)$, are substituted by a discrete number of model heads, h_i.

The second step, approximation, can be made in different manners. For the purpose of this section, it is sufficient to bear in mind that the flow equation is nothing but a mass balance. Therefore, we will express the mass balance in cell i as change in storage equals inflows minus outflows.

$$\Delta S_i = f_{ij} + f_{il} + f_{im} + f_{in} + g_i \tag{1}$$

where ΔS_i is the rate of change in storage during one time step (say, between time t^k and time t^{k+1}); f_{ij} is the inflow into cell i from cell j (and the same for f_{il}, f_{im}, and f_{in}); and g_i are external inflows into cell i (for example, recharge, minus pumping, minus evaporation, minus river outflow, etc.). Each of the terms in Eq. (1) is relatively easy to approximate. Storage variation can be derived from the definition of storage coefficient, (S is the change in volume of water stored per unit surface area of aquifer and per unit change in head):

$$\Delta S_i = SA_i \frac{(h_i^{k+1} - h_i^k)}{\Delta t} \tag{2}$$

where A_i is the surface area of cell i, h_i^k is the head in node i at time k and $\Delta t = t^{k+1} - t^k$ is the time step. Darcy's law gives lateral inflows

$$f_{ij} = -Tw_{ij} \frac{h_i - h_j}{L_{ji}} = a_{ij}(h_i - h_j) \tag{3}$$

where T is transmissivity; w_{ij} is the width of the connection between nodes i and j; L_{ji} is the length of such connection; and a_{ij} is implicitly defined as $-Tw_{ij}/L_{ji}$. The remaining inflow terms, f_{il}, f_{im}, and f_{in} are defined likewise. Changing these terms to the left-hand side of Eq. (1) and rearranging terms yields:

$$SA_i \frac{(h_i^{k+1} - h_i^k)}{\Delta t} + a_{ii}h_i + a_{ij}h_j + a_{il}h_l + a_{im}h_m + a_{in}h_n = g_i \tag{4}$$

where $a_{ii} = -a_{ij} - a_{il} - a_{im} - a_{in}$. If an equation like Eq. (4) is written for all cells from $i = 1$ through N, N being the number of cells (nodes), the resulting system of equations can be rewritten in matrix form as:

$$\mathbf{D}\frac{(\mathbf{h}^{k+1} - \mathbf{h}^k)}{\Delta t} + \mathbf{Ah} = \mathbf{g} \tag{5}$$

where $\mathbf{D}$ is a diagonal matrix whose i-th diagonal term is precisely SA_i. This matrix is often called storage matrix. $\mathbf{A}$ is the conductance matrix, a square symmetric matrix whose components are a_{ij}. Finally, $\mathbf{g}$ is the source vector.

All the numerical methods to be outlined in subsequent sections lead to equations analogous to Eq. (5). Moreover, the meaning of the terms in such equations is always similar to that in Eq. (5). Namely, the system represents the mass balance at each of the N nodes (cells); specifically the i-th equation represents the mass balance at the i-th node. The first

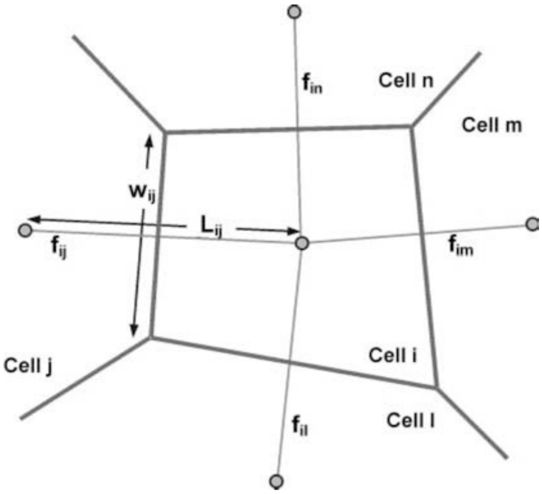

Fig. 1 The system of equations for a generic groundwater model is obtained by establishing a water balance (inputs minus outputs equal storage variations) at each cell. Inputs and outputs include water exchanges with the outside (pumping Q_i, recharge, r_i, etc.) and with adjacent cells (f_{ij}). The latter are expressed, using Darcy's law, as $f_{ij} = T_{ij}w_{ij}(h_j - h_i)/L_{ij}$.

term, $\mathbf{D}(\mathbf{h}^{k+1} - \mathbf{h}^k)/\Delta t$, always represents storage variations. The second term, $\mathbf{Ah}$, represents outflows from minus inflows into the i-th cell from the adjacent cells. Finally, term $\mathbf{g}$ represents external inflows minus outflows (recharge, pumping, etc.) at all i.

Eq. (5) needs to be integrated in time. For this purpose, let us assume that $\mathbf{Ah}$ is evaluated at time $k + 1$ ($\mathbf{Ah}^{k+1}$). Then, Eq. (5) can be rewritten as:

$$\left(\mathbf{A} + \frac{\mathbf{D}}{\Delta t}\right)\mathbf{h}^{k+1} = g + \frac{\mathbf{D}}{\Delta t}\mathbf{h}^k \tag{6}$$

This is simply a linear system, which can be solved using conventional methods.

$$\mathbf{Bh}^{k+1} = \mathbf{b} \tag{7}$$

where $\mathbf{B} = \mathbf{A} + \mathbf{D}/\Delta t$ and $\mathbf{b} = \mathbf{g} + \mathbf{Dh}^k/\Delta t$. This system is solved sequentially in time.

That is, most codes solve Eq. (7) using the following steps (Fig. 2):

1. Input all data. Set $k = 0$.
2. Compute $\mathbf{g}$, $\mathbf{A}$ [Eq. (3)]; $\mathbf{D}$ [Eq. (5)] and $\mathbf{B}$ [Eq. (7)].
3. Set $k = k + 1$.
4. Build $\mathbf{b}$ [Eq. (7)].
5. Solve $\mathbf{Bh}^{k+1} = \mathbf{b}$.
6. If $k = k_{\max}$ (maximum number of time steps), end. Otherwise, return to step 3.

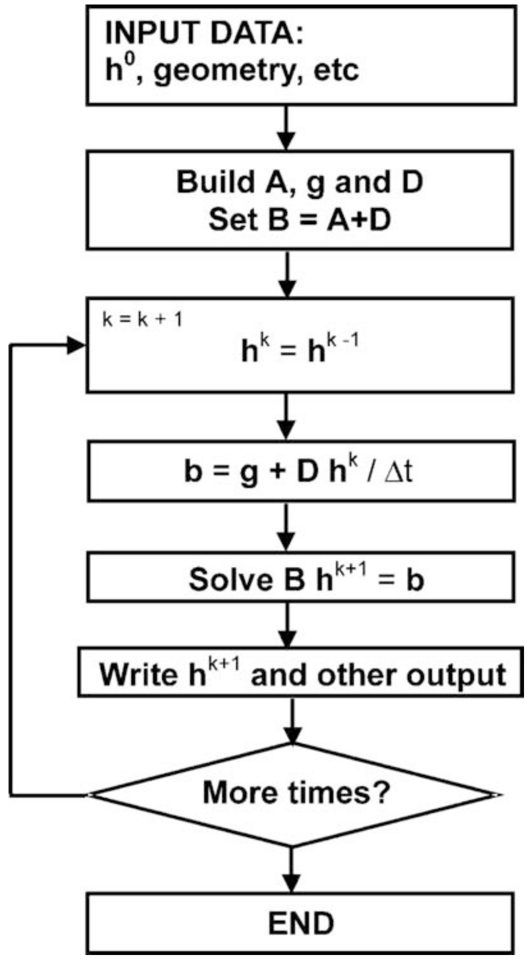

Fig. 2 Basic steps involved in simulating groundwater flow. Heads $\mathbf{h}^{k+1}$ are computed by solving equation $\mathbf{Bh}^{k+1} = \mathbf{b}$. They may be written for later drawings. They are used as initial head for the next time increment. These steps (time loop) are repeated sequentially until the last time is reached.

Most codes follow a structure such as this, although each method displays specific features. Some of these are outlined below.

FINITE DIFFERENCES (FD)

As mentioned at the beginning, numerical methods differ in the way in which the domain is discretized and in the way in which the partial differential equation is transformed into a linear system of equations. In finite differences, the problem domain is discretized in a regular grid (Fig. 3A), usually rectangular (equilateral triangles or hexagons are possible, but very rare). The grid may be centered at the corners (nodes are located at the vertices of the squares) or at the cells (nodes are located at the center of the squares, such as in Fig. 3A.)

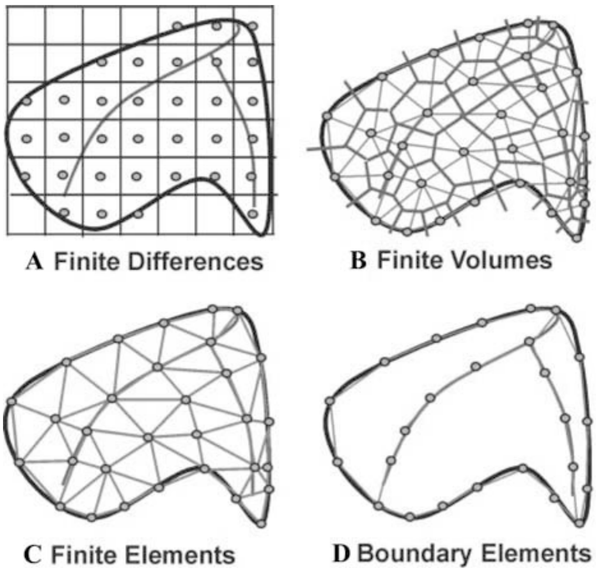

Fig. 3 The most widely spread methods of discretization are Finite Differences, which consists of subdividing the model domain into regular rectangles, and Finite Elements, which is based on dividing the aquifer region into elements of arbitrary shape (often triangles). Finite Volumes, also called Integrated Finite Differences, divides the region into polygons. The Boundary Element Method is very convenient, when applicable, because it only requires discretizing boundaries (both internal and external).

Regarding the approximation of the partial differential equations, several alternatives are possible. The most intuitive consists of substituting all derivates by an incremental ratio. That is, the derivative between adjacent nodes i and j is approximated as:

$$\frac{\partial h}{\partial x} = \frac{h_i - h_j}{\Delta x} \tag{8}$$

where h_i and h_j are heads at nodes i and j, respectively, and Δx is the distance between them. Approximating all derivatives by means of equations analogous to Eq. (8) leads to a system identical to Eq. (5). In fact, the finite differences method is often introduced using a mass balance approach such as the one in the section "A Generic Numerical Method for Solving Groundwater Flow," only using a regular instead of a generic grid. This is the method used in MODFLOW,[1] HST3D,[2] and their children.

INTEGRATED FINITE DIFFERENCES (IFD)

The basic philosophy of this method is very similar to that of the generic method introduced in the generic numerical section. Basically, the domain is discretized in a number of cells centered around arbitrarily located nodes. Frequently, the cells are the Thiessen polygons of the set of nodes. This allows adapting the node density to the problem (e.g., increasing nodes density where accuracy is needed most).

Model equations can be derived using a mass balance approach, such as in the generic method section. Integrating the flow equation over each cell and applying Green's identity to transform volume integrals in boundary fluxes can also yield model equations. This type of approach is the basis of the finite volume method, which is widely used nowadays.

FINITE ELEMENT METHOD

Finite element method (FEM) discretization consists of elements and nodes. Elements are generalized polygons (normally triangles or curvilinear quadrilaterals). Nodes are points located at the vertices and, sometimes, at the sides or the middle of the element. Unlike FD or IFD, cells around the nodes are not defined. Still, in many cases, one may write the equations in such a way that the mass balance formulation of the generic method section is still valid. However, the most singular feature of the FEM is the way the solution is interpolated, so that it becomes defined at every point. That is, head (or concentrations) is approximated as:

$$h(x) \cong \hat{h}(x) = \sum_i h_i N_i(x) \tag{9}$$

where h_i are nodal heads and N_i are interpolation functions. Since $\hat{h}$ is not the exact solution, it would yield a residual if substituted in the flow equation. Minimizing this residual, which requires somewhat sophisticated maths, leads to a system similar to Eq. (5).

BOUNDARY ELEMENT METHOD

The idea behind the boundary element method (BEM) is similar to that of the FEM. The main difference stems from the choice of interpolation functions, which are taken as the fundamental solutions of the flow equation (or whatever equation is to be solved). As a result, when the corresponding $\hat{h}$ is substituted in the flow equation, the residuals are zero. Since the equation is satisfied exactly in the model domain, one is only left with boundary conditions. In fact, as shown in Fig. 3D, discretization is only required at the boundaries, where boundary heads are defined so as to satisfy approximately the boundary conditions. This method is extremely accurate, but its applicability is limited by the need of finding the fundamental solutions. This constrains the BEM to flow problems in relatively homogeneous domains.

SIMULATING SOLUTE TRANSPORT

All the methods discussed above can be used for simulating solute transport. They are called Eulerian methods because they are based on a fixed (as opposed to moving) grid and all derivatives are based on a fixed coordinate system. They work fine when dispersion is dominant. Otherwise, they may lead to numerical problems (Fig. 4). Two dimensionless numbers are used to anticipate numerical difficulties. Specifically, discretization must satisfy the following conditions.

Peclet number

$$Pe = \frac{v\Delta x}{D} \cong \frac{\Delta x}{\alpha} < \frac{1}{2} \tag{10}$$

Courant number

$$Co = \frac{v\Delta t}{\Delta x} < 1 \tag{11}$$

where v is the solute velocity, α is dispersivity, Δx is the distance between nodes and we have assumed that $D \cong \alpha v$. The condition on the Courant number implies that the solute at one node will not move beyond the following node downstream during one time step. This condition is easy to meet because usually groundwater moves slowly and also reducing Δt to satisfy Eq. (11) is not difficult. The condition on the Peclet number, Eq. (10), implies that Δx is smaller than $\alpha/2$, which may require very small elements, leading to a huge computational burden. Because of this, conventional Eulerian methods are not applicable to many groundwater problems, which have motivated the search of alternative methods.

Alternative methods can be Eulerian or Lagrangian. Among the former, the most popular is upstream weighting, introduced by Heinrich et al.[3] in the FEM, but with a huge number of papers thereafter. It consists of slightly modifying Eulerian equations so as to ensure stability. The problem is that, in doing so, it introduces numerical dispersion. As a result, the wiggles at the solute front in Fig. 4 are substituted by an artificially smeared front. However, the vast majority of alternative formulations for solute transport are Lagrangian in the sense that time variations are written in terms of the material derivative, which expresses the rate of change in concentration of a particle that moves with the water. In this way, the advective term, which is the cause of problems in eulerian formulations, disappears.

The number of Lagrangian methods is very large and many researchers have devoted much effort to find one, which is universal. The fact that so many methods have survived to date suggests that the effort has not been fully successful. Still, in practical problems, one can usually find a suitable method. Following is an outline of some of the most popular methods, with a discussion of their advantages and disadvantages and early references. The interested reader should seek further.

The most natural Lagrangian method is to write the equations on a moving grid, that is on a grid whose nodes move with water. This method is highly accurate, but expensive because the grid has to be updated every time step. Moreover, the grid can become highly deformed over time.

To avoid problems with moving grids it is frequent to work with particles. Displacing the particles with the moving water represents advection, while dispersion can be represented with a variety of methods. One such possibility is to add a random component to each particle basis displacement. This is statistically equivalent to each particle basis dispersion and is the basis of the "random walk" method.[4] The method requires careful implementation, but its main drawback is the fact that the solution is given in terms of number of particles per cell. If one is interested in spatial distributions of the solute, a huge number of particles may be needed.

The method of characteristics (MOC) overcomes the above difficulty by assigning concentrations to

Global–Groundwater

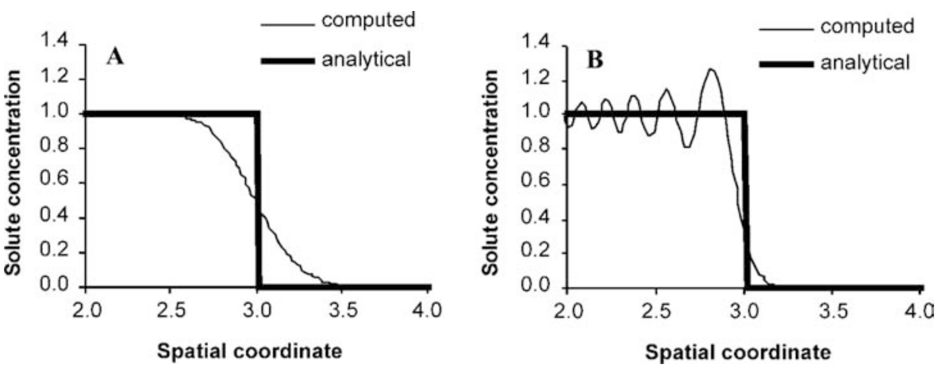

Fig. 4 Difficulties typically associated to numerical simulation of solute transport: A) front smearing: the concentration front is more dispersed than it should; B) instability oscillations: too high and/or too low (even negative) concentrations.

particles and interpolating them onto a fixed grid, where dispersion and, possibly, other transport processes are modeled. Concentrations are then interpolated back onto the particles. The method has become very popular in groundwater because of the USGS MOC Code.[5] The method is very practical, but the interpolation back-and-forth between particles and grid may introduce numerical dispersion and mass balance errors.

The modified method of characteristics[6] tries to overcome the problems associated to interpolating particle concentrations by redefining them in each time interval so that at the end of the time step they coincide with a node location. The method is very accurate, although some interpolation errors still occur when the front is abrupt. Some of these problems are overcome by the Eulerian–Lagrangian Localized Adjoint Method,[7] which looks as the most promising method.

CONCLUSION

Computer codes are available for simulating all phenomena affecting groundwater. In essence, they represent the balance of water (or salt, contaminants, or energy) in a manner that can be solved by the computer. This is achieved by, first, discretizing the problem and, second, rewriting it as a system of equations. This type of approach has been successful for flow problems. Solute transport, on the other hand, remains ellusive. No single method is universally successful. Instead, one must seek the appropriate code in each case.

Groundwater: Pollution from Mining

Jeffrey G. Skousen

George F. Vance
Agricultural Experiment Station, University of Wyoming, Laramie, Wyoming, U.S.A.

INTRODUCTION

Surface and underground mining activities can have direct and indirect impacts on the quantity, quality, and usability of groundwater supplies. The nature of the mining activity, geological substrata, and redistribution of surface and subsurface materials will determine to a large degree how groundwater supplies will be impacted. As waters interact and alter the disturbed geologic materials, constituents such as salts, metals, trace elements, and/or organic compounds become mobilized.[1,2] Once mobilized, the dissolved substances can leach into deep aquifers, resulting in groundwater quality impacts. In addition to concerns due to naturally occurring contaminants, mining activities may also contribute to groundwater pollution from leaking underground storage tanks, improper disposal of lubricants and solvents, contaminant spills as well as others.

In the United States, the *Clean Water Act* (CWA), which was enacted in 1948 as the *Water Pollution Control Act* (WPCA), and the CWA amendments in 1977, establishes the authority for all water pollution control actions at the federal level.[3] The *Safe Drinking Water Act* (SDWA), which was enacted in 1974 and amended in 1996, was promulgated to protect drinking water supplies by legislating maximum contaminant levels (MCLs) above which waters are considered unsafe for human consumption, and defined enforcement standards that states are required to use for determining minimum treatments needed to improve water quality.[4] Examples of some MCLs that may be associated with water quality issues relating to mining activities are listed in Table 1.

Because mining activities can result in poor quality groundwaters, enforcement of regulations is needed to minimize and/or eliminate potential problems. The Surface Mining Control and Reclamation Act (SMCRA) of 1977 specifies policies and practices for mining and reclamation to minimize water quality impacts.[6] The SMCRA requires that specific actions be taken to protect the quantity and quality of both on- and off-site groundwaters. All mines are required to meet either state or federal groundwater guidelines, which are generally related to priority pollutant standards described in the CWA.

GROUNDWATER RESOURCES

Our groundwater resources are the world's third largest source of water and represent 0.6% of the earth's water content. Approximately 53% of the U.S. population uses groundwater as a drinking water source, but this percentage increases to almost 97% for rural households. In areas of low rainfall, weathering and translocation of dissolved constituents is relatively slow compared to high rainfall areas. In addition, physical disruption of rocks into small particles can enhance mineral weathering that results in mineral dissolution and migration of dissolved substances. Transport of contaminants from surface and subsurface environments to groundwaters is generally accelerated as the amount of percolating water increases.

Infiltrating water moves through the vadose zone (unsaturated region) into groundwater zones (saturated region). The upper boundary of the groundwater system (e.g., water table) fluctuates depending on the amount of water received by, or depleted from, the groundwater zone. Groundwater movement is a function of hydraulic gradients and hydraulic conductivities, which represent the ease with which water moves as a function of gravitational forces and the permeability of substrata materials. Groundwater moves faster in coarse textured substrata and as the slope of the water table increases. Aquifers are groundwater systems that have sufficient porosity and permeability to supply enough water for a specific purpose. In order for an aquifer to be useful, it must be able to store, transmit, and yield sufficient amounts of good quality water. Important hydrogeological characteristics of a site that determine groundwater quantity and quality are listed in Table 2.

Table 1 Select contaminants in drinking waters that may be influenced by mining activities

Contaminant	MCL[a] (mg/L)	MCLG[b] (mg/L)
Inorganics		
Arsenic	0.006	0.006
Cadmium	0.005	0.005
Chromium	0.1	0.1
Copper	LV[c]	1.3
Cyanide	0.2	0.2
Fluoride	4	4
Lead	0.015	0
Mercury	0.002	0.002
Nickel	0.1	0.1
Nitrate (NO_3-N)	10	10
Selenium	0.05	0.05
Sulfate	500	500
Thallium	0.002	0.0005
Radionuclides		
Radon	300 q/L	0
Uranium	0.02 q/L	0
Organics		
Benzene	0.005	0
Carbon tetrachloride	0.005	0
Pentachlorophenol	0.001	0
Toluene	1	1
Xylenes	10	10
Microbiological		
Total coliforms	LV	0
Viruses	LV	0

[a]MCL = maximum contaminant levels permissible for a contaminant in water that is delivered to any user of a public water system.
[b]MCLG = maximum contaminant level goals of a drinking water contaminant that is protective of adverse human health effects and which allows for an adequate margin of safety.
[c]LV = lowest value that can be achieved using best available technology.
Source: From Ref.[5].

Table 2 Important hydrogeological characteristics of a site that determine groundwater quantity and quality

Geological
Type of water-bearing unit or aquifer (overburden, bedrock)
Thickness, areal extent of water-bearing units and aquifers
Type of porosity (primary, such as intergranular pore space, or secondary, such as bedrock discontinuities, e.g., fracture or solution cavities)
Presence or absence of impermeable units or confining layers.
Depths to water tables; thickness of vadose zone.
Hydraulic
Hydraulic properties of water-bearing unit or aquifer (hydraulic conductivity, transmissivity, storability, porosity, dispersivity)
Pressure conditions (confined, unconfined, leaky confined)
Groundwater flow directions (hydraulic gradients, both horizontal and vertical), volumes (specific discharge), rate (average linear velocity)
Recharge and discharge areas
Groundwater or surface water interactions; areas of ground water discharge to surface water
Seasonal variations of groundwater conditions
Groundwater use
Existing or potential underground sources of drinking water
Existing or near-site use of groundwater

Global–Groundwater

GROUNDWATER CONTAMINANTS

There are several types of substances that can affect groundwater quality.[1,7] Water contaminants include inorganic, organic, and biological materials, of which some have a direct impact on water quality, whereas others indirectly cause physical, chemical, or biological changes. Substances that can impact groundwaters include nutrients, salts, heavy metals, trace elements, and organic chemicals, as well as contaminants such as radionuclides, carcinogens, pathogens, and petroleum wastes (Table 3). Some groundwaters are derived from mining activities contain natural (e.g., methane gas) and synthetic organic chemicals. Organic contamination may result from leaking gas tanks, oil spills, or run-off from equipment-servicing areas. In these cases, the source of the contamination must be identified and removed. Gasoline, diesel, or oil-soaked areas should be immediately excavated and disposed of by approved methods.

The chemistry of groundwaters and potential levels of naturally occurring contaminants are related to:

Table 3 Different classes of groundwater contaminants and their origins

Water Contaminant Class	Contributions
Inorganic chemicals	Toxic metals and acidic substances from mining operations and various industrial wastes
Organic chemicals	Petroleum products, pesticides, and materials from organic wastes industrial operations
Infectious agents	Bacteria and viruses from sewage and other organic wastes
Radioactive substances	Waste materials from mining and processing of radioactive substances or from improper disposal of radioactive isotopes

Source: From Ref.[8].

1) groundwater hydrologic conditions; 2) mineralogy of the mined and locally impacted geological material; 3) mining operation (e.g., extent of disturbed materials and its exposure to atmospheric conditions); and 4) time. Movement of metal contaminants in groundwater varies depending on the chemical of concern, and include considerations such as with cobalt (Co), copper (Cu), nickel (Ni), and zinc (Zn) mobility being greater than silver (Ag) and lead (Pb), which tend to be more mobile than gold (Au) and tin (Sn).[1] As conditions such as pH, redox, and ionic strength change over time, dissolved constituents in groundwaters may decrease due to adsorption, precipitation, and chemical speciation reactions and transformations.

Acid mine drainage (AMD) is most prevalent at inactive and abandoned surfaces and underground mine sites. If geological substrata containing reduced S minerals [e.g., pyrite (FeS_2)] is exposed to oxygen (O_2), such as when pyritic overburden materials are brought to the earth surface during mining activities and then re-buried, high concentrations of sulfuric acid (H_2SO_4) can develop and form acid waters with pH levels below 2. Neutralization of some of the acidity produced during the oxidation of reduced S-compounds occurs when silicate minerals dissolve; however, during this process, high levels of potentially toxic metals such as aluminum (Al), copper (Cu), cadmium (Cd), iron (Fe), manganese (Mn), Ni, Pb, Zn, may be released. For example, mining of coal in the Toms Run area of northwestern Pennsylvania resulted in groundwater contamination by AMD containing high concentrations of Fe and sulfate (SO_4) that leached into the underlying aquifer through joints, fractures, and abandoned oil and gas wells.

The Gwennap Mining District in the United Kingdom contained numerous mines that operated over several centuries to extract various mineral resources. One of these mines, the Wheal Jane metalliferous mine in Cornwall, extracted ores that included cassiterite (Sn-containing mineral), chalcopyrite (Cu), pyrite (Fe), wolframite [tungsten (W)], arsenopyrite [arsenic (As)], in addition to smaller deposits of Ag, galena (Pb), and other minerals.[9] After closure in the early 1990s, extensive voids remaining in the Wheal Jane mine that contained oxidized and weathered minerals were flooded. Initial groundwater quality was poor with a pH of 2.8 and a total metal concentrations close to 5000 mg/L, which contained high levels of Fe, Zn, Cu, and Cd. Water quality worsened with depth, and at 180 m the groundwater had a pH of 2.5 and metal concentrations of 2200, 1500, 44, and 5 mg/L for Fe, Zn, Cu, and Cd, respectively. Current treatment of discharge waters originating from the mine involves an expensive process and will continue to be long-term if environment quality in the region is to be preserved. A similar situation occurred when a Zn mine in southwestern France was closed. However, after flooding, discharge mine waters contained high concentrations of Zn, Cd, Mn, Fe, and SO_4 even though the solution pH was near neutral.

Within the Coeur D'Alene District of Idaho, location of the Bunker Hill Superfund site, groundwater samples have been found to contain high concentrations of Zn, Pb, and Cd.[10] The contamination was believed to originate from the leaching of old mine tailings that were deposited on a sand and gravel aquifer. When settling ponds were developed nearby the old tailings, re-charge of the local groundwaters resulted in a rise in the water table that saturated the tailings causing considerable metal leaching to occur.

Gold mining operations have used cyanide as a leaching agent to solubilize Au from ores, which often contain arsenopyrite [As, Fe, sulfur (S)], and in some cases pyrite.[1] During the leaching process, Ag is also recovered as a by-product if present. Unfortunately, cyanide is a powerful non-selective solvent that will solubilize numerous substances that can be environmental contaminants. These ore waste materials are often stored in tailing ponds, and depending on the local geology and climate, cyanide present in the tailings can exist as free cyanide (CN^-, HCN), inorganic compounds (NaCN, $HgCN_2$), metal–cyanide complexes with Cu, Fe, Ni, and Zn, and/or the compound CNS. Because cyanide species are mobile and persistent under certain conditions, there is the potential for trace element and cyanide migration into groundwaters. For example, a tailings dam failure resulted in cyanide contamination of groundwater at a gold mining operation in British Columbia, Canada.[1]

Arsenic and uranium (U) contamination has resulted from extensive mining and smelting of ores containing various metals (Ag, Au, Co, Ni, Pb, and Zn) and/or non-metals (As, phosphorus (P), and U). Contaminated As groundwaters have been a source of surface re-charge and drinking water supplies; As in a contaminated river of Canada were 7 and 13 times greater than the recommended national and local drinking water standards, respectively.[1] Arsenic is known as a carcinogen and has been the contributing cause of death to humans in several parts of the world that rely on As-contaminated drinking waters.[7] Waters from dewatering a U mine in New Mexico had elevated levels of U and radium (Ra) activities as well as high concentrations of dissolved molybdenum (Mo) and selenium (Se), which were detected in stream waters 140 km downstream from the mine.

GROUNDWATER ANALYSIS

Both remediation and prevention of groundwater contamination by nutrients, salts, heavy metals, trace elements, organic chemicals (natural and synthetic), pathogens, and other contaminants requires the evaluation of the composition and concentration of these constituents either in-situ or in groundwater samples.[2] Monitoring may require the analysis of physical properties, inorganic and organic chemical compositions, and/or microorganisms according to well-established protocols for sampling, storage, and analysis.[11] For example, if groundwaters will be used for human or animal consumption, the most appropriate tests would be nitrate-nitrogen (NO_3-N), trace metals, pathogens, and organic chemicals. Several common constituents measured in groundwaters are listed in Table 4; however, other tests can be conducted on waters including tests for hardness, chlorine, radioactivity, or water toxicity.[12]

Recommendations based on interpretation of the groundwater test results should be related to the ultimate use of the water.[2] The interpretation and recommendation processes may be as simple as determining that a drinking water well exceeds the established MCLs for NO_3-N and recommending the well should not be used as a drinking water source or that a purification system be installed. However, interpretations of most groundwater analyses can be quite complicated and require additional information for proper interpretation. If a contaminant exceeds an acceptable concentration, all potential sources contributing to the pollution and pathways by which the contaminant moves must be determined. In many cases, multiple groundwater contaminants are present at different concentrations. Because the interpretation of water analyses is a complex process, recommendations should be based on a complete evaluation of the water's physical, chemical, and biological properties. Integrating water analyses into predictive models that can assess the effects of mining activities on water quality is needed in the long term to determine the most effective means to preserve and restore water quality.

STRATEGIES FOR REMEDIATING CONTAMINATED GROUNDWATERS

Mine sites that have been contaminated generally contain mixtures of inorganic and/or organic constituents, so it is important to understand these multicomponent systems in order to develop remediation strategies. Therefore, a proper remediation program must consider *identification*, *assessment*, and *correction* of the problem.[13] Identification of a potential problem site requires that either the past history of the area and activities that took place are known, or when a water analysis indicates a site has been contaminated. Assessment addresses questions such as is there a problem, where is the problem, and what is the extent of the problem? Afterwards a *remediation action* plan must be developed that will address the specific problems identified. A remediation action program may require that substrata materials (e.g., backfill) and groundwater be treated.

If remedial action is considered necessary, three general options are available—containment, in-situ treatment, or pump-and-treat (Fig. 1). The method(s) used for the containment of contaminants are beneficial for restricting contaminant movement. Of the remediation techniques, in-situ treatment measures are the most appealing because they generally do less surface damage, require a minimal amount of facilities, reduce the potential for human exposure to contaminants, and when effective, reduce or remove the contaminant. In-situ remediation can be achieved by physical, chemical, and/or biological techniques. Biological in-situ techniques used for groundwater bioremediation can either rely on the indigenous (native) microorganisms to degrade organic contaminants or on amending the groundwater environment with microorganisms (bioaugmentation). The pump-and-treat method, however, is one of the more commonly used processes for remediating contaminated groundwaters. With the pump-and-treat method, the contaminated waters are pumped to the surface where one of many treatment processes can be utilized. A major consideration in the pump-and-treat technology is the placement of

Table 4 Groundwater quality parameters and constituents measured in some testing programs

Physical parameters	Metals and trace elements	Non-metallic constituents	Organic chemicals	Microbiological parameters
Conductivity, salinity, sodicity, dissolved solids, temperature, odors	Al, Ag, As, Ca, Cd, Cr, Cu, Fe, Mg, Mn, Na, Ni, Pb, Se, Sr, Zn	pH, acidity, alkalinity, dissolved O_2, B, CO_2, HCO_3, Cl, CN, F, I, NH_4, NO_2, NO_3, P, Si, SO_4	Methane, oil and grease, organic acids, volatile acids, organic C, pesticides, phenols, surfactants	Coliforms, bacteria, viruses

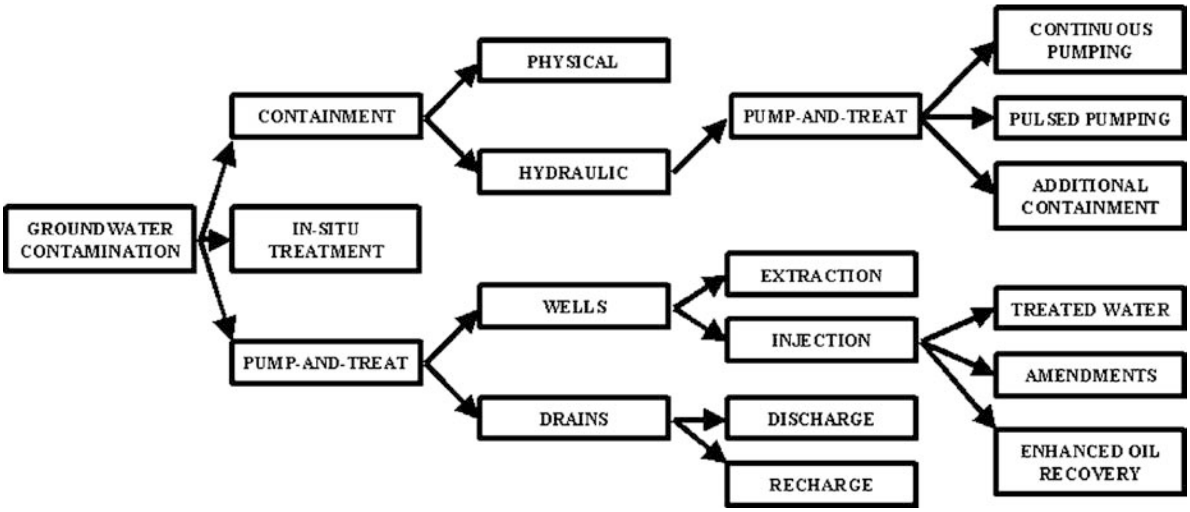

Fig. 1 Remediation options to consider if cleanup of contaminated groundwater is required.

wells, which is dependent on site characteristics (see Table 2. Extraction wells are used to pump the contaminated water to the surface where it can be treated and re-injected or discharged. Injection wells can be used to re-inject the treated water, water containing nutrients and other substances that increase the chances for chemical alteration or microbial degradation of the contaminants, or materials for enhanced oil recovery.

Treatment techniques can be grouped into three categories including physical, chemical, and biological methods.[2,13]

Physical methods include several techniques. *Adsorption* methods physically sorb or trap contaminants on various types of resins. *Separation* treatments include physically separating contaminants by forcing water through semipermeable membranes (e.g., reverse-osmosis). *Flotation*, or density separation, is commonly used to separate low-density organic chemicals from groundwaters. *Air and steam stripping* can remove volatile organic chemicals. *Isolation* utilizes barriers placed above, below, or around sites to restrict movement of the contaminant; containment systems should have permeabilities of 10^{-7} cm/sec (approximately 0.1 ft/yr) or less.

Chemical methods are also numerous. *Chemical treatment* involves addition of chemical agent(s) in an injection system to neutralize, immobilize and/or chemically modify contaminants. *Extraction (leaching)* of contaminants uses one of several different aqueous extracting agents such as an acid, base, detergent, or organic solvent miscible in water. *Oxidation and reduction* of groundwater contaminants is commonly done using air, oxygen, ozone, chlorine, hypochlorite, and hydrogen peroxide. *Ionic and non-ionic* exchange resins can adsorb contaminants, reducing their leaching potential.

Biological methods for contaminant remediation are less extensive than physical and chemical techniques. *Land treatment* is an effective method for treating groundwaters by applying the contaminated waters to lands using surface, overland flow, or subsurface irrigation. *Activated sludge and aerated surface impoundments* are used to precipitate or degrade contaminants present in water and include both aerobic and anaerobic processes. *Biodegradation* is one of several biological-mediated processes that transform contaminants and utilizes vegetation and microorganism.

Groundwater: Pollution from Nitrogen Fertilizers

Lloyd B. Owens
Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Coshocton, Ohio, U.S.A.

INTRODUCTION

Why is nitrogen in groundwater a problem? High nitrate levels in water consumed by humans can cause adverse health problems, and groundwater is a major source of water for human consumption. A part of groundwater resurfaces to feed surface water from streams to oceans. High levels of nitrogen can cause excess plant and bacterial growth, which upon death and decay can deplete much of the oxygen in water. This causes fish kills and "dead zones," such as the area of hypoxia in the Gulf of Mexico. This encyclopedia article discusses agricultural practices, e.g., row crops, grasslands/turf, container horticultural crops, that contribute to nitrogen in groundwater. Some agricultural practices to reduce the contributing factors are also presented.

WHY NITROGEN IN GROUNDWATER IS A PROBLEM

Human Health Impacts

Groundwater is a major source of water for human consumption. Nitrogen present in groundwater is usually in the form of nitrate (NO_3), and at high levels can pose major human health concerns, especially for infants. The link between high NO_3 in polluted water and serious blood changes in infants was first reported in 1945. From 1947 to 1950, 139 cases of methemoglobinemia were reported, including 14 deaths in Minnesota alone. Thus, a standard has been set that NO_3 in excess of $45\,mg\,L^{-1}$ ($10\,mg\,L^{-1}$ NO_3-N) is considered hazardous to human health.[1]

Environmental Impacts

A part of groundwater, especially shallow groundwater, resurfaces to feed streams, rivers, and reservoirs and eventually estuaries and oceans. Nutrients, pollutants, in the groundwater are carried via these routes as well and can cause excess plant and bacterial growth in aquatic systems. The decay of this organic matter can deplete much of the oxygen in the water causing fish kills and "dead zones" to occur. Phosphorus receives much of the attention in regards to eutrophication in fresh waters because it often is the limiting nutrient. But as water systems become more brackish, there is a shift to N limitation.[2] A major example of this situation is the area of hypoxia in the Gulf of Mexico.[3] Hypoxia occurs when the concentration of dissolved oxygen is less than $2\,mg\,L^{-1}$.

Nitrogen contributions to the Gulf of Mexico, and other large bodies of water, come via surface runoff and resurfacing of groundwater. There are also several agricultural sources of nitrogen, e.g., nitrogen fertilizer, surface application of manure, manure from grazing systems, and mineralization of organic matter. However, the focus of this chapter will be only on groundwater, and how it is impacted by the leaching of nitrogen fertilizers. Although several aspects of nitrate leaching will be addressed and accompanied by supporting references, space does not permit this chapter to be a comprehensive literature review.

AGRICULTURAL PRACTICES CONTRIBUTING TO THE NITROGEN IN GROUNDWATER PROBLEM

Row Crops

High levels of NO_3-N in subsurface drainage from row crops, especially corn (*Zea mays* L.), are well documented. Nitrate-N concentrations in tile lines draining silt loam soils in Iowa with fertilized, continuous corn, or corn in rotation already exceeded $10\,mg\,L^{-1}$ two decades ago.[4,5] Other high NO_3-N levels have been reported in tile lines with clay loams in Minnesota;[6–8] with silty clay loams in Illinois;[9] with silt loams in Indiana;[10] with silt loams/silty clay loams in Ohio;[11] and with clay over silty clay loam and fine sand over clay in Ontario, Canada.[12] Analyses of subsurface water collected with monolith lysimeters[13,14] and ceramic porous-cup samplers[15,16] are in agreement with these findings.

Nitrate-N concentrations have been studied in tile drains frequently because of their wide spread use and the relative ease of collecting a sample. The majority of NO_3-N moves in the subsurface water during the winter recharge period.[9,10,13] There are several factors

Global–Groundwater

that impact the amount of N export from tiles, including timing and area of N fertilization.[9] Increasing the drain spacing decreases the NO_3-N losses in tiles[6,10] although the NO_3-N concentration in the tiles may change very little.[10] Even though the increased drain spacing should reduce the NO_3-N losses in the tile, it probably increases the NO_3-N losses in seepage below the drains. Model simulation studies show that reducing N fertilization rates will have much greater impact for reducing NO_3-N losses than changing tile drain spacing or depth.[6]

Too often, inexpensive N fertilizer has been applied in excess to crops to ensure that inadequate N will not limit crop yields. The difficulty in synchronizing N applications with crop needs contributes to such practices. It has been shown that there is a direct relationship between NO_3-N loss by leaching and application rates of N that exceed crop needs.[15,17] Excess N in soil can result from overapplication of N fertilizers or manure or from residual N from the previous year (as well as from mineralization of organic N). This can be a particular problem following a dry year because reduced crop growth will not utilize as much N fertilizer as during a year when a ''normal'' amount of water was available.[8] Therefore, there is an increased amount of residual N to begin the next cropping season. Even at economic optimum N (EON) levels, considering all sources of N, concentrations of NO_3-N in subsurface water have been found to exceed the $10\,mg\,L^{-1}$ maximum contaminant level (MCL).[15,17] The conclusion can be drawn that optimum corn production will likely produce elevated NO_3-N concentrations in groundwater.[17]

In irrigated agriculture, a similar impairment to groundwater quality exists from N fertilizer management. High concentrations of NO_3-N were found in subsurface water under a sprinkler irrigated crop rotation in Spain,[18] a sprinkler irrigated corn–soybean rotation in Nebraska,[19] and flood irrigated wheat in Arizona.[20] Even with irrigation BMPs, NO_3-N concentrations in groundwater above the MCL can be expected.

Grasslands/Turf

Because of the animal component, NO_3-N leaching in grazed grassland is quite complex. Leaching of NO_3-N from grasslands is greatly increased with the presence of grazing livestock.[21,22] Even on highly fertilized pastures, much of the leached NO_3-N has been attributed to excreta.[23,24] Studies in England,[25,26] the Netherlands,[27] and the eastern USA[28,29] have shown that NO_3-N concentrations in subsurface water are often greater than $10\,mg\,L^{-1}$ when $>100\,kg\,N\,ha^{-1}$ is applied annually to grazed grasslands. Other processes, such as the accumulation of fertilizer-N during drought or the release of N from decaying plant material, e.g., resulting from tilling or killing the sod in preparation for reseeding, may influence N leaching from the pasture as a whole, rather than acting specifically on areas affected by urine.[23] In some non-grazed systems, NO_3 leaching from highly fertilized systems is low, e.g., $29\,kg\,N\,ha^{-1}$ lost from ryegrass (*Lolium perenne* L.) receiving $420\,kg\,N\,ha^{-1}$.[30]

Fertilized turf, whether it be home lawns or golf courses, raises environmental issues. Annual applications up to $244\,kg\,N\,ha^{-1}$ to turfgrass on sandy loam soils in Rhode Island do not appear to pose a threat to drinking water aquifers,[31] although overwatering can cause increased N loadings to bays and estuaries in coastal areas. The excess N movement would be more prevalent with late summer N applications. Nitrate-N concentrations in subsurface water were the highest on an Ohio silt loam in the late summer and early autumn but did not exceed the MCL when $220\,kg\,N\,ha^{-1}$ per year was applied to turfgrass.[32] The exception was the occurrence of high NO_3-N concentrations with the soil disturbance during establishment of the turf. Grass sod has the capacity to use large amounts of N; 85–90% of fertilizer N can be retained in the turf–soil ecosystem.[33] Roots and thatch can represent a large N pool because it becomes available for mineralization and subsequent leaching if disturbed.[34] Reseeding and sod establishment within 2 mo of ''turf death'' can stabilize this N pool.[33] High rates of NO_3 leaching can occur at very high N fertilizer rates, e.g., $450\,kg\,N\,ha^{-1}$ per year. Even though most of the NO_3 leaching occurred in the autumn and winter, it was an accumulation of all N fertilizer application and not just the autumn application.[35] Excess NO_3 in the fall is the driving force that causes NO_3 leaching, regardless of the N source or time of application. Therefore, high rates of N application to turf should be avoided in the fall, because it can result in high NO_3 leaching rates. A survey of several golf courses across the USA indicated that NO_3-N concentrations above the MCL occurred in only 4% of the samples;[36] most of these were apparently due to prior agricultural land use. Pollution of groundwater by NO_3 leaching from N fertilized turf should be minimal with good management, which includes consideration of soil texture, N source, rate and timing, and irrigation/rainfall.[37]

Container Horticultural Crops

Although the acreage for container horticultural crops is small compared to row crops or grasslands, the production intensity is great and ''hot spots'' of potential NO_3 leaching could develop. Assuming 80,000 pots ha^{-1}

for a typical foliage plant nursery and using a soluble granular fertilizer, over 650 kg N ha^{-1} could be lost through leaching annually.[38] During a 10-week greenhouse study of potted flowers, average NO_3-N in the leachate ranged from 250 mg N L^{-1} to 450 mg N L^{-1}.[39] As long as the amount of water applied to the plants did not exceed plant usage (and the greenhouse canopy remained intact to prevent precipitation inputs), there would be little NO_3 movement from the soil beneath the pots, unless there was a high water table. Nevertheless, this area of N accumulation would eventually need to be addressed. The use of controlled release fertilizers is one practice that can significantly reduce leaching losses.[38] Also, vegetable crops that have high N demand but low apparent N recovery, e.g., sweet peppers, can leave large amounts of N in the soil and residues at harvest.[40]

AGRICULTURAL PRACTICES TO MITIGATE THE NITROGEN IN GROUNDWATER PROBLEM

Use of Winter Cover Crops

Winter cover crops have been shown to be an effective strategy in reducing NO_3 leaching during the winter period.[41–44] A variety of crops, e.g., annual grasses, cereals, legumes, have been used with varying degrees of success depending on soils, climate, cropping sequences, etc. Care needs to be exercised with long-term cover crops, because if they are disturbed, some of the accumulated N may become mineralized and actually increase NO_3 leaching.[45] Sometimes cover crops cannot be counted on as a best management practice (BMP) to reduce NO_3 leaching.[46] On the Delmarva Peninsula in the Mid-Atlantic U.S.A, a rye winter cover crop following corn did not reduce NO_3 leaching. One factor was that the existing crop did not permit a sufficiently early seeding of the cover crop.

Use of Soil Nitrate Tests

Preplant N tests (PPNT) or presidedress N tests (PSNT) can assess the N stored in soil from cover crops and help to give adequate N credits for legume N carry-over in a crop rotation, such as a soybean N credit in a corn–soybean rotation. Nitrification inhibitors used with N fertilizer in the ammoniacal form can slow the rate of oxidation of reduced forms of N to NO_3-N, and subsequently decrease the amount of NO_3-N leaching,[47] especially with fall N applications.

Even with these improved practices, it may be necessary to reduce the N fertilization rate below the EON level to achieve NO_3-N concentrations in groundwater below the MCL.

Use of Alternate Grassland/Turf Management

Several management options to reduce nitrate leaching from grasslands include the use of grass–legume mixtures instead of highly fertilized grass;[24,48] coordinating the timing and N fertilizer application rate with other N sources, e.g., manure applications, to avoid excessive N application;[49] use of irrigation, especially during dry periods, to encourage N uptake;[24] and an integration of cutting forage and grazing, especially cutting in late summer areas that have been intensively grazed earlier in the year. In areas where NO_3 contamination from turf is a concern, late summer N fertilizer applications should be reduced and watering should be limited.[31]

Groundwater: Pollution from Phosphorous Fertilizers

Bahman Eghball
Soil and Water Cons Research Unit, Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Lincoln, Nebraska, U.S.A.

INTRODUCTION

Phosphorus (P) is a primary nutrient necessary for plant growth. When the P level in soil is below what is essential for plant needs, P is supplied to the soil by the addition of P fertilizer or organic residuals (i.e., manure). Because of the P fertilizer use in the past few decades or application of manure or other organic residuals, a greater portion of the soils in each state in the United States have soil test P levels that exceed the critical level for plant growth. The excess P in soil is then subjected to leaching loss or transport in surface runoff either in soluble or in particulate (sediment-bound) forms. Phosphorus that is moving downward in the soil profile can eventually reach the ground water, especially in areas with shallow or perched groundwater. Phosphorus moving downward in the soil may also be intercepted by artificial drainage systems (i.e., tile drains) that are located within 1–2 m from the soil surface.

PHOSPHOROUS LEACHING AND FIXATION

Phosphorus leaching can occur as a slow process in the soil or rapidly with preferential flow, which is the movement of water and solute through cracks and earthworm holes in soil. The point at which P might come in contact with groundwater depends on soil properties and the proximity of the groundwater to the soil surface. The U.S. Environmental Protection Agency has no safe drinking water concentration limit for P. The major concern about P enrichment of groundwater is that groundwater frequently emerges as surface water and if it contains sufficient P, can cause eutrophication (nutrient enrichment that causes algae bloom and oxygen depletion in water).

Phosphorus movement in soil is primarily through the diffusion process with the rate influenced by the amount of P applied, soil water content, bulk density (i.e., porosity), and chemical reaction of P with the soil constituents. The average rate of diffusion in three Nebraska medium and fine-textured soils was $0.00011\,\text{cm}^2\,\text{hr}^{-1}$ ($0.000017\,\text{in.}^2\,\text{hr}^{-1}$) following the application of P fertilizer ($15\,\text{kg P ha}^{-1}$) to replace what is needed by a corn crop with the expected yield of $5600\,\text{kg ha}^{-1}$ ($90\,\text{bu acre}^{-1}$).[1] The P in soil is not usually an environmental concern until the soil test P is in the very high (excessive) category for plant needs (Fig. 1). High levels of P in soil can be a source of groundwater pollution when P is leached in soil. This is especially of concern when the groundwater is near the soil surface; groundwater has an upward movement toward the soil surface in certain times of the year, and in coarse-textured soils. In areas where groundwater is deep, the pollution of groundwater with P is of little concern even if the P level in soil is excessive. For example, P fertilizer applied at a rate of $100\,\text{kg ha}^{-1}\,\text{yr}^{-1}$ to a sandy loam soil with a P adsorption capacity of $150\,\text{mg kg}^{-1}$ and a bulk density of $1.4\,\text{kg m}^{-3}$ would take 21 yr to reach a 1 m (3.3 ft) soil depth, assuming no preferential flow. If the water table was located several meters deep, it would take many years for the applied P to reach the groundwater. Factors that can influence P leaching in soil are given in Table 1.

Applied fertilizer P interacts with various constituents in soil and can be readily immobilized. Phosphorus in all chemical fertilizers (except rock phosphate) is about 100% plant-available and therefore, their reaction in soil should be similar. The mechanism involved in reducing P movement in acid soils includes the reaction of orthophosphate ions ($H_2PO_4^-$ and HPO_4^{2-}) with iron and aluminum to form insoluble compounds. In alkaline soils, the P retention mechanisms include precipitation of calcium phosphate compounds, surface precipitation of P on solid phase calcium carbonate, and retention of P by clay particles that are saturated with calcium. Therefore, P leaching in soil is very limited since P interacts with the soil constituents. Eghball, Sander, and Skopp[1] found that maximum fertilizer P movement from a band applied at $60\,\text{kg P ha}^{-1}$ was about 4 cm in 3 mo in three different soils. The size of the band was not expected to expand much after 3 mo. The most P movement occurred in the first few weeks after application. However, P can leach deep into the soil with preferential flow (a small number of pores is used to move water) where P moves with water through cracks and earthworm holes. Preferential flow is the primary mechanism for deep movement of P in fine-textured soils (clayey types) either in particulate form or in soluble form.

There are several factors that influence fixation of P in the soil. These include amount and type of clay, time

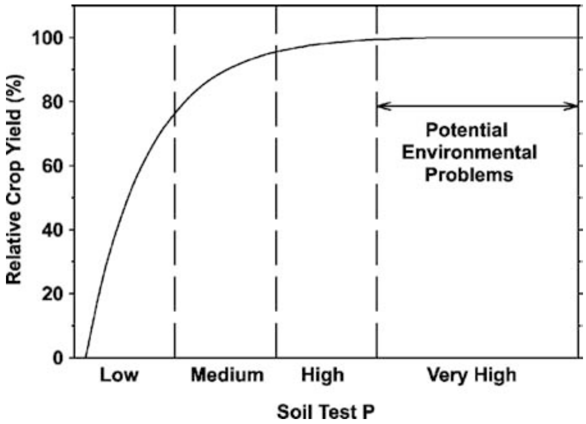

Fig. 1 Relative crop yield as influenced by soil test P level. *Source*: From Ref.[4].

of reaction, soil pH, temperature, and organic matter. The greater the clay content of a soil, the more P is adsorbed. More P is retained by the 1 : 1 clays (i.e., kaolonitic type) that are found in the humid and tropic areas (high rainfall high temperature) than other clay types. Phosphorus fixation in soil increases with time after P addition indicating that P gradually becomes more insoluble with time unless plants remove P from soil. Phosphorus fixation also increases with increasing temperature. Increasing soil organic matter usually results in increased P solubility and thus reduces P fixation in soil. Soils that are primarily made up of muck and peat are subject to increased P leaching from added P fertilizer.

PHOSPHOROUS IN TILE DRAINS

Phosphorus can leach into the drainage water in fields with tile drains. Tiles are placed 1–2 m (3.3–6.6 ft) deep in poorly drained soils, so there is a potential for the applied fertilizer P to leach into the soil and reach the tile drain. The tile water usually empties into the surface water and if it contains sufficient P, can cause eutrophication. Since most of the tile drains are located in humid and semi-humid regions with large rainfall potential, leaching of P through thin soil layers above the tile-drains can especially be high. In a study conducted in Canada,[2] tile-drain water samples were collected from 27 fields that mainly received P fertilizer. Drain water from 14 out of 27 fields exceeded the Canadian standard of 0.03 mg total PL^{-1} in the water. More than 80% of the P in tile drain was particulate (sediment-bound) and dissolved organic P. Of those exceeding the standard, 10 out of 14 were clayey soils with medium to high soil P levels indicating loss of P through preferential flow.

Table 1 Factors that can influence phosphorus leaching in the soil

Factor	P leaching risk
Excessive soil P level	High
Shallow or perched water table, waterlogged conditions	High
Fine-textured soils	Low
Fine-textured soils with preferential flow	High
Coarse-textured soils (sandy)	High
Tile drain	High
Soils with high organic matter	Low
Organic soils (soil with organic matter >20%)	High
High soil Ca, Al, or Fe contents	Low

PHOSPHOROUS SATURATION

Phosphorus leaching can also occur in areas with a naturally high P level in the soil. In these areas, P can leach deep into the soil, especially coarse-textured soils, and reach the groundwater. The closer the ground water is to the soil surface, the greater the potential of P reaching the water body. The capacity of a soil to retain P is limited. Repeated and/or heavy application of P fertilizer can saturate the upper soil layers with P. Usually the fraction of P saturated soil decreases with depth. However, when the upper layers of soil have been saturated, P movement to the subsoil can occur. Long-term (>50 yr) application of beef cattle feedlot manure and chemical fertilizer resulted in P leaching to a maximum of 1.8 m (6 ft) depth in a sandy loam soil.[3] Phosphorus from manure source moved deeper in the soil than P from chemical fertilizer indicating that some of the manure P components were not subject to P fixation by the calcium carbonate layer located about 0.75 m (2.5 ft) deep in this soil.

Groundwater: Pumping and Land Subsidence

Steven P. Phillips
Devin Galloway
U.S. Geological Survey (USGS), Sacramento, California, U.S.A.

INTRODUCTION

Land subsidence is a gradual settling or sudden sinking of the Earth's surface owing to subsurface movement of earth materials. Subsidence is a global problem and, in the United States, more than 17,000 mi^2 have been directly affected by subsidence. The associated costs from flooding and structural damage exceeded an estimated $125 million by 1991.[1] About 60% of the subsidence is attributed to permanent compaction of subsurface sediments caused by the withdrawal of underground fluids—groundwater, oil and gas.[1] This article will discuss the single largest cause of subsidence—the compaction of susceptible aquifer systems resulting from groundwater pumping for water supply. Thus, the development of groundwater resources has had a major impact on the landscape and the increasing development of land and water resources threatens to exacerbate subsidence problems.[2,3]

MINING GROUNDWATER

The overdraft of susceptible aquifer systems has resulted in regional, permanent subsidence and related ground failures. In the affected alluvial aquifer systems, especially those that include semi- and unconsolidated silt and clay layers (aquitards), long-term groundwater-level declines created a vast one-time release of "water of compaction" from compacting aquitards, which manifests as land subsidence. A largely non-recoverable reduction in the pore volume of the compacted aquitards and of the associated storage capacity accompanied this release of water.

The reduction of water levels and pore-fluid pressure in unconsolidated aquifer systems is inevitably accompanied by deformation of the aquifer system. Because the granular structure, or "skeleton," of the aquifer system is not rigid, a shift in the balance of support for the overlying material causes the skeleton to deform. Both the aquifers and aquitards that constitute the aquifer system undergo deformation, but to different degrees. Almost all permanent subsidence occurs as a result of the irreversible compression or compaction of aquitards during the typically slow process of aquitard drainage.

Reversible Deformation Occurs in all Aquifer Systems

The relation between changes in groundwater levels and deformation of the aquifer system is based on the principle of effective stress.[4] By this principle, when the support provided by pore-fluid pressure is reduced, such as when groundwater levels are lowered, this support is transferred to the aquifer-system skeleton, which compresses. Conversely, when the pore-fluid pressure is increased, support previously provided by the skeleton is transferred to the fluid and the skeleton expands. As the pore-fluid pressure fluctuates within the aquifer system the skeleton alternately undergoes compression and expansion. When the load (stress) on the skeleton remains less than any previous maximum load, the groundwater-level fluctuations create small elastic (reversible) deformations of the aquifer system. This recoverable deformation occurs to some degree in all aquifer systems in response to seasonal changes in groundwater levels.

Irreversible Compaction of Aquifer Systems

The maximum previous stress on the skeleton is termed the preconsolidation stress. When the load on the aquitard skeleton exceeds the preconsolidation stress, the aquitard may undergo permanent rearrangement, resulting in irreversible compaction and a permanent reduction of pore volume. In confined aquifer systems, the volume of water derived from irreversible aquitard compaction is equal to the volume of subsidence, which can represent a substantial portion of the total volume of water pumped. This represents a one-time mining of stored groundwater and a small permanent reduction in the storage capacity of the aquifer system.[5]

Aquitards—Important Role in Compaction

In many confined alluvial aquifer systems, aquitards in the form of discontinuous interbedded layers of silts and clays constitute the bulk of the groundwater storage capacity. This is by virtue of their greater porosity and compressibility and, often, their greater aggregate thickness compared to coarser-grained sand and gravel layers. Because aquitards are much less permeable than aquifers, the vertical drainage of aquitards into adjacent pumped aquifers may lag far behind the seasonal fluctuations in water levels in adjacent aquifers. The lagged response in the middle of a thick aquitard may be less influenced by seasonal fluctuations and more influenced by longer-term trends in groundwater levels. When the internal stresses in an aquitard exceed the preconsolidation stress, the compressibility increases, typically by a factor of 20 to 100 times, and the resulting compaction is largely irreversible. The delay in aquitard drainage increases by comparable factors owing to decreased aquitard permeability, and compaction may occur over decades or centuries.

ROLE OF SCIENCE

A combination of scientific understanding and careful management can minimize subsidence that results from developing our land and water resources. A key role of science is in the recognition and assessment of subsidence.[1]

Recognition

Where groundwater mining is involved, subsidence is typically gradual and widespread, and its discovery becomes an exercise in detection. Gazing out over the San Joaquin Valley, California, one would be hard pressed to recognize that nearly 30 ft of subsidence has occurred in some locations (Fig. 1).[6] Possible indicators of land subsidence include protruding wells (Fig. 2) and failed well casings; the formation of earth fissures; changes in flood-inundation frequency and distribution; stagnation or reversals of streams, aqueducts, storm drainages, or sewer lines; failure, overtopping, or reduction in freeboard along reaches of levees, canals, and flood-conveyance structures; and cracks and (or) changes in the gradient of linear-engineered structures such as pipelines and roadways. In the absence of these indicators, measurements of land-surface elevation changes are needed to reveal the subsidence.

Assessment

The principal methods for assessing land subsidence are measurement of the magnitude and extent of subsidence, and characterization of aquifer systems undergoing compaction.

Subsidence measurement

Relative changes in the position of the land surface are measured using geodetic methods such as leveling and satellite-based global positioning system (GPS) surveys. Leveling is accurate and suitable for small

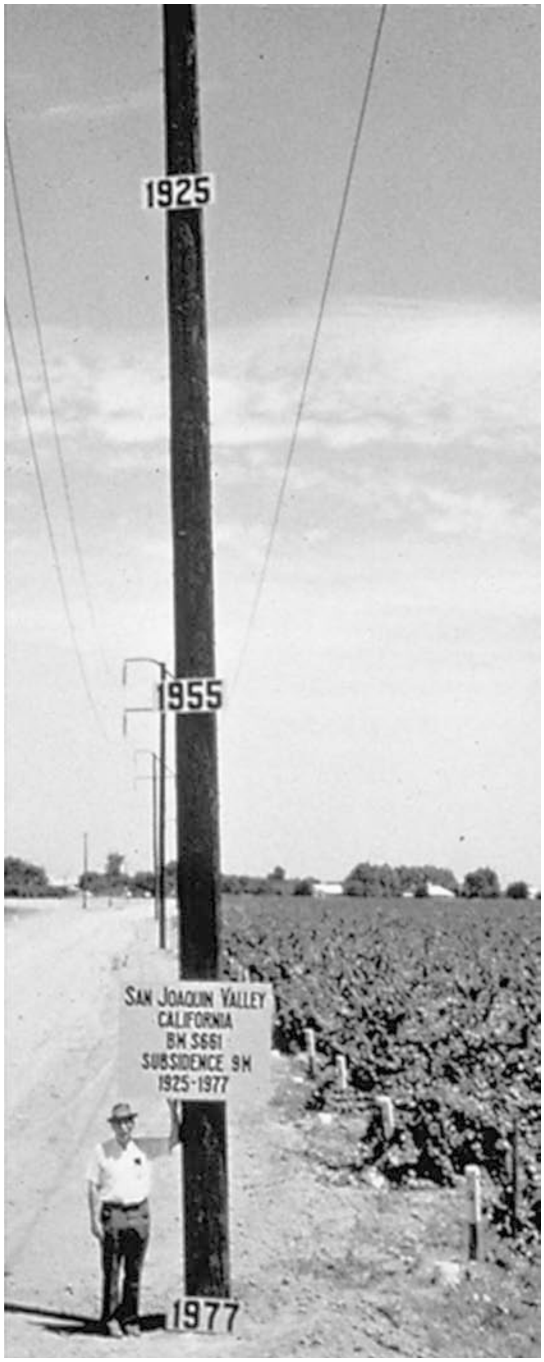

Fig. 1 Approximate location of maximum subsidence in United States identified by Joseph Poland, U.S. Geological Survey (pictured). Signs on pole show approximate altitude of land surface in 1925, 1955, and 1977 in the San Joaquin Valley southwest of Mendota, California. *Source*: From Ref.[2].

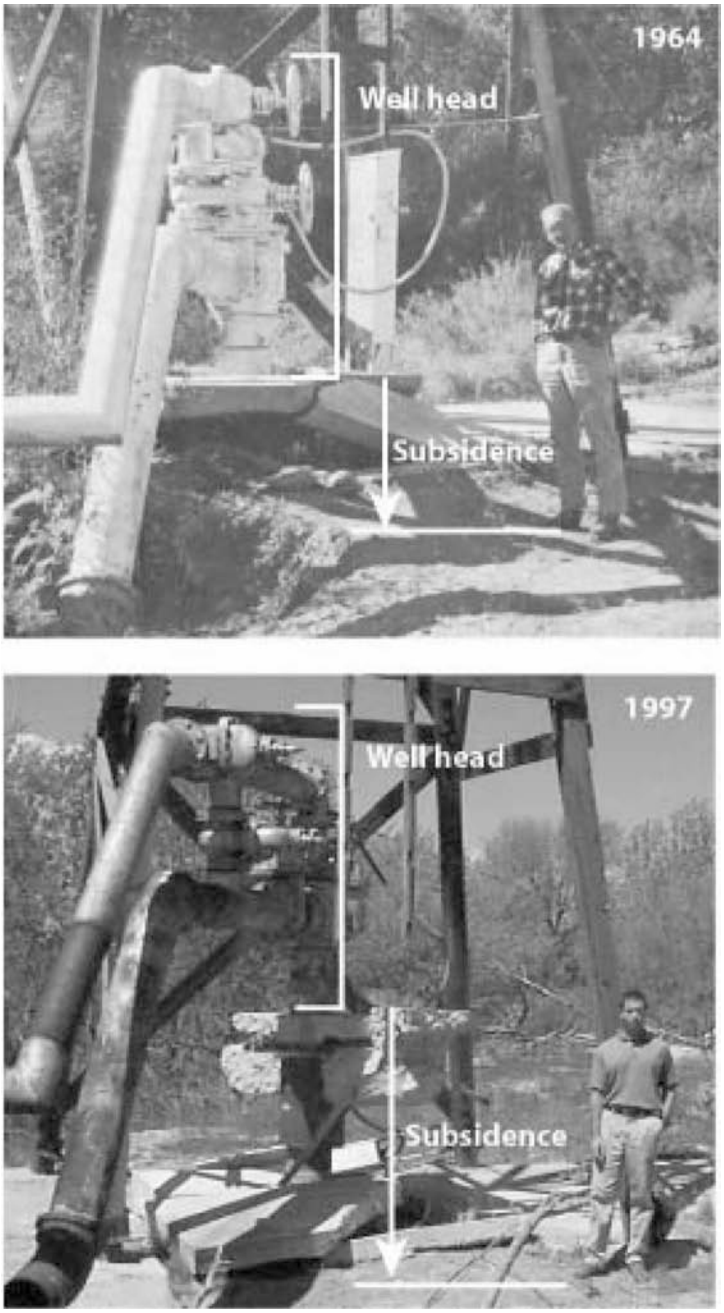

Fig. 2 Two photographs of a well near Las Vegas, Nevada, show the well progressively protruding from the ground as the surrounding land-surface subsides.

areas; large regional networks warrant use of more efficient GPS surveying. In GPS surveys, the relative positions of two points can be determined when receivers at each point receive signals simultaneously from the same set of GPS satellites. When the same points are later reoccupied, relative motion between the points can be measured. Subsidence can be monitored over hundreds of square miles with a geodetic network.

Borehole extensometers (Fig. 3) can generate precise, continuous measurements of vertical displacement between the land surface and a reference point at the bottom of a borehole.[7] Used in conjunction with water-level data, extensometer measurements can provide the basis to estimate the average compressibility and vertical hydraulic conductivity of the aquitards, and constrain subsidence predictions.[8,9]

Interferometric synthetic aperture radar (InSAR) is a tool that uses radar signals to measure land-surface deformation at a high spatial resolution. For landscapes with stable reflectors, high-precision measurements of the change in the position of these features are made by subtracting or ‘‘interfering’’ two radar scans. Regional-scale land subsidence has been mapped using InSAR, and hydrogeologic understanding has

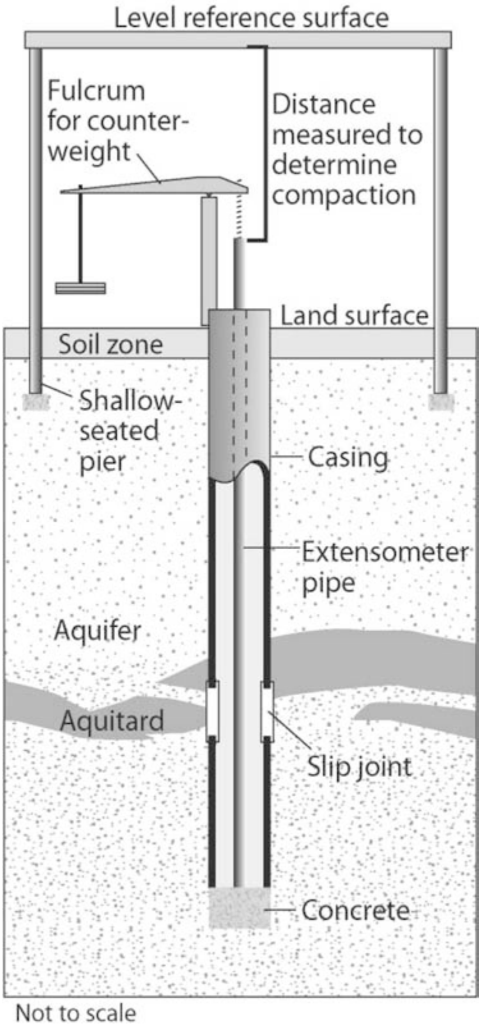

Fig. 3 Conceptual diagram of a borehole extensometer used to measure compaction occurring in a specific vertical interval of an aquifer system.

improved as geohydrologic features, such as buried faults, are revealed.[10]

Aquifer-system characterization

The stress history of subsidence-prone materials governs the potential for aquifer-system compaction and land subsidence. Preconsolidation stress is estimated from paired measurements of groundwater levels and land subsidence, groundwater flow model calibration, or consolidation tests on sediment cores. All estimates are highly uncertain because initial preconsolidation stresses are unknown. Determining the new preconsolidation stresses in a system that has subsided is equally difficult.

Groundwater flow models are important tools for analyzing, visualizing, and managing subsidence.[11,12] Simulation models are powerful tools, but are non-unique and limited by simplifying assumptions of groundwater flow and aquifer-system compaction. Models remain non-unique because the available hydrogeologic data are always limited. Nevertheless, simulation models may be used cautiously to evaluate management strategies.

CONCLUSIONS

With adequate monitoring programs and institutional mechanisms in place, optimal benefits may be achieved for both subsidence mitigation and resource development. Effective management of our land and water resources requires definition of the relevant interacting processes. In the case of land subsidence and groundwater resources, this means understanding the hydrogeologic framework of the resource as well as the demands placed on it, and identifying a set of objectives and policies to guide usage of the resources.

For alluvial groundwater basins subject to aquifer-system compaction, the preconsolidation stress defines the threshold between recoverable compaction, and non-recoverable compaction and associated subsidence. Consequently, management of land subsidence is inextricably linked to other facets of water-resource management. One such facet is the conjunctive use of surface water and groundwater, which serves to augment and stabilize water supplies, and often plays a critical role in maintaining minimum groundwater levels and arresting or reducing land subsidence.

Groundwater: Pumping Methods

Dennis E. Williams
Geoscience Support Services, Inc., Claremont, California, U.S.A.

INTRODUCTION

Groundwater has been used for municipal, industrial, irrigation, and other purposes since prehistoric times. In today's world, groundwater is becoming increasingly more important as a reserve against drought, especially in the arid and semiarid lands. Extraction of groundwater from aquifers beneath the earth is the subject of this section. Various methods of pumping groundwater will be discussed ranging from simple hand-powered systems to high-capacity deep-well turbine pumps.

REVIEW OF BASIC GEOHYDROLOGIC PRINCIPLES

Prior to any discussion of groundwater pumping methods, the reader should be familiar with some fundamental principles of groundwater—how it occurs, how it moves, and what governs its movement from areas of recharge to areas of discharge—irrespective of whether the discharge is natural or withdrawn through man-made devices (e.g., wells and pumps).

Aquifers are geologic formations or groups of formations capable of yielding water in usable quantities. Groundwater is the subsurface runoff component of the hydrologic cycle, which moves through and is stored in the interstitial spaces found between the solid particles of geologic formations. In unconsolidated materials such as sand and gravel, groundwater moves through the pore space, which occurs, between individual grains of solid material. This pore space is called primary porosity. In consolidated rocks (e.g., granite, volcanics, and limestone), groundwater moves through secondary porosity created as the result of fracturing, fissuring, or weathering. Groundwater flows from areas of recharge to areas of discharge with the rate and direction of flow governed by both the magnitude of the decreasing hydraulic head and the nature of the aquifer materials. Under the same hydraulic gradient, groundwater moves faster through more permeable materials (e.g., coarse sand and gravel) and slower through less permeable materials such as silty sands.

Aquifers may be grouped into three main types: confined, unconfined, and semiconfined, depending upon their subsurface layering and permeability. Confined aquifers, also known as artesian aquifers, are saturated formations found between low permeability materials. The low permeability materials prevent movement of water into or out of the saturated zone. Unconfined or water table aquifers have no upper confining layers. Semiconfined or "leaky" aquifers have semipervious layering either above or below and as a result, may allow water to flow vertically into or out of the aquifer depending on the difference in vertical hydraulic gradients.

As groundwater moves, it may discharge naturally to the earth's surface resulting in a spring, or contributing to the inflow of a lake or stream. Groundwater may also be artificially extracted from the subsurface through pumping or flowing wells. Flowing wells occur in confined (artesian) aquifers where the hydraulic head rises above the top of the well casing. Groundwater discharge to springs occurs when the groundwater surface intersects the land surface—usually in the sides of steep canyons (Fig. 1). Similarly, groundwater may flow into a subsurface drain or trench when groundwater levels in the aquifer are higher than that in the drain or trench. The Ghanats of Iran are an example of groundwater flowing into man-made subterranean tunnels. A Ghanat consists of a series of vertical (hand-dug) shafts typically spaced approximately 100 m (~300 ft) apart roughly paralleling the slope of alluvial fans located near the base of mountain ranges. Starting in the lowermost vertical shaft, a horizontal tunnel is dug which laterally connects the vertical shafts, working upslope until the water table is encountered. At this point, groundwater flows by gravity into the tunnel and is conveyed downslope for irrigation or domestic use. Ghanats are still used extensively throughout Iran as a method for tapping deep groundwater without the use of any type of pumping equipment. In ancient times, the Romans also used the technique in conjunction with aqueducts to serve urban water supply systems.[1]

Shallow, hand-dug wells have been used for centuries for irrigation and domestic use where surface water is not a reliable source. In modern times, deep vertical wells are used extensively in arid and semiarid environments to supply water for all purposes including domestic, industrial, agricultural, and municipal applications.

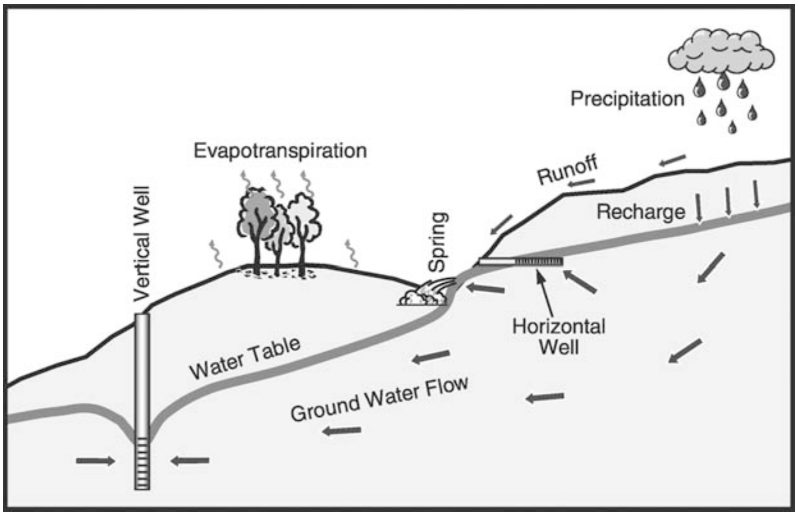

Fig. 1 Hydrologic cycle.

WELLS AND GROUND WATER PUMPING SYSTEMS

Water wells may be constructed in a variety of different aquifer materials in order to supply water for different uses. Most wells are vertical (Fig. 2); however, in specialized cases, wells may be horizontal (to enhance the flow from springs or seeps) or may include a central caisson with lateral ''spokes'' to induce greater infiltration from the aquifer (i.e., Ranney collector well—Fig. 3A and B).

To withdraw water from non-flowing water wells, a variety of pumping methods may be employed. The simplest of these do not require electrical energy or fuel-powered motors. These methods include positive displacement-type pumps such as windmills or hand pumps, or more simply a bucket attached to a rope used to raise water to the surface. Most pumps, however, require some sort of mechanical energy—supplied by a drive motor or engine—to lift water to the land surface.

When a well pump is turned on, groundwater first flows into the pump intake from the volume stored within the well casing and borehole area itself. As this volume is typically small compared to the capability of the pump to produce water, a hydraulic gradient forms between the pumping level inside the well and the groundwater level in the near-well zone. A ''cone of depression'' thus develops around the well, which assumes a general logarithmic shape (Figs. 4 and 5). As pumping continues, the cone of depression expands outward from the well until the recharge captured by the cone of depression equals the discharge requirements of the well. When the cone of depression reaches a steady or non-changing condition the well discharge rate is said to be in equilibrium with the recharge rate to the well. The type of aquifer materials and amount of water being pumped from the well determine the size and shape of the cone of depression. For example, domestic wells generally pump for short periods of time [measured as gallons per minute (gpm)] at rates of 1–15 gpm. This results in small, poorly defined cones

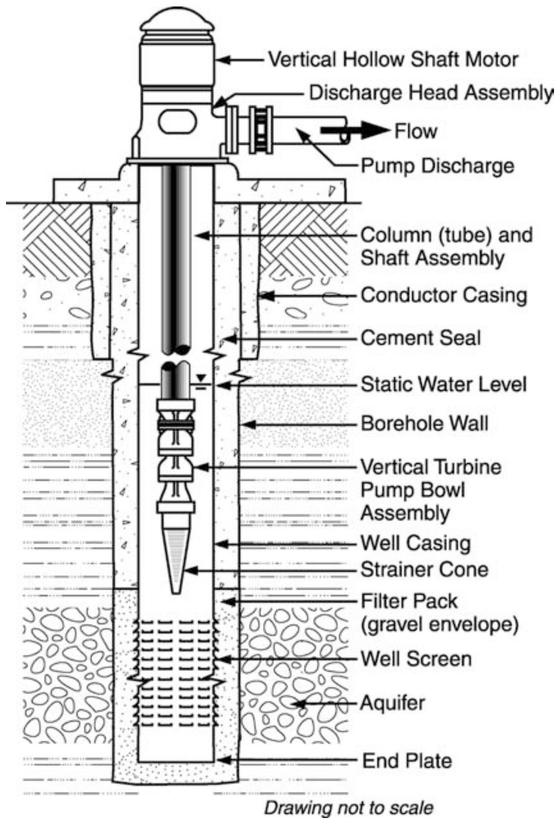

Fig. 2 Example of municipal water well showing deep-well turbine pump (Roscoe Moss Company).

Global–Groundwater

of depression. On the other hand, deep, large diameter, municipal water supply wells completed in coarse-grained alluvial aquifers can easily produce 2000–4000 gpm for long periods of time with cones of depressions extending several thousand feet. Fig. 5 defines pumping well terminology as related to the cone of depression.

COMMON GROUND WATER PUMPING METHODS

Types of Pumps

Pumps may be classified in accordance to use (e.g., shallow or deep wells), design (positive or variable displacement), and method of operation (rotary, reciprocating, centrifugal, jet, or airlift).[2] Shallow-well pumps (suction-lift pumps) are generally installed above ground. Deep-well pumps are always installed in the well casing with the pump intake submerged below the pumping level. Intake areas to deep-well pumps are always under a positive head and do not require suction to pump the water. Fig. 6 shows examples of centrifugal, jet, and rotary pump types.

Positive displacement (e.g., piston) and variable displacement (e.g., centrifugal pumps) are the two types most commonly used in water wells. In positive displacement-pumps, water is moved mechanically (for a given pump) and directly related to the speed of the pump (e.g., hand strokes per minute) and independent of the total lift (i.e., head). Pump discharge rate is changed by varying pump speed and decreases only slightly with increasing head.[3] In variable displacement-pumps on the other hand (e.g., airlift or centrifugal), the discharge rate depends largely on the total dynamic head (TDH) and decreases as the head increases.

Positive displacement-pumps are used for hand-pumped wells or windmill type of power with cylinders

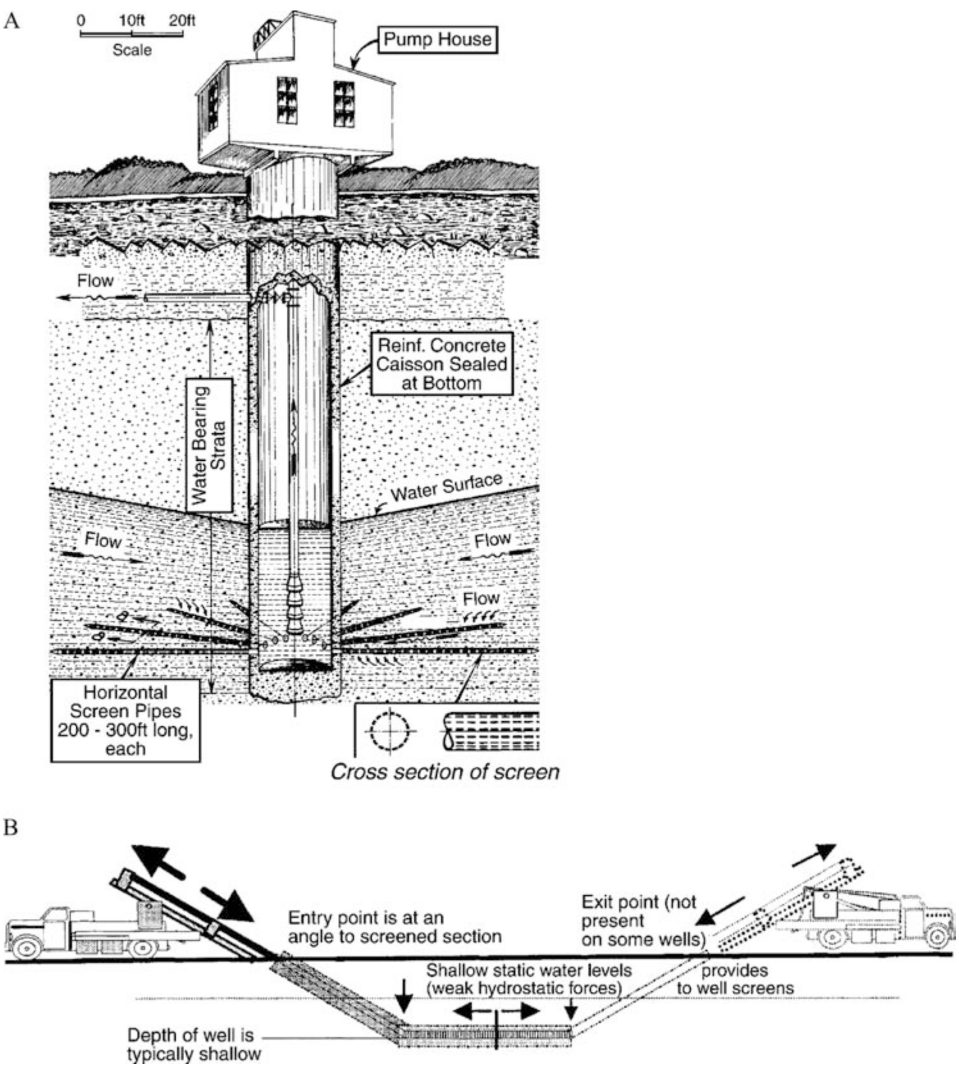

Fig. 3 (A) Typical radial collector well (Ranney Water Systems, Inc.). (B) Horizontal well (Ground Water Publishing Co.).

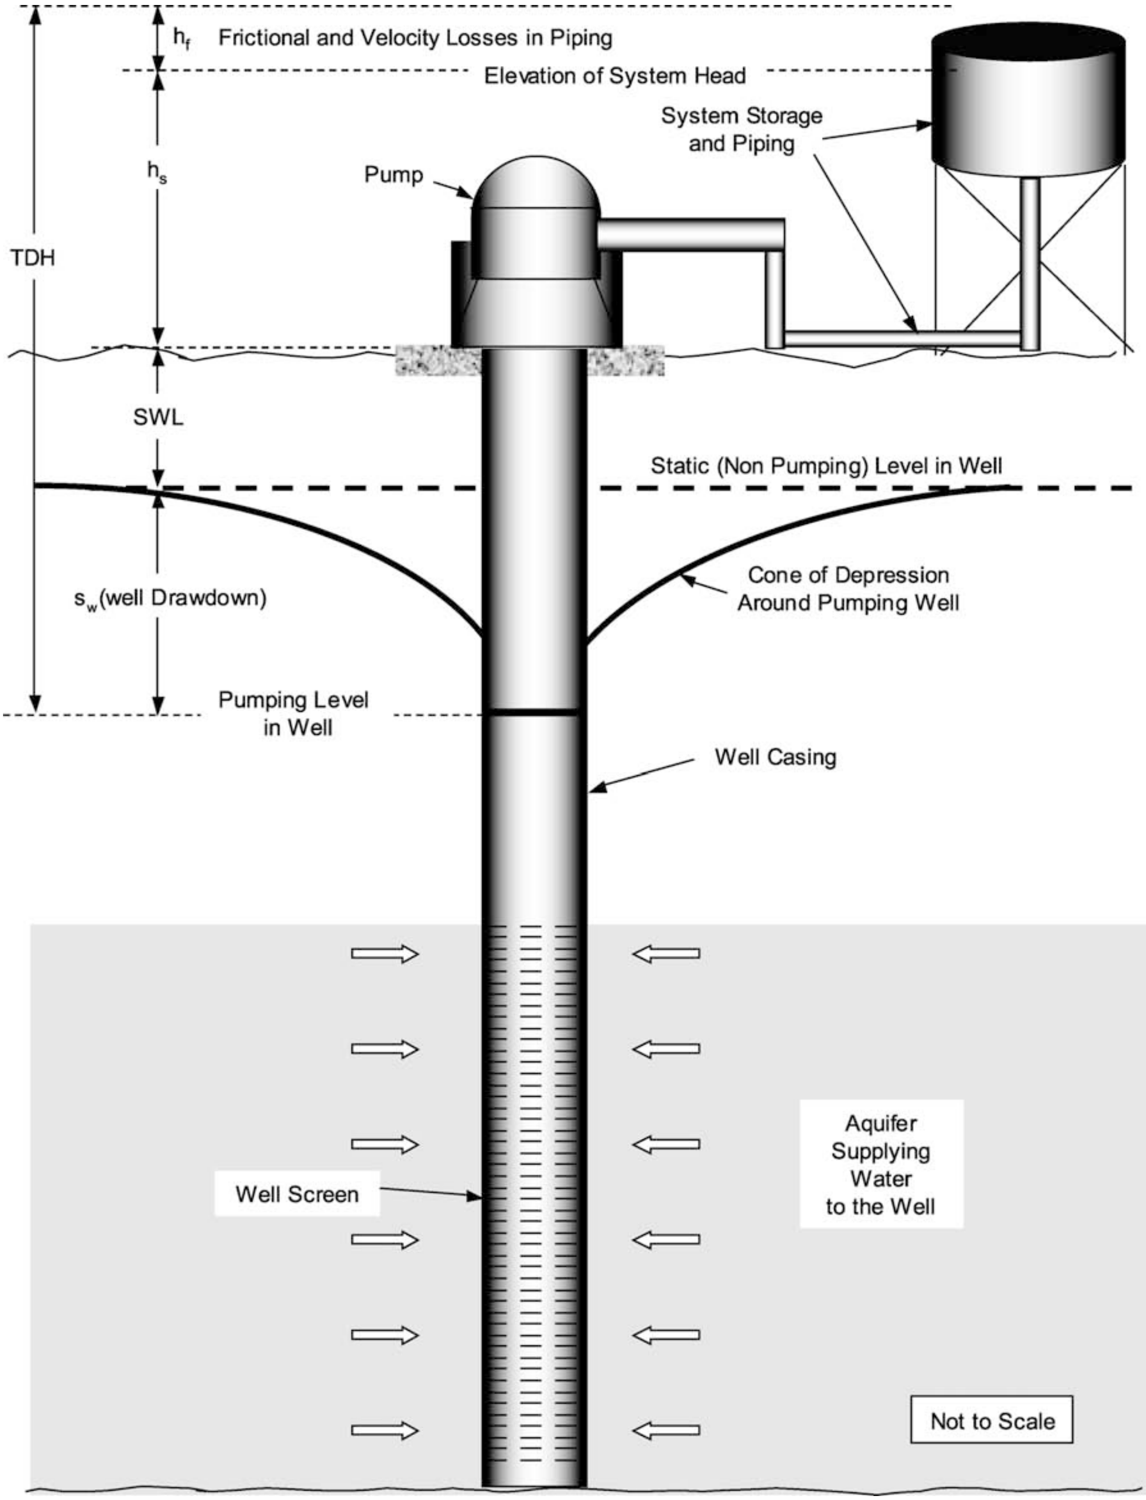

Fig. 4 Schematic of vertical deep water supply well, pump, and storage system.

mounted at the surface for shallow lifts (or down the well for deeper applications). Centrifugal pumps run at higher speeds than hand-operated pumps with electric, gasoline, or diesel motors typically providing the power source. Single-stage centrifugal pumps (Fig. 6(A)) can be used at the surface to pump water from shallow wells, but multiple stages are needed in wells where depths to pumping levels are deep.

Global–Groundwater

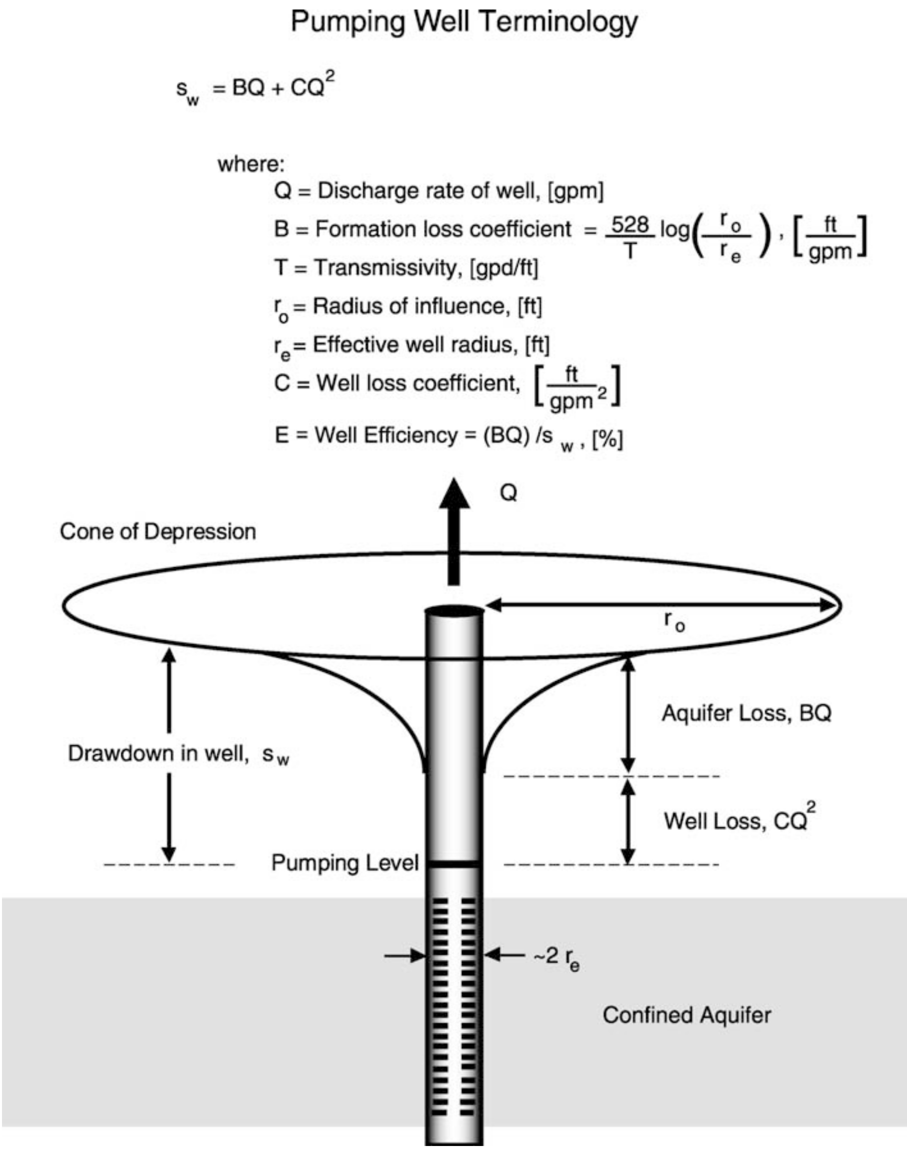

Fig. 5 Cone of depression around a pumping well.

Another type of pump is the jet pump. Jet pumps (Fig. 6(B)) may also be used at the surface for pumping shallow groundwater. A jet pump forces water down one pipe (through a high-pressure nozzle), and returns the water to the surface through a second pipe, where the discharge is used. Jet pumps are typically used for applications where the depth to water is less than approximately 22–25 ft.

Power is required to lift groundwater to the surface, either indirectly by suction pumps or directly from hand or mechanically driven pumps. Windmills may be a good choice for lifting water from shallow or deep-water wells in rural communities, or where conventional power supplies or fuel costs are either unavailable or very expensive. Modern technology has also produced solar cells that convert sunlight directly into electricity. One of the most important applications for solar cells in rural areas all over the world is for pumping water.[4]

Hand Pumps

A variety of inexpensive positive displacement-pumps are available to pump water from wells. One such type is called a "pitcher" pump (Fig. 7) and is commonly used when the water table is less than approximately 22–25 ft below the surface.[2,5] (The theoretical maximum suction lift equal to atmospheric pressure ~34 ft or 14.7 pounds per square inch (psi), cannot be achieved with these pumps). Pitcher pumps are surface-mounted, reciprocating or single-acting piston pumps utilizing a hand-operated plunger inside a cylinder set on top of the well casing. The pump suction pipe is attached to the bottom of the cylinder. The plunger has a simple ball valve that opens on the down stroke and closes on the upstroke. A check valve at the lower end of the cylinder opens on the upstroke of the pump and closes on the down stroke. Through

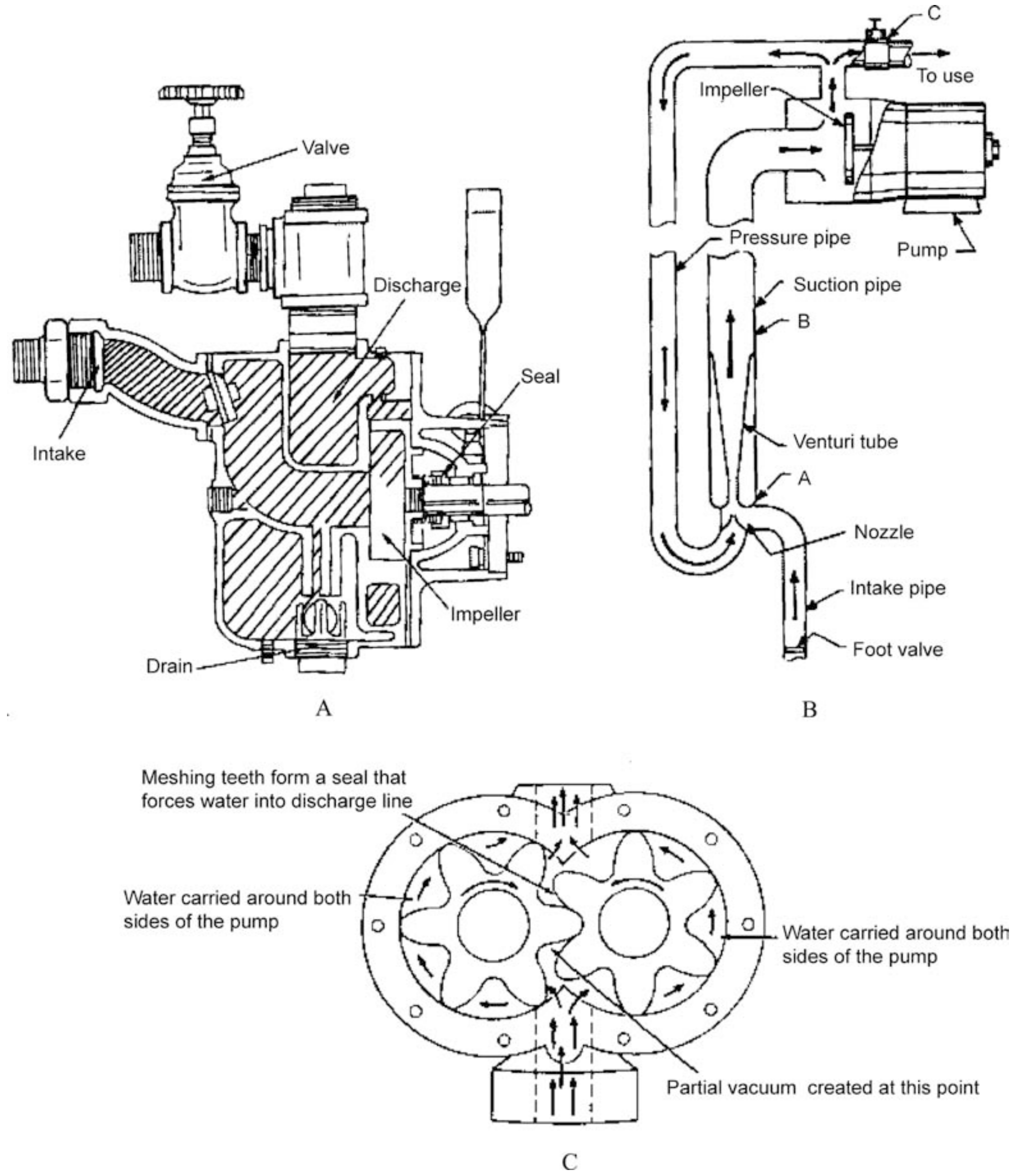

Fig. 6 (A) Single-stage centrifugal pump (U.S. Government Printing Office). (B) Jet pump (U.S. Government Printing Office). (C) Rotary pump (U.S. Government Printing Office).

continuous upstroke and down stroke actions water flows out of the discharge pipe. For deeper depths (up to 250 ft), a surface pump stand and separate lift cylinder can be installed down the well, which effectively ''pushes'' the water to the surface with the help of interconnecting rods. The latter method is often employed in a windmill system. Fig. 7 illustrates a typical suction pump.

Another manually operated water pump is the Treadle Pump. The Treadle Pump was developed to provide low cost, sustainable, environment friendly technology, which can be sold at a fair market price, in rural areas.[6]

The Treadle Pump relies upon the basic suction lifting principle of the hand pump consisting of two barrels, plungers, and treadles. One person through use of foot pedals can operate it. The discharge rate of a Treadle Pump can achieve approximately 10–15 gpm depending on the size of the pump/suction depth etc.

Rotary Pumps

These pumps use a system of rotating gears to create a suction at the inlet and force a water stream out of the discharge. The gears' teeth move away from each other at the inlet port. This action causes a partial vacuum and the water in the suction pipe rises. In the pump, the water is carried between the gear teeth and around

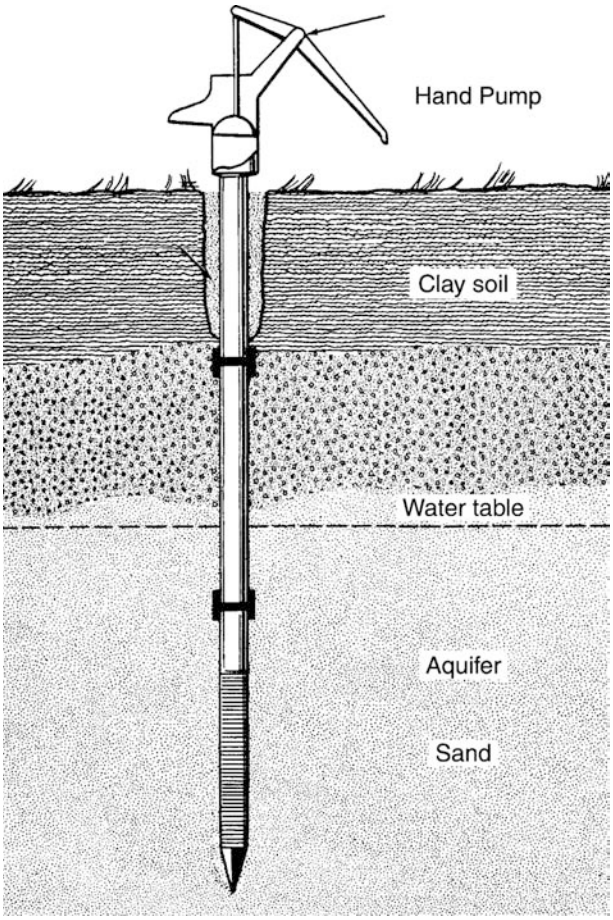

Fig. 7 Example of suction pump (U.S. Government Printing Office).

both sides of the pump case. At the outlet, the teeth moving together and meshing causes a positive pressure that forces the water into the discharge line. In a rotary gear pump, water flows continuously and steadily with very small pulsations. The pump size and shaft rotation speed determine how much water is pumped per hour. Gear pumps are generally intended for low-speed operation. The flowing water lubricates all internal parts. Therefore, the pumps should be used for pumping water that is free of sand or grit. If sand or grit does flow through the gears, the close-fitting gear teeth will wear, thus reducing pump efficiency or lifting capacity.

Airlift Pumps

Water can also be pumped from a well using an airlift pump (Fig. 8(A) and (B)). The airlift pump assembly consists of a vertical discharge pipe (eductor pipe) and a smaller air pipe which are both submerged below the well's pumping level for approximately two-third of their length.[7] Compressed air is forced through the air pipe to within a few feet of the bottom of the eductor pipe. The mixture of air bubbles and water formed inside the eductor pipe results in the air/water fluid being lighter than the water outside the eductor pipe (i.e., inside the well casing). This results in the air/water fluid flowing upward and out the top of the eductor pipe. Airlift pumps produce the best results when the submergence ratio of the air and eductor pipe is approximately 60%, however, reasonable results can be obtained with submergence as low as 30%.[8] An example of a 60% submergence is when the length of the air pipe is 200 ft (B on Fig. 8(A)) and the pumping water level depth is 80 ft (C on Fig. 8(A)). This results in a submergence of 120/200 (60%).

Centrifugal Pumps

Centrifugal pumps are variable displacement-pumps with the discharge rate being inversely related to the head supplied. That is, when the TDH increases, the discharge rate decreases.[9] A centrifugal pump contains a rotating impeller within a housing. The centrifugal forces generated by the spinning impeller impart kinetic energy to the water. This kinetic energy is converted into pressure at the discharge side of the pump. The general characteristic pump performance curves for centrifugal pumps are shown in Fig. 9 and relate TDH, pump efficiency, and horsepower.

Centrifugal pumps may be used to pump water from shallow wells with high water tables and low drawdowns. Centrifugal pumps may also be used in deep wells (deep-well vertical centrifugal pumps or commonly known as deep-well turbine pumps), and are installed inside the well casing below the water level. These latter pumps consist of a number of pump bowls with impellers, each set above another, which are added so as to ''build'' the head required. The impellers may be driven by either a motor at the surface (typically, electric, gasoline, or diesel) and connected to the pump by a long shaft and tube assembly (surface drive). The impellers may also be powered by a submerged electric motor directly coupled to the pump (submersible drive).

When a centrifugal suction pump is used to produce water from shallow wells, all pump components and suction lines must be completely filled with water or ''primed'' in order to operate. Hand-operated or motor-powered vacuum pumps are typically used for priming.

Deep-Well Turbine Pumps

Deep-well turbine pumps are the most common type of pump used in cased water wells where the groundwater surface is below the practical limits of centrifugal suction pumps.

The turbine pump has three main parts: 1) the head assembly; 2) the column (tube) and shaft assembly; and

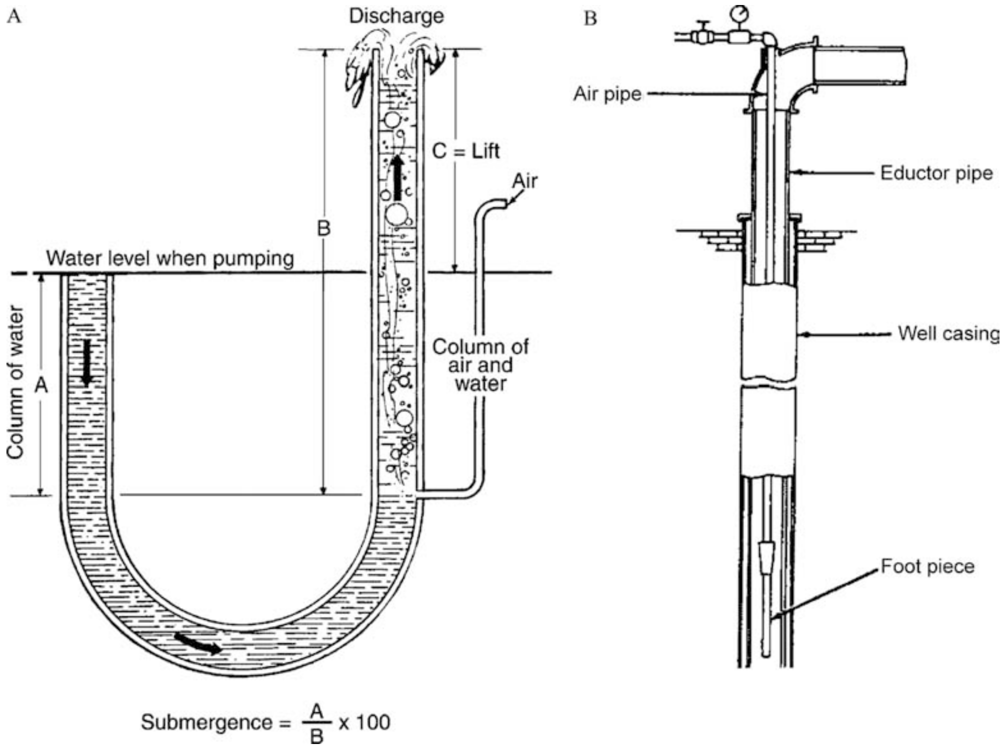

Fig. 8 (A) Principle of airlift pump (U.S. Government Printing Office). (B) Example of airlift pump (U.S. Government Printing Office).

3) the pump bowl assembly. The discharge head is typically cast iron or fabricated steel, and is designed to be installed on a foundation. The discharge head supports the column (tube), shaft, and bowl assemblies and directs the discharge of water. Additionally, it also provides a base to support an electric motor, a right angle gear drive or a belt drive (Fig. 2).

The column and shaft assembly connects the head and pump bowls. The line shaft transfers the power from the motor to the pump impeller(s). The impellers lift the water and the column conveys the lifted water to the surface. The line shaft on a deep-well turbine pump may be either water- or oil-lubricated. The oil-lubricated pump has an enclosed shaft (oil

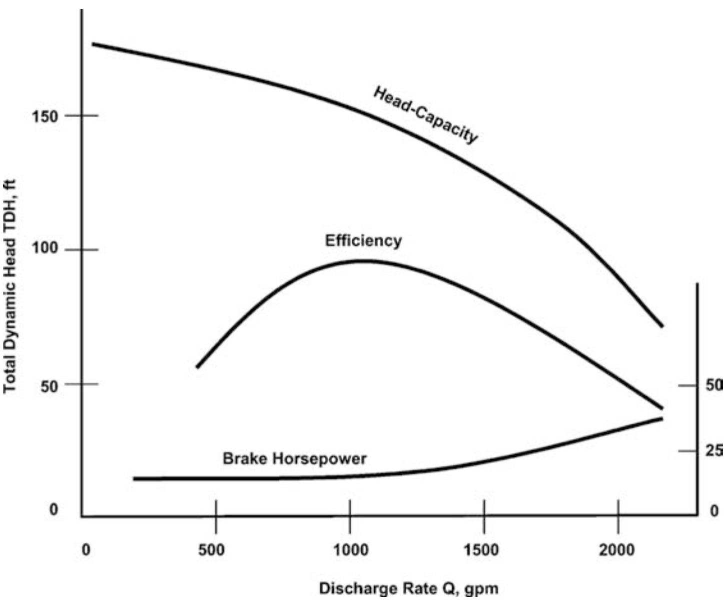

Fig. 9 Typical pump performance curves for centrifugal pumps.

tube) into which oil drips at the surface, lubricating the bearings by gravity. The water-lubricated pump has an open shaft, where the pumped water itself lubricates the bearings. If a high content of sand in the discharge is anticipated, an oil-lubricated pump should be selected in order to keep the bearings clean. The pump bowl encloses the impeller. In most deep-well turbine installations, several bowls (stages) are stacked in series. A four-stage bowl assembly contains four impellers attached by a common shaft, and will operate at four times the discharge head of a single-stage pump.[10]

Impellers used in turbine pumps may be either semi-open or enclosed. The vanes on semiopen impellers are open on the bottom and rotate with a very close tolerance to the bottom of the pump bowl (enclosure).

The operating characteristics of deep-well turbine pumps are determined by laboratory testing and depend largely on bowl design, impeller type, and speed. Vertical turbine pumps are generally designed for specific speeds [measured as revolutions per minute (rpm)]; generally, either 1800 rpm or 3500 rpm for deep-well turbine pump applications. Other speeds are used for specialized applications.[11] Pump

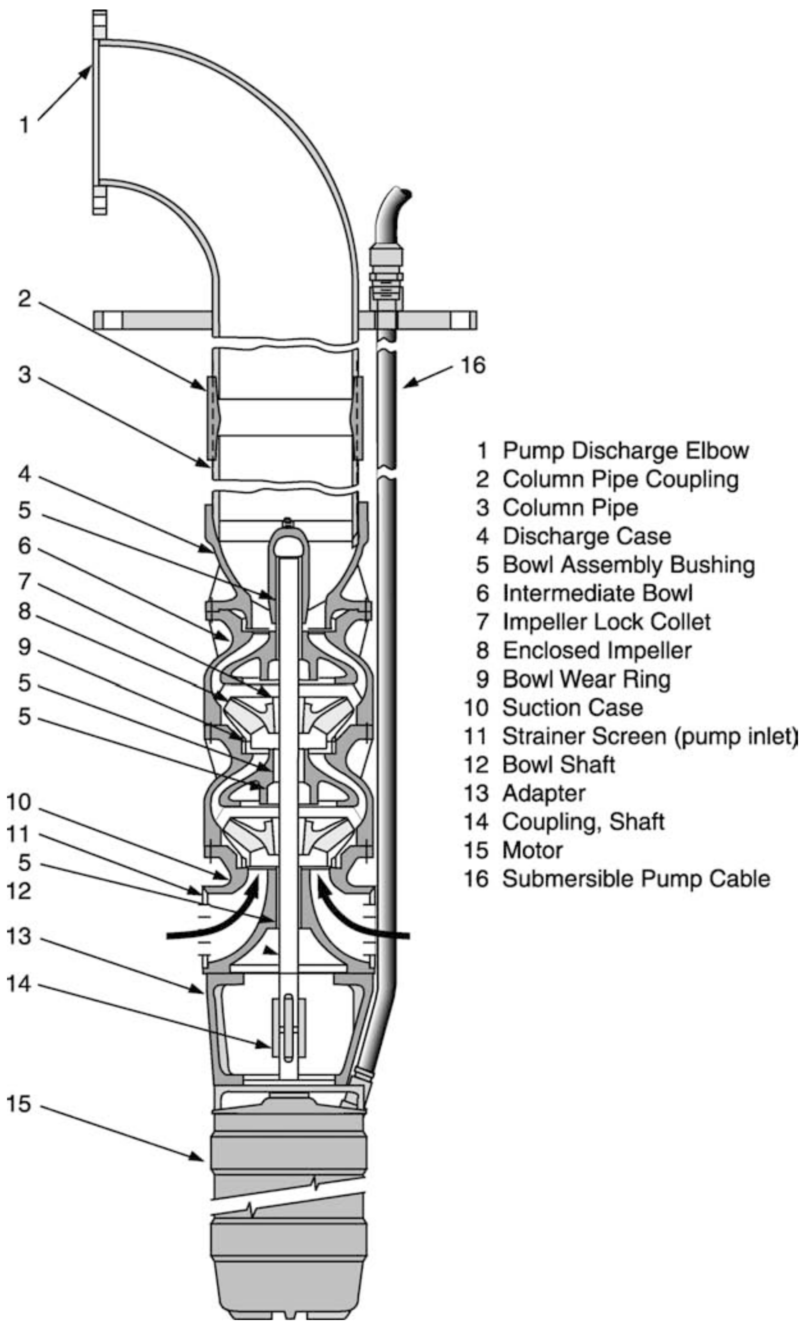

Fig. 10 Vertical turbine multi-stage submersible pump (Roscoe Moss Company).

performance curves at these speeds can be obtained from the manufacturer of each pump.

Submersible Pumps

A submersible pump is a turbine pump close-coupled to a submersible electric motor (Fig. 10). Both pump and motor are suspended below the water surface, eliminating the long drive shaft and bearing retainers required for a deep-well turbine pump. The pump bowl assembly is located above the motor. Water enters the pump through a screen located between the pump and motor. The pump curve for a submersible pump is very similar to a deep-well turbine pump.[10]

Submersible motors are smaller in diameter and much longer than ordinary motors. Because of their smaller diameter, they are lower in efficiency than those used for centrifugal or deep-well turbine pumps.

Most submersible pumps used for domestic purposes use either single or two-phase power, while larger pumps used for agricultural, industrial, or municipal purposes require three-phase power. Electrical wiring connecting the pump motor to the surface power supply must be watertight with all connections sealed. Submersible pumps can be selected to provide a wide range of flow rate and TDH combinations.

Pump Head and Power Requirements

Before selecting a pump, a careful and complete inventory of the conditions under which the pump will operate must take place. The discharge rate and TDH will be determined by the specific use and distribution system (Figs. 4 and 11). The TDH of a pump is the sum of the elevation and pressure heads plus head losses due to friction and velocity[3] (Fig. 4). Friction head is the sum of the energy loss due to the flow of water through a pipe, and is a function of the velocity and pipeline diameter including losses through fittings and valves as well as changes in flow direction and pipeline diameter. Values for these losses can be calculated or obtained from friction loss tables. The discharge rate, which will be produced, is a function of both the system and pump characteristics. The intersection of the system head curve and the pump head curve determine the discharge rate at which the pump will operate (Fig. 11).

Cavitation (i.e., implosion of air bubbles and water vapor on the impeller, causing pitting) occurs when the hydraulic head at the pump intake is too low. The head must be high enough so that as velocity increases (and pressure decreases), within the pump, the pressure cannot drop below the vapor pressure of the water. The minimum head needed at the pump intake is termed

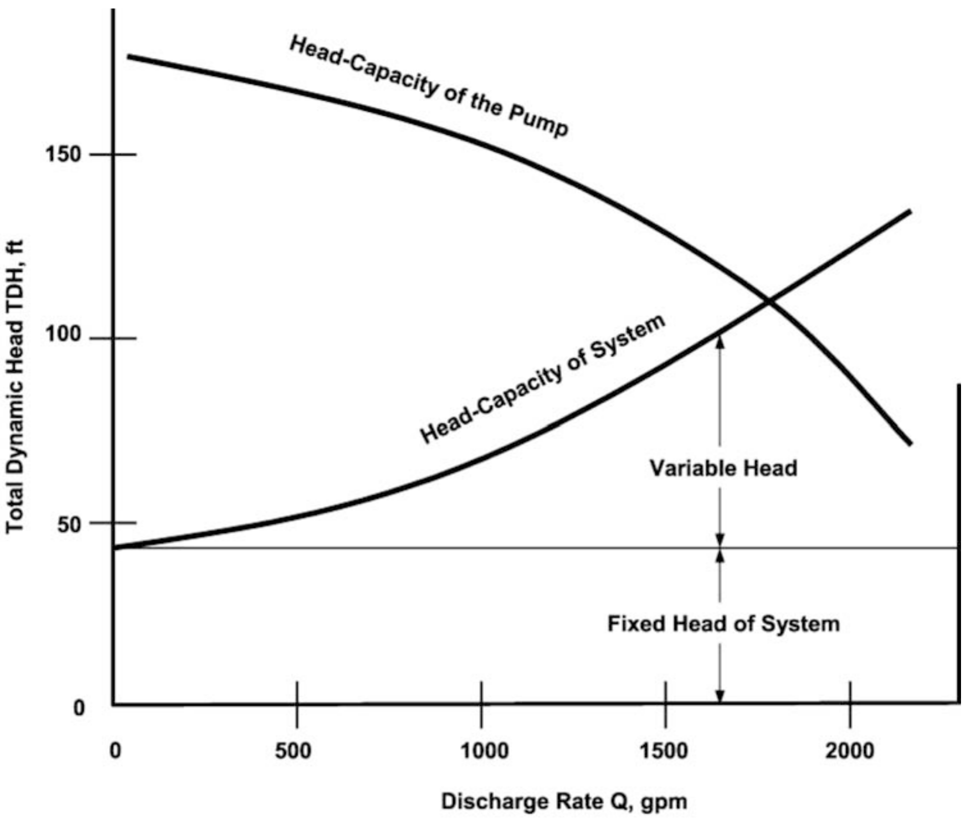

Fig. 11 Typical system head and pump curves.

Table 1 Pump selection criteria

Type of pump	Practical suction lift[a]	Usual well-pumping depths	Usual pressure heads	Advantages	Disadvantages	Remarks
Reciprocating						
1. Shallow Well 2. Deep Well	22–26 ft 22–25 ft	22–26 ft Up to 600 ft	100–200 ft	1. Positive action 2. Discharge against variable heads 3. Pumps water containing sand and silt 4. Especially adapted to low capacity and high lifts	1. Pulsating discharge 2. Subject to vibration and noise 3. Maintenance cost may be high 4. May cause destructive pressure if operated against closed valve	1. Best suited for capacities of 5–25 gpm against moderate to high heads 2. Adaptable to hand operation 3. Can be installed in very small diameter walls (2-in. casing) 4. Pump must be set directly over well (deep well only)
Centrifugal						
1. Shallow well				1. Smooth, even flow 2. Pumps water containing sand and silt 3. Pressure on system is even and free from shock 4. Low-starting torque 5. Usually reliable and good service life		
Straight centrifugal (single stage)	20 ft maximum	10–20 ft	100–150 ft		1. Loses prime easily 2. Efficiency depends on operating under design heads and speed	Very efficient pump for capacities above 50 gpm and heads up to about 150 ft
Regenerative vane turbine type (single impeller)	28 ft maximum	28 ft	100–200 ft		Same as straight centrifugal except maintains priming easily	Reduction in pressure with increased capacity not as severe as straight centrifugal
2. Deep well						
Vertical line shaft turbine (multi-stage)	Impellers submerged	50–300 ft	100–800 ft	Same as shallow-well turbine	1. Efficiency depends on operating under design head and speed 2. Requires straight well large enough for turbine bowl and housing 3. Lubrication and alignment of shaft critical 4. Abrasion from sand	

(Continued)

Table 1 Pump selection criteria *(Continued)*

Type of pump	Practical suction lift[a]	Usual well-pumping depths	Usual pressure heads	Advantages	Disadvantages	Remarks
Submersible turbine (multi-stage)	Pump and motor submerged	50–400 ft	80–900 ft	1. Same as shallow-well turbine 2. Easy to frost proof installation 3. Short pump shaft to motor	1. Repair to motor or pump requires pulling from well 2. Sealing of electrical equipment from water vapor critical 3. Abrasion from sand	Difficulty with sealing has caused uncertainty as to service life in data
Jet						
1. Shallow well	15–20 ft below ejector	Up to 15–20 ft below ejector	80–150 ft	1. High capacity at low heads 2. Simple in operation 3. Does not have to be installed over the well 4. No moving parts in the well	1. Capacity reduces as lift increases 2. Air in suction or return line will stop pumping	
2. Deep well	15–20 ft below ejector	25–120 ft, 200 ft maximum	80–150 ft	Same as shallow-well jet	Same as shallow-well jet	The amount of water returned to ejector increases with increased lift—50% of total water pumped at 50 ft lift and 75% at 100 ft lift
Rotary						
1. Shallow well (gear type)	22 ft	22 ft	50–250 ft	1. Positive action 2. Discharge constant under variable heads 3. Efficient operation	1. Subject to rapid wear if water contains sand or silt 2. Wear of gears reduces efficiency	
2. Deep well (Helical-rotary type)	Usually submerged	50–500 ft	100–500 ft	1. Same as shallow-well rotary 2. Only one moving pump device in well	Same as shallow well rotary except no gear wear	A rubber stator increases life of pump; flexible drive coupling has been weak point in pump; best adapted for low capacity and high heads

[a]Practical suction lift at sea level. Reduce lift 1 ft for each 1000 ft above sea level.

the net positive suction head (NPSH) and is specific to the operation and pump design.

The power required to move water through a pump may be calculated using the following formula:

$$WHP = (Q \times TDH)/(3960)$$

where, WHP = water horsepower, Q = discharge rate of the well pump, [gpm], TDH = total dynamic head, [ft] = $s + \text{SWL} + h_s + h_f$, s = drawdown in the pumping well, [ft], SWL = depth to static water level below reference point, [ft], h_s = elevation of system head above reference point, [ft], h_f = friction (and velocity) head losses in piping system from pump to system storage, [ft].

However, the actual horsepower required to run a pump will be greater than the water horsepower as pumps and drivers are not 100% efficient. The horsepower required to pump a specified flow rate against a specified TDH therefore is the brake horsepower (BHP), and is calculated using the following formula:[10]

$$BHP = (Q \times TDH)/(3960 \times e)$$

where, BHP = water horsepower (horsepower rating of the power unit), e = pump efficiency × drive efficiency (expressed as a decimal).

The pump efficiency (percentage) may be read directly from the pump curve provided by the manufacturer. The drive efficiency is the efficiency value (percentage) given the driver unit (source of power to the pump) by the manufacturer.

Pump Selection Criteria

Proper selection of a pump must consider both anticipated pumping conditions and well type, which include the following main design parameters:[10]

- Diameter of the well.
- Required discharge rate.
- TDH.
- Depth to static ground water.
- Friction losses.
- Power requirements.
- Power source.
- Water quality and/or potential for sand production.

Centrifugal suction pumps are generally used for shallow groundwater levels (e.g., less than 22–25 ft) while most installations utilize deep-well turbine or submersible pumps. The discharge rate of the well is often overlooked when selecting a pump for small wells. If too large a pump is installed in a small capacity well, the result will be to either temporarily drain the well (i.e., "break suction"), or exceed the maximum possible suction lift. It is very important, therefore, to match pumping requirements and well characteristics when selecting the optimum pump for each installation. Table 1 provides general guidelines for pump selection.[2]

Groundwater: Quality

Loret M. Ruppe
Timothy R. Ginn
Department of Civil and Environmental Engineering, University of California–Davis, Davis, California, U.S.A.

INTRODUCTION

Groundwater quality refers to the type and concentration of constituents in a given source of groundwater. Constituents in groundwater may originate from the natural environment with which the groundwater comes in contact, or may be introduced as pollutants from external sources. Constituents can be dissolved solids and gases, suspended solids, hydrogen ions, and microorganisms. There is wide variation in the chemical and biological constituents in groundwater due to the differing qualities of water that recharge groundwater, and due to the different environments through which groundwater passes. The unique polar nature of the water molecule makes it a ready solvent, with the capacity to dissolve many solid-phase minerals into solution, and many of the elements comprising the subsurface environment dissolve into ground water.

Groundwater is never free from all impurities. A principal and ubiquitous constituent class is that of ions in solution, that have dissolved into the groundwater from the earth materials in which it flows. Total ionic concentration includes various dissolved salts and associated mineral species as well as hydrogen, and is quantified as total dissolved solids (TDS). The concentration of TDS in units of mass of ions per volume of water is used to classify water, with fresh water (0–1000 mg/L TDS) differing from brackish (1000–10,000 mg/L TDS), saline (10,000–100,000 mg/L TDS), and brine (greater than 100,000 mg/L TDS) waters in dissolved solids concentration. Potable water typically has less than 500 mg/L TDS, while the concentration in seawater is approximately 35,000 mg/L.[1]

TYPICAL CONSTITUENTS IN GROUNDWATER

Inorganic solids comprising the geologic material of the subsurface constitute the greatest concentrations of constituents in groundwater, with bicarbonate, calcium, chloride, magnesium, sodium, and sulfate typically 90% of the TDS in groundwater.[1] As groundwater ages in an aquifer, dominant ions tend to shift from calcium (Ca^{2+}) and bicarbonate (HCO_3^-) to sodium (Na^+) and chloride (Cl^-). Constituents generally found in uncontaminated groundwater are classified in Table 1 according to relative abundance.[2,3]

MECHANISMS INFLUENCING GROUND-WATER QUALITY

The processes by which chemicals are dissolved into the groundwater are primarily: mineral dissolution and precipitation, microbially mediated oxidation and reduction reactions, ion exchange and adsorption, and hydrolysis.[4] Each of these processes is described later.

Mineral Dissolution and Precipitation

Rainwater is slightly acidic (pH $<$ 7), and more so in regions with acidic air pollutants that dissolve into water droplets. Once the rainwater reaches the ground and percolates through the root zone, the degree of acidity can increase further as the oxygen in the water is consumed by the decay of organic matter and by the respiration of plant roots. Oxygen removal creates an oxygen sink that is filled by the further dissociation of aqueous compounds containing oxygen such as bicarbonate, that also puts more hydrogen ions into solution, thus reducing pH. Water from rainfall, lakes, streams, and other sources travels through the unsaturated vadose zone, and accumulates in the saturated zone of an aquifer. As the water passes through the vadose zone and through the aquifer, the acidity of the water causes the dissolution of the geologic features into which it comes in contact. An example is the dissolution of calcite, $CaCO_3$, the basic constituent of limestone, marble, and chalk that is commonly found in sedimentary rock. In the presence of acidity in the groundwater, in the form of carbonic acid, H_2CO_3, calcium and bicarbonate become dissolved ions in the groundwater solution.

$$CaCO_3 + H_2CO_3 \rightarrow Ca^{2+} + 2HCO_3^-$$

Table 1 The dissolved constituents in potable groundwater classified according to relative abundance

Major constituents (greater than 5 mg/L)	
Bicarbonate	Silicon
Calcium	Sodium
Chloride	Sulfate
Magnesium	Carbonic acid
Nitrogen	
Minor constituents (0.01–10.0 mg/L)	
Boron	Nitrate
Carbonate	Potassium
Fluoride	Strontium
Iron	Bromide
Oxygen	Carbon dioxide
Trace constituents (less than 0.1 mg/L)	
Aluminum	Nickel
Antimony	Niobium
Arsenic	Phosphate
Barium	Platinum
Beryllium	Radium
Bismuth	Rubidium
Cadmium	Ruthenium
Cerium	Scandium
Cesium	Selenium
Chromium	Silver
Cobalt	Thallium
Copper	Thorium
Gallium	Tin
Germanium	Titanium
Gold	Tungsten
Indium	Uranium
Iodide	Vanadium
Lanthanum	Ytterbium
Lead	Yttrium
Lithium	Zinc
Manganese	Zirconium
Molybdenum	
Organic compounds (shallow)	
Humic acid	Tannins
Fulvic acid	Lignins
Carbohydrates	Hydrocarbons
Amino acids	
Organic compounds (deep)	
Acetate	
Propionate	

Source: Domenico and Schwartz,[2] modified from Davis and DeWiest.[3]

Given an adequate supply of calcite and carbonic acid, calcium will continue to dissolve into solution until an equilibrium state is reached.

Oxidation and Reduction Reactions

Microorganisms, primarily bacteria, are ubiquitous throughout the subsurface environment, with population diversity and density typically decreasing logarithmically with depth. The metabolic activities of the microorganisms catalyze reactions within the groundwater that involve transferring electrons to form different compounds. Organic material can be converted to inorganic compounds such as carbon dioxide and water through this process. Such reactions are the basis for in situ bioremediation of organic contaminants.

Ion Exchange and Adsorption

Essentially all surfaces of aquifer materials are electrically charged. For instance sands are quartzitic materials generally carrying negative charges, but are often partly coated with mineral oxide (iron, manganese, aluminum) compounds that have a net positive charge. Ions in the groundwater attach (adsorb) to the charged surfaces, thereby altering the chemical make-up of the groundwater. Ion exchange refers to the preferential sorption due to electrostatic forces of multivalent ions over monovalent ions, that is reversible if the aqueous concentration of monovalent ions is high enough. Clay minerals have dense surface charges and are typically involved in ion exchange and adsorption. Ion exchange in clay minerals involves intra-particle sites, and exchange is associated with swelling or shrinking of the clay medium on the macroscale. For instance when a single bivalent ion is replaced by two monovalent ions, the clay particle swells.

Hydrolysis

As noted earlier, the polar structure of water facilitates reaction with chemical compounds to form new compounds. The replacement of ions in a compound with H^+ or OH^- ions of water is termed hydrolysis. The chemical make-up of groundwater will influence the degree to which hydrolysis will occur.

Some of these geochemical and biochemical reactions occur simultaneously, while others occur sequentially. The rates at which these reactions occur vary considerably, ranging from nearly instantaneously to slowly enough that the equilibrium is never reached. Knowledge about the processes is critical in predicting the way in which groundwater quality evolves and responds to treatment, and the rate of the change; efforts continue by scientists and engineers to accurately model the reactions occurring in the complex groundwater environment.

GROUND WATER QUALITY ISSUES

Groundwater contamination has a direct effect on the quality of drinking water for many people. More than fifty percent of the drinking water in the United States is groundwater.[5] Contaminants to groundwater can originate from a "point source" (PS; single specific discharge point) or from a "non-point source" (NPS; diffuse source that contributes a contaminant, or contaminants, to the environment). PS of groundwater contamination include industrial waste discharges, leaking petroleum storage facilities, and municipal wastewater treatment plant discharges. NPS discharges are often associated with rainfall runoff and snowmelt events from agricultural operations, roadways and vehicle emissions, construction sites, mining operations, landfills, and logging activities. Other sources of NPS pollution include soil erosion (sediment transfer), failing onsite wastewater treatment systems, animal wastes in feedlot runoff, or animal waste holding pond overflows.

Agricultural Wastes

Agricultural operations contribute many constituents that contaminate the groundwater. The chemical pesticides, herbicides, and fertilizers applied to crops can reach the groundwater through land application and in rainfall runoff. Animal manure wastewater, which harbors human pathogens such as *Cryptosporidium parvum* oocysts, can similarly migrate to the groundwater. NPS contamination can result from irrigation using animal manure wastewater, as well as land application of waste solids or liquids for non-irrigation purposes.

Industrial Wastes

The disposal of the chemical byproducts of industrial processes is regulated to varying degrees around the world. The wastes may not be adequately treated before being discharged to the environment, where they frequently migrate to groundwater. Additional sources of contamination are chemical spills and leaking storage tanks. Such sources include those from military and energy facilities, which often involve heavy metals and/or radionuclides in solution, as well as dissolved explosives and solid fuels for propellants.

Municipal Wastewater

The increase in synthetic chemical usage around the home results in the discharge of portions of these chemicals into the wastewater sewerage system. Treatment plants are designed to purify human wastewater, but are not designed to remove these additional chemicals, with the result that increasing concentrations of chemicals are bypassing the treatment process and are released into the environment, eventually being detected in groundwater.

Synthetic Chemicals

Increasingly, groundwater contamination results from the growing usage of synthetic chemicals. With over 65,000 synthetic chemicals in common use in the United States today, these chemicals are being detected in groundwater supplies with increasing frequency. Products that contain organic chemicals include solvents, pesticides, paints, inks, dyes, varnishes, and gasoline. The U.S. Environmental Protection Agency performed groundwater surveys in the 1990, that have confirmed the widespread presence of organic contaminants.[5]

Groundwater Salinization

In coastal regions, the pumping of groundwater from an aquifer can result in the intrusion of saline waters, thereby severely altering the quality of water. As groundwater mining increases, this is becoming an increasing problem in many regions as salinity can degrade the quality to the extent that it is no longer potable.

Groundwater is a resource that is increasing in value for the support of human activities and life itself. Increasing efforts are required to slow the degradation of groundwater quality in much of the United States.

INTRODUCTION

Irrigation water quality can have a profound impact on crop production inasmuch as irrigated agriculture can affect groundwater quality. Irrigated agriculture not only involves the application of water, which contains dissolved mineral elements, but is often coupled with other inputs such as fertilizers and pesticides. Many of these constituents can leach past the crop rootzone and pollute the underlying aquifer. Other chapters in the Encyclopedia will address impacts of irrigated agriculture on groundwater quality. The emphasis of this chapter is on groundwater quality, and its potential impacts on irrigated agriculture.

GROUNDWATER QUALITY

All groundwater sources used for irrigation contain dissolved mineral salts, but the concentration and composition of the dissolved salts vary from one aquifer to another. Dissolved mineral salts form ions; either positively charged cations or negatively charged anions. The most common cations are calcium (Ca^{2+}), magnesium (Mg^{2+}), and sodium (Na^+) whereas the most abundant anions are chloride (Cl^-), sulfate (SO_4^{2-}), and bicarbonate (HCO_3^-). Potassium (K^+), carbonate (CO_3^{2-}), nitrate (NO_3^-), and trace elements also exist in groundwater supplies but most often concentrations of these constituents are comparatively low. On the other hand, some groundwater sources contain boron (B) at comparatively low concentrations but at levels that may be detrimental to certain crops.

An understanding of the quality of water used for irrigation and its potential negative impacts on the crop, soil, and irrigation system is essential to avoid problems and optimize production. The salinity of the water is important because too much salt can reduce crop production while too little salt or certain compositions of salt (i.e., sodic waters) can reduce water infiltration, which indirectly affects the crop. Certain elements or combination of elements in the groundwater can be toxic to sensitive crops or pose a management or maintenance problem. More detailed information on water quality and impacts on agriculture can be found in Ref.[1]. For more information on the nature and extent of agricultural salinity, see Ref.[2] or visit http://water.usgs.gov/nwis/gw for actual groundwater quality data in the United States.

Characterizing Salinity

There are two water quality parameters that characterize the salinity of the irrigation water: electrical conductivity (ECw) and total salt concentration or total dissolved solids (TDS). The units of TDS are usually in milligrams of salt per liter of water ($mg\ L^{-1}$). This term is used by many commercial analytical laboratories and represents the total mg of salt that would remain after a liter of water is evaporated to dryness. Often, TDS is reported as parts per million (ppm), which is numerically equivalent to $mg\ L^{-1}$. The higher the TDS, the higher is the salinity of water.

Electrical conductivity is a much more useful term because the measurement can be made instantaneous in the field. Salts that are dissolved in water conduct electricity and therefore the salt content in the water is directly related to the ECw. Units of EC reported by labs are usually in decisiemens per meter ($dS\ m^{-1}$) or millimhos or micromhos per centimeter ($mmhos\ cm^{-1}$ or $\mu mmhos\ cm^{-1}$). One $mmho\ cm^{-1} = 1000\ \mu mmhos\ cm^{-1} = 1\ dS\ m^{-1}$.

Often, a conversion between ECw and TDS is made based on guidelines from Ref.[3] (i.e., ECw $\times$ 640 $=$ TDS) but caution is advised because this conversion is dependent on both salinity and composition of the water. The USDA-ARS Salinity Laboratory has a web site that has educational material, models, databases, and lists of publications on various chemical, physical, and phyto-biological aspects of salinity including a pdf version of Handbook 60 http://www.ussl.ars.usda.gov/.

Characterizing Sodicity

The sodicity or alkalinity of the groundwater is characterized on the basis of its Na^+ relative to Ca^{2+} and Mg^{2+} concentration. Sodicity[4] refers to either the exchangeable Na percentage (ESP), or the sodium adsorption ratio (SAR) of the soil solution. The SAR $= Na^+/(Ca^{2+} + Mg^{2+})^{0.5}$ where ion concentrations

Global–Groundwater

are millimolar and the ESP is the percentage of the soil's cation-exchange-capacity (CEC) occupied by Na^+.

RELATIONS BETWEEN IRRIGATION WATER, SOIL SALINITY, AND LEACHING

Salts can accumulate in the root zone from the irrigation water due to insufficient leaching. To prevent salt accumulation in the root zone from the irrigation water, the soil must be adequately leached. Leaching is the process of applying more water to the field than can be held by the soil in the crop root zone such that the excess water drains below the root system carrying salts with it. The more water that is applied in excess of the crop water requirement, the less the salinity in the root zone will be despite the fact that more salt has been added to the field. The term ''leaching fraction'' (LF) is used to relate the fraction or percent of water infiltrated to the field that actually drains below the root zone.

Below are some useful relationships between the salinity in the irrigation water (ECw) and the average root zone salinity (ECe). The ECe is the electrical conductivity of the saturate soil paste (i.e., soil samples are saturated with distilled water, the soil water is then extracted, and the EC is measured on the extracted water). These relationships predict what would happen over the long-term if the LFs indicated are achieved, assuming steady-state conditions and a 40-30-20-10 root water extraction pattern where the top and bottom quarters of the root zone extracts 40% and 10% of the crops consumptive water use.

$$\text{LF } 10\% \quad \text{ECw} \times 2.1 = \text{ECe}$$

$$\text{LF } 15-20\% \quad \text{ECw} \times 1.5 = \text{ECe}$$

$$\text{LF } 30\% \quad \text{ECw} = \text{ECe}$$

The leaching requirement is an attractive concept but has limitations. First, the ET of the crop is assumed to be independent of the average root zone salinity.[5] Thus, calculated crop water requirements will be high where the average root zone salinity exceeds the threshold salinity of the crop, which corresponds to a yield potential less than 100%. Second, the leaching requirement is based on steady-state conditions and does not account for the initial salinity status in the root zone. Finally, applying irrigation water to a field to achieve a given LF is very difficult, if not impossible, particularly with fine textured soils in climates with high evaporative demand. Nevertheless, in order to control salinity, leaching must occur whether it is achieved before the season, midway through the season, or at the end of the season.[1]

In fields where salinity has increased in the root zone to damaging levels, ''reclamation leaching'' is recommended. Ref.[6] provides additional information on reclamation of soils.

For more information on relations between irrigation water salinity, leaching, and root zone salinity—see Refs.[7,8].

IMPACT ON CROPS

Salinity, caused by either too much salts in the groundwater supply and/or insufficient leaching, can directly affect the crop in two ways, by osmotic effects and by specific ion effects. The osmotic effects are responsible for growth reduction, the most common whole-plant response to salinity. Within limits, isosmotic concentrations of different combinations of salts cause nearly equal reductions in growth. On the other hand, specific ions such as Na^+, Cl^-, and B may be particularly injurious to certain crops or under specific management practices. A detailed discussion of mechanisms of salt tolerance and injury can be found in Refs.[9,10] and references cited therein.

Estimating Yield Potential

Crops vary widely in their response to salinity. Some crops such as bean and onion are very sensitive to salinity while others such as cotton and asparagus are tolerant. The salt tolerance of a crop is best described by plotting its relative yield as a function of the average root zone salinity (ECe). This response curve is represented by two line segments; one, a tolerance plateau with zero slope and the second, a concentration-dependent line whose slope indicates the yield reduction per unit increase in ECe[11] (Fig. 1).

Maas and Hoffman[11] assembled a table with salinity coefficients. The point where the first line segment meets the second line segment is referred to as the yield threshold coefficient (a). This represents the maximum soil salinity a crop can tolerate before its yield declines. The slope of the second line is the second salinity coefficient (b), which represents the percent decrease in yield per unit increase in ECe. Thus, the relative yield (%) $= 100 - b(\text{ECe} - a)$. Additional salinity coefficients can be found in Ref.[12].

These salinity coefficients are particularly useful in predicting yield potentials based on either the average root zone salinity or based on the irrigation water itself by using the relations between ECw, ECe, and LF described earlier.

Global–Groundwater

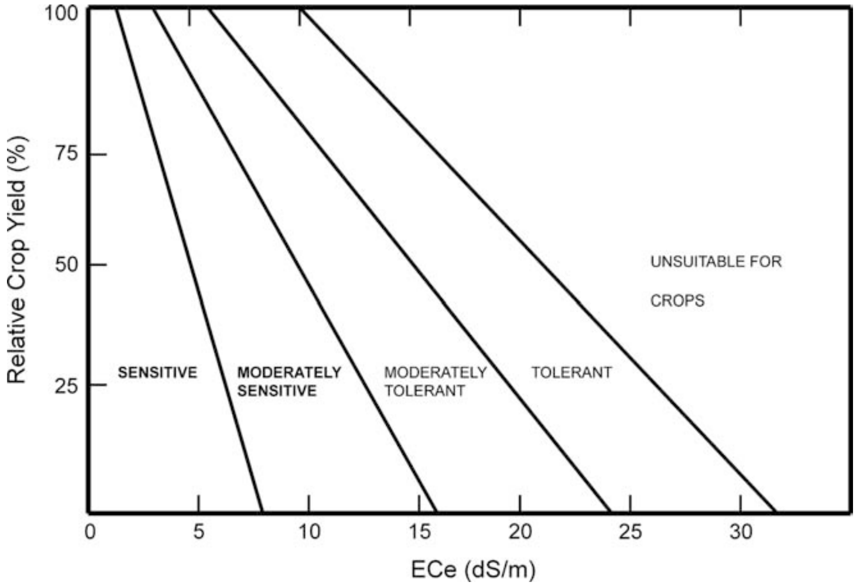

Fig. 1 Divisions for classifying crop tolerance to salinity. *Source*: From Ref.[12].

It is important to emphasize that these are only guidelines and assume that all other factors such as fertility, irrigation scheduling, and pest control are managed to maximize crop performance. It is also important to note that most of the experiments that were used to generate these guidelines were conducted in the interior of California where the climate is hot and dry during the summer. Crops grown in the coastal regions or where the climate is milder will likely tolerate greater salinities than indicated in these publications. For more detailed information on relations between crop yields and salinity, see Refs.[1,12].

Crop Toxicity to Specific Elements

In addition to salinity's general osmotic effect, some crops, particularly tree and vines, are injured by certain elements, specifically Na^+, Cl^-, and boron (B). These elements are absorbed by the root and move with the transpirational stream to the leaves where they concentrate. Thus, older leaves or older portions of leaves such as margins and tips transpire more than younger tissue and develop injury first. Injury usually begins as chlorosis and advances into necrosis as injury becomes more severe. Fig. 2 shows both Cl and B injury to tomato leaves. Although the injury is similar, Cl injury in most crops has more chlorosis (leaf yellowing) contiguous to the necrotic tissue whereas necrotic portions from B injury are often darker with a reddish-brown coloration.

This additional injury complicates salt-tolerance in that the combined osmotic and specific-ion effects may affect the yield potentials of the crop more than the salt-tolerance guidelines would indicate. Tables are provided that list the maximum concentration of Cl or B in the soil water that a crop can tolerate before it develops symptoms of ion toxicity.[12]

The irrigation method can affect crop sensitivity to water quality. With drip and furrow irrigation, chloride and sodium injury does not generally occur in most

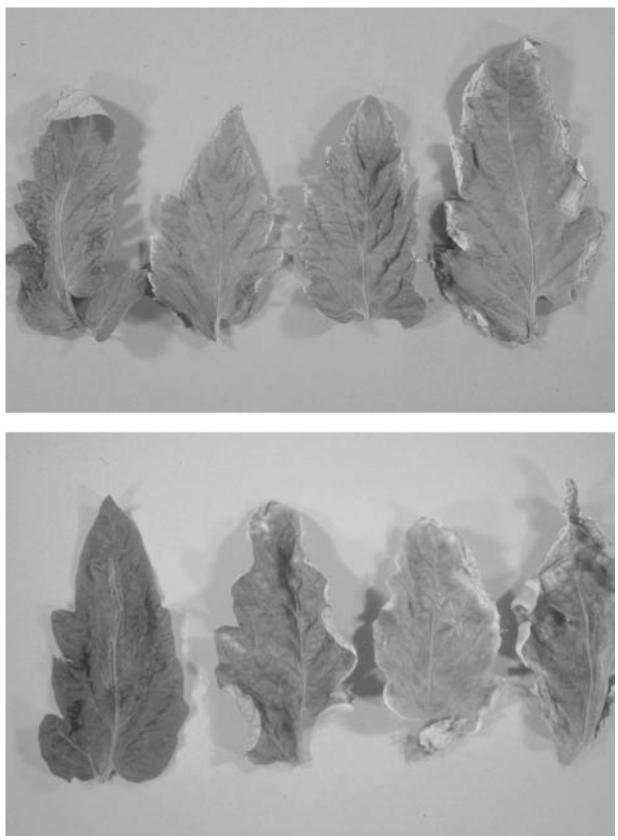

Fig. 2 Progression of injury to tomato leaves due to boron toxicity (upper) and chloride toxicity (lower).

Global–Groundwater

vegetable and row crops unless salinity is severe. Under sprinkler irrigation, injury may develop on wetted leaves of susceptible plants such as peppers, potatoes, and tomatoes if the ECw exceeds $1.5\,\mathrm{dS\,m^{-1}}$ (see Ref.[12]). Injury occurs due to direct foliar absorption of salts. Susceptibility to leaf injury is related to leaf wettability, leaf morphology, and the rate of foliar salt absorption and not tolerance to soil salinity. Increased frequency of sprinkler irrigation is usually more damaging that increased duration.

Some vegetable and row crops are sensitive to boron. Generally, leaf injury must be severe to cause reduced yields and crop quality. Long-term use of irrigation water containing more than $0.5 - 0.7\,\mathrm{mg\ L^{-1}}$ boron can reduce the yields of bean, onion, garlic, strawberry, broccoli, carrot, potato, and lettuce and greater than $2\,\mathrm{mg\ L^{-1}}$ can reduce yields of cabbage and cauliflower.

Unlike most annual crops, tree and vine crops are generally sensitive to boron, chloride, and sodium toxicity. Tolerances vary among varieties and rootstocks. Tolerant varieties and rootstocks resist the uptake and accumulation of toxic ions in the stem and leaf tissue. Continued use of irrigation water with boron concentrations in excess of $0.75\,\mathrm{mg\,L^{-1}}$ can reduce the yields of grapes and many deciduous tree and fruit crops. This represents a threshold concentration and does not imply that irrigation water with boron at or slightly above this level cannot be used successfully.

Chloride moves readily with the soil water and is taken up by the roots. It is then transported to the stems and leaves. Sensitive berries and avocado rootstocks can tolerate only up to $120\,\mathrm{mg\,L^{-1}}$ Cl while grapes can tolerate up to $700\,\mathrm{mg\,L^{-1}}$ or more.

The ability of the tree to tolerate sodium varies considerably. Sodium injury on avocado, citrus, and stone-fruit trees has been reported at concentrations as low as $115\,\mathrm{mg\,L^{-1}}$. Initially sodium is retained in the roots and lower trunk but after 3 or 4 yr the conversion of sapwood to heartwood apparently releases the accumulated sodium, which then moves to the leaves causing leaf burn. It is unclear how extensive sodium toxicity occurs because when injury is evident, levels of chloride are often high as well. Ref.[12] contains information on crops as they are affected by specific ion toxicity.

Climate and soil factors affect crops response to specific-ion injury. Under cool, moist climatic conditions, higher concentrations of B, Cl, or Na can be tolerated. Hot dry weather on the other hand could cause more severe injury at a given tissue-ion concentration. In addition, soil conditions influence the time it takes for injury to occur. The finer the soil texture, the longer it will take for injury to occur. Furthermore, there is an evidence that salinity may reduce boron's injurious effect so that plants can tolerate a higher concentration of B than the guidelines indicate. For more information on boron, see Refs.[12,13].

Indirect Na Effects on Plants

In addition to osmotic and specific-ion toxicity, sodic or saline–sodic groundwater may also induce an indirect effect such as Na-induced Ca deficiency. Ca deficiency in the crop maybe obvious such as whip-like appearances in young emerging leaves, blackheart in celery, blossom end rot in tomato and pepper, but are more likely to be subtle where visual symptoms are absent.[14] Such an interaction has been described in Refs.[10,14].

IMPACT ON SOILS

Soil physical properties can be affected by irrigation with sodic or saline–sodic groundwater particularly when good quality water or rains follow.[15] Potential consequences include reduced infiltration and redistribution rates within the soil, poor soil tilth, and inadequate aeration resulting in anoxic conditions for roots. These negative impacts are enhanced with decreasing soil salinity and with increasing exchangeable Na (i.e., ESP).

At the soil surface, infiltration rates and soil tilth are particularly sensitive to salt and exchangeable Na levels. The mechanical impact and stirring action of the irrigation water, or rain, combined with the freedom for soil particle movement at the soil surface, can result in low infiltration rates when the soil is wet, and hard, dense soil crusts when the soil is dry. Crusts can block the emergence of seedlings thereby reducing stand establishment (Fig. 3). Tillage of crusted soils can result in hard soil clods that are difficult to reduce in size when the clod is dry. Extensive tillage can be

Fig. 3 Reduced stand establishment in cotton in a field previously irrigated with saline–sodic water.

Global–Groundwater

required to prepare a seed bed with sufficient tilth to assure adequate soil/seed contact for seed germination.

Infiltration of Irrigation Water

There are two water quality parameters that are currently used to assess irrigation water quality for potential water infiltration problems. These are the ECw and the SAR. Both a low salt content (low ECw) and high SAR can cause permeability or water infiltration problems even on sandy soils.

A low ECw and/or high SAR can act separately or collectively to disperse soil aggregates, which in turn reduces the number of large pores in the soil. These large pores are responsible for adequate aeration and drainage. A negative effect from the breakdown of soil aggregates is soil sealing and crust formation. Table 1 provides guidelines that can be used to assess the potential likelihood of water infiltration problems based on ECw and SAR.

Table 1 indicates that water infiltration problems are likely if the ECw is less than $0.3\,\mathrm{dS\,m^{-1}}$ regardless of the SAR. For example, if the ECw falls below $0.4\,\mathrm{dS\,m^{-1}}$, infiltration rates can drop to less than 0.1 in. $\mathrm{hr^{-1}}$ ($2.5\,\mathrm{mm\,hr^{-1}}$). An infiltration rate of $2.5\,\mathrm{mm\,hr^{-1}}$ would require 30 hr for a full irrigation of 75 mm to infiltrate the soil. Thus, very high quality water can cause infiltration problems even when applied on soils with a high sand content. Soils may also be prone to water infiltration problems in late Fall and Winter months after high quality rainwater falls on fields previously irrigated with sodic or saline–sodic groundwater. For more information on soil response to saline and sodic conditions, see Refs.[15,16].

Fortunately, infiltration problems due to a low salt content or high SAR can easily be improved by the addition of amendments to either the irrigation water or soil that directly (e.g., gypsum) or indirectly (e.g., acidifying agents) supply free calcium (Ca^{2+}) to the soil water. When the irrigation water contacts gypsum, it dissolves into Ca^{2+} and SO_4^{2-} ions, which slightly increases the salinity of the water while simultaneously reducing the SAR. The Ca^{2+} cations are then free to displace Na^+ cations adsorbed onto the negatively charged clay particles enhancing flocculation, improving soil structure, and increasing the water infiltration rate. Information on the management and reclamation of sodic soils is provided in Ref.[15].

Table 1 Likelihood of potential water infiltration problems based on ECw and SAR

	Potential water infiltration problem	
SAR of irrigation or soil water	**Unlikely if ECw is (dS m^{-1})**	**Likely if ECw is (dS m^{-1})**
0–3	>0.6	<0.3
3–6	>1.0	<0.4
6–12	>2.0	<0.5
12–20	>3.0	<1.0
20–40	>5.0	<2.0

IMPACTS ON IRRIGATION SYSTEMS

Irrigation water supplies, particularly those from wells, can contain other constituents that may affect water quality and its potential use for irrigated agriculture. Of particular concern are carbonates (HCO_3^- and CO_3^{2-}), nitrate (NO_3^-), and reduced iron (Fe^{2+}) and manganese (Mn^{2+}).

High pH and excessive amounts of bicarbonate can be problematic. In fields that are irrigated with low-pressure systems such as drip or minisprinklers, calcite or scale can build up near the orifice of the sprinkler or emitter, which can reduce the water discharge. This type of problem can be corrected by injecting acid-forming materials in the irrigation water. Unsightly white residues (calcium carbonates) can be left behind on leaves and fruits that have been sprinkler irrigated, potentially affecting the aesthetic quality. In addition, bicarbonate could increase the SAR of the soil water by precipitating calcium. This problem can usually be corrected by frequent gypsum applications. Bicarbonate has also been found to be toxic to some plants under certain conditions.[1]

Nitrates are often found in groundwater supplies particularly in areas where intensive irrigated agriculture has occurred over the years. From a public health perspective, there are concerns when excessive levels are found in domestic wells. From an irrigation perspective, NO_3^- in the groundwater can be viewed as a resource. For example, 27 lb of N can be applied to a field with each acre ft of water if the water supply contains $10\,\mathrm{mg\,L^{-1}}$ (or ppm) NO_3-N ($45\,\mathrm{mg\,L^{-1}}$ when expressed as NO_3^-). It is important that the grower with water of such a quality reduces the N application rates in the field accordingly to accommodate this extra input of nitrogen. Should this be ignored, excessive vegetative growth and re-contamination of the aquifer can occur. Certain shallow groundwaters such as drainage waters sources may contain enough nitrates to affect crop quality. Examples are delayed maturity or extensive vegetative growth in grape, citrus, and tomatoes or reduced sugar contents in sugar beet and grape.

Iron, manganese, and sulfur are often present in groundwater in the soluble yet chemically reduced forms (Fe^{2+}, Mn^{2+}, and sulfides). Certain bacteria in the water can oxidize these soluble reduced forms to insoluble oxidized forms. Bacterial colonies are associated with these oxidized constituents and form a gel or slime responsible for clogging filters and drip emitters. Reduced iron and manganese can create emitter-clogging problems at concentrations as low as $0.1-0.2\,\mathrm{mg\,L^{-1}}$. High concentrations of iron and manganese can be reduced by chemical precipitation, which is enhanced by aerating the water and allowing the residue to settle out before it is used for irrigation. Low, yet still problematic, concentrations of iron and manganese may be maintained in a soluble form by reducing the pH of the irrigation water by injecting acid in the system.

Groundwater: Regulation

Kevin B. McCormack
U.S. Environmental Protection Agency (US-EPA), Washington, District of Columbia, U.S.A.

INTRODUCTION

Much of the momentum for groundwater protection and remediation began in the late 1970s and continued to grow through the 1980s. Many environmental statutes and regulations that directly and indirectly concern groundwater protection were enacted at the federal, state, and local levels during this period.[1] At the time, groundwater protection remained a relatively new undertaking for many states and localities. Within the past 15 yrs, numerous reports have documented the need for more effective coordination of groundwater protection programs at the federal, state, and local levels.[2] National and local studies increasingly indicate that many activities adversely impact groundwater quality.[3] Contamination incidents and impairment from overpumping, such as permanent loss of aquifer storage capacity and land subsidence, remain a local problem because of the relatively slow rate at which groundwater travels. ''What These Threats Mean to the Nation'' describes a variety of agricultural, industrial/commercial, and waste disposal practices that are known to contaminate groundwater.

Based on the data that have been collected to date, groundwater quality appears to be generally good nationwide (that is, groundwater contaminant levels are usually below applicable drinking water standards). Locally, however, groundwater quality is being threatened by a variety of land uses.[4] Although groundwater appears to be of higher quality than surface water throughout the United States, contamination incidents and overpumping remain a problem for numerous localities. A variety of agricultural, industrial, commercial, and waste disposal practices are known to contaminate groundwater. The occurrence of nitrates, pesticides, organic chemicals, and other contaminants reveal the impact of certain land uses on groundwater quality. Overpumping can limit water availability to nearby wells; reduce groundwater flow to streams, lakes, and wetlands; permanently damage aquifer storage capacity; and induce salt-water intrusion to freshwater aquifers.[5,6] Because no one federal, state, or local authority can manage all these threats, a coordinated approach for groundwater management is needed.

BARRIERS TO SUCCESSFUL PREVENTION AND PROTECTION PROGRAMS

There are probably as many groundwater protection programs as there are states. States differ in the goals they set for groundwater, the standards they apply to it, and the mechanisms through which it is protected, and their approaches to drinking water protection of supplies drawn from groundwater sources. Groundwater quality is typically protected at the state level through programs, which control the potential sources of contamination and address remediation of contamination. States identify their maximum contaminant limit goals for groundwater, which function as ambient standards. Classification of groundwater, and of land uses which might affect it, are common tools. Discharge permits or other regulatory controls can be used to prevent groundwater contamination, through the imposition of performance or effluent-type limits on dischargers. States vary as to both the sources of groundwater contamination which they regulate, and the standards to which these sources are subject.

States have identified three primary barriers for achieving a more comprehensive approach:[7]

1. Fragmentation of groundwater programs among and within agencies impedes effective management. At the state level, authorities to manage the resource are often held among different state agencies with conflicting priorities and goals. Communicating and coordinating among departments with groundwater responsibilities can be difficult. In turn, these barriers

Disclaimer: This work consists of excerpts of material previously published by the U.S. Environmental Protection Agency, Washington, DC, in the form of Rules, Regulations, Guidance Documents, Position Papers, Scientific Studies, and national meetings and workshops sponsored by EPA and by private concerns, and as such is considered public domain. Further, the views expressed by the author are his own, and should in no way be construed as representing official EPA policy.

can create an impediment for accessing funds for comprehensive planning efforts.

2. There is a lack of understanding of groundwater resources locally and regionally (e.g., the extent and condition of the resource, the physical nature of the aquifer, the behavior of contaminants within and their movement through aquifers, the influence of surface water to groundwater and vice versa). Better information to assess the effectiveness of groundwater protection efforts and to determine the impact of certain land uses on groundwater is needed to set priorities for groundwater protection efforts.
3. Lack of funding targeted directly to groundwater is the reason most often cited by states for limited efforts in undertaking a more comprehensive resource-based approach. Groundwater protection is often not a high priority for funding; mandated programs usually prevail for funding. Most states indicate that the mandates under other federal programs often preclude the state from exercising flexibility to use funds for non-mandated groundwater protection priorities.

THREATS TO GROUND WATER

Although groundwater quality in this country is generally good, many local activities threaten the resource by point and non-point contaminant sources as well as by overpumping. Sources, most frequently cited as being of greatest concern, include underground storage tanks (USTs), landfills, septic systems, hazardous waste sites, surface impoundments, above-ground storage tanks, industrial facilities, spills, fertilizer and pesticide applications, pipelines and sewer lines, agricultural chemical facilities, shallow injection wells, salt water intrusion, animal feedlots, land application, mining, urban runoff, salt storage and road salting, and hazardous waste generators.[7–13]

Various federal, state, and academic information relates agricultural, industrial, waste disposal, and other land uses with groundwater degradation. Certain land uses are known to impair groundwater quality, but the ability to predict the level of impairment from specific activities is difficult, especially over long periods of time.[14] The US Geological Survey (USGS) National Water Quality Assessment (NAWQA) Program is the principal source of information on groundwater quality available in the United States today. Under the NAWQA program, USGS collects new water quality data in 60 special study regions of the country, conducts retrospective analyses of existing data (such as state data), and prepares national-scale syntheses of the results.[7,10,11,15]

EPA is also developing a National Contaminant Occurrence Database (NCOD) to track contaminants in groundwater and surface water sources of drinking water supply.

WHAT THESE THREATS MEAN TO THE NATION

Public Health Impacts

Both short-term illness and chronic health impacts are associated with the consumption of contaminated drinking water. For example, the presence of pathogenic microorganisms can cause acute gastrointestinal illness, Hepatitis A, and other diseases. Carcinogenic chemicals can increase the incidence of cancer. Other chemicals can adversely impact the growth and development of children. For instance, high levels of nitrate in drinking water consumed by newborns can lead to a fatal condition known as ‘‘blue baby syndrome.’’ Once groundwater is contaminated with certain compounds, certain treatment processes, such as disinfection with chlorination used by public water systems, can transform these compounds into chemicals that may also pose concern (such as trihalomethanes, a group of carcinogenic disinfection-byproducts), thereby exposing the population to other health risks. In addition, some contaminants, such as nitrates, are expensive to treat and may be very costly to remove through home treatment. Groundwater contamination in rural areas is a particular public health concern.[16]

Economic Impacts

Groundwater contamination can also impair the economic well-being of a nation. In 1995, EPA examined costs associated with 6 communities that had experienced actual or imminent contamination of the groundwater supplied through their public water systems. The costs associated with alternative water supplies, water treatment, and contaminant source removal or remediation ranged from over \$0.5 million to about \$2.4 million. A 1992 analysis by EPA indicated that for 51 selected communities with contaminated or threatened drinking water systems, the cost of remediation averaged \$5.9 million per community water system, with most costing between \$1 million and \$10 million.[17–21]

Ecological Impacts

Groundwater is also critical to the ecological health of the country. Groundwater provides many ecological benefits through its linkage with surface water.

The interrelationships of groundwater with wetlands, lakes, ponds, and streams are complex. In areas where groundwater has been contaminated (by domestic wastewater or industrial discharges), ecological impacts can be detected in the form of eutrophication and loss of native fish and plants.[22]

REGULATION OF GROUNDWATER

Over the past 25 years, federal laws, regulations, and programs have come to reflect the growing importance that the nation places on using groundwater wisely and protecting the resource. Beginning with the 1972 amendments to the federal Water Pollution Control Act, and followed by the Safe Drinking Water Act (SDWA) in 1974, the federal government's role in groundwater protection has increased. With the passage of the Resource Conservation and Recovery Act (RCRA) in 1976 and the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) in 1980, the federal government's current focus on groundwater remediation was established.

The cleanup approach to groundwater protection at the federal level has been very costly, and has left the management of many contaminant threats to state and local government authorities, including Indian tribes.[23] In the absence of a federal regulatory framework, the degree to which states and local governments address groundwater concerns varies considerably.[24] Some states have well-coordinated, effective groundwater protection programs, while others have all they can do to maintain programs that are minimally protective of the public health.

Protection and Prevention Programs

Below is a chronological list of EPA's protection and prevention-related rules, regulations, and activities specifically targeted towards groundwater-based drinking water supplies:

- 1972 Federal Water Pollution Control Act Amendments
- 1972 Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA)

- 1998 Underground Storage Tank Closure/Upgrade Requirements
- 1999 Class V Underground Injection Control Final Rule
- 2000 Proposed Ground Water Rule

The most salient of these programs and activities are described briefly as follows.

Wellhead protection (WHP) programs

WHP is essentially a pollution prevention program oriented towards reducing threats to groundwater quality in sources destined for use as public drinking water supply. The basic elements of the WHP program are: 1) statement of purpose; 2) defining roles and duties or participating agencies; 3) delineation of WHP areas; 4) identification of potential contaminant sources within the delineated area; 5) development of differential management techniques to deal with these sources; 6) development of long- and short-range contingency planning for water supply replacement in the event of contamination or physical disruption; and 7) Development of a decision-making process for siting new wells.[25–27]

Comprehensive state groundwater protection programs (CSGWPPs)

About a dozen states have developed an EPA-approved CSGWPP that promotes a more strategic,

Global–Groundwater

resource-based approach to groundwater protection, and more than half the states are undertaking efforts that are essential to a comprehensive approach to groundwater protection. However, only a few states have been able to complete, or have begun to develop, a comprehensive list of groundwater protection priorities. Even fewer states have indicated that they have identified available program funding sources to address their comprehensive groundwater protection priorities in a systematic, consistent way.[28,29]

Source water assessment and prevention programs

Section 1453 of the SDWA as amended in 1996 established the source water assessment progam (SWAP), which requires all states to complete assessments of their public drinking water supplies. By 2003, each state and participating Indian tribe will delineate the boundaries of areas in the state (or on tribal lands) that supply water for each public drinking water system (PWS), identify significant potential sources of contamination, and determine how susceptible each system is to sources of contamination.[30]

Federal, State, and Local Regulations

Federal regulations

Clean Water Act (CWA). Groundwater protection is addressed in Section 102 of the CWA, providing for the development of federal, state, and local comprehensive programs for reducing, eliminating, and preventing groundwater contamination.

SDWA. Under the SDWA, EPA is authorized to ensure that water is safe for human consumption. To support this effort, SDWA gives EPA the authority to promulgate maximum contaminant levels (MCLs) that define safe levels for some contaminants in public drinking water supplies. One of the most fundamental ways to ensure consistently safe drinking water is to protect the source of that water (i.e., groundwater). Source water protection is achieved through four programs: the WHP Program, the Sole Source Aquifer (SSA) Program,[31] the Underground Injection Control (UIC) Program,[4] and, under the 1996 Amendments, the Source Water Assessment Program (SWAP).[30]

RCRA. The intent of RCRA is to protect human health and the environment by establishing a comprehensive regulatory framework for investigating and addressing past, present, and future environmental contamination or groundwater and other environmental media. In addition, management of USTs is also addressed under RCRA.

CERCLA. CERCLA provides a federal ‘‘Superfund’’ to clean-up soil and groundwater contaminated by uncontrolled or abandoned hazardous waste sites as well as by accidents, spill, and other emergency releases of pollutants and contaminants into the environment. Through the Act, EPA was given power to seek out those parties responsible for any release and assure their cooperation in the clean-up. The program is designed to recover costs, when possible, from financially viable individuals and companies when the clean-up is complete.[32]

FIFRA. FIFRA protects human health and the environment from the risks of pesticide use by requiring the testing and registration of all chemicals used as active ingredients of pesticides and pesticide products. Under the Pesticide Management Program, states and tribes wishing to continue use of chemicals of concern are required to prepare a prevention plan that targets specific areas vulnerable to groundwater contamination. Mandates may not address the most pressing groundwater protection concerns of a particular community or area.

State regulations

Although most states have begun implementing components of a comprehensive program, many states report that much work remains to be completed. Funding, lack of agency coordination, and an absence of priority-setting mechanisms are obstacles most frequently identified by the states to explain the lack of comprehensive planning and coordination. The 1999 GroundWater Protection Council report examined the state's level of achievement in implementing the components of a comprehensive groundwater protection program.[28]

OUTLOOK FOR THE FUTURE

Over the past 20 yr, thousands of local groundwater contamination incidents have been identified and the nation has devoted many billions of public and private dollars to clean-up these problems. Although these efforts have protected many people from exposure to groundwater contaminants released from sources, such as hazardous waste sites and leaking USTs, some incidences of groundwater contamination have not yet been fully cleaned up. In some instances, groundwater remediation can take a decade or more to be completed. Furthermore, in many parts of the country, we are using groundwater at a faster rate than it can be replenished through natural recharge, and, in some cases, we are permanently losing future storage capacity. Although many of these programs emphasize surface waters and need to integrate groundwater management for a truly comprehensive approach to water resource management, they provide models for better coordination and integration. Some examples follow:

The Clean Water Action Plan (CWAP)

At the federal level, CWAP emphasizes the importance of a comprehensive approach for restoring and protecting waters among nine federal agencies (EPA, Department of Interior, Department of Defense, Department of Energy, Department of Agriculture, Department of Transportation, Department of Commerce, Department of Justice, and Tennessee Valley Authority). CWAP is both a vision statement and a blueprint for the future. It focuses on: 1) promoting water quality protection and restoration on a watershed basis; and 2) strengthening core clean water programs to protect human health, increase natural resources stewardship, reduce polluted runoff, and provide citizens and officials with crucial information.

Intergovernmental Task Force on Monitoring Water Quality (ITFM)

The ITFM was established in 1992 and given the charge of reviewing water quality monitoring nationwide and developing an integrated national monitoring strategy. In 1995, ITFM produced The Strategy to Improve Water-Quality Monitoring in the United States. In 1997, the National Water Quality Monitoring Council (NWQMC) was formed as a successor to ITFM. During overall strategy development, a Ground Water Focus Group (GWFG) concentrated on issues related to groundwater and aquifer systems. The GWFG recommended that water quality monitoring must consider differences in spatial, temporal, and other characteristics between ground and surface water resources.

State Watershed Protection Frameworks

State Watershed Protection Frameworks are designed to coordinate existing resource management programs and build new partnerships that result in more effective and efficient management of land and water resources. These frameworks provide not only a mechanism for coordinating the point and non-point source management activities that have been the historic focus of state water quality programs, but also a forum for meeting the objectives of groundwater, wellhead, and drinking source water protection programs. Many State Watershed Protection Frameworks incorporate a priority-setting and targeting mechanism to focus resources on watersheds requiring the highest degree of management to remediate existing problems or address emerging threats.

SWAPs

SWAPs established under the 1996 Amendments to the SDWA provide an additional coordination mechanism for state programs. The states are required in their SWAPs to assess the degree to which all PWS in the state are susceptible to contamination. These assessments will be accomplished by: 1) delineating the sources of water supply to the PWS; 2) inventorying the contaminants and contaminant sources within that delineated area; and 3) assessing how susceptible the PWS are to those sources of contamination. In many states, these assessments will be accomplished through cooperative efforts, involving several state agencies, local governments, and private water suppliers.

Groundwater: Saltwater Intrusion

Alexander H.-D. Cheng
Department of Civil Engineering, University of Mississippi, University, Mississippi, U.S.A.

INTRODUCTION

The origin of saltwater intrusion into freshwater aquifers can come from natural sources such as seawater, and deep formation brines, or from anthropogenic sources such as de-icing salt, agricultural return flow, and leachate from landfills. The most frequent occurrences are found in coastal regions where overexploitation of groundwater has caused the encroachment of seawater into freshwater aquifers. Once an aquifer is invaded, a part of the salt will adsorb onto the solid surface making it difficult to reverse the process and restore the aquifer. The slow movement of groundwater also makes the remediation time long. Salinity in water poses health hazard for human and livestock, damages crops, and corrode pipes and boilers in industrial uses. Hence, the invasion of saltwater into a freshwater aquifer means the loss of that aquifer for water sources.

MECHANISMS OF SALTWATER INTRUSION

Fig. 1 gives a schematic view of seawater intrusion into an *unconfined aquifer*. We observe that saltwater is heavier, hence tends to move underneath the freshwater layer. The freshwater, however, has a *hydraulic gradient* downward towards the coast, hence will flow to the sea. This outflow momentum force can counter balance the density-driven seawater. Without it, seawater will continue to move inland until the entire aquifer below sea level is occupied by it. Since such a hydraulic gradient always exists due to the precipitation recharge inland, an equilibrium position will establish, shown as the *interface* in Fig. 1. The *toe* then marks the maximum extent of intrusion.

A simple theory that allows a rule-of-thumb estimate of the salt–fresh water interface location is given by the Ghyben–Herzberg relation:[1]

$$\xi = \frac{\rho_f}{\rho_s - \rho_f} h_f \approx 40 h_f$$

where ξ is the interface location below sea level, h_f the freshwater head above sea level (referring to Fig. 1, ρ_f the freshwater density (1 g/cm^3), and ρ_s the saltwater density (approximately 1.025 g/cm^3). What the above relation says is, for every meter of freshwater head above sea level, the interface is pushed down 40 m. When the interface touches the bottom of aquifer, the toe is located. This 40 : 1 ratio may sound like a good news for repelling saltwater; however, if pumping activity is increased inland, as quite often is the case due to increased population in coastal zones, the reduced freshwater head level close to the coast will allow saltwater to move a large distance landward. If a pumping well is situated above the interface in the freshwater zone, any small *drawdown* will cause the interface to rise up sharply to meet the well, known as *upconing*. This means that it is nearly impossible to sustain extraction of freshwater above the invaded saltwater wedge. This portion of freshwater, including the natural recharge, is considered lost.

GEOPHYSICAL AND GEOCHEMICAL INVESTIGATIONS

The presence of salinity in aquifers, its source, and the underlying physical, chemical, and geological processes leading to the intrusion can be detected or interpreted by a combination of geophysical and geochemical investigations. Geophysical methods measure the spatial distribution of physical properties of the earth, such as bulk electrical conductivity and seismic velocity. For investigation of saltwater intrusion in shallower depths, the *DC resistivity method*, which introduces electrical current into the ground through electrodes driven into soil, is most effective because the presence of salt increases the bulk conductivity of the soil. The *electromagnetic method* sends out a time varying magnetic field that generates electrical currents in the ground whose strength is dependent on the conductivity of the earth. The varying electrical field in turn generates a secondary electromagnetic wave that can be detected above ground. There are several variations of the electromagnetic method, including frequency-domain, airborne, loop–loop, time-domain, very low frequency, and ground penetration radar method.[2] These surface geophysical methods have the advantage of being able to map the salinity variation over a large horizontal area. Its resolution in the vertical direction, however, decreases with depth. The *borehole method* allows the introduction of tools

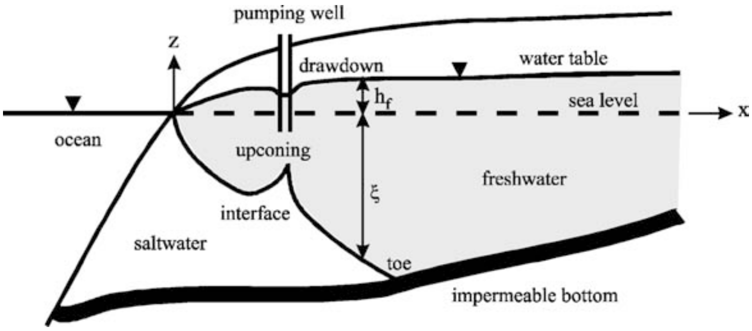

Fig. 1 Seawater intrusion into an unconfined aquifer.

into the formation at larger depths to produce higher resolution electrical resistivity, electromagnetic, and radiometric logs.

The geochemical method investigates the chemical composition of groundwater for not only the presence of chloride and sodium, but also other ions such as K, Mg, Ca, Br, SO_4, and HCO_3. Ratio of these ions, such as Cl/Br, Na/Cl, Ca/Mg, $Ca/(HCO_3 + SO_4)$, can often provide a chemical signature to the origin of salt contamination—whether it comes from seawater, fossil water, or anthropogenic sources.[3] Isotope studies can indicate the age of the water, hence can further help in identifying the source.

MATHEMATICAL MODELING

The use of field surveys, such as geophysical and geochemical studies, can reveal the present state of saltwater intrusion, and perhaps some insight into its history. It, however, cannot make prediction into the future, and particularly cannot be used for scenario building and impact assessment based on different levels of anthropogenic activities. Mathematical models are needed for these purposes.

The Ghyben–Herzberg relation is a highly simplified model. More rigorously, the dynamic movement of groundwater flow and the solute transport of salt needs to be considered. Generally speaking, there does not exist a sharp division between saltwater and freshwater zones, as implied in Fig. 1. The salt concentration continuously changes from that of seawater to that of freshwater. A solute transport model including advection and dispersion is needed for the modeling. In addition, the salt at higher concentration is an active solute, because it can affect the density of water and can drive the flow. Hence a *density-dependent solute transport model* should be used. There are occasions, however, when the predominant change of concentration from saltwater to freshwater takes place within a narrow region called the *transition zone*. In that case, a simplification using the *sharp interface model* can be attempted. Furthermore, if the aquifer modeled is of regional scale, then the flow is often integrated in the depth direction to reduce the three-dimensional problems to two-dimensional ones. The governing equations, boundary conditions, and justification of using the various models can be found in Ref.[4].

COMPUTER MODELS

With the exception of some simple geometries of saltwater intrusion for which analytical solutions are available,[5] numerical solutions are needed for practical applications. Two of the most widely used computer codes are: SHARP[6]—for sharp interface model—and SUTRA[7]—for density-dependent solute transport model—both developed by the U.S. Geological Survey. However, like many complex engineering problems, there is no single code that can be most versatile, efficient, accurate, and stable at the same time, thus dominating the rest of the codes. Depending on the availability and reliability of input data, and the limited resources dedicated to modeling, different computer codes have been developed to offer a wide range of choices. A comprehensive survey of the computer codes can be found in Ref.[8].

COMBATING SALTWATER INTRUSION

One of the most effective ways of combating saltwater intrusion is to regulate pumping activities. Generally speaking, the amount of groundwater extraction should not exceed that of natural replenishment. Optimization of pumping patterns to maximize the yield and minimize the extent of intrusion is a high-priority management issue. Recharge of natural surface water or reclaimed wastewater into aquifers can increase the freshwater outflow rate to push back the saltwater wedge. A recharge near the coast can build a local freshwater mound that forms a barrier to protect the *water table* depression inland. Extraction of saltwater in an invaded saltwater wedge can also protect the freshwater behind, if a proper way can be found to dispose of the extracted saltwater. A similar method involving pumping simultaneously in the upper freshwater zone and the lower saltwater zone to prevent upconing, known as *double pumping*, has been attempted. Using *collector wells* (horizontal wells) to skim the thin layer of freshwater floating on top of the saltwater wedge has been effectively used in water-poor countries such as Israel. Land reclamation has the added effect of pushing saltwater to the sea. Finally, in places where large freshwater springs flowing to the sea can be identified, physical barriers, such as solid walls or slurry curtains, can be used to intercept freshwater.

Groundwater: Western United States Law

J. David Aiken
Department of Agricultural Economics, Institute of Agriculture and Natural Resources, University of Nebraska, Lincoln, Nebraska, U.S.A.

INTRODUCTION

Groundwater law in the United States is a bewildering mix of state court decisions and state statutes. While some generalization is possible, each state's groundwater law is unique.

COMMON LAW STATES

The common law doctrines of absolute ownership, reasonable use, correlative rights, and eastern correlative rights, are based on state court decisions and are implemented through litigation or private negotiation. While prior appropriation was initially adopted in a few western states by court decision, it will be discussed separately as a statutory rather than a judicial doctrine.

Absolute Ownership

The earliest judicial theory of groundwater rights is the doctrine of absolute ownership, also referred to as the English rule. Under the absolute ownership doctrine the landowner is, by virtue of land ownership, considered owner of the groundwater in place, similar to mineral ownership. Thus in absolute ownership jurisdictions, a landowner may pump as much groundwater as he is able to, without regard to the effect of his pumping on neighboring landowners.

The English rule of absolute ownership reflected 19th century judicial observations that the movement of groundwater was unknowable and thus it was unfair to hold a landowner liable for interfering with a neighbor's well when it was not knowable whether the defendant's pumping actually affected plaintiff's well or not. The English rule was once quite popular in the United States, but now only Texas, among the western states still is an absolute ownership jurisdiction.

Reasonable Use

The reasonable use rule, or American rule, was developed in the 19th century. Under the American rule, a landowner is entitled to use groundwater on his own land without waste. If his use exceeds this "reasonable use," he is liable for damages. The American rule is followed in a few eastern states where it is being judicially replaced by the eastern correlative rights doctrine. The reasonable use doctrine is part of the groundwater jurisprudence of Nebraska, Arizona, and California.

Correlative Rights

The California doctrine of correlative rights also initially developed in the 19th century but has continued to develop to this day. Under the correlative rights doctrine, if the groundwater supply is inadequate to meet the needs of all users, each user could be judicially required to proportionally reduce his use until the overdraft ends. The policy significance of correlative rights is that each well owner is treated as having an equal right to groundwater regardless of when first use was initiated.

The correlative rights doctrine is part of the groundwater jurisprudence of California and Nebraska, although its sharing feature has been incorporated into the groundwater depletion statutes of a few other western states as well.

APPROPRIATION STATES

Most western states (except Texas, Nebraska, Arizona, and California) apply the doctrine of prior appropriation to groundwater. This means that the right itself is dependent upon obtaining a state permit rather than simply owning land overlying the groundwater supply. Between groundwater users, priority of appropriation gives the better right. This means that first in time is first in right.

GROUNDWATER RIGHTS

In the common law states, groundwater rights are based upon owning land overlying the groundwater supply and are defined by court decision. In appropriation states, groundwater rights are based upon obtaining a state permit and complying with its terms. In appropriation states, state statutes generally define the extent of groundwater rights.

WELL INTERFERENCE CONFLICTS

Well interference is where the cone of depression of one well intersects with the cone of depression of another well, reducing the yield of both wells. In an artesian aquifer, well interference may occur when the pumping from one well drops the water level below the pumps of another well. Well interference may occur even when there is sufficient water available to supply all users—it may be the result of inadequate wells rather than an inadequate supply. Most groundwater disputes have tended to be well interference disputes.

Common Law States

In absolute ownership states, a landowner is not liable for interfering with a neighbor's well. Thus the neighbor's only recourse is to drill a new well deeper than the neighbor's well. This has been described as "the race to the pumphouse." In reasonable use states, a landowner complaining of well interference is entitled to relief only if the complained-of use is wasteful or not on overlying land. Thus, plaintiffs complaining of well interference have little legal remedy in the absence of gross waste or non-overlying uses. The courts' definition of what constitutes a wasteful use is rather generous. Arizona courts have defined overlying land to include only the tract of land where the well is located. Nebraska, a reasonable use state, minimizes well interference conflicts between high-capacity wells through statutory well-spacing restrictions. In correlative rights states, competing pumpers have equal rights during shortages.

Appropriation States

In appropriation states, well interference conflicts may be reduced through permit conditions, such as well-spacing restrictions and pumping restrictions. Prior appropriation is primarily a surface water doctrine that has been applied rather uncritically to groundwater. As groundwater problems developed, the principles of prior appropriation were modified to better apply to the groundwater context. Two modifications that were made in response to well interference conflicts are, establishment of reasonable pumping depths and problem area regulations.

Reasonable pumping depths

Sometimes the senior or oldest wells may not be fully penetrating. To allow senior appropriators to insist upon original pumping depths being maintained could seriously constrain groundwater development. Thus several appropriation states do not strictly maintain priority during well interference disputes, but only protect "reasonable pumping depths" through well permit restrictions on pumping. If a senior's well cannot pump at that depth, typically the senior appropriator is responsible for replacing the well at his own expense.

Problem area regulations

In some appropriation states, groundwater development and use has resulted in chronic well interference problems. In some appropriation states, special pumping and development restrictions may be imposed by the state engineer in designated problem areas. Regulations include a ban on new high-capacity wells and pumping restrictions to maintain reasonable pumping depths and reduce interference conflicts.

GROUNDWATER DEPLETION

Safe Yield

Groundwater depletion may be defined as the situation where average annual withdrawals from the aquifer exceed average annual recharge. This is sometimes referred to as groundwater overdraft. Overdraft is significant in the Ogallala aquifer region, including Nebraska, Kansas, Colorado, Texas, and New Mexico, as well as in California and Arizona. The amount of water that may be safely withdrawn without leading to long-term aquifer depletion is sometimes referred to as the "safe-yield" amount.

Common Law Doctrines

Of the overlying rights doctrines, only correlative rights doctrine addresses depletion. Pumpers can completely ignore depletion in absolute ownership states, and need be concerned about depletion only to the extent their uses are wasteful or non-overlying in reasonable use states. In eastern correlative rights states, courts can apportion water between competing users. However, Florida (a permit state) is the primary eastern state with significant groundwater depletion concerns.

In theory courts in correlative rights states can limit withdrawals to the aquifer's safe yield, thus preventing depletion. In practice, in California safe-yield adjudications are used primarily to define baseline pumping rights so that groundwater recharge agencies can charge pumpers a pumping fee for using more than their safe-yield allocation.

Problem Area Regulations

In western states, the most common way to deal with depletion is to establish special problem area regulations. Once the problem area has been administratively defined, typically no new high-capacity wells may be drilled within the problem area. Less frequently are the uses of existing appropriators limited, a significant policy failing. Initial groundwater appropriation allocations are typically generous, not requiring a high degree of water use efficiency. Where problem area allocations have been established, they typically are high enough to allow current irrigation practices to be maintained with little or no change. Any changes in irrigation management typically come only as well yields decline.

CONJUNCTIVE USE

In California, the courts have recognized the rights of entities storing water underground to control the use of that water. As a result, when groundwater pumpers have received their safe-yield allocation through a court adjudication, they typically are required to pay a fee to the recharge entity for pumping water stored underground, i.e., for pumping groundwater in excess of their safe-yield allocation. Where both surface water and groundwater are available to groundwater pumpers, the recharge entity can raise or lower groundwater pumping fees to encourage surface water use during periods of ample surface supplies, or to discourage surface water use during periods of surface water shortage.

SURFACE–GROUNDWATER INTERFERENCE

Where ground and surface water supplies are hydrologically connected, courts typically have followed the ‘‘underground stream’’ doctrine to interrelate surface and groundwater rights of use. This means that wells will be treated as surface diversions and governed by surface water law. In the West, priority would govern surface–groundwater disputes (except in Nebraska). Under the ‘‘Templeton’’ doctrine, the New Mexico State Engineer has required a junior groundwater appropriator to purchase and retire sufficient surface appropriations to compensate for the expected stream depletion effect of his proposed well. Colorado has an elaborate system for integrating surface appropriations and appropriations of subflow and tributary groundwater. Generally junior groundwater appropriators are expected through plans of augmentation to compensate the stream for their expected stream depletion effects of well pumping.

Groundwater: World Resources

Lucila Candela
Departmento Ingenieria del Terreno, Technical Univiersity of Catalonia – Universitat Politècnica de Catalunya (UPC), Barcelona, Spain

INTRODUCTION

Groundwater constitutes an important source of water supply for domestic, industrial, and irrigation uses in different countries due to its availability, which is not subject to multiannual and seasonal fluctuations. At present it is the main source of domestic water supply in most European countries, the United States, Australia, and some countries of Asia and Africa both in large and small towns and in rural areas.[1,2] Groundwater is used for irrigation in about one-third of all irrigated lands.[3]

Natural groundwater resources are understood to be the total amount of recharge (replenishment) of groundwater under natural conditions as a result of infiltration of precipitation, seepage from rivers and lakes, leakage from overlying and underlying aquifers, and inflow from adjacent areas. In some cases, the average annual recharge of aquifers, evaluated from average annual precipitation, equals groundwater runoff. Natural groundwater resources may be equated to groundwater discharge (runoff) when the evaporation from the water table may be ignored or estimated separately.[4] Under this assumption, groundwater runoff data are widely used to characterize regional groundwater resources and are an important component of the hydrologic cycle and environment.[5–7]

The role of groundwater in the water balance and water resources of regions is quantitatively characterized by the groundwater runoff/precipitation ratio or groundwater recharge. The runoff/precipitation ratio is extremely variable depending on meteorological factors, composition of rocks, etc. Distribution of groundwater recharge to river/total river runoff ratios shows the effect of geographical and altitudinal zonality. The quantity of recharge ranges widely. Analysis of conditions of generation of groundwater resources within continents shows that this global process depends on a complex combination of various natural factors. Principal amongst these are precipitation, vegetation, soil type and geology, and the hydrogeological features of the area.

In regions where aquifers are mainly composed of sands, specific groundwater discharge values are twice as large as in regions where the percentage of sands in aquifers is small. In this regard distribution of specific values of groundwater discharge on a global scale is subject to latitudinal zonality. Values generally increase from subartic regions to medium-latitude zones, in humid tropics and tropics, and decrease in semiarid and arid regions. Large groundwater discharge values may be found in karst limestones (up to $20\,\mathrm{L\,sec^{-1}\,km^{-2}}$), sand quaternary deposits (up to $18\,\mathrm{L\,sec^{-1}\,km^{-2}}$) or highly fractured rocks (up to $10\,\mathrm{L\,sec^{-1}\,km^{-2}}$), although values are normally dependent on topographic elevations and annual precipitation. Marine sandy and clayey sediments show minimal discharge values ($0.1\,\mathrm{L\,sec^{-1}\,km^{-2}}$ and smaller).[4]

The main task of areal hydrogeological subdivision when compiling groundwater runoff and resources maps is to distinguish territories which are sufficiently uniform in terms of groundwater distribution and particularities of groundwater generation.[8]

AQUIFER TYPES

The principal aquifers are found in six types of permeable geologic materials:[8] unconsolidated deposits of sand and gravel; semiconsolidated sand; sandstone; carbonate rocks interbedded sandstone and carbonate rocks; and basalt and other types of volcanic rocks. Large areas of the world are underlain by crystalline rocks permeable only where they are fractured or weathered, and generally yield only small amounts of water to wells. In many places, they are the only source of water supply. However, because these rocks extend over large areas, important volumes of groundwater are withdrawn from them.

Unconsolidated Sand and Gravel Aquifers

Unconsolidated sand and gravel aquifers are characterized by intergranular porosity and all contain water primarily under unconfined or water-table conditions, but locally confined conditions may exist where aquifers contain beds of low permeability. Different categories can be distinguished, which occupy different geologic settings. The sediments are mostly alluvial deposits, but locally may include windblown sand, coarse-grained glacial outwash, and fluvial sediments deposited by streams recharge. Large areas of the world are covered with sediments deposited during several advances and retreats of continental glaciers. The glacial sand and gravel deposits form numerous local but productive aquifers.

Aquifers commonly receive direct recharge from precipitation and streamflow infiltration. Regional movement is down the valley in the direction of stream flow, lake or playa (located in the center of the basin). Basins in arid regions might contain deposits of salt, anhydrite, gypsum or borate produced by evaporation or mineralized water in their central parts. Also, much of the infiltrating water is lost by transpiration by riparian vegetation.

Consolidated/Fractured Sedimentary Aquifers

Aquifers in sandstones are more widespread than those in all other kinds of consolidated rocks. Sandstone retain some primary porosity unless cementation has filled all the pores, but most of the porosity in these consolidated rocks consists of secondary openings such as joints, fractures, and bedding planes. The water is not highly mineralized in areas were the aquifer outcrops or are buried to shallow depths, but mineralization generally increases as the water moves downgrading toward the structural basin.

Carbonate Rock Aquifers

The water-yielding properties of carbonate rocks are highly variable; some yield almost no water and are considered to be confining units, whereas others are among the most productive aquifers known. The original texture and porosity of carbonate deposits can range from 1% to more than 50%. Recharge water enters the aquifer through sinkholes, swallow holes, and sinking streams, some of which terminate at large depressions called blind valleys.

Basaltic and Other Volcanic-Rock Aquifers

Volcanic rocks have a wide range of chemical, mineralogic structural, and hydraulic properties due largely to rock type. Unaltered pyroclastic deposits have porosity and permeability characteristics like those of poorly sorted sediments; rhyolites have low permeability except where they are fractured.

AVAILABILITY AND USE

Except for widely scattered places, existing data are not uniformly distributed in space and time because hydrologic investigations have been mostly conducted in areas where water supply or water quality problems existed, or where large quantities of groundwater were withdrawn. Long-term hydrologic records are rare and usually collected only during the course of a study or perhaps for a few years after the study has ended. No systematic investigation on groundwater resources and exploitation in many regions of the world have been conducted.[3,9]

The annual groundwater use for the world as a whole can be placed at 750–800 $\times$ $10^9\,m^3$, a modest value when compared to overall water availability (Tables 1 and 2). But an overwhelming majority of the world's cities and towns depend on groundwater for municipal water supplies. Over 35 countries of the world use more than 1 $\times$ $10^9\,m^3$ of groundwater annually.[10] Because of spatial imbalances in the occurrence of groundwater and the pattern of demand, massive problems of groundwater overexploitation are found in areas where high population exist or under intensive agriculture development.

Table 1 Annual groundwater recharge and withdrawals in the world

World region	Average annual recharge ($km^3\,yr^{-1}$)[a]	Annual groundwater withdrawals ($km^3\,yr^{-1}$)[b]
Asia	2505	352
Europe	1368	78
Middle East and N. Africa	137	75
Sub-Saharan Africa	1548	9
North America	1884	110
C. America and Caribbean	344	29
South America	3693	14
Oceania	270	2

[a]Amount of water that is estimated to annually infiltrate into aquifers. It would represent the amount of water that could be annually withdrawn.
[b]Abstractions from aquifers. These data are scarce and not currently available for all countries in each region.

GROUNDWATER RESOURCES DISTRIBUTION

Europe

All types of aquifers are currently exploited: large well fields in artesian basins of platform type, such as Paris and London; river valleys (France, Volga region); cones and intermontane depressions (Italy, Switzerland).[11,12] In many cases their exploitation is accompanied by the generation of large and deep cones of depression.

Groundwater runoff in Europe is quite irregular, depending on the geostructural, climatic, and orographic conditions and the flow media generation: karst, porous fractured, and porous. Specific discharge values distribution is governed by the geological structure.

According to the available data (Table1), groundwater use estimation in Europe is $78\,km^3\,yr^{-1}$, which constitutes 21% of the total water consumption. Urban and rural population constitute the most important water consumers, accounting for 56% of the total water consumption. Groundwater is the main source for public water supply (more than 70% of total resources), especially on islands and some European countries like Denmark. More than 90% of big cities and towns are exclusively supplied by groundwater (among them Berlin, Rome). Although groundwater is mainly used for irrigation in Southern countries like Spain with values ranging between $0.7\,km^3\,yr^{-1}$ and $5\,km^3\,yr^{-1}$, other European countries, like the Netherlands, may also use it during dry years.

Africa

Africa is one of the regions of the world facing serious water shortages because of greater disparities in water availability and use, and because water resources are unevenly distributed. Groundwater, first considered as a main resource for water in urban, rural areas, and mining, especially in coastal areas and arid regions, is now tending to be extended to the most isolated desert and tropical regions. In Libya, groundwater accounts for 95% of country's freshwater withdrawals, while in some areas of North Africa it is a significant source for irrigated agriculture. In many parts of the continent, groundwater resources have not yet been fully explored and tapped. According to the geographic and climatic homogeneity, which has a direct influence on water resources, Africa can be divided into several regions: Northern, Sudano-Sahelian, Gulf of Guinea, Central, Eastern, Indian Ocean Islands and Southern. This vast territory can be subdivided into a number of large aquifer systems subject to very varied climatic conditions.[13,14]

Basement rocks cover most of the central territory and aquifers are not very productive except in few cases. Sedimentary formations of sandstones overlaying the basement areas may constitute good aquifers, such the Karoo basin. The coastal sedimentary basins are the most productive aquifers, being intensely exploited along the shoreline. Alluvials are among the most important and also serve large populations, especially in Northern Africa. Karstified limestones of North-West Africa and Madagascar can yield flow rates up to $100\,m^3\,hr^{-1}$. Also large fossil aquifers are present in the Saharan and Nubian deserts made of sedimentary basins and being largely exploited.

South America, Central America, and the Caribbean

This area extending from the Central America Isthmus to South America has the most abundant river flow. Groundwater is unevenly distributed in quantity, but quality is usually good for domestic and industrial supply, presently the highest priority. Total water withdrawal from the aquifers is difficult to estimate because most comes from uncontrolled private and public wells. Based on UN estimates, 50–60% of total population domestic and industrial supply is from groundwater. Water withdrawn can be estimated at between $12\,km^3\,yr^{-1}$ and $14\,km^3\,yr^{-1}$, very low in comparison with the estimated renewable resources. Groundwater reserves estimation is $238{,}000\,km^3$, discharge to rivers being $3898\,km^3\,yr^{-1}$. Discharge values are high in the humid equatorial zone and minimum in the Atlantic Andean Cordillera and northeast Brazil.

According to geologic and tectonic features, four major water-bearing domains can be distinguished:[15,16] superficial deposits; deep aquifers in sedimentary basins; folded mountain chains; and precambrian basement bedrocks. Vast areas of South America are composed of Precambrian crystalline rocks which are not highly productive unless weathered or intensively fractured. The hydrogeologic map of South America[16] shows 16 hydrogeological provinces with similar characteristics including the previously-mentioned water-bearing domains. Some of the formations' resources are considered as the most important water-bearing formations, such as the Amazon Sedimentary Basin

(32,500 km^3), Parnaíba-Maranhao (17,000 km^3), and the Paraná Sedimentary basin, where the Guarani aquifer extending over 1,500,000 km^2 has 50,000 km^3 of storage.

North America

Groundwater is an important source of water in the United States and Mexico, but it represents less than 5% of Canada's total water use. About 22% of the total water use in the United States ($290 \times 10^6 m^3 day^{-1}$) is supplied by groundwater; about 50% of the US population depends on groundwater for domestic uses and also major cities and metropolitan areas and irrigation has made the High Plains one of the most important agricultural areas. Half of the U.S. population draws its domestic water supply from groundwater.[1] In Mexico, where desert and semiarid conditions prevail over two-thirds of the country, groundwater is widely used. Urban areas of Mexico use groundwater as their sole or principal source.

Unconsolidated sand and gravel are the most widespread aquifers, with intergranular porosity, and water primarily under water-table conditions.[17,18] Some unconsolidated aquifers have supplied large amounts of water for irrigation, like the High Plains aquifer ($56 \times 10^6 m^3 day^{-1}$ withdrawn from the aquifer for irrigation in 1990); in the United States, about 20% of the groundwater withdrawn is derived from the High Plains aquifer.

Carbonate rock aquifers are most extensive in eastern United States and in the Bahamas, western Canada and Yucatan (Mexico), and some of them are considered among the most productive aquifers known. Most of them consist of limestone but dolomite and marble locally yield water. More than $13 \times 10^6 m^3 day^{-1}$ (1990 data) were withdrawn from the Floridan aquifer system, the sole source of water supply for the city of Miami.

Oceania

While groundwater resources in New Zealand, Pacific Islands, and New Guinea are difficult to quantify due to the limited information, the aridity of much of the Australian continent is a significant factor in the occurrence and assessment of groundwater resources.[19] A large part of western and central Australia is arid, with a mean annual rainfall below 250 mm. Total amount of groundwater used in Australia is estimated at $2460 \times 10^6 m^3$ in 1983 from more than 500,000 tubewells, 14% of the total amount of water used.[20] The greatest concentrations are near Perth, Adelaide, South Australia, western Victoria, and on the central Queensland coast. Surficial aquifers are the most important sources for irrigation, urban, and industrial supply. Fractured rock aquifers of igneous and metamorphic rocks are of relative importance, although they may locally provide high groundwater yields.

Most highly productive aquifers are the surficial sedimentary aquifers associated with inland or eastern coastal rivers, up to 100 m thick. Also sand dunes, coastal, and deltaic alluvium sediments form important aquifers along the east coast and in central Queensland. Australia's main arid-zone irrigation scheme is based on groundwater extracted from sands and gravel of Central Australia. Several large deep sedimentary basin aquifers (Amadeus, Canning, Great Artesian, Murray, Otway, Perth, Eucla, Officer), extending over more than 24,000 km^2, constitute a reliable source of old, good quality groundwater. The Great Artesian basin covers $1.7 \times 10^6 km^2$, is up to 300 m thick and is one of the largest basins in the world.[21] More than 20,000 non-flowing and more than 4000 flowing artesian wells have been drilled. Individual well flows exceeding 100 L sec^{-1} have been recorded. Diffuse natural discharge from the Great Artesian Basin has been calculated to be about $1.4 \times 10^6 m^3 day^{-1}$.

Asia and Middle East

Continental Asia is an immense and complex geographical area of great extremes. Some parts of China and India are among the most populated in the world while the deserts of central Asia and the interior high plateau are extremely thinly populated. Most of the land of the Arabian Peninsula and in central and eastern Iran is a desert, reflecting different patterns of groundwater use.

In Asia and Middle East groundwater has been developed since ancient times, especially in arid regions where no other source of water supply is permanently available.[22,23] Large-scale developments are found in northern and coastal areas of China, where artesian aquifers and the loess and karst areas of the central south are tapped for urban and industrial supply. Groundwater irrigation distribution by subregions is, according to AQUASTAT,[3] in the Arabian peninsula 96.6%; Middle East 18.2%; and Central Asia 34% (although for Bangladesh it represents 69%).

Groundwater exists in the area as semiconfined, unconfined shallow, and deep aquifers. Recharge is faster in the Middle East countries although the aquifers of the Arabian Peninsula contain much larger reserves. The interior arid regions of the Middle East countries may include geological formations which can be considered as aquicludes or aquitards. Among the groundwater-bearing zones, the most important are alluvial of large rivers, vast, complex sedimentary formations holding artesian water and sedimentary basins in coastal areas (Israel). Some carbonate basins of importance are also present in the Mediterranean area (Lebanon, Syria) and Pakistan. Weathered crystalline rocks and lava flows constitute important aquifers in peninsular India and Northern Syria.

Although groundwater quality is suitable for irrigation and domestic uses, salinization of groundwater has occurred in several areas of the Indus Plain and Pakistan.

Hydrologic Cycle

John Van Brahana
Division of Geology, Department of Geosciences, University of Arkansas, Fayetteville, Arkansas, U.S.A.

INTRODUCTION

The hydrologic cycle describes the dynamic, water-circulation system of the Earth. Water we see today is the same water that was originally derived from degassing of volcanoes as the Earth cooled from the molten mass that was our primordial planet several billion years ago. This water has been continuously recycled by natural processes, changing from liquid to solid or vapor and then back again, moving and flowing endlessly in response to the physical and chemical conditions of the environment of our planet.

PROCESSES AND PATHWAYS

The dominant processes of the hydrologic cycle, and the pathways along which we can trace water movement, include the following (Fig. 1): evaporation from oceans and open bodies of water on the Earth's surface into the atmosphere; evapotranspiration by plants of soil water into atmospheric vapor; condensation of water vapor into liquid or solid particles (clouds); precipitation as the condensed water or ice falls from the atmosphere back to the surface; infiltration of the water into subsurface (soil and groundwater) reservoirs; baseflow contribution to streams from groundwater; streamflow recharging of groundwater; streamflow runoff if the precipitation rate exceeds the infiltration rate; surface and subsurface flow back to oceans or intermediate reservoirs; and storage.[1–10]

In one sense, the hydrologic cycle is one of the most basic concepts of water science, yet in detail the concept is complex because it involves all forms of water of the hydrosphere, and it is affected by many influencing factors that are not always obvious. Because this circulation of water is intimately tied to energy transfer, it is helpful to start with the basic physics of the forces that drive this seemingly endless flow of water on our planet.

ENERGY SOURCES

The underlying source of energy that drives the movement of water throughout the hydrosphere of the Earth is solar radiation—thermal energy from our sun. Solar energy heats water, causes it to evaporate and change state from liquid to a gas, and in so doing, facilitates its movement through the atmosphere in response to wind and pressure changes. Every gram of liquid water at its point of vaporization requires an input of 540 cal of thermal energy to convert it to a gas. Worldwide, water vapor represents a huge source of energy storage and transport in a hydrologic link between atmosphere, oceans, and continents, which we call "climate." The residence time of water vapor in the atmosphere is short, usually no more than several days or weeks, until it condenses and falls as precipitation. In undergoing condensation to a liquid, the energy stored in the vapor is released.

As a liquid, water is controlled by gravity. If it can move, it will, always move downhill to a lower potential energy state, and always along the path of least resistance, down the steepest gradient. As water moves, it expends energy. Fast-flowing runoff, particularly in streams, is the single most dominant agent of erosion of the surface of our planet. Glaciers likewise are effective at sculpting the land surface, but owing to their limited occurrence on only 10% of the continents, their impact is not nearly as widespread as that of flowing streams. Thus, erosion and the Earth's landforms are intimately tied to the hydrologic cycle. Ultimately, water reaches the lowest accessible level possible, which for most places on the Earth is sea level. Internally drained basins that are isolated from the oceans by mountain ranges and other high divides may exist below sea level (i.e., Death Valley in California; Caspian Sea in Kazakhstan; Dead Sea in Jordan), but these represent local base-level conditions rather than regional or global conditions. These areas of internal drainage are typically formed by tensional tectonics, where blocks of rock are downfaulted (grabens) due to forces that tend to pull the continents apart. Water drains into these depressions under the force of gravity from the surrounding highlands, and escapes only by evaporation.

HYDROLOGIC RESERVOIRS AND IMPLICATIONS FOR HUMANS

Oceans form the largest of our hydrologic reservoirs (Table 1), covering about 70% of the Earth's surface,

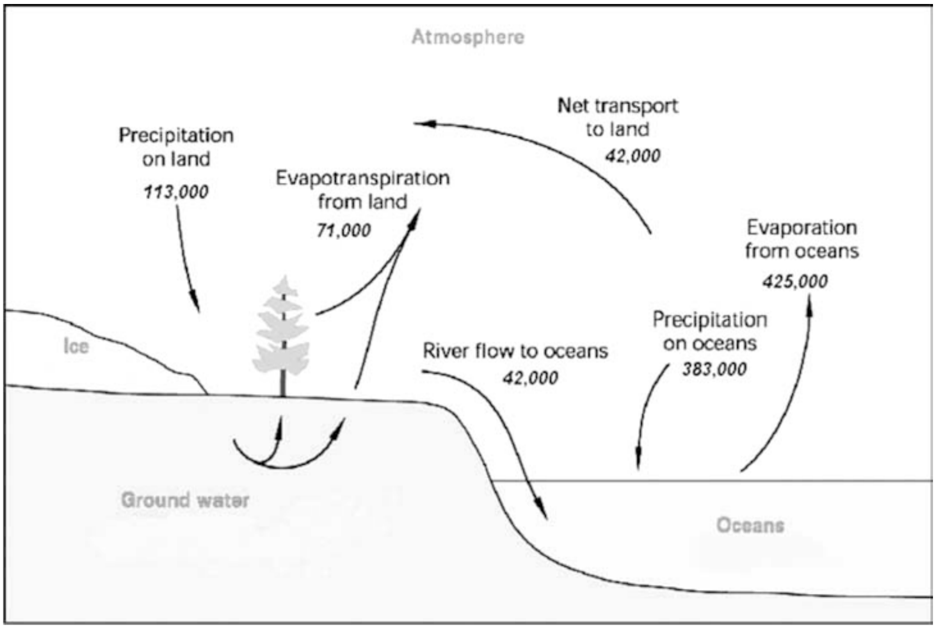

Fig. 1 Quantitative representation of processes in the hydrologic cycle showing transfer rates between reservoirs in units of cubic kilometers per year. *Source*: From Ref.[5].

and including about 96% of all of its water.[8,11,12] Ocean water unfortunately is saline and non-potable (undrinkable), containing about 35,000 mg L^{-1} of dissolved solids,[13] much too salty for human consumption. Of the remaining 3–4% of the Earth's water found in reservoirs on the continents, approximately 1% of this (principally saline lakes or deep, saline groundwater) also is non-potable.[6,8,11–13] Thus, about 97% of all the water on this Earth is too mineralized for humans to drink without expensive desalinization. Of the approximately 3% of the total water that is fresh, the largest percentage, estimated as 1.7–2.97% by different experts, is stored in icecaps and glaciers, far removed from most of the Earth's population and its water needs. Thus, the freshwater needs of the world are served by a fraction of 1% of the total hydrologic budget, primarily water in storage and transit as shallow groundwater, freshwater lakes, soil moisture, water in manmade reservoirs, and rivers. These data are synthesized from several comprehensive studies, and although the values do not match exactly, they generally do not vary by more than 1% or 2%.[8,12]

As an integrated earth system, the hydrologic cycle has no discrete beginning or ending point, but from a consumptive human point of view, the oceans are the major source of water, the atmosphere is the deliverer, and the land is the user. In this system, no water is lost or gained, but the amount of water available to the user may fluctuate mostly because of variations in the delivering agent. In the geologic past, large alterations in

Source: From Refs.[8,12].

the cyclic roles of the atmosphere and the oceans produced deserts and glaciation across entire continents. During the last ice age, the colder climate resulted in a greater percentage of water being stored as snow and ice, with a decreased percentage of water being stored in the oceans. Scientists see evidence that major sea-level declines corresponded with maximum glacial development, and in fact, point to ''drowned'' valleys (e.g., Chesapeake Bay in the United States, and the fiords in the Scandanavian countries) that were eroded and formed when sea level was much lower, and have since been inundated and flooded by rising sea level as the glacial ice melted.

Historically, freshwater in the hydrologic cycle has been enough to serve human needs, but exponential population growth and water usage in regions with little freshwater are posing ever-increasing political and planning problems. For these areas, freshwater has to be imported from great distances, at great expense, and to the detriment of other regions that need the water for their own use. Many of the most pressing problems of the 21st century will be related to obtaining freshwater for the world's expanding population.

Hydrologic Management of Contaminated Sites Using Vegetation

Tessa Marie Mills
Brett H. Robinson
Environment and Risk Management Group, Horticulture and Food Research Institute of New Zealand, Palmerston North, New Zealand

INTRODUCTION

Near-constant growth of the world economy has been accompanied by a corresponding increase in contaminated sites and degraded lands. In North America and Western Europe alone, there are over 300,000 and 400,000 contaminated sites, respectively.[1] The range of contaminants polluting these sites is broad and consists of both organic and inorganic compounds, many of which are mobile within the soil profile and thus pose a threat to underlying groundwater and to surrounding environments. The negative effects these sites have on agricultural production and human health results in lowered economic growth and reduced quality of life. Mitigation of these negative effects is therefore imperative.

Traditional cap-and-contain technology may be used at sites leaching contaminants to ground or surface waters; however, such caps are generally costly to install and may not retain their integrity long-term. Moreover, sealing the site in this manner does not result in contaminant degradation; thus, the initial problem may reappear if the cap degrades.

In some instances a vegetative cap may offer a sound alternative to traditional caps while allowing work toward future remediation of the site via phytostimulation and/or phytoextraction.[2] Here, we investigate the principles behind the hydrologic sealing of contaminated sites and discuss the application of vegetative caps. A case study is presented that outlines the establishment of a vegetation cap on a disused sawdust pile contaminated with boron, arsenic, copper, chromium, and pentachlorophenol (PCP).

PLANTS AS BIOPUMPS

Roots have been described as "the big movers of water and chemicals in soil."[3] Indeed, of the global average of 720 mm of rainfall per annum, some 410 mm are transpired from the earth surface by plants.[3] Plants require water for growth and regulation. Upward of 95% of water taken up by plants is returned to the atmosphere via evapotranspiration. This both cools the plant and translocates many essential, and non-essential, elements to the aboveground portions.

Solar radiation is the primary driver of plant growth and water use, and climatic conditions set an upper limit on evapotranspiration. Biological variables determine the actual evapotranspiration of various vegetation types, which may be much less than the theoretical upper limit. In many climates, annual evapotranspiration is much greater from fast-growing deep-rooted trees than from shallow rooted herbs or grasses.[4] During periods of drought, deep-rooted species have greater access to water and continue to transpire long after shallow-rooted species have gone dormant. Tree canopies act as umbrellas where at least 15% of rainfall may be evaporated before it reaches the ground.[5] Some species have sunken stomata, and hairy or waxy leaves that can greatly reduce actual transpiration.[6] By closing stomata, many plants conserve water in conditions that would otherwise result in excessive water loss. Some species such as kiwifruit sometimes transpire at night.[7] Evapotranspiration is dependent on the developmental stage of the plants, primarily through the development or senescence in leaf area or leaf function.

These biological parameters should be carefully considered when choosing a vegetative cap for landfills. Species should be chosen that tolerate the range of local climatic and edaphic conditions. Shallow-rooted turf species do control surface erosion and dust from a contaminated site; however, turf does not give the same level of water removal from deep within the profile as tree species may. The shallow-rooted nature of many turf species means contaminant leaching is generally greater under a grass cover when compared to trees.[4]

Vegetative caps using several species or varieties overcome the risk of all plants being destroyed by pests or environmental conditions. If the substrate to be vegetated is not soil, trials may be needed to determine the optimal species for the vegetative cap. Fig. 1

Fig. 1 Variation in growth of poplar clones growing on a contaminated sawdust pile.

demonstrates the effect of genetic differences among poplar clones grown on a contaminated sawdust pile.

Low-growing species may be combined with deciduous tree species to provide a transpiring green surface during the winter months. Legumes can be used to fix nitrogen in low-fertility substrates such as mine tailings or sawdust piles (Fig. 2).

Before planting, contaminated sites may be capped with soil to provide a fertile substrate for plant growth and a buffer zone that captures and stores rainfall. Although more expensive, such ‘‘sponge and pump’’ systems reduce leaching by providing the vegetation with a longer period to transpire infiltrated water. This is due to the retention of water within the soil buffer zone and subsequent uptake by the plants. The soil cap thickness may be critical to the success of the vegetative cap, and must be balanced with the costs of earthmoving.

Modeling the performance of the vegetative cap can provide information on project viability and optimal site management, such as the thickness (if any) of the soil cap, species selection, fertilization, and required irrigation.

Plant water use can be calculated using a modified Penman–Monteith equation[8] that integrates environmental factors, including net solar radiation, ambient air temperature, and vapor pressure deficit between air and plant leaves, and that includes stomatal conductance and tree leaf area data. Whole-system models can calculate water and contaminant movement in the substrate–plant–atmosphere continuum and may predict the vegetative caps performance for mitigating environmental effects.

Vegetative caps are porous and leaching may occur in some climates. In systems where rainfall is greater than evapotranspiration, leaching can be managed by trapping the leachate leaving the site and circulating it back onto the vegetation.[9] In effect this can be done ad infinitum and with each pass through the root zone the leachate is further modified and more contaminants removed. An increase in the level of solutes including sodium and chloride within the leachate may be of concern if leachate is to be reapplied to the site. However, depending on the composition of the leachate, it may have beneficial effects on plant growth when compared to unirrigated vegetation.[9] If leachate is applied via overhead sprinklers, there may be a negative effect on plant foliage and growth; thus, application directly onto the substrate surface is recommended.[9]

Where rainfall is greater than evapotranspiration, there is no possibility of eliminating drainage. However, vegetative caps may be used to eliminate drainage during low-rainfall periods. Depending on the contaminants in the drainage, the small volumes leached during wet periods may be diluted in receiving waters to the point so that they do not pose an environmental risk.

Limitations of Vegetative Caps

Vegetative caps will not always provide a suitable solution for contaminated sites. Contaminant toxicity

Fig. 2 Clover planted between establishing poplars on a sawdust pile.

or extreme environmental conditions may prevent plant establishment and effective seal development. In high-rainfall regions, plant transpiration will not be able to keep pace with drainage from the site, thus rendering the vegetative cap ineffective. If an instant solution is sought then a vegetative cap may not be appropriate. The time to establish a sound vegetative cap is dependent on the species of plant selected, but in general it will take 2–4 years with perennial tree species. Common choices include *Populus* sp., including cottonwood, and the *Salix* sp. These tree species are chosen because of their rapid establishment, high water-use characteristics, high tolerance of environmental and contaminant extremes, ease of establishment, and ability to take up some contaminants.[10] Drying the soil profile may create an aerobic environment where metal mobility is reduced.[2] Biological activity is enhanced under vegetation, which stimulates the decomposition of some organic compounds.[11]

Application

Long-term management of closed landfills has posed problems in the past. Generally, a clay cap is installed and turf is established. Because of the settling of waste under the cap with time, clay caps can lose integrity as they age. The establishment of a deep-rooted species on closed landfills can control leachate migration from the site and allows circulation of leachate back onto the site, closing the hydrological system.

The establishment of vegetation directly on metalliferous mine tailings controls leaching and erosion and also wind-borne dust contamination of surrounding environments. Sites contaminated with organic compounds may be remediated through plants via phytostimulation of soil microflora and fauna, which degrade organic compounds to their primary products.[12]

Soluble fertilizers and nutrients, such as N and P, pose a serious pollution threat to ground and surface water bodies. Plants can be used to protect riparian areas from stock effluent and from applied fertilizers. Work currently progressing in New Zealand indicates that dairy shed effluent may be applied to poplar and willow species as an alternative to application directly onto pasture (data not currently published). This has advantages in that the water use of trees is greater than grass.[4] Trees therefore work more effectively as N sponges and require less area in systems where excess N tends to leach and become a contaminant. The biomass produced by palatable species may be fed to stock as fodder.

Case Study

A disused sawdust pile, 15 m deep and 5 ha in size, contaminated with As, B, Cu, and Cr was continuously leaching B, As, and tannins into local surface water bodies and into the nearby harbor. Under New Zealand's Resource Management Act (1991), the site owners were required to avoid, remedy, or mitigate any adverse effects of their activity on surrounding environs. A traditional clay cap was initially proposed for the site; however, the cost of cap installation was approximately $750,000. An alternative strategy proposed included the establishment of selected poplar species on the site and the installation of a dam to trap escaping leachate to recirculate it onto the sawdust pile. A risk assessment, using the soil plant atmosphere model (SPASMO) similar to that described in Ref.[13] demonstrated the change in site water balance with the establishment of vegetative cap (Fig. 3). Table 1 gives mean monthly precipitation, mean monthly potential evapotranspiration, and the mean monthly number of expected rainfall days for the site to aid interpretation of Fig. 3. Parallel lysimeter studies were conducted in conjunction with plant establishment on the pile. SPASMO was parameterized for the poplar species grown at Kopu from data collected during the lysimeter study.[2] Full details for the lysimeter experiment are outlined in Ref.[14]. The lysimeter study demonstrated the efficacy of poplar to remove B from the exiting leachate (Fig. 4). Data from this study also show accumulation of B within poplar leaves of lysimeter grown trees to levels as high as 700 mg kg^{-1} dry mass.[2] Traces of Cu and Cr were also recorded in poplar leaves from the lysimeter study.[2] Boron removal coupled with the poplar trees capacity to dewater the site suggest poplars provide a suitable phytoremediation tool for B contaminated sawdust.[2] As the trees mature, hydrologic management of the field site will be further enhanced.
