Macropores are large, continuous voids in soil and include structural, shrink–swell, and tillage fractures, old root channels, and soil fauna burrows (Fig. 1). They are important because they can increase infiltration and may result in bypass flow where water and solutes move rapidly through the profile and do not interact with the soil matrix. This is one type of preferential flow. Other types of preferential flow include finger flow[1] and funnel flow.[2] Reviews of macropores were published by Beven and Germann,[3] White,[4] Germann,[5] Brusseau and Rao,[6] Beven,[7] and Bouma.[8]

MACROPORE FLOW OF WATER

One of the earliest documentations of macropore flow was by Lawes, Gilbert, and Warington:[9]

> The drainage water of a soil may thus be of two kinds: it may consist[1] of rainwater that passes with but little change in composition down the open channels of the soil; of[2] of the water discharged from the pores of a saturated soil.

Suggested lower limits for macropore diameters and widths are in the 0.03–3.00 mm range.[10,3,4] The lower limit would include some pores that would fill by capillarity and the upper limit would exclude all capillary pores. Consequently, the dominant driving force in macropore flow is gravity, whereas matrix flow is driven primarily by capillarity. Continuity is also an important feature of macropores.

To a certain extent, the effect of macropores on water flow can be incorporated into conventional flow equations based on Darcy's law by careful measurement on large undisturbed samples of the unsaturated hydraulic conductivity function ($K(h)$). For example, Jarvis and Messing[11] used a tension infiltrometer to measure $K(h)$ at values of h between -5 mm and -150 mm on 6 soils of contrasting texture. When the data were plotted (ln $K(h)$ vs h), the best fit was two straight lines, the line near saturation being much steeper and representing macropores.

An approach based on Darcy's Law, however, will not capture the bypass effect of macropores. Therefore, a number of approaches have been developed for describing water flow in individual macropores. Flow in water-filled macropores that are cylinders or cracks has been described by a modified Poiseuille equation but the number and dimensions of macropores must be known.[4] In addition, using Poiseuille's law assumes that macropores are open-ended, which is probably not the case. Beven and Germann[12] developed a kinematic wave equation that allows flow down the sides of macropores not filled with water. Macropore water flux was described by a power function of the macropore water content. The power term is usually obtained through calibration.

Since macropores are, for the most part, non-capillary pores, it has been assumed that macropore flow cannot occur unless there is free water at the soil surface. Experimentally, however, macropore flow has been observed in very dry soils at the onset of a rain when these conditions are unlikely. For example, Shipitalo and Edwards[13] used intact soil blocks and added water with a rainfall simulator. They observed more macropore flow in blocks that were initially dry than in blocks that were at higher antecedent water content. This may be due to a hydrophobic organic soil surface that develops under dry conditions and causes free water to run across the surface and enter macropores.[14] In addition, Phillips et al.[15] showed that water could continue to flow in open macropores under slightly negative pressure potentials, provided a continuous water film was established on the wall over the full length of the macropore. Layers beneath the soil surface that impede water flow and can raise water potentials sufficiently cause free water to enter macropores below the surface.[16]

MACROPORE FLOW OF SOLUTES

The amount of water that flows via macropores is probably a small percentage of the total water flux in most cases and has a limited effect on the overall water balance. However, macropore flow has a very important effect on movement of solutes, especially adsorbed solutes with limited half-lifes. For example, the only way some pesticides can reach ground water may be through macropore flow.[17] This is due to the rapid movement of solutes via macropores and bypass of adsorption sites within the soil matrix. Macropores do not always result in deeper movement of solutes.

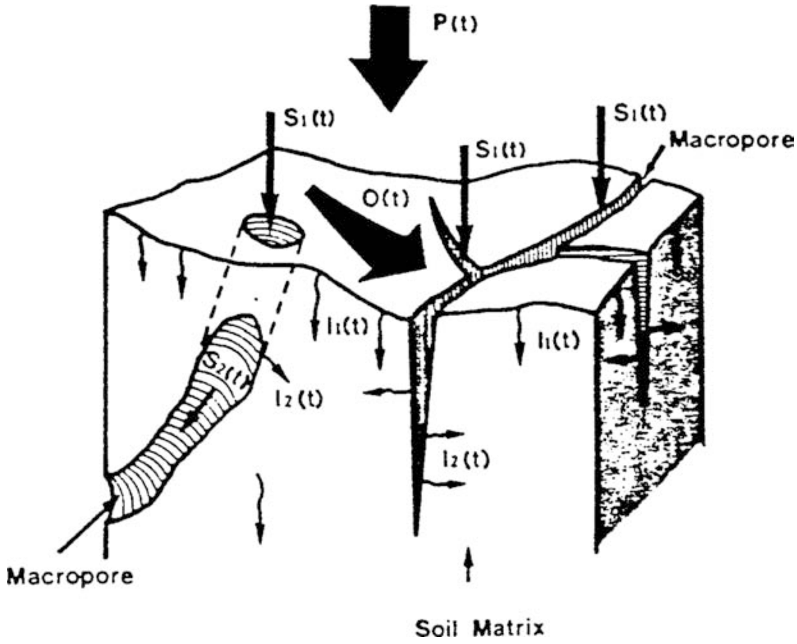

Fig. 1 Infiltration into a block of soil with macropores. $P(t)$, overall input (precipitation, irrigation); $I_1(t)$, infiltration into the matrix from the surface; $I_2(t)$, infiltration into the matrix from the walls of the macropores; $S_1(t)$, seepage into the macropores at the soil surface; $S_2(t)$, flow within the macropores; $O(t)$, overland flow. *Source*: From Ref.[3].

If a solute somehow enters the soil matrix, as a result of a small rain that did not cause surface ponding for example, then infiltrating water from larger storms may travel in macropores and bypass the solute.[18]

To a certain extent, the effects of macropore flow can be included in the conventional Convection Dispersion Equation (CDE) for solute transport through the use of large values of dispersivity (λ). However, the CDE assumes a high degree of mixing among flow paths, which is unlikely to occur at the local scale when macropores are present. In contrast, the stochastic convective log normal transfer function (CLT) is a stream-tube model that assumes there is no mixing among flow paths[19] and has been used to incorporate the effect of macropores.

Another common approach to simulating the effect of macropores is the dual porosity or mobile–immobile model developed by van Genuchten and Wierenga.[20]

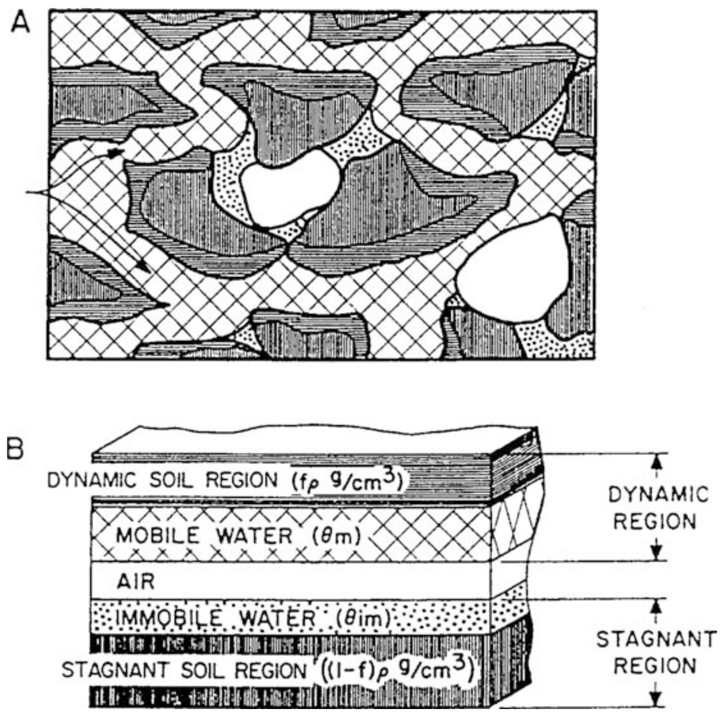

Fig. 2 Schematic diagram of soil showing mobile and immobile water. (A) Actual model. (B) Simplified model. *Source*: From Ref.[20].

Soil porosity is divided into a relatively mobile (macropore) and a relatively immobile (matrix) region with exchange between regions by diffusion or convective flow (Fig. 2). Parameters describing the relative size of the regions and exchange are usually obtained through calibration using breakthrough curves.

The importance of local-scale macropore flow can be judged by its effect on field-scale solute transport. Local-scale macropore flow can cause dispersion of the field-scale breakthrough curve if it is a large source of variation in solute velocity, compared to the variation in mean local-scale solute velocities (v) within a field. A deterministic approach that includes macropore flow (by using a large value of local-scale λ, for example) is appropriate in this case. Variation in v within a field can also cause dispersion of the field-scale breakthrough curve. A stochastic approach that includes the variation in v is appropriate in this case. The two sources of dispersion can be compared using mean local-scale λ and coefficient of variation of local-scale v.[21] If variation in v is the principal source of field-scale dispersion, then local-scale macropore flow is of little consequence at the field scale.

A number of models have been developed that describe water and solute movement and include the effect of macropores using the dual porosity approach,[22,23] the CLT approach,[24,25] Poiseuille's Law,[26] the kinematic wave approach,[12] and Darcy's Law with $K(h)$ including macropores.[27]

Soil Moisture Measurement by Feel and Appearance

Rick P. Leopold
National Resources Conservation Service, U.S. Department of Agriculture (USDA), Bryon, Texas, U.S.A.

INTRODUCTION

Measuring soil moisture by feel and appearance is one of several methods used to plan and determine the effectiveness of irrigation applications. Its simplicity makes it suitable to use in nearly all irrigation situations from urban lawns and golf courses to agricultural settings worldwide. Proper irrigation water management maximizes the positive impact of the irrigation water for the intended use, while minimizing the costs associated with irrigation and decreasing the potential for off-site movement of nutrients and pesticides from irrigated land.

BACKGROUND

Measuring soil moisture by using feel and appearance is a simple low cost method that may be used by land managers. In irrigated agriculture, this method can be used to:

- Determine when irrigation is needed.
- Estimate the available water in the root zone prior to planting or irrigation.
- Estimate the amount of irrigation water to apply.
- Determine the depth of penetration of irrigation water.

Table 1 Typical AWC (in./ft) for given textural range

	AWC
Coarse texture	0.6–1.2
Fine sand and loamy fine sand	
Moderately coarse texture	1.3–1.7
Sandy loam and fine sandy loam	
Medium texture	1.5–2.1
Sandy clay loam, loam, and silt loam	
Fine texture	1.6–2.4
Clay, clay loam, and silty clay loam	

Source: From Ref.[3].

During the process of collecting soil samples for moisture assessment, the land manager will have an opportunity to identify restrictive layers caused by compaction, as well as, some non-water related problems such as weed or insect pressure and nutrient deficiencies.

Prior to the collection of samples for estimating soil moisture, the land manager must determine the soil type, texture, and available water holding capacity of each layer sampled.[1] Soil texture, which is the relative amounts of sand, silt, and clay contained in soil, plays an important role in determining the amount of water

Table 2 Example for a uniform soil profile

Sample depth (in.)	Soil layer thickness (in.)	USDA texture by layer	Field capacity[a] (%)	AWC for layer[b] (in.)	Water available (in.)	Water needed to get to 100% field capacity (in.)
6	0–12	Sandy loam	30	1.4	0.42	0.98
18	12–24	Sandy loam	45	1.4	0.63	0.77
30	24–36	Loam	60	2.0	1.20	0.80
42	36–48	Loam	75	2.0	1.50	0.50
			Totals	6.8	3.75	3.05

a soil will hold.[2] The portion of water in the soil that can be readily used by plants is the available water capacity (AWC) of the soil.[3] The AWC ranges shown in Table 1 for various textural groups may be used as a guide in estimating soil moisture. Soil maps, soil texture, and AWC for each soil type can be found in a published soil survey that may be available through the local extension or agricultural agencies.

Available Soil Moisture Remaining	Appearance of soil
0--25 percent available	Dry, forms a very weak ball, clustered soil grains break away easily from ball.
25--50 percent available	 Slightly moist, forms a weak ball with defined finger marks, darkened color, no water staining on fingers, grains break away.
50--75 percent available	 Moist, forms a ball with defined finger marks, very light soil/water staining on fingers, darkened color will not stick.
75--100 percent available	 Wet, forms a ball with wet outline left on hand, light to medium staining on fingers, makes a weak ribbon between the thumb and forefinger.
100 percent available	Wet, forms a soft ball, free water appears briefly on soil surface after squeezing or shaking, medium to heavy soil/water coating on fingers.

Klocke and Fischbach, 1998.

SAMPLING PROCEDURES

Soil moisture is typically sampled mid-way through 1-ft increments in uniform soils,[4] or mid-way through increments that correspond to the natural soil layers in the profile. For example, if a soil had 14 in. of fine sandy loam over clay, the first sample would be 7 in. deep, then sample in 1-ft increments thereafter to bottom of the root zone. For most agronomic crops, a sampling depth of 3–4 ft will be sufficient to comprise the active root zone.[2] Table 2 provides an example for a uniform soil. Three or more sampling sites per field should be evaluated depending on the crop, field size, irrigation method, and soil variability.[1]

For each sample, the feel and appearance method involves the following:

1. Obtaining a soil sample at the selected depth by using a probe, auger, or shovel.
2. Squeezing the soil sample firmly in one hand several times to form an irregular ball.
3. Observing the ability to a form ball, ability to ribbon, loose particles, soil/water stains on fingers, and soil color. A ribbon is formed when soil is squeezed out of hand between the thumb and index finger. Note: A very weak ball falls apart in one bounce of the hand. A weak ball falls apart in 2–3 bounces.
4. Comparing observations with Figs. 1–4.

Soil Water Measurement: Capacitance

Ioan Paltineanu
Paltin International, Inc., Laurel, Maryland, U.S.A.

James L. Starr
Environmental Chemistry Laboratory, National Resources Institute (NRI), Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Beltsville, Maryland, U.S.A.

INTRODUCTION

Soil-water content is often the primary limiting factor for plant growth. Water is also the primary vehicle for moving plant nutrients and pesticides through and over soil to ground- and surface-water bodies. Conversely, the fate of water in soil is affected by many natural and management factors, such as soil texture and structure, presence or absence of plants, stage of plant growth, climate, rainfall intensity, tillage practices, residue covers, etc. These various factors are interactive, and their net effect continually changing in time and space. Until recently, soil water content measurements were made either by destructive soil sampling or by the use of portable neutron probes. Both methods were limited to fairly large time intervals (e.g., days, weeks). Capacitance probes and monitoring systems now provide the means to quantify soil water dynamics in real-time, at discrete soil depth increments, and over large areas, leading to improved soil and plant management practices, more efficient use of water and chemicals, and minimizing groundwater contamination.

HOW DOES THE CAPACITANCE PROBE MEASURE SOIL WATER CONTENT?

Electromagnetically, a soil can be represented as a dielectric mixture of air, bulk soil, and water. At radio frequencies, and at standard pressure and temperature conditions, the dielectric constant of pure water is 80, that of soil solids are 3–7, and that of air is 1. The dielectric constant of soil can be measured by capacitance, by including the soil as part of a capacitor in which the permanent dipoles of water molecules present in the surrounding soil become polarized and respond to the frequency of an imposed electric field. Measurement of the soil's capacitance gives its apparent dielectric constant, and thereby the soil water content.[1,2] Capacitance probe measurements are a function of the apparent or bulk dielectric constant (ε_b) of the soil, the imposed electromagnetic frequency, and the electrode configuration. The relationship between the ε_b and the total capacitance (C) is:

$$C = g\varepsilon_b$$

where g is a geometrical constant based on the electrode configuration (size, shape, and distance between electrodes). Capacitance probes consist of an inductor (L) and a capacitor connected to circuitry that oscillates at a frequency that is dependent on the values of L and the electrode-soil capacitor. With L set by the electronic circuitry the frequency of oscillation depends only on variations of capacitance. The oscillation frequency (F) is an inverse square root function of the capacitance:

$$F = (2\pi\sqrt{LC})^{-1}$$

where L is the total circuit inductance, and C is the total capacitance that includes the soil–water–air mixture together with some constants. For most accurate measurements of soil water content, the functional relationship between oscillation frequency and soil water content should be determined empirically by calibration for specific soils.

Under field conditions the ratio of air to water in the soil continuously changes, resulting in large variations of the soil's apparent dielectric constant. Advances in microelectronics have led to rapid development of capacitance probes in the last decade. Some of the manufacturers of capacitance probes that have been reported in the scientific literature[2–10] are shown in Table 1.

CAPACITANCE PROBE DESIGNS

Individual capacitance probes measure water content at fixed frequencies that commonly vary from 38 MHz to 150 MHz, depending on the probe design. Operational frequencies of 100–150 MHz will minimize interferences from soil acidity and salinity.[10] Capacitance probes are commonly configured, as schematically shown in Fig. 1, with: 1) two or more parallel

rods designed to be pushed into, or buried in the soil; or 2) one or more pairs of cylindrical metal electrodes, with a separating plastic ring between the pair electrodes, and mounted on a support rod that is inserted into a previously installed polyvinylchloride (PVC) access pipe. Other configurations are possible, such as a combination of one circular ring and one rod.[6] Accurate soil water content measurement for all electromagnetic based sensors requires careful installation procedures to prevent formation of air-gaps along the sensors or changes in soil properties within the sensor's zone of influence.

Portable capacitance probes configured as parallel rods are simple in design, comparatively inexpensive, and well suited for surface soil-water measurements. Some of these probes can be buried in soil at different depths with transmission cables connected to data loggers for near-continuous and real-time measurements. The sensor's zone of influence, i.e., measuring soil volume, for rod-type capacitance probes is largely contained between the electrode rods (Fig. 1).

Capacitance probes configured as one or more pairs of cylindrical metal rings are well suited for measuring soil water content at discrete depth intervals in the soil profile. These cylindrical ring sensors are normally placed inside a PVC access pipe, and form together with the soil surrounding the access pipe, a fringe-sensing volume. The radial zone of fringe influence for cylindrical ring capacitance probes, for the size shown in Fig. 1, is primarily within 10 cm of the wall of the 5-cm diameter access pipe and about 10 cm along the pipe, centered at the insulator between the two metal rings.[2] The semipermanently installed probes can be automated for real-time measurements over large areas, with probe readings essentially unaffected by cable length up to 500 m.[3]

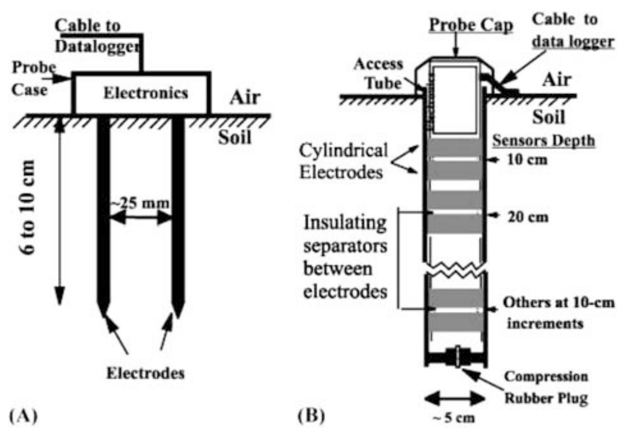

Fig. 1 Two common capacitance probe designs: (A) two or more parallel electrodes in direct soil contact, and (B) cylindrical metal ring electrodes placed inside a PVC access pipe.

HOW ARE CAPACITANCE PROBES CALIBRATED?

Published research reports on testing and applications of capacitance probes are still largely limited to those

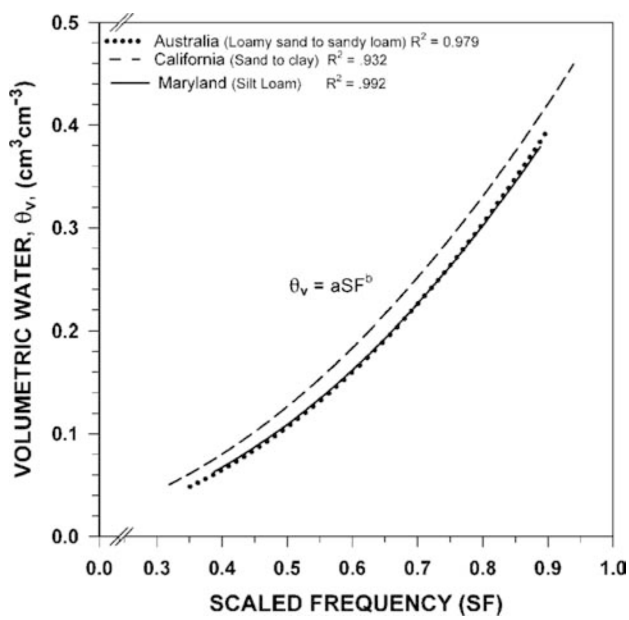

Fig. 2 Volumetric water content (θ_v) vs. scaled frequency (SF) at three sites. *Source*: Adapted from Ref.[2].

configured as cylindrical ring sensors. For example, calibration experiments with cylindrical ring, multisensor capacitance probes were reported on a wide range of soil textures—using soils collected from California, Maryland, and Australia.[2] Calibration results, as shown in Fig. 2, indicate a highly significant, nonlinear relationship between the volumetric soil water content (θ_v) and scaled frequency (SF), that was characterized mathematically as:

$$\theta_v = aSF^b$$

The scaled frequency represents the ratio of frequencies measured by each sensor (inside the PVC pipe) in the surrounding soil (F_s) compared with sensor responses in the air (F_a) and in non-saline water (F_w) at room temperature (~22°C),

$$SF = (F_a - F_s)/(F_a - F_w)$$

The use of a scaled (i.e., normalized) frequency minimizes sensor specific electronic differences, so that the same calibration curve can be used for all the capacitance sensors.

REAL-TIME SOIL WATER PROFILE DYNAMICS MONITORED WITH MULTISENSOR CAPACITANCE PROBES

Laboratory and field studies have shown that capacitance probes are accurate, robust, stable in time, and amenable to near-continuous and real-time measurements.[1–9] Sample output from a multisensor capacitance probe that was set to measure water content at 10-min intervals is shown in Fig. 3. The depth and magnitude of water infiltration following the rainfall event (8/1/95) shows water penetration to the third sensor depth, reaching maximum water contents of 35–40% volumetric water contents ($cm^3\,cm^{-3}$) for the top three sensor depths. After the initial rapid drop in soil water content, i.e., drainage of the largest soil pores, the water drainage continued during the first night followed by a combined drainage and plant-water uptake during the first day after irrigation. Very little additional drainage was evident the second night, as indicated by the nearly constant water content over night, followed by a lower total rate of loss the next day—due to plant water evaporation. The expanded time scale shows additional detail of the water penetration. Note the sequence and speed of water penetration from the first sensor depth (measuring water over the 5–15 cm interval) to the third depth, with the peak in water contents moving from one sensor depth to the next in less than 2 hr.

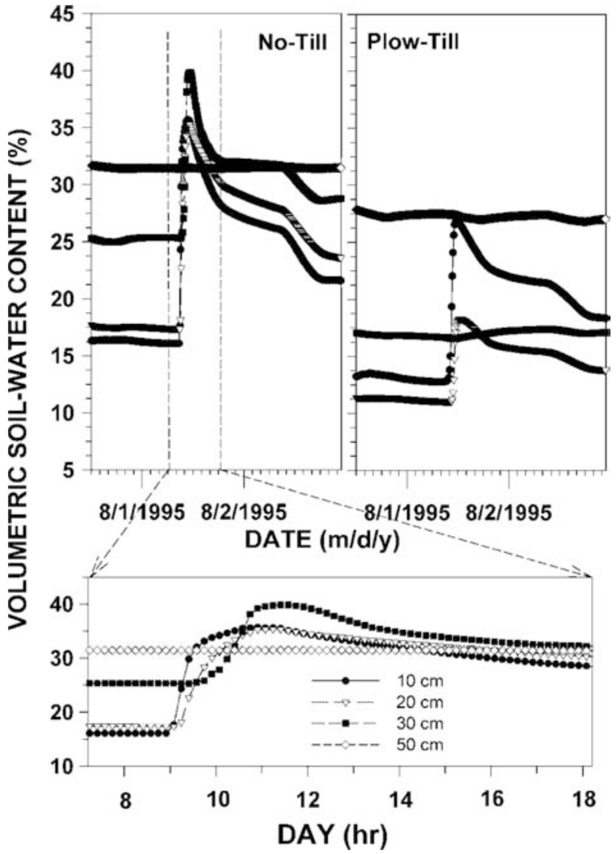

Fig. 3 Real-time soil water dynamics at four sensor depths under field-corn, as influenced by rainfall or irrigation and daytime evaporative demand. *Source*: Adapted from Ref.[5].

Another example of the kind of information that can be gained from near-continuous measurement of soil water content using capacitance probes is shown in Fig. 4. Early in the 1995 growing season (7/3/95) the soil water content was still quite moist from the spring rains. The 7/4/95 rainfall event raised the soil water content to its full point, e.g., apparent water holding capacity (aWHC), and was repeated again on 7/7/95 and 7/8/95. This figure also shows rapid water uptake by the corn crop at the 10-cm sensor depth that lasted for about 8 day, then quite abruptly the rate of water uptake slowed, as the corn shallow roots were not able to continue extracting water at the same rate from the drying soil. The same pattern can be observed at the 20-cm and 30-cm soil depths. By 7/24/95, the corn roots had penetrated to and started removing water from the 50 cm depth. The presence of active plant roots to a given depth can also be seen by the diurnal changes in soil water content (daytime uptake of soil water, and some night-time gains in water content by a complex of hydrologic processes). This kind of information, which can only be obtained by near-continuous real-time soil water content monitoring, is of utmost importance for irrigation water management.

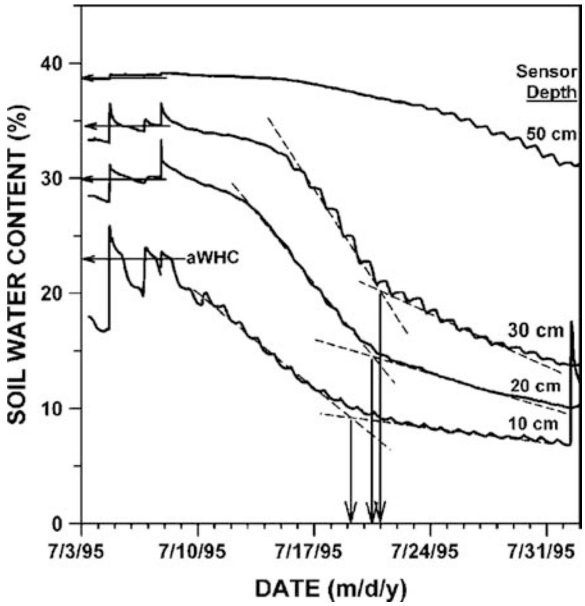

Fig. 4 Real-time soil water dynamics, at four capacitance sensor depths, associated with early summer rainfall events and evaporative demand under corn. The arrows show the apparent water holding capacity (aWHC), and the dates for the breaking points from fast to slow water uptake by corn.

The speed at which the soil water content changes during wetting and drying cycles for any specific soil will vary with the soil–crop–climate conditions. In all cases, the multisensor capacitance probes have the capacity to reveal real-time changes in soil water content, and have proven to be a powerful tool for plant, soil, and water management, and a scientific basis to implement best use of natural resources while minimizing harmful side effects on the environment.

CHALLENGES OF THE NEW CENTURY

New developments in precision agriculture, remote sensing, preferential water flow patterns, simulation models for watershed hydrology and for soil–water–plant–atmosphere relationships over large areas, and permanent monitoring for leakage from waste material deposal sites, can all benefit from real-time soil water dynamics data. Reliable soil water content profile dynamics monitoring over large areas, using multisensor capacitance probes to provide ‘‘the ground truth,’’ is needed for validation and real-time calibration of the actual and future remote sensing sensors installed on orbital platforms.

Scaling–
Soil Water

Soil Water Measurement: Granular Matrix Sensors

Clinton C. Shock
Malheur Experiment Station, Oregon State University, Ontario, Oregon, U.S.A.

Scaling–
Soil Water

INTRODUCTION

Like a tensiometer, the granular matrix sensor (GMS) is an instrument for measuring soil water potential.[1] The GMS eliminates regular maintenance required by tensiometers. Granular matrix sensor technology reduces the problems inherent in gypsum blocks (slow response time and dissolution of the block) by using a mostly insoluble granular fill material held in a fabric tube supported in a metal or plastic screen.[2,3] Like gypsum blocks, GMS sensors operate on the principle of variable electrical resistance. The electrodes inside the GMS are embedded in the granular fill material above a gypsum wafer, with additional granular matrix below the wafer in the fabric tube where water enters and exits the sensor. The gypsum wafer slowly dissolves to buffer the effect of salinity of the soil solution on electrical resistance between the electrodes. Particle size of the granular fill material and its compression determine the pore size distribution in the GMS and its response characteristics.[2]

OVERVIEW

Granular matrix sensors have been calibrated in the field in the range of −10 kPa down to −75 kPa for the irrigation of water stress-sensitive plants.[1] Calibrations have varied depending on the sensor model, soil, and other experimental conditions.[1,4–6] These sensors are most useful on soils that maintain intimate hydraulic contact with the sensor and are usually least useful on coarse textured soils.

A GMS for electronically measuring soil water was first patented by Larson,[2] and a commercial model is marketed as the Watermark Soil Moisture Sensor Model 200SS (Irrometer Co. Inc., Riverside, CA, USA, http://www.irrometer.com). The Model 200SS incorporates improvements in production and technology, with a perforated stainless steel exterior and uniform internal compaction.[3] The steel models can be manufactured more uniformly because of automated packing of the granular matrix to a prescribed pressure. The steel also exposes more fabric (Fig. 1) for greater sensor contact with the soil than the previous commercial GMS, Model 200.

GMS Placement and Installation

Granular matrix sensor performance is affected by placement[7] and installation techniques. Sensor placement depends upon the irrigation system, crop rooting depth, cultivation practices, and field topography. Sensor placement needs to be representative of the parts of the soil that become wet upon irrigation and respond fairly quickly to crop water use and soil drying. Locations for GMS placement in the field need to be representative of topography, soil types, and any large-scale heterogeneity created by the irrigation system.

Granular matrix sensors are soaked overnight in irrigation water before installation, and they are installed wet. This can improve GMS response in the first few irrigations after installation. The manufacturer recommends that the user make a 22 mm (7/8″) diameter access hole to the desired depth, pour water into the hole, and push the GMS down into the bottom. A snug fit in the soil is important, and the hole is then refilled with soil.

For very coarse or gravely soils, an oversized hole (25–30 mm diameter) may be needed to prevent abrasion damage to the GMS fabric. In this case, a hole is augered to the desired depth and a thick slurry with the soil and some water is used. Partially fill the hole with this slurry, install the GMS, and then finish filling the hole. This will "grout in" the GMS to ensure a snug fit.

Another method of installing GMS in difficult gravely soils, or at greater depths is to use a "stepped" installing tool. This makes an oversized hole for the upper portion and an exact size hole (GMS is 22 mm in diameter) for the lower portion of the hole where the GMS is installed. The hole must be carefully filled and tamped down to prevent air pockets, which could allow water to channel down to the GMS.

For silt loam and loam soils, GMS can be installed using a 22 mm (7/8″) diameter soil sampling probe and a ruled insertion rod.[7] The sampling probe is used to make a hole in the soil the same diameter as the GMS. The GMS can be installed vertically, placing the tip 22 mm deeper than the desired depth of measurement, which centers the water exchange perforations at the desired depth. The depth of the GMS can be confirmed by pushing the sensor to the bottom of the hole in

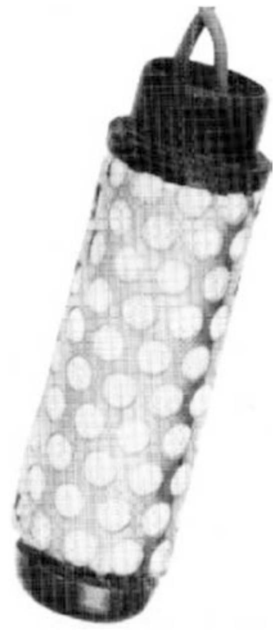

Fig. 1 A granular matrix sensor, Watermark Model 200SS, diagram courtesy of Irrometer Co., Riverside, CA.

the soil with the ruled insertion rod. If the hole is too deep, it can be partially refilled before GMS installation. Once the GMS is at the correct depth, 60 ml of water is poured on top of the GMS, and the hole is gently refilled with soil with light tamping as the hole is filled.

When a GMS is installed, it is essential that the GMS be in firm contact with the soil so that water will move from the soil into the GMS during wetting cycles and will move out of the GMS into the soil during drying cycles. The GMS will have variable resistance in most soils, but in soils with very coarse texture, the hydraulic connection with the soil may not allow water to move into and out of the GMS, or may result in the GMS responding too slowly for standard reading practices.

Calibrated Range of Measurements

The nominal range of Watermark soil moisture sensor Model 200SS (GMS) measurements is from 0 kPa to −200 kPa or −2 atm. Thomson and Armstrong[4] calibrated Watermark soil moisture sensor Model 200 from 0 kPa to −100 kPa in a pressure plate. Later, the same model was calibrated from 0 kPa to −75 kPa in silt loam planted to potato.[1] Three different GMS models were calibrated from −10 kPa to −80 kPa in silt loam in a controlled temperature growth chamber planted to grass.[5] The model 200SS was calibrated in two sandy soils, one from −10 kPa to −80 kPa and the another from −11.5 kPa to −23 kPa.[6]

Calibration equations of GMS resistance to soil water potential include terms for soil temperature, because GMS resistance is affected by temperature (Fig. 2,[5]).

Calibration equations are used in meters and data loggers to read GMS resistance. The hand held 30 KTCD-NL meter (Irrometer Co.) has a manual temperature correction. Independent soil temperature data can be recorded into the meter before measuring the GMS.

GRANULAR MATRIX SENSOR MEASUREMENT OF WATER POTENTIAL

Why Measure Water Potential?

Water potential is of economic and environmental importance because it is the measure of how strongly water is held in the soil, which relates to the difficulty of removing water from the soil by plant roots. Plant performance has been closely associated with water potential measurements using GMS.[8–15] Water potential data are also important in irrigation to avoid saturated soil, lack of aeration of plant roots, and leaching losses of water or nutrients. Water potential differences indicate the direction of flow in unsaturated media. Water potential information can help evaluate the risks of erosion and slippage on steep slopes.[16]

Scaling–
Soil Water

Water Potential Measurements at Multiple Depths

Granular matrix sensors can be installed at multiple depths to develop an understanding of the relative water potential at different depths in the soil. As can

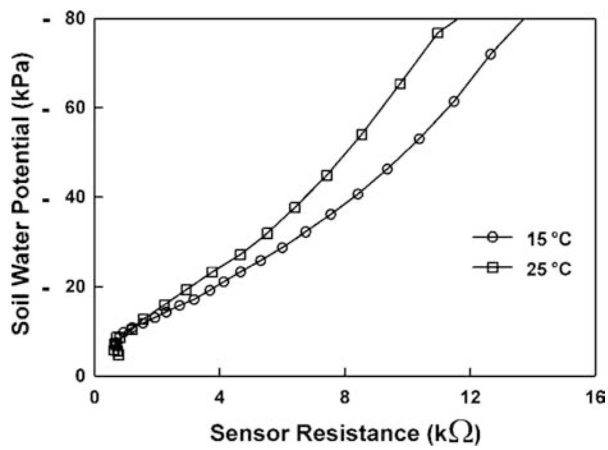

Fig. 2 Granular matrix sensor (Watermark Model 200SS) resistance responds to both temperature as well as soil water potential. *Source*: From Ref.[5].

be expected, GMS at shallow depths respond quickly to wetting and drying cycles.[10,11,13] The soil in Fig. 3 has a hard layer that is both semi-impermeable to water and impenetrable to poplar tree roots at 0.6–0.7 m depth. Consequently, the soil water potential at 0.8 m depth varies little during the growing season, irrespective of irrigation or water use.

Irrigation Scheduling

Growers need rapid and convenient ways to monitor soil water status to improve their irrigation scheduling. Growers and field men can make GMS readings with a hand held meter (Model 30 KTCD-NL, Irrometer Co. Inc., Riverside, CA, USA), and record the data manually. The GMS data may be graphed manually or entered and graphed by computer. The graph can be used to demonstrate whether the soil water potential is wetter or drier than the irrigation criteria for that particular crop. The soil water potential in graphical form is easier for growers to interpret, because the relative position (wet or dry) is clearer and the rate of drying over time is more easily understood in graphical form. Distinctly different irrigation regimes can be easily established and maintained in an arid climate (Fig. 4,[13]).

Benefits of Irrigation Scheduling

Crop yields and quality can be directly related to irrigation management using GMS. Soil water potential from GMS is being used by potato growers for

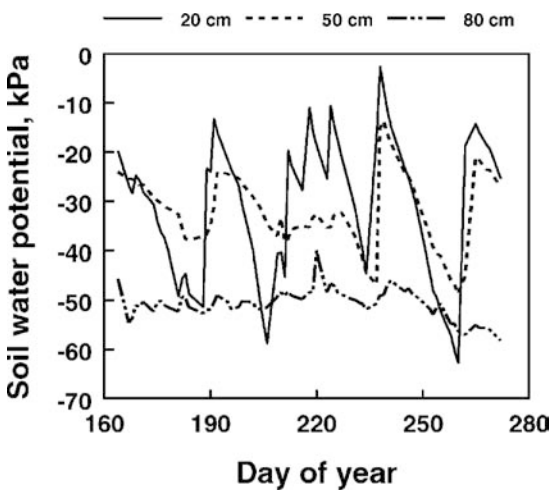

Fig. 3 Soil water potential responses to sprinkler irrigation under poplar trees. Granular matrix sensors nearest the soil surface (20 cm deep) respond to each irrigation while those below an impermeable layer (80 cm deep) show less variation. *Source*: From Ref.[10].

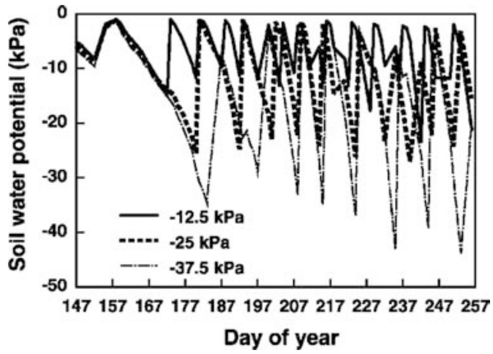

Fig. 4 Different irrigation criteria result in distinctly different soil water potential patterns over time. The figure shows soil water potential patterns for three irrigation criteria: −12.5 kPa, −25 kPa, and −37.5 kPa. *Source*: From Ref.[13].

irrigation scheduling,[7–9,12,14] and that use has expanded to onions and other crops. Onion yield and grade improve with careful irrigation scheduling based on GMS.[11,13] Optimum growth of poplar trees is also closely related to the maintenance of soil water potential within narrow bounds by careful irrigation scheduling.[10] Alfalfa productivity also benefits from careful irrigation scheduling using GMS.[15]

Automated Logging of Soil Water Potential Data

Automated collection of GMS data for field crop production research has been accomplished using a wide range of data loggers and multiplexers. Ideally, the data logger sends out an AC signal in the range of 130–200 Hz, and GMS response is measured with a half-bridge circuit.

The AM400 Soil Moisture Data Logger with Graphic Display (Mike Hansen, Wenatchee, WA, USA, http://www.mkhansen.com) is an aid to irrigation scheduling designed for use with GMS.[17] Each AM400 can be wired to up to six GMS and one temperature probe. The AM400 reads the GMS three times a day, automatically stores the data, and displays a graph of each sensor on request. The AM400 graphs the soil water potential individually for each GMS for the last 5 weeks. The soil water potential irrigation criterion for alfalfa forage on silt loam is approximately −60 kPa. Regular use of sensor readings to schedule irrigations allowed the average soil water potential to remain within the ideal range for alfalfa (Fig. 5). The frequency of irrigation depends on the weather and the stage of growth of the alfalfa. Since the AM400 screen displayed data from the last 5 weeks, the soil water potential changes over time were easy to interpret. The AM400 has been used to read GMS in a variety of crops.

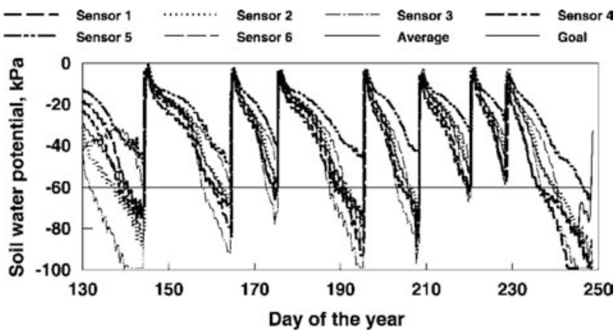

Fig. 5 Carefully scheduled sprinkler irrigation using GMSs can be used to refill the surface of the soil. *Source*: From Ref.[17].

Automated Irrigation Scheduling Using GMS

Automatic feedback control of precision irrigation scheduling using GMS has facilitated the determination of optimum crop irrigation criteria,[11] close determination of N fertilizer requirements,[18] and measures of crop development and yield responses. In these studies, the sensors were connected to a datalogger (CR 10 datalogger, Campbell Scientific, Logan, Utah, USA) via multiplexers (AM 416 multiplexer, Campbell Scientific). The datalogger was programmed to read the GMS in each irrigation zone 4–8 times a day and irrigate each zone individually as necessary according to its irrigation criteria. Irrigations were controlled by the datalogger using a controller (SDM CD16AC controller, Campbell Scientific) connected to solenoid valves for each plot. The pressure in the drip lines was maintained constant by pressure regulators in each plot, and the amount of water applied in each zone was recorded by a water meter installed between the solenoid valve and the drip tape. The irrigation criteria for onion drip irrigation were determined based on the water use and crop response in this automated way.[11]

Automation of Landscape Irrigation with GMS

A substantial part of urban water use can be landscape irrigation. Although, findings are not unanimous, studies of landscape irrigation show that it is often strongly associated with air temperature rather than landscape plants' water needs.[19] Landscape irrigation is less strongly related to total precipitation, soil moisture content, and landscape plant evapotranspiration. Yet, the actual needs for irrigation are closely tied to precipitation, soil moisture content, or landscape plant evapotranspiration. Typical landscape irrigation systems consist of a timer that schedules the irrigations and valves controlled by the timer. The timer initiates the irrigation at a frequency and duration set by the water user. Any change in landscape water need requires the user to reset the timer, but in practice, most fluctuations in landscape water needs are ignored.

Granular matrix sensors have been used in simple automatic feedback control systems to override irrigation timers since 1993.[20] By adding GMS and an electronic module (WEM, Watermark Electronic Module, Irrometer Co.), it is possible for the WEM to read the GMS and either allow or prevent an irrigation that has been scheduled on the timer.[19,20] When used in this configuration, it is common to set the timer to irrigate more frequently, but the system only irrigates when the soil is sufficiently dry to need irrigation. The addition of GMS and WEMs to automated irrigation systems has proven to be durable and cost effective in saving water in Boulder, Colorado, USA.[19]

Special Uses in Studies of Water Movement

Grids of GMS can be placed horizontally and vertically in the soil to monitor soil water movement over time.[7] Sensor placement can help assure that irrigations do not exceed soil water holding capacity of the crop or landscape root zone, providing environmental protection from nitrate leaching.[18] Tensiometers and GMS have been used on steep, unstable slopes to anticipate saturation and risks of slippage.[16]

Limitations of GMS

Calibrations used in the 30 KTCD-NL meter and the AM400 data logger were derived for silt loam soils[5] and different calibration equations may be needed in different soils and different climates.[6] The range of published calibrations is limited from -10 kPa to -100 kPa at 15–25°C. The successful operation of GMS depends upon water entering the sensor during soil wetting cycles and leaving the sensor during drying cycles. Soils with coarse textures or high shrink–swell clays can pull away from the GMS and limit its response. Even when perfectly calibrated and operational, the GMS reading only indicates when to irrigate, not how much water to apply. The amount of water to apply is largely determined by soil properties, the effective rooting depth, and the nature of the irrigation system. Current methods of reading GMS usually require wiring, which can be cumbersome or limiting for crops needing cultivation.

Each GMS only provides information about the soil water potential in the immediate vicinity of the sensor. Because of variability in soil water potential from place to place in a field and sensor to sensor variation, six or more GMS will provide more reliable estimates of soil water potential than the use of individual GMS.

CONCLUSION

The use of GMSs is increasing because they are a practical, inexpensive, and effective tool for many landscape and agricultural irrigation scheduling needs. Water can be conserved without sacrificing landscape aesthetic appearance or crop productivity and quality. The application of GMS plus WEM in automated urban landscape irrigation has saved costs and water for private and public water users.

Soil Water Measurement: Gravimetric

Joseph L. Pikul Jr.
Northern Grain Insect Research Laboratory, Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Brookings, South Dakota, U.S.A.

INTRODUCTION

Water limits crop production in most agricultural soils and directly or indirectly affects soil physical, chemical, and biological properties and processes. Quantity of water held in soil is commonly determined by measuring the mass of water relative to the mass of dry soil. The ratio is called gravimetric soil water,[1,2] oven-dry,[2,3] or soil water content.[3] This measurement has been a mainstay of many field studies and is generally accepted as a calibration standard for many indirect soil water measurement methods.[2]

A brief sampling of literature from 1907 to 1930 (Agronomy Journal, American Society of Agronomy) revealed that scientists then, as now, rarely provide detail on methodology used to measure soil water content. Often the reader was left to assume that an investigator followed expected procedure. For example, reports from the early 1900s might state that "moisture was determined in the usual way;"[4] or "samples of soil for moisture determination were taken;"[5] or "oven-dry method" was used;[6] or soil was dried "to constant weight at the temperature of boiling water."[7] Davisson and Sivaslian[8] provided standards for scientists of that era with a review of important findings in the German literature.

In the current literature, the term "gravimetric water content" is commonly used to identify the base in which soil water content is being reported (gravimetric vs. volumetric base) and to suggest to the reader that a standard procedure was followed.[9–13] Unfortunately, the term "gravimetric water" was not defined in the Soil Science Society of America, Glossary of Soil Science Terms 1996.[3] Some text books[1] and Methods of Soil Analysis: Part 1[2] include a definition of gravimetric water. Other terms commonly seen are "oven-dry water," "soil moisture," "soil water content," "soil water content (105°C, 24 hr)," and "gravimetric procedure." Often there is no reference to a standard method. In the reporting of soil water content, it is important to identify that a standard method, such as that provided by Gardner,[2] was used.

FIELD PRACTICE

Soil water is rarely at equilibrium. Water moves from regions of high water potential (wet soil) to low water potential (dry soil). To minimize temporal variability in water content among samples, it is best to sample quickly and at a time of day when evaporational demand is lowest. Early morning and late afternoon are ideal. Indirect methodology, such as neutron thermalization,[2] may be best suited for repeated measures of soil water content. Gravimetric soil water sampling is destructive and requires the investigator to sample across a spatially diverse field. This may or may not be advantageous.

Soil water content near the surface can change rapidly. The work of Idso, Aase, and Jackson[14] and Pikul and Allmaras[9] are examples of dynamic fluctuations in soil water content that can be expected near the surface under different environmental conditions. Idso, Aase, and Jackson[14] investigated soil heat flux relations in non-frozen soil as influenced by soil water content of a loam soil that was recently wetted by irrigation. Pikul and Allmaras[9] investigated the phenomena of freezing induced soil water redistribution.

Idso, Aase, and Jackson[14] found diurnal fluctuations in soil water content to a depth of about 100 mm. Soil water content changes were a consequence of water evaporation and redistribution. In the top 10 mm of soil, water content decreased about $0.08\,m^3\,m^{-3}$ (8% water content on a volumetric basis) in 10 hr. In the case of soil freezing, Pikul and Allmaras[9] found that water content near the surface changed dramatically within hours. Their measurements show that in some cases water content of the surface 5-mm layer increased by $0.17\,kg\,kg^{-1}$ (17% soil water on a gravimetric basis) in as little as 6 hr when the soil froze.

Soil sampling tools are designed to meet the purpose for sampling and the condition of the soil being sampled. Soil structure, whether compact or loose, determines the layer refinement attainable. Directly after tillage, the size of soil structural units and their fragility prohibit conventional sampling in thin layers as described by Idso, Aase, and Jackson[14] or Pikul and Allmaras.[9] Alternative soil investigation methods such as the random roughness technique presented by Allmaras et al.[15] may be necessary when working with extremely disturbed soil surface conditions.

For a moderately compacted and moist soil with a bare, smooth surface, Reginato[16] developed a soil sampler for delineating soil-water distribution in the

Scaling–
Soil Water

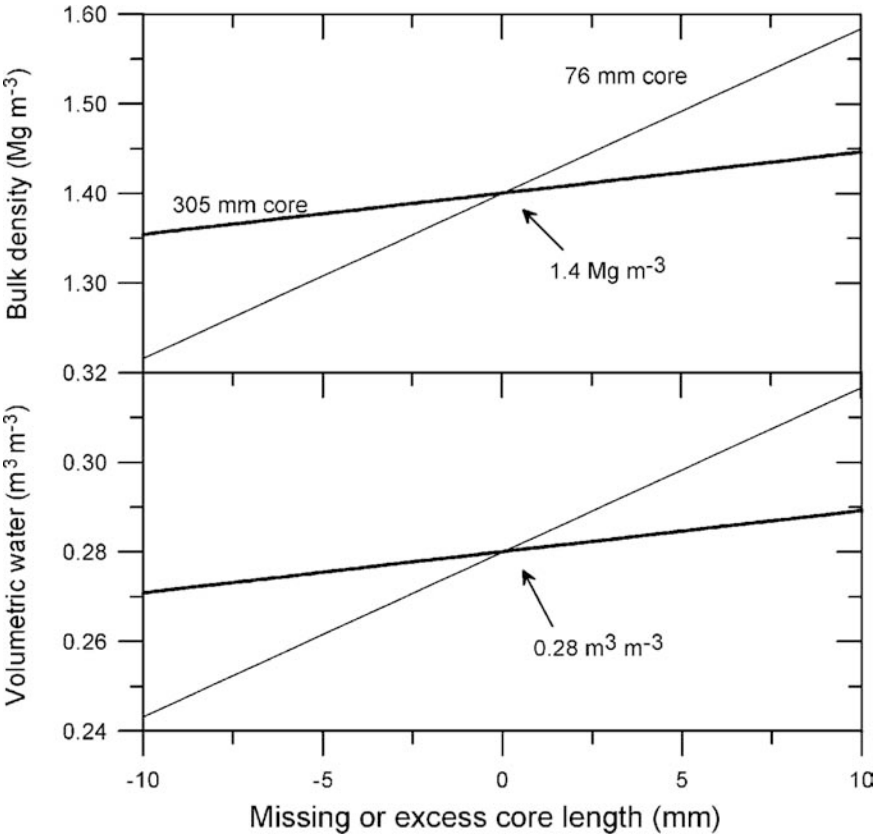

Fig. 1 Soil bulk density (ρ_b) and volumetric water (θ_v) as a function of missing or excess soil (cutting error) for cores of 76 mm (3 in.) and 305 mm (12 in.). Deviation from expected $\rho_b = 1.4\,\mathrm{Mg\,m^{-3}}$ and $\theta_v = 0.28\,\mathrm{m^3\,m^{-3}}$ are a consequence of missing or excess soil mass associated with a core of 30 mm diameter.

top 10-mm layer. Increments as fine as 1 mm could be sampled for gravimetric water. Bulk density, however, was measured with segmented soil cores obtained with a cylindrical Oakfield type core sampler. Pikul, Allmaras, and Fischbacher[10] developed an incremental soil sampling tube for sampling 10-mm increments of unconsolidated surface soil. This tool containerized loose soil layers thereby enabling measurement of both soil water content and soil bulk density in one sampling operation.

Sampling methods that enable simultaneous measurement of both bulk density and water content are desirable because bulk density is essential for converting water content from a gravimetric to a volumetric base. Expression of soil water on a volumetric basis enables calculation of several fundamental attributes of soil water condition related to volume fraction.[1]

FUNDAMENTAL RELATIONS

Gravimetric water content is defined as the mass of water (M_w) relative to the mass of dry soil (M_s). Determination of gravimetric water content requires three independent measurements that include mass of wet soil (M_{ws}), mass of dry soil, and mass (t) of the collection can (commonly called tare weight). Wet soil samples are placed in metal cans with tight fitting lids and the combined mass of wet soil and container ($M_{ws} + t$) is measured. The term "wet" is relative to the soil water content at time of sampling. Collection cans, with lids off, are placed in a drying oven and the sample is dried to a constant mass. Standard practice is to dry samples for 24 hr at 105°C in a forced-draft oven. The term "dry" is specific and refers to soil that has been dried to a constant mass. Gardner[2] provides a complete description of standard procedures. After drying, the cans are capped, cooled, and the combined mass of dry soil and container ($M_s + t$) is measured. Mass of water is calculated as $M_w = (M_{ws} + t) - (M_s + t)$. It follows that $M_s = (M_s + t) - t$. Gravimetric water content (θ_g) is calculated as

$$\theta_g = M_w/M_s \tag{1}$$

and volumetric water content (θ_v) as

$$\theta_v = \theta_g(\rho_b/\rho_w) \tag{2}$$

where ρ_b is soil bulk density (Mg m^{-3}) and ρ_w is density of water. Soil bulk density is defined as

$$\rho_b = M_s/V_t \tag{3}$$

where V_t is the total volume of soil sample. Eq. (2) is dimensionally correct. However, for most field applications, a working formula for θ_v is simply

$$\theta_v = \theta_g \rho_b \qquad (4)$$

when ρ_w is assumed to be $1\,\mathrm{Mg\,m^{-3}}$.[1]

Special attention must be given to samples collected for both ρ_b and θ_g. There is serious error associated with cutting soil cores improperly. Soil bulk density is based on mass and volume of the sample. Thus, it is important to collect the entire mass of soil associated with a given volume.

Missing or excess soil results in an error in ρ_b and consequently θ_v. For samples with the same diameter, a small cutting error is more serious in cores of short length rather than long length. Bulk density and volumetric water are shown in Fig. 1 as calculated for conditions where a soil core may have been undercut (missing core) or overcut (excess core). Volume of sample was based on an intended length of 76 mm (3 in.) or 305 mm (12 in.). Core diameter was 30 mm. True value of ρ_b was $1.4\,\mathrm{Mg\,m^{-3}}$ and θ_g was $0.2\,\mathrm{kg\,kg^{-1}}$ ($\theta_v = 0.28\,\mathrm{m^3\,m^{-3}}$). For soil cores having an assumed length of 76 mm, an error of about 13% in both ρ_b and θ_v would occur if these cores were cut 10 mm short (or long). In contrast, a 10 mm undercut (or overcut) would result in an error of only 3% for cores having an assumed length of 305 mm. In many studies, soil from the 0- to 76-mm depth (0- to 3-in. depth) and 76- to 152-mm depth (3- to 6-in. depth) is important. Soil water content plays a vital role in respect to biological activity and it is important to accurately determine ρ_b and θ_v for shallow soil depths. Unfortunately, the investigator is most apt to accrue serious errors because of poor sampling technique of thin layers.

Soil Water Measurement: Neutron Thermalization

Steven R. Evett
Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Bushland, Texas, U.S.A.

INTRODUCTION

Nearly 50 yr after its first use, the neutron thermalization method remains the best available method for repeated measurement of soil profile volumetric water content (VWC)[1] because it is non-destructive, can be field calibrated with high precision, works successfully to depths not easily attained with other methods, and works well in stony soils and cracking clays in which other methods work poorly. Also, the large volume of measurement means that fewer replicates are required than for other methods to produce a given precision, that soil disturbance during tube installation has minimal effect on results (unlike electronic sensor methods), and that field calibration is successful because volumetric soil samples can be obtained from within the volume measured by the probe at each depth (unlike electronic methods used in access tubes that have much smaller measurement volumes). The technology is mature with a wide literature base describing applications and problems.

The neutron thermalization method employs a radioactive source of fast neutrons (mean energy of 5 MeV) and a detector of slow neutrons ($\sim$0.025 eV or 300 °K). High-energy neutrons emitted from the source ($\sim 10^9\ \mathrm{sec}^{-1}$) are either slowed through repeated collisions with the nuclei of atoms in the soil (scattering and thermalization), or are absorbed by those nuclei. A small fraction of scattered neutrons will be deflected back to the detector. Of these, an even smaller fraction ($\sim 10^3\ \mathrm{sec}^{-1}$) will have been slowed to thermal (room temperature) energy levels and will be detected. Soil density and chemical composition affect the concentration of thermalized neutrons around the detector. The most common atoms in soil (aluminum and silicon) scatter neutrons with little energy loss because they have much greater mass than a neutron. However, if a neutron hits a hydrogen atom its energy is halved, on average, because the mass of the hydrogen nucleus is the same as that of the neutron. On average, 19 collisions with hydrogen are required to thermalize a neutron. Carbon, nitrogen, and oxygen are also relatively efficient as neutron thermalizers (about 120, 140, and 150 collisions, respectively). On the timescales of common interest in water management, changes in soil carbon and nitrogen content are minor and have little affect on the concentration of thermal neutrons. Also, on these timescales, changes in soil hydrogen and oxygen content occur mainly due to changes in soil water content. Thus, the concentration of thermal neutrons is most affected by changes in water content; and VWC can be accurately and precisely related to the count of thermal neutrons through empirical calibration.

Because hydrogen and carbon effectively thermalize neutrons, the organic matter content of soil affects the calibration. Also, organic matter and most clays contain important amounts of hydrogen, some not in the form of water, that may not be driven off by heating to 105°C (the standard temperature for drying soil samples). So, separate calibrations are often required for soil layers that differ in organic matter or clay content from layers above or below. In arid or semi-arid zones, many soils have layers rich in $CaCO_3$ and $CaSO_4$ that require separate calibration.[3] Atoms that absorb neutrons include boron, cadmium, chlorine, iron, fluorine, lithium, and potassium. Although these usually comprise a small fraction of soil material, soils, or soil horizons that contain large or fluctuating amounts of such elements will require separate calibrations or adjustments in data interpretation. For example, soils high in iron, such as Oxisols or soils rich in magnetite, typically require separate calibration, as may soils high in chloride salts. In some U.S. soils, boron is present in sufficient quantity to affect calibration.

NEUTRON MOISTURE METERS

Neutron moisture meter (NMM) equipment comes in two forms: 1) a profiling meter with a source–detector pair assembled into a cylindrical probe that is lowered into a hole in the soil; and 2) a flat-based meter that is placed on the soil surface with the source and detector fixed at separate locations inside the base of the meter. The volume measured by the surface meter is roughly hemispherical and extends into the soil for a distance that decreases as soil water content and soil density increase, and which varies from $\sim$0.15 m in wet soil to $\sim$0.3 m in dry soil.[3] The precision is less than can be attained with a profiling meter; and it suffers even more when soil moisture changes greatly with depth near the surface,[4] a common occurrence. Good precision has been reported under fairly stringent conditions including: 1) flattening the surface to fit the meter bottom with no air gaps; 2) marking the measurement site so that the meter can be repeatedly placed in identical position; and 3) using a neutron absorber shield made of cadmium around the meter (except for the bottom) to reduce effects of surrounding vegetation.[5] However, even in the latter study, the strong depth dependency of calibration coefficients and the inability to accurately estimate the depth of reading led to great uncertainty as to the accuracy of measurements.

More commonly used in soil and water science is the profiling NMM, which is operated at user-chosen depths in the soil (Fig. 1). A cylindrical access tube is used to line the hole, protecting the probe and ensuring a constant hole diameter. The probe is connected to a counter, data storage, and display module by a cable that allows the probe to be lowered into the tube and stopped at intervals to measure the thermal neutron concentration. Common probe diameters are 38 mm and 51 mm. When not in use, the probe is locked in the instrument shield, which comprises a block of high-density polyethylene, and which is commonly attached to the readout and control unit. In the probe, the source is either directly beneath the detector, or is centered around or on one side of it. The relative position of the source and detector affects the calibration;[6] but for modern meters, source–detector geometry has little effect on the attainable precision.[2,7,8] In modern meters, the source is a mixture of americium-241 and beryllium with an activity ranging from 0.4 GBq to 1.9 GBq. The nuclear reaction is (^{9}Be(α,n)^{12}C) in which ^{241}Am emits an alpha particle that is absorbed by a Be atom, which then produces ^{12}C and a fast neutron.

The measurement volume is approximately a sphere. For a soil of specified VWC ($m^3\,m^{-3}$), about 95% of the measured slow neutrons are from a sphere of radius R (cm).[9]

$$R = 15(\mathrm{VWC})^{-1/3} \tag{1}$$

ACCESS TUBES AND DEPTH CONTROL

Access tubing materials that have been used successfully include stainless steel, mild steel, polyvinylchoride (PVC), polycarbonate, and polyethylene plastics, and aluminum. The hydrogen in plastics affects calibration, as does the neutron absorber chlorine in PVC tubes. Aluminum is nearly transparent to neutrons, while the neutron absorber iron affects calibration in steel tubes. Thus, it is important that a NMM be calibrated in the same tubing as will be used in the field. Although calibration precision decreases slightly if plastic tubes are used,[7] precision and accuracy are much more dependent on the tube installation and calibration methods employed than on tube material. Recommendations for installation of access tubes are given in Ref.[10].

It is a common practice to place the NMM on top of the access tube near the soil surface before

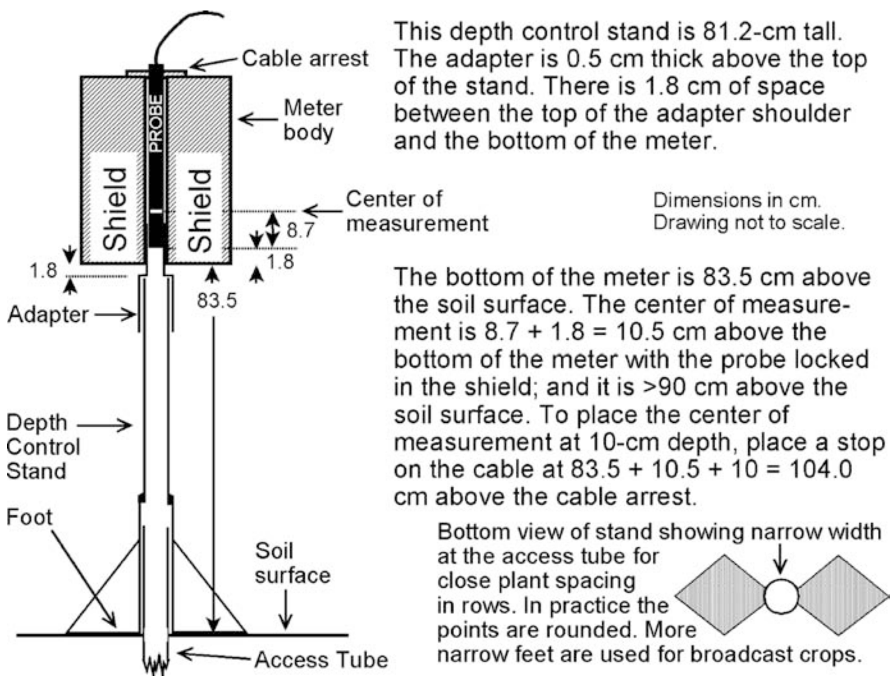

Fig. 1 Cross-sectional schematic of a profiling NMM in place on top of a depth control stand. The probe is locked in the meter shield; and the stand is in place over an access tube that has been inserted into the soil. For the dimensions given here, to measure at 10-cm depth, the probe must be lowered 104 cm through the stand and into the access tube. Dimensions will vary for meters of different manufacture.

lowering the probe for readings. This practice is not recommended for two reasons. First, when the NMM is placed near the soil surface, the shield in the meter body may influence near-surface counts to a degree that depends strongly on the height of the meter above the soil.[11] Second, in field use, the height of access tubes above the soil is likely to change with tillage, rainfall induced settling, erosion or deposition, or other factors, resulting in an equivalent change in the depth of probe placement. For readings above 0.3-m depth, the depth of the probe will strongly influence the reading and the calibration equation due to loss of neutrons to the atmosphere.[4,12]

These problems are addressed by using a depth control stand.* This device comprises a length of access tube fixed to a 0.2-m length of slightly larger tubing that is in turn supported by a foot resting directly on the soil (Fig. 1). The larger diameter of the lower length of tubing allows it to be slipped over the top of an access tube so that the foot rests on the soil surface. This maintains the reading depth at an exact distance relative to the soil surface. Cable stops are arranged to achieve the desired depth placement of the probe. The stand described is tall enough to be suitable for taking standard counts with the NMM mounted on the stand and the probe locked in the meter shield. Standard counts taken with the meter too close to the soil surface may vary with the moisture content of the soil.[13,14]

STATISTICS OF NEUTRON EMISSION

Neutron emission is a random process that occurs according to a Poisson probability distribution. An important property of the Poisson distribution is that, for a series of counts over equal time periods, the standard deviation is equal to the square root of the mean value. One result of this fact is that the coefficient of variation of counts can be reduced by increasing the counting time. The sample mean, m, is computed as

$$m = \frac{1}{N}\sum_{i=1}^{N} x_i \tag{2}$$

where x_i is the value of a single count and N is the number of counts (all taken with the probe in one position).

The sample standard deviation, s, is computed as

$$s = \left[\frac{1}{N - 1}\sum_{i=1}^{N}(x_i - m)^2\right]^{1/2} \tag{3}$$

For a properly operating meter with the probe in a constant environment, the ratio of $s/(m)^{1/2}$, called the Chi ratio, should be close to unity. This ratio is related to the χ^2 statistic by

$$\frac{s}{m^{1/2}} = \left(\frac{\chi^2}{N - 1}\right)^{1/2} \tag{4}$$

Values of χ^2 (Chi-squared) for a given probability level (P) are given in statistical tables for different values of ($N - 1$). We may write the right-hand-side of Eq. (4) for the upper and lower limits of χ^2 and thus obtain upper and lower values of the Chi ratio for the chosen probability level and number of samples. For example, for a 95% probability level and 32 samples, we find the values of χ^2 as 17.5 for $P = 0.975$ and 48.1 for $P = 0.025$; and from Eq. (4) the Chi ratio should be between 0.75 and 1.25 about 95 times in every hundred. Some meters divide the count by a fixed number in order to reduce the displayed count to a reasonably small value. In computing Chi ratios for such meters, the user should first multiply the recorded counts by the factor that the meter used to reduce them.

CALIBRATION

Manufacturers' calibration equations are seldom useful for soil moisture determination (e.g., Ref.[13]). Calibration of NMMs involves correlating measured count ratio values with independently determined VWC ($m^3 m^{-3}$). For modern meters and the normal range of values of soil water content, the calibration is linear and of the form

$$VWC = b_0 + b_1 C_R \tag{5}$$

where b_0 and b_1 are the calibration coefficients as determined by linear regression, and C_R is the count ratio defined as

$$C_R = x/x_s \tag{6}$$

where x is the count in the measured material and x_s is a standard count taken with the probe within a standard and reproducible material. Count ratio values are used because the source activity and thus counts will decline over time, and because the detector efficiency is somewhat temperature dependent.[15] Recommendations for taking standard counts are

Table 1 Calibration of water content (θ_v, $m^3 m^{-3}$) vs. count ratio (C_R) for the Amarillo fine sandy loam using the method in Ref.[2]. A depth control stand was used

Depth (cm)	Equation	RMSE	r^2	N
10	$\theta_v = 0.014 + 0.2172C_R$	0.004	0.997	6
30–190	$\theta_v = -0.063 + 0.2371C_R$	0.007	0.988	44
30–90	$\theta_v = -0.066 + 0.2421C_R$	0.008	0.988	24
110–190	$\theta_v = -0.057 + 0.2299C_R$	0.006	0.992	20

RMSE is the root mean squared error, *N*, the number of samples, and r^2, the coefficient of determination for the regression analysis.

given in Ref.[10], as are recommendations for field calibration using the wet site–dry site method of Evett and Steiner.[2] Careful field calibrations done using the wet site–dry site method and the depth control stand should attain root mean squared errors $<0.01\,m^3 m^{-3}$ and r^2 values greater than 0.9, even for depths near the surface (e.g., 10 cm in Table 1).

SAFETY AND USE CONSIDERATIONS

Safety concerns relate to radiation safety and to back and knee strains incurred during repeated bending and kneeling to operate meters placed on access tubes. The depth control stand described earlier allows users to work standing up, and has virtually eliminated physical injuries where it is used. Due to the low levels of radioactivity involved, the principle of reducing exposure to as low as reasonably achievable (ALARA) guides most radiation safety rules. Users may lower radiation received by increasing distance from the meter, decreasing time spent near the meter, and increasing shielding. The probe should always be locked into the shield except when it is lowered into an access tube. Users should be made aware that the source emits radiation at all times, even when the meter is turned off and batteries removed. Guidelines for ALARA use of the NMM are found in Ref.[16]. The USDA Radiation Safety Staff maintains an Internet site of useful information on radiation safety and hazardous materials transport (http://www.usda.gov/da/shmd/rss1.htm) as does the International Atomic Energy Agency (http://www.iaea.org/worldatom/).

Due to regulation, the method is not usable for automatic measurements. Due to its large measurement volume, the method is inappropriate where detailed vertical definition is required. This can be particularly important near the surface where water content often changes rapidly with depth. In such cases, the NMM can be used for deeper measurements in conjunction with time domain reflectometry (TDR) measurement of the near-surface soil water content.[17] The time and effort required to install access tubes and calibrate for each soil type is non-trivial. There is also a substantial cost for the equipment and for necessary training and licenses to handle and transport radioactive materials.

Soil Water Measurement: Soil Probes

Clay A. Robinson
Division of Agriculture, West Texas A&M University, Canyon, Texas, U.S.A.

INTRODUCTION

Knowledge of soil water content can improve irrigation scheduling and management. In dryland conditions, soil water content may determine when and/or which crop to plant. There are many methods of determining water content or potential without disturbing the soil, including neutron probes, time domain reflectometry (TDR) probes, electrical conductance/resistance methods, psychrometry, etc. These methods require extensive technology and calibration for best performance. Cost and technology limit their use primarily to researchers and a few, large-scale producers. In contrast, soil probes are low-cost devices that require no special technology to estimate soil water storage.

DESIGN AND PRINCIPLES

Soil probes are simple in design, and are also marketed as tile probes. Most soil probes are made of 9.5 mm diameter (3/8 in.) high tensile steel rod with a handle (Fig. 1A). The handle can be a 7.6 cm (3 in.) diameter ball or a 30 cm × 22.2 mm o.d. pipe perpendicular to the rod. The probe tip is flared to approximately 12.5 mm (1/2 in.) and can be either pointed or rounded (Fig. 1B). The flared tip allows less friction when inserting and removing the probe from the soil. Probes range from 1.2 m to 1.8 m in length, depending on usage and crop rooting depth.

Soil penetration resistance is affected by texture, aggregation, bulk density, and soil water content. Penetration resistance is inversely related to water content, so wet soils (high water content) have less penetration resistance. When the soil is near field capacity (FC), it contains water that is available to plants [plant available water (PAW)], and penetration resistance is low enough to allow probe insertion. When a soil layer dries below FC, the probe cannot be easily inserted into that layer. The depth of probe insertion indicates the depth in which high PAW is present. The PAW capacity in a soil is a function of soil texture, structure, and organic matter content (see also Table 1 in the article *Soil Moisture Measurement by Feel and Appearances*).

PLANT AVAILABLE WATER

Plant available water is defined as the difference in water content between the soil water contents at FC and wilting point. Field capacity is defined as the soil water content 2 to 3 days after a soaking rain or irrigation when the soil surface has been covered to limit evaporation, or the water content at a soil water potential of −33 kPa. The water in large pores, called gravitational water, drains under the influence of gravity. The water remaining in the soil at FC is held in small pores against gravity. Wilting point is the soil water content below which plants are unable to extract water, typically –1500 kPa, though it varies with plant type.

For a simple example, completely saturate a sponge, then hold it above the water with the long side parallel to the water surface. Water dripping from the sponge comes from large pores or voids that are unable to retain the water against gravity. Once the water has stopped, turn the sponge so the long side is perpendicular to the water surface. Gravitational water flows from the sponge again. Why? Gravity now has a greater distance through which it can act on the water in the sponge. When the water stops dripping, the sponge represents a soil at FC with all gravitational water removed.

To represent plant water uptake by roots, squeeze the sponge. At some point, squeezing the sponge no longer yields water. This represents wilting point, the water content at which plants can no longer extract water. The water squeezed out of the sponge represents the PAW. Notice the sponge is not dry at wilting point. Most soils contain between 5% and 20% water by volume at wilting point.

The amount of water held at FC is primarily a function of soil structure and the quantity of large, continuous pores. The amount of water held at wilting point is primarily a function of soil texture, especially the clay content. Organic matter increases wilting point, FC, and PAW. Silt loam soils have the highest PAW content while clays hold the most total water.

EXAMPLE

Once the soil water content of a layer drops below FC, the penetration resistance increases, and the probe

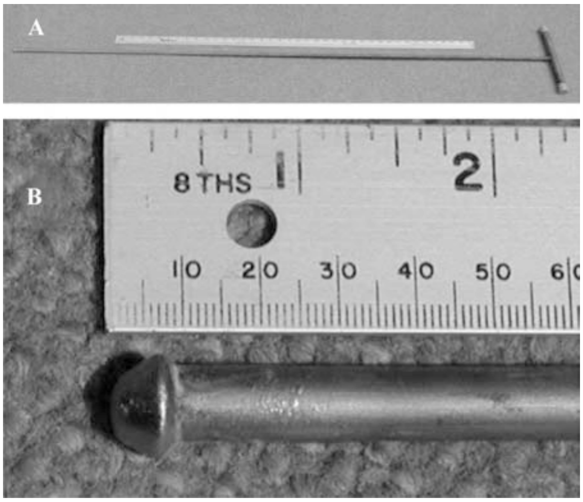

Fig. 1 Soil probe (A) and close-up of tip (B).

cannot be easily inserted into that layer. Because the PAW is a volumetric water content, the equivalent depth of available water in the soil can be calculated as the product of the depth of insertion and the PAW for that soil. Table 1 demonstrates the calculation of profile PAW for a profile of a typical Pullman clay loam (fine, mixed, superactive, thermic, Torrertic Paleustolls) from the Texas High Plains. The last row in the heading gives the formula used for that column: depth interval (D_i), PAW (volumetric, %), and PAW (depth equivalent, cm). The next row shows the calculations for the first layer, 0–30 cm. The data for each subsequent layer are calculated in the same manner. The depth equivalent data for each layer are summed to yield the profile PAW.

The result using Table 1 is more exact than can be determined with a soil probe, but is given for a comparison. In the Texas High Plains, farmers are given generalizations by region based on the dominant soil types present.

- Silty clay loam soils hold approximately 2 in. ft^{-1}, 0.167 cmc m^{-1}
- Sandy loam soils hold about 1.5 in. ft^{-1}, 0.125 cmc m^{-1}
- Clay loam soils hold about 1.75 in. ft^{-1}, 0.146 cmc m^{-1}

The Pullman is a clay loam soil and holds about 0.146 cmc m^{-1} (1.75 in. ft^{-1}). If the probe could be inserted to approximately 3 ft (90 cm), the Pullman soil would have about 13.1 cm (5.25 in.) of PAW. A sandy loam soil would have about 1.9 cm (0.75 in.) less, while a silty clay loam would have about that much more.

LIMITATIONS

The soil probe, by itself, cannot identify water available below a dry layer. This condition often exists in the Great Plains after fallow periods. There are usually 5–7 precipitation events of sufficient amount to store water in the soil. Afterward, the soil surface layer dries by evaporation. If no rain occurs before planting, the soil probe will likely penetrate only 2.5–7.6 cm (1–3 in.), though there may be PAW stored below the dry surface layer. If the information on water storage is necessary, dig through the dry layer with a shovel, then use the probe for the underlying layers.

Some researchers place little faith in estimates of PAW by soil texture because organic matter levels and soil structure strongly affect FC, and because organic matter levels and structure vary among soils of similar texture. Crop and tillage management systems can alter PAW on adjacent plots on the same soil. Still, these estimates are a valuable starting point in improving irrigation management when no previous information on soil water content has been available. With continued use, estimates can be refined as producers monitor soil water storage, precipitation, irrigation, and crop water use. A 1.2-m (4-ft) probe is recommended for homeowners to manage their turf

Table 1 Calculation of profile plant available water, Pullman clay loam

and lawn irrigation scheduling, primarily to avoid excess water application. Most turf root systems are in the top meter of the profile. If a homeowner can insert the probe to the full depth, it is time to cut back on irrigation frequency or quantity. Most agronomic producers use a 1.5–1.8 m probe to cover the rooting depth of the crop grown. Probes can be used to identify management effects on soil water storage (see also Fig. 3 in the article *Dryland Farming*).

CONCLUSION

Soil probes offer a simple, economical method to obtain valuable information about soil water storage. The PAW is estimated from depth of probe insertion and soil texture. Their use is limited when the surface soil is dry but lower layers are moist. Consistent use of soil probes with other information, e.g., evapotranspiration, precipitation, and irrigation amounts, can improve irrigation scheduling and water use efficiency of irrigated crops. Using soil probes in dryland cropping systems provides information to make crucial management decisions; e.g., when to plant, which crop to plant, and whether to fertilize, and allows producers to project yields.

Soil Water Measurement: Tensiometers

James "Buck" Sisson
Joel M. Hubbell
Idaho National Engineering and Environmental Laboratory (INEL), Idaho Falls, Idaho, U.S.A.

INTRODUCTION

Tensiometers, which are used to indicate when plants should be irrigated, are widely used in agricultural and research applications. Research applications include characterizing and monitoring disposal sites to evaluate the presence of recharge, determining the direction of moisture flow, and estimating the water content and unsaturated hydraulic conductivity of the geologic materials at a site.

TENSIOMETER DESIGN AND OPERATION

The tensiometer is an instrument for measuring soil water potential. Soil water potential indicates how tightly water is held by soil. Fig. 1 shows the three basic components of a tensiometer: a water chamber, a rigid porous semipermeable membrane, and a pressure measurement device. The tensiometer is filled with water and sealed. The porous membrane is placed in contact with the soil to be measured, and water moves in and out of the porous membrane until the pressure in the sealed chamber is the same as the soil water potential. This pressure is then determined with a pressure sensor.

The semipermeable membrane is commonly made of a ceramic material, with pore sizes in the submicron range, which holds water tightly in its pores, but prevents air from entering the device. The water in the pores moves freely between the water chamber and the soil. The pore size is selected to be as small as possible to hold the water but large enough to allow the movement of water through the membrane.

Tensiometer measurements are obtained by placing the rigid semipermeable porous material in contact with the soil. A hydraulic connection is formed between the soil and the porous membrane. Water moves between the water chamber and the soil in response to pressure differences between the soil and the interior of the tensiometer until the pressure in the chamber is equivalent to the water potential in the soil. Since the tensiometer is a sealed tube, the pressure inside the tube will be equivalent to the soil water potential in the adjacent soil. Tensiometers require a pressure measurement device such as a Bourdon gauge, electronic transducer, manometer, or have an access port to measure the pressure in the chamber.

Range of Measurements

The range of measurements from tensiometers is limited to water potentials of about −800 cm of water pressure or −0.8 atm pressure. This is due to a combination of factors including the difficulty in maintaining a hanging water column that exceeds 8 m of water or 0.8 atm pressure, vaporization of water at low pressures and air entry into the porous membrane.[1,2] Tensiometers measure only a portion of the entire range of water potentials found in soils.

This range of water potential (0 atm to −0.8 atm) is called the tensiometric range. The majority of moisture flow occurs in the tensiometric range as the highest unsaturated hydraulic conductivities occur over this range. This range is critical in agricultural applications where the tensiometers are used to determine when plants need to be irrigated.

Depth Limitation Based on Design

The design of the tensiometer determines the operational depth (Fig. 1). Conventional tensiometers have a water chamber that extends from the measurement point at the porous cup to land surface (Fig. 1A). These instruments can be operated from near land surface to depths of a maximum of 5–7 m, due to the length of the hanging water column. In this design, the sensor is located at land surface and may be influenced by temperature fluctuations that reduce the accuracy of the measurements. Negative pressure from the hanging water column increases the degassing of water within the tensiometer and results in accumulation of air in the tensiometer. Air accumulation slows down the measurement response to changes in the water potential. As more air builds up inside the tensiometer a pore may open, allowing airflow into the device and failure of the instrument.

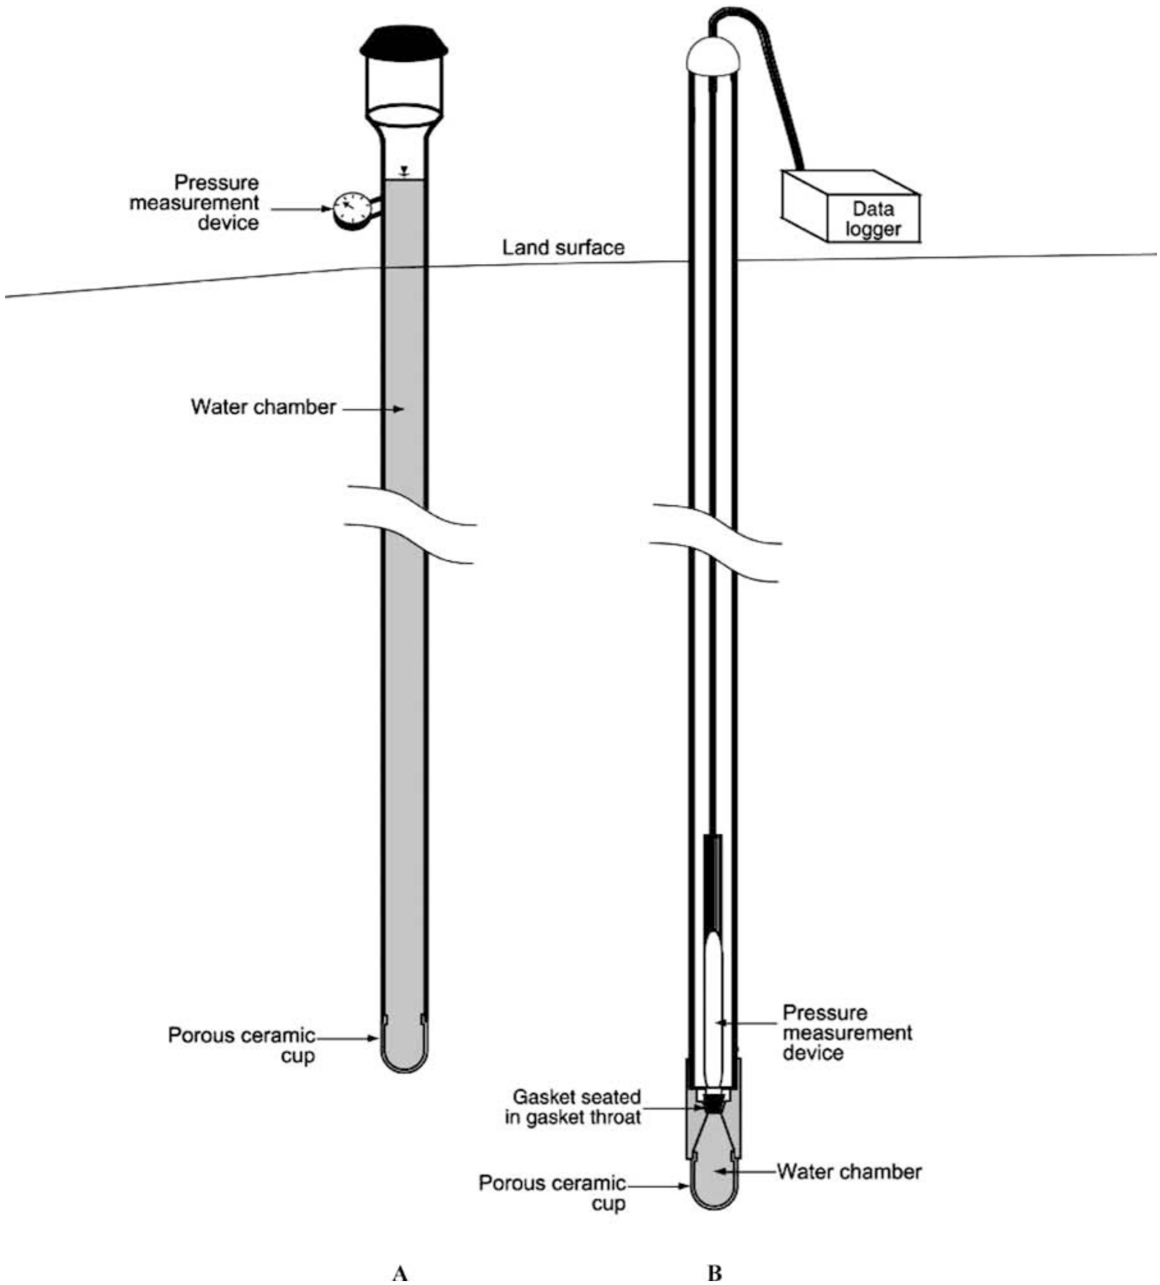

Fig. 1 Tensiometer designs.

A second basic tensiometer design allows tensiometers to be installed either permanently or on a temporary basis at any depth below land surface by moving the pressure sensor near the measurement location and eliminating the long water column.[3,4] This design reduces temperature induced measurement fluctuations while allowing monitoring for longer time periods than conventional tensiometers. The water in the chamber can be easily refilled and the sensors can be maintained and serviced from land surface (Fig. 1B). The use of pressure sensors and data loggers to monitor soil water potential in tensiometers increase equipment costs and but provide a better data set and reduces overall labor costs.

Installation Techniques

Tensiometers are installed by one of several techniques, depending on the depth and geologic media being monitored. They can be installed by making an opening slightly larger than the diameter of the tensiometer then pressing the device into the opening and placing the porous cup to the depth of interest. They can be installed in boreholes by placing the porous ceramic at the depth of interest and then backfilling the borehole with native materials or silica flour to provide a hydraulic connection.[5,6] Portable tensiometers are installed by lowering them into a borehole and placing the porous cup in contact with the sediment at the bottom and then sealing the surface cap to reduce air flow out of the well.[3] A better hydraulic connection allows the tensiometer to respond quicker. If multiple tensiometers are placed in a single borehole, a sealing material such as bentonite, can be used to seal between the monitored intervals. Tensiometers have been used to monitor soil water potential in sediments ranging from gravel to clay, as well as porous rock such as basalt, tuff, and sandstone.

SOIL WATER POTENTIAL MEASUREMENTS USING TENSIOMETERS

What is Water Potential?

Water potential tells us how tightly water is held by a soil. Water added to an unsaturated soil will tend to be pulled into the soil. The soil water is said to be under tension. This pulling action is produced primarily by capillary and adsorptive forces, similar to the wicking of water by using a paper towel. When the soil is saturated, it is under pressures greater than atmospheric pressure. Increasing water pressure keeps the soil saturated and indicates positive water potentials, corresponding to the height of the water level in the soil. If the volume of water held in the soil is decreased so the soil is no longer saturated, the water potential will decrease into the negative range. Tensiometers are designed to measure over the negative soil water potential range but will also measure over the positive range with a suitable measurement device.

Water potential is measured in units of pressure per unit area. It is given as the pressure exerted by an equivalent length of water column (cm). Water potentials in unsaturated soils are expressed in the negative range, indicating the soil is under tension relative to atmospheric pressure. The point of saturation in a soil is defined as zero pressure, which is the standing water level in the soil.

Water potential is important because it can be used to indicate the direction of water flow in unsaturated zones. It describes the energy required by plants to take the water from the soil and defines when sediment is saturated or unsaturated.

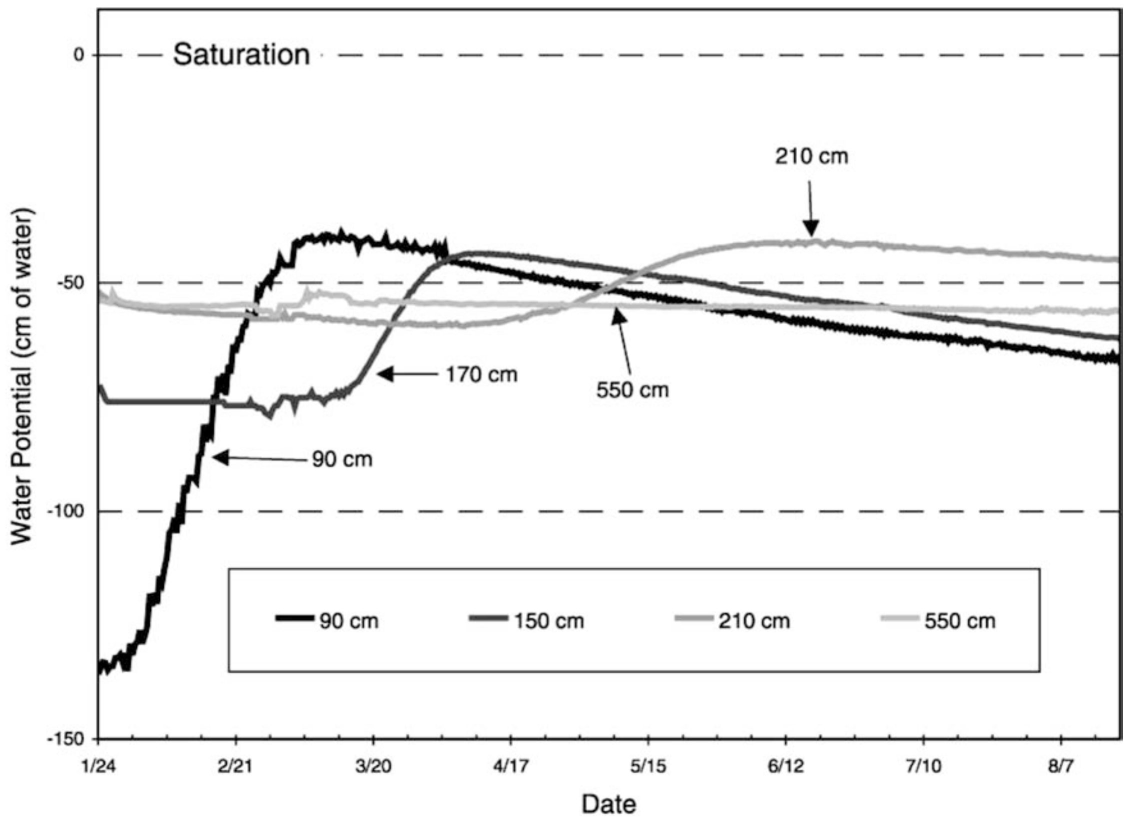

Fig. 2 Water potential measurements at depths from 90 to 550 cm.

Total Energy Status

The term potential in soil water potential comes from the two forms of energy (potential energy and kinetic energy) as defined in physics. Because water generally moves slowly through unsaturated sediments, the kinetic energy portion of the moisture movement is negligible. The potential energy, which comprised position (elevation head) and the condition (pressure) of the water, is dominant. Centimeters of water are commonly used for water potential because it can be easily combined with the gravity potential for expressing the total energy status.

Total potential energy difference between two locations drives the movement of water between locations (hydraulic gradient), with water moving from higher energy states (closer to saturation) to lower energy states. The total potential energy state is the combination of the elevation head and pressure head. Thus, water located in a soil with a greater total potential energy (wetter) will move into a similar soil with a lower total water potential in saturated soil (dryer).

Water Potential Measurements at Multiple Depths

Fig. 2 shows soil water potentials in a sand column over a 7-mo time period from 90 cm to 550 cm below land surface. Several interesting points are shown in this graph. The shallowest three instruments (90 cm, 150 cm, and 210 cm) show a wetting trend followed by a drying or moisture redistribution trend. The shallowest instrument (90 cm) shows a wetting trend from 1/24 to 3/5 and then a slow drying trend to the end of the time period. This infiltration event is seen at the 150 cm and 230 cm depths following a time delay of 4 weeks and 12 weeks, respectively. The soil water potential response is dampened with depth so that the water potential at 550 cm does not change.

The instruments near land surface generally show the greatest variation in response to wetting and drying events. Water potential fluctuations are dampened as depths increase. Infiltration events generally indicate a rapid wetting trend and then a slower drying trend. Water potential measurements are more stable with increasing depths and often approach the gravity drainage value for the material. Locally, the water potential may vary, controlling the direction of moisture flow. In deep unsaturated zones, the changes in water potentials with depth are small compared to the differences in elevation head. This makes the elevation head the dominant driving force.

Soil Water Measurement: Time Domain Reflectometry

Steven R. Evett
Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Bushland, Texas, U.S.A.

Scaling–
Soil Water

INTRODUCTION

Time domain reflectometry (TDR) became known as a useful method for soil water content and bulk electrical conductivity (BEC) measurement in the 1980s through the publication of a series of papers by Topp, Dalton, and others.[1–5] Automated TDR systems for water content measurement have been described in Refs.[6–10]. Commercial systems became available in the late 1980s and continue to evolve with TDR instruments, probes, and multiplexers (e.g., see Ref.[11]) available from a few companies.

THEORY

In the TDR method, a very fast rise time (approx. 200 ps) step voltage increase is injected into a waveguide (usually coaxial cable) that carries the pulse to a probe placed in the soil or other porous medium (Fig. 1). The velocity of the pulse in the probe is measured and related to soil water content, with smaller velocities indicating wetter soils. In a typical field installation, probes are connected to the instrument through a network of coaxial cables and multiplexers. Part of the TDR instrument (e.g., Tektronix[a] model 1502B/C) provides the voltage step and another part, essentially a fast oscilloscope, captures the reflected waveform. The oscilloscope can capture waveforms that represent all or any part of the waveguide (this includes cables, multiplexers, and probes), beginning from a location that is actually inside the instrument. For e.g., Fig. 1 shows a waveform that represents the waveguide from a point inside the cable tester, before the step pulse is injected, and extending beyond the pulse injection point to a point that is 4.2 m from the cable tester. The relative height of the waveform represents a voltage, which is proportional to the impedance of the waveguide. Although most TDR instruments display the horizontal axis in units of length (a holdover from the primary use of these instruments in detecting the location of cable faults), the horizontal axis is actually measured in units of time.

The TDR instrument converts the time measurement to length units by using the relative propagation velocity factor setting, v_p, which is a fraction of the speed of light in a vacuum. For a given cable, the correct value of v_p is inversely proportional to the permittivity, ε, of the dielectric (insulating plastic) between the inner and outer conductors of the cable

$$v_p = v/c_o = (\varepsilon\mu)^{-0.5} \tag{1}$$

where v is the propagation velocity of the pulse along the cable, c_o is the speed of light in vacuum, and μ is the magnetic permeability of the dielectric material. For a TDR probe in a soil, the dielectric between the probe rods is a complex mixture of air, water, and soil particles that exhibits a variable apparent permittivity, ε_a. Water is the largest determinant of permittivity in soils. It has a permittivity of approx. 80, whereas the permittivity of soil minerals varies in the range 3–5; the permittivity of organic matter is likewise low; and the permittivity of air is unity. Also, soil water is the only rapidly changing determinant of ε_a. Thus, we are able to usefully calibrate soil water content vs. measured ε_a. The fact that frozen water has a low permittivity impedes accurate measurement of frozen water content, but allows the use of TDR for investigations of freezing depth and extent.[12]

The TDR method relies on graphical interpretation of the waveform reflected from that part of the waveguide that is the probe (Fig. 2). An example of waveform interpretation for a 20-cm TDR probe in wet sand shows how tangent lines are fitted to several waveform features (Fig. 3). Intersections of the tangent lines define times related to: 1) the separation of the outer braid from the coaxial cable so that it can be connected to one of the probe rods in the handle, t1.bis; 2) the time when the pulse exits the handle and enters the soil, t1; and 3) the time when the pulse reaches the ends of the probe rods, t2. The time taken for the step voltage pulse to travel along the probe rods, $t_t = t2 - t1$, is related to the propagation velocity as

$$t_t = 2L/v \tag{2}$$

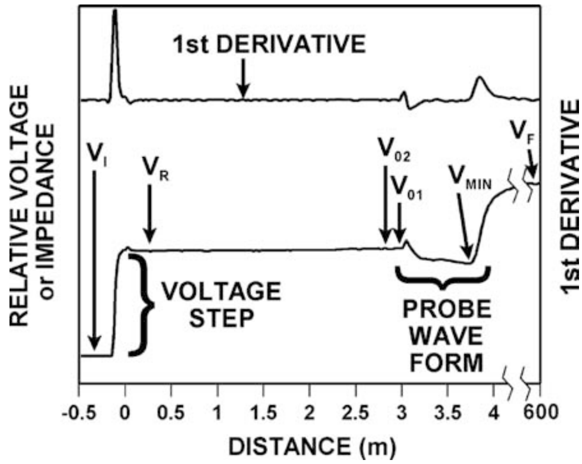

Fig. 1 Plot of waveform and its first derivative from a Tektronix 1502C TDR cable tester set to begin at -0.5 m (inside the cable tester). The voltage step is shown to be injected just before the zero point (BNC connector on instrument front panel). The propagation velocity factor, v_p, was set to 0.67 because electricity travels at 0.67 of the speed of light in the coaxial cable. At 3 m from the instrument, a TDR probe is connected to the cable. The relative voltage levels, V_I, V_R, etc., are used in calculations of the BEC of the medium in which the probe is inserted. Inflections in the first derivative of the waveform are used in software or firmware to help determine pulse travel times, which, for the probe, are proportional to water content.

where L is the length of the rods (Fig. 2), and the factor 2 signifies two-way travel.

Substituting ε_a and Eq. (2) into Eq. (1), and assuming $\mu = 1$, one sees that ε_a may be determined for a probe of known length, L, by measuring t_t

$$\varepsilon_a = [c_o t_t/(2L)]^2 \qquad (3)$$

Topp, Davis, and Annan[1] found that a single polynomial function described the relationship between

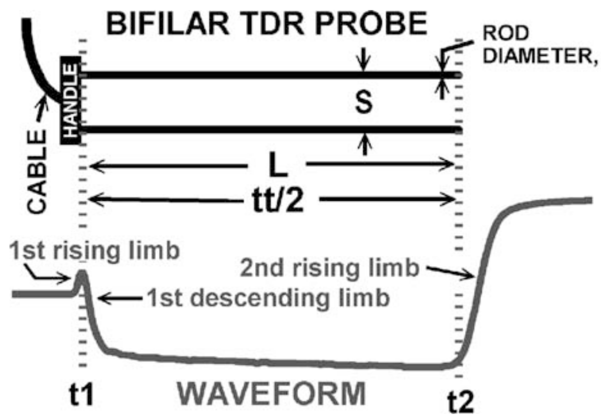

Fig. 2 Schematic of a typical bifilar TDR probe and the corresponding waveform, illustrating probe rod length, L; one-way travel time, $t_t/2$; rod spacing, s; and rod diameter, d.

volumetric water content, θ_v, and values of ε_a determined from Eq. (3) for four mineral soils.

$$\theta_v = (-530 + 292\varepsilon_a - 5.5\varepsilon_a^2 + 0.043\varepsilon_a^3)/10^4 \qquad (4)$$

Since 1980, other researchers have noted that the quantity $[t_t/(2L)]$ in Eq. (3) is quadratic, and have shown that the relationship between θ_v and $t_t/(2L)$ is practically linear (e.g., Ref.[15]). Several attempts have been made to predict ε_a of soils from theoretical considerations using dielectric mixing models that consider the volumetric proportions of soil mineral, organic, water, and air constituents, as well as soil mineralogy and particle shape and packing considerations (e.g., Refs.[16–18]). Success could lead to a more universal calibration, but has been elusive;[19] so that Eq. (4) and like empirical calibrations for specific soils (particularly electrically conductive soils including clays with high charge, and organic soils) are still considered to be the accepted standards.

APPLICABILITY

For most soils, excluding those very high in organic matter ($OM > 10\%$), the TDR method provides water content in the range from 0 to 0.5 $m^3 m^{-3}$ with accuracy better than 0.01–0.02 $m^3 m^{-3}$ without calibration. With calibration, accuracy of better than 0.01 $m^3 m^{-3}$ for a specific soil is attainable. Repeatability is excellent, with standard deviations of measurement ranging from 0.0006 $m^3 m^{-3}$ (see Ref.[11]) to 0.003 $m^3 m^{-3}$ (see Ref.[8]). Probe lengths reported in the literature range from 0.05 m to 1.5 m. Probe rod spacing, s, may also vary, so long as $d/s \leq 0.1$ where d is the rod diameter (Fig. 2).[20] As d/s becomes much smaller than 0.1, the volume of soil sensed becomes very small and TDR measurements may become overly sensitive to soil heterogeneity close to the rods. Because of this flexibility in probe width and length, TDR probes may be designed to measure a wide range of soil volumes. Because the volume measured extends only 1–2 cm above and below the plane of the rods for most probe designs, TDR is ideal for measurements in thin layers near the soil surface. It is also very useful in root water uptake studies where information from discrete parts of the root zone is desired. Because TDR integrates soil water content changes occurring along the length of the probe rods accurately, TDR probes may be inserted vertically into soils to assess accurately mean water content over the length of the rods, even in soils exhibiting sharp water content changes with depth.

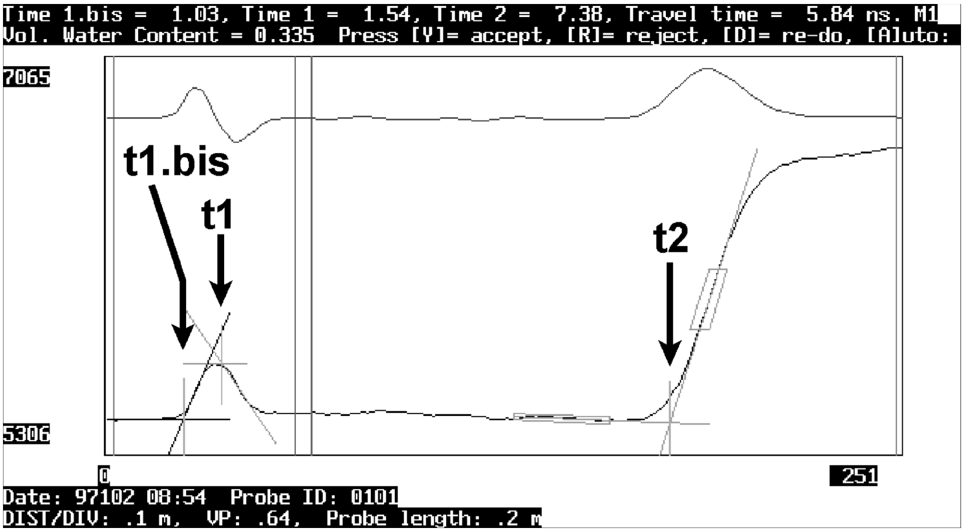

Fig. 3 Example of graphical interpretation of a waveform from a probe in wet sand using the TACQ computer program. Vertical lines denoting times t1.bis, t1, and t2 have been marked by arrows and labels. The first peak in the waveform occurs just before t1. A horizontal line, drawn tangent to the waveform base line at the far left, intersects with a line drawn tangent to the first rising limb of the waveform to define t1.bis. A horizontal line drawn tangent to the peak intersects with a line drawn tangent to the descending waveform after the peak to define t1. Time t2 is defined by the intersection of a line fitted to the waveform before t2, and a line fitted to the second rising limb of the waveform after t2. The water content is calculated from Eq. (4). The width of the waveform window is 1 m, or 5.2 ns with the cable tester set to $v_p = 0.64$. *Source*: From Refs.[13,14].

WAVEFORM INTERPRETATION

Graphical interpretation (e.g., Fig. 3) depends on the fact that the probe design itself introduces impedance changes in the waveguide. The impedance, $Z(\Omega)$, of a transmission line (i.e., waveguide) is

$$Z = Z_0(\varepsilon)^{-0.5} \tag{5}$$

where Z_0 is the characteristic impedance of the line (when air fills the space between conductors) and ε is the permittivity of the homogeneous medium filling the space between conductors. For a parallel transmission line (the two rods in the soil), the characteristic impedance is a function[21] of the wire diameter, d, and spacing, s (Fig. 2):

$$Z_0 = 120 \ln\{2s/d + [(s/d)^2 - 1]^{0.5}\} \tag{6}$$

or, if $d \ll s$:

$$Z_0 = 120 \ln(2s/d) \tag{7}$$

For a coaxial transmission line, the characteristic impedance is:

$$Z_0 = 60 \ln(D/d) \tag{8}$$

where D and d are the diameters of the outer and inner conductors, respectively.

From Eqs. (5)–(8) it is apparent that impedance, Z, increases as wire spacing increases, and decreases as ε (or water content) increases for any probe type (Fig. 4). In the probe handle, the wire spacing increases from that of the coaxial cable to that of the probe rods. The resulting impedance increase causes the waveform level to rise (first rising limb in Fig. 2). If the porous medium in which the probe rods are embedded is wet, then the permittivity of that medium will be higher than that of the epoxy probe handle. This causes a decrease in impedance, which results in the descent of

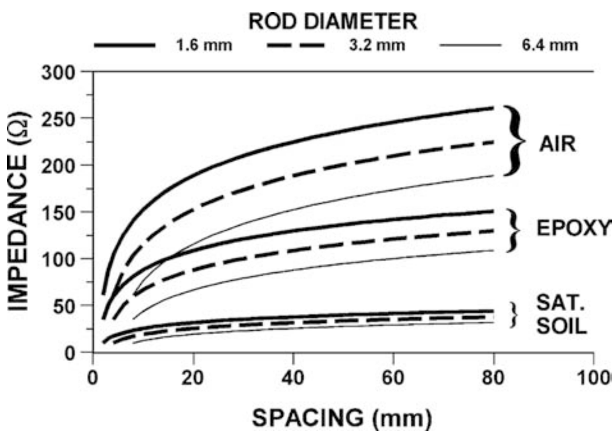

Fig. 4 Influence of rod spacing, rod diameter, and permittivity of the medium on impedance of the waveguide according to Eq. (6). Permittivities are: AIR, unity; EPOXY, close to 3; and SATurated SOIL, approx. 35.

the reflected waveform level as the step voltage leaves the handle and enters the rods in the soil (first descending limb, Fig. 2). The combination of impedance increase at the handle and impedance decrease after the handle gives the peak in the waveform. The rod ends are another impedance change in the waveguide; in this case an open circuit. The remaining energy in the voltage step is reflected back at the rod ends, which represent an impedance increase (second rising limb, Fig. 2). Although a bifilar probe design is illustrated in Fig. 2, the most common design uses three parallel and coplanar rods. Such trifilar probes are electrically unbalanced (signal is on the middle rod) as is the connecting coaxial cable. Thus, impedance is more closely matched between cable and probe and the waveform has less noise and is more easily interpretable.[22]

Waveform shapes different from those shown in Figs. 1–3 result from different soil types and conditions (e.g., dry soil, saline soils, wet clays, etc.). Different methods from the literature, used for graphical interpretation of the waveform, can cause errors in water content as large as $0.05\,m^3\,m^{-3}$.[14] Therefore, choice of interpretation methods or computer programs for automatic interpretation is important. Manufacturers' equipment contains embedded interpretation algorithms that are not usually made public. Two computer programs available to the public and well documented are TACQ[13,14,23] and WinTDR.[24] An improved signal to noise ratio results from the shorting diode approach[25] in which the waveform is alternately captured with and without the probe shorted to ground at the ends of the rods. This approach has not been popular, however, due to increased cost and complexity of switching, and problems with designing probes that ensure signal penetration into the soil.

BULK ELECTRICAL CONDUCTIVITY MEASUREMENT

An important use of the TDR method is to calculate the soil BEC from values of the waveform relative voltage or impedance at various points along the waveguide (Fig. 1) (e.g., Refs.[2–5,22,26–30]). The measured load impedance, Z_L (ohms) is used in most methods for calculating BEC:

$$Z_L = Z_{REF}(1 + \rho)/(1 - \rho) \tag{9}$$

where Z_{REF} is the output impedance of the cable tester (e.g., 50 ohms), and:

$$\rho = E- \,/E+ \tag{10}$$

where

$$E- = V_F - V_{O2} \tag{11}$$

$$E+ = V_{O2} - V_I \tag{12}$$

and where V_{O2}, V_I, and V_F are defined in Fig. 1. For most methods, only V_{O2}, V_I, and V_F are needed. Calculation of BEC from TDR data is still a subject of active research. The other values of relative voltage illustrated in Fig. 1 are used in other methods of calculating BEC reported in the literature. The TDR method has been even extended to measurement of atmospheric CO_2 based on the solution electrical conductivity increase caused by its dissolution in water.[31]

Soil Water: Antecedent

Sally D. Logsdon
National Soil Tilth Laboratory, U.S. Department of Agriculture (USDA), Ames, Iowa, U.S.A.

INTRODUCTION

Antecedent soil water is the amount of water in the soil before infiltration of new water, and is often used interchangeably with initial soil water. The infiltration rate is affected by the antecedent soil water content; however, this effect varies for wettable and non-wettable soils and for soil profiles that are uniform or vary with depth.

HOMOGENEOUS, WETTABLE SOIL

For a homogeneous, deep, wettable soil, infiltration decreases as initial soil water content increases[1–3] (see Fig. 1). This occurs because there is less water storage capacity when the soil is already partly wetted. Once the soil is wetted, the infiltration rate is controlled by the saturated hydraulic conductivity of the soil, i.e., the ability of the soil to transport water through the profile. The sorptivity parameter decreases as relative initial soil water content increases.[3] Sorptivity is a function of the square root of time, and is the cumulative amount of water infiltrated at relative time $t = 1$, which is the time when the infiltration rate is half the original rate. Sorptivity is proportional to the capillary forces, which are greater for dry soil. After the soil surface is saturated, the infiltration rate decreases exponentially to the final infiltration rate (Fig. 1).

Tisdall[4] examined ring infiltration measurements as a function of initial soil water content. As initial volumetric soil water content (θ) increased, the infiltration rate (I) at 2 hr decreased. The relationship between I (mm hr^{-1}) and θ (m^3 m^{-3}) varied with soil texture:

sandy loam soil: $I = 28.1 - 133\theta$

clay loam soil: $I = 1/(-0.224 + 1.62\theta)$

clay soil: $I = 1/(-0.218 + 1.32\theta)$.

The clay and clay loam soils were affected by soil cracking, that resulted in greater lateral spread of water that had infiltrated compared with the sandy loam soil that did not crack.

NON-HOMOGENEOUS, WETTABLE SOIL

Soil may be non-homogeneous due to soil layers of different texture (fine over coarse, or coarse over fine,[3]). A common example of layering is the fine surface seal that forms over the coarser whole soil underneath.

Water content at the soil surface influences the degree of breakdown of aggregates and formation of a surface seal. For an uncovered surface soil, the breakdown of surface aggregates decreases when the initial soil water content is higher.[5,6] This should decrease the formation of a surface seal when the soil is initially wet compared with an initially dry soil surface. The effect on infiltration is less direct because the surface seal may either increase or decrease infiltration, depending on other factors.[7] The surface seal formation contributes to the decline in infiltration rate with time for uncovered soils, but the formation of the surface seal results in a head gradient that allows infiltration to continue.[8]

Jones[9] (as reported in Ref.[10]) measured sprinkler infiltration (100 mm hr^{-1}) on a bare corn seedbed and on a seedbed covered with brome grass residue. The next day the infiltration measurements were repeated on the same site that had been wetted the previous day. For the bare sites, the I decreased from 21 to 7 mm hr^{-1} for the dry and prewetted measurements, and on the residue-covered sites the I decreased from 24 to 17 mm hr^{-1}. For the bare sites the sprinkler infiltration measurements resulted in formation of a surface seal, whereas a surface seal formation was minimized on the residue-covered sites. For the prewetted measurements, I was reduced less when surface seal formation was minimized.

NON-WETTABLE SOIL

For some soils, the effect of initial soil water content on infiltration is complicated by water repellency, which may be more pronounced when the soil is dry. For reviews on water repellency, see Refs.[11,12]. Water repellency initially reduces the local infiltration rate,[13] but also creates instability. Instability may create wetting fingers that increase infiltration rate within the

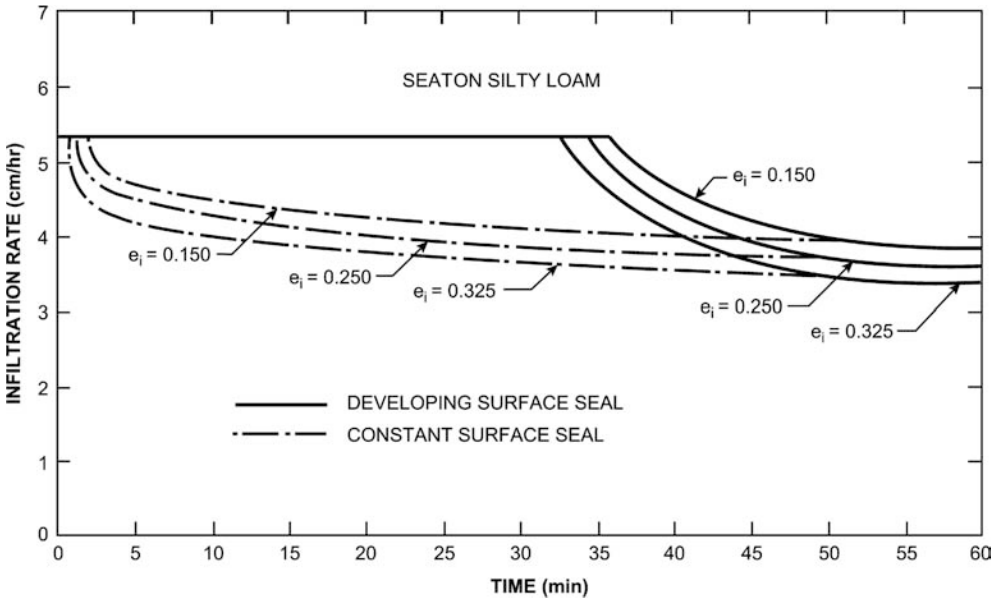

Fig. 1 Influence of antecedent soil water content and presence of a surface seal on infiltration rate as a function of time for a final infiltration rate of $3.83\,cm\,hr^{-1}$. *Source*: From Ref.[1].

wetting finger. For some soils, water repellency is reduced as water content increases, which may cause an increase in infiltration rate after the initial decrease.[14] Water that does not infiltrate may run off and infiltrate downslope. Non-wettable soil can contribute to macropore flow because water that does not readily enter the soil surface is routed to surface-connected macropores.[15] Because of unstable wetting, non-wettable soils have a non-homogeneous wetting pattern even without the presence of macropores.

VARIABLE SOIL WATER IN THE LANDSCAPE

The landscape contributes to variability of antecedent soil water content because of surface and subsurface runoff and runon. Small- or large-scale depressions allow accumulation and ponding of water in localized zones. Conversely, the antecedent soil water content influences the landscape variability. If soil is initially dry but still wettable, infiltration is mostly vertical; however, if soil is initially wet, more water runs off or moves laterally in the subsurface.[16] The regions of water accumulation as well as transmission channels will be wetter.

The arrangement of soil water content across the landscape influences runoff at the larger catchment scale.[17] Predicted runoff was greater if there was a spatial structure (clustered arrangement or connectedness) of initial soil water content than for a random or constant initial soil water content.

Soil Water: Capillary Rise

James E. Smith
School of Geography and Geology, McMaster University, Hamilton, Ontario, Canada

INTRODUCTION

Capillary rise of water in soils is a phenomenon that has both beneficial and detrimental effects for agricultural soils. It is an important mechanism by which plants can draw water from below the root zone, but it is also a primary mechanism which can contribute to the accumulation of salts and resultant salination of soils.

CAPILLARITY

Capillary rise in soils refers to water moving upward from the water table against the force of gravity. Capillarity is the direct effect of the surface tension of the soil water (σ) and the affinity of water for the soil particles. The affinity for the soil is expressed as the contact angle (β) of the interface with the solid surface. That is, the water wets the surface of the soil particles and the interface between the two immiscible fluids (i.e., air and the water) is under tension. This fundamental relation is presented in most textbook on the subject of soil water, for example, Refs.[1–5]. Fig. 1 is a schematic diagram showing the configuration of water and air within the pores of a soil.

Natural soil water tends to have lower surface tension than pure water primarily due to the presence of naturally occurring organic solutes.[6] However, this effect is only in the order of 10–15% and consequently is commonly ignored. In addition, the contact angle in soils can vary. However, it is common to assume that the contact angle of a water wet soil is 0° (i.e., $\cos\beta = 1$).

The equilibrium height of rise of water (H_c) above a water table in a capillary tube can be expressed by

$$H = \frac{2\sigma\cos\beta}{\rho g r} \quad (1)$$

where ρ is the density of water, g is the acceleration due to gravity, β is the contact angle of the air–water interface with the solid surface, and r is the radius of the capillary tube.

The effect of water being pulled up into a capillary tube is due to the pressure difference across the air–water interface. The pressure difference across a curved interface between two immiscible fluids, in this case air and water, is also expressed by the Laplace equation of capillarity,[4] i.e.,

$$P_c = P_A - P_w = \sigma\left(\frac{1}{r_1} + \frac{1}{r_2}\right) \quad (2)$$

where P_c is the capillary pressure, P_A is the absolute air pressure, P_w is the absolute water pressure, σ is the surface tension of the air–water interface, and r_1 and r_2 are the principle radii of curvature of the interface. Eqs. (1) and (2) can be directly related by expressing the pressures in Eq. (2) in head units, i.e., an equivalent depth of water. This leads to

$$H = \frac{P_c}{\rho g} \quad (3)$$

and

$$\frac{2\cos\beta}{r} = \left(\frac{1}{r_1} + \frac{1}{r_2}\right) \quad (4)$$

A useful conceptual model is to envision the soil as a bundle of capillary tubes of various radii (Fig. 2, modified from Ref.[5]). In the case of a soil, r represents the radius of an equivalent circular soil pore and the ratio $(\cos\beta)/r$ represents the equivalent radius of curvature of the air-water interface.

SOIL-WATER PRESSURE

A number of conventions exist for expressing the pressure of water in a soil. Soil-water pressure head (ψ) is negative relative to gauge pressure. This is because the water pressure (P_w) is less than atmospheric pressure (P_A), which is by definition zero gauge pressure. The terms soil tension, soil suction, soil capillary pressure, and soil matric potential are positive valued expressions of the same pressure. It is useful in the present context to express the soil-water pressure in head units relative to gauge pressure (atmospheric pressure), e.g., meters of water head less than atmospheric. At hydrostatic equilibrium (i.e., no flow conditions), the soil-water pressure head is equal in magnitude to the height above the water table (H)

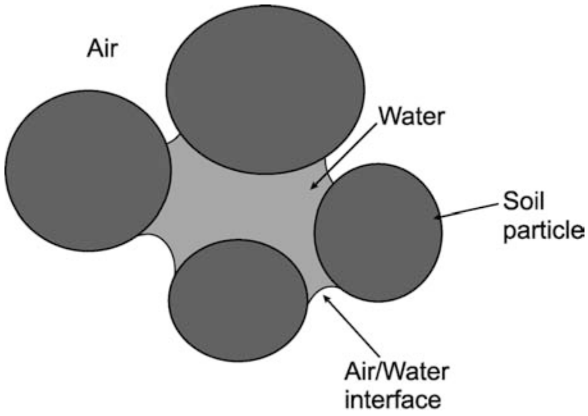

Fig. 1 Schematic of soil water.

(Fig. 3). It then follows from the above that

$$\psi = -H = -\frac{2\sigma\cos\beta}{\rho g r} \tag{5}$$

Using the bundle of capillary tubes conceptual model, it is readily apparent that the water content variation with depth in a soil in static equilibrium with a shallow water table will be an expression of the pore size distribution of the soil. It also follows that the pressure head is lower (more negative) at lower water contents as depicted in Fig. 3.

SOIL-WATER FLOWDYNAMICS

The proceeding discussion has focused on the static (no flow) condition and the fundamental relation between the pressure of the water and the water content in the soil. To extend our discussion to the conditions that induce capillary rise of water, i.e., upward flow, we need to consider the hydraulic gradient. The hydraulic head (h) in a soil is the sum of the pressure head (ψ) and the elevation head (z). It represents the ability to do mechanical work on a unit weight of water due to pressure differences and gravity. Water flows in soil when there exists a change in hydraulic head with distance, which means that the hydraulic gradient differs from zero. The volumetric flux of water in unsaturated soils can be expressed by the Darcy–Buckingham flux law,

$$q = -K(\psi)\frac{dh}{dz} = -K(\psi)\left[\frac{d\psi}{dz} + 1\right] \tag{6}$$

where q is the volumetric flux, K is the unsaturated hydraulic conductivity which is a function of pressure head, and dh/dz is the hydraulic gradient. When there is no hydraulic gradient there is no water flow.

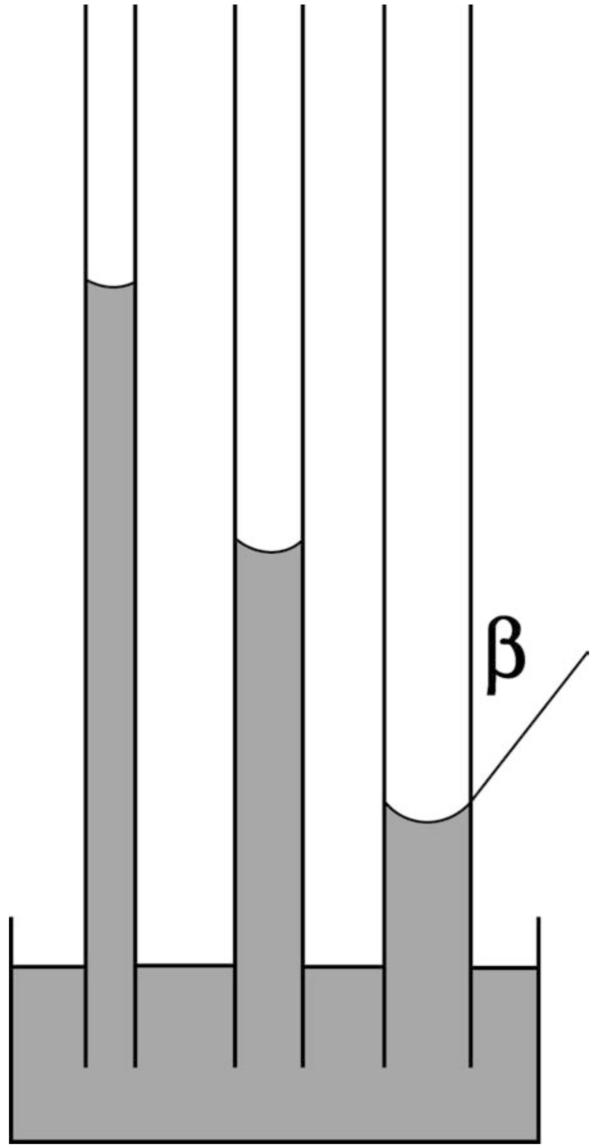

Fig. 2 Capillary rise in tubes of differing sizes.

Figs. 3 and 4 show cases of static (no flow) equilibrium with a water table. Fig. 3 shows the case for a homogeneous system. Fig. 4 depicts the case of a soil with layered heterogeneity having a finer middle layer. While these static equilibrium conditions essentially never exist in the field,[2] they are instructive as reference cases to explain the conditions that generate capillary rise. It should be noted that Fig. 4 depicts a no flow condition even though there are ‘‘wetter’’ layers and ‘‘drier’’ layers within the profile. This illustrates that the driving force for flow is the hydraulic head, not water content alone.

To induce capillary rise (vertical flow upward) there must be the condition that the hydraulic head increases with depth. Physically this means that pressure head must increase with depth more than elevation head

Scaling–Soil Water

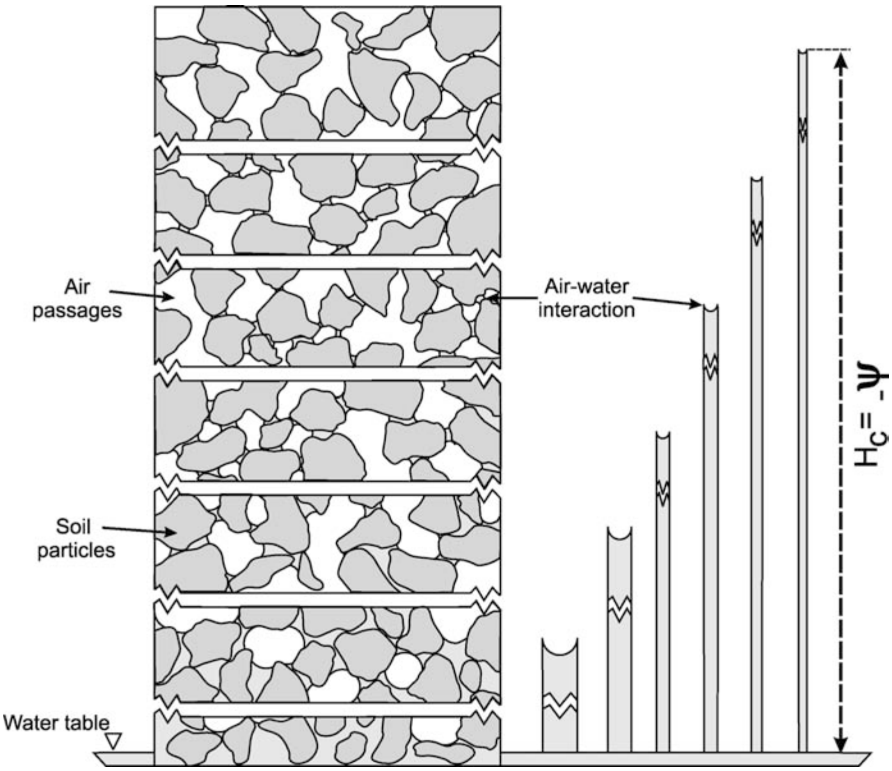

Fig. 3 Hydrostatic equilibrium in soil above a shallow water table. *Source*: Modified from Ref.[5], p. 28.

decreases. Using upward as positive, the elevation head gradient is always one (i.e., $dz/dz = 1$), the pressure head gradient must be less than -1 to induce upward flow. This means that relative to the no flow conditions depicted in Figs. 3 and 4, there must be a mechanism that removes water from the soil and thereby creates a pressure head gradient greater than unity.

SOIL-WATER EVAPORATION AND EXTRACTION

There are two primary mechanisms in agricultural soils that remove water from shallow soils thereby potentially inducing capillary rise. One is direct evaporation from the soil surface. The second is extraction of soil water within the root zone. Fig. 5 is a schematic depicting the effect of water extraction from the root zone and/or by evaporation from the surface. The reduced pressure heads within the root zone generate a hydraulic gradient that drives upward flow of water.

CAPILLARY RISE OF WATER IN SOILS

As expressed in Eq. (6), the actual rate of upward water flux depends not only on the hydraulic gradient but also on the unsaturated hydraulic conductivity function. However, capillary rise in soils can only occur when a hydraulic head gradient induces it.

It follows from the discussion above that the condition most favorable for capillary rise of water in

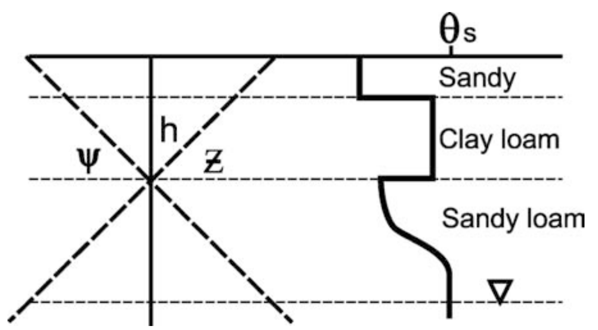

Fig. 4 Water content versus depth in layered heterogeneous soil for conditions of hydrostatic equilibrium.

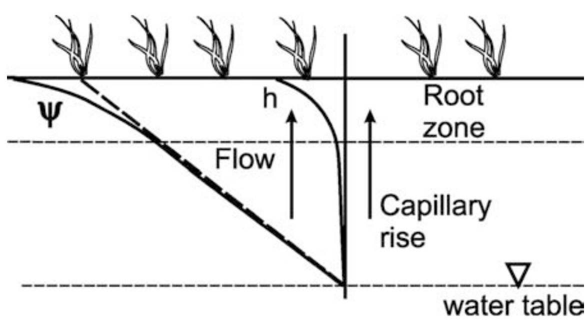

Fig. 5 Evaporation and root zone extraction of water inducing upward gradients.

soil is a shallow water table and loamy soil. Conversely, a deep water table favors drainage. A very fine textured soil has low hydraulic conductivities at all water contents. A very coarse soil has large pores that drain readily and have little capillarity and low unsaturated hydraulic conductivities at those low water contents. While the exact flux of water delivered by capillary rise will vary based on soil hydraulic properties and climatic conditions it is instructive to consider a couple of example calculations of the effect of water table depth. Hillel[2] provides a sample calculation based on data and a formulation from Ref.[7] for the case of evaporation from a bare soil surface of a sandy loam soil with various water table depths. With the water table at depths of 0.9 m, 1.8 m, and 3.6 m the evaporative flux from the soil surface was 8 mm day^{-1}, 1 mm day^{-1}, and 0.12 mm day^{-1}, respectively. This illustrates that water table depth alone can have a large effect on fluxes due to capillary rise. It also shows that the potential for soil salination due to capillary rise of groundwater is consequently greater for shallower water table conditions.

CONCLUSION

Capillary rise of water in soil is a direct result of the affinity of water for natural materials and the surface tension of water generating a hydraulic gradient. When conditions prevail such that the capillarity induced upward pressure head gradient is greater than the downward acting gravity induced elevation head gradient, then soil water will flow upwards. Water losses from the soil by evapotranspiration contribute to maintaining upward fluxes by capillary rise. The magnitudes of those fluxes are higher when the water table is shallower. While this source of water is favorable for temporary drought conditions in temperate climates, it can be a direct cause of severe soil degradation by salination in arid and semiarid zones.

Soil Water: Diffusion

Laosheng Wu
Department of Environmental Sciences, University of California–Riverside, Riverside, California, U.S.A.

Scaling–
Soil Water

INTRODUCTION

Diffusion of mass in a medium is a spontaneous process leading to the net movement of a substance from a region of high concentration to its adjacent regions of low concentrations. It takes place in the liquid, gas, and even solid phase. Diffusion results from the random thermal motion of the molecules. A general diffusion-type equation has many applications such as the transport of heat (Fourier's law), electricity (Ohm's law), and mass (Fick's law).

The movement of water in partially saturated soils is frequently described as a diffusion process. We will introduce soil water diffusivity in terms of Fickian diffusion.

To express diffusion process quantitatively, Fick in 1855 postulated that the one-dimensional diffusion flux (J) of a substance i is proportional to the concentration gradient:

$$J_i = -D_i \frac{\mathrm{d}C_i}{\mathrm{d}x}, \tag{1}$$

where D_i is the diffusion coefficient and C_i is the concentration for substance i, and x is the distance. Eq. (1) is referred to as Fick's first law of diffusion.

A mass balance for a certain volume of a medium with a unit area perpendicular to the x-axis requires the net flux (the difference between influx at position x and outflux at position $x + \mathrm{d}x$) to be equal to the concentration change during an arbitrarily small time ($\mathrm{d}t$):

$$\frac{\partial C_i}{\partial t} = -\frac{\partial J_i}{\partial x}. \tag{2}$$

where the "–" sign indicates the direction of a flux. Eq. (2) is a continuity equation, which is a statement of mass conservation in mathematical form.

Substituting Eq. (1) into Eq. (2) results in:

$$\frac{\partial C_i}{\partial t} = \frac{\partial}{\partial x}\left(D_i \frac{\partial C_i}{\partial x}\right). \tag{3}$$

Eq. (3) is Fick's second law. An equivalent equation will be used in the following discussion to describe liquid and vapor movement of water in unsaturated soils.

WATER DIFFUSION

Although the movement of liquid water in the soil is a convection rather than a diffusion process, the purpose of applying the diffusion concept to describe soil water movement is to simplify the mathematical and experimental treatment of unsaturated flow. In the diffusion theory, soil water flow is considered to be analogous to heat transmission in solids or to Fickian diffusion in gas or solution. Gardner and Widtsoe[1] and Childs[2] were among the first researchers to apply the diffusion concept to describe water movement in soils.

The soil water flux is given by the Buckingham–Darcy law[3] using the following assumptions:

1. The driving force for water flow in an isothermal, rigid, and unsaturated soil with no solute membrane and zero air pressure potential (zero gauge pressure) is the soil matric head $h(\theta)$, which is a function of water content (θ, $\mathrm{L^3\,L^{-3}}$).
2. Transfer of potential energy of water is always perfectly correlated with the transfer of a water mass at the scale of a representative volume.
3. The hydraulic conductivity of unsaturated soil is a function of the water content or matric head.
4. The flow of water in unsaturated soil is assumed to be localized, i.e., the soil pores where flows exist are saturated, but there is no moving water in air-filled pores.

The horizontal water flux according to the Buckingham–Darcy law is:

$$J_\mathrm{w} = -K(\theta)\frac{\partial h(\theta)}{\partial x}, \tag{4}$$

where $K(\theta)$ ($\mathrm{L\,T^{-1}}$) is the unsaturated hydraulic conductivity, which may change several orders of magnitude over the range of values for θ.

Applying chain rule allows Eq. (4) to be written in terms of water content gradient ($\partial\theta/\partial x$):

$$J_\mathrm{w} = -K(\theta)\frac{\mathrm{d}h}{\mathrm{d}\theta}\frac{\mathrm{d}\theta}{\mathrm{d}x} = -D(\theta)\frac{\partial\theta}{\partial x}, \tag{5}$$

where $\partial h/\partial\theta$ is the slope of water retention (h–θ) curve, $D(\theta) = K(\theta)\ \mathrm{d}h/\mathrm{d}\theta \equiv K(\theta)/C(h)$ is called hydraulic (or soil–water) *diffusivity* (L^2T^{-1}), and $C(h)$ is the *specific water capacity* (L^{-1}). The diffusivity is usually expressed as a function of θ, but it may also be given in terms of h.

Substituting Eq. (5) into the continuity Eq. (2) yields:

$$\frac{\partial\theta}{\partial t} = \frac{\partial}{\partial x}\left[D(\theta)\frac{\partial\theta}{\partial x}\right]. \tag{6}$$

This is the diffusion equation for horizontal flow, or the "θ-based" formulation of the Richards' equation for flow in unsaturated soils.

In the special case where the hydraulic diffusivity remains constant with respect to the x, the above equation can be written as:

$$\frac{\partial\theta}{\partial t} = D\frac{\partial^2\theta}{\partial x^2}. \tag{7}$$

To account for the effect of gravity on water flow, x in Eq. (4) is replaced by z (distance in vertical direction), and $h(\theta)$ is replaced by the hydraulic head, $H = h(\theta) + z$. The Richards' equation for vertical water movement is:

$$\frac{\partial\theta}{\partial t} = \frac{\partial}{\partial z}\left[D(\theta)\frac{\partial\theta}{\partial z}\right] + \frac{\partial K(\theta)}{\partial z}. \tag{8}$$

In defining $D(\theta)$ we tacitly assumed that $K(\theta)$, $h(\theta)$ and $\mathrm{d}h(\theta)/\mathrm{d}\theta$ are unique functions of θ. In other words, the $D(\theta)$ relationship of a soil is the same for both imbibition and drainage of water. This is rarely the case with practical problems, however, where *hysteresis* will occur due to differences in initial water content, the "ink bottle" effect, the contact angle (i.e., "raindrop" effect), entrapped air, and swelling and shrinking.[3] One should therefore be mindful of hysteresis when applying the above hydraulic functions.

In addition to the use of the well-known diffusion equation, the advantage of the θ-based Richards' equation [Eq. (8)] is that the magnitude of the hydraulic diffusivity varies considerably less with θ or h as does the hydraulic conductivity. Disadvantages are that the equation cannot be used to model water flow in soils at or near saturation since D becomes infinite in that range.[4] In addition, due to the abrupt transition (discontinuity) of water content [and hence $C(h)$] from one layer to another, the water diffusion equation can only be applied to uniform soil profiles.

HYDRAULIC DIFFUSIVITY

Since $D(\theta)$ is defined as the ratio of the hydraulic conductivity to the specific water content, it can be viewed as the ratio of the flux to the soil–water content gradient when gravitational and hysteresis effects can be neglected. Thus $D(\theta)$ provides a measure of the rate of water movement through soil.

Measurement of hydraulic diffusivity can either be done in the laboratory or in the field, depending on the purposes of the measurements, sample sources, equipment availability, and the desired range of water content. The most common laboratory procedure is the non-steady-state method[5] based on a Boltzmann transformation. The instantaneous profile method, however, is a popular method for the field.

In the non-steady-state Boltzmann transformation method, a Boltzmann variable, $\lambda = xt^{1/2}$, is used to transform Eq. (6) to an ordinary differential equation. During horizontal infiltration, one measures the water content distribution along the x-axis direction at one or more distinct times. By plotting $\lambda = xt^{1/2}$ vs. θ and evaluating the slope $\mathrm{d}\lambda/\mathrm{d}\theta$ and integral $\mathrm{I}\lambda(\theta)\mathrm{d}\theta$ one can obtain $D(\theta)$.

The instantaneous profile method[6] employs Richards' equation in its mixed form (i.e., both θ and h are dependent variables):

$$\frac{\partial\theta(z,t)}{\partial t} = \frac{\partial}{\partial z}\left[K(\theta)\frac{\partial H(z,t)}{\partial z}\right], \tag{9}$$

By integrating Eq. (9) with respect to z between $z = 0$ (soil surface) to any depth $z = \mathrm{L}$, one can determine $K(\theta)$ at any desired depth from analysis of the $\theta(z, t)$ and $H(z, t)$ profiles measured at frequent time intervals. The hydraulic head $H(z, t)$ can be measured with tensiometers while the water content can be measured with time-domain reflectometry (TDR) or neutron thermalization. Alternatively, the water content may be inferred from the tensiometer readings and water retention curves for soil samples that are measured in the laboratory. Since the method measures water content and matric potential simultaneously, the hydraulic diffusivity can readily be calculated from $K(\theta)$ using Eq. (5).

Measurements of $D(\theta)$ typically provide data for only a limited range of soil water contents. Such measurements are often costly, time consuming, and inaccurate. Instead, it is often convenient to use indirect estimates of the soil water retention, hydraulic conductivity, and hydraulic diffusivity curves from more widely available data such as soil texture.[7]

WATER VAPOR DIFFUSION

Vapor transfer is an important mechanism for water movement under relatively dry soil conditions (Fig. 1). Eqs. (1) and (3) can be used to describe vapor

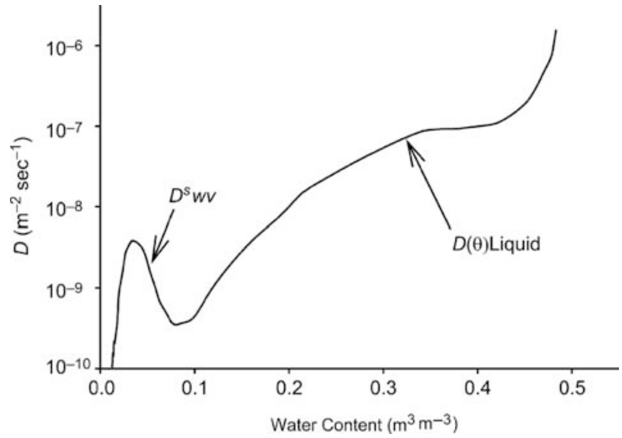

Fig. 1 Relationship between hydraulic diffusivity and soil water content for a Yolo light clay. Vapor diffusion is dominant mode of water movement for $\theta < 0.06$. (Reproduced after Philip.[8])

diffusion in porous media with minor alterations that account for the reduction of cross-sectional area due to solid and liquid barriers and the reduced concentration gradient and longer pathway in soils. To account for these factors, a tortuosity factor (ξ_{wv}) is introduced to calculate the water vapor diffusion coefficient in soil (D^{s}_{wv}):

$$D^{s}_{wv} = \xi_{wv} D^{a}_{wv}, \tag{10}$$

where D^{a}_{wv} is water vapor diffusion coefficient in air. Millington and Quirk's method[9] is one of the most commonly used models for estimating ξ_{wv}:

$$\xi_{wv} = a^{10/3}/\phi^2 = (\phi - \theta)^{10/3}/\phi^2, \tag{11}$$

where a is air-filled porosity and ϕ is total porosity of a soil. After substituting D^{a}_{wv} and Δ_{wv} (water vapor concentration, $\mathrm{M\,L^{-3}}$) for D_i and C_i in Eq. (1), one obtains the water vapor flux equation:

$$J_{wv} = -D^{s}_{wv} \frac{d\rho_{wv}}{dx}. \tag{12}$$

Unless the soil is very dry, the relative humidity of the soil air is close to saturated. Thus the above equation can be expressed in terms of temperature and $\rho^{*}_{wv}(T)$, which is the saturated vapor density as a function of temperature:

$$J_{wv} = -\xi_{wv} D^{a}_{wv} \frac{d\rho^{*}_{wv}(T)}{dT} \frac{\partial T}{\partial x} \tag{13}$$

The above equation underestimates water vapor movement by several folds. Philip and de Vries[10] indicated that Eq. (11) underestimates the tortuosity effect because vapor transfer can occur through "short circuiting." Therefore, they proposed to use total porosity for calculating the tortuosity factor. Another reason why Eq. (11) underestimates water vapor transfer might be that the temperature gradient in the vapor phase is much greater than that in the bulk phase. When these two factors were included, the modified equation predicted experimental measured water vapor transfer with greater accuracy.

Soil Water: Energy Concepts

Sally D. Logsdon
National Soil Tilth Laboratory, U.S. Department of Agriculture (USDA), Ames, Iowa, U.S.A.

INTRODUCTION

The state of soil water is often described in energy relations. Kinetic energy is the result of motion and temperature fluctuations, but most of soil water energy is described by potential energy. The historic development of the soil water potential energy concept is described in Refs.[1–3].

Although the concept of soil water retention was early recognized as important for sustained plant growth, it was not linked with soil water potential energy until later.[1] The difference in soil water energy state is often of greater interest than the state itself.[3]

THERMODYNAMICS

Definitions

Thermodynamically, the potential of soil water at a given position is the amount of work required to move a parcel of water isothermally and reversibly from a reference state to the soil site.[4,5] Table 1 summarizes the type of soil water energy examined, what parcel of water is being moved, what conditions are held constant between the reference state and the soil site, and what conditions are changed in the soil site compared with the reference site. Soil water energy can be given as energy per mass (chemical potential in $\mathrm{J\,kg^{-1}}$), energy per volume (soil water potential or pressure in $\mathrm{N\,m^{-2}}$ or Pa), or energy per unit weight (soil water pressure head in m). Energy per volume can be calculated by multiplying energy per mass by the density of water. Energy per weight can be calculated by dividing energy per mass by the density of water and acceleration due to gravity.[6,7]

At potential energy equilibrium, soil water does not move. Thermodynamic equilibrium of soil water energy[2] depends on thermal equilibrium (uniform temperature throughout or isothermal), mechanical equilibrium (no convection forces), and chemical equilibrium (no net diffusion forces nor chemical reactions). The hydraulic head is the sum of gravitational, matric, and hydrostatic heads (Table 1, Fig. 1). Fig. 1 shows hydraulic equilibrium (no movement of soil solution).

The direction of soil solution movement is from high hydraulic pressure head to low hydraulic pressure head. Notice from Table 1 that hydraulic head is the work to move soil solution; whereas, osmotic pressure is the work to move pure water.[2] Osmotic pressure considerations are often due to a membrane or interface that is permeable to water but not permeable or only partly permeable to solutes. Examples are the water–air interface (vapor movement), and the cell membranes in the root (water uptake).

Iwata, Tabuchi, and Warkentin[3] describe five types of work that thermodynamically affect soil water. The first is compression, but within pressure ranges normally encountered in the soil, water is incompressible. The second is surface tension, due to the air–water surface, or due to the interface between the soil particle and water. The third is electrical work, in which the state of water (a dielectric material) is altered when placed in an electrical field. The fourth is gravitational, due to the external gravitational field, which influences water movement. The last is conservative force field, due to the colloid surface effects on water properties sorbed to the surface.

Other Factors and Terminology

Different terms are sometimes used for the various components of soil water potential.[4,5,7] Matric potential can be called wetness potential or tensiometric potential, which is a negative potential due to an interaction with soil pore walls. The matric potential can be divided into a matric potential occurring without an external load present, and with an overburden potential. The overburden potential is also called envelope-pressure potential, due to the weight of overlying soil and water on a swelling soil.[1,8,9] The overburden potential reduces the water content at a given water potential, compared with an unconfined sample at the same water potential. Air potential is considered another component of pressure potential, and is often called pneumatic potential due to air pressure applied externally. Hydrostatic potential is sometimes called submergence potential, or positive potential below the groundwater level.

Other factors can contribute to water potential,[3] such as electrical potential due to the electrical field

Table 1 The type of soil water energy upon which work is done, what parcel of water is being moved, what conditions are held constant between the reference state and the soil site, and what conditions are changed in the soil site compared with the reference site

Energy source	Reference parcel	Constant	Destination change
Gravitational	Soil solution	Atmospheric pressure	Elevation
Matric, above water table	Equivalent soil solution	Atmospheric pressure, elevation	Solution in soil
Hydrostatic, below water table	Equivalent soil solution	Atmospheric pressure, elevation	Solution in soil
Hydraulic	Equivalent soil solution	Osmotic pressure	Elevation, solution in soil
Air	External air pressure	Elevation	Soil air
Osmotic	Pure water	Atmospheric pressure, elevation	Soil solution

generated by charged colloid surfaces, radius of meniscus curvature effect on surface tension, van der Waal forces that draw surfaces together, internal pressure that develops in water to balance a non-uniform field such as van der Waals force or gravity, and temperature. If a temperature gradient is present, kinetic energy may be introduced, so movement in response to a water potential gradient assumes isothermal conditions.

Complex Interactions

Macroscale processes are not always easily described by microscale thermodynamics. If osmotic gradients occur, mass flow of soil solution can follow a macroscale gradient in one direction, and diffusion of pure water can follow a microscale gradient in the another.[2,7] Also at the macroscale, the contribution of electrical potential, van der Waals forces, and internal pressure are often ignored.[3] Discrepancies arise because water is not homogeneous, but has different properties near solutes in the water and near colloid surfaces.[3]

The definition for water potential describes the work to move reversibly a parcel of water from the reference state to a point in the soil. Yet water movement is usually not completely reversible, resulting in hysteresis.[7] At a given water potential, the soil is wetter during drainage than during wetting due to variation in pore sizes, different contact angles during wetting and drainage, and heterogeneities due to interactions of water with clay surfaces.[3]

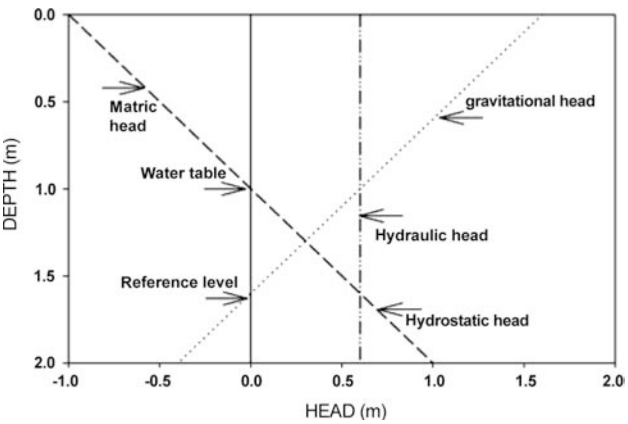

Fig. 1 Diagram of equilibrium hydraulic head with the water table at 1.0 m and the reference level at 1.6 m.

MEASUREMENT OF SOIL WATER POTENTIAL

The working definition for soil water potential is not a practical way for determining soil water energy in the field, because a parcel of water cannot realistically be moved from a reference state to the field site. The pressure potential can be measured with a piezometer (below the water table for hydrostatic potential) or a tensiometer (above the water table for matric potential). The piezometer is a hollow tube in the soil with a slotted screen opened at the bottom of the tube. The screened end of the peizometer is placed in the soil so that it is in contact with the soil solution. The height of water in the piezometer relative to a reference level is the pressure potential.[10] A tensiometer is also a tube that is connected to a ceramic cup that is placed in contact with the unsaturated soil.[11,3] The tube is filled with de-aired water and sealed. The force of the soil water matric potential on the water in the tensiometer creates a vacuum (negative pressure) that is read by a manometer, pressure gage, or pressure transducer. The reading is subtracted from the elevation of the gage. Even so, the measured matric potential is only an apparent matric potential.[2] The matric potential measured by a tensiometer may not indicate the microscale condition because there is no correction for for water–clay interactions.[3] Most tensiometers cannot measure water potential more negative than 10 m (around 1 atm), because air moves into the ceramic and the vacuum is broken. A technique that is used to determine water potential in drier soil involves the use of a thermocouple psychrometer that relates the

Scaling–Soil Water

vapor pressure to a soil water potential, i.e., the sum of osmotic and matric components.[12,13]

CONCLUSION

The soil water hydraulic pressure head is composed of matric, overburden, and hydrostatic pressures. The soil solution will flow from higher hydraulic pressure heads to lower hydraulic pressure heads. Piezometers are used to measure the hydrostatic pressure head, and tensiometers are used to measure the negative matric pressure head. The osmotic pressure head is due to solutes in the soil water. Pure water in the soil will move from higher osmotic pressure heads to lower osmotic pressure heads, usually caused by semipermeable membranes. Thermocouple psychrometers can be used to measure a combination of matric and osmotic pressure heads.

Soil Water: Flow under Saturated Conditions

Jan W. Hopmans

Graham E. Fogg
Hydrology, Department of Land, Air and Water Resources (LAWR), University of California–Davis, Davis, California, U.S.A.

INTRODUCTION

Water flow in soils may occur in both unsaturated and saturated conditions; however, clear differentiation between flows requires a review of definitions first.[1] In the saturated zone, it is generally assumed that the pore space within the soil matrix is saturated with water, and that the hydrostatic pressure in the water is greater than atmospheric pressure. In contrast in the unsaturated zone, the pore space is only partly filled with water, resulting in a soil water pressure smaller than atmospheric pressure. The region between the unsaturated zone and the groundwater is called the capillary fringe, where the soil is satiated but where the soil water is held by capillary forces (Fig. 1). The difference between satiated and saturated water content is caused by the general presence of entrapped air within the soil matrix of saturated soils. The unsaturated zone is bounded by the soil surface at the top and merges with the groundwater of an unconfined aquifer in the capillary fringe of the water table or phreatic surface at the bottom. By definition, the phreatic surface is the soil depth at which the water pressure is atmospheric.

The distinction between groundwater and unsaturated zone is usually made within a hydrologic context, emphasizing water as the agent of change of the subsurface and the main driver for transport of chemicals between the atmosphere and groundwater. This region of the unsaturated zone is also known as the vadose zone that incorporates local saturated regions, and is so defined to emphasize the desired integration of physical, chemical, and biological processes in the unsaturated soil zone and its interactions with the groundwater and atmosphere. The soil is the most upper part of the vadose zone, subject to fluctuations in water and chemical content by infiltration and leaching, water uptake by plant roots, and evaporation from the soil surface. Within the context of crop production, the spatial scale of interest is the field scale.

The need to incorporate saturated soil conditions in the root zone comes about for many reasons, affecting both water quantity and water quality. First and foremost, above a shallow groundwater, the capillary fringe bounds the bottom of the plant root zone. Water infiltration by either rainfall or irrigation causes a rise of the water table, thereby temporarily creating anaerobic soil conditions, unfavorable for plant growth. In contrast, up to 40% of plant transpiration may come from shallow water table contribution, depending on soil texture, distance between the water table and bottom of the root zone, and shallow groundwater salinity. Historically, much research has been invested in designing improved water management practices, such as by soil drainage.[2,3] Secondly, saturated soil conditions can also occur by regional groundwater flow, as caused by rising water tables elsewhere, or by subsurface flow along hill slopes.[4] Thirdly, local saturated soil water conditions can occur by spatial variations and layering of soil texture, creating favorable conditions for preferential saturated water flow towards the groundwater, thereby affecting groundwater and surface water quality by accelerated transport of surface-applied chemicals. Consequently, spatial variations in soil hydraulic conductivity within the unsaturated zone can lead to local or extended regions with positive soil water pressure values, causing the so-called perched water. A temporary saturated soil in the plant root zone causes anoxic conditions, thereby affecting chemical and microbial processes. For example, it can lead to dissolution of salts, chemical transformation of specific chemical compounds, and denitrification of applied fertilizers.

BASIC LAWS OF SATURATED WATER FLOW

Rather than characterizing soil water flow at the pore scale, soil water quantities are usually defined at the macroscopic level by using the continuum approach, at which each soil phase is regarded as a continuum. The flow of liquid water through the macroscopic soil matrix is generally viscous and laminar, because of the small pore sizes in which water movement takes place.

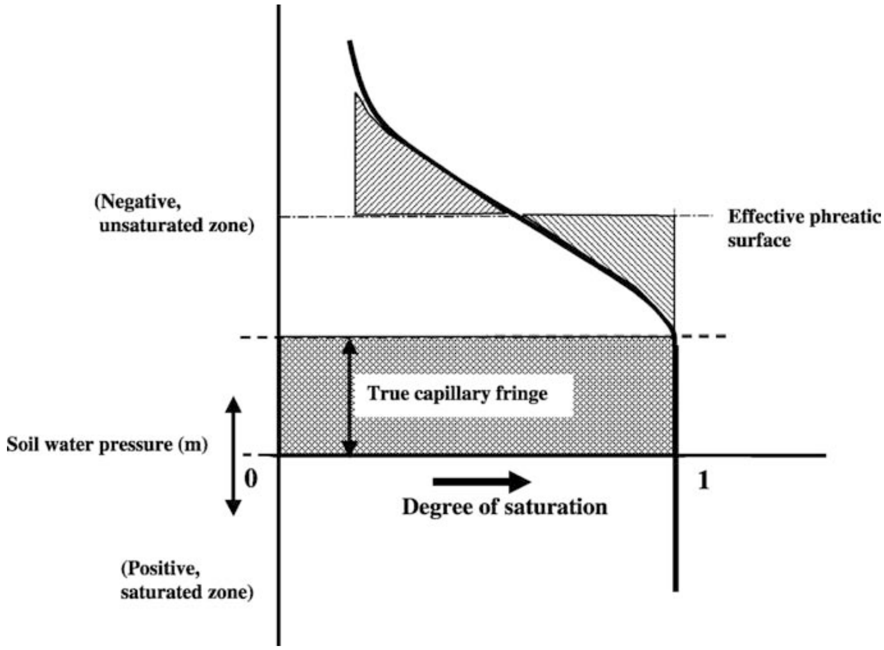

Fig. 1 The capillary fringe, separating the unsaturated and the saturated soil zone.

Under these conditions, the water flux density or specific discharge q (m sec^{-1}) is proportional to the driving force or total head gradient, $\Delta H/L$ (dimensionless), where ΔH denotes the change in piezometric head over the distance L. In unsaturated flow, it is customary to use total head (soil water flow under unsaturated conditions), instead of piezometric head. For one-dimensional flow, the magnitude of q is defined as the volume of water V (m^3) passing through a cross-sectional area of soil A (m^2) normal to the direction of flow for time t (sec). The head H (m) represents the potential energy (J) of water on a weight (N) basis. It incorporates the influences of forces such as gravity and pressure. The relationship between water flux and head gradient is known as Darcy's law:

$$q = -K\frac{\Delta H}{L} \tag{1}$$

where the proportionality factor is defined as the saturated hydraulic conductivity K (m sec^{-1}). Thus, the units for the water flux density and the hydraulic conductivity are identical. The decrease in hydraulic head in the direction of flow is caused by friction or drag forces as water moves through the small tortuous flow paths of the soil matrix. The value for the water flux density, or the Darcy flux, should not be mistaken for the average velocity of the water in the pores, known as the seepage or pore-water velocity ν (m sec^{-1}). The difference between the water flux density and the pore-water velocity is due to the fact that water only occupies a limited fraction of the soil's total volume. In the case of a water-saturated soil, the pore-water velocity is equal to the ratio of the Darcy flux and the soil porosity.

K varies between and within soil types, as it depends on soil properties such as texture, solid particle arrangement (soil structure), organic matter content, and water content. In addition, for anisotropic soils, K varies with spatial direction (x, y, or z), as caused by the process of soil deposition or soil formation. Even for isotropic soils, K is usually heterogeneous because of soil spatial variability. In most applications, though, the soil's saturated hydraulic conductivity is assumed to be characterized by a single K-value, assuming isotropy and homogeneity.

Fig. 1 shows a schematic presentation of the soil water distribution between the saturated and unsaturated zone, by plotting soil water pressure as a function of degree of saturation. The capillary fringe separates the phreatic surface from the unsaturated zone. For practical purposes, one sometimes approximates the top of the capillary fringe as the distance above the phreatic surface, above which soil water is immobile, and below which the soil is saturated. While conserving mass, an effective phreatic surface (see Fig. 1) is then chosen that includes this approximate capillary fringe.[1] For conditions where saturated water flow is dominantly horizontal, i.e., the pressure distribution in the vertical direction is hydrostatic and the variations in H are much smaller than total aquifer thickness, the hydraulic head gradient can be approximated by the slope of the phreatic surface (the Dupuit assumption). Substitution of the hydraulic head by this effective, vertical-averaged phreatic surface simplifies a three-dimensional flow problem to two dimensions.

Using these assumptions, a broad suite of analytical solutions to unconfined steady groundwater drainage flow have been obtained,[1–3] e.g., for the purpose of drainage design calculations.

In addition to the Darcy type of equation, an additional expression is required for a complete description of saturated flow, allowing the prediction of both flux density and hydraulic head. This second equation is obtained by invoking mass conservation over a specified control volume. Using the assumptions that water is incompressible, and that the porous matrix is non-deformable, the mass balance equation combined with the Darcy equation for steady-state flow in a homogenous, isotropic, constant saturated thickness soil, yields the so-called Laplace equation:[1–3]

$$\frac{\partial^2 H}{\partial x^2} + \frac{\partial^2 H}{\partial y^2} = 0 \qquad (2)$$

Eq. (2) can be applied for an unconfined, saturated soil with a variable phreatic surface, H, if the variation in H is much smaller than the aquifer's thickness.

In order to analytically solve for transient groundwater drainage, the specific yield, S (dimensionless), was defined to quantify the exchange of soil water between the unsaturated and saturated soil zones in unconfined aquifers.[5] It is computed from the volume of water given up by or extracted from the groundwater per unit area of water table and per unit groundwater table change. In practice, S is assigned a constant soil-texture dependent value, and is also called the drainable porosity. In theory, however, this is only approximately true, since the specific yield is a function of the rate of water table change, its proximity to the soil surface, thereby varying with time depending on drainage and redistribution rates. Nevertheless, this approximation of specific yield allows the quantification of water flux across the water table as a result of changes in water table position, without solving the unsaturated water flow equation for the combined saturated–unsaturated soil domain. When applying the Dupuit and the specific yield assumptions, changes in the water height, H, with lateral position and time can be computed from solution of the so-called Boussinesq's equation, which is written as

$$S\frac{\partial H}{\partial t} + q_s = K\frac{\partial}{\partial x}\left(H\frac{\partial H}{\partial x}\right) + K\frac{\partial}{\partial y}\left(H\frac{\partial H}{\partial y}\right) \qquad (3)$$

where q_s is the steady-state water flux through the phreatic surface.[5] A full suite of numerical techniques is available that do not require such assumptions, but can solve for variably-saturated flow with or without decoupling the saturated and unsaturated flow regimes.[6,7]

PREFERENTIAL FLOW

It is widely accepted that preferential flow of water through soils occurs through different mechanisms, and can have wide implications. Preferential flow can be loosely defined as the accelerated flow of water and associated chemicals through soil, relative to the corresponding flow through the soil matrix. Preferential flow occurs locally, and is mostly saturated. Consequently, such a flow is fast and difficult to quantify. In general, one recognizes three different types: bypass, fingering, and funneled flows.[4,8] Under water-ponded soil surface conditions, bypass flow occurs through highly permeable zones such as macropores and cracks that are connected to the land surface (Fig. 2). Fingering flow is generally associated with non-uniform flow caused by flow instabilities as caused by soil air

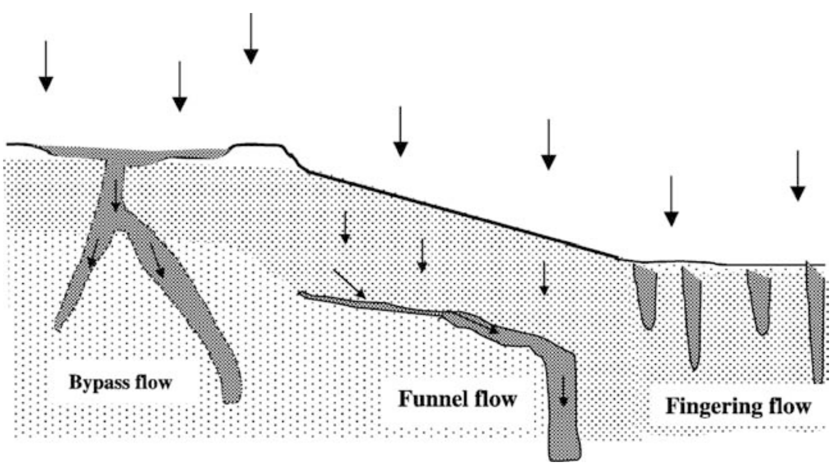

Fig. 2 Schematic diagram of preferential flow mechanisms.

compression, soil hydrophobicity, and soil layering. Funneled flow[8] occurs because of the interbedding of coarse and fine soil layers. If the layer interface is along a slope, unsaturated water flow accumulates, and becomes saturated. Eventually, the water may breakthrough the interface into funnels, depending on local values of water pressure and soil textural changes along the bedding. Due to uncertainties of the occurrence and magnitude of preferential flow, however, prediction of saturated flow in these conditions is difficult.

CONCLUSION

In addition to groundwater flow, saturated soil conditions can occur in the unsaturated or vadose zone by perched water, by preferential flow at or near the soil surface, and in the capillary fringe above the water table. For the latter case, relative simple solutions are available to account for the variably-saturated conditions. However, characterization of saturated water flow as caused by preferential flow or by perched water is much more difficult to quantify, mostly due to complications caused by soil heterogeneity.

Soil Water: Flow under Unsaturated Conditions

Jacob H. Dane
Department of Agronomy and Soils, Auburn University, Auburn, Alabama, U.S.A.

Jan W. Hopmans
Department of Land, Air and Water Resources (LAWR), University of California–Davis, Davis, California, U.S.A.

INTRODUCTION

Soils make up the upper part of the unsaturated zone, where water flow occurs mainly under unsaturated conditions. The unsaturated zone consists of a complex arrangement of mostly connected solid, liquid, and gaseous phases, with the spatial distribution and geometrical arrangement of each phase, and the partitioning of solutes between phases, controlled by physical, chemical, and biological processes. The unsaturated zone is bounded by the soil surface and merges with the groundwater in the capillary fringe (see the article *Soil Water: Flow under Saturated Conditions*). The distinction between groundwater and water in the unsaturated zone is determined by the degree of water saturation (see the article *Soil Water: Capillary Rise*). For groundwater, it is generally assumed that the pore space within the solid matrix is saturated with water, and that the hydrostatic pressure in the water is larger than atmospheric pressure. In contrast, in the unsaturated zone, the pore space is only partly filled with water, while the remaining space is occupied by the gas phase. Water is held in the soil matrix of the unsaturated zone by capillary and adsorptive forces. The unsaturated zone is usually considered to be the region for water flow and its concomitant transport of chemicals between the atmosphere and groundwater. Although, the importance of water as carrier of chemicals is paramount, it is becoming increasingly clear that chemical and biological phenomena in the unsaturated zone play a profound role on chemical fate. It is therefore that vadose zone notation is preferred, emphasizing the multidisciplinary approach in subsurface characterization.

The upper part of the vadose zone is the most dynamic and changes occur at increasingly greater time and spatial scales when moving from the soil surface towards the ground water. The most upper part of the vadose zone is subject to fluctuations in water and chemical content by infiltration and leaching, water uptake by plant roots (transpiration), and evaporation from the soil surface. Water is the primary factor leading to soil formation from the weathering of parent material such as rock or transported deposits, with additional factors of climate, vegetation, topography, and parent material determining soil physical properties. Generally, the soil depth is controlled by the maximum rooting depth (generally within a few meters from the soil surface). However, the vadose zone can extend much deeper than the surface soil layer and includes unsaturated rock formations and alluvial materials to depths of 100 m or more, determined by hydrologic, topographic, and lithographic characteristics.

Scientists are becoming increasingly aware that soil is a critically important component of the earth's biosphere, not only because of its food production function, but also as the safe-keeper of local, regional, and global environmental quality. For example, it is believed that management strategies in the unsaturated soil zone will offer the best opportunities for preventing or limiting pollution, or for remediation of ongoing pollution problems. Because chemical residence times in ground water aquifers can range from a few to thousands of years, pollution is often essentially irreversible. Prevention or remediation of soil and groundwater contamination starts, therefore, with proper management of the unsaturated zone (see the article *Vadose Zone and Groundwater Protection*).

Both introductory[1,2] and advanced references[3,4] of unsaturated flow are suggested for further reading, whereas in addition, comprehensive reviews[5,6] provide selected references on relevant areas of study.

SOIL-WATER RETENTION

Unsaturated water flow is largely controlled by the physical arrangement of soil particles in relation to the water and air phases within the soil's pore space, as determined by pore size distribution and water-filled porosity or volumetric water content, θ (m^3 water/m^3 bulk soil; see the article *Soil Water Measurement: Gravimetric*). In addition to θ, the volume of water is sometimes defined by degree of saturation, $S = \theta/\theta_s$, or effective saturation (S_e),

$$S_e = \frac{\theta - \theta_r}{\theta_s - \theta_r} \tag{1}$$

normalizing the mobile water between values of zero and one, while defining a residual water content, θ_r, for which water is considered immobile (see the article *Soils: Hygroscopic Water Content*). In addition to simple gravimetric methods, various devices are available to measure the soil's water content nondestructively (see the articles *Soil Water Measurement: Capacitance; Soil Water Measurement: Neutron Thermalization; Soil Water Measurement: Time Domain Reflectometry*).

The soil-water retention function determines the relation between volume of water retained by soil capillary and adsorptive forces, as a function of θ, and is also known as the soil-water release or soil-water characteristic function. These two water-retaining forces in unsaturated soils combined are defined as the matric forces, and are sometimes also called suction forces (see the article *Soil Water Energy Concepts*). These suction forces increase as the size of the water-filled pores decreases, as may occur by drainage, water uptake by plant roots, or evaporation. When expressed relative to the reference potential of free water, the water potential in unsaturated soils is negative (the soil-water potential is less than the water potential of water at atmospheric pressure). It is often referred to as the soil water matric potential. Hence, the matric potential decreases or becomes more negative as the soil water content decreases. Since the matric forces are controlled by pore size distribution, specific surface area, and type of physico-chemical interactions at the solid–liquid interfaces, the soil water retention curve is soil specific. It provides an estimate of the soil's capacity to hold water after free drainage (see the article *Soils: Field Capacity*), minimum soil water content available to the plant (see the article *Soils: Permanent Wilting Points*), and water availability for plants.

Whereas in physical chemistry, the chemical potential of water is usually defined on a molar or mass basis, in soils potential is usually expressed with respect to a unit volume of water, thereby attaining units of pressure (Pa); or per unit weight of water, so that the potential represents the equivalent height of a column of water (m). The pressure head equivalent of the combined adsorptive and capillary forces is defined as the matric pressure head, h_m.

By way of the unique relationship between capillary water pressure and the radius of curvature of the air–water interface, and using the analogy between capillary tubes and the irregular pores in porous media, a relationship can be derived between soil water matric head (h_m) and effective pore radius, r_e, or

$$\rho g h_m = \frac{-2\sigma \cos\alpha}{r_e} \tag{2}$$

where σ and α are defined as the surface tension and wetting angle (of wetting fluid with solid surface), respectively, ρ is the density of water, and g is the acceleration due to gravity ($9.8\,\mathrm{m\,sec^{-2}}$). This capillary equation simplifies to $h_m = -0.15/r_e$, when both h_m and r_e are expressed in cm. As a result, the effective pore size distribution can be determined from the soil water retention curve in the region where capillary forces dominate.

The measurement of the matric potential in situ is difficult and is usually done by tensiometers in the range of matric head values larger (less negative) than -6.0 m (see the article *Soil Water Measurement: Tensiometers*). A tensiometer consists of a porous cup, usually ceramic, connected to a water-filled tube. The suction forces of the unsaturated soil draw water from the tensiometer into the soil until the water pressure inside the cup (at pressure smaller than atmospheric pressure) is equal to the pressure equivalent of the soil water matric potential just outside the cup. The water pressure in the tensiometer is usually measured by a vacuum gauge or pressure transducer. When tensiometers are used at matric potential values lower than -6.0 m, the tensile strength of the water in the tensiometer device may be exceeded, causing development of air or vapor bubbles in the water column, which is called cavitation, thereby rendering the tensiometer readings useless. Other devices that are used to indirectly measure the soil water matric potential include buried porous blocks, from which either the electrical resistance or thermal conductivity is measured in situ, after coming into hydraulic equilibrium with the surrounding soil. Laboratory and field techniques to measure the soil water retention curve, and functional models to fit the measured soil water retention data, such as the van Genuchten and Brooks and Corey model, are described in Refs.[7,8].

UNSATURATED HYDRAULIC CONDUCTIVITY

The relation between the unsaturated hydraulic conductivity, K, and volumetric water content, θ, is the other essential fundamental soil hydraulic property needed to describe water movement in the vadose zone. It is also a function of the water and soil matrix properties, and determines water infiltration and drainage rates (see the articles *Soils: Water Infiltration;*

Soils: Water Percolation; *Soil: Waterborne Chemicals Leaching through*), and is strongly affected by water content. It is defined by Darcy's equation (*Darcy's law*), which relates the soil water flux density to the total driving force for flow, with K being the proportionality factor. Except for special circumstances, pneumatic and osmotic forces are irrelevant, so that the total driving force for water flow is determined by the matric and gravitational forces, expressed by the total water potential gradient, $\Delta H/L$, where ΔH denotes the change in total head over the distance L, and $H = h_m + z$. Applying Darcy's law in the vertical dimension only, the magnitude of flow can be computed from the steady state flow equation (Darcy's law):

$$Q = -K(\theta)A\left(\frac{\partial h_m}{\partial z} + 1\right) \quad \text{or}$$

$$q_w = -K(\theta)\left(\frac{\partial h_m}{\partial z} + 1\right) \tag{3}$$

where Q denotes the volumetric flux ($m^3\,sec^{-1}$), A is the cross-sectional area of the bulk soil domain perpendicular to flow (m^2), q_w is the Darcy flux density ($m\,sec^{-1}$), z is vertical position ($z > 0$, upwards, m), and $K(\theta)$ denotes the unsaturated hydraulic conductivity ($m\,sec^{-1}$). In this expression, the unsaturated hydraulic conductivity is related to the intrinsic soil permeability, k (m^2), by

$$K = \frac{\rho g k}{\mu} \tag{4}$$

where μ denotes the dynamic viscosity of water ($N\,sec\,m^{-2}$), and ρ and g were defined earlier. The usage of permeability instead of conductivity allows application of the flow equation to liquids other than water with different density and viscosity values. Using the analogy of soil pores represented by varying-size capillaries, the average pore water velocity in soils can be estimated from the ratio of the Darcy flux and the volumetric water content, or

$$\hat{v} = \frac{q_w}{\theta} \tag{5}$$

Functional models for unsaturated hydraulic conductivity are based on pore size distribution, pore geometry and connectivity, and require integration of soil water retention functions to obtain analytical expressions for the unsaturated hydraulic conductivity. The resulting expressions relate the relative hydraulic conductivity, K_r, defined as the ratio of the unsaturated hydraulic conductivity, K and the saturated hydraulic conductivity, K_s, to the effective saturation, and can be written in the following generalized form

$$K_r(S_e) = S_e^l\left[\frac{\int_0^{S_e}|h_m|^{-\eta}\,dS_e}{\int_0^1|h_m|^{-\eta}\,dS_e}\right]^\gamma \tag{6}$$

where l and η are parameters related to the tortuosity and connectivity of the soil pores, and the value of the parameter γ is determined by the method of evaluating the effective pore radii. The moisture-dependency is highly non-linear, with a decrease in K of 4–5 or more orders of magnitude within field-representative changes in water content. Methods to measure the saturation dependency of the hydraulic conductivity are involved and time-consuming.[9] Moreover, measurement errors are generally large, due to: 1) the difficulty of flow measurements in the low-water content range; and 2) the dominant effect of large pores (macropores), cracks, and fissures in the high-water content range (see the article *Soil Macropores: Water and Solute Movement*). Model fitting techniques assume a certain form for the soil water retention curve, such as the Mualem-van Genuchten relationship, and use parameters associated with the water retention relationship to express the hydraulic conductivity as a function of water content or matric head.[8]

MODELING OF UNSATURATED SOIL WATER FLOW

Since the Darcy equation is strictly defined for steady state water flow conditions, the mass conservation principle is applied and combined with Eq. (3) to yield the so-called Richards equation to solve for temporal changes in h_m or θ, at any depth z and time t:

$$\frac{\partial \theta}{\partial t} = -\frac{\partial q_w}{\partial z} = \frac{\partial}{\partial z}\left[K(h_m)\left(\frac{\partial h_m}{\partial z} + 1\right)\right] \tag{7}$$

Because of the highly non-linear soil water retention and unsaturated hydraulic conductivity functions, advanced numerical models are required to solve for $h_m(z,t)$ or $\theta(z,t)$ for either one, two or three dimensions,[10] using known boundary and initial conditions. Eq. (7) may include a sink term, describing changes in soil water content with time as a result of root water uptake.[11] If solution of time-changes of water content within the soil domain are not required, but only total soil water storage changes are needed at time scales of days or longer, Eq. (7) can be simplified to a capacity model, thereby requiring input of the boundary fluxes only, resulting in the so-called water budget models.[12]

SUMMARY

Prevention or remediation of soil and groundwater contamination requires proper management of the vadose zone. Therefore, a solid understanding of unsaturated water flow is required. However, because of the highly non-linear soil hydraulic functions that control soil water retention and unsaturated hydraulic conductivity, advanced numerical models are required to predict temporal changes of soil water matric potential, soil water content, and water fluxes in one or more spatial dimensions.

INTRODUCTION

There are several models of soil water that consider the soil medium as an active site for chemical, physical, and biological processes with a bimodal porous medium, micro- and macropore systems. Few of these models consider the soil medium as a structured medium with aggregates. However, none considered the swelling–shrinkage properties of these aggregates and the resulting hydrostructural properties of the soil medium, which significantly contribute to the formulation of transfer functions and their parameterization. Thus, soil dynamics literature describes soil properties independently from the aggregated organization of soils and their structural dynamic with water.

OVERVIEW

Typically, soil hydraulic parameters were estimated from measured basic soil data, such as texture, soil organic matter, etc., through pedotransfer functions (PTFs).[1–3] Hence, their development is strongly related to that of soil moisture characteristic measurement techniques and models. Historically, PTFs were developed using regression equations. A thorough review of the different types of pedotransfer functions, the number of horizons used to derive them and their application ranges can be found in Refs.[4–6]. One of the drawbacks of pedotransfer functions is that soil structure, namely, macroporosity and pedality, cannot be taken into account when deriving the PTFs.[7] Although bulk density and organic carbon content could be used as indicators of soil structure, the information they provide is not always sufficient to describe macropore flow. This restricts the applicability of PTFs to micropore flow and, as a direct consequence, PTFs cannot be applied to farmed catchments or tilled soils. In fact, the hierarchical structure of soils poses a challenge for defining soil hydraulic properties per se.[8,9]

Taking into account the limitations of PTFs in addressing the impact of the internal soil organization on soil water dynamics, this article will present a conceptual model of the unsaturated soil water medium functionality based on the pedostructure concept. Pedostructure is defined as the soil fabric for which the functional organization is characterized by the medium shrinkage curve (SC).[10] The objective of this article is to present a characterization and parameterization of the hydrostructural functions of the soil fabric defined by the following:

1. The shrinkage curve or the specific volume of the pedostructure as a function of its water content $V(W)$.
2. The swelling curve of the pedostructure specific volume V as a function of time $V(t)$ during wetting of a dry soil sample put in contact with water.
3. The tensiometric curve or the interped water potential as a function of interped water content $h_{ma}(W_{ma})$ measured by a tensiometer.
4. The conductivity curve or the interped conductivity as a function of the interped water content $k_{ma}(W_{ma})$.

In this approach, the shrinkage curve represents the state of equilibrium of the soil–water–air configurations of the pedostructure; whereas the swelling curve represents the dynamics of the pedostructure when this medium is out of equilibrium. The tensiometric and conductivity curves are the parametric variables of Darcy's law extended to the unsaturated soil medium that is described by the pedostructure model.

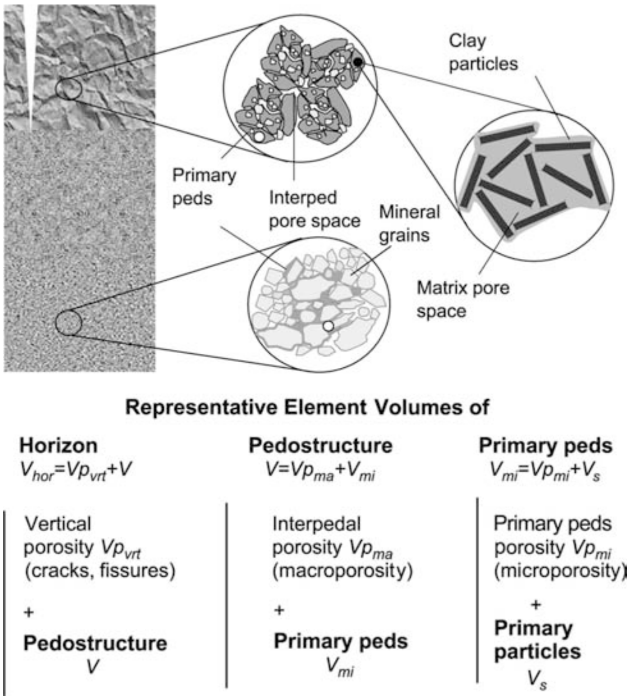

Fig. 1 Schematic representation and nomenclature of the internal soil–water–air organization, taking into consideration the functional levels of the soil: the horizon, the pedostructure, the primary peds, and the primary particles. All variables of the nested REVs are referred to mass of primary particles.

SOIL MEDIUM HIERARCHY, ORGANIZATIONAL LEVEL, AND FUNCTIONALITY

Fig. 1 shows a schematic representation of the soil horizon showing its four hierarchical structural levels: the horizon, the pedostruture, the primary peds, and the primary particles. In this representation, we define hierarchical representative elementary volumes (REVs) where different physical laws such as Darcy's law can be applied. The REV of a soil horizon is large enough to comprise cracks or fissures that are opened to air when soil dries and includes vertical porosity. It is delimited vertically by the soil horizon, thus its volume change is only one-dimensional (vertical). The REV of the pedostructure is composed of the primary peds, V_{mi}, and the pore space created by their assembly, Vp_{ma}; its volume change is three-dimensional and isotropic. In that pore space, two water pools are differentiated and defined by the shrinkage curve (Fig. 2): a ''swelling'' water w_{ip}, which leaves the pore system without air intake (peds approaching each other) and a non-swelling water w_{st}, which leaves the same pore system while being replaced by air (peds are jointed). The primary peds pore system is quantitatively defined by its air entry point that is clearly identified on a continuously measured SC. At point B of the SC (Fig. 2), the specific pore volume of the primary peds (Vp_{mi}) are equal in value to the water content W_{B} ($Vp_{\mathrm{mi}} = W_{\mathrm{B}}/\rho_{\mathrm{w}}$, where ρ_{w} is the water bulk density). The primary peds are composed of the primary particles, of specific volume, V_{s}, and of the micropore space between them. In this micropore space, two water pools are also defined using the SC: swelling water, w_{bs}, and a non-swelling water, w_{re}. The subscripts ip, st, and bs are referred to as interped, structural, basic, and residual, which are the classical names of the different linear shrinkage phases to which a single water pool is associated (at inflection point of the structural shrinkage, e.g., $\mathrm{d}W = \mathrm{d}w_{\mathrm{st}}$).

Geometrical equations are used as geometrical laws to link the different nested volumes in the pedostructure, as well as to link the pedostructure and the horizon REVs.[10,12] Consequently, the SC equation was written as a linear combination of the water pools:

$$\mathrm{d}V = K_{\mathrm{re}}\mathrm{d}w_{\mathrm{re}} + K_{\mathrm{bs}}\mathrm{d}w_{\mathrm{bs}} + K_{\mathrm{st}}\mathrm{d}w_{\mathrm{st}} + K_{\mathrm{ip}}\mathrm{d}w_{\mathrm{ip}} \tag{1}$$

that after integration Eq. (1) yields:

$$V = V_{\mathrm{o}} + K_{\mathrm{re}}w_{\mathrm{re}} + K_{\mathrm{bs}}w_{\mathrm{bs}} + K_{\mathrm{st}}w_{\mathrm{st}} + K_{\mathrm{ip}}w_{\mathrm{ip}} \tag{2}$$

where the subscripts re, bs, st, and ip refer to the mean residual, basic, structural, and interpedal, respectively; K are the slopes of the linear shrinkage phase, w are the corresponding water pool; V_{o} is the specific volume at the dry state.

USING THE SHRINKAGE CURVE TO DETERMINE THE SPECIFIC PARAMETERS OF THE PEDOSTRUCTURE

In the ''geometrical'' equation above, the water pools were determined by integrating the logistic functions that describe the probable composition of the water pools present in the element of water evaporating:[10]

$$\begin{aligned}
w_{\mathrm{ip}} &= \frac{1}{k_{\mathrm{L}}}\log[1 + \exp(k_{\mathrm{L}}(W - W_{\mathrm{L}}))]\\
w_{\mathrm{st}} &= -\frac{1}{k_{\mathrm{M}}}\log[1 + \exp(-k_{\mathrm{M}}(W - W_{\mathrm{M}}))]\\
&\quad - \frac{1}{k_{\mathrm{L}}}\log[1 + \exp k_{\mathrm{L}}(W - W_{\mathrm{L}})]\\
w_{\mathrm{bs}} &= \frac{1}{k_{\mathrm{N}}}\log[1 + \exp(k_{\mathrm{N}}(W - W_{\mathrm{N}}))]\\
&\quad + \frac{1}{k_{\mathrm{M}}}\log[1 + \exp(-k_{\mathrm{M}}(W - W_{\mathrm{M}}))]\\
w_{\mathrm{re}} &= -\frac{1}{k_{\mathrm{N}}}\log[1 + \exp(-k_{\mathrm{N}}(W - W_{\mathrm{N}}))] + W_{\mathrm{N}}
\end{aligned} \tag{3}$$

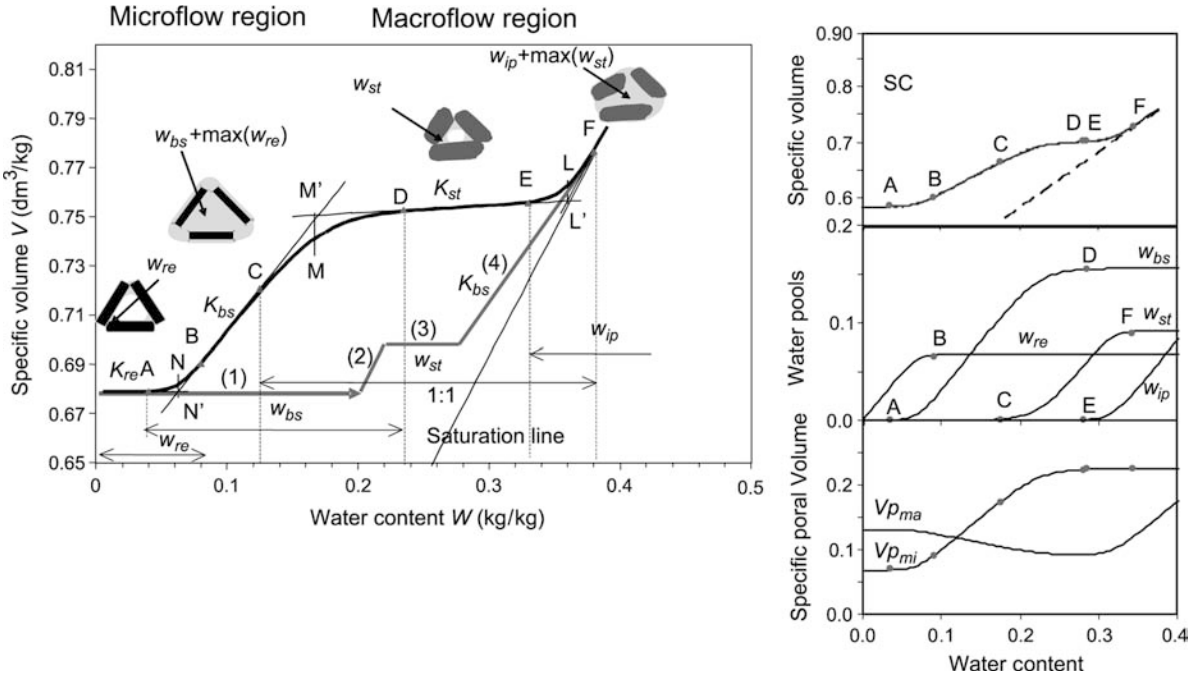

Fig. 2 Various configurations of air and water repartition partitioning into the two pore systems, inter and intra primary peds, related to the shrinkage phases of a standard SC. The various pools of types of water, w_{re}, w_{bs}, w_{st}, and w_{ip}, are represented by their domains of variation. The linear and curvilinear shrinkage phases are delimited by the transition points (A, B, C, D, E, and F), which are hydrostructural characteristics of soil determined by a parametric modeling of the measured shrinkage curve according to the method of Braudeau et al.[11] Points N′, M′, and L′ are the intersection points of the tangents at those linear phases of the SC. Graphs on the right side represent a continuously measured SC along with the modeled water pools, the modeled specific pore volumes, and the calculated position of the transitional points.

The parameters used in these equations are those of the characteristic SC: k_N, k_M, k_L, W_N, W_M, W_L. They can be graphically obtained from the measured SC knowing points N′, M′, and L′, the intersection points of the straight lines tangent to the linear sections of the SC. These parameters have physical meanings: W_N and W_M represent, respectively, the dry micropore and the maximal saturated micropore specific volumes; W_L can be taken to represent the water content at saturation; and k_M, k_N, and k_L represent the distance between the intersection points M′, N′, L′ and the corresponding point N, M, L, of the curve, via equations such as the following for k_M: $k_M/\ln(2) = (K_{bs} - K_{st})/(V_M - V'_M)$.

Eqs. (2) and (3) constitute a total of 11 parameters required for modeling all structural volume variables of the pedostructure. Fig. 2 shows an example of the continuously measured SCs with the corresponding water pools (w_{re}, w_{bs}, w_{st}, and w_{ip}) and of the two specific pore volumes (Vp_{mi} and Vp_{ma}), which are represented according to their definition, $Vp_{mi} = (w_{bs} + \max(w_{re}))/\rho_w$ and $Vp_{ma} = V - Vp_{mi} - V_s$.

USING THE SWELLING CURVE TO DETERMINE PARAMETERS OF THE PEDOSTRUCTURE DYNAMICS

The swelling curve is the complementary part of the shrinkage curve in the wetting–drying cycles of soils observed under natural conditions. Whereas the SC defines the equilibrium configuration at certain water content *W*, the swelling curve describes the absorption rate of water and can be used to define the kinetics of the medium, at a given *W*, to reach the equilibrium configuration starting from a point outside the equilibrium state defined by the SC. In the swelling phase (see the swelling path, Fig. 2), when the aggregates are immersed in water, four events occur immediately before the plasma swelling: 1) the entry of water into the soil medium through the interpedal voids of the sample; 2) the spacing of aggregates; 3) the entry of water into the dry micropores of the primary peds, filling the residual micropore dry space in a few seconds, and 4) the swelling of the primary peds in 1 or 2 hr. Braudeau and Mohtar[13] gave the equation of the swelling curve, physically based on the following equation analogous to Darcy's law:

$$\mathrm{d}w_{\mathrm{bs}}/\mathrm{d}t = k_{\mathrm{mi}}(h_{\mathrm{mi}} - h_{\mathrm{mi}}^{\mathrm{eq}}) \tag{4}$$

where k_{mi} is a constant, h_{mi} is the micropore water suction (inside primary peds) and $h_{\mathrm{mi}}^{\mathrm{eq}}$ the micropore water suction at equilibrium with interped water outside. Micropore potential equation h_{mi} was derived from the swelling pressure equation given by Voronin[14] and adapted to the pedostructure medium:

$$h_{\mathrm{mi}} = \rho_{\mathrm{w}} E_{\mathrm{mi}} \left(\frac{1}{w_{\mathrm{bs}}} - \frac{1}{\max(w_{\mathrm{bs}})} \right) \tag{5}$$

where ρ_{w} is the water bulk density; $E_{\mathrm{mi}} = Q_{\mathrm{s}}RT$ is the potential energy of the solid phase resulting from the surface charge of the soil (joules/kg soil); Q_{s} is the effective electric charge of the surface or effective exchange capacity (moles/kg solids); R is the molar gas constant (J mol^{-1} K^{-1}); and T is the absolute temperature.

Using the "geometrical law" for the pedostructure ($\mathrm{d}V = K_{\mathrm{bs}}\,\mathrm{d}w_{\mathrm{bs}}$), the equation of the swelling curve is thus, for $h_{\mathrm{mi}}^{\mathrm{eq}} = 0$ and $\max(w_{\mathrm{bs}}) = (W_{\mathrm{M}} - W_{\mathrm{N}})$:

$$\log\left(1 - \frac{V - V_{\mathrm{o}}}{B}\right) + \frac{V - V_{\mathrm{o}}}{B} = -At \tag{6}$$

where

$$A = \rho_{\mathrm{w}} k_{\mathrm{mi}} E_{\mathrm{mi}} / (W_{\mathrm{M}} - W_{\mathrm{N}})^2 \tag{7}$$

$$B = K_{\mathrm{bs}}(W_{\mathrm{M}} - W_{\mathrm{N}}) \tag{8}$$

where V_{o}, W_{M}, W_{N}, and K_{bs} are parameters of the SC. Thus, the only parameter needed to model the swelling curve is the product $k_{\mathrm{mi}}E_{\mathrm{mi}}$. The observed very good fit of Eq. (6) with experimental data validates both expressions of h_{mi} and that of Eq. (4). Parameter A is also determined from this fitting operation.

We assume that k_{mi}, in Eq. (7), is always the same for all initial pedostructure configurations at a given water content W, and that the final configuration is the point of the SC at this water content. Thus, according to Eq. (4), the governing equation for the local flux between the primary peds (microporosity) and the interped pore space (macroporosity) that maintains the equilibrium configuration of the pedostructure can be defined as:

$$\frac{\mathrm{d}w_{\mathrm{bs}}}{\mathrm{d}t} = A(W_{\mathrm{M}} - W_{\mathrm{N}})^2 \left(\frac{1}{w_{\mathrm{bs}}} - \frac{1}{w_{\mathrm{bs}}^{\mathrm{eq}}} \right) \tag{9}$$

where w_{bs} is the actual micropore water content and $w_{\mathrm{bs}}^{\mathrm{eq}}$ the water content corresponding to the equilibrium point of the SC corresponding to the actual w_{st}.

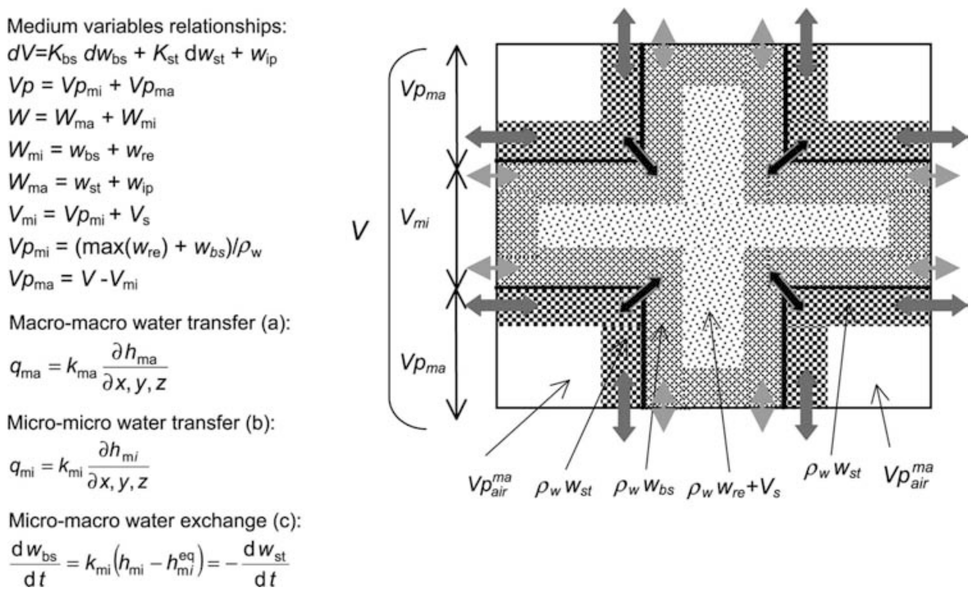

Fig. 3 Conceptual model of the hydraulic functioning of the pedostructure. V is the pedostructure specific volume, Vp is the poral volume, W is the water content, w is the content of the water pools, q are the fluxes, K is the slope of a linear phase of the SC, and k is the hydraulic conductivity. Subscripts ma and mi refer to macro and micro; and re, bs, st, and ip refer to residual, basic, structural, and interped shrinkages, respectively. h_{mi} and h_{ma} are the suction in the microporosity of the primary peds and in the interaggregate macroporosity, respectively. Arrows represent the different types of water movements, governed by Eq. (a) within macroporosity, Eq. (b) within microporosity, and Eq (c) between micro- and macroporosity.

Table 1 Summary of parameters and variables used in the pedostructure soil water model

Variables

Organization level	Specific poral volume	Water content	Specific volume	Water potential	Hydraulic conductivity
Horizon	Vp_{vrt}	W	V_{hor}		
Pedostructure	Vp	W	V		
Interpedal pore space	Vp_{ma}	W_{ma}		h_{ma}	k_{ma}
Primary peds	Vp_{mi}	W_{mi}	V_{mi}	h_{mi}	k_{mi}
Primary particles			V_{s}		

Pedostructure functions $f(W,V)$	Equations	Parameters
		Shrinkage curve
Vp_{mi} (from $\mathrm{d}V/\mathrm{d}W_{\mathrm{mi}} = K_{\mathrm{bs}}$	$\rho_{\mathrm{w}} Vp_{\mathrm{mi}} = \left(\frac{V - V_{\mathrm{N}}}{K_{\mathrm{bs}}}\right) + W_{\mathrm{N}}$	V_{N}, W_{N}, K_{bs}
W_{ma}	$W_{\mathrm{ma}} = W - \rho_{\mathrm{w}} Vp_{\mathrm{mi}}$	V_{N}, W_{N}, K_{bs}
w_{bs}	$w_{\mathrm{bs}} = \rho_{\mathrm{w}} Vp_{\mathrm{mi}} - W_{\mathrm{N}}$	V_{N}, W_{N}, K_{bs}
$w_{\mathrm{bs}}^{\mathrm{eq}}$ (at equilibrium for W^{eq})	$w_{\mathrm{bs}}^{\mathrm{eq}} = W^{\mathrm{eq}} - W_{\mathrm{N}} + \frac{1}{k_{\mathrm{M}}} \times \ln[1 + \exp(-k_{\mathrm{M}}(W^{\mathrm{eq}} - W_{\mathrm{M}}))]$	k_{M}, W_{M}, W_{N}
		Tensiometric curve
h_{ma} (thermodynamical approach)	$h_{\mathrm{ma}} = \rho_{\mathrm{w}} E_{\mathrm{ma}} \left(\frac{1}{W_{\mathrm{ma}} + \sigma} - \frac{1}{W_{\mathrm{L}} - W_{\mathrm{M}} + \sigma}\right)$	E_{ma}; σ
h_{ma} (fractal approach)	$\frac{h_{\mathrm{ma}}}{h_{\mathrm{oF}}} = \left(\frac{W_{\mathrm{ma}}}{\rho_{\mathrm{w}} V} + \frac{V_{\mathrm{mi}}}{V_{\mathrm{L}}}\right)^{1/(D-3)}$	h_{oF}; D
		Swelling curve
h_{mi} (suction pressure)	$h_{\mathrm{mi}} = \rho_{\mathrm{w}} E_{\mathrm{mi}} \left(\frac{1}{w_{\mathrm{bs}}} - \frac{1}{W_{\mathrm{M}} - W_{\mathrm{N}}}\right)$	E_{mi}
$\mathrm{d}w_{\mathrm{bs}}/\mathrm{d}t = -\mathrm{d}w_{\mathrm{st}}/\mathrm{d}t$ (micro–macro exchange equation)	$\frac{\mathrm{d}w_{\mathrm{bs}}}{\mathrm{d}t} = \rho_{\mathrm{w}} k_{\mathrm{mi}} E_{\mathrm{mi}} \left(\frac{1}{w_{\mathrm{bs}}} - \frac{1}{w_{\mathrm{bs}}^{\mathrm{eq}}}\right)$	$k_{\mathrm{mi}} E_{\mathrm{m}} = A\,(W_{\mathrm{M}} - W_{\mathrm{N}})^2$

E_{ma} and E_{mi} are surface charge potential of particles outside and inside primary peds (J/kg soil); σ is microporal water at the skin surface of primary peds ($\approx$0.01 kg/kg); D is the fractal diameter of the interpedal pore space; and A is the time constant of the swelling curve. *Source*: From Ref.[15].

WATER POTENTIAL AND CONDUCTIVITY IN PEDOSTRUCTURE: EQUATIONS AND PARAMETERS

Two water potential modeling approaches were adapted by Braudeau and Mohtar[15] to the pedostructure concept, namely, fractal[16] and thermodynamic approaches.[17,18] Analysis of modeled and observed results showed that the tensiometric curve, for its entire range of measurement, is directly linked to the interped water pool W_{ma}. Both the modified fractal and thermodynamical equations [Eqs. (10) and (11)] fit well the experimental tensiometric curves:

$$\frac{h_{\mathrm{ma}}}{h_{\mathrm{ma}}^{\mathrm{o}}} = \left(\frac{W_{\mathrm{ma}}}{\rho_{\mathrm{w}} V} + \frac{V_{\mathrm{mi}}}{V_{\mathrm{sat}}}\right)^{1/(D-3)} \tag{10}$$

where $h_{\mathrm{ma}}^{\mathrm{o}}$ is the water potential at saturation (W_{L}) and D the fractal dimension, and

$$h_{\mathrm{ma}} = \frac{\rho_{\mathrm{w}} E_{\mathrm{ma}}}{W_{\mathrm{ma}} + \sigma} - \frac{\rho_{\mathrm{w}} E_{\mathrm{ma}}}{W_{\mathrm{L}} - W_{\mathrm{M}} + \sigma} \tag{11}$$

where E_{ma} is the potential energy of surface of peds (joules/kg soil) and σ is a part of primary peds water content, which intervenes in the water layer and surface of peds interaction.[15]

The good fit of Eq. (10) to experimental data shows that the ''natural'' partition of the medium into aggregates agrees with a fractal description of which the fractal dimension is D. Braudeau and Mohtar[15] also showed that the fractal equation has the same expression for the capillary approach (meniscus curvature radius) than for the osmotic approach (thickness of the structured water film on the surfaces of pores and particles). Thus, this equation can be used to calculate the hydraulic conductivity for the two approaches.

CONCEPTUAL REPRESENTATIVE ELEMENTARY VOLUME OF PEDOSTRUCTURE

The conceptual representative elementary volume of the pedostructure is shown in Fig. 3. This representation integrates all the functional volumes and their variables.

Arrows represent the water flow exchange and the Darcian transfers. The pedohydral functions and parameters of the soil fabric are summarized in Table 1.

The shrinkage curve and the swelling curve represent, via the medium variables' geometrical relationships and the micro–macro water exchange equation (Eq. (c) in Fig. 3), the state of equilibrium of the soil–water–air configurations of the pedostructure and the dynamics of the pedostructure, respectively. The tensiometric and conductivity curves are the parametric variables of Darcy's law extended to the unsaturated soil medium that is described by the pedostructure model.

CONCLUSION

This article presented a comprehensive conceptual REV soil water model of the soil fabric, namely, pedostructure, with physically based functions and parameters describing the dynamics and equilibrium of a well-defined structured soil–air–water medium. The parameters of this characterization are based on the hydrostructural function of this soil fabric and are defined by the shrinkage curve, the swelling curve, the tensiometric curve, and the conductivity curve. The ability of the pedostructure concept to form the basis of the determination of soil water properties gives the physical meaning of some important agronomic concepts such as wilting point and field capacity that up until now are considered empirical. Thus, PTFs used for estimating these agronomic concepts can be used for the physically based parameters of the pedostructure model.[12]

Soil Water: Hysteresis

Dan Jaynes
National Soil Tilth Laboratory, Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Ames, Iowa, U.S.A.

INTRODUCTION

Since at least the early work of Haines,[1] it has been recognized that volumetric soil water content, θ, and hydraulic conductivity, K, are not singular functions of soil water pressure head, h, but rather exhibit considerable variation depending on the wetting and drying history of the soil.[2,3] The non-uniqueness or hysteresis in $\theta(h)$ and $K(h)$ appears to be an ubiquitous phenomenon in porous materials and the magnitude of the effect is intimately related to the pore distribution of the material. However, numerous studies have shown that when K is expressed as a function of θ instead of h, hysteresis either disappears[4–8] or is so slight as to be masked by the error of the measurements. By expressing K as a function of θ instead of h, it can be treated as a non-hysteretic function. Thus, the focus here is on the hysteretic nature of $\theta(h)$, which for brevity will be termed simply hysteresis.

BACKGROUND INFORMATION

Fig. 1 illustrates the hysteretic θ–h relation for a hypothetical soil. The curve S–P_c represents drying from total saturation where θ equals the total soil porosity, φ, to a point where the hysteresis curves close together, often equal to the limit of measurement or considered the residual water content of the soil. Upon wetting from a dry condition, $\theta(h)$ follows the curve P_c–E–D, the main wetting curve. The water content at D is the effective or ''field saturated'' water content of the soil which is usually less than φ because of entrapped air in some soil pores during wetting. Given sufficient time, the entrapped air will diffuse into the soil water, and the water content at $h = 0$ will approach φ.[9,10] When the soil dries from the field saturated water content $\theta(h)$, follows the curve D–P_a–P_c which is the main drying curve. The loop D–P_a–P_c–E–D is often called the reproducible boundary hysteresis loop. Point P_w in Fig. 1 represents the water-entry pressure head—the pressure head at which the main wetting curve reaches the saturated water content—while P_a represents the air-entry pressure head, the pressure head at which the soil first starts to lose water when drying from field saturation.

The main hysteresis curves are followed when the soil is dried from field saturation or wetted from the residual water content. Curves that depart from the main, or boundary curves between the points P_w and P_c are called primary wetting and drying curves. Primary drying curves (e.g., A–B–P_c in Fig. 1) are followed when the wetting process reverses before the soil water content reaches P_w. Primary wetting curves (e.g., C–F–D in Fig. 1) are followed when the drying process reverses before the soil dries to point P_c. Additional reversals in the wetting or drying cycle will result in secondary and higher order scanning curves. A secondary drying curve is illustrated by curve F–G–C in Fig. 1.

Several factors affect hysteresis in the field and laboratory. While, $\theta(h)$ depends on the temperature at which it is measured, the magnitude of the hysteresis effect does not appear to change.[11–13] The magnitude of the measured hysteretic effect is dependent on the rate at which the water content of the soil is changed when making the measurements.[5,14] Measurements made during unsteady flow conditions tend to overestimate the amount of water held at a given pressure head during drying and underestimate the water content during wetting when compared to steady-state or static-equilibrium conditions. This observation is important because most measurements of hysteresis are made during unsteady conditions, because the measurements can be completed more rapidly. Transient-state measurements should be treated with caution since they are influenced not only by the water holding characteristics of the soil, but also by the $K(\theta)$ characteristics.

Measuring hysteresis in $\theta(h)$, whether in the laboratory[15] or field,[16] is difficult and time consuming because both θ and h must be measured over a wide range of water contents, and the drier soil conditions are often difficult to establish in the field, especially for fine-grained soils with low hydraulic conductivities. Consequently, almost all measurements of hysteresis have been on disturbed, coarse-grained soils in the laboratory, and most observations of the impact of hysteresis on soil water relations have been made in the laboratory or by numerical simulation. However, hysteresis has been measured in the field for both sand and clay soils[17,18] and shown to be of the same magnitude as measured in laboratory experiments. Thus,

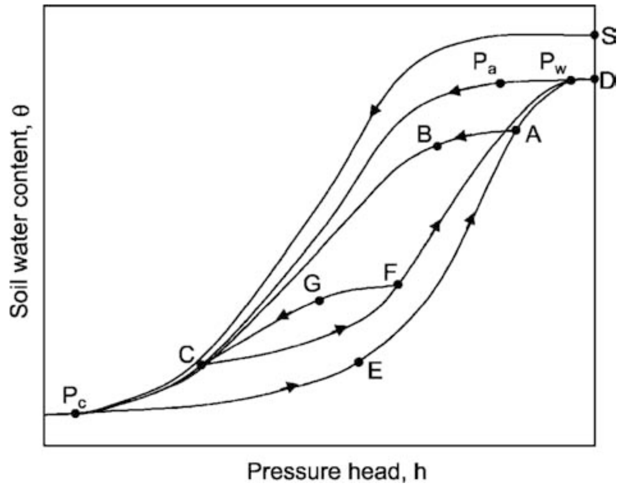

Fig. 1 Hysteretic soil water content, θ–pressure head, h, relation for a typical soil.

the impacts of hysteresis observed in the laboratory should be the same as in the field.

Hysteresis in $\theta(h)$ implies that to completely characterize the state of water in the soil, not only do θ and h need to be known, but also the wetting and drying history of the soil as well. For a hysteretic soil, the specific soil pores that are filled with water depend on the wetting and drying history of the soil. Thus, all transport processes in soil, including infiltration, evaporation, and chemical movement can be affected by hysteresis.

IMPLICATIONS OF HYSTERESIS

Results from laboratory column experiments and model simulations show the effect of hysteresis to depend very much on the $K(\theta)$ relation. For soils with very steep $K(\theta)$–$\theta(h)$ relations, the effect of hysteresis on processes such as water redistribution is minimal.[19] Hysteresis effects are greatest in soils with large differences in the wetting and drying curves for $\theta(h)$ and with a $K(\theta)$ that does not decrease rapidly. In these soils, the following generalizations can be made.

Infiltration/Redistribution

Hysteresis can have a profound effect on the redistribution of water after infiltration. Following infiltration, the wetted profile switches from a wetting process to a drying process, while at the wetting front the soil is still undergoing wetting. With hysteresis, a relatively large change in h will produce only a small change in θ when a drying scanning curve is followed (e.g., A–B–P_c in Fig. 1) compared to the change in θ if no hysteresis was present and the θ–h relation followed only a single curve such as the main wetting or drying curve (e.g., A–E–P_c in Fig. 1). The effect of hysteresis is to hold water in the upper reaches of the soil profile and to slow redistribution of water after infiltration has ceased, keeping the deeper soil profile drier.[3,19–24]

Evaporation

Hysteresis will cause the soil surface to remain wetter after infiltration. Thus, under a constant evaporative demand, hysteresis will cause more evaporation from the soil after an infiltration event because deep drainage is slowed.[19,25,26] If, however, the evaporative demand is cyclical causing the soil surface to dry during the day and rewet at night, evaporation from the soil will decrease because hysteresis will slow the nightly rewetting process at the soil surface resulting in less moisture near the surface available for evaporation the following day.[27]

Water Table Response

The response of a phreatic aquifer can be influenced by hysteresis. Water table rise in response to infiltration will be faster for a water table that had been falling than for one that had been rising.[28–30] For the wetter half of the hysteresis loop, the same increase in water content will cause a much larger change in h when $\theta(h)$ follows a primary rewetting curve than when it follows the main wetting curve. As a result, hysteresis will tend to cause water table heights to rise and seepage faces to develop much more rapidly during infiltration events in soils with falling water tables than in soils with rising water tables. The capillary fringe of a water table will also be affected by whether the water table is rising or falling. A rising water table will follow the wetting curve P_c–E–D and the height of the capillary fringe will be equal to the difference in pressure heads at points P_w and D. A falling water table will follow the drying curve D–P_a–P_c and the height of the capillary fringe will be equal to the difference in pressure heads at points D and P_a. In shallow aquifers, the greater capillary fringe thickness in the falling water table can cause significantly greater lateral flow rates[31] than for a rising water table.

Solute Movement

Hysteresis tends to reduce the redistribution of water from wetted areas of the soil to drier areas. Thus during redistribution, hysteresis will retard the rate of downward movement of solute added with irrigation water relative to movement in a soil without hysteresis.[23,32] Slightly less hydrodynamic dispersion is also expected because the infiltrating water is restricted to a smaller area of the soil profile.[32,33] Similarly, hysteresis will tend to decrease the leaching of a solute already present in a soil profile.[33]

Soil Water: Plant-Available

Judy A. Tolk
Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Bushland, Texas, U.S.A.

INTRODUCTION

The soil stores the water used by plants to sustain life. The amount of soil water that can be used by the plant varies, due to characteristics of the soil (e.g., texture) and of the plant (e.g., root distribution and depth). Knowledge of the amount of water available to the plant, or plant available water (PAW), is needed to determine the agricultural or ecological potential of soils and is used in many agronomic applications, such as irrigation scheduling programs or crop production models. It helps define the water content limits beyond which plant growth is affected because of insufficient or excessive amounts of water, or beyond which water is lost out of the root zone due to deep percolation. The water content is typically expressed on a weight ($g\,m^{-3}$) or volume ($m^3\,m^{-3}$) basis.

Another term associated with PAW is the non-limiting water range, which is defined as the region bounded by the upper and lower soil water content over which water, oxygen, and mechanical resistance are not limiting to plant growth.[1] The two soil water content boundaries that help determine PAW are the upper or ‘‘full’’ boundary, which is referred to as field capacity (FC), and the lower or ‘‘dry’’ boundary, or the permanent wilting point (PWP). Field capacity has been defined as the water remaining in the soil two to three days after having been wetted with water and after free drainage is negligible.[1] Permanent wilting point has been defined as the largest water content of a soil at which indicator plants, growing in that soil, wilt and fail to recover when placed in a humid chamber.[1] Both boundaries are not ‘‘sufficiently precise or general to be much more than a rough index,’’ according to an uncited quotation in Ref.[2]. In the field, determining when drainage is ‘‘negligible’’ is extremely difficult; soils often have complex horizons with different water-holding characteristics; and plants may root differently from their genetically predetermined pattern due to soil physical and chemical characteristics or environmental conditions. Also, soil water determined as ‘‘available water’’ is not necessarily the portion of water that can be absorbed by all plants, but can be plant specific.[1] Richards[3] stated that ‘‘availability’’ involved both the ‘‘ability of the plant root to absorb and use the water with which it is in contact,’’ and the ‘‘readiness with which the soil water moves in to replace that which has been used by the plant.’’

Water moves through the soil and plant in response to gradients in the potential energy of the water, going from regions of higher water potential to those with lower water potential. Water potential (ψ) is the measure of the free energy status of water and its ability to do work, which can be changed by the presence of solutes (osmotic potential), pressure (pressure potential), gravity (gravitational potential), and components which bind with water molecules (matric potential). For water to be available to a plant, the plant's roots first must be present; water must move through the soil to the root, pass into the root, and travel from the root to the leaf surface; and the rate of water supply must be able to meet transpiration requirements and maintain cellular functions. At high evaporation rates, the soil may be unable to transport enough water to meet transpiration demands and the plant may go into water stress at higher soil water contents than it would at lower evaporation rates.

CROP ROOTING CHARACTERISTICS

The characteristics of a root system depend upon heredity, but may be modified by environmental factors such as soil texture, depth, moisture content, mineralogy, chemistry, aeration, and solute concentration.[4] Monocots develop fibrous root systems, while dicots tend to have taproot systems (Fig. 1) that can take many different forms.[5] A species may always be deep rooted, or always shallow rooted, while still others develop different types of root systems in different types of soils. The age of the plant also determines rooting patterns and water uptake as well. As a plant grows, its roots extend downward and outward at varying rates. Kaigama et al.[6] reported rates of root extension for grain sorghum (*Sorghum bicolor* Moench.) of one to two centimeters a day. The rate of exploration by roots is controlled primarily by plant vigor and by soil environmental conditions, especially temperature, moisture, and strength.[5] Warm, moist soil encourages root development while increased soil strength can severely restrict it. As a plant matures, many roots die or lose much of their ability to absorb water. The success of cultivated plants subjected to

Fig. 1 The fibrous root system (left) of witchgrass (*Panicum capillare* L.) and the taproot (right) of cotton (*Gossypium hirsutum* L.).

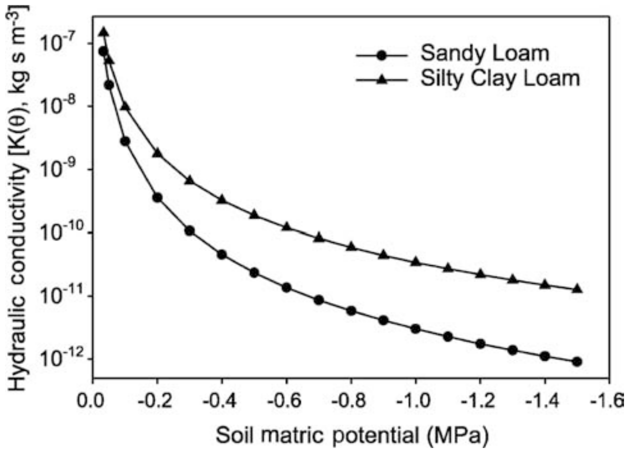

Fig. 2 Approximate hydraulic conductivity of a sandy loam and a silty clay loam in a range of soil matric potentials within plant available water (-0.033 to -1.5 MPa) as determined by the pressure outflow apparatus.

drought may depend on the development of deep, profusely branched root systems that absorb water from a large volume of soil.[4]

WATER MOVEMENT THROUGH THE SOIL

Most of the water flow through the soil can be described by Darcy's law, given as

$$J_w = -K(\psi)(d\psi/dz) \tag{1}$$

where J_w is the water flux density ($kg\,m^{-2}\,sec^{-1}$) in a soil with hydraulic conductivity $K(\psi)$ ($kg\,sec\,m^{-3}$), and water potential gradient $d\psi/dz$ ($J\,kg^{-1}\,m^{-1}$ or $m\,sec^{-2}$) with the components of water potential most responsible for flow being the matric and gravitational potentials.[7] Water flow through the soil in the range of PAW is determined by its unsaturated hydraulic conductivity, which can be approximated by Campbell and Norman[7]

$$K(\psi) = K_s(\psi_e/\psi)^{2+3/b} \tag{2}$$

where ψ_e is air entry water potential and K_s is the saturated conductivity of the soil. The parameter b is the exponent of the moisture release equation which, along with ψ_e and K_s, depends on soil physical characteristics such as texture. As the size of the pore space in a soil decreases (coarse textured to fine textured), the air entry potential decreases and b increases, resulting in unsaturated conductivity that is higher for finer-textured soils than coarse-textured ones (Fig. 2).

WATER MOVEMENT THROUGH THE PLANT

The ultimate destination for most of the soil water moving into a plant is the leaf surface, where it is lost as vapor through the stomatal pore. The driving gradient to move the liquid water from the root to the leaf is the water potential gradient between them. The resistances to flow through this system has been compared to a resistor network in an electric circuit, where water and current flow are analogous and can be described using Ohm's law in the form of[7]

$$U = (\psi_s - \psi_L)/(R_R + R_L) \tag{3}$$

where U is the rate of water uptake, ψ_S is the soil water potential, ψ_L is the leaf water potential, R_R is the root resistance, and R_L is the leaf resistance. The root resistance varies with the permeability of the root due to age or distance from the root apex, and changes due to dehydration, temperature, rate of water flow, or time of day.[4] Leaf resistance is affected by the location, size, shape, and abundance of stomata; environmental conditions affecting stomatal activity; and the size of the boundary layer surrounding the leaf, which is determined by the size and shape of the leaf and wind speed. At the leaf's surface, the sun's energy converts the water from a liquid to vapor state in the substomatal cavity. A vapor pressure gradient must then move the water vapor through the stomatal pore and boundary layer into the atmosphere surrounding the leaf. As the vapor pressure deficit between leaf and air increases, the demand for water flow through the soil and the plant also increases, with the rate of vapor loss also being controlled in part by the size of the stomatal opening.

MEASUREMENT OF PAW

The upper and lower boundaries that help determine PAW are FC and PWP. No simple, accurate method exists for either field or laboratory determinations. Numerous methods are available to approximate these boundaries, with procedures and limitations to the results outlined in Ref.[8]. A commonly used procedure is laboratory measurements using a pressure outflow apparatus. In this method, a soil sample is placed on a porous ceramic plate or permeable membrane in a chamber and saturated with water. Pressure is applied to the samples until equilibrium soil water contents at matric potentials of -1.5 MPa for PWP and -0.033 MPa for FC are achieved.[8] Among the many other methods developed to determine these boundaries are ones based on soil texture and bulk density;[9] bulk density, particle density, and particle-size distribution curve,[10] and electrical conductivity.[11]

Ideally, PAW should be measured in the field for each crop and soil combination. Field capacity is primarily a function of soil properties, while PWP is a function of a combination of soil, plant, and environmental factors. Fig. 3 shows the differences between measured lower limits of water use (θ_{LL}), or approximate PWP, for corn (*Zea mays* L.), grain sorghum, and wheat (*Triticum aestivum* L.) and soil water contents measured at -1.5 MPa matric potential ($\theta_{-1.5}$) using the pressure outflow apparatus procedures. The crops were grown in lysimeters containing a monolithic soil core of Ulysses silt loam (fine-silty, mixed, superactive, mesic Aridic Haplustoll), which is a deep, uniform soil formed in calcareous loess. Soil water content data were collected at harvest using neutron scattering. The vertical, dashed line represents the ''zero'' point of $\theta_{-1.5}$ such that values to the left of the dashed line represent the field-measured water contents less than $\theta_{-1.5}$ and those to the right the field-measured water contents greater than $\theta_{-1.5}$. Volumetric water contents were converted to mm by multiplying it by the measurement depth. Summed for the 2.2-m profile, grain sorghum used 46 mm and wheat 65 mm more than that summed for $\theta_{-1.5}$, while corn was similar to $\theta_{-1.5}$ levels. All crops showed a distinct decline in soil water use at the 0.9-m depth, possibly associated with

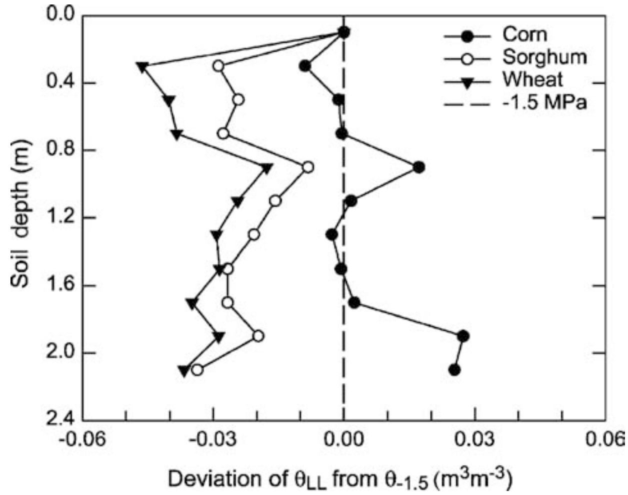

Fig. 3 The deviation of the lower limit of water extraction by corn, grain sorghum, and wheat (θ_{LL}) from the soil water content measured at 1.5 MPa ($\theta_{-1.5}$) by the pressure flow apparatus in a lysimeter containing a monolithic core of Ulysses silt loam. Data points to the left of the vertical dashed line indicate that the crop used more water than that at $\theta_{-1.5}$ and to the right it used less than $\theta_{-1.5}$.

the abrupt increase in bulk density in that layer compared with the layers above and below (data not shown). Fig. 3 shows the variability in lower limit of water availability among crops and the difference from $\theta_{-1.5}$. The figure suggests that PWP determined by laboratory methods is similar to field-measured PWP of

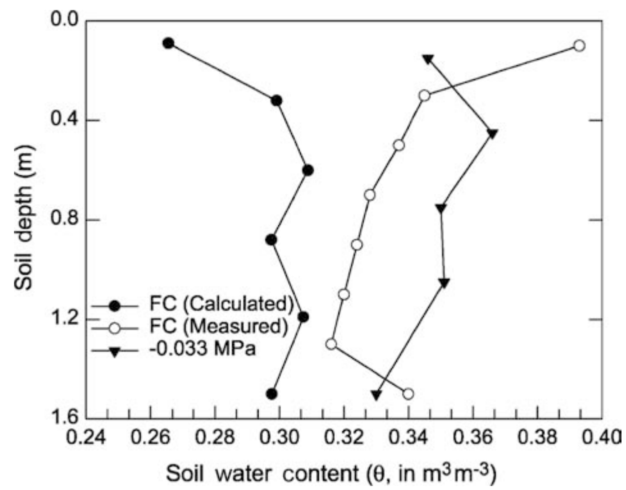

Fig. 4 Field capacity (FC) by depth of a monolithic soil containing Pullman clay loam measured by neutron scattering after the core was saturated and allowed to drain (open circles), calculated from equations of Ritchie, Gerakis, and Suleiman using measured bulk density and percentages of sand and clay for the soil horizons (closed circles), and measured by the pressure outflow apparatus at 0.033 MPa pressure (triangles). *Source*: From Ref.[9].

short season corn, but not necessarily to that of grain sorghum or wheat.

Measurement of FC can be equally as problematic. Cassel and Nielsen[8] stated that ‘‘personal experiences suggest that the uncertainty in FC is greater than that for PWP’’ with ‘‘no good alternative for measuring FC other than the in situ field method.’’ Fig. 4 shows FC measured by neutron scattering in a lysimeter (same dimensions as above) containing a monolithic soil core of Pullman clay loam (fine, mixed, superactive, thermic Torrertic Paleustoll). Also shown is water contents measured at 0.033 MPa by the pressure outflow apparatus and FC calculated using procedures outlined by Ritchie, Gerakis, and Suleiman[9] The calculated FC required textural analysis for the clay and sand proportions as well as bulk density, which was determined from samples taken at the lysimeter monolith collection site. Converted from volumetric water contents and summed for the 1.5-m depth, the measured FC was 507 mm, the calculated was 447 mm, and the laboratory method was 523 mm.

CONCLUSION

Knowledge of PAW is important for determining the agricultural and ecological potentials of a soil and the best management practices that maximize crop productivity and minimize water losses. Laboratory determination of both FC and PWP is usually adequate for most applications, but the user must be aware of its limitations (Figs. 3 and 4). Soil texture, structure, layering, and chemistry along with crop type, rooting characteristics, stage of development, as well as environment are just some of the many factors that can impact PAW. The procedures for more accurate determination of PAW are often complicated, requiring specialized equipment and an extensive number of measurements, because it is a function of the interactions between the plant, the soil, and the environment.

Soil Water: Salinity Measurement

Dennis L. Corwin
U.S. Department of Agriculture (USDA), Riverside, California, U.S.A.

INTRODUCTION

The measurement of soil salinity is a quantification of the total salts present in the liquid portion of the soil. The measurement of soil salinity is important in agriculture because salinity reduces crop yields by 1) making it more difficult for the plant to extract water; 2) causing specific-ion toxicity; 3) influencing the soil permeability and tilth; and/or 4) upsetting the nutritional balance of plants. A discussion of the basic principles, methods, and equipment for measuring soil salinity is presented. The concise discussion provides a basic knowledge of the background, latest equipment, and current accepted methodologies for measuring soil salinity with suction cup extractors, porous matrix/salinity sensors, electrical resistivity, electromagnetic induction (EM), and time domain reflectometry (TDR).

SOIL SALINITY: DEFINITION, EFFECTS, AND GLOBAL IMPACTS

Soil salinity refers to the presence of major dissolved inorganic solutes in the soil aqueous phase, which consist of soluble and readily dissolvable salts including charged species (e.g., Na^+, K^+, Mg^{+2}, Ca^{+2}, Cl^-, HCO_3^-, NO_3^-, SO_4^{-2}, and CO_3^{-2}), non-ionic solutes, and ions that combine to form ion pairs. The predominant mechanism causing the accumulation of salt in irrigated agricultural soils is loss of water through evapotranspiration, leaving ever increasing concentrations of salts in the remaining water. Effects of soil salinity are manifested in loss of stand, reduced plant growth, reduced yields, and in severe cases, crop failure. Salinity limits water uptake by plants by reducing the osmotic potential making it more difficult for the plant to extract water. Salinity may also cause specific-ion toxicity or upset the nutritional balance of plants. In addition, the salt composition of the soil water influences the composition of cations on the exchange complex of soil particles, which influences soil permeability and tilth. Irrigated agriculture, which accounts for 35–40% of the world's total food and fiber, is adversely affected by soil salinity on roughly half of all irrigated soils (totaling about 250 million ha) with over 20 million ha severely effected by salinity worldwide.[1] Because of these detrimental impacts, the measurement, monitoring, and real-time mapping of soil salinity is crucial to sustaining world agricultural productivity.

METHODS OF SOIL SALINITY MEASUREMENT

Historically, five methods have been developed for determining soil salinity at field scales: 1) visual crop observations; 2) the electrical conductance of soil solution extracts or extracts at higher than normal water contents; 3) in situ measurement of electrical resistivity; 4) non-invasive measurement of electrical conductance with EM; and most recently 5) in situ measurement of electrical conductance with TDR.

Visual Crop Observation

Visual crop observation is a quick and economical method, but it has the disadvantage that salinity development is detected after crop damage has occurred. For obvious reasons, the least desirable method is visual observation because crop yields are reduced to obtain soil salinity information. However, remote imagery is increasingly becoming a part of agriculture and potentially represents a quantitative approach to visual observation. Remote imagery may offer a potential for early detection of the onset of salinity damage to plants.

Electrical Conductivity of Soil Solution Extracts

The determination of salinity through the measurement of electrical conductance has been well established for decades.[2] It is known that the electrical conductivity (EC) of water is a function of its chemical composition. McNeal, Oster, and Hatcher[3] were among the first to establish the relationship between EC and molar concentrations of ions in the soil solution. Soil salinity is quantified in terms of the total concentration of the soluble salts as measured by the EC of the solution in dS m^{-1}.[2] To determine EC, the soil solution is placed between two electrodes of constant geometry and distance of separation.[4]

At constant potential, the current is inversely proportional to the solution's resistance. The measured conductance is a consequence of the solution's salt concentration and the electrode geometry whose effects are embodied in a cell constant. The electrical conductance is a reciprocal of the resistance [Eq. (1)]:

$$EC_t = k/R_t \quad (1)$$

where EC_t is the EC of the solution in $dS\,m^{-1}$ at temperature t (EC), k is the cell constant, and R_t is the measured resistance at temperature t. One $dS\,m^{-1}$ is equivalent to $1\,mmho\,cm^{-1}$.

Customarily, soil salinity has been defined in terms of laboratory measurements of the EC of the saturation extract (EC_e), because it is impractical for routine purposes to extract soil water from samples at typical field water contents. Partitioning of solutes over the three soil phases (i.e., gas, liquid, and solid) is influenced by the soil–water ratio at which the extract is made, so the ratio must be standardized to obtain results that can be applied and interpreted universally. Commonly used extract ratios other than a saturated soil paste are 1:1, 1:2, and 1:5 soil–water mixtures.

Soil salinity can also be determined from the measurement of the EC of a soil solution (EC_w). Theoretically, EC_w is the best index of soil salinity because this is the salinity actually experienced by the plant root. Nevertheless, EC_w has not been widely used to express soil salinity for various reasons: 1) it varies over the irrigation cycle as the soil water content changes and 2) methods for obtaining soil solution samples are too labor, and cost intensive at typical field water contents to be practical for field-scale applications.[5] For disturbed samples, soil solution can be obtained in the laboratory by displacement, compaction, centrifugation, molecular adsorption, and vacuum- or pressure-extraction methods. For undisturbed samples, EC_w can be determined either in the laboratory on a soil solution sample collected with a soil-solution extractor or directly in the field by using in situ, imbibing-type porous-matrix salinity sensors.

There are serious doubts about the ability of soil solution extractors and porous matrix salinity sensors (also known as soil salinity sensors) to provide representative soil water samples.[6–8] Because of their small sphere of measurement, neither extractors nor salt sensors adequately integrate spatial variability;[9–11] consequently, Biggar and Nielsen[12] suggested that soil solution samples are "point samples" that can provide qualitative measurement of soil solutions, but not quantitative measurements unless the field-scale variability is established. Furthermore, salinity sensors demonstrate a response time lag that is dependent upon the diffusion of ions between the soil solution and solution in the porous ceramic, which is affected by 1) the thickness of the ceramic conductivity cell; 2) the diffusion coefficients in soil and ceramic; and 3) the fraction of the ceramic surface in contact with soil.[13] The salinity sensor is generally considered the least desirable method for measuring EC_w because of its low sample volume, unstable calibration over time, and slow response time.[14]

Electrical Resistivity

Because of the time and cost of obtaining soil solution extracts, developments in the measurement of soil EC have shifted to the measurement of the soil EC of the bulk soil, referred to as the apparent soil electrical conductance (EC_a). The apparent soil EC measures the conductance through not only the soil solution but also through the solid soil particles and via exchangeable cations that exist at the solid–liquid interface of clay minerals. The techniques of electrical resistivity, EM, and TDR measure EC_a.

Electrical resistivity methods introduce an electrical current into the soil through current electrodes at the soil surface and the difference in current flow potential is measured at potential electrodes that are placed in the vicinity of the current flow (Fig. 1). These methods were developed in the second decade of the 1900s by Conrad Schlumberger in France and Frank Wenner in the United States for the evaluation of ground electrical resistivity.[16,17]

The electrode configuration is referred to as a Wenner array when four electrodes are equidistantly spaced in a straight line at the soil surface with the two outer electrodes serving as the current or transmission electrodes and the two inner electrodes serving as the potential or receiving electrodes.[18] The depth of penetration of the electrical current and the volume of measurement increase as the inter-electrode spacing, a, increases. For a homogeneous soil, the soil volume measured is roughly Πa^3. There are additional electrode configurations that are frequently used, as discussed by Burger,[16] Telford et al.,[17] and Dobrin.[19]

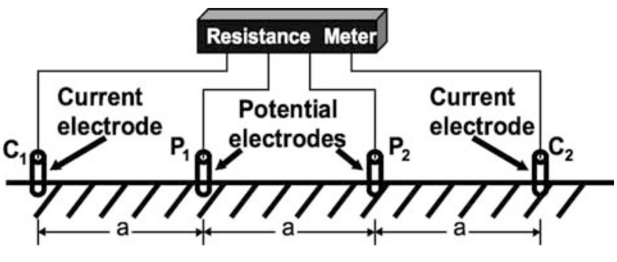

Fig. 1 Schematic of electrical resistivity of four electrodes (the Wenner array configuration). C_1 and C_2 represent the current electrodes, P_1 and P_2 represent the potential electrodes, and a represents the inter-electrode spacing. *Source*: Modified from Rhoades and Halverson.[15]

Scaling–Soil Water

By mounting the electrodes to ''fix'' their spacing, considerable time for a measurement is saved. A tractor-mounted version of the ''fixed-electrode array'' has been developed that geo-references the EC_a measurement with a GPS.[20–22] The mobile, ''fixed-electrode array'' equipment is well suited for collecting detailed maps of the spatial variability of average root zone soil electrical conductivity at field scales and larger. Veris Technologies[a] has developed a commercial mobile system for measuring EC_a using the principles of electrical resistivity.

Electrical resistivity (e.g., the Wenner array) and EM, are both well suited for field-scale applications because their volumes of measurement are large, which reduces the influence of local-scale variability. However, electrical resistivity is an invasive technique that requires good contact between the soil and four electrodes inserted into the soil; consequently, it produces less reliable measurements in dry, frozen, or stony soils than the non-invasive EM measurement. Nevertheless, electrical resistivity has a flexibility that has proven advantageous for field application, i.e., the depth and volume of measurement can be easily changed by altering the spacing between the electrodes.

Electromagnetic Induction

A transmitter coil located at one end of the EM instrument induces circular eddy-current loops in the soil with the magnitude of these loops directly proportional to the EC in the vicinity of that loop. Each current loop generates a secondary electromagnetic field that is proportional to the value of the current flowing within the loop. A fraction of the secondary induced electromagnetic field from each loop is intercepted by the receiver coil of the instrument and the sum of these signals is amplified and formed into an output voltage which is related to a depth-weighted soil EC_a. The amplitude and phase of the secondary field will differ from those of the primary field as a result of soil properties (e.g., salinity, water content, clay content, bulk density, and organic matter), spacing of the coils and their orientation, frequency, and distance from the soil surface.[23]

The two most commonly used EM conductivity meters in soil science and in vadose zone hydrology are the Geonics[b] EM-31, and EM-38. The EM-38 (Fig. 2) has had considerably greater application for agricultural purposes because the depth of measurement corresponds roughly to the root zone (i.e., 1.5 m), when the instrument is placed in the vertical coil configuration. In the horizontal coil configuration, the depth of the measurement is 0.75–1.0 m. The operation of the EM-38 equipment is discussed in Hendrickx and Kachanoski.[23]

Mobile EM equipment developed at the Salinity Laboratory[20,22] is available for appraisal of soil salinity and other soil properties (e.g., water content and clay content) using an EM-38. Recently, the mobile EM equipment developed at the Salinity Laboratory was modified by the addition of a dual-dipole EM-38 unit (Fig. 3). The dual-dipole EM-38 conductivity meter simultaneously records data in both dipole orientations (horizontal and vertical) at time intervals of just a few seconds between readings. The mobile EM equipment is suited for the detailed mapping of EC_a and correlated soil properties at specified depth intervals through the root zone. The advantage of the mobile dual-dipole EM equipment over the mobile ''fixed-array'' resistivity equipment is the EM technique is non-invasive so it can be used in dry, frozen, or stony soils that would not be amenable to the invasive technique of the ''fixed-array'' approach due to the need for good electrode–soil contact. The disadvantage of the EM approach would be that the EC_a is a depth-weighted value that is non-linear with depth McNeill.[24]

Time Domain Reflectometry

TDR was initially adapted for use in measuring water content. Later, Dalton et al.[25] demonstrated the utility of TDR to also measure EC_a, based on the attenuation of the applied signal voltage as it traverses the medium of interest[26]. Advantages of TDR for measuring EC_a include 1) a relatively non-invasive nature; 2) an ability to measure both soil water content and EC_a; 3) an ability to detect small changes in EC_a under representative soil conditions; 4) the capability of obtaining continuous unattended measurements; and 5) a lack of a calibration requirement for soil water content measurements in many cases.[26]

Soil EC_a has become one of the most reliable and frequently used measurements to characterize field variability for application to precision agriculture due to its ease of measurement and reliability[27]. Although TDR has been demonstrated to compare closely with other accepted methods of EC_a measurement,[28–31] it is still not sufficiently simple, robust, or fast enough for the general needs of field-scale soil salinity assessment.[5] Only electrical resistivity and EM have been adapted for the geo-referenced measurement of EC_a at field scales and larger.[5,27]

Details for conducting a field-scale EC_a survey can be found in Corwin and Lesch.[32]

FACTORS INFLUENCING THE APPARENT SOIL ELECTRICAL CONDUCTIVITY MEASUREMENT

Three pathways of current flow contribute to the apparent soil EC (EC_a) of a soil: 1) a liquid phase pathway via salts contained in the soil water occupying the large pores; 2) a solid–liquid phase pathway primarily via exchangeable cations associated with clay minerals; and 3) a solid pathway via soil particles that are in direct and continuous contact with one another.[5] Because of the three pathways of conductance, the EC_a measurement is influenced by several soil physical and chemical properties: 1) soil salinity; 2) saturation percentage; 3) water content; and 4) bulk density. The saturation percentage and bulk density are both closely associated with the clay content. Measurements of EC_a as a measure of soil salinity must be interpreted with these influencing factors in mind.

Another factor influencing EC_a is temperature. Electrolytic conductivity increases at a rate of approximately 1.9% per °C increase in temperature. Customarily, EC is expressed at a reference temperature of 25EC for purposes of comparison. The EC (i.e., EC_a, EC_e, or EC_w) measured at a particular temperature t (°C), EC_t, can be adjusted to a reference EC at 25°C, EC_{25}, using the following equations from Handbook 60:[2]

$$EC_{25} = f_t \cong \mathrm{EC}_t \tag{2}$$

Fig. 3 Mobile dual-dipole EM-38 equipment for the continuous measurement of EC_a. Dual-dipole EM meter rests in the tail section or sled at the rear of the vehicle with a GPS antenna overhead at the midpoint of the meter.

where

$$f_t = 1 - 0.20346(t) + 0.03822(t^2) - 0.00555(t^3)$$

Traditionally, EC_e has been the standard measure of salinity used in all salt-tolerance plant studies. As a result, a relation between EC_a and EC_e is needed to relate EC_a back to EC_e, which in turn is related to crop yield.

Soil Water: Sensor-Based Automatic Irrigation of Vegetable Crops

Michael D. Dukes
Rafael Muñoz-Carpena
Agricultural and Biological Engineering Department, University of Florida, Gainesville, Florida, U.S.A.

INTRODUCTION

Improving irrigation efficiency can contribute greatly in reducing production costs of vegetables, making the industry more competitive and sustainable. Through proper irrigation, average vegetable yields can be maintained (or increased) while minimizing environmental impacts caused by application of excess water and subsequent nutrient leaching. Recent technological advances have made soil water sensors available for efficient and automatic operation of irrigation systems. Automatic soil water sensor-based irrigation requires maintenance of a desired soil water range in the root zone that is optimal for plant growth. The target soil water status is usually set in terms of soil tension or matric potential (expressed in kPa or cbar, 1 kPa = 1 cbar), or volumetric moisture (expressed in vol.% of water in a volume of undisturbed soil). Another benefit of automatic irrigation techniques is convenience. In a previous experience working with a soil moisture-based automatic irrigation system, Dukes et al.[1] found that once such a system is set up and verified, only weekly observation is required. This type of system adapts to the amount of water applied according to plant needs and actual weather conditions throughout the season. This translates not only into convenience for the manager but into substantial water savings compared to irrigation management based on average historical weather conditions.

Although soil water status can be determined by *direct* (soil sampling) and *indirect* (soil moisture sensing) methods, direct methods of monitoring soil moisture are not commonly used for irrigation scheduling because they are intrusive and labor intensive and they cannot provide immediate feedback. Soil moisture probes can be permanently installed at representative points in an agricultural field to provide repeated moisture readings over a period of time that can be used for irrigation management. Special care is needed when using soil moisture devices in coarse soils because most devices require close contact with the soil matrix that is sometimes difficult to achieve in these soils. In addition, the fast soil-water changes typical of these soils are sometimes not properly captured by some types of sensors.[2–4]

SOIL MOISTURE SENSORS FOR IRRIGATION CONTROL

Many indirect methods are available for monitoring soil water content. Soil moisture can be estimated through these methods by a calibrated relationship with some other measurable variable. The suitability of each method depends on several issues like cost, accuracy, response time, installation, management, and durability. Depending on the quantity measured (i.e., volumetric water content or soil tension), indirect techniques are first classified into *volumetric* and *tensiometric*. Both quantities are related through the soil water characteristic curve specific to a given soil. It is important to remember that each soil type (texture/structure) has a different curve; therefore, they cannot be related to each other in the same way for all soil types. In addition, this relationship might not be unique and may differ along drying and wetting cycles, especially in finer soils. To calculate irrigation requirements (the amount of water that has to be applied with each irrigation), suction values from tensiometric methods need to be converted to soil moisture sensing methods through the soil characteristic curve. An in-depth review of available techniques is given by Muñoz-Carpena, Ritter, and Bosch[5] focusing on working principles, advantages, and drawbacks (Tables 1 and 2). Among the available tensiometric techniques, tensiometers and granular matrix sensors (GMS) are the most used for automatic irrigation. Most of the currently available volumetric sensors suitable for irrigation are dielectric. This group of sensors estimates soil water content by measuring the soil bulk permittivity (or dielectric constant) that determines the velocity of an electromagnetic wave or pulse through the soil. In a composite material like the soil (i.e., made up of different components like minerals, air, and water), the value of the permittivity is made up by the relative contribution of each of the components.

Table 1 Evaluation criteria for volumetric soil water monitoring methods

	Neutron moderation	TDR	FD (capacitance and FDR)	ADR	Phase transmission	TDT
Reading range	0–0.60 cm^3/cm^3	0.05–0.50 cm^3/cm^3 0.05—Saturation (with soil specific calibration)	0—Saturation	0—Saturation	0.05–0.50 cm^3/cm^3	0.05–0.50 cm^3/cm^3 0–0.70 cm^3/cm^3 Depending on instrument
Accuracy (with soil-specific calibration)	±0.005 cm^3/cm^3	±0.01 cm^3/cm^3	±0.01 cm^3/cm^3	±0.01–0.05 cm^3/cm^3	±0.01 cm^3/cm^3	±0.05 cm^3/cm^3
Measurement volume	Sphere (15–40 cm radius)	About 3 cm radius around length of waveguides	Sphere (about 4 cm effective radius)	Cylinder (about 4 cm^3/cm^3)	Cylinder (15–20 L)	Cylinder (0.8–6 L) of 50 mm radius

As the dielectric constant of liquid water is much larger than that of the other soil constituents, the total permittivity of the soil or bulk permittivity is mainly governed by the presence of liquid water. The dielectric methods use empirical (calibrated) relationships between volumetric water content and the sensor output signal (time, frequency, impedance, and wave phase). These techniques are becoming widely adopted because they have good response time (almost instantaneous measurements), do not require maintenance, and can provide continuous readings through automation. Although these sensors are based on the dielectric principle, the various types available [frequency domain reflectometry (FDR), capacitance, time domain transmission (TDT), amplitude domain reflectometry (ADR), time domain reflectometry (TDR), and phase transmission] present important differences in terms of calibration requirements, accuracy, installation and maintenance requirements, and cost (Tables 1 and 2).

WATER USE AND YIELD IMPLICATIONS OF SOIL WATER-BASED CONTROL

A soil water-based irrigation control system uses feedback on the soil water status to bypass a time-based preprogrammed schedule or to maintain soil water content with a specified range. The two approaches are *bypass* and *on-demand*, respectively. Bypass configurations skip an entire timed irrigation event based on the soil water status at the beginning of that event or by checking the soil water status at intervals within a time-based event.

Tensiometers and GMS sensors were among the first types of sensors adapted to automatic irrigation control. Phene and Howell[6] first used a custom-made soil matric potential sensor to control subsurface drip irrigated processing tomatoes. Their results indicated that yields of the automated system were similar to those from tomatoes irrigated based on pan evaporation with the potential to use less irrigation water. Switching tensiometers are devices that operate in bypass mode typically with a timer such that irrigation will be allowed within a timed irrigation window if the soil matric potential exceeds a threshold setting. Smajstrla and Locascio[7] reported that using switching tensiometers, placed at 15 cm depths and set at 10 and 15 kPa tensions in a fine sandy soil in Florida, reduced irrigation requirements of tomatoes by 40–50% without reducing yields. Meron et al.[8] discussed the use of tensiometers to automatically irrigate apple trees. They noted that spatial variability was problematic when the tensiometers were installed 30 cm from the drip irrigation emitters. Smajstrla and Koo[9] discussed the problems associated with using tensiometers to initiate irrigation events in sandy soils in Florida. Problems included entrapped air in the tensiometers, organic growth on the ceramic cups, and the need for recalibration. Muñoz-Carpena et al.[4] studied tensiometer and GMS controlled high frequency-low volume drip irrigation systems on tomatos grown in sandy soils. The irrigation savings of switching tensiometers set at 15 kPa on a coarse soil compared to farmer practices was 70%. The GMS controlled system failed to bypass most irrigation events owing to slow response time. Tomato yields were similar across all soil water-based control systems and the farmer field. Shock et al.[10] described a system to irrigate onion with frequent bypass control using GMS. The amount of overall water used was slightly less than calculated crop evapotranspiration with acceptable yields.

Although dielectric sensors have only found limited use in vegetable production, research to date shows promising results in terms of water savings. Nogueira et al.[11] described an automatic subsurface drip irrigation control system used in a sweet corn/peanut crop rotation. This system makes use of TDR sensors to control a subsurface drip irrigation system on-demand. During subsequent testing of this system, 11% irrigation savings with the on-demand subsurface drip irrigation system (23 cm deep) compared to sprinkler irrigation was reported, with similar yields between the systems.[12] Dukes et al.[1] used a commercially available dielectric sensor for lawns and gardens to control irrigation on green bell pepper (*Capsicum annuum* L.). They found 50% reduction in water use with soil water-based automatically irrigated bell pepper when compared to manually irrigated treatments done once per day that had similar yields; however, maximum yields and water use was reported for the treatment similar to local farmer practices that was irrigated one to two times each day. Recently, an irrigation controller has been developed that uses a voltage signal from a dielectric probe that is related to soil water.[13] The performance of this system was similar to that of switching tensiometers (both in bypass mode), by reducing irrigation water by 70% on drip-irrigated tomato in South Florida.

CONCLUSIONS

As water supply becomes scarce and polluted, there is a need for an efficient irrigation system to minimize water use and chemical leaching. Recent advances in soil water sensoring make the commercial use of this technology possible to automate irrigation management for vegetable production. However, research indicates that different types of sensors may not perform alike under certain conditions. Experimentally measured reductions in water use range as

Scaling–
Soil Water

high as 70% compared to farmer practices with no negative impact on crop yields. Owing to the soil's natural variability, location and number of soil water sensors may become crucial and future work should include optimization of sensor placement. Additional research should also include techniques toovercome the limitation of requiring a soil-specific calibration.

INTRODUCTION

Water content at field capacity, or simply field capacity, provides an operational concept for managing soil-water in the root zone. Following thorough wetting of deep, well-drained soils, excess water is re-distributed, and field capacity is reached when the downward drainage flux is materially ceased in the profile.[1–5] Veihmeyer and Hendrickson[1,6] related field capacity to soil-water content held at certain negative pressure or suction, implying that perhaps the field capacity is an intrinsic property of soils. Modern theory of soil-water movement and precise measurement have shown, however, that field capacity is not a constant or an intrinsic property, but rather a transient value that is impacted by initial conditions in soil, depth to water table, and soil profile layering.[7–10] Nonetheless, field capacity remains a useful operational concept in deep, well-drained soils where downward drainage flux may not cease completely, but becomes negligibly small so that processes of evaporation and root water uptake dominate the depletion of root zone soil-water. Determining field capacity is important in soil-water management like scheduling of irrigation because the water content between field capacity and wilting point becomes available for root water uptake by crops.

OVERVIEW

Field capacity is commonly taken as the soil-water content at a given drainage time (e.g., 48 hr) or matric potential (-33 kPa or -10 kPa).[11–13] Although these approaches can be suitable for certain field conditions, they are imprecise and even misleading for certain other conditions. Nachabe,[4] among others, has shown that the drainage time to reach field capacity varies with initial wetness and soil texture and is not fixed for all soils. A second, commonly accepted approximation of field capacity is soil-water content at -33 kPa matric potential (-0.33 bar pressure) for fine textured soils, and sometimes -10 kPa matric potential (-0.1 bar pressure) for coarse textured soils (e.g., Refs.[3,13]). Hillel,[14] Nachabe,[4] and Meyer and Gee[5] noted that this pressure-based approximation of field capacity is inconsistent because there is no guarantee that the same negligible drainage flux is reached for all soils at this value of soil-water pressure. Quoting Hillel[14] "it is a fundamental mistake to expect [pressure-based approximations of field capacity] to apply universally, since they are solely static in nature while the process they purport to represent is highly dynamic.'' Also this pressure-based approximation is misleading for drainage in layered profiles with impervious clay pans or in root zones with perched or shallow water table depth.

A dynamic interpretation of field capacity described by the magnitude of a time variable slow drainage flux is preferable. The adoption of this interpretation of field capacity restores its important dynamic nature, while allowing the user to specify the small drainage flux from the root zone when field capacity is practically reached. For root zone water management, Nachabe[4] recommended relating the magnitude of the small drainage flux at field capacity to daily evapotranspiration, and Hillel[14] proposed using a negligible flux of 0.5 mm day^{-1}, equal to about 10% of the daily average evapotranspiration. Meyer and Gee[5] argued that drainage fluxes between 0.01 mm day^{-1} ($\approx 10^{-8}$ cm sec^{-1}) and 1 mm day^{-1} ($\approx 10^{-6}$ cm sec^{-1}) can be considered small enough, depending on type of field application. Clearly, field capacity is an operational concept and the selection of the magnitude of the negligible flux should be left to the type of application. In environmental applications, where mobility and leaching of toxic pollutants through the soil are an issue, the user may define the (dynamic) field capacity to occur at a very small flux (e.g., 0.01 mm day^{-1}). In root zone water management, a flux of 0.5 mm day^{-1} might be appropriate to define field capacity when evaporation and transpiration, rather than downward drainage, become the dominant processes in depleting soil-water of the root zone.

We briefly review the physics of drainage, and provide equations that allow the user to: 1) determine field capacity when a negligibly small drainage flux is reached; 2) approximate the time to reach this dynamic field capacity; and 3) estimate the wetted depth of the root zone at field capacity for specific infiltration events. We distinguish between deep, well-drained soils, and field situations where drainage is hindered by clay pans or shallow depth to water table.

FIELD CAPACITY IN DEEP, WELL-DRAINED SOIL PROFILES: ESTIMATION AND APPROXIMATION

During drainage, a unit hydraulic gradient in the profile provides a good approximation of Darcy's law, which can be written as:

$$q_t = K(\theta_t) \tag{1}$$

where q_t, in mm day^{-1}, is the drainage flux as a function of time t, in days, $K(\theta_t)$ is the unsaturated hydraulic conductivity in mm day^{-1} at any water content θ_t in mm^3 of water per mm^3 of soil. The unsaturated hydraulic conductivity is expressed as:[15]

$$K(\theta) = K_s\Theta^n \tag{2}$$

where K_s is the saturated hydraulic conductivity, Θ is the normalized water content equal to $(\theta-\theta_r)/(\theta_s-\theta_r)$, where θ_r is residual soil-water content, and θ_s is saturated soil-water content, and n is an exponent. Usually $n = (2 + 3\lambda)/\lambda$, where λ is the pore size distribution index of the Brooks and Corey model. The Brooks and Corey model has been widely adopted in the past, and its parameters can be easily derived from soil texture data (e.g., Refs.[16–18]) or directly obtained from scientific literature and reference textbooks (e.g., Refs.[16,19]). Assuming a rectangular soil-water profile during drainage, the rate of decrease of water content is given by:

$$\frac{d\theta_t}{dt} = \frac{-(q_t + e)}{z_f} \tag{3}$$

where e is a constant evaporation flux at the surface, and z_f is depth to the wetting front during drainage. If e is ignored, conservation of mass of soil-water in the profile requires that:

$$z_f = \frac{I}{\theta_t - \theta_r} \tag{4}$$

where I is the initial cumulative infiltration water depth in millimeters at the beginning of drainage. Substituting Eqs. (1) and (4) into Eq. (3) and integrating the resulting ordinary differential equation with respect to time yields:

$$\frac{\theta_t - \theta_r}{\theta_s - \theta_r} = \left(\Theta_I^{-n} + \frac{K_s n t}{I}\right)^{-1/n} \tag{5}$$

where Θ_I is the normalized water content distribution at the beginning of soil moisture distribution (equal to 1 if soil is initially saturated). The drainage flux can

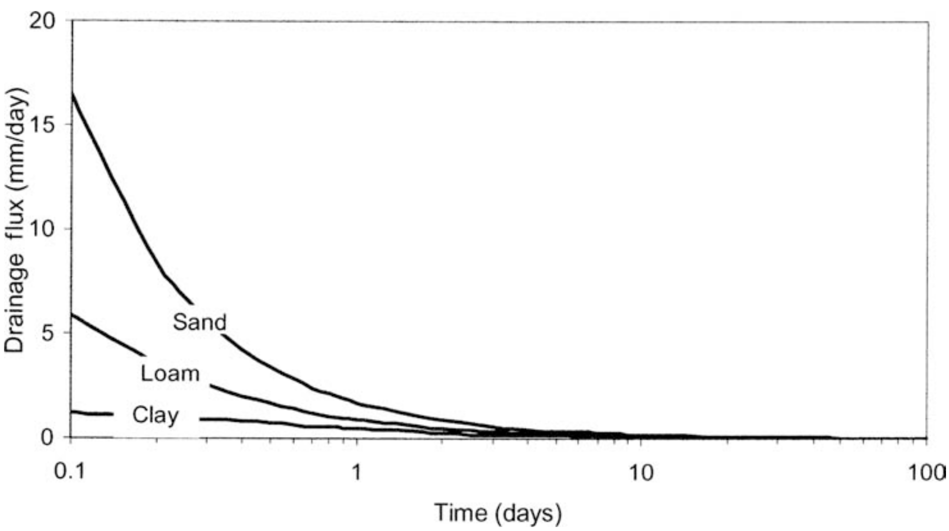

Fig. 1 Estimated evolution of drainage flux with time for three soils for an initial infiltration depth of 10 mm. *Source*: From Ref. [4].

Soils–Suspended

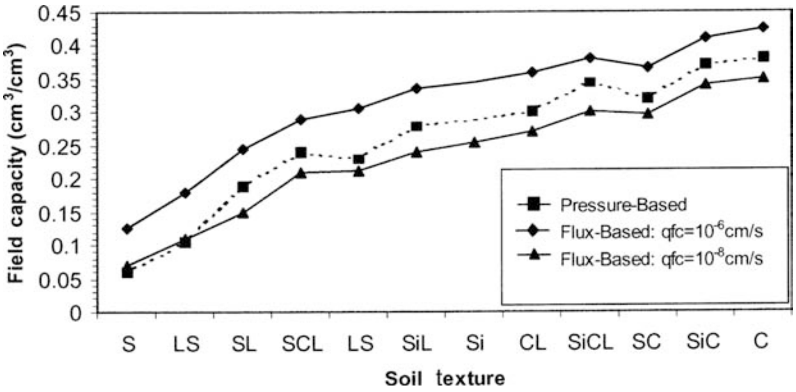

Fig. 2 Dynamic [Eq. (8) with $q_{fc} = 10^{-6}\,\text{cm sec}^{-1}$ and $10^{-8}\,\text{cm sec}^{-1}$] and pressure-based (−33 kPa) field capacity by soil class texture (S, sand; L, loam; Si, Silt; C, clay). *Source*: From Ref.[5].

be found by substituting Eq. (5) into Eq. (2) resulting in:

$$q_t = \frac{K_s}{\left(\frac{nK_s t}{I} + \Theta_I^{-n}\right)} \tag{6}$$

Fig. 1 illustrates the rapid decrease in drainage flux q_t with time for three soils with initial infiltration depth of 10 mm, showing that drainage flux becomes negligibly small within a few days. Solving Eq. (6) for time, and adopting the subscript "fc" for field capacity results in t_{fc}, the drainage time to reach field capacity:

$$t_{fc} = \left(\frac{K_s}{q_{fc}} - \Theta_I^{-n}\right)\frac{I}{nK_s} \tag{7}$$

Eq. (7) can be used to estimate the time to reach a negligibly small flux, q_{fc}, at field capacity. The time to reach this flux is not an intrinsic soil property, but depends on the soil hydraulic properties, the initial infiltration depth, and the magnitude of q_{fc}. Normalized water content at field capacity can be calculated from Eq. (2) as:

$$\Theta_{fc} = \frac{\theta_{fc} - \theta_r}{\theta_s - \theta_r} = \left(\frac{q_{fc}}{K_s}\right)^{1/n} \tag{8}$$

In Eq. (8), the water content at field capacity has a dynamic nature because it is expressed as a function of a user specified, small drainage flux q_{fc}. Nachabe[4] and Meyer and Gee[5] compared the soil-water content at field capacity (dynamic or flux-based concept, from Eq. (8), with the soil-water content at −33 kPa of pressure (pressure-based concept of field capacity). Results are shown in Fig. 2. Results in this figure indicate that the flux-based estimation of field capacity is more consistent than the pressure-based estimate of field capacity. Using the −10 kPa pressure to estimate field capacity of coarse textured soils like sand will result in larger drainage fluxes, which is more consistent with the dynamic estimation of field capacity (Fig. 2).

FIELD CAPACITY IN SHALLOW WATER TABLE ENVIRONMENTS AND CLAY PANS

In certain agricultural soils, drainage can be hindered by clay pans or shallow depth to water table. In these cases, the dynamic concept of field capacity holds, but the equations above for a homogenous profile will not describe conditions at field capacity. If a clay pan is at shallow depth in the root zone, then soil-water accumulates in a surface horizon, and drainage flux will be limited to the saturated conductivity of the clay pan below. Under these conditions, field capacity of the soil horizon above the clay pan might be close to saturated water content. In many parts of southern United States and other parts of the world, agricultural soils are fine sand with shallow depth to water table (1–5 ft). In these soils, rapid rise in water table is observed and drainage of the root zone results in an equilibrium soil-water profile above a new, shallower, water table. When drainage seizes to be significant, the field capacity of the root zone is the equilibrium drainage (or water retention) curve above the new water table.

CONCLUSION

We propose to use field capacity as an operational concept for root zone water management, and avoid treating it as an intrinsic soil property. Field capacity is reached when downward drainage flux is negligibly small (while recognizing that drainage may not cease completely) so that evaporation and transpiration are more significant in depleting soil-water of the root zone. Depending on type of application, a negligibly small drainage flux between $0.01\,\text{mm day}^{-1}$ and $1\,\text{mm day}^{-1}$ can be assumed for field capacity in a deep, well-drained soil profile. In a layered soil profile, drainage can be hindered by a clay pan, whereas in a soil with shallow depth to water table, an equilibrium soil-water profile is usually achieved when drainage ceases to be significant.

INTRODUCTION

Much of life depends on our ability to make efficient use of our water resources. Because of this, the characterization of the fraction of precipitation and snowfall which run off the earth's surface and which infiltrate into the soil are very important to society. Infiltration of water into the soil and subsequent movement of this water to plant roots are critical considerations for agricultural production. Other interests which involve understanding the movement of water through the soil include water flow to subsurface drains and wells, surface water flow, and evaporation from the soil to name a few.

OVERVIEW

Water moves through the earth in response to forces acting upon it. The property which describes the rate at which water flows through a porous material is called the hydraulic conductivity. In 1856, a French hydraulic engineer named Henry Darcy published a report on the water supply of the city of Dijon, France.[1] In his report Darcy described an experiment that he had conducted to analyze the flow of water through sands. The results of his experiment became generalized into an empirical law that now bears his name.[a]

$$Q = KA\frac{\Delta h}{l} \tag{1}$$

In this equation, A is the cross-sectional area through which the water flows [L^2], Δh is the difference in hydraulic head of the water between two observation points [L], and l is the distance between the two points [L]. The hydraulic head is the sum of gravitational and pressure heads, while the rate of change of the hydraulic head over a given length is termed the hydraulic gradient. The coefficient relating the hydraulic gradient to the flow of water through the porous media was termed the hydraulic conductivity, K, [LT^{-1}]. The hydraulic conductivity is thus a measure of a media's ability to transmit a fluid. If the porous media is saturated it is referred to as the saturated hydraulic conductivity, K_s. For unsaturated conditions it is called the unsaturated hydraulic conductivity.

Saturated hydraulic conductivity is a function of the properties of the soil and of the fluid. We primarily think of the flow of water, but oil or other fluids also flow through porous media and would have a different hydraulic conductivity than would water. The properties of the porous media that affect the hydraulic conductivity include particle arrangement, size, shape, and distribution. Experiments with glass beads established the relationship:[4]

$$K = \frac{Cd^2\rho g}{\mu} \tag{2}$$

where C is another coefficient of proportionality, d is the diameter of the glass beads [L], ρ is the density of the fluid [ML^{-3}], g is the acceleration of gravity [LT^{-2}], and μ is the fluid dynamic viscosity [$ML^{-1}T^{-1}$]. As the temperature of the fluid changes so does it's viscosity. Thus, K is also affected by temperature.

The hydraulic conductivity can be broken down into properties of the fluid ($\rho\mu^{-1}$) and properties of the medium (Cd^2). To separate these components, the hydraulic conductivity is often written in terms of the specific or intrinsic permeability, k [L^2].

The intrinsic permeability is often used because it is a property of the porous media alone.

$$K = \frac{k\rho g}{\mu} \tag{3}$$

Contribution from the USDA Agricultural Research Service, Southeast Watershed Research Laboratory, PO Box 946, Tifton, GA USA 31793, in cooperation with Univ. of Georgia Coastal Plain Exp. Stn.

[a]Darcy's law fails for conditions of high flow velocities, where inertial forces are no longer negligible compared to viscous forces.[2] Deviations from Darcy's law may also occur at very low gradients and in small pores.[3]

Table 1 Representative saturated hydraulic conductivity values for various materials

Unconsolidated material	Consolidated rock	Saturated hydraulic conductivity (m day^{-1})	Relative saturated hydraulic conductivity
Clean gravel	Basalt, cavernous limestone, and dolomite	10^4	Very high
Clean sand, sand, and gravel	Clean sandstone and fractured igneous and metamorphic rocks	10^2	High
Fine sand	Weathered granite	1	Moderate
Silt, clay, and mixtures	Laminated sandstone, shale, and mudstone	10^{-3}	Low
Massive clay	Massive igneous and metamorphic rocks	10^{-5}	Very low

Source: From Ref.[7])

Hydraulic conductivity is a function of not only the position in the porous media, but the direction of flow as well. Because geologic materials are often layered, flow in the direction of the layers often has a higher conductivity than flow perpendicular to the layering. Thus, K_s is often characterized in three dimensions. For layered soils, an effective saturated hydraulic conductivity may be determined.[5] For flow perpendicular to the layers the expression is:

$$K_e = \frac{D}{\frac{D_1}{K_1} + \frac{D_2}{K_2} + \cdots \frac{D_n}{K_n}}; \text{(geometric mean)} \qquad (4)$$

For flow parallel with the layers the expression is:

$$K_e = \frac{K_1 + K_2 + \cdots K_n}{n}; \text{(arithmetic mean)} \qquad (5)$$

where, K_e is the effective saturated hydraulic conductivity [LT^{-2}], D is the total profile depth [L], D_1–D_n and K_1–K_n are the thickness and saturated hydraulic conductivity of each layer, respectively.

In light of recent awareness on preferential flow of water and chemicals through the soil profile and the impact of soil heterogeneity on macropore flow, dependence of the saturated hydraulic conductivity on both location within a profile and direction of the flow have been used to distinguish between homogeneous isotropic soils where the conductivity is the same in all directions and heterogeneous anisotropic soils where it varies with direction. If K is the same in all locations within the profile and in all flow directions, the soil is called homogeneous and isotropic. On the other hand, if K is dependent both on location and the direction of the flow, such a profile is referred to as heterogeneous and anisotropic.[6]

In practice, various units are used for K. Hydrologists prefer the unit m day^{-1} or ft day^{-1}, while soil scientists often use ft sec^{-1}, cm sec^{-1}, or mm sec^{-1}. For description of aquifer properties, hydraulic conductivity is also expressed in terms of the volume of flow through a given cross-sectional area under a unit gradient at a fixed temperature. In this case the dimensions of K are $L^3\ T^{-1}\ L^{-2}$. Some of the units used are gal $day^{-1}\,L^{-2}$ and $m^3\,day^{-1}\,m^{-2}$.

REPRESENTATIVE VALUES

Representative values of K_s are listed in Table 1. As would be expected, values for coarse textured sandy soils are considerably higher than those for fine textured clay soils. Hydraulic conductivity is also affected by the structure of the medium. A highly porous, fractured material would conduct water more readily than would a tightly compacted one. Hydraulic conductivity depends also on the arrangement of the soil pores. Interconnected pores conduct more readily than do closed end pores. A gravely or sandy soil with large pores can have a conductivity much greater than a clay soil with narrow pores even though the total porosity of the clay may be greater than that of the sand.

Field studies have shown soil hydraulic characteristics can vary greatly.[8,9] Because of the variation in soils across a field, a large variability in hydraulic conductivity can be observed. This in turn leads to a large variation in infiltration and subsequently in runoff.

UNSATURATED CONDITIONS

The hydraulic conductivity of a material varies considerably with the degree of saturation of the soil. Eq. (1) was developed for a saturated material, but has been extended for unsaturated materials by making K a function of the matric potential[b] (φ) of the soil:

$$q = -K(\varphi)\nabla H \qquad (6)$$

[b]Matric potential is a measure of the negative pressure which exists within the soil due to capillary and adsorptive forces.

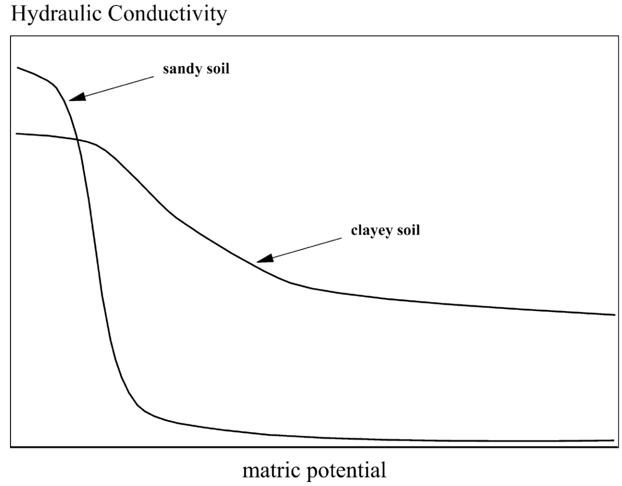

Fig. 1 Unsaturated hydraulic conductivity as a function of matric potential.

where q is the flow rate or flux [LT^{-1}], $K(\varphi)$ is the unsaturated hydraulic conductivity [LT^{-1}], and ∇H is the hydraulic head gradient [LL^{-1}]. Eq. (6) fails to take into account the effects of hysteresis, i.e., whether the soil is wetting or drying, which has been found to effect $K(\varphi)$.

As the soil becomes drier, $K(\varphi)$ decreases. The rate of decrease is a function of the properties of the soil (Fig. 1). While $K(\varphi)$ may be high for a fully saturated sand, it rapidly decreases as the sand de-waters and the matric potential in the soil decreases. In contrast, because a clay soil is able to maintain more water as the matric potential increases $K(\varphi)$ does not decrease as rapidly for a fine textured soil.

DETERMINATION OF HYDRAULIC CONDUCTIVITY

Hydraulic conductivity can be determined through a variety of numerical,[10] field,[11] and laboratory[12] techniques. Many investigators have attempted to relate hydraulic conductivity to properties of the porous media.[13] As a result, many formulas exist which can be used to predict the hydraulic conductivity or the permeability based upon information about the soil. It is difficult to obtain accurate estimates with these formulas because of the extreme variability observed in porous media. Because of this, actual field or laboratory measurements are preferred.

Most laboratory methods used to measure saturated hydraulic conductivity are directly based upon Eq. (1). The hydraulic head is varied between the inflow of a given sample and the outflow and the flow rate through the core measured. For unsaturated hydraulic conductivity, the same basic principles are followed. However, for unsaturated hydraulic conductivity a pressure is induced on the soil sample to bring it to a given matric pressure during the flow measurement. Field measurement techniques for hydraulic conductivity can involve measuring the rate at which a given tracer is transported through the soil, the rate at which a given amount of water flows into the soil, or that rate at which the groundwater recovers when the water table is pumped from a well. One of the more reliable methods for estimating the saturated hydraulic conductivity for an aquifer material is a pump test. A pump test is conducted by observing the decrease in the water table depth in a well near the well being pumped. This method measures K_s over a fairly large area and minimizes the effects of heterogeneity of the aquifer material. In addition, it minimizes disturbance of the porous media.

CONCLUSION

Hydraulic conductivity has risen from it's simple beginnings as a means through which Henry Darcy related his observations in flow rate to his observations of forces acting upon the fluid to an extremely useful soil characteristic. While Darcy's law is empirical, based upon experimental evidence, it is widely used by hydrologists, soil physicists, agricultural engineers, and civil engineers. Hydraulic conductivity is a widely used soil parameter, used to describe the flow of water, oil, and gas within porous media. It is also used in the design of filters and flow through porous ceramics.

Soils: Hygroscopic Water Content

Daniel G. Levitt
Science and Engineering Associates, Inc., Sante Fe, New Mexico, U.S.A.

Michael H. Young
Division of Hydrologic Sciences, Desert Research Institute, Las Vegas, Nevada, U.S.A.

INTRODUCTION

Hygroscopic water content has been defined as the moisture that an initially dry soil will adsorb when brought into equilibrium with an atmosphere of 50% relative humidity (RH) at 20°C.[1] It has also been defined as the moisture that adheres to soil particles and does not evaporate at ordinary temperatures.[2] Hillel[3] describes soil *hygroscopicity* as the phenomenon where air-dry soil will generally contain several percent more water than oven-dry soil.

The word *hygroscopic* is derived from its Greek roots *hygro*, meaning atmospheric water, and *scopic* meaning to view or examine. One measure of hygroscopic water content in soils is the hygroscopic coefficient, which is defined as the water, on a gravimetric percentage basis that is absorbed by a completely dry mass of soil when brought into equilibrium with a saturated atmosphere.[2] The hygroscopic coefficient has also been defined as the level of tension at which water is considered to be bound to the soil particles (31 atm).[4] Below a water content defined by hygroscopic coefficient (Fig. 1), water will be unavailable to plants.[1]

Understanding the behavior of hygroscopic soil water is critically important to arid-land ecology, agriculture, and waste management. Vast areas of the Earth are occupied by desert, and as human population increases, agricultural efficiencies on arid lands must increase. In addition, as deserts are gaining acceptance as locations for disposal of hazardous or radioactive waste, understanding hygroscopic water content in soils is critical to understanding the behavior of water flow and contaminant transport under these dry conditions.

PROPERTIES OF HYGROSCOPIC SOIL WATER

Physical Properties

Jury, Gardner, and Gardner[5] state that the two most important characteristics of the soil water phase are the amount of water in soil, and the force holding the water in the soil matrix. The amount of water in the soil influences many processes, including gas exchange, diffusion of nutrients to plant roots, and the rate of water and solute movement through soil. The force with which water is retained by the soil matrix affects plant water uptake, water drainage from soils, and upward movement of water against gravity.

Surface Tension

Water molecules at the air–water interface exhibit a net attraction into the liquid because the density of molecules on the air side of the interface is lower than on the liquid side. This unequal attraction deforms the hydrogen bonds of the molecules at the interface and imparts "membrane-like" properties to the interface, which stretches over the water volume like a skin. As a consequence, water molecules require extra energy to remain at the interface. The extra energy per unit surface area possessed by molecules at the interface is called the surface tension.[5]

Surface Area

Soil texture, or particle size distribution, strongly influences its hygroscopic coefficient. Whereas the surface area of sand is often less than $1\,m^2\,g^{-1}$, surface area of clay can be as high as several hundred square meters per gram.[6] This large difference in surface area between soil textures generally results in the hygroscopic coefficient of clay being several times greater than the hygroscopic coefficient of sand under identical conditions.

Hydraulic Properties

Soil water characteristic

The relationship between soil water content and the soil water potential is a fundamental part of the characterization of soil hydraulic properties, and is

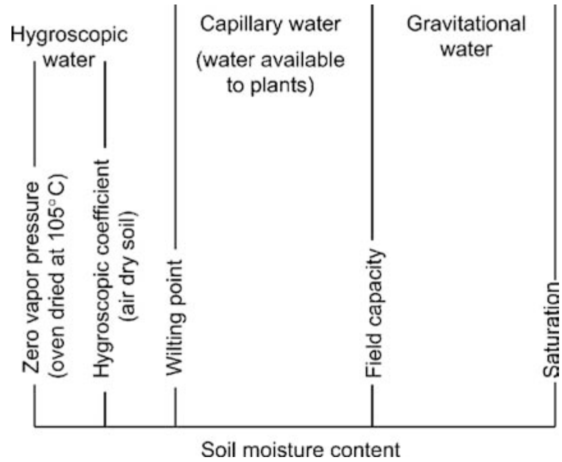

Fig. 1 Soil moisture classes and equilibrium points. *Source*: From Ref.[1].

identified by various terms including water retention function, moisture characteristic, and the capillary pressure–saturation curve. This function relates a capacity factor, the water content, to an intensity factor, the energy state of the soil water. This function primarily depends on soil texture.[7] Note the significant difference in water content between sand and clay at soil water tension of greater than 10,000 cm (Fig. 2). The clay material with its higher surface area (and charged surfaces) retained more water than the sand, which has a much lower surface area of water with lower charge density.

Soil will move from regions of higher potential to regions of lower potential at a rate that depends on the hydraulic resistance of the medium.[8] Water flow in unsaturated soils is particularly interesting because of the highly non-linear nature of unsaturated water flow. For example, unsaturated hydraulic conductivities can range by 20 or more orders of magnitude between saturation and the hygroscopic coefficient. Fig. 3 illustrates the relationship between soil water content and hydraulic conductivity for sand and clay; note on the inset graph that the hydraulic conductivity is higher in sand than clay at low tension, but that clay eventually exhibits a higher conductivity than sand at higher tension because clay material has more water-filled pores at higher tension then sandy material. The low hygroscopic coefficient in sand means that liquid water movement is essentially zero under very dry conditions.

Engineering Properties

Understanding the properties of hygroscopic soil water is critical to the field of engineering. Soil strength usually increases with increasing bulk density and decreasing water content. The bonds linking clay crystals into clay packets, and the packets into aggregates, lead to higher cohesion, and thus higher strength. These include van der Waals forces, attraction between oppositely charged surfaces, organic matter in various forms, and inorganic cements. The bond strength is

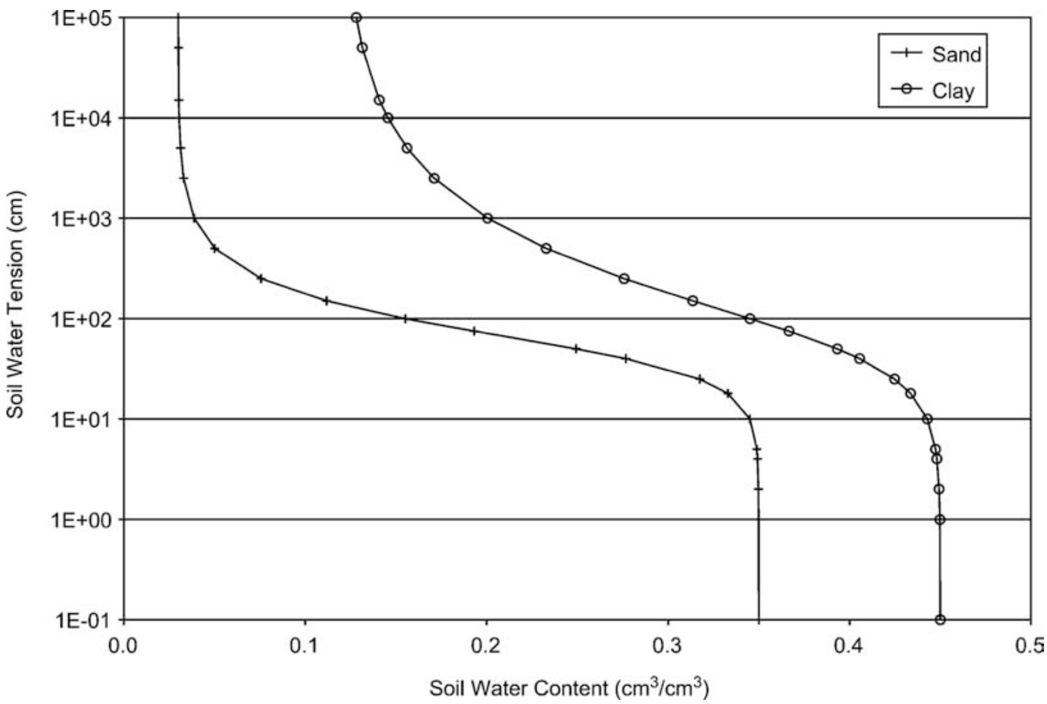

Fig. 2 Typical soil water characteristic curve for sand and clay.

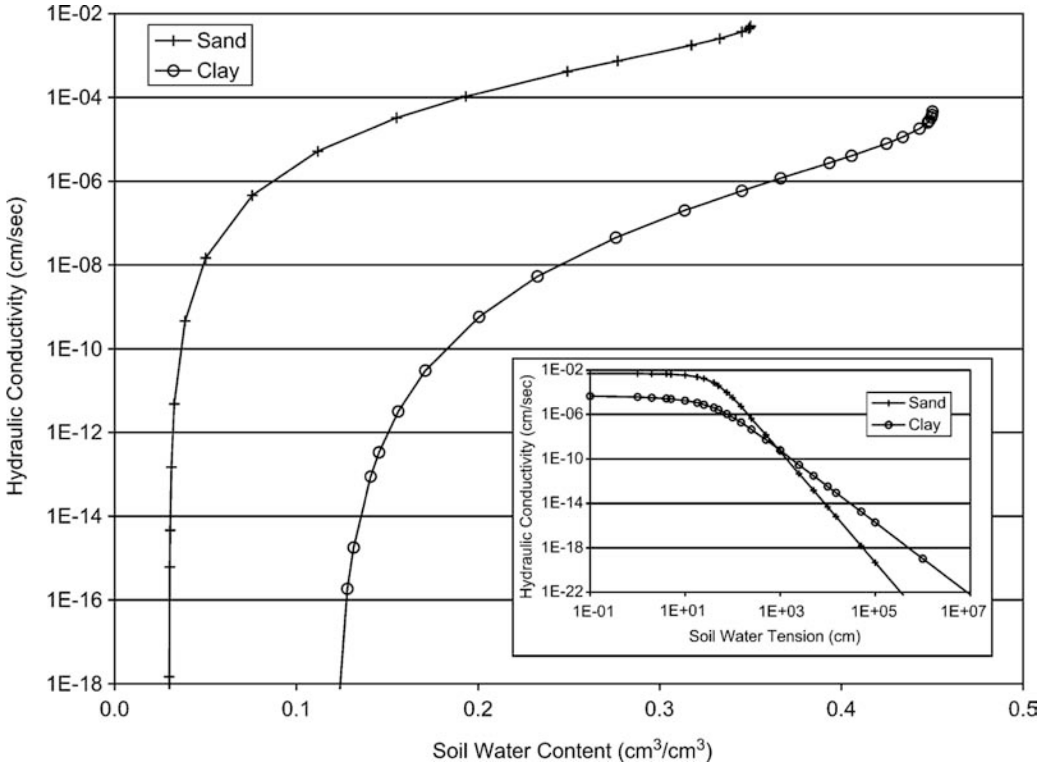

Fig. 3 Typical soil water content, soil water tension, and hydraulic conductivity relationships for sand and clay.

reduced by water through the softening of cements and the increased separation of particles as water is absorbed. However, cracking acts in an opposite way to the general trend by weakening soil as it dries.[9]

MEASUREMENT OF HYGROSCOPIC WATER CONTENT IN SOILS

Hygroscopic soil water content or hygroscopic soil water potential can be measured in the laboratory by a variety of methods, including water content determination by oven drying, and soil matric potential determination by thermocouple psychrometry, chilled mirror, and heat dissipation methods.

Oven-Drying Method

One of the simplest methods for determining soil water content is by oven drying. A soil sample is weighed, placed in an oven at a temperature between 100 and 110°C for 24 hr, and then weighed again. On a gravimetric basis, water content is calculated by

$$\text{Water content} = (\text{wet mass} - \text{dry mass})/(\text{dry mass})$$

It is important to note that ''dry'' is a subjective term, and that all water within a soil sample may not be removed by oven drying after 24 hr. However, this method serves as a standard for determining soil water content.[10]

Thermocouple Psychrometry

Thermocouple psychrometers infer the soil water potential of the liquid phase of a soil sample by measuring the RH. Water potential is related to the RH of soil water by the Kelvin equation:

$$\text{Water potential } (\mathrm{J\,kg^{-1}}) = RT/M \times \ln(\mathrm{RH})$$

where M is the molecular weight of water ($0.018\,\mathrm{kg\,mol^{-1}}$), R, the ideal gas constant ($8.31\,\mathrm{J\,K^{-1}\,mol^{-1}}$), and T, the Kelvin temperature of the liquid phase. Most thermocouple psychrometers consist of a sensor with a thermocouple junction, which is cooled until water condenses on it. The temperature depression, measured as this water evaporates, is proportional to RH, which provides a direct measure of soil water potential. The operational range of thermocouple psychrometers (~2 atm to ~50 atm) does not generally extend throughout the entire

Soils–Suspended

range of water potentials corresponding to hygroscopic water contents.[11]

Chilled Mirror Method

Like thermocouple psychrometry, the chilled mirror method is used to measure the RH of soil sample. Gee et al.[12] described a commercial water activity meter that can be used for rapid measurement of soil water RH in the range from 0.100 to 1.000 (which corresponds to a soil water potential range −3119 atm to 0 atm) with essentially the same RH resolution (±0.003) across the entire range. Gee et al.[12] suggested that this type of meter is best adapted for measurements in dry soils, making it very appropriate for measurement of hygroscopic soil water.

Heat Dissipation Method

Heat dissipation probes measure the heat dissipation characteristics of the soil matrix, which are proportional to soil water potential. Heat dissipation rates are determined by applying a heat pulse to a heater within a probe, and monitoring the temperature at the center of the probe. The operational range of heat dissipation probes extend from near-saturation to a dryness of thousands of atmospheres, well into the range of water potentials corresponding to hygroscopic water contents.[11,13]

Soils: Permanent Wilting Points

Judy A. Tolk
Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Bushland, Texas, U.S.A.

INTRODUCTION

Permanent wilting point (PWP) is defined as the largest water content of a soil at which indicator plants, growing in that soil, wilt and fail to recover when placed in a humid chamber. It is often estimated by the water content at $-1.5\,\mathrm{MPa}$ soil matric potential.[1] The water content is typically expressed on a weight ($\mathrm{g\,m^{-3}}$) or volume ($\mathrm{m^3\,m^{-3}}$) basis. As the lower boundary, PWP, along with the upper boundary determined at field capacity, establishes the size of the reservoir of water held in the soil that may be withdrawn by plants, known as plant available water. Field capacity is primarily a function of soil characteristics, while PWP is the product of a combination of plant, soil, and atmosphere factors.

BACKGROUND

The soil, plant, and atmosphere act as a continuum along which soil water moves in response to gradients in energy. The energy potential of the water relative to that of pure water helps determine the amount of water stored in the soil, moved through the soil, and moved into and through the plant to the transpiring surface of the leaf. Water will flow from a region of high potential to that with low potential. The energy required to move water is expressed in terms of water potential, which is the sum of the gravitational potential, the osmotic potential, the matric potential, and the pressure potential. The matric potential is a combination of capillary and adsorptive forces due to the shape, size, and chemical nature of surfaces in the soil and plant. The osmotic potential results from the presence of dissolved substances. Pressure potential represents the solution pressure within the plant cells. For the movement of water in the soil, the pressure potential is insignificant, and the gravitational potential has little significance once it has drained to field capacity. For the movement of water through the plant, the gravitational and matric potentials are less important.

Many factors in the soil–plant–atmosphere continuum influence the amount of water a plant can extract from the soil before wilting. Soil texture affects the matric potential of the soil by determining capillary pore size and adsorptive properties, and so controls both the amount of water held in and the movement through the soil at low soil water potentials. To extract the soil water, plant roots must be distributed throughout the soil, which is a function of soil properties such as soil strength and texture as well as the rooting characteristics of the crop. Also, an osmotic potential gradient between the soil solution at the root surface and within the root must be maintained so that the water can be absorbed into the plant roots. A water potential gradient between the plant leaf and the roots helps to move water through the plant to the leaves. Water is then evaporated (or transpired) through the stomata of the leaves due to the differences in water vapor pressure between the leaf and the atmosphere. If atmospheric demand for water exceeds the water supply to the plant's evaporating surfaces (possibly due to limited soil water supply and/or movement through the soil, limited rooting by the plant, or inadequate water potential gradients between soil and leaf), the plant will experience water stress and biological activity will decline. Unless resupplied with water, the plant cells will lose pressure potential, or turgor, and the leaves will permanently wilt and ultimately die.

THE SUNFLOWER METHOD

The wide range in soil water contents at which wilting in plants occurred was noted by German researchers as early as 1859, according to Briggs and Shantz.[2] To evaluate whether plant species varied significantly in their ability to reduce the soil water content before wilting, Briggs and Shantz[2] determined the wilting coefficient for a range of soils and plant species that included native vegetation of semiarid lands as well as crop species. Veihmeyer and Hendrickson[3] and Furr and Reeve[4] continued the work of Briggs and Shantz, using sunflower (*Helianthus annuus* L.) as the indicator plant for wilting. The procedures of Furr and Reeve[4] were standardized into the sunflower method ($\mathrm{PWP_{sun}}$).[5] In this method, the plants are grown in containers of uniform soil that are sealed to limit water loss other than that by transpiration. They are kept adequately watered until the third set of leaves appears at which time the watering ceases. The plants remain in an environment with a low evaporative demand until all three sets of leaves wilt. To insure the wilting is permanent, plants are placed overnight in a humid, dark chamber. If all leaves remain wilted in the morning, PWP_{sun} has been reached, and the soil water content or water potential can be determined.

PRESSURE OUTFLOW APPARATUS APPROXIMATION

Permanent wilting point can be estimated as the soil water content held in the soil at –1.5 MPa matric potential ($PWP_{-1.5}$). The similarity between PWP_{sun} and $PWP_{-1.5}$ was shown by Richards and Weaver,[6] who compared the two values for 119 soils and found that $PWP_{-1.5}$ formed a fairly definite lower limit below which PWP_{sun} seldom fell. In this method, a sieved soil sample is placed on a porous ceramic plate or permeable membrane in a chamber and saturated with water. A pressure of 1.5 MPa is applied until equilibrium in water content between the plate or membrane and the soil sample is reached[5] at which time soil water content is determined.

FIELD MEASUREMENT

Ratliff, Ritchie, and Cassel[7] defined field measurement of PWP (PWP_{field}) as the lowest field-measured water content of a soil after plants had stopped extracting water and were at or near premature death or became dormant as a result of water stress. Field measurement of PWP may be the most desirable method,[8] because it provides more realistic information about how a plant grows in a certain soil because the soil–plant–environment interactions are allowed to occur. But, the controls on the experiment (e.g., uniform soil in pots, low evaporative demand environment, a well-defined root zone) are gone, and the complex soil horizons, different rooting depths and patterns by crops or by the same crop from year to year, and different environmental demands can cause substantial variation. Additional problems include refilling of the profile due to rainfall, the inability to determine when plant dormancy occurs, and the drying of the upper soil layers below PWP due to soil water evaporation. In this method, the soil profile is wetted sufficiently throughout the normal rooting depth so that the plant does not undergo severe water stress until maximum vegetative growth when maximum rooting occurs. This insures that normal rooting and water use patterns develop. Water depletion patterns throughout the growing season are monitored so that the cessation of water use from a soil layer can be determined. Once plant dormancy or premature death and the cessation of water use occur, soil water content or water potential is determined.

DISCUSSION

The applicability of PWP_{sun} and $PWP_{-1.5}$ to PWP_{field} has been questioned. Ratliff, Ritchie, and Cassel[7] found that $PWP_{-1.5}$ was significantly less than PWP_{field} for sands, silt loams, and sandy clay loams, and significantly more for loams, silty clays, and clays for a variety of crops. Additionally, PWP may be crop

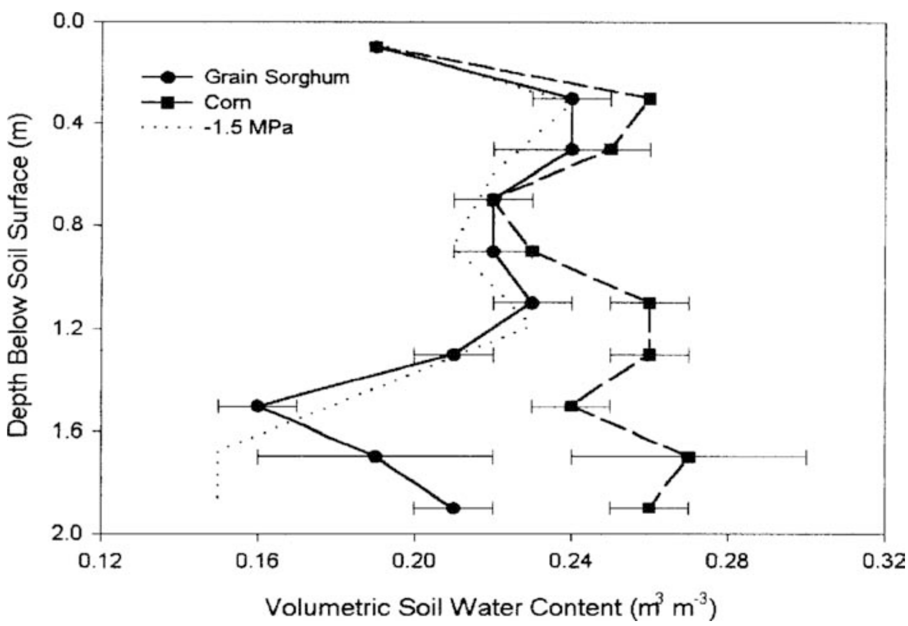

Fig. 1 Water contents of a 2-m soil profile measured for corn and grain sorghum after the available soil water had been depleted. The data points are mean values of two cropping seasons, with standard deviations (horizontal error bars). Error bars may not be visible on data points with low standard deviations. Also presented is the soil water content measured at the −1.5 MPa soil matric potential.

and climate specific. Cabelguenne and Debaeke[9] reported that corn (*Zea mays* L.), sorghum [*Sorghum bicolor* (L.) Moench], and winter wheat (*Triticum aestivum* L.) varied in their degree and depth of lower limit of water use in a deep silty clay loam, and these capacities were representative only of the climate in which they were obtained. Savage et al.,[10] however, concluded that $PWP_{-1.5}$ corresponded to PWP_{field} for grain sorghum and cotton (*Gossypium hirsutum* L.) and values lower than measured $PWP_{-1.5}$ represented only minor amounts of available soil water.

An example of PWP for different crops is shown in Fig. 1. Grain sorghum and corn were grown in an undisturbed soil column contained in a lysimeter with a surface area of 1 m by 0.75 m and a depth of 2.3 m. The soil was a Pullman clay loam, which has a dense clay horizon about 0.4 m below the soil surface, and soil horizons containing substantial amounts of calcium carbonate beginning at about 1 m below the soil surface. The water content of the soil was measured by neutron thermalization. The vertical lines connect the means of the soil water contents for each 0.2-m depth measured at harvest for two cropping seasons for each crop, as well as the $PWP_{-1.5}$ for the different soil horizons. The horizontal lines (error bars) at each data point indicate the range in the measurements that occurred between seasons. Both crops showed a similar PWP pattern, but differed in the amount of water remaining at PWP. The dense clay horizon appears to have limited water use by both crops, probably due to restricted rooting. Grain sorghum, a more deeply rooting crop than corn, used more water from the lower soil depths. The presence of calcium carbonate in the lower depths may also have inhibited rooting. The $PWP_{-1.5}$ was similar to PWP of grain sorghum, but considerably lower for that of corn. When the volumetric soil water contents were converted to millimeters for the 2-m soil depth, the PWP for corn was 488 mm, 420 mm for grain sorghum, and the $PWP_{-1.5}$ was 398 mm. The difference between cropping seasons was 40 mm for grain sorghum, and 16 mm for corn.

Each method for the determination of PWP has advantages and disadvantages. The method selected must take into consideration the application for which it will be used, the resources available for making the measurements, and the accuracy needed.

Soils–Suspended

Soils: Water Infiltration

Sally D. Logsdon
National Soil Tilth Laboratory, U.S. Department of Agriculture (USDA), Ames, Iowa, U.S.A.

INTRODUCTION

Infiltration, the process of water entering the soil surface, is part of the water cycle (Fig. 1). Water infiltrates the soil because of absorptive (capillary) and gravitational forces,[3] which are strongly influenced by soil texture and structure. (For more detail, see the article *Soil Water: Energy Concepts*.) The infiltration water comes from rain, melted snow, irrigation, or upslope runoff or seepage.[9] As infiltration occurs, the wetting soil profile can be divided into several zones:[3,8] saturation right at the surface to perhaps 1 cm deep, a transition zone of rapidly changing soil water content, a transmission zone with slowly changing soil water content, a wetting zone of rapidly changing soil water content, and a wetting front with a very steep hydraulic gradient.

The infiltration rate varies with time (Fig. 2). For a homogeneous soil, the rate depends on the initial water content (see article *Soil Water: Antecedent*), the application rate, the depth of the soil profile, and the surface and boundary conditions. If the application rate is less than the hydraulic conductivity, then all the water infiltrates. If the application rate is greater than the hydraulic conductivity, first the surface layer becomes saturated with water, then excess water collects at the surface. If a slope or outlet is present, then the excess water will runoff.

PREDICTION OF INFILTRATION

Physical and empirical based infiltration equations are described in the literature.[4–6,9,11,12] The physically based models[9] are developed from Richards[13] equation (see topic), Darcy's[14] law (see topic), and early developments by Buckingham.[15] Often these must be solved numerically for given initial and boundary conditions. Philip[3] discusses some of the assumptions when applying the physical-based models to water flow into and through the soil. These assumptions may not always be valid in the field,[16] and that is why the soil is often treated empirically in larger-scale applications. Another class of infiltration equations is the rainfall excess model types,[9] which assume no applied water ponds in depressions or is intercepted by plants (Fig. 1). Empirical infiltration models[9] determine infiltration rate or volume as a function of soil properties and application rate. The Horton[17] model is an example of an early empirical model. An intermediate type of model is approximately theory-based,[9] but the parameters are more difficult to estimate than for the empirical models. The earliest and most-used approximate model is the Green–Ampt model.[18] All of these models have numerous variations and recent developments, too numerous to discuss here. Based on these equations, the different infiltration models are used at various scales.

FACTORS AFFECTING

The rate that water infiltrates the soil is affected by surface and subsurface properties, both of which are affected by management and natural phenomena.[4] The rainfall intensity, duration, and distribution are also important considerations. (See related topics under precipitation.)

Surface Properties

Important surface properties include development of a surface seal, degree of water repellency, and presence of macropores or fractures. A surface seal impedes infiltration.[19–21] The development of a surface seal increases as the residue cover decreases and as soil aggregate stability decreases. The surface seal is affected by physical and chemical processes.[22]

Subsurface Properties

Once the water is in the soil, the water is redistributed[9] both vertically and laterally (Fig. 1). Water may be held in the soil by surface and capillary forces, may drain out of the soil into tiles, may recharge the water table, or may come back out at the soil surface from a down slope position (see page). The soil profile affects

This short article cannot cover all aspects of infiltration, since book-size conference proceedings have been written on the topic,[1,2] as well as many review articles[3–6] or sections of book chapters.[7–10]

Soils–Suspended

continuing infiltration due to hydraulic conductivity of the soil (see the articles *Soil Water: Flow under Saturated Conditions* and *Soil Water: Flow under Unsaturated Conditions*), continuity of macropores, air pressure build-up, and presence of impeding layers, frozen soil (see article *Frozen Soil: Water Movement in*), or high water table.

Water saturation due to a high water table or frozen soil near the surface prevents formation of a surface seal but also greatly restricts infiltration. Soil aggregate stability is increased by organic matter which somewhat increases the water repellency, allowing concentrated water flow around the aggregates. Continuous macropores and fractures also allow rapid infiltration to continue if the surface seal does not form over the macropore.

Crop and Soil Management

Crop and soil management greatly influence formation of a surface seal, existence of macropores, and compaction, all of which influence the infiltration rate.[4,9] Surface seal formation is less likely on forested and pasture land. Conservation tillage on cropland and use of perennial crops allow more residue to remain at the soil surface, reducing surface seal formation. Surface seal formation is reduced as the crop canopy develops, and is reduced by off-season ground cover. Forests, pastures, and cropland that is not tilled encourage macropore formation by mesofauna, especially earthworms.

Within Landscape Variability

Infiltration varies within the landscape due to rainfall variability (see articles *Precipitation: Stochastic Properties* and *Erosion and Precipitation*), plant effects (stem flow and interception), and varying soil properties.[9] Landscape infiltration is more than an accumulation of processes at individual sites because of water movement within the landscape (Fig. 1). Runoff water from higher landscape positions may move down slope at the surface and later infiltrate at down slope positions, depending on surface and profile characteristics. Seepage water may also infiltrate at a down slope position. A well-developed stream system moves water off site, but a poorly developed stream system combined with closed depressions results in temporary or permanent ponding on site. The natural flow pattern has been altered by tiles, ditches, and channelized streams. In addition, local variations occur because of funneling by crop canopy and compaction due to wheel traffic or hoof traffic.

Infiltration rate is not a static soil function because the soil properties are changing over time. Surface residue can be incorporated by tillage or be subject to decay or washed off by runoff waters. Fractures can close from prolonged wetting. Air pressure can build-up as infiltration continues.[23] Surface soils can form during infiltration or be disrupted by mesofauna activity. The temporal variability is often greater than the spatial variability within a given land-use practice or ecosystem.

MEASUREMENT

The type of infiltration measurement should relate to the application of the results.[8] Ponded ring infiltration measurements (see article *Ring and Tension Infiltrometers*) would relate to flood irrigation or to pond seepage. Sprinkler infiltration measurements relate to rainfall on the soil surface, especially if a surface seal develops. Tension infiltration relates to the rate water moves into the soil matrix, without the macropores present. Furrow irrigation measurements are important when the flowing water is critical.

Soils: Water Percolation

Kurt D. Pennell
School of Civil and Environmental Engineering, Georgia Institute of Technology, Atlanta, Georgia, U.S.A.

INTRODUCTION

The term ‘‘percolation’’ refers to the downward flow or movement of water through the soil profile. More precisely, percolation is defined as the downward flow of water in saturated or nearly saturated soil at hydraulic gradients of 1.0 or less.[1] Although the terms ‘‘infiltration’’ and ‘‘percolation’’ are often used interchangeably, infiltration refers to the entry of water into soil,[1] which typically occurs after rainfall or irrigation. In contrast, percolation refers to water movement that occurs following an infiltration event, once the soil profile has become saturated or nearly saturated with water. Such post-infiltration water movement is commonly referred to as internal drainage. Hillel[2] employed the term ‘‘deep percolation’’ to specify internal drainage of water occurring below the root zone, which is not influenced by water losses due to evaporation or transpiration (evapotranspiration) via plant roots.

To illustrate the general concept of soil water percolation, a schematic diagram of an idealized soil profile in contact with an unconfined aquifer is shown in Fig. 1. Following an infiltration event, in which the entire soil profile becomes saturated with water (indicated by a solid vertical line corresponding to a water saturation of 1.0), water will drain from the soil profile primarily under the influence of gravity (i.e., the pressure gradient is negligible). Assuming that no additional water enters the system, the soil water saturation profile at static equilibrium (dashed line) will decrease from a value of 1.0 in the saturated zone (groundwater and capillary fringe) to a value corresponding to field capacity below the root zone. In effect, the soil water profile is analogous to a soil water retention (pressure–saturation) curve. Hence, the solid and dashed lines represent the limits in water content (saturation) between which soil water percolation occurs in soils overlying an unconfined aquifer.

ESTIMATING SOIL WATER PERCOLATION

Vertical (downward) soil water percolation can be described by the Buckingham–Darcy flux law

$$q = \frac{Q}{A} = -K(h)\frac{\partial}{\partial z}(h + z) = -K(h)\left(\frac{\partial h}{\partial z} + 1\right) \quad (1)$$

where q is the Darcy velocity or flux ($\mathrm{L\,T^{-1}}$), Q is the flow rate ($\mathrm{L^3\,T^{-1}}$), A is the cross-sectional area across which flow occurs ($\mathrm{L^2}$), $K(h)$ is the unsaturated hydraulic conductivity ($\mathrm{L\,T^{-1}}$), h is the negative pressure or suction head (L), and z is the elevation head (L). If water is assumed to flow downward at a constant rate, the pressure head gradient ($\partial h/\partial z$) approaches zero,[3] and hence the Buckingham–Darcy flux law reduces to

$$q = -K(h) = -K(\theta) \quad (2)$$

where θ is the volumetric soil water content ($\mathrm{L^3\,L^{-3}}$). This condition is often referred to as gravity drainage. If water is assumed to drain uniformly from the soil profile over time, a simplified approach can be used to estimate the flux of water from a specific depth increment (z), based on the change in volumetric soil water content with time:[2]

$$q = K(\theta) = -z\frac{\mathrm{d}\theta}{\mathrm{d}t} \quad (3)$$

This scenario is illustrated by the horizontal arrow shown in Fig. 1, for which the water content decreases from saturation to field capacity, and is not strongly influenced by the water table (saturated zone).

To more accurately describe the soil water percolation, the functional relationship between the hydraulic conductivity (K) and the pressure head (h) or water content (θ) must be known. Unsaturated hydraulic conductivity may be written with respect to the intrinsic soil permeability (k_{i}):

$$K(\theta) = \frac{k_{\mathrm{rw}}(\theta)k_{\mathrm{i}}\rho_{\mathrm{w}}g}{\mu_{\mathrm{w}}} \quad (4)$$

where $k_{\mathrm{rw}}(\theta)$ is the relative permeability to water as a function of θ, ρ_{w} is the liquid density of water ($\mathrm{M\,L^{-3}}$), g is the gravity constant ($\mathrm{L\,T^{-2}}$), and μ_{w} is the dynamic viscosity of water ($\mathrm{M\,L^{-1}\,T^{-1}}$). However, this approach requires that the relative permeability function, $k_{\mathrm{rw}}(\theta)$, is known or can be measured. Fortunately, a number of unsaturated conductivity functions have been developed based on pressure–saturation

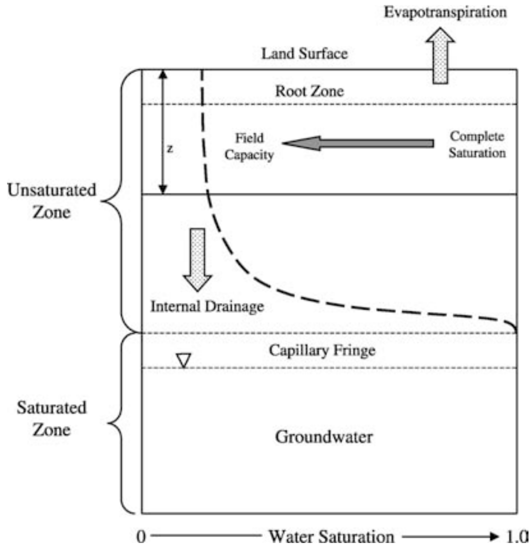

Fig. 1 Schematic diagram of soil profile showing the initial (water-saturated) and equilibrium condition following internal drainage.

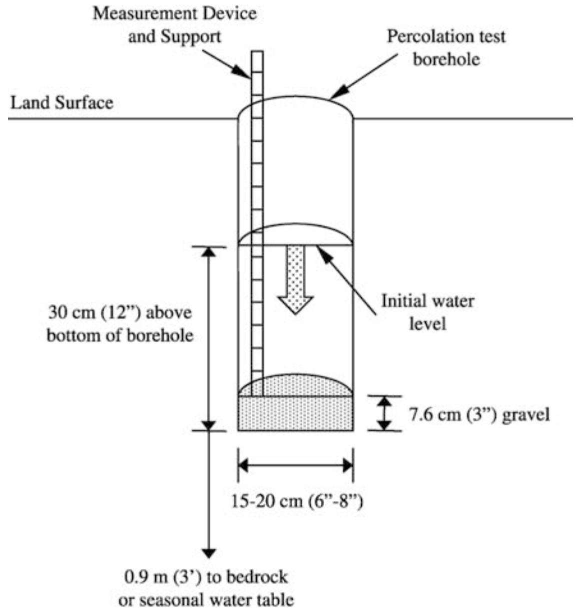

Fig. 2 Cross-sectional view of percolation test borehole.

relationships, which are more readily available and easier to measure than relative permeability. One of the equations most commonly used to describe soil water retention data was developed by van Genuchten:[4]

$$S_e = \frac{\theta - \theta_r}{\theta_s - \theta_r} = \frac{1}{(1 + |\alpha h|^n)^{(1-1/n)}} \tag{5}$$

$$\alpha = \frac{1}{h_b}(2^{1/m} - 1)^{1-m} \tag{6}$$

$$m = \frac{1}{1 - n} \tag{7}$$

where S_e is the effective water saturation, α and n are fitting parameters, and θ_r and θ_s are the residual and saturated volumetric water contents ($L^3 L^{-3}$), respectively. Using the fitting parameters defined above, van Genuchten[4] then developed relationships for $K(\theta)$ and $K(h)$:

$$K(\theta) = K_s S_e^{1/2}[1 - (1 - S_e^{1/m})^m]^2 \tag{8}$$

$$K(h) = K_s \frac{\{1 - (\alpha h)^{n-1}[1 + (\alpha h)^n]^{-m}\}^2}{[1 + (\alpha h)^n]^{m/2}} \tag{9}$$

where K_s is the saturated hydraulic conductivity ($L T^{-1}$). The fitting parameters needed for unsaturated hydraulic conductivity relationships (i.e., α and n) can be obtained by fitting moisture release curve data to Eq. (5) using a non-linear, least-squares approach (e.g., SYSTAT) or by using the RETC program.[5] More advanced approaches for describing water percolation (internal drainage) and water redistribution in partially wetted soils, such as the rectangular profile model and kinematic wave model, are presented by Hillel,[2] Jury, Gardner, and Gardner[3] and Charbenau.[6]

PERCOLATION TESTS

From a practical perspective, the term percolation is frequently encountered during home construction and zoning regulations in reference to a percolation or ‘‘perc’’ test. Percolation tests are widely used throughout the United States and Canada to locate and size absorption (leaching) fields for residential sewage treatment systems. The basic procedure involves digging several (e.g., 4–6) cylindrical boreholes, at least 15 cm (6 in.) in diameter and not greater than 20 cm (8 in.) in diameter, to the intended depth of the sewage treatment trench, as shown in Fig. 2. In addition, the bottom of the borehole is often required to be at least 0.9 m (3 ft) above the seasonal high water table or bedrock.[8] It is usually recommended that the bottom 0.3 m (1 ft) of the borehole sidewalls be scarified to improve water entry, and that 8 cm (3 in.) of gravel be placed in the bottom of the borehole. Prior to the percolation test, water is added to a depth of at least 0.3 m (1 ft) above the bottom of the borehole, and allowed to infiltrate until the soil in the vicinity of the borehole is completely saturated. For most soils an infiltration or wetting period of 4 hr, with the water level maintained at approximately 0.3 m (1 ft) above the bottom of the borehole, is adequate.[7,8] However, soils that exhibit substantial swelling, usually due to high clay or organic matter content, may require an extended wetting period, up to three or four days. Once the soil surrounding the borehole is completely saturated, water is allowed to stand in the borehole for 12 hr (overnight).

To run the actual percolation test, set the initial water level to 30–46 cm (12–18 in.) from the bottom of the borehole. From a fixed reference position, measure the height of water in the borehole to the nearest 4 mm (1/16 in.) every 15 or 30 min.[7] The percolation rate is obtained by dividing the time of measurement (e.g., 15 min) by the drop in the height of the water level (e.g., 1.5 cm), expressed as minutes per cm (mpc) or minutes per inch (mpi). Continue the test until three consecutive measurements are within approximately 20% of one another, indicative of steady water flow. A minimum of 15 cm (6 in.) of water should remain in the borehole throughout the test. Measured percolation rates of less (fast water flow) than 0.04 mpc (0.1 mpi) for coarse-textured soils, and more (slower water flow) than 24 mpc (60 mpi) for fine-textured soils are generally considered to be unsuitable for sewage absorption fields. Specific requirements for the percolation test vary by jurisdiction, and thus, it is essential that local public health and building permit offices be contacted prior to conducting a percolation test.

Soils: Waterborne Chemicals Leaching through

John Hutson
School of Chemistry, Physics and Earth Sciences, Flinders University, Adelaide, South Australia, Australia

INTRODUCTION

Agricultural, urban, and industrial activities have increased the variety and quantity of chemicals and wastes released into the environment. In agriculture, fertilizers, pesticides, and animal wastes have led to widespread pollution. Non-point source pollution is particularly difficult to predict and control. Pollutants and chemicals in soil are dissipated by various fate and transport processes. Concentrations are reduced by chemical and microbial degradation and transformation, by plant uptake, and through volatilization, and chemicals are transported by flowing water. Chemical flow pathways can be across the soil surface and downwards through the soil profile or vadose zone, and terminate via lateral subsurface flow and deep drainage in surface water bodies and aquifers. Transport pathways are diverse and difficult to predict with certainty.

The major non-point source pollutants from agricultural areas are nutrients, pesticides, and pathogens. In irrigated areas and regions where there is a risk of salinity, the transport of the major inorganic ions is a concern. Fuel, and industrial or non-agricultural chemicals, are also a pollution risk. Organic contaminants can be classified as largely miscible with water, non-aqueous immiscible liquids, and volatile compounds. Some organic chemicals partition into all three phases. This article discusses leaching of water-miscible chemicals.

TRANSPORT PROCESSES

Miscible chemicals can be leached from one zone in the soil to another via the movement of water in which they are dissolved. An understanding of solute leaching requires knowledge of water-flow patterns in soil. Infiltration of rain and irrigation water leads to downward movement flow, while evaporation from the soil surface, transpiration by plants, and redistribution of water can lead to both downward and upward movement of water.

Chemicals in soil are redistributed in soil profiles by four processes: 1) chemical diffusion in the liquid phase in response to an aqueous concentration gradient; 2) diffusion of volatile chemicals in the gas phase in response to a vapor density gradient; 3) forced convection (mass flow, or advection) of chemical dissolved in flowing water; and 4) transport of chemical in the vapor phase driven by barometric pressure fluctuations, wetting and drying cycles, and watertable fluctuations.

In natural unsaturated soils, vertical convective fluxes predominate. Transport of chemicals is complicated by reactions with mineral or organic surfaces, which retards the movement of chemical. Mixing between large and small pores as a result of local variations in mean water-flow velocity, and the tortuous nature of soil pore geometry leads to dispersion of solute molecules during-their movement through soil.[1] Dispersion tends to smear what may originally have been a sharp concentration front.

In 1-D, across a plane normal to the direction of flow, the convective flux of solute (J_{C_L}, $\mathrm{M\,L^{-2}\,T^{-1}}$) is represented as

$$J_{C_L} = \theta D_M(q,\theta)\frac{dc_L}{dz} + qc_L \tag{1}$$

where D_M is the hydrodynamic dispersion coefficient, a function of q, the macroscopic water flux density ($\mathrm{L\,T^{-1}}$), and θ, the volume fraction of water in the soil. C_L is the solute concentration in the soil solution ($\mathrm{M\,L^{-3}}$), and z is the depth (L).

The value of D_M is often estimated from

$$D_M = \lambda\left|\frac{q}{\theta}\right| \tag{2}$$

where λ is the diffusivity (L). Dispersivity is determined by soil geometry. It is usually independent of solute properties, except in cases where solute diffusion from mobile to stagnant areas is important.[2]

Solute leaching may be retarded if the chemical interacts with soil solids. Solute concentrations are controlled by the amount of chemical introduced into the system, chemical solubility, and partitioning between solution and solid phases (and the gas phase for volatile chemicals). The mechanisms of sorption in soil are poorly understood or quantified, but include retention on soil surfaces by chemical and physical binding as well as ion-exchange processes. Sorption sites differ in their binding energies. The sorption process may be kinetic, owing to slow sorption reactions and accessibility of sorption sites. Molecules may need to diffuse from bulk solution to sorption surfaces.

For these reasons, sorption is usually described operationally rather than mechanistically. Simple sorption isotherms or exchange equations, which assume local equilibrium, are fit to measured sorption data. However, solutes in flowing water do not react instantaneously with solid surfaces; most reactions are kinetic. In addition, molecules may have to diffuse from stagnant areas to reach larger pores where flow is more rapid. Sometimes, two-site or multi-site conceptual models are included.[3]

Sorption is often described using a Freundlich sorption isotherm

$$S = K_f C_L^n \quad (3)$$

where K_f is a Freundlich sorption coefficient and n is an exponent. When $n = 1$, the Freundlich sorption isotherm reduces to a linear sorption isotherm,

$$S = K_d C_L \quad (4)$$

where K_d is a partition or distribution coefficient. Linear sorption is often used to describe sorption over small concentration ranges and is easily manipulated mathematically. Databases containing K_d values for a wide range of chemicals are widely available.[4]

The total amount of chemical (C_T, $M\,L^{-3}$) in a soil can be expressed in terms of soil bulk density, water content, and the sorption coefficient,

$$C_T = C_L(\theta + \rho_b K_d) \quad (5)$$

where ρ_b is soil bulk density ($M\,L^{-3}$).

Since only dissolved chemical can be transported in water, the ratio of the rate of water flow to that of the chemical is equivalent to the ratio of the total concentration of chemical (C_T) to the dissolved concentration ($C\theta$). This ratio is known as the retardation factor (R),

$$R = 1 + \frac{\rho K_d}{\theta} \quad (6)$$

which is a useful index of the relative rates of transport of different chemicals.

Solute concentrations can be reduced through chemical and biotic transformations and uptake. Microbial transformations may produce degradation products. Again, these processes can be very complex. Degradation, for example, may depend upon the presence and growth of a suitable microbial species. For simplicity, degradation is often described using first-order kinetics, but in reality it is more complex, owing to processes such as diffusion, sorption, microbial composition, and growth.[5]

CONVECTION–DISPERSION EQUATION

Combining and equations for convective transport, dispersion, and partitioning leads to the convection–dispersion equation (CDE), which allows calculation of the rate of change of concentration of a chemical in soil,

$$\frac{\partial C_L}{\partial t}(\theta + \rho_b K_d) = \frac{\partial}{\partial z}\left[\theta D_M(\theta, q)\frac{\partial C_L}{\partial z} - qC_L\right] \pm \Phi \quad (7)$$

where t is time, and Φ is a source or sink term.

The CDE can be solved analytically for certain defined boundary conditions and steady-state water flow.[6] Transport parameters can be measured, but are almost invariably obtained by fitting to controlled laboratory chemical breakthrough curves from soil columns at constant water content and subject to steady-state water flow.[7] For transient water flow, the CDE is best solved numerically. Water fluxes in natural, unsaturated soils are often sporadic, especially in areas of variable rainfall (Fig. 1). Examples of simulation models of chemical transport in soils are LEACHM,[8] UNSATCHEM,[9], and RZWQM.[10] For some scenarios, 2-D and 3-D models are necessary, for e.g., leaching under drip irrigation and hillslope flow.

The CDE is most applicable to homogeneous soils. Structured and heterogeneous soils have cracks and channels giving rise to preferential water and chemical flow paths, and many soils exhibit more complex chemical and microbial reactions. Conceptually, soil porosity can be divided into immobile, mobile, and preferential flow regions. Preferential flow takes place

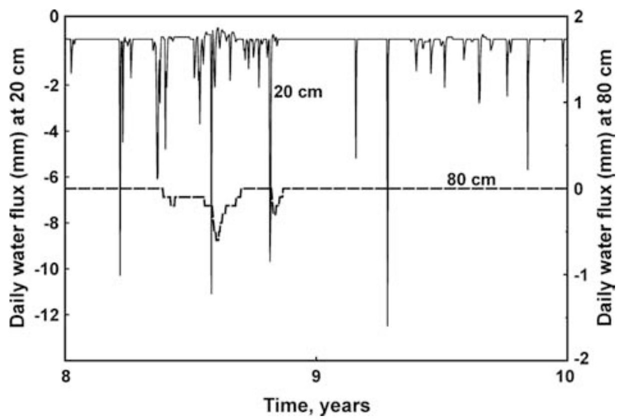

Fig. 1 An example of simulated daily water fluxes in a clay loam soil, using daily rainfall for Adelaide, Australia.

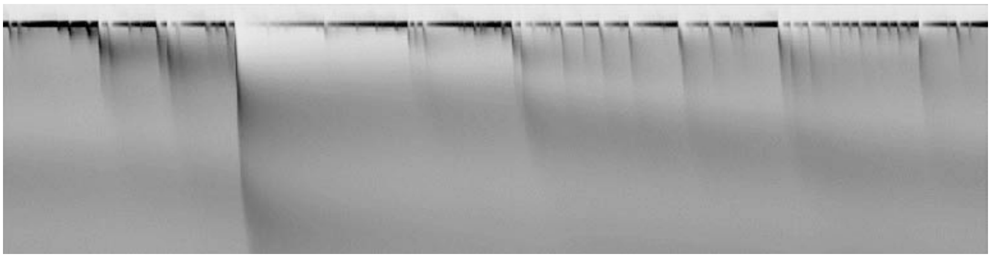

Fig. 2 A simulation showing the sporadic nature of chloride leaching in a sandy loam soil, South Australia, using 100 yr of daily rainfall data. Color intensity is proportional to chloride concentration. The x axis is soil depth (to 12 m) and the y axis is time (to 100 yr).

through larger pores and cracks. Water and solutes are transported very rapidly in these channels, and bypass the soil matrix, so there is little opportunity for sorption or degradation. Conversely, solute-free water flowing in preferential pathways may bypass chemical in the matrix, leading to less leaching. Preferential flow is important during periods of intense rainfall or irrigation, when surface runoff and ponding can lead to ingress into cracks and channels. Preferential flow is difficult to predict or quantify. An example of a model that describes preferential flow is MACRO.[11]

Capacity, or tipping-bucket models offer a simpler approach to solute transport simulation. Water moving between soil layers moves dissolved chemical, which then mixes with the water in the receiving layer, and the mixed concentration moves to the next layer.[12]

Assessments of chemical transport in natural soils need to take spatial and temporal variability into account. Downward water fluxes in soil are intermittent and sometimes, especially in arid climates, infrequent. This means that solutes can accumulate in subsoils until flushed during periods of heavier rain. So while leaching may be frequent and regular in temperate humid climates, it may be infrequent in more arid areas (Fig. 2).

CONCLUSION

The recognition of spatial variability has led to increased efforts to combine GIS and simulation models in order to describe solute transport on a farm and catchment scale, accounting for soil, land management, vegetation, and terrain differences. Soil leaching models focus on processes described at the soil profile. Upscaling to larger areas require boundary conditions to be described in more detail, which means that output from associated surface hydrology, groundwater, and crop models need to be reflected. Describing solute leaching on a catchment scale, accounting for management, spatial, and climatic variability, is a current priority.

Stomatal Responses to the Environment: Quantifying

Matthias Langensiepen
Department of Modeling Plant Systems, Institute of Crop Science, Humboldt University of Berlin, Berlin, Germany

INTRODUCTION

Plants transpire water into the atmosphere through stomata that are tiny openings embedded in green plant surface tissues. The width of each pore is altered by changes in guard cell osmotic pressure, which is determined by solute influx in response to a proton-motive force created by plasma membrane H^+-ATPases. Alterations of environmental state variables such as soil water, air vapor pressure deficit, light, nutrition availability, air carbon dioxide concentration and others, directly or indirectly, activate signal transduction pathways that transmit information throughout the plant. Stomatal responses to the environment are a result of various metabolic reactions that are triggered by this information. Stomatal closing or opening is thus highly co-ordinated, causing difficulties in finding adequate mathematical expressions for simulating stomatal behavior. As water resources are getting increasingly scarce, there is yet a growing need for finding expressions that can be practically applied in quantifying stomatal control of transpiration. The following gives an overview over practical methodologies that are frequently applied in quantifying stomatal responses to the principal controlling environmental factors: air vapor pressure deficit, water, carbon dioxide, and light.

VAPOR PRESSURE DEFICIT

When a plant leaf is exposed to dry air, vapor partial pressure deficit (VPD) causes a local cellular water stress in the leaf epidermis that feeds back on stomatal aperture.[1] The exact mechanisms remain unclear; but there is mounting evidence that stomata sense the transpiration rate induced by VPD.[2–4] Leaf transpiration E_l can thus be determined by the product of a proportionality factor (stomatal conductance g_{lv}) and the vapor partial pressure difference between the leaf mesophyll e_{mv} and the surrounding air and e_{av}, which is the driving force:

$$E_l = g_{lv}(e_{mv} - e_{av}) \tag{1}$$

The stomatal response to VPD is frequently determined by solving Eq. (1) for g_{lv} and measuring vapor flux, leaf temperature, and ambient air humidity with vapor diffusion porometers.[5]

SOIL WATER, CHEMICAL AND HYDRAULIC SIGNALING

Plants can be divided into two distinctive groups according to their responses to changing VPD and soil water availability:[6,7] Anisohydric plants adjust their leaf water potential according to variations of both factors. Isohydric plants, in contrast, maintain their leaf water status over wide ranges of vapor pressure deficits and soil water availabilities. This phenomenon is a consequence of decreased stomatal conductance, which is triggered by increased concentrations of abscisic acid (ABA) in the sap-conducting system.[8] ABA is synthesized in leaves and root tissues depending on the level of water stress experienced by these organs. Under steady-state conditions, leaf ABA concentrations [ABA] can be empirically modeled as the balance between total ABA synthesis, dilution in the water flux F [see Eq. (3) below], and an effective ABA sequestration rate a:[9]

$$[\mathrm{ABA}] = \frac{-\lambda_r \Psi_r - \lambda_l \Psi_l}{V_w(F + a)} \tag{2}$$

where λ is an ABA synthesis coefficient, Ψ the water potential (r, root; l, leaf epidermis), V_w the partial molal volume of water, and F the water flux from the roots to the canopy. The flexible parameterization of λ allows the application of Eq. (2) for a variety of conditions including anisohydric behavior. Other plant hormones (auxins and cytokinins) are known to affect stomatal behavior as well,[10] but there are no practical methodologies available yet for quantifying these effects.

The water flux from soil to leaves F is often expressed with a simple catenary model,[11] which gives the relationship between steady-state flow and the water potentials within the hydraulic system:

$$F = -K\frac{d\Psi}{dx} \tag{3}$$

where K is the hydraulic conductivity expressed per unit leaf area and $d\Psi/dx$ the water potential gradient driving flow. The hydraulic system is commonly discretized into characteristic subunits that reflect known conductivity variations along the soil–plant pathway.[12] The usage of capacitance, voltage, or diode analogues must be taken into consideration when the assumption of a steady-state flow condition is violated.[5,13]

The actual ABA effect on stomata is modulated by the pH concentration of the plant sap, which is affected by inorganic and organic nutrition cycling within the sap-conducting system.[1,14] Information is still lacking about the nature of the underlying mechanisms. Tardieu and Davies[7] formulated a simplified model that accounts for the effects of hydraulic and chemical signaling through ABA on leaf conductance:

$$g_{\mathrm{lc}} = g_{\mathrm{lc\,min}} + (g_{\mathrm{lc\,max}} - g_{\mathrm{lc\,min}}) * \exp\{-[\mathrm{ABA}]\exp(\delta\Psi_{\mathrm{l}})\} \quad (4)$$

where is the basal sensitivity of stomatal conductance to [ABA] at $\Psi_{\mathrm{l}} = 0$ and δ is an empirical factor accounting for the increase in stomatal sensitivity to [ABA] as Ψ_{l} falls. g_{lc} is the leaf carbon dioxide conductance that can be correlated to leaf vapor conductance, g_{lw}, as both gases pass through the same transport system:[7]

$$g_{\mathrm{lw}} = 0.62 g_{\mathrm{lc}} \quad (5)$$

CARBON DIOXIDE

Carbon dioxide concentrations in the intercellular spaces c_{i} affect stomatal conductance through a number of metabolic processes that have not been clearly identified yet.[15,16] It has been hypothesized that alterations of chloroplastic levels of zeaxanthin play a key role in integrating CO_2 and light sensing.[17] Three additional sensing mechanisms seem to exist that independently operate under light and dark conditions.[16] An empirical model has been proposed by Ball, Woodrow, and Berry[18] that describes the effect of carbon dioxide assimilation and vapor pressure deficit on stomatal conductance. It was later modified by Leuning[19] and extended by Dewar[9] for considering additional effects of [ABA] and Ψ_{l}:

$$g_{\mathrm{sc}} = \frac{a_1(A_{\mathrm{net}} + R_{\mathrm{d}})}{c_{\mathrm{i}}[1 + (\mathrm{VPD_s}/D_0)]} * \exp\{-[\mathrm{ABA}]\exp(\delta\Psi_{\mathrm{l}})\} \quad (6)$$

where A_{net} is the net assimilation rate, R_{d} the leaf dark respiration rate, and c_{i} the intercellular CO_2 concentration. The empirical coefficient a_1 accounts for the effects of guard cell solute balance and the mechanical tension in its cell walls on stomatal carbon dioxide conductance g_{sc}, and D_0 is a measure for the relation between hydraulic conductivity along the epidermal guard cell pathway and the mechanical tension of the cell walls (further theoretical explanations and calculation procedures can be found in Dewar[9] and Buckley, Mott, and Farquhar[20]).

LIGHT

Stomata have a strong sensitivity to quantitative and qualitative changes of the light environment. Receptor pigments located in the guard cells sense alterations of the light environment and have a direct effect on stomatal aperture.[21,22] There are also two other unknown sensors located in the guard cells that indirectly trace alterations of the light environment through changes in intercellular partial CO_2 pressures, which are influenced by the intensity of photosynthetic activity.[23] In spite of this lack of knowledge, many experiments show strong correlations between light absorption and stomatal conductance. They can be established by parallel measurements of stomatal conductance and impinging photosynthetically active radiation, which should be performed under known soil-moisture supply conditions to trace possible effects of water stress.[24] An inverse hyperbolic function is a frequently applied model for quantifying stomatal responses to light:[25]

$$g_{\mathrm{lv}} = \frac{g_{\mathrm{lv\,max}}}{1 + (M/\mathrm{PAR})} \quad (7)$$

where PAR is the photosynthetically active radiation, M an empirical curve fitting coefficient, and g_{lv} the leaf vapor conductance defined as

$$g_{\mathrm{lv}} = \frac{1}{(1/g_{\mathrm{sv}}) + (1/g_{\mathrm{bv}})} \quad (8)$$

where g_{sv} is the stomatal conductance and g_{bv} the leaf boundary layer conductance. When g_{lv} is determined under the standardized flow conditions of diffusion porometers, fixed values are assigned to the boundary layer conductance. However, when determined under ambient conditions, g_{bv} must be adapted to account for variable laminar air flow (see Jones[5] for calculation procedures).

INTEGRATION OF ENVIRONMENTAL RESPONSES

The individual factors influencing stomatal conductance are typically summarized by the application of simplified approaches such as the frequently used multiplicative model initially proposed by Jarvis:[26]

$$g_{lv} = g_{lv}(\mathrm{PAR}) * f(\mathrm{VPD_b}) * f(\Psi_l) * f(\mathrm{ABA_l}) * f(c_i) * f(\cdots) \quad (9)$$

where g_{lv}(PAR) defines the response of leaf conductance to photosynthetically active radiation and the zero to unity functions account for other known stomatal responses. It must be cautioned that the Jarvis model is limited by a lack of considering any interaction or feedback responses[27] (see Jones[5] for further explanations and alternative approaches). However, in spite of the complexity of stomatal regulation, it is one of the few approaches that can actually be applied under practical conditions.

CONCLUSIONS

Modeling plant transpiration requires quantitative information about stomatal responses to environmental factors. The complex nature of plant metabolic networks controlling stomatal behavior causes difficulties in finding corresponding mathematical functions. The simulation of stomatal behavior must thus be still largely based on empirical observation. Future advances in understanding the molecular basis of stomatal regulation will provide the theoretical basis for improving stomatal response functions.

INTRODUCTION

Storativity and specific yield quantify the storage properties of an aquifer. Thus, they are fundamentally important to groundwater resource investigations. Estimates of storativity and specific yield can be used to predict changes in the volume of water stored in an aquifer with changing groundwater levels. Moreover, storativity and specific yield affect the hydraulic response of an aquifer to pumping. Predictions of pumping response may influence the locations of wells for such purposes as water supply, construction dewatering, and groundwater remediation.

EFFECTIVE STRESS AND PORE-WATER PRESSURE

Consider an enlarged, hypothetical cross-section of a saturated aquifer matrix as shown in Fig. 1. The pore space is occupied by water, and the mineral matrix is assumed to be sand grains. The porous-medium system (mineral plus water) of Fig. 1 is taken, herein, to be a representative elementary volume (REV) of the aquifer. The mineral matrix sustains an intergranular or effective stress σ_e, while the pore-water pressure is P_w. The total stress (σ) in the REV is given by $\sigma = \sigma_e + P_w$. Both the water and the mineral matrix are compressible, i.e., their volumes depend on the stresses to which they are subjected. The compressibility of water at a typical ambient temperature (e.g., 15°C) is $\beta = 4.6 \times 10^{-10}\,\mathrm{m^2\,N^{-1}}$, a small number indeed. The compressibility of a substance, water or mineral, is the absolute value of the change in its volume per unit change in compressive stress divided by the initial volume of the substance, hence the compressibility units of $\mathrm{Pa^{-1}}$ ($=\mathrm{m^2\,N^{-1}}$).

The effective stress $\sigma_e = \sigma - P_w$, in which the total stress may be assumed to be approximately constant. Therefore, taking differentials on both sides of the latter stress relationship, it follows that $\Delta\sigma_e = -\Delta P_w$, i.e., as the pore-water pressure increases, the effective stress decreases, and vice versa. Aquifer dewatering by groundwater pumping, e.g., reduces the pore-water pressure and augments the effective stress, thus compressing the mineral matrix and reducing its volume. This is the basic mechanism that causes aquifer subsidence, i.e., compaction of the aquifer and associated lowering of the ground surface as a result of groundwater extraction. The degree of land subsidence is a function of the amount of change in groundwater storage, and of the compressibility of the mineral matrix. The latter is greatest in fine-textured and cohesive formations. A well-known case of aquifer subsidence is that in the lacustrine formations that underlie Mexico City. There, the ground surface at various locations fluctuates with the cycle of aquifer dewatering (ground surface drops), and recharge (ground surface rises). Aquifer subsidence is a common phenomenon associated with pumped aquifer systems throughout the world.[1]

WATER RELEASE IN AN AQUIFER

When groundwater is pumped from an aquifer, there results a series of water-release mechanisms. Depending on the deformation properties of the aquifer, the significance of each specific mechanism may be enhanced or diminished. Those mechanisms may also overlap over time. As groundwater is pumped out of an aquifer, its pore pressure is reduced and the effective stress increases. The groundwater in storage expands its volume while the mineral matrix is compacted. As a result, some groundwater in storage is removed from the pore space. This mechanism of water release is primarily a strain–stress response of the aquifer to reduced pore pressure. It occurs in confined and unconfined aquifers, and it is accentuated by cohesive sediments prone to compaction. In unconfined aquifers (with a free-moving water table), a second mechanism of water release may take place as the water table begins to fall. Pore water is drained by gravity as the water table recedes. Drainage of pore water is rapid soon after pumping starts and the decline of the water level in observation wells (i.e., the drawdown) is pronounced. Some pore water continues to drain after the water table has receded as gravitational drainage

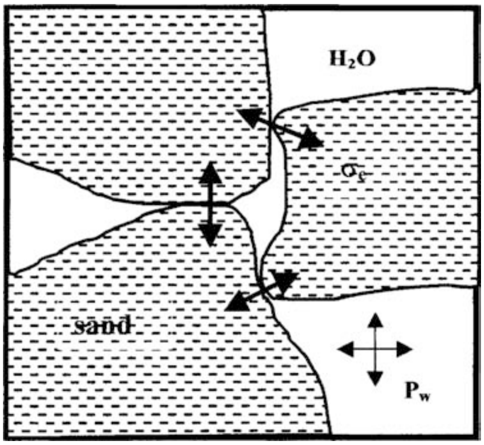

Fig. 1 An enlarged cross-section of the pore space in a saturated sand.

lags behind the rate of water-table descent. This is caused by limited air replacement of the pore space vacated by the falling water table. Delayed drainage (or delayed yield) can continue for a long period of time and contribute to further drawdown. A third mechanism may take place in unconfined aquifers following delayed drainage. The rate of water-table decline decreases relative to the early phase of rapid drainage, and the groundwater flow towards pumping wells is essentially horizontal, driven by hydraulic gradients.

The previous mechanisms of water release take place primarily in aquifers formed by unconsolidated geologic deposits whose porosity stems from the intergranular pore space in the aquifer matrix. This is called primary porosity. Other aquifers, called bedrock aquifers, exhibit pore water that arises largely from secondary porosity. In this case, the pore space is created by dissolution cavities (such as in carbonate or karst systems), fossil cavities (in formations that have harbored past biological activity in them), and rock fractures and joints induced by tectonism (folding, extension, and faulting). Fig. 2 illustrates primary and secondary porosities. Whether primary or secondary, porosity is

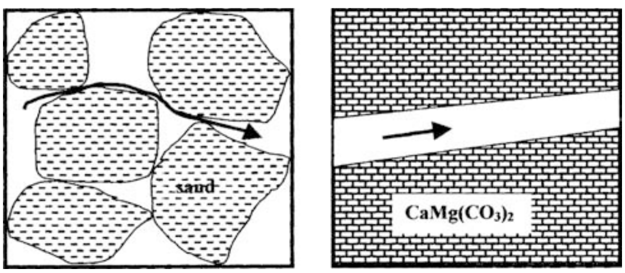

Fig. 2 On the left, primary porosity in a sand aquifer. On the right, secondary porosity in a dolomite aquifer. The arrowed line denotes pore-water pathway.

defined as the volume of pore space per bulk volume of aquifer. Groundwater in bedrock aquifers moves through complex fracture and cavity networks driven by hydraulic gradients from zones of natural recharge towards wells. If aquifer recharge does not equilibrate with the rate of pumping, the secondary pore space may be dewatered leading to the depletion of bedrock water and dry wells. Depending on the nature of the fracture network and the compressibility of the rock matrix, there may be compaction of the mineral matrix as the water pressure in the fractures and cavities is relieved. The magnitude of delayed drainage in a bedrock aquifer with a free-moving water surface depends on the aperture of bedrock fractures and cavity diameters. Very small fracture apertures hinder gravitational drainage in unconfined bedrock aquifers. Unconfined and confined bedrock aquifers are prone to complete dewatering during droughts and have relatively low sustainable groundwater yield. For example, the sandstone aquifers of the Santa Ynez mountains of southern California have a groundwater yield range from $38\,\mathrm{L\,min^{-1}}$ to $190\,\mathrm{L\,min^{-1}}$. Unconsolidated aquifers have typical yields at least one order of magnitude greater.

STORATIVITY AND SPECIFIC YIELD

Hydrologists introduced the concepts of storativity and specific yield to quantify the effect of changes in hydraulic head on groundwater storage. Recall that hydraulic head (h, dimension of L) is the mechanical energy content of pore water per unit weight of water, i.e., $h = z + P_w/\rho g$, in which z is the elevation head (potential energy per unit weight of water), and $P_w/\rho g$ is the pressure head (fluid-pressure energy per unit weight of water), where ρ is the density of liquid water and g is the acceleration of gravity.

A fundamental parameter is the specific storage S_s, which is the volume of groundwater (V_w) released (or gained) per unit decline (or rise) in hydraulic head and per unit bulk volume of aquifer (V). Thus, $S_s = V_w/(\Delta h V)$, dimensions of L^{-1}. The specific storage may be related to the properties of pore water and the mineral matrix. Let β be the compressibility of pore water, α, the compressibility of the mineral matrix, and n the porosity, it is possible to show that $S_s = \rho g\ (\alpha + n\beta)$. The latter expression for the specific storage rests on the assumption that the aquifer matrix deforms elastically, i.e., the amount of aquifer compaction (or expansion) is proportional to the compressive stress exerted on it. More complex analysis of aquifer deformation is needed when aquifer deformation is non-elastic (plastic).

The storativity (S) is a parameter that is widely used in the analysis of compaction effects and groundwater

Soils–Suspended

release in aquifers. S is the volume of groundwater released (or gained) per unit decline (or rise) in hydraulic head and per unit (horizontal) area of aquifer (A), $S = V_w/(\Delta h A)$, a dimensionless parameter. Let b be the thickness of a confined aquifer, then $S = bS_s = b\rho g(\alpha + n\beta)$ is the relationship that links the specific storage to the storativity. This relationship is useful to establish a lower bound for the storativity when the porosity and aquifer thickness are known. For example, if $b = 10$ m and $n = 0.3$, then that lower bound is given by (ignoring the effect of mineral matrix compressibility) $b\rho g n\beta = 10\,\text{m} \times 1000\,\text{kg}\,\text{m}^{-3} \times 9.8\,\text{m}\,\text{s}^{-2} \times 0.30 \times 4.6 \times 10^{-10}\,\text{m}^2\,\text{N}^{-1} = 1.4 \times 10^{-5}$.

Generally, the storativity, instead of the specific storage, is the preferred parameter in the study of aquifers. This is so because the storativity is more prone to empirical estimation than the specific storage. The storativity may be estimated by means of pumping tests. It can also be inferred from maps of hydraulic head drawn at two different times if the groundwater pumped (or recharged) between those dates in the mapped area is known. The latter inference is possible by a direct application of the definition of storativity based on the water withdrawn (or recharged) to an aquifer per unit area and per unit decline (or rise) of the hydraulic head. Numerical methods generically known as ''inversion theory'' are also used to estimate S and S_y, as well as other aquifer parameters. The storativity of most confined aquifers is on the order of 10^{-5} to 10^{-3}.

The storativity is used to characterize unconfined aquifers also, where changes in groundwater storage are caused by the fall or rise of the water table. Recall that unconfined aquifers may release pore water by compaction of the mineral matrix as well as by gravitational drainage. The specific yield (S_y) was introduced to differentiate between these two mechanisms of water release. Specifically, S_y represents the volume of groundwater released by pore-water drainage per unit drop in the water table and per unit (horizontal) area of unconfined aquifer. It is a dimensionless parameter. If the saturated thickness of an unconfined aquifer is denoted by b_s, the storativity in an unconfined aquifer may be written as the sum of two terms. One term reflects water release by drainage while another accounts for aquifer compaction. Specifically, $S = S_y + b_s S_s$. The term involving the specific storage S_s captures the role of aquifer compaction on water release in the last equation. In unconfined aquifers formed by coarse sediments (sand and gravel), the specific yield is much larger than the specific storage and $S \approx S_y$. In fine-textured, unconfined, aquifers, drainage is negligible and $S \approx b_s S_s$.

From the definition of specific yield, there arises a relationship between the porosity (n) and what is called the specific retention, S_r. The specific retention is the volume of pore water held against gravitational drainage per unit bulk volume of aquifer (S_r is a dimensionless parameter). Clearly, $n = S_y + S_r$. The specific yield is less than porosity, an intuitive fact imposed by the impossibility of draining more water from pore space than was originally held in it. The specific yield ranges between 0.1 and 0.3 in most unconfined aquifers.

FIELD ESTIMATION OF STORATIVITY AND SPECIFIC YIELD

The preferred method to estimate storativity and specific yield is via pumping tests, and, in particular, pumping tests in which there is at least one observation well where measurements of the time-dependent drawdown are made at a distance from the pumping well. If properly designed and executed, pumping tests produce representative storativity and specific-yield estimates that average out geological variability over tens to hundreds of meters. These are the most useful estimates in the analysis of aquifer response to human and natural stresses. The classical analysis of pumping-test data relies on several assumptions, i.e., a large, homogeneous, aquifer with isotropic radial flow

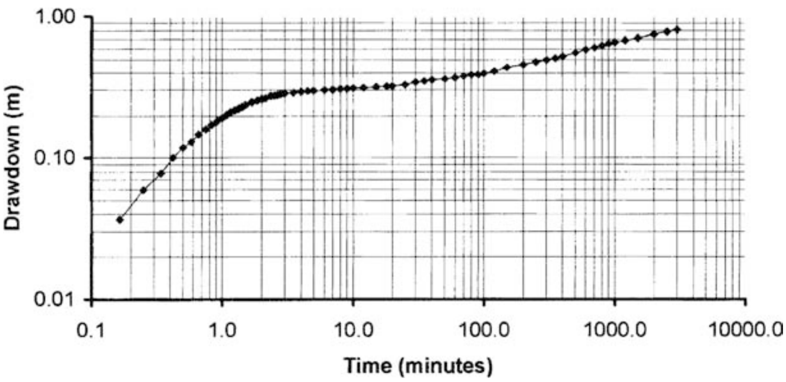

Fig. 3 Drawdown data in an observation well 22.25 m away from a well pumped at a constant rate of 4088 L min^{-1} in an unconfined aquifer in Fairborn, Ohio. *Source*: From Ref.[4].

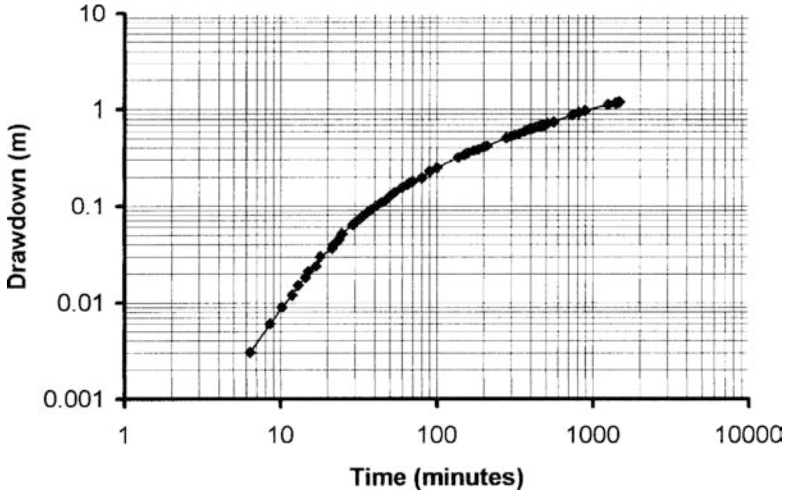

Fig. 4 Drawdown data in an observation well 467 m away from a well pumped at a constant rate of 2839 L min^{-1} in a semiconfined aquifer in Pixley, California. *Source*: From Ref.[4].

towards a fully penetrating pumping well. The theory and practice of pumping-test analysis[2] is beyond the scope of this article. Herein, we highlight the role of pumping-test data in the interpretation of specific yield and storativity.

Consider the drawdown vs. time data collected during a pumping test in an unconfined aquifer, which has been graphed in Fig. 3. The drawdown is pronounced during the first four minutes. This is caused by aquifer compaction and rapid gravitational drainage. Some authors[3] define an early-time apparent specific yield to describe the water-release mechanism during this early phase. The early-time specific yield for the data in Fig. 3 was estimated to be approximately 3×10^{-3}.[4] In the interval between 4 min and 30 min, the rate of drawdown levels off as gravitational drainage diminishes. Thereafter, the rate of drawdown increases and is sustained by delayed drainage through the last observation taken 3000 min after pumping started. This latter drawdown phase is associated with a later-time specific yield[3] that was estimated in Ref.[4] to be approximately 0.1.

Fig. 4 shows pumping test data for a semiconfined aquifer in Pixley, California. The aquifer has suffered considerable subsidence from prolonged pumping. The mechanism of groundwater release in this instance is matrix compaction and water expansion as the aquifer is depressurized by pumping. Based on the data in Fig. 4, the storativity was estimated at 4×10^{-5}.[4]

FIELD CONDITIONS AND RANGE OF VALUES

Specific yields for unconfined aquifers generally range from 0.1 to 0.3. They are less than 0.02 for most aquicludes (i.e., formations with very low water-bearing capacity) Table 1 lists representative ranges of specific yield for different types of unconsolidated sediment. Generally, specific yield increases with particle size and degree of sorting. Due to a larger surface area per unit volume and smaller pores, fine-grained sediment holds more water against the force of gravity. Multiplying the specific yield of an unconfined aquifer by its total saturated volume gives an indication of the maximum usable volume of water stored in the aquifer.

Sorting also affects specific yield because it impacts the porosity of unconsolidated sediment. Thus, a coarse sand mixed with silt has a lower specific yield than uniform coarse sand. This is so because the small silt particles fill spaces between the larger sand particles, thus reducing total porosity in the mixed sand relative to that of the uniform sand.[6] Clay has a high porosity, sometimes exceeding 0.50, but a low specific yield, due to a large surface of clay plates per unit volume and tiny pore spaces.

Specific yield values are lower for detrital sedimentary rocks (e.g., conglomerate, sandstone, siltstone,

Table 1 Representative ranges of specific yield for unconsolidated sediment

Sediment	Range of specific yield, S_y
Clay	0.01–0.18
Silt	0.01–0.39
Loess	0.14–0.22
Fine sand	0.01–0.46
Medium sand	0.16–0.46
Coarse sand	0.18–0.43
Eolian sand	0.32–0.47
Fine gravel	0.13–0.40
Medium gravel	0.17–0.44
Coarse gravel	0.18–0.43

Table 2 Range of specific yield in selected sedimentary formations

Sedimentary formation	Range of specific yield, S_y
Siltstone	0.01–0.33
Limestone	0.00–0.36
Fine sandstone	0.02–0.40
Medium sandstone	0.12–0.41
Tuff	0.02–0.47
Schist	0.06–0.33

Source: From Ref.[5].

and shale) than their unconsolidated counterparts. Cement fills pore spaces in such rocks, creating smaller and less connected pores. Moreover, specific yield values are extremely low (less than 0.01) in most unweathered chemical sedimentary, igneous, and metamorphic rocks due to a low effective (interconnected) porosity.[7] Secondary porosity from weathering and fracturing increases specific yield in consolidated rocks. Weathering and fracturing are most common within 20 m of the land surface, but may extend to depths of 100 m in tropical regions.[7] Underground solution also enhances porosity and specific yield, especially in carbonates (e.g., limestone) and evaporites (e.g., gypsum and halite). Table 2 presents specific yield ranges for sedimentary formations.

Storativity values are much lower in confined aquifers than specific yield values in unconfined aquifers. Water-release mechanisms in confined aquifers (compression of aquifer solids and water expansion) release small amounts of water per unit decline in hydraulic head compared to those in unconfined aquifers (gravity drainage). During pumping, small storativity values in confined aquifers result in rapid expansion of cones of depression. Interference of expanding cones around adjacent wells occurs more rapidly in confined aquifers than in unconfined ones. Substantial declines in hydraulic head over large areas are needed to produce large amounts of water. Thus, confined aquifers are more vulnerable to being overexploited. For example, the potentiometric surface of the Trinity aquifer beneath Dallas and Fort Worth, Texas has declined more than 200 m over the past century.[8] However, the land surface above the aquifer has incurred negligible subsidence due to the granular structure of the aquifer and overlying rock aquicludes.

CONCLUSION

The previous review of specific yield and storativity highlights the importance of these parameters in all aspects of groundwater hydrology. They play a role in important processes of aquifer compaction and expansion at the pore scale. Furthermore, they are very useful in characterizing the response of aquifers to pumping and recharge at the field and regional scales. Specific yield and storativity become indispensable in the numerical simulation of transient aquifer flow. The combined application of pumping tests and inverse theory is a powerful tool for their estimation and interpretation.

Stormwater Management

Derek B. Booth
Center for Water and Watershed Studies, University of Washington, Seattle, Washington, U.S.A.

INTRODUCTION

Stormwater management is the term broadly applied to how runoff from human-disturbed landscapes is collected, treated, and conveyed. Its focus is typically in urban and suburban areas, where changes to natural hydrologic processes are commonly severe and their consequences are most problematic.

WHY DOES STORMWATER NEED TO BE MANAGED?

The need for stormwater management of any type results from the changes to the land that accompany urban development. Wherever grasslands and forests are replaced by rooftops and roads, the movement of water across the landscape is radically altered. Flooding, channel erosion, landsliding, and destruction of aquatic habitat are some of the unanticipated changes that can result from these alterations, recognized by many decades of studies because of the loss of both lives and property that sometimes result. With urbanization, stream channels expand catastrophically to consume adjacent land never before affected by either flooding or erosion, sediment inundates low-lying areas seemingly far away from active channels, stormwater facilities are overwhelmed by frequent flows far beyond their design capabilities, and populations of aquatic organisms are decimated.[1,2]

Nearly all of these problems result from one underlying cause: loss of the water-retaining function of the soil in the urban landscape. This loss may be literal, in that the loose upper layers of the soil are stripped away to provide a better foundation for roads and buildings. The loss may also be functional if the soil remains, but precipitation is denied access to it by paving or rooftops. In either case, a stormwater runoff reservoir of tremendous volume is removed from the stormwater runoff system; water that may have lingered in this reservoir for a few hours or a few days or many weeks now flows rapidly across the land surface and arrives at the stream channel in short, concentrated bursts of high discharge (Fig. 1).

STORMWATER MANAGEMENT FACILITIES

Conveyance Facilities

Stormwater management is intended to reduce or eliminate the human and ecological consequences of these landscape alterations to the natural hydrologic cycle. Most commonly, stormwater management is accomplished through constructed facilities, which can be grouped into a few basic types depending on their primary function: conveyance, water-quantity reduction, or water-quality improvement. Conveyance facilities simply move water from one place to another with the least impact or inconvenience to people and human infrastructure. Pipes, channels, swales, and ditches are all conveyance facilities. In many cities, sanitary sewers have also been used to carry stormwater, presenting an attractive, broadly distributed network for collecting and disposing of wet-weather flows. During large storm events, however, overflows of sanitary sewers from such combined systems are common because the pipes and treatment facilities are generally sized for the relatively uniform loading of residential and commercial water use and disposal, not the brief (but extreme) discharges of runoff. As treatment requirements for wastewater discharges have increased, overflows (i.e., releases of untreated stormwater plus sewage into receiving waters) have become less acceptable, and the increased peak volumes of stormwater runoff arriving at the treatment plant have required ever-expanding (and costly) treatment facilities. Efforts to separate once-combined storm/sanitary sewers are therefore becoming much more common.

The natural channel network is also commonly used as a stormwater conveyance system, one with seemingly little associated costs because the channel system already exists. Hidden or deferred expenditures, however, are a common legacy of using once-natural channels in this fashion—geomorphic adjustment of the channel form as a result of increased discharge can lead to channel expansion, incision, or lateral migration; changes to the flow regime and introduction of contaminants can degrade or eliminate instream biota.[4] Once this strategy has been initiated, however, removing stormwater from these channels or

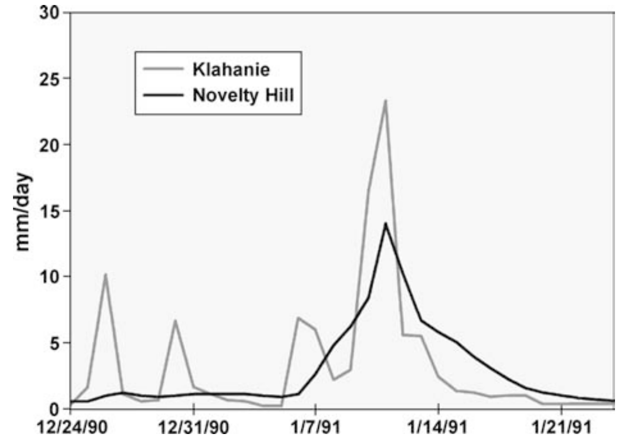

Fig. 1 Hydrographs from two nearby watersheds in western Washington, displaying dramatically different responses to the same rainfall over a 1-month period in the early winter. Novelty Hill is an undeveloped watershed, whereas Klahanie is fully built out to suburban densities. *Source*: Data from Mark Wigmosta, University of Washington, and Ref.[3].

adequately treating it for both quantity and quality is extremely expensive and typically ineffectual.

Water Quantity Facilities

Performance Goals

Facilities designed for water quantity control generally seek to achieve one of two common goals. The first is a classic approach to stormwater management and is called peak discharge control (or conveyance control). Its guiding principle is to hold postdevelopment peak discharges to their predevelopment peak discharges for a given rainstorm (the ''design storm''). If such a goal is met, areas adjacent to downstream conveyances (be they natural streams or constructed pipes or channels) should experience no more frequent episodes of flooding.[5] However, the duration of any given peak discharge will normally increase because the total volume of stormwater increases after development. If the control of peak discharge is successful, that additional runoff volume must be released by increasing the time over which it occurs. Thus, flooding, when it does occur, will persist for much longer than under predevelopment conditions. Sediment transport in natural downstream systems, and thus stream channel erosion and deposition, will also be more vigorous because transport conditions will persist for longer; thus, channel morphology may change substantially.

In recognition of the shortcomings of peak discharge control, greater attention has been paid to the aggregate duration of flows above a selected discharge (typically, one that is sufficient to transport sediment on the bed of a natural channel). The goal of such ''duration controls'' is to hold the aggregate *durations* of these moderate postdevelopment discharges to their corresponding predevelopment durations, as determined over a long (and continuous) record of rainfall and runoff. Note, however, that only the *aggregate* durations are analyzed. In other words, there is no guarantee that a specific rainstorm will meet this criterion in isolation. Rather, when we consider the accumulated period of time that the stream's flow exceeded a chosen value, over all storms in the rainfall record, the postdevelopment time does not exceed the predevelopment time. This requires a hydrologic analysis that uses a continuous rainfall record, not a discrete design storm ''event.'' The advantage of this goal is that it achieves all of the benefits of peak discharge control, *and* it should maintain the overall pattern and magnitude of sediment transport in the downstream channel. However, the timing and pattern of sediment-transporting events, particularly their seasonality, will differ in the pre- and postdevelopment conditions (with potential consequences for instream biota). This goal also requires substantially larger stormwater facilities than for conveyance control because a much greater volume of runoff must be managed for a much longer period.[6]

Implementation Approaches

Achieving either of these water-quantity performance goals requires a method to manage the greater volume of stormwater that accompanies urban development. The most common approach is a constructed facility known as a detention pond (Fig. 2), designed to release

Fig. 2 Detention pond serving a residential development and constructed to a peak discharge standard in the late 1980s, King County, Washington. Inlet channel functions as bioswale (visible at left); outlet drains under road to right.

runoff from a developed area more slowly than it is produced off the land surface. Because the intended outflow is less than the inflow, an excess volume of runoff is present, which must be (temporarily) stored and subsequently released at a controlled rate—this is why a "pond" is needed. The release rate is determined by the size of the contributing watershed area and the chosen goal of the detention (peak discharge or duration control). The pond can function in that fashion, however, only for as long as its total volume is not exceeded. Once flows spill over the top of the pond, no runoff control is possible and damaging downstream flows are normally assured. Thus, pond volume is the ultimate determinant of performance, as the "excess" water input must be stored while awaiting (delayed) release. The outflowing discharge can always be changed by simple adjustment of the pond outlets, but the pond volume (i.e., the depth and footprint of the facility) can almost never be changed after construction. Ponds are easy to construct and maintain, they can be accommodated on almost any site, the design methodologies are well established (although not always well executed), and their performance is generally not soil dependent. However, ponds release all of the catchment's runoff as surface flow at a single point of discharge, which does not necessarily mimic the predevelopment pattern of runoff delivery to downstream watercourses. Standard detention ponds also provide minimal water quality benefits.

Infiltration (also known as retention) ponds and trenches form a second broad category of water quantity control facility. Their principle is to reintroduce runoff from developed areas back into the ground by infiltration. As with detention ponds, however, the rate of infiltration from the pond area is almost always slower than the rate at which runoff is produced from the developed area, and so the excess must be (temporarily) stored. Infiltration ponds can be combined with detention ponds (in sequence or as part of the same facility) to allow some surface discharge of large runoff volumes together with infiltration of lesser volumes. As a partial or total water quantity approach, infiltration ponds largely mimic predevelopment runoff process in humid climates in which subsurface flow predominates, and they can provide substantial water quality benefits. They are not well suited everywhere, however, because their performance is very soil dependent and they are easily clogged, especially by construction-related sediment. They also require careful site evaluation, design, and attentive maintenance after construction. Although the water quality of the runoff is generally improved by these facilities, infiltrating surface water contaminants may compromise the water quality of the groundwater.[7]

A recent variant on formal, centralized infiltration facilities is the distribution of infiltration sites and small-scale facilities across the developed landscape. In combination with more opportunistic site design that takes advantage of intrinsic features such as infiltrative soils, existing watercourses, and mature native vegetation, this suite of runoff management strategies is known as "low-impact development."

Water quantity can also be managed by routing some fraction of the runoff collected from developed areas around a flood-prone or otherwise sensitive stream reach, normally via pipeline, to an eventual discharge in a much larger water body (such as a major river, lake, or ocean) that is unaffected by the relatively modest additional input of untreated runoff. These bypass pipelines do not necessarily "pipe the stream," particularly if the collected runoff originates only from paved surfaces. They reduce total postdevelopment runoff volume in non-infiltrative soils and can provide nearly fail-safe reductions of peak flows and/or flow durations if properly designed. They consume minimal land area and are nearly as feasible in previously developed areas as in newly developing areas. Depending on their design, however, bypass pipelines may alter the predevelopment flow regime by leaving small and moderate discharges from paved surfaces nearly unaffected, or, conversely, they may eliminate all baseflow once contributed from now paved upland areas. As with detention ponds, they also provide no water quality benefits and release all runoff as surface flow at a point discharge.

Water Quality Facilities

Water quality facilities are also selected and designed with an implicit or explicit performance goal. Generally, a return to predevelopment water chemistry is not sought because neither model nor empirical results suggest this is ever achieved in the runoff from urban or suburban development. Instead, removal efficiency is specified for one or more target pollutants, together with a particular maximum volume of runoff to be treated. Typical performance standards in the United States are for 80% removal of total suspended solids and 50% removal of phosphorus and dissolved metals, and treatment of a 6-month 24-hr storm (i.e., the 24-hr storm volume that is exceeded only twice in an average year, which in humid climates results in treatment of about 90% of the total annual runoff volume).[8]

Facilities for water quality improvement rely on a range of processes that remove impurities from the water column: physical processes, such as filtration or sedimentation; chemical processes, such as sorption or precipitation; and biological processes, such as uptake or bacterial transformation. Combination of physical and chemical processes, such as flocculation followed by sedimentation, are also common approaches. The facilities themselves comprise a range of types, including settling ponds, tanks, or vaults, with a permanent pool of standing or only slow-flowing water; linear channels lined with vegetation (known as biofiltration swales or bioswales); and constructed filters using a variety of natural or synthetic media. Water quality facilities also include applications as simple as straw bales staked across a shallow watercourse, or as sophisticated as patented, hydraulically designed tanks that separate debris from water as water passes through them.

CONCLUSION

The effectiveness of stormwater management varies greatly and is a function of the articulated objectives of the management effort, the appropriateness of the strategy or strategies chosen to implement those objectives, and the long-term maintenance of any facilities that are ultimately constructed.

Streambank Stabilization

F. Douglas Shields Jr.
National Sedimentation Laboratory, Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Oxford, Mississippi, U.S.A.

INTRODUCTION

Streambank erosion is a serious worldwide problem, causing many millions of dollars in damages to riparian lands and structures each year. Streambank stabilization refers to the practice of preventing streambank erosion using erosion control structures or materials. In come cases stabilization involves controlling streambank soil properties, including soil moisture and drainage. Use of various types of vegetation and vegetation in combination with structures for streambank stabilization is becoming increasingly popular. Selection of streambank stabilization strategies should begin with a good understanding of the important processes operating at the treatment site.[1,2]

STREAMBANK EROSION

Streambank erosion processes may be classified as local (operating over a relatively short distance) or general (operating over a long reach). Another classification divides processes into fluvial erosion (those related to the flow of water) and geotechnical (those primarily due to the action of gravity). Fluvial erosion occurs when water flowing past, over, or through the bank erodes soil grains or aggregates. Gravity-driven erosion occurs when bank height and angle are large enough that gravity forces exceed soil strength. Gravity failures usually involve the collapse of relatively large sections of the bank.

Additional erosion processes include human and animal traffic, freeze–thaw action, and abrasion by waterborne ice and debris. Perhaps the most pernicious erosion problems are caused by multiple processes (Fig. 1). For example, fluvial erosion of the bed often increases bank height and angle, leading to gravitational failure. Materials remaining from the collapsed bank are gradually removed by fluvial erosion, leading to a resteepened profile that again fails under gravity loading. Training and experience are needed to reliably diagnose bank erosion processes.

DIRECT METHODS

Many bank protection methods, and selection strategies have been developed.[2,3] Several of the more common methods are listed in Table 1. Direct and continuous bank protection methods are used to stabilize banks subjected to fluvial erosion. Blankets or layers of material more erosion resistant than the bank soils are used to cover the portions of the bank subjected to erosion. These bank coverings are also called revetments, and design guidelines are available from several sources.[1,2,4–6] Vertical walls or bulkheads are also forms of direct protection, but are less common and generally more expensive than revetments.[1]

Perhaps the most common form of direct protection is riprap revetment or stone blanket (Fig. 2). Riprap is an angular stone usually obtained from a quarry. Riprap is usually placed using heavy equipment, and contains a wide range of stone sizes with the larger sizes selected to resist fluvial forces and the smaller sizes providing interlocking support and preventing loss of underlying material through interstitial spaces. Key aspects of riprap revetment design include blanket thickness, filter layers or fabric, and treatment of the blanket margins, particularly the lower edge[1] (Fig. 2). A typical riprap gradation suitable for streambanks where the maximum velocity is less than 3 m/sec would contain stones weighing between 10 and 100 kg. One approach for sizing riprap is as follows[6]:

$$D_{30} = S_1 C_s y \left[\left(\frac{s}{s-1} \right)^{0.5} \frac{U_d}{\sqrt{K_1 g y}} \right]^{2.5}$$

where D_{30} is the riprap size of which 30% is finer by weight, S_1 is a safety factor, usually between 1.1 and 1.5, $C_s = 0.3$ for angular rock and 0.375 for rounded rock, y is the local water depth at the bank toe, s is the specific gravity of the stone, usually 2.5–2.7 in freshwater, U_d is the depth-averaged velocity at the bank toe, g is the acceleration due to gravity, K_1 is a side slope correction factor given by

$$K_1 = -0.672 + 1.49\cot(\alpha) - 0.449\cot^2(\alpha) + 0.045\cot^3(\alpha)$$

where α is the angle of the bank to the horizontal. This equation is valid for values of α between 14° and 39°.[6]

Gravel, soil cement, geotextiles, brush mattresses, concrete, asphalt, articulated mattresses made from concrete blocks held together by wire or plastic rope,

Soils–Suspended

Fig. 1 Streambank showing gravitational failure. Man is standing on accumulated material resulting from failure of bank in background. This material will be rapidly removed by fluvial erosion.

and many other materials have also been used for direct protection with varying degrees of success.[1] Less common are methods designed to change the basic properties of bank soils using various amendments.[5] Vegetation, particularly sod-forming grasses and groundcovers, is also a form of direct protection, as discussed below. Designers must select direct methods adequate to resist the imposed shear forces. In addition, sometimes layers of fine material or filter fabric must be placed between the protective layer and the bank to prevent piping of soil particles. Reinforcement of direct protection at its boundaries, particularly along the lower edge parallel to the stream, is most important.

Some direct, continuous methods are also used to stabilize banks experiencing gravitational failures. Slopes may be re-graded to more gradual angles, and continuous protection such as stone blanket applied to maintain the stability of the new slope.

INDIRECT METHODS

Indirect methods for bank stabilization include techniques for diverting flows away from the bank face or removing groundwater moving through the bank. The former category includes building spur-like structures of wood, stone, or other materials that project from the bank into the flow at some angle (Fig. 3). Indirect methods can be quite effective when erosive flows impinge on the bank, as often occurs on the concave side of meanders. Sills or weirs that completely span the flow channel may also be classified as indirect methods because they tend to redirect overtopping flow such that exiting vectors are at right angles to the structure crest. Bed sills or weirs, when properly constructed, may also be used as grade control structures that prevent bed erosion leading to gravitational bank failure as described above. Various types of flow diversion are also used when runoff from the floodplain erodes the bank face as it moves toward the stream, and these include the use of culverts, drop pipe, and small armored drainage channels or waterways to conduct flow. Methods used to control subsurface fluvial erosion are also indirect, including pumping out ground water, installing wicks and drains at vertical intervals when bank slopes are reconstructed, and reinforcing bank slopes with various types of structural inclusions.

VEGETATION

Vegetation is becoming increasingly popular for streambank stabilization due to its aesthetic quality, effects on riparian habitats, and potential to improve stream water quality.[7] Vegetation promotes bank stability by increasing the erosion resistance of the soil, reducing water velocities adjacent to the bank face, and increasing resistance to gravitational failure through reinforcing properties of roots. Vegetation reduces bank soil moisture through transpiration. Use of vegetation in combination with various types of manufactured materials and structures that provide protection during the period of plant establishment and support and reinforcement over the long term are most common (Fig. 4).

Despite the many benefits of using vegetation for streambank stabilization, the relationships between vegetation and streambank properties are complex.[8] Despite its undoubted positive effects on stability, large, woody riparian vegetation also increases

Table 1 Selected streambank stabilization techniques

Functional group	Category	Method	Description	References
Direct methods	Fabric	Rolled erosion control products	Mulch, mesh, netting, and other products sold in rolls. Secured to slope by nail-like fasteners	[3]
	Blanket or revetment	Clay blanket	Layer of cohesive soil, often compacted and vegetated	[5]
		Riprap	Quarry stone of specific size gradation	[1,3–6,9]
		Gabions	Wire baskets filled with stones	[1,3–5,9]
		Interlocking or articulated blocks	Flat, rectangular blocks fastened together with wire or plastic rope or with interlocking edges	[1,3–5,9]
		Concrete	Concrete slab	[1,3–5]
	Retaining walls	Concrete	Vertical retaining wall	[3,4]
		Timber	Vertical retaining wall	[3,4]
	Soil bioengineering and biotechnical methods	Grass	Sod or turf. Often reinforced with various types of porous fabric or mesh	[3]
		Fascines	~30-cm-diameter cylindrical bundles of live cuttings fastened to bank with wire and stakes	[4,9]
		Brushmattress	Layers of small diameter woody cuttings secured with wire and stakes	[4]
		Willow stakes	Cuttings 1–8 cm in diameter, planted in bank in grid fashion	[4,9]
		Willow posts	Cuttings more than ~8 cm in diameter, planted in bank in grid fashion	[4]
		Geogrids	Mesh with large diameter openings often used in various configurations with vegetation for soil reinforcement	[1,3–5,9]
		Cribwalls	Rectangular structures made of criss-crossed timbers or concrete beams with wide openings. Often filled with soil and cuttings	[4]
		Reed clump	Root propagules wrapped in natural geotextile fabric to create long cylinders that are staked into trenches excavated parallel to the flow	[3,4]
		Coir or coconut fiber rolls	Sausage-like rolls placed along bank toe parallel to flow. May be impregnated with vegetative propagules	[1,3,4]
Indirect methods	Continuous structures	Board fence	Fence-like structures built along bank toe parallel to flow	[4,5]
		Tree revetment	Felled trees placed along an eroding bank, usually with butts secured to bank in shingled fashion	[3,4]
		Jacks	Flow-retarding structures about 2 m high made of concrete, wood, or metal members fastened together at their centers to resemble a toy jack. Deployed in large, dense arrays known as jack fields	[4]
		Live siltation	Small-diameter cuttings placed in trenches excavated at some angle to the flow. Cuttings protrude from the ground surface at an angle of about 45–60° to the ground surface pointing downstream	[4]
	Intermittent structures	Spur dikes or current deflectors	Structures that protrude from the bank into the current to displace faster-moving flow. Referred to by many different names	[3–5]
		Rootwad	Felled tree with intact root ball buried in bank with root ball protruding. Usually deployed in series along outside of bends	[4]

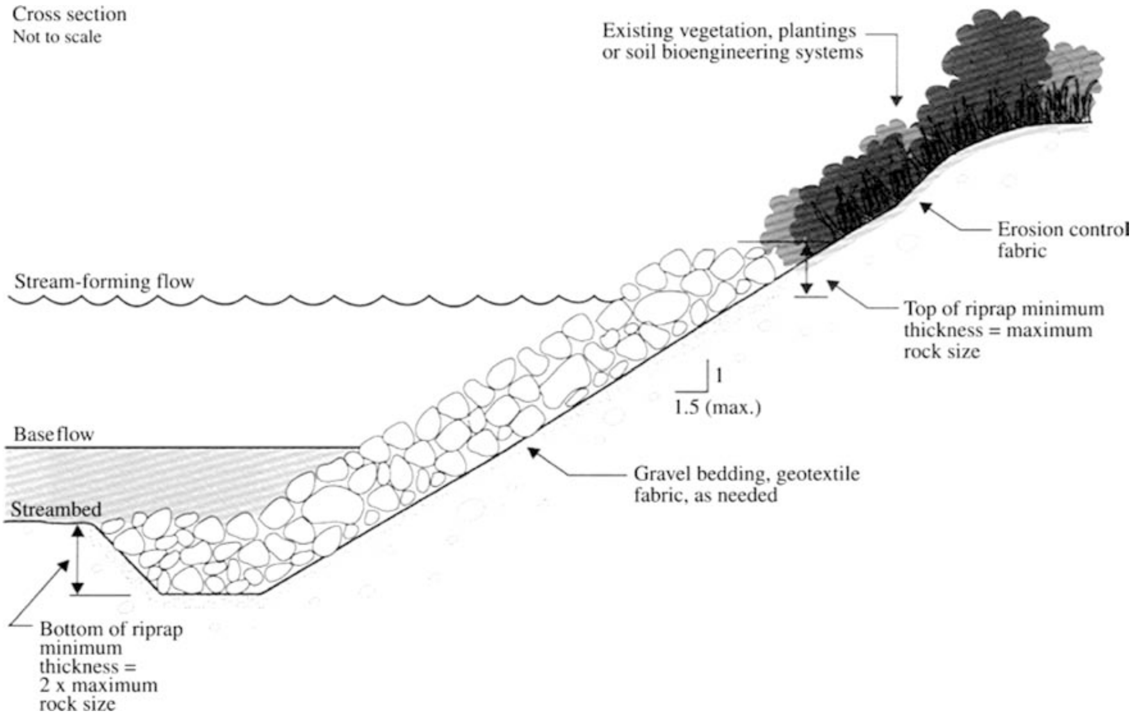

Fig. 2 Typical riprap revetment. *Source*: Adapted from Ref.[4].

gravitational loads on the bank and increases the rate of infiltration into bank soils, thus increasing soil unit weight and reducing soil strength. Fallen trees and limbs may divert flows against banks, triggering erosion. On high banks, gravitational failure planes may pass under the rooting zone, where root reinforcement will have no effect.

Vegetative techniques include soil bioengineering (the use of living and dead plant materials for erosion control) and biotechnical stabilization (the use of living and dead plant materials as components within schemes employing various types of inert materials and structures).[9]

Vegetation is likely to become more important as a streambank stabilization tool, but design, construction, monitoring, and maintenance requirements are different and perhaps more complex than for more orthodox, inert materials and structures. Vegetation may fail due to surpluses or deficits of soil moisture, infertile soils, shade, competition from herbivores or exotic plants, pests, or high flows that occur during the crucial period of plant establishment.

Fig. 3 Stone spur, a form of indirect protection, used to deflect erosive flows away from bank. Spur was made from quarried riprap.

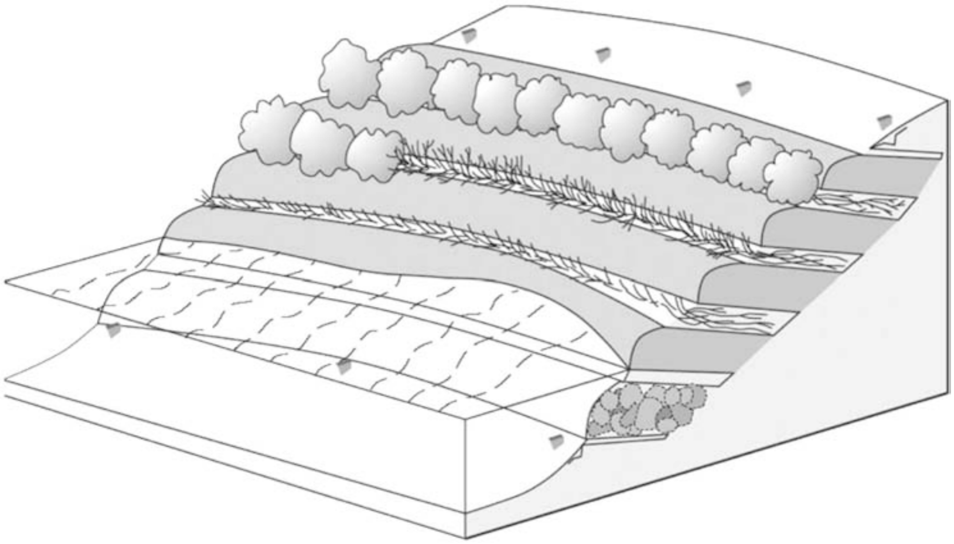

Fig. 4 Brushlayering with geogrids, a form of biotechnical streambank stabilization. The slope is constructed by placing alternating layers of compacted earth, geogrid, and willow cuttings. Cuttings rapidly root and link layers together. *Source*: Adapted from Ref.[7].

CONCLUSIONS

Streambanks may be stabilized using a wide range of techniques, but techniques must be selected with a good understanding of the important erosion mechanisms operative at the treatment site in order to be effective.

INTRODUCTION

Summer fallow has been a controversial practice in many semiarid regions of the United States and Canada. Crop production in these regions has been limited by low and variable precipitation. Summer fallow has been practiced to increase the water available for succeeding crops in regions that receive less than 500 mm of precipitation.[1] The basic objectives of summer fallow are: 1) maximize soil water storage; 2) make plant nutrients available; 3) reduce soil erosion hazards; 4) minimize energy and economic inputs; 5) control weeds during the entire fallow period; 6) take advantage of standing stubble to capture snow; and 7) suppress soil water evaporation during the warm season.[2]

Summer fallow was adopted in the semiarid regions following the dust bowl era of the 1930s in the United States. Since then; considerable changes in equipment and technology have taken place. Summer fallow discussions in this article will focus primarily on the semiarid Great Plains of the United States and Prairie Provinces of Canada. Statements about the semiarid Pacific Northwest will be included. Two major summer fallow systems discussed will be winter wheat-fallow and spring wheat-fallow. Fallow will be divided into seasonal fallow segments that consist of after-harvest (harvest though October), over-winter (November through April), summer fallow (May through October, or until seeding winter wheat), and second over-winter for spring wheat (November until spring wheat seeding). Summer fallow segment for this paper will be defined as a practice where no crop was grown and all plant growth was controlled with herbicides or cultivation during the season when a crop would normally be grown.

FALLOW PRINCIPLES

In the Great Plains, early fallow (prior to and during the 1930s) used tillage implements that inverted and mixed the soil for control of weeds. The number of tillage operations ranged from 7 to 10 per season and usually destroyed crop residue cover and soil protective clods to create a dust mulch. Dust mulches served two purposes in summer fallow: 1) suppress weeds from germinating and growing and 2) suppress evaporation of stored soil water by creating a discontinuity in the capillary soil pores that transport water and water vapor to the soil surface. Variants of the dust mulch principle are still used in the Pacific Northwest.[3]

During this same time, summer fallow and annual crop research was conducted throughout the Great Plains. Mathews and Army[4] summarized 450 crop–fallow periods from 25 locations, with some locations having 40 yr of research. They found that the average fallow efficiency (percent of precipitation stored in the soil during fallow) was about 16% and concluded that most of the 84% of the precipitation lost was due to evaporation. Key fallow efficiency principles they found were: 1) soil water loss due to deep percolation below the rooting depth of wheat was negligible or non-existent; 2) evaporation losses were great and fallow efficiencies were not likely to improve unless a method of reducing evaporation losses was devised; 3) average annual runoff losses were very low and accounted for only a negligible portion of the precipitation received during fallow; 4) fallow efficiency decreased from the Northern Plains to Southern Plains; and 5) the decreased fallow efficiencies were associated with increased potential evaporation from north to south. Their regression analysis indicated little relationship between the total precipitation received during fallow and fallow efficiency and that soil water storage was not significant until large quantities of precipitation were received.

CONSERVATION TILLAGE FALLOW

Since the soil inversion fallow era, subsurface tillage implements and development of cost effective herbicides have resulted in more wheat residue being left

Table 1 Winter wheat-fallow equations used to predict stored soil water (Y) for precipitation (x in mm) received during each seasonal segment of fallow for Akron, CO (central Great Plains) and Sidney, MT (northern Great Plains) (unpublished research from Tanaka and Anderson)

[a]Fallow methods include no-till (NT) and stubble-mulch (SM). Fallow details are defined by Smika[12] and Tanaka.[14]
[b]Significant at 0.05 probability level.
[c]No significant difference occurred among fallow methods; therefore NT, MT, and SM fallow methods were combined.

on the soil surface during the summer fallow segment. Researchers have found that increased quantities of surface residue significantly increased soil water storage during the fallow period in a wheat-fallow system.[5–8] Wheat residue on the soil surface reduces rain drop impact and prevents puddling and facilitates water infiltration. Residues have increased fallow efficiencies from about 16% for bare soils that were intensively tilled to 40% for no-till.[9–11] Therefore, wheat residue can significantly suppress evaporation losses and greatly improve fallow efficiencies. Greater fallow efficiencies improve wheat production, which in turn increases residue production.[12] However, improved fallow efficiencies, during average or above-average precipitation years, can result in the movement of nutrients and water below the rooting depth of wheat grown in wheat-fallow systems causing potential ground water problems or saline seep conditions.[13] Saline seep conditions have become prevalent in the northern Great Plains of the United States and Prairie Provinces of Canada where wheat-fallow systems are used.[13]

In the northern Great Plains, spring wheat-fallow systems dominate. The potential for no-till to store more soil water than intensively tilled systems is greater for winter wheat-fallow systems than for spring wheat-fallow systems because winter wheat produces more residue than spring wheat, winter wheat stubble remains standing longer than spring wheat stubble, and winter wheat has a 14-mo fallow compared to the longer 21-mo spring wheat fallow.[14,15] Soil water storage for winter wheat-fallow is equal to or greater than soil water storage for spring wheat-fallow even though the spring wheat fallow is 21 mo. The second over-winter segment for spring wheat follow stores very little soil water. In regions where winter wheat–fallow systems dominate, mostly in the central and southern Great Plains, no-till fallow has the potential to store more soil water during the after-harvest and over-winter segments of fallow because of greater residue production than systems in the northern Great Plains.

Research (Tanaka and Anderson personal communication) suggests that soil water storage in the central Great Plains for the after-harvest and over-winter fallow segments had less variability and resulted in more soil water storage than in the northern Great Plains (Table 1). Both locations receive 20–25% of the yearly precipitation as snow and standing stubble in no-till helps hold snow. In the northern Great Plains, 70–80% of the precipitation that fell on frozen soil in the northern Great Plains was lost as runoff[16] resulting in low fallow efficiencies for the over-winter segment in the northern Great Plains.[17] During the over-winter segment in the central and southern Great Plains, soils remain unfrozen for a longer period of time increasing the potential to store snowmelt water. The over-winter segment usually has the highest fallow efficiency in the central and southern Great Plains because evaporation and runoff are low.[2]

The summer segment of fallow has been considered to be inefficient because of high evaporative demands. In general, 60% or greater of the total soil water stored during fallow occurred during the after-harvest and over-winter segments.[18] For fallow to effectively store soil water, three criteria must be met. First, the

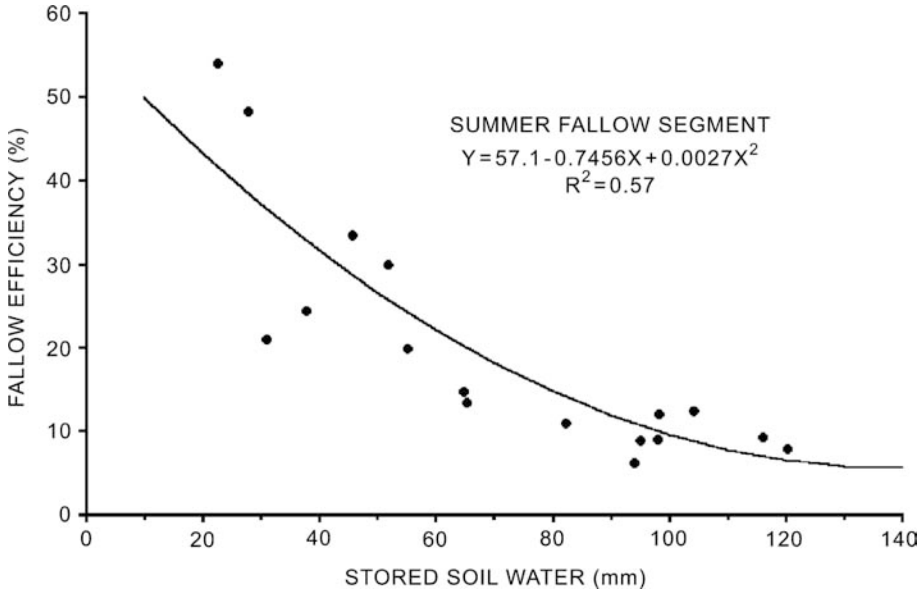

Fig. 1 Fallow efficiency for the summer fallow segment as influenced by soil water storage during the after-harvest plus the over-winter segments at Sidney, Montana. *Source*: From Tanaka and Anderson.[17]

quantity of surface residue present must be adequate to suppress evaporation. In the northern Great Plains, at least 2500 kg/ha must be present in mid-May before surface residues will suppress evaporation enough to increase soil water storage.[19] Second, soils cannot be at or near field capacity in the soil root-zone. Fig. 1 illustrates the decrease in fallow efficiency as the soil water storage in the after-harvest and over-winter segments increase. The efficiency for the summer segment of fallow in the northern Great Plains was <10% when soil water storage during the after-harvest and over-winter segments was >120 mm. Third, precipitation must occur in sufficient quantity and frequency to effectively permit soil water to move deep enough into the soil profile to significantly reduce or eliminate evaporative losses. In the northern Great Plains, surface residues suppressed evaporation for 10 days. Cumulative evaporation for bare and residue covered soil surfaces become equal if at least 10 mm of rain did not fall within the 10-day period.[20]

Since Mathews and Army[4] developed the principles for fallow, technology and techniques have been developed to manage surface residues using no-till. The best wheat-fallow systems have not been able to exceed 40–45% fallow efficiencies. Research in the Great Plains indicates that 60–95% of soil water accumulation during 14- and 21-mo fallow was stored before the summer fallow segment.[15,17] Fallow efficiencies have become stagnant and farming systems in the Great Plains need to be modified to include: 1) cropping systems that reduce the frequency of fallow and 2) inclusion of deep rooted or full season crops such as sunflower, safflower, soybean, or corn.[21] The wheat-fallow cropping system may no longer be sustainable in the Great Plains.[22]

Soils–Suspended

SUMMER FALLOW IN THE FUTURE

Summer fallow will undoubtedly remain useful in future dryland systems, but the frequency and length of the fallow period may be reduced and cropping systems will include more crop diversity. In areas traditionally considered crop-fallow, the ultimate goal is to increase soil water storage during the non-crop periods so that continual cropping can be practiced. Crop rotation, crop sequence, management practices, and weather will influence the success of a cropping system that replaces crop-fallow. The more dissimilar the crops and their management practices, the less opportunity individual pest species have to become dominant.[23] New intensive cropping systems may include fallow but fallow will be perceived in a different way. Goals of the no-till or reduced till fallow would be a period when plants are grown for the purpose of soil building in a no-till system, enhancement of soil water storage during the inefficient summer fallow segment, pest control, and improvement of environmental quality.[24] This would transform evaporative water loss during fallow into transpirational water loss through plants while conserving or enhancing our natural resources.

INTRODUCTION

The number of confined animal feeding operations in the United States has increased dramatically over the last half century. Manure from these operations is most often land applied to pastures or cropland. Runoff from land, where manure has been applied, has been implicated in eutrophication of U.S. surface waters. Phosphorus from these non-point sources is of great concern in most areas of the United States where the animal industries are concentrated. This article discusses feed and manure treatment methods that can be used to reduce the potential impact of manure on surface water quality, and other management strategies that producers can use to further reduce these risks.

RECENT TRENDS IN ANIMAL AGRICULTURE

In recent years, the number of U.S. farms has declined, while agricultural production has increased.[1] For instance, swine operations have declined from just under 1.1 million in 1965 to around 86,000 operations in 2000.[2] The number of small swine operations (less than 100 head) has steadily decreased since 1992, while the number of very large operations (greater than 5000 head) has steadily increased from less than 1,000 operations in 1992 to almost 2,100 in 2000. Similar trends occurred for poultry and cattle operations during this period.[1] Animal operations tend to be concentrated in geographic areas also. In 2000, 84% of the U.S. broiler production occurred in 13 states, mainly in the east and southeast.[2]

These trends in animal agriculture have been important to modern agriculture, but they have also been very important to the environment as well. Millions of tons of animal manure are produced annually. Many of the animal manures, such as that from swine and dairy, contain very high moisture content (80% or higher). While the manure contains valuable fertilizer nutrients, transporting the manure outside of the watershed may be cost prohibitive due to the amount of water in the manure. Therefore, the majority of manure is applied to pasture or crop land very near the site of production.

ANIMAL MANURE AS A SOURCE OF NUTRIENTS TO SURFACE WATERS

Declines in surface water quality have been attributed to the recent trends in animal agriculture and the application of animal manure on pastures and cropland. When manure is applied on pasture land, it is generally broadcast on the surface of the soil and often not tilled in. When a rainfall event occurs, particularly within a few days after manure application (Fig. 1), nutrients, pathogens, antibiotics, hormones, and metals can enter surface water through runoff.[3,4] Nutrient runoff, especially phosphorus (P) runoff from fields fertilized with animal manure has received particular attention in recent years.[5] In most surface water reservoirs, P is the primary nutrient that limits algae growth, or eutrophication.[6] This has been the circumstance in the Eucha-Spavinaw watershed in Northwest Arkansas and Northeast Oklahoma, an area of intensive poultry and swine production. Most of the manure from these facilities is applied to forage pastures, and it is generally applied in the spring of the year. In recent years, extensive eutrophication has occurred in Lake Eucha, a drinking water reservoir for Tulsa, Oklahoma, and geosmin has been released into the water supply. Geosmin is a chemical that is released during certain algae blooms. While it is not harmful to human health, geosmin gives drinking water bad taste and odor, and is very difficult to remove through conventional water treatment procedures.

Mention of trade name, proprietary product, or specific equipment does not constitute a guarantee or warranty by the USDA and does not imply its approval to the exclusion of other products that may be suitable.

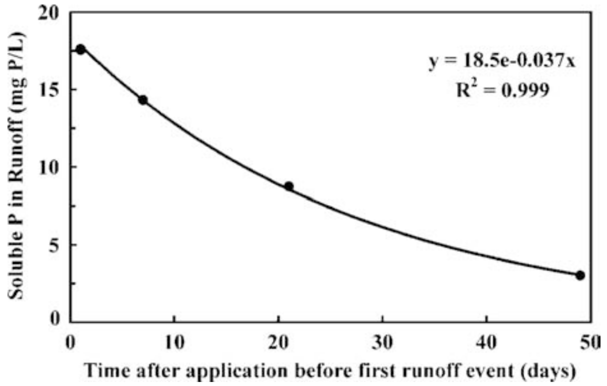

Fig. 1 Effect of time after manure application on soluble P runoff from pastures. *Source*: From Ref.[11].

Problems associated with P losses from fields fertilized with animal manure have occurred in other areas of the country as well. In North Carolina, recent outbreaks of Pfisteria, a dinoflagellate that releases a toxin that causes open sores on fish, have been blamed on P released from swine farms.[7] Phosphorus releases from this area of the country have been associated not only with manure applications; in 1999, Hurricane Floyd flooded many swine farms, causing lagoons to overflow, and directly enter surface waters.

REDUCING POTENTIAL PHOSPHORUS LOSSES FROM ANIMAL MANURE

There are two major methods to reduce potential P losses from animal manure: reduce P inputs into the animal, or reduce the solubility of P in the manure. Phosphorus in most grains fed to livestock is in the form of inositol hexaphosphate (phytate), a six membered carbon (C) ring with a phosphate group attached to each C.[8] This form of P is not readily absorbed by monogastric animals, such as swine and poultry. Therefore, many feed rations for these species require supplemental forms of P, such as dicalcium phosphate. Reducing the P inputs requires the use of some technology that improves the P availability in grains. This can be accomplished through modifying the diet with special grains or adding enzymes to break down the phytate molecule. Special grains used in feed refers to varieties of corn that have been developed for their ability to store P in forms other than phytate (Table 1).[9] Such corn is often referred to as high available P (HAP) corn. The future of this product could be very promising in the livestock industry. However, it faces two major hurdles. This variety of corn is not as productive as most common varieties, and there is no simple method to distinguish between HAP corn and other varieties.

Table 1 Total and phytate bound phosphorus in normal and HAP corn varieties

Corn type	Total phosphorus ($lb\,tn^{-1}$)	Phytate phosphorus ($lb\,tn^{-1}$)
Normal	7.6	6.4
HAP	7.8	2.6

Source: From Ref.[9].

Another technology that can be used to reduce the total P inputs in livestock rations is the use of enzymes. Phytase is an enzyme that has received much attention lately, because it is the enzyme that cleaves phosphate groups from the phytate molecule.[8] It can be cultured rather easily using various fungi, such as *Aspergillus* sp., that produce exogenous phytase. This technology has been shown[10] to reduce soluble P in swine manure by 15% compared to swine fed normal diets (Fig. 2). Currently, one of the major drawbacks to this technology, is that many feeds, especially for swine, are pelleted at temperatures high enough to denature the phytase molecule. Another question that some researchers have raised concerning this technology is that manure from phytase fed animals may actually increase soluble P in runoff. A 25% increase in P runoff from plots fertilized with manure from nursery pigs fed phytase diets compared to normal diets has been noted.[10] Increased P runoff from phytase fed animals of more than two fold (Fig. 3) compared to normal diet animals has been seen in other studies.[11] The reasons for these increases are not fully understood, but studies are currently being undertaken to identify possible explanations (Personal Communication, Philip A. Moore, Jr., April 2002).

The other main treatment that can be used by animal production facilities is the treatment of manure

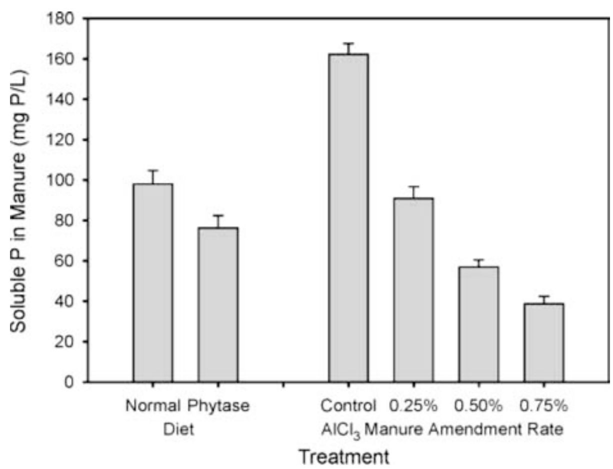

Fig. 2 Effects of phytase amended diets and aluminum chloride manure amendments on soluble phosphorus in swine manure. *Source*: From Ref.[10].

Soils–Suspended

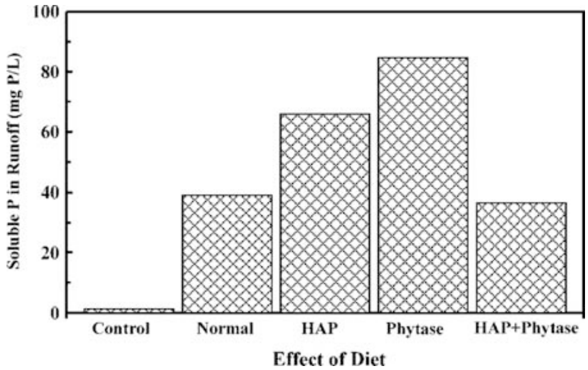

Fig. 3 Effect of poultry diet on soluble P runoff from pasture. *Source*: From Ref.[11].

with chemical amendments to reduce P solubility. Calcium, iron, and aluminum amendments have been used to reduce P solubility.[12] Calcium amendments reduced P solubility at high pH, however, at slightly acidic pHs, thermodynamics dictate that Ca-phosphates can dissolve, thereby releasing P. Iron phosphates are more stable over a wide range of pH values, however under anaerobic conditions, ferric iron can be reduced to ferrous iron. Ferrous phosphates generally dissociate more readily than ferric phosphates, thereby posing the risk of releasing P into the environment. Aluminum phosphates are stable over a wide range of physio-chemical environments naturally occurring in soils. In fact, one of the reasons Al-phosphates would dissociate under "normal" field conditions would be very low P status in the soil solution.

Aluminum sulfate (commonly referred to as alum) has been used in poultry litter for several years to reduce P solubility. Phosphorus solubility in poultry litter treated with alum was reduced as much as 99% compared to normal poultry litter.[13] In a study with treated and untreated poultry litter applied to plots cropped to tall fescue, P runoff was 87% lower in plots fertilized with alum treated litter compared to those to which normal litter was applied.[14] In this study, P runoff from plots fertilized with alum treated litter was not statistically higher than plots that were unfertilized. These two studies indicate tremendous potential for this technology to reduce the pollution potential from the poultry industry. Smith et al., demonstrated that alum could also effectively reduce P solubility in swine manure.[15] Concern over possible sulfide production from the sulfate in alum however necessitated the testing of another Al chemical in liquid manure to accomplish this goal. Aluminum chloride was also used in this study to reduce P solubility. Both chemicals reduced P solubility by as much as 99% and reduced P runoff from plots fertilized with treated manure by 84% compared to plots treated with normal manure.

In addition to reducing the potential impacts of P runoff, these treatments provide the added benefit of reducing ammonia volatilization from manure. Alum has been shown to reduce ammonia volatilization as much as 99% in broiler houses. Swine manure treated with aluminum chloride had 50% less ammonia loss through volatilization compared to normal manure.[10] This decrease in ammonia improves the air quality in the production facility and can improve animal performance as well as reduce costs associated with heating the production facility.[13]

RISK BASED MODELS FOR MANURE APPLICATION

Diminished water quality in watersheds with intensive animal agriculture has caused many states to scrutinize production practices and manure application. Most states have adopted risk based models to aid producers in their manure management.[16] The Arkansas P index for pastures identifies several risk factors, including soil test P levels, amount of P in manure, the slope and infiltration rate of the pasture, timing of manure application, and annual precipitation to asses the risk of P losses from pastures after manure application.[11] Farmers are also given credit for best management practices. These factors are plugged into a matrix that then assesses the risk of P loss from a specific pasture. This risk level then aids the producer in determining whether to apply manure at normal agronomic rates for N, agronomic rates for P, or not apply manure at all. Validation of this model[11] showed a strong correlation between the P index value obtained from the matrix and P lost from pastures (Fig. 4). Several other states have worked on similar tools, and have been generally specific to their local soil type, production practices, and climatic conditions. Some states such as Texas, use a similar system, but their P index incorporates a soil test P threshold (400 lb acre^{-1}), above which no manure is applied.

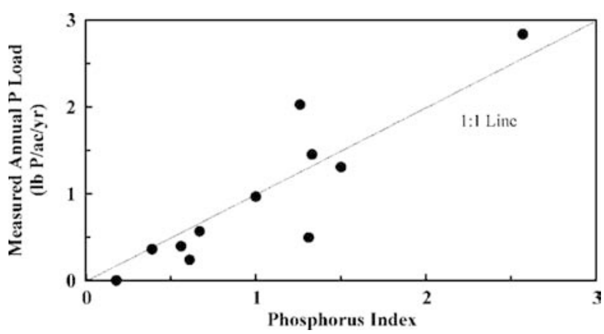

Fig. 4 Relationship between P index value and actual P runoff from pastures. *Source*: From Ref.[11].

CONCLUSION

Recent trends in animal agriculture have been increased numbers of animals with decreasing numbers of animal operations. These trends have restricted land available to producers for manure application and have corresponded to water quality problems associated with non-point sources. Phosphorus induced eutrophication has been one of the main problems associated with animal agriculture. There are two major technologies that can be used to reduce the potential P losses from animal manure. They are reducing P levels in the diet through increased P availability in grains or binding the P in the manure with chemicals such as alum or aluminum chloride. Phytase and HAP corn have the potential to reduce P levels in manure as much as 20%. The question still remains as to whether or not these technologies might increase P solubility, and hence P runoff losses. Phosphorus solubility can be reduced by as much as two orders of magnitude when treated with alum or aluminum chloride. Aluminum phosphates are stable over a wide range of naturally occurring soil conditions, thereby reducing the risk of bio-available P losses.

Many states are currently searching for methods to aid producers in manure management. One of the most common trends for this is the use of a P index. These are site-specific risk assessment tools used to identify fields that are susceptible to P losses. The P indices then provide a manure application rate for the producer.

Surface Water: Nitrogen Enrichment

Tim P. Burt
Penny E. Widdison
Department of Geography, Science Laboratories, University of Durham, Durham, U.K.

INTRODUCTION

Nitrogen is essential for plant growth and comprises nearly 79% of the earth's atmosphere in the form of N_2 gas. In order for nitrogen to be used for plant growth, it must be "fixed" in the form of ammonium (NH_4) or nitrate (NO_3). In the terrestrial nitrogen cycle, microbes break down organic matter to produce much of the available nitrogen in soils. Nitrate is completely soluble in water and it is not adsorbed to clay particles; therefore, it is vulnerable to being leached out of the soil by percolating rainfall or irrigation water. Generally, the movement of nitrogen can be described in three ways: 1) upward, crop uptake and gaseous loss; 2) downward, as leaching to groundwater; and 3) lateral, via surface and subsurface flow to surface waters. The nitrogen cycle under arable soils is shown in Fig. 1.

NITRATE LEVELS IN SURFACE WATERS

The natural water quality of a river will be determined primarily by the catchment soil type and underlying geology to which water, falling on the catchment as rain, is exposed as it drains to the river. Climate provides an important context for nitrogen cycling by controlling the propensity for carbon and nitrogen to be stored within the catchment; thus, in the United Kingdom, upland soils tend to conserve organic matter as peat, whereas organic matter tends to decompose much more readily in lowland soils. Deviations from this baseline water quality are generally caused by the influence of human activities through point and diffuse pollution sources. Up to 40% of total nitrogen reaches the aquatic system through direct surface runoff or subsurface flow.[1] Nitrogen delivery to surface waters is further controlled by: 1) soil structure and type; 2) rainfall; 3) the amount of nitrate supplied by fertilizers; and 4) plant cover and root activity.[2]

In pristine river systems, the average level of nitrate is about 0.1 mg/L as nitrogen (mg/L N). However, in Western Europe, high atmospheric nitrogen deposition results in nitrogen levels of relatively unpolluted rivers to range from 0.1 to 0.5 mg/L.[3] In recent years, nitrate concentrations in European rivers have been rising (Fig. 2) and "No progress has been made in reducing the concentration of nitrates in Europe's rivers."[4] High rates of nitrogen input to rivers and coastal waters are not confined to Europe. In an average year, the Mississippi River discharges 1.57 million metric tons of nitrogen into the Gulf of Mexico.[5] About 7 million metric tons of nitrogen in commercial fertilizers are applied annually in the basin leading to nitrate concentrations in agricultural drains of 20–40 mg/L or more.[5] In the United States, in 1998, more than one-third of all river miles, lakes (excluding the Great Lakes), and estuaries did not support the uses for which they were designated under the Clean Water Act.[6] Table 1 illustrates N inputs to rivers and coasts in areas of America, Africa, and Asia.

It is now widely acknowledged that agriculture is the main source of N pollution in surface waters and groundwater in rural areas of Western Europe and the United States.[2,7,8] The U.K. House of Lords' report *Nitrate in Water*[9] commented on the conflicts that can arise when the use of land for farming comes into conflict with the use of land for water supply. Concern initially focused on alleged links between high nitrate concentrations in drinking water and two health problems in humans: the "blue-baby" syndrome methemoglobinemia and gastric cancer. Now, there are also concerns for environmental degradation. Nutrient enrichment in water bodies encourages the growth of aquatic plants (see Fig. 3). Reed beds and other marginal plants may be attractive on a small scale, but when these and, particularly, underwater plant growth are excessive, this can cause a narrowing of waterways and become a nuisance to recreational users of rivers and lakes. Furthermore, eutrophication (a group of effects caused by nutrient enrichment of water bodies) can adversely affect the aquatic ecosystem. An algal bloom may cut out light to the subsurface, and when it dies back, decomposition uses the oxygen supply needed by other species. Some algae are toxic to fish, whilst others, for example, cyanobacterial species, are toxic to mammals including domestic pets.[10] Studies in Asia have demonstrated the link between increasing use of fertilizers and increasing incidence of algal blooms. Table 2 illustrates rates of fertilizer application for selected Asian countries. In some Chinese provinces, fertilizer application is greater

Soils–Suspended

than 400 kg/ha. This is usually applied as a single application, and with crop utilization efficiency as little as 30–40%, a high proportion is lost to rivers, lakes, and coastal waters.[11] The environmental impact at the regional level has led to a rise in the incidence of red tides (algal blooms). During the 1960s, less than 10 red tides per year were recorded, but in the late 1990s over 300 per year were recorded.[11]

The popular misconception that the nitrate problem is caused by farmers applying too much nitrate fertilizer

is too simplistic. Nevertheless, there is now little doubt that the high concentrations of nitrate in fresh waters noted in recent years have mainly resulted from runoff from agricultural land and that the progressive intensification of agricultural practices, with increasing reliance on the use of nitrogenous fertilizer, has contributed significantly to this problem. Since 1945, agriculture in the industrialized world has become much more intensive. Fields are ploughed more frequently; more land is devoted to arable crops, most of which demand large amounts of fertilizer; grassland too receives large applications of fertilizer to ensure a high quality silage for winter feed; stocking densities in general are higher, leading to increased inputs of manure on grassland and problems of disposal of stored slurry; cattle often have direct access to water courses resulting in soil and bank erosion and direct contamination from animal waste; many low-lying fields are now underdrained, encouraging more productive use of the land and speeding the transport of leached nitrate to surface water courses. It is true that lowland rivers close to urban areas receive larger quantities of nitrogen from sewage effluent, but budgetting studies confirm that agriculture is the main source of nitrate in river water.[11,12]

Fig. 3 Choked watercourse, River Skerne, County Durham, August 2002. *Source*: From p. Widdison.

Betton, Webb, and Walling[13] have mapped nitrate concentrations for mainland Britain. A marked northwest to southeast gradient is evident, reflecting relief, climatic conditions, and agricultural activity. Upland areas in the north and west are usually characterized by nitrate concentrations below 1 mg NO_3–N L^{-1}. This reflects the high rainfall and low temperatures of such areas: upland soils tend to conserve organic matter and mineralization rates are low. In contrast, a decreasing ratio of runoff to rainfall and an increasing intensity of agricultural land use towards the south and east of Britain result in higher mean concentrations of nitrate in river water. Many of the lowland rivers are characterized by concentrations above 5 mg NO_3–N L^{-1}; in East Anglia and parts of the Thames basin, mean nitrate concentrations in rivers are close to the E.C. limit of 11.3 mg NO_3–N L^{-1}, a level exceeded in some spring waters especially in the Jurassic limestones of the Cotswolds and Lincolnshire Wolds.[14]

The changing pattern of lowland agriculture since 1945 is reflected in long-term records of nitrate for surface and ground waters.[14] For both large and small rivers, there has been a relatively steady upward trend in nitrate concentrations, often of the order of 0.1–0.2 mg NO_3–N L^{-1}. Analyses for relatively short time series of just a few years (e.g., Ref.[13] have shown that the upward trend may be interrupted, either because of climatic variability (drier years are associated with lower nitrate concentrations) or because of land use change. Nevertheless, statistical analysis of long time

Soils–Suspended

series shows that the main effect is a steady increase in nitrate levels over time that is independent of climate.[14] If trends continue, the mean nitrate concentration of many rivers in Europe will soon be above the E.C. limit; in many cases, this level is already exceeded during the winter when nitrate concentrations reach their maximum. In catchments where groundwater is the dominant discharge source, this long-term trend may be prolonged since it may take years for nitrate to percolate down to the saturated zone. In such basins, nitrate pollution may remain a problem for decades to come. In recent years, a number of options have been considered as a means of halting the upward trend.

LAND USE CONTROLS TO REDUCE N ENRICHMENT TO SURFACE WATERS

Trends in water management in Europe include moves toward catchment-level management, improved intersectoral co-ordination and co-operation, and frameworks facilitating stakeholder participation. This approach is developed by the European Union in its Water Framework Directive, which sets targets for good ecological status for all types of surface water bodies and good quantitative status for groundwater.[3] More localized schemes, like the U.K. Nitrate Vulnerable Zones, involve greater restrictions on farming practice, such as restricting the amount and timing of organic and inorganic fertilizer application. The EU Common Agricultural Policy is to change the way payments are made to farmers. Single-farm payments will encourage farming in a more environment friendly way. Financial payments may be available to farmers for loss of income or for changing farming practice such as improving slurry storage and fencing off watercourses to restrict livestock access.[2] Much interest currently focuses on the use of riparian land as nitrate buffer zones.[15]

The terrestrial–aquatic ecotone (boundary zone) occupies the zone between the hillslope and the river channel, usually coinciding with the floodplain. Given their position, nearstream ecotones can potentially function as natural sinks for sediment and nutrients emanating from farmland. Observed denitrification rates in floodplain sediments may be sufficient to remove all nitrate from groundwater flowing under a riparian woodland, with a floodplain width of 30 m. Saturated, anoxic soils, rich in carbon, are exposed to nitrate-rich groundwater. Rates of denitrification are high within this zone since the nutrients required by denitrifying bacteria are abundant. Wetlands and wet meadows (defined as areas where the water table is at or above land surface for long enough each year to promote the formation of hydric soils and support the growth of aquatic vegetation) also have potential as nitrogen sinks.[16] High production rates by wetland vegetation result in an abundance of carbon providing an organic substrate for bacterial processes. Wetland plants transport oxygen into anaerobic sediments, which can enhance denitrification leading to losses of nitrogen as N_2O or N_2 from wetland sediments.

The type of vegetation found on the floodplain controlling the efficiency of nitrate absorption is the subject of much debate (see, for example, Ref.[15]). Several studies have argued the presence of trees is crucial; yet others state the role of surface vegetation is secondary to the presence of saturated conditions together with a carbon-rich sediment. Denitrifying bacteria operate best at the junction of anaerobic/aerobic zones where both carbon and nitrate are abundant. It is clear that nitrate losses may be reduced by creating a nutrient-retention zone between the farmland and the river. Given that many floodplains around the world are part of an intensive agricultural system, creating permanently vegetated buffer strips between field and water courses is an idea that should be actively promoted. However, buffer strips will only be successful nutrient sinks if they are managed in an appropriate way. Underlying artificial drainage should be broken or blocked up to prevent a direct route to the watercourse for solutes, and grassland strips need maintenance to prevent them becoming choked with sediment and losing their sediment retention potential.

Solving the problem of nutrient enrichment of surface waters cannot be seen in the short term. Long-term land use change is needed. Taking farm land immediately adjacent to water courses out of production is one option that could go some way to allow modern agriculture and water supply to coexist in the same basin.

Surface Water: Pollution by Nitrogen Fertilizers

Gregory McIsaac
Natural Resources and Environmental Sciences, University of Illinois, Urbana, Illinois, U.S.A.

INTRODUCTION

The use of industrially manufactured nitrogen (N) fertilizers increased rapidly in developed countries between 1960 and 1980. This facilitated a large increase in the production of feed and food grains (maize, wheat, and rice) per unit of cultivated land, but in some regions it also contributed to enrichment of surface and groundwater with various forms of nitrogen. Fertilizer, however, is not the only source of nitrogen that can cause contamination of surface waters. Biological nitrogen fixation, mineralization of soil organic nitrogen, and animal wastes can also contribute to nitrogen enrichment of water bodies. Additionally, under some conditions, nitrogen applied to the soil may be converted to gaseous or immobile forms of nitrogen that do not contribute to surface water contamination. Because of these various sources and transformations of nitrogen, the severity of surface water contamination by nitrogen fertilizer has been difficult to precisely quantify. Existing research indicates that the amount of contamination from fertilizer varies depending on the amount of fertilizer applied, and characteristics of the soils, crops, climate, and the receiving water bodies.

Problems Caused by Nitrogen Pollution of Surface Waters

There are three water quality concerns associated with different forms of nitrogen. First, the combined concentrations of nitrate (NO_3^-) plus nitrite (NO_2^-) in excess of 10 mg N L^- can contribute to methemoglobinanemia (“blue baby syndrome”) in infants if ingested.[1] To guard against this, the U.S. Public Health Service limits nitrate plus nitrite concentration in public drinking water supplies to 10 mg N L^-. Secondly, unionized ammonia (NH_3) may be toxic to fish at concentrations as low as 0.02 mg N L^-. Finally, elevated total nitrogen concentrations (including nitrate, ammonia, and organic forms) in rivers can promote the process of cultural eutrophication in coastal waters, whereby increased production and decomposition of algae, leads to reduced oxygen concentrations. This, in turn, may reduce the abundance and diversity of marine life and may promote the outbreak of nuisance algae.[2]

Sources of N Pollution

Nitrogen contamination may come from a variety of sources: municipal sewage, animal manure, atmospheric deposition, biological N fixation, soil organic N, and/or nitrogen fertilizers. The consequences of contamination in a specific water body will depend upon the amount of contamination from all sources and characteristics of the receiving waters. Shallow rivers, wetlands, lakes, and reservoirs, have some capacity to remove nitrogen by microbial denitrification. The susceptibility of estuaries and coastal waters to eutrophication depends on temperature, availability of phosphorus and silica for algae production, and the rate of water exchange with the open ocean.

Fertilizers

The contribution of inorganic fertilizer to surface water N contamination increased after 1960 as the widespread and intensive use of inorganic N fertilizers rapidly expanded.[3] The use of N fertilizer has allowed greater production of feed and food crops per unit area cultivated. In the United States, 75% of N fertilizer is applied to maize, while in other countries, N fertilizer is primarily used on wheat and rice. Prior to 1960, nitrogen for crop production was obtained primarily by using crop rotations that included legumes such as clover and alfalfa, which can establish a symbiotic relationship with soil bacteria that can convert atmospheric N_2 gas to biologically available forms of N.

Commercial nitrogen fertilizer is primarily manufactured as gaseous ammonia (NH_3), using the Haber-Bosch process in which gaseous nitrogen is reacted with gaseous hydrogen under pressure. The gaseous ammonia may be injected into the soil, which is a common fertilizer application practice in the United States. Additionally, a wide variety of granular and aqueous fertilizer products containing nitrogen are manufactured from manufactured ammonia.

WHAT HAPPENS WHEN FERTILIZER IS APPLIED TO SOIL?

Biochemical Processes

In the soil, ammonia reacts with water and is largely converted to ammonium (NH_4^+), which tends to be strongly adsorbed on soil particles. This adsorption inhibits the movement of ammonium through the soil. Ammonium is an energy rich substance and certain soil bacteria can utilize this energy by decomposing the ammonium to nitrate (NO_3^-). Unlike ammonium, nitrate is not adsorbed to soil particles and, therefore, moves readily with water in the soil. Nitrate that is not taken up by plant roots or soil micro-organisms can be transported to groundwater and surface water by a variety of mechanisms.

Hydrologic Processes

Rainfall, snow melt, or irrigation water input to the soil periodically exceeds the water holding capacity of the soil in the root zone. Depending on the characteristics of the soil, this may lead to one or more of the following: 1) saturation of the root zone with water; 2) surface runoff; and 3) drainage of water through the soil profile to groundwater and/or surface water bodies. Each of these has different consequences for transport of nitrate to surface waters.

If the soil becomes saturated, oxygen may become scarce and in anoxic conditions, denitrifying bacteria may convert the nitrate to nitrogen gases (NO, N_2O, and N_2). Nitrogen converted to these gases becomes unavailable for plant uptake or for surface water contamination. Additionally, saturated soil during the growing season is harmful to many crops like maize that cannot tolerate low oxygen concentrations in the root zone for more than a few days.

Surface runoff has the capacity to transport soil, vegetation, and surface applied granular fertilizers from agricultural fields to surface water bodies. If a granular form of nitrogen fertilizer had been applied immediately prior to the event that caused the surface runoff to occur, nitrate and ammonia concentrations in runoff can be very high.[4] This does not appear to be a common phenomenon, however. Small rainfall events are much more common than large events that typically produce surface runoff. After granular fertilizer is applied, it is likely that a series of small rainfall events will dissolve the granules and move the nitrogen into the soil profile, where it is less likely to contaminate surface runoff. Surface runoff usually has a low nitrate concentration but it can be high in organic and particulate N derived from soil and vegetation.

Drainage of water through the soil profile to groundwater and surface water appears to be the hydrologic pathway that most frequently leads to problematic nitrate contamination of surface waters in agricultural watersheds. This can occur in two ways: by natural drainage where ground water contributes to stream flow and river flow, and by artificial subsurface drainage, where perforated pipes (sometimes called tile drains) have been buried in the soil for the purpose of removing water to reduce damage caused by saturated conditions and thereby enhance crop production (Fig. 1).

Artificial subsurface drainage improves aeration of the soil root zone and increases the length of time that machinery can be used on the soil.[6] It is a common practice in the North Central United States, and in Northwestern Europe, where flat and swampy land has been converted to cropland. The water removed from the soil by artificial drainage is usually directed to surface ditches, streams, and rivers. This water can have high concentrations of nitrogen, principally in the nitrate form, especially where nitrogen fertilizers are applied in excess to the amount necessary for crop production.[7,8] This nitrate can also be derived from microbial conversion of soil organic matter to inorganic N in the process of mineralization. Mineralized soil organic N may come from crop residues (unharvested leaves, stalks, and roots). Of course, some of the N in crop residues may have originated from fertilizer applied in previous years, but it can also derive from biological N fixation or animal manures applied on a field.

SPATIAL VARIABILITY

In most agricultural settings, commercial fertilizer provides only one source of N used for crop production. Animal manure, biological N fixation, mineralization from soil organic N, and deposition of N from the atmosphere can also contribute to soil fertility and surface water contamination. Because there are multiple sources and sinks of N in the soil, the relationship between N fertilizer application rate and nitrogen loss in drainage water is not always consistent across locations and across studies. If denitrification and plant and microbial uptake of N are large, nitrate concentrations in subsurface drainage may be low in spite of high fertilizer N inputs. If mineralization of soil organic matter is large, nitrogen in drainage water may be large without N fertilizer input. High rates of mineralization of soil organic N occurs after the initial cultivation of virgin land, and after a leguminous forage crop such as alfalfa or clover are cultivated into the soil. Appropriate use of N fertilizer should take

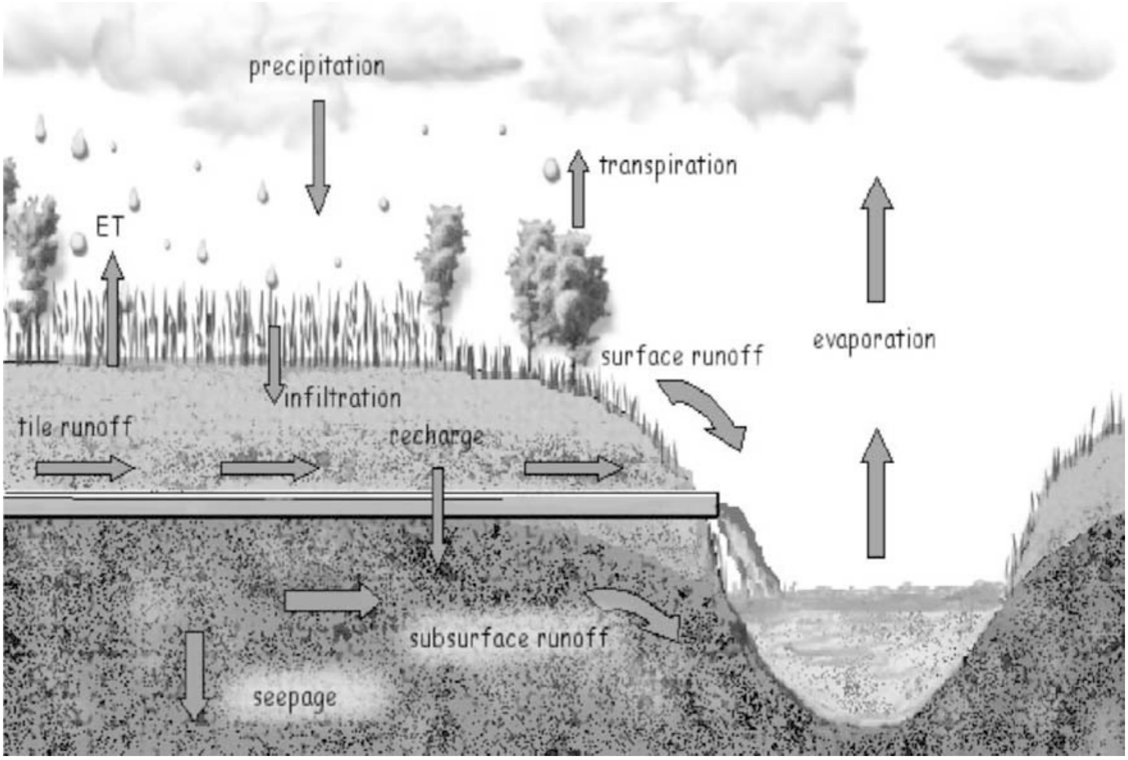

Fig. 1 Illustration of the hydrologic cycle with artificial subsurface drainage (tile runoff) contributing to surface channel flow. *Source*: From Ref.[5].

all of these N sources into account, as should studies examining the relationship between N fertilizer use and water quality.

WATERSHED SCALE ANALYSES

Regional Nitrogen Input–Output Analyses

Howarth et al.[10] developed an approach for estimating the net nitrogen inputs to a region N that is highly correlated with average nitrogen transport in the rivers draining temperate regions (Fig. 2). Net N input to a region was defined as sum of N in fertilizer used, biological N fixation of agricultural crops, oxidized N in atmospheric deposition in the region, and the N in food and feed imported to the region minus the N in food and feed exported from the region. This approach assumes that there is no net gain or loss of N from soil organic matter. This assumption appears to be reasonable in regions where most soils have been under continuous cultivation for 60 yr or more, at which time, annual mineralization of soil organic N is roughly replaced by organic N returned to the soil in crop residues and microbial biomass.[11]

In temperate regions, riverine N transport was, on average 25% of the net N input to the region. The fate of the other 75% of the net N is unknown, but much of it is probably converted to gaseous forms of N by microbial denitrification. The high net N input in countries draining to the North Sea, most notably the Netherlands, is in part due to high density of domestic animals as well as use of N fertilizers. In tropical regions, riverine N flux was much greater than 25% of net N inputs, even in regions where little N fertilizer was used. The reasons for this are not precisely known but it is believed to be due, in part, to greater rates of biological N fixation in both cultivated and non-cultivated land in the tropics. This may also be due to the recent conversion of forest, wetlands, and grasslands to crop production, which leads to high rates of mineralization of soil organic N to nitrate which is highly mobile.

Hydrologic Process Models

The quantity of nitrate transported in rivers is also related to the quantity of water flowing in the rivers per unit of land area, which is also known as water yield. Caraco and Cole[12] demonstrated that riverine nitrate N transport in major rivers in the world was a function of water yield, fertilizer use, population density, and atmospheric deposition of oxides of N. Building on these results, McIsaac et al.[13] developed

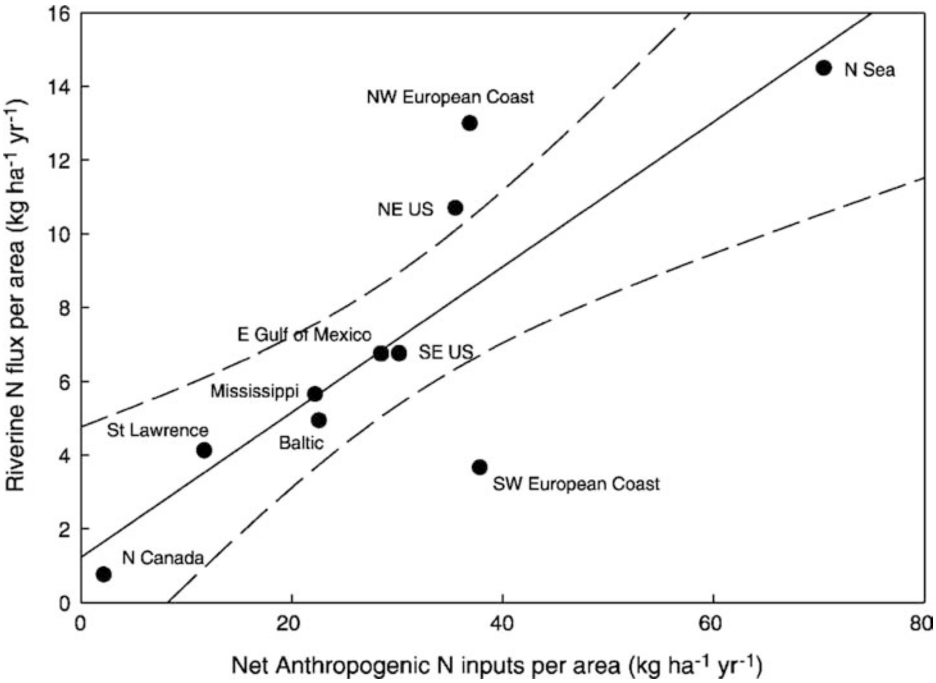

Fig. 2 Average annual riverine total N flux as a function of net anthropogenic N inputs to temperate regions draining to the North Atlantic Ocean. *Source*: From Ref.[10].

the following model of annual nitrate discharge in the Lower Mississippi River 1960–1998:

$$NF_m = 0.66WY^{0.93}e^{(0.13NNI^{2-5}+0.06NNI^{6-9})} \quad (1)$$

where NF_m = annual nitrate N flux in Lower Mississippi River ($\mathrm{kg\,N\,ha^{-1}\,yr^{-1}}$), NNI^{2-5} = average annual net N input during the previous 2–5 yr ($\mathrm{kg\,N\,ha^{-1}\,yr^{-1}}$), NNI^{6-9} = average annual net N input during the previous 6–9 yr ($\mathrm{kg\,N\,ha^{-1}\,yr^{-1}}$), and WY = annual water yield ($\mathrm{m\,yr^{-1}}$).

This equation accounted for 95% of the annual variation in nitrate flux in the Mississippi River from 1960 to 1998 and suggested that riverine nitrate in a given year was correlated with net N input averaged over the previous 2–9 yr. Furthermore, calculations with the model suggest that if the N fertilizer use in the basin had been 12% lower than actual during this period, nitrate flux to the Gulf of Mexico would have been 33% less than observed (Fig. 3), assuming crop yields were not limited by N shortages.

The Role of Fertilizer Use Efficiency

The efficiency of fertilizer used for maize production in the major maize producing states (Illinois, Iowa, Indiana, Minnesota, and Nebraska) in the Mississippi River Basin increased between 1986 and 2000. Maize yields have increased about 20% from 1986 to 2000, while N fertilizer use has remained roughly constant.

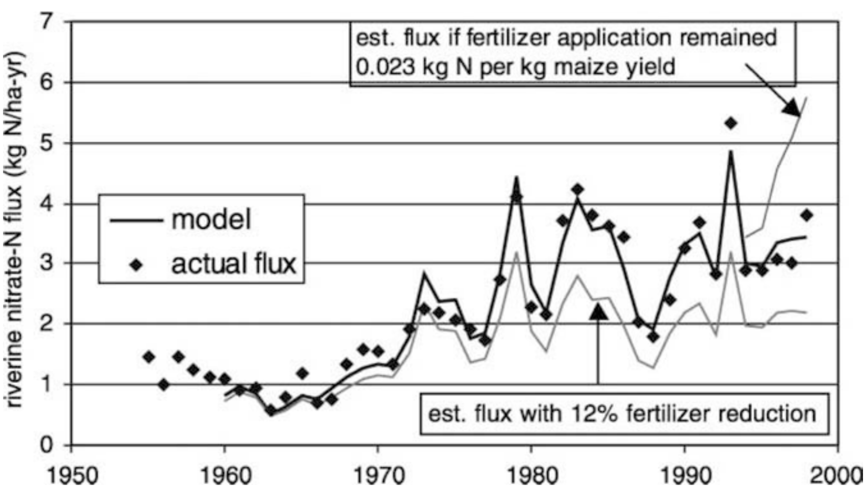

Fig. 3 Annual riverine nitrate flux in the Lower Mississippi River at St. Francisville, Louisiana, as determined from measurements (diamonds) as estimated from Eq. (1) (thick line), as estimated from Eq. (1) assuming a 12% reduction in N fertilizer input (thin lower line), and assuming fertilizer applications remained 0.023 kg N per bushel of harvested maize rather than declining to 0.018 kg N per bushel of harvested maize (thin upper line). *Source*: From Ref.[13].

Soils–Suspended

Between 1976 and 1986, an average of 0.023 kg N of fertilizer was applied for each kg of maize harvested. Between 1996 and 2000, an average of 0.018 kg N of fertilizer was applied per kg of maize harvested. If this improvement in fertilizer use efficiency had not occurred, nitrate flux in the Mississippi River in 1996–1998 would have been about 50% greater than the measured flux, according to the model of McIsaac et al.[13] (Fig. 3).

Farmers face two major uncertainties when making fertilizer application decisions: they do not know what their yields will be nor how weather conditions might influence the availability of N fertilizer to the crop. The cost of nitrogen fertilizer has been relatively low in relation to the value of the increased yields, and consequently many farmers have believed that applying more N fertilizer than necessary provides ‘‘cheap insurance’’ against the uncertainties. In some instances, farmers did not consider N available from animal manure or from previously harvested legume crops like soybeans.

A number of factors are likely responsible for the increased fertilizer use efficiency. Research and outreach efforts have provided farmers with better information for making N fertilizer decisions. Water quality concerns have focused attention on the need for improved nutrient management. Weather during the 1990s was generally more favorable for corn production than the 1980s, when three major droughts occurred in the corn growing region of the Mississippi River Basin.

ADDITIONAL NEEDS AND APPROACHES FOR REDUCING NITROGEN TRANSPORT

A recent improvement in the efficiency of N fertilizer use has also been observed in wheat production in the United Kingdom and rice production in Japan.[3] However, improved fertilizer use efficiency alone may not be sufficient to address water quality problems in some settings. Jaynes et al.[8] reported that even with N fertilizer rates at recommended levels, nitrate concentration in tile drainage water sometimes exceeded the drinking water standard of 10 mg N L^{-} in Iowa.

Zucker and Brown[9] recommended several additional practices that can reduce nitrogen contributions in tile drainage: water table management, treatment of drainage water in wetlands, and use of crop rotations that reduce N losses. Additional monitoring and documenting the changes in water quality associated with changing fertilizer management practices are needed to improve our understanding of the connections between N fertilizer use and water quality in different geographic settings.

CONCLUSIONS

In many settings nitrogen enrichment of surface water bodies has increased following the increased use of N fertilizers. The precise contribution of nitrogen fertilizers to surface water nitrogen has been difficult to quantify because there are multiple sources of nitrogen contributing to most water bodies, and, depending on environmental conditions, a certain portion of soil nitrogen may be converted to gaseous or immobile forms. In general, however, agricultural regions with extensive artificial subsurface drainage systems or with sandy soils tend to have the most nitrogen enriched surface waters.

The efficiency of nitrogen fertilizer used for crop production increased in many areas in the 1990s and this has very likely limited or reduced the subsequent contamination of surface waters. Continued improvements in fertilizer use efficiency, and the use of wetlands for removing nitrogen from surface waters will help alleviate problems caused by nitrogen enrichment. Additional monitoring and research are needed to more precisely quantify how nitrogen management practices influence surface water nitrogen concentrations in different settings. A more precise understanding of the causal relationships between nitrogen inputs to the land and the contamination of surface waters could provide more effective guidance for management, policies, and programs intended to protect aquatic resources while maintaining optimal use of land resources.

Surface Water: Pollution by Surface Mines

Agricultural Experiment Station, University of Wyoming, Laramie, Wyoming, U.S.A.

INTRODUCTION

The impacts of surface mining on stream quality result directly from the land disturbance activity. Unweathered earth materials brought to the surface during mining undergo rapid alterations due to exposure to air and water, thereby releasing many of their structural constituents into water.[1] When disturbed rock and soil is exposed to precipitation (e.g., rainfall, snow, hail, dew, etc.), water running off these materials carries solid particles (also known as sediments) as well as dissolved constituents such as salts, metals, trace elements, and/or organic compounds that can pollute nearby surface waters. Water may also percolate into the disturbed materials causing movement and leaching of salts, metals, and trace elements into deeper levels causing potential groundwater quality impacts.[2] The chemistry of the water is highly dependent on the overburden or earthy materials that were disturbed during the mining process.

Surface mining activities can result in disturbed lands with poor drainage unless this problem is controlled, minimized, and even eliminated by reclaiming the areas.[2,3] Reclamation of disturbed sites usually involves grading the areas to achieve a land surface that is stable and compatible with surrounding undisturbed areas, possibly replacing topsoil on the regraded surface and seeding with plants capable of controlling erosion and runoff, and to provide forage for both indigenous wildlife and/or domestic livestock.[3] The Surface Mining Control and Reclamation Act (SMCRA) of 1977 specifies policies and practices for reclaiming areas after surface mining to minimize water quality impacts and to encourage the development of stable, diverse plant communities after mining.[4]

The Clean Water Act (CWA) of 1977 and previous water control legislation [Federal Water Pollution Control Act of 1972] require restoring and maintaining the chemical, physical, and biological integrity of our nation's water.[5,6] The intention of these laws was to establish a framework for permitting and regulating all point discharges into surface waters, with the laws particularly targeting the discharge of sewage and wastewater from communities into streams, rivers, and lakes. The CWA was designed to place limits or standards on water being discharged into the waters of the United States, but also to maintain drinking water and recreational uses of water, and to restore the quality of streams and lakes that had been degraded.[7] The law has been interpreted as requiring all waters to be "fishable and swimmable."[8]

Water discharged from surface mines is regulated by the CWA,[5] and all mines are required to only discharge water that meets CWA effluent standards. Therefore, all water that comes from a permitted mine (whether the water was received as rainfall, snow, hail, etc. at the surface or from underground seepage) must pass through a sedimentation or treatment pond and meet or exceed discharge standards before it can be released into receiving surface waters.[8]

Nationwide, over 20,000 km of rivers and streams and over 75,000 ha of lakes and reservoirs are adversely affected by contaminated water draining from abandoned mines.[4] The vast majority of these problem areas occur in the eastern United States where coal mine drainage is considered by the United States Environmental Protection Agency (U.S. EPA) to be the most significant non-point pollution problem. Although Wyoming is currently the leading coal producing state in the country (approximately, one-third of our nation's coal is mined in this state), Wyoming and other western United States are plagued with historic mining activities involving metal ores, such as copper (Cu), lead (Pb), zinc (Zn), and silver (Ag), with the trace elements molybdenum (Mo) and uranium (U) also mined in certain regions. In addition to surface water impacts from coal, metal, and trace element mining that can generate acid mine drainage (AMD) from oxidation of pyritic ores (e.g., iron sulfide FeS_2), other pollutants are also of concern including metals [aluminum (Al), antimony (Sb), cadmium (Cd), cobalt (Co), chromium (Cr), Cu, iron (Fe), manganese (Mn), nickel (Ni), Pb, and Zn], trace elements [arsenic (As), Mo, and selenium (Se)], radioactive elements [cesium (Cs), radium (Ra), thorium (Th), U, and vanadium (V)], and mining operation by-products [mercury (Hg) and cyanide (CN)].

Many areas in the United States and other parts of the world were disturbed prior to the enactment of any laws regulating their drainage quality and water release into streams.[7] These disturbed areas may contribute significant amounts of pollutants to surface waters because they often are devoid of minimum vegetative cover and because their soil properties limit natural reclamation of the site.[3] Pre-1977 mining activities were also considered in SMCRA legislation.[4] Including provisions for reclaiming ''abandoned'' mined lands, which are surface-mining disturbances that occurred prior to enactment of the law and where no individual or company is held responsible for the damaged land. Drainage from these surface-mining operations has had and continues to have a dramatic effect on surface water quality because these ''abandoned'' pre-1977 sites discharge acid mine drainage into surface water bodies such as rivers, streams, creeks, and impoundments. Money generated by the ''abandoned mine land reclamation fund'' since 1977 goes to reclaiming abandoned areas, which aids in the improvement of water quality from abandoned mine sites (Table 1).

CLASSIFICATION OF SURFACE WATER POLLUTANTS

At surface coal mines, drainage waters generally reflect the chemistry of the rock layers disturbed during the mining process. For example, if the overburden material chemistry is dominated by calcareous shales or limestone, water draining from these materials will generally have a pH value above 6.0, low concentrations of dissolved metals and possibly trace elements, potentially high amounts of bases or salts [such as calcium (Ca), magnesium (Mg), and sodium (Na)], and high alkalinity. If, on the other hand, the overburden materials comprised sandstone with high sulfur coal or ores containing pyrite (such as those associated with hard rock mining of Cu, Fe, Pb, Ni, Ag, or Zn), the drainage water quality may have a pH value less than 3.5, and high concentrations of dissolved metals such as Fe and Al, and high sulfate (SO_4^{2-}). Some surface mines are dominated by neither acid nor alkaline strata, and the impact of disturbing these rock materials on water quality is not significant.

The primary water quality impacts from surface mining can be classified into physical, chemical, or biological categories. Physical impacts are color, which relate to dissolved and suspended constituents. Chemical impacts of water draining from surface mines can vary from acid water laden with metals and trace elements to alkaline water with excess Ca, Na, and carbonates (e.g., HCO_3^-, CO_3^{2-}). Biological impacts relate to sanitary chemistry, where microorganisms may contaminate the water.

Physical Impacts

The most noticeable, dramatic physical impact to water is color.[1] Bentonite (a type of clay material mined predominately in Wyoming) surface mining produces a distinct greenish tint to water that has accumulated in open pits. Orange water results in many areas where acid-generating, pyritic materials are found, such as in coal and hard rock metal mining due to iron coating of rocks and sediments. White turbid waters are indicative of high levels of Al, which

Soils–Suspended

is generally related to acidic water conditions and disturbed geological materials high in aluminosilicates. Water carrying high loads of sediment, which is common during storm events, appears murky, cloudy, and turbid.

Chemical Impacts

Chemical impacts can vary from acidic and metal-laden waters to highly alkaline waters containing excess Na.[1,2] As mentioned earlier, acid water conditions result where rocks containing pyrite are exposed to the atmosphere with a release of Fe, hydrogen (H^+), and SO_4^{2-}. The low pH conditions of these waters tend to dissolve other nearby rocks releasing more Fe and other elements into the water such as Al, Mn, silicon (Si), and base cations such as potassium (K), Ca, and Mg (Fig. 1).

Excess alkalinity in water is generally a much less significant problem. Water containing high levels of bicarbonate (HCO_3^-) usually begin precipitating calcite ($CaCO_3$) if the water pH value is above 8.3. There have been a few examples where acid-containing materials have been added to high pH water to reduce the pH for discharge into surface waters.

If the water contains excess amounts of Na, usually the water is collected in ponds or reservoirs and evaporated, thereby leaving the salts in these closed basins.[9] Methane exploration from coal deposits in the Powder River Basin in northeastern Wyoming, however, has resulted in tremendous amounts of product waters being brought to the land surface, with some of these waters directly discharged into nearby streams and channels. Because of their potentially high salt contents, and in some case high Na concentrations, negative impacts to the surrounding ecosystems include soil and sediment dispersion, vegetation die-off, and potential aquatic organism mortality.[2]

Some waters from surface mines contain organic compounds.[1,9] These are often a result of contamination from gas tanks, oil spills, or run off from equipment-servicing areas. In these cases, the source of the contamination must be identified and removed. Gasoline or oil-soaked soil can be excavated, aerated, and fertilized so that microbes inherent in the soil will have sufficient nutrients and oxygen to decompose the organic matter.[2]

Biological Impacts

Biological contamination is not generally associated with surface mines, although some contamination could occur if water used in bathhouses and restroom facilities is not properly treated. The most common biological impacts to surface water are associated with the discharge of water from individual households where no septic system is installed or from municipal wastewater effluents.[2] Wastewater from municipal treatment plants or from untreated households can contain bacteria, viruses, and other microorganisms. Fecal coliform bacteria are routinely used to indicate the level of microorganism contamination from water

Fig. 1 Acidic and iron laden water flowing from a small underground coal mine into a natural stream in West Virginia. The iron dissolved in the water coats the streambed downstream and makes the water unsuitable for use.

impacted by human waste.[10] If high levels of fecal coliform bacteria are identified in water, the source must be located and the water must be directed to a wastewater treatment plant or be introduced into the soil via a septic tank/soil absorption field of adequate design.

WATER TREATMENT

If the water to be released from a mining operation does not meet effluent limitations established by the CWA, surface mine operators are obligated to control or treat the water to meet effluent standards.[8] These treatments include routing the water through sedimentation ponds to allow settling of solids, the addition of base chemicals [CaO, $Ca(OH)_2$, NaOH, etc.] to raise pH and cause the precipitation of dissolved metals and trace elements, transferring the water through microbial chambers to remove organic matter, chlorination, and filtering.

For acid mine drainage, the acid-generating reactions will continue until the pyrite is exhausted, until the pyrite becomes coated with iron hydroxides [e.g., $Fe(OH)_2$, FeO(OH), and FeO] or until the water cannot leach the acid products away.[11] Control practices to reduce the amount of pyrite oxidation employ the use of barriers to restrict water flow through the material, the addition of alkaline materials to neutralize the acid or stop the acid-generating reaction, and flooding or compacting the material to reduce oxygen influx to the material.[1] If acid water results, then a treatment plan must be established and the water must be treated by base chemicals to neutralize the water and precipitate the metals before release into streams (Fig. 2).

REGULATORY ENFORCEMENT

Current surface mining operations must comply with CWA and SMCRA standards.[8] SMCRA established the ''abandoned mine land reclamation fund'' that generates money from current coal operations ($0.35 per ton of surface mined coal and $0.15 per ton of coal mined underground), which is used to reclaim

Fig. 2 Two types of drainage are shown here from an abandoned mine site north of Yellowstone National Park, Wyoming. The white-colored water on the right is laden with aluminum and is derived from waste rock, while the stream on the left contains high iron and is the result of acid mine drainage from an abandoned metal mine shaft.

abandoned lands as deemed necessary by the Office of Surface Mining and Enforcement (e.g., OSM). Due to the liabilities and financial penalties, surface mining operators have strong incentives for compliance with SMCRA regulations. Enforcement of current regulations and standards by OSM and state governing agencies will continue to minimize the impacts of surface mining on surface water quality. Operators of surface mines also recognize that an environmental stewardship policy and the implementation of practices to reduce pollution of water on and near their sites will ultimately reduce the costs and liabilities associated with surface mining.

INTRODUCTION

Eutrophication is a major water quality concern in the United States[1,2] and worldwide.[3] Its economic impact on the fishing and water-treatment industries in the eastern United States alone, has amounted to over $2 billion over the last decade.[4] While phosphorus (P) and nitrogen (N) contribute to eutrophication, P is the limiting nutrient in most fresh waters. This is due to the fact that P is ultimately derived from land, where as N can exchange freely between the atmosphere and surface water and many aquatic biota can fix N. Although eutrophication is a natural process, it is accelerated by increased inputs of P by humans. This can have several detrimental effects on surface-water quality. Perhaps the most obvious is the proliferation of harmful algal bloom, parasites (e.g., *Pfiesteria* and *cyanobacteria*) and aquatic weeds, which can interfere with the use of water for recreation, extraction, and drinking (foul taste and odor and treatment problems such as the formation of carcinogens during chlorination). As aquatic biota die and decompose, the increased microbial activity depletes oxygen supply and increases fish mortality.

Over the last 30–40 yr, attention has been centered on agriculture as the primary origin of P loss to surface waters. This is due, in part, to the general ease of identification and mitigation of point sources of P loss. In addition, the intensification and specialization of farming systems has led to regional surpluses of P imported in fertilizer and animal feed compared with P exported in farm produce.[5] Now, many farms possess soil–P concentrations well in excess of plant needs and therefore an increased potential for P loss.[6]

MECHANISMS OF AGRICULTURAL P LOSS TO SURFACE WATERS

The loss of P from agricultural lands to surface waters is largely controlled by the coincidence of areas of high P availability (source factors) with the physical transport of P within hydrological pathways such as overland and subsurface flow (transport factors). High P availability is determined by the management of soils (and its physiochemical characteristics), crops, manures, and fertilizers. Where the source and transport factors coincide, we have "critical source areas" for P loss. These areas are usually small yet well defined (<20% of land area) but can contribute most of the P exported from a watershed (>90%).[7]

Several surveys of U.S. watersheds have shown P loss in runoff, increases as the portion of the watershed under forest decreases and agriculture increases.[8,9] Overland flow from forests, grasslands, and other non-cultivated soils carries little sediment, so P losses are low and generally dominated by dissolved P, which is immediately algal-available[10,11] (Fig. 1). The cultivation of agricultural land greatly increases erosion, and with it, the loss of particle-bound P. Typically, particulate losses constitute 60–90% of P exported from most cultivated land.[12] Some of the particle-bound P is not readily available, but much of it can be a long-term source of P for aquatic biota.[11,13]

Release of Phosphorus from Soil

In acidic soils, P occurs largely as Al- and Fe-phosphates, whereas in neutral to alkaline soils P occurs more so as Ca- and Mg-phosphates and sorbed onto the surface of Ca- and Mg-carbonates. Organic P can form a significant part of soil P especially in acidic soils and soils that contain more organic matter and N. The solubility of soil P is controlled by three chemical characteristics: i) concentration of P in solution; ii) quantity of P in the soil that equilibrates with the solution; and iii) buffering capacity of the soil (controlled by sorption strength and the saturation of sorption sites with P). For P loss, these components can be described by a quantity–intensity relationship such as plots of soil test P (i.e., agronomic tests such

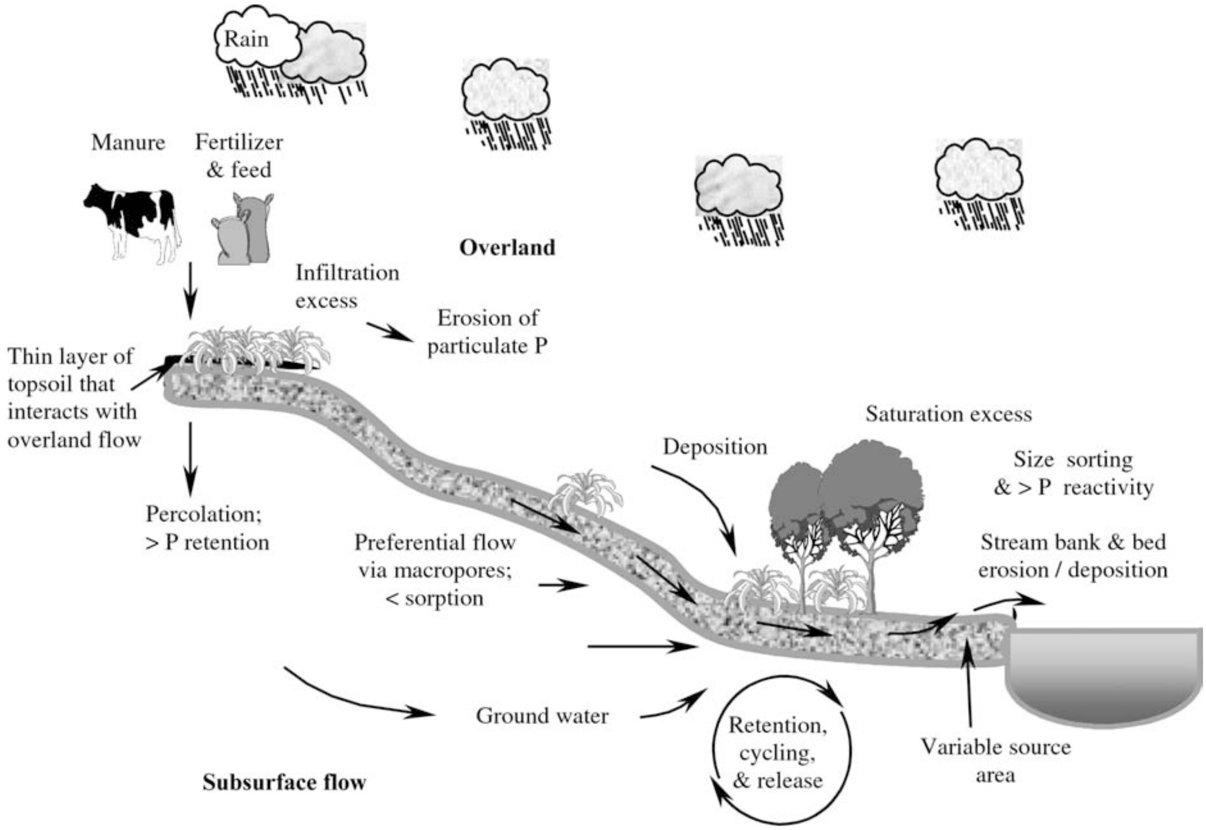

Fig. 1 Processes and loss of P from land to fresh waters.

as Bray, Mehlich or Olsen) against either P loss in overland flow, subsurface flow or 'gentle' soil extracts that approximate P loss (e.g., 0.01 M $CaCl_2$).[14] The relationship between soil P and overlend flow P can be split in two, on either side of an environmental soil P threshold, where soils greater than the threshold have a much greater P loss potential.

Coupled with soil P solubility is the kinetics of release. Kinetic exchange experiments using ^{33}P, have confirmed that soil P exchangeable within 60 sec is closely related to P in overland or subsurface flow. With time, P transport in overland flow becomes less related to this pool and more dependent upon the slow diffusion of P from the inside of the soil aggregate.[15,16] This serves to illustrate that soil P release to overland flow is a function of the surface area available to the solution, as well as the quantity of P in soil. For example, Holford and Mattingly[17] showed that in a selection of near neutral pH soils, P release and sorption was correlated to $CaCO_3$ surface area, but not total $CaCO_3$ concentration.

Transport and Loss of Phosphorus

Using these simple chemical principles we can describe the release of P, however, the physical transport of P determines whether these processes are translated into actual losses within a watershed and beyond. Rainfall is the primary driving force behind P transfer. Rainfall events can be divided into two types: one which describes rainfall of low intensity and high frequency that tends to move P in subsurface flow, and a second that describes rainfall of high intensity and low frequency that tends to move P in overland flow from a thin layer of P-rich topsoil (Fig. 1). Due to the greater kinetic energy and erosive power of high frequency storms, more P and total quantities of P are lost during overland flow in particulate forms than in subsurface flow. For example, Pionke, Gburek, and Sharpley[7] showed that a few short, intense storms accounted for about 90% of the annual P export from an upland watershed. Overland flow can be further divided into Hortonian (limited by infiltration rate) overland flow and saturation excess (limited by soil water storage capacity) overland flow. Infiltration-rate limited overland flow will have a greater capacity to detach and move soil particles, however, this pathway is largely restricted to high-intensity, extreme rainfall events.

In humid and temperate climates, saturation excess overland flow can be described by variable source area (VSA) hydrology.[18] Flow from these areas varies rapidly in time and space, expanding and contracting rapidly during a storm as a function of precipitation, temperature, soil-type, topography, ground water, and moisture status over the watershed. The onset of flow from these areas is limited by soil water storage capacity and thus, usually results from high water tables or soil moisture contents in near-stream areas. During a rainfall event, area boundaries will migrate upslope as rainwater input increases. In dry summer months, overland flow will come from areas closer to the stream than during wetter winter months, when the boundaries expand away from the stream channel. In watersheds where infiltration excess overland flow dominates, and areas of the watershed can alternate between sources and sinks of overland flow, again as a function of soil properties, rainfall intensity and duration and antecedent moisture condition. Thus, consideration of hydrologic controls and variable source areas is critical to understanding P loss.

Combining Soil Chemistry and Hydrology

Transport and loss of P generally occurs from areas where overland flow contributes to stream flow, although some subsurface flow pathways may be important under certain hydrologic conditions. However, even in watersheds where subsurface flow pathways dominate, areas contributing P to drainage waters can be localized (e.g., Ref.[19]. Loss of P in subsurface flow is generally less than that in overland flow, and will decrease as the degree of soil–water contact increases, due to sorption by P-deficient subsoils. Exceptions occur where organic matter may accelerate P loss together with Al and Fe, or where the soil has a small P sorption capacity (e.g., some sandy soils) or where subsurface flow travels from P-rich topsoil in/via macropores or is intercepted by drainage (Fig. 1).

The hydrologic and chemical factors controlling P loss vary temporally and spatially. Increased net precipitation (precipitation–evapotranspiration) to a watershed increases the amount of discharge and the quantity of P lost by accelerating those transformations that occur before and after P reaches stream flow. For example, whereas dissolved forms of P are immediately available to aquatic flora, particulate forms of P can represent a more long-term source of P via desorption. During overland flow, soil and associated P is lost in order of decreasing particle density and increasing weight. Thus, fine and/or light soil particles that contain many Al- and Fe-oxide-associated P or organic associated P are transported before coarser and/or heavier sized particles (Fig. 1). Eroded fines will be able to maintain a greater equilibrium stream or P concentration for longer than coarser particles with less P in reserve. However, coarser particles have a lesser affinity for P and will release it faster initially.

MANAGEMENT TO DECREASE P LOSS

Source factors regulate the chemistry of released P to transport mechanisms. The most important factors influencing the concentration and solubility of P in soil include soil type and P inputs as fertilizer and manure. Effective management ultimately aims to balance P inputs with off-takes as produce, at the farm gate. However, in areas of concentrated animal production, sufficient land may not be available for manure disposal leading to an increase in soil P concentration.

Efficient management of P sources involves placing P away from critical source areas likely to loose more P such as hydrologically active zones in a watershed and soils already high in P. Cultivation immediately after application can decrease P losses if erosion is minimized. Periodic tillage of the soil may also decrease P loss by redistributing high-P topsoil throughout the root zone. Applications of manure or fertilizer during drier periods avoiding precipitation or snowmelt will further decrease the potential for P loss in overland flow by increasing the contact time (and uptake) with the soil and crop.

The presence of crop covers and crop residues help decrease P loss by decreasing erosion and overland flow. Equally, anything that keeps surface roughness high or intercepts overland flow, which encourages rainwater infiltration and sediment retention, can be effective. Such measures include riparian zones, buffer strips, terracing, cover crops, contour tillage, and impoundments or small reservoirs. However, these measures are better at stopping particulate than dissolved P transport.

Other remedial measures include manure and soil treatment and amendment to decrease P solubility and potential release to runoff; feeding animals no more P than they actually need; use of soil testing to guide future P application (particularly as manure); identifying critical areas or ‘‘hot spots’’ for P loss to which conservation measures should be targeted; and redistribution of manure within and among farms. These are mostly short-term or ‘‘stop-gap’’ measures to decrease P loss. Long-term solutions will involve balancing P inputs with outputs at farm, watershed, or regional scales.

Surface Water: Western United States Law

J. David Aiken
Department of Agricultural Economics, Institute of Agriculture and Natural Resources, University of Nebraska, Lincoln, Nebraska, U.S.A.

Soils–Suspended

INTRODUCTION

The prior appropriation doctrine, the primary water law doctrine of the western United States, is a legal rejection of the riparian rights doctrine, which originated in England (see Ref.[1] pp. 3–3 to 3–6). Under the riparian rights doctrine, only those whose land bordered a stream had a right to use water from the stream (see Ref.[1] pp. 3–47 to 3–52). Under the early appropriation doctrine, water rights were created by diverting water from the stream and making a beneficial use of the water. Under most modern state appropriation systems, the water appropriator must also comply with state appropriation permit requirements.

APPROPRIATION OF WATER

Actual Diversion Requirement

Under prestatutory appropriation systems, water was required to be diverted from the stream in order for the water user to have legally appropriated the water (see Ref.[1] pp. 5–5 to 5–10; 5–72). This actual diversion requirement was carried over into many appropriation statutes. For many years, the actual diversion requirement was a legal barrier to obtaining appropriations for instream water uses, such as fish, wildlife, and recreation (see Ref.[1] pp. 5–109 to 5–112). Beginning in the 1970s, most western states modified their appropriation statutes to specifically provide for instream appropriations (see Ref.[1] pp. 5–47 to 5–48).

Beneficial Use

Under prestatutory appropriation systems, water diverted from a stream was required to be put to a beneficial use in order for the water user to have legally appropriated the water (see Ref.[1] p. 5–112). The beneficial use requirement was carried over into many appropriation statutes. The beneficial use concept has two dimensions: the purpose of use and the quantity of water.

Purpose of Use

While most appropriation statutes enumerate specific uses that are legally considered to be beneficial, most enumerations also include language indicating that other non-enumerated uses may be beneficial as well. Western courts have generally taken the position that if the use is beneficial to the appropriator, the purpose of use portion of the beneficial use requirement has been satisfied (see Ref.[1] pp. 5–114 to 5–116).

Duty of Water

Duty of water refers to the quantity of water appropriated (see Ref.[1] p. 5–113). Irrigation has been and remains the largest consumptive use of water in the West, and most duty of water issues relate to irrigation water-use efficiency. Courts and western state appropriation administrators have tolerated what would today be considered less-efficient irrigation practices in establishing the duty of water for irrigation appropriations. The basic test is whether the use is reasonably efficient at the time that irrigation is initiated. Irrigators are usually allowed to maintain their traditional irrigation practices despite improvements in irrigation technology, leading to the charge that the prior appropriation system foster's inefficiency (see Ref.[1] pp. 5–118 to 5–21). In fact, most of the irrigation water ‘‘waste’’ returns to the stream as irrigation return flows and is relied upon by downstream water users (see Ref.[1] pp. 5–125 to 5–128). Many appropriation states establish specific statutory ceilings on diversion rates and annual diversion quantities for irrigation appropriations.

Water Rights Administration

Virtually all western states have comprehensive appropriation water administrative systems. State appropriation administrators, often referred to as state engineers, are responsible for determining priority dates and water quantities for all appropriations, maintaining an appropriation registry, approving applications for new appropriations, cancelling unused appropriations, and administering priorities during periods of water shortage (see Ref.[1] pp. 5–74 to 5–81).

PRIORITY OF APPROPRIATION

Junior and Senior Appropriators

Disputes between appropriators when there is insufficient water for all appropriators are resolved on the basis of temporal priority, or "first in time is first in right." The appropriator with the earliest appropriation priority date is called the senior appropriator, while the appropriator with the more recent priority date is called the junior appropriator (see Ref.[1] pp. 5–48 to 5–55).

An appropriator may be junior to some appropriators and senior to others. Appropriators are subject to priority calls by downstream senior appropriators. Appropriators may issue a priority call against upstream junior appropriators. Any appropriator may request the state engineer to restrict diversions by any upstream appropriator (including upstream senior appropriators) to the authorized amount if excess diversions are being made.

Senior appropriations represent a more secure water supply than junior appropriations.

Relation Back Doctrine

Because of the significance of priority in the appropriation system, establishing priority dates is an important issue. Generally, the priority date for an appropriation will relate back to the earliest definite step that the appropriator took to establish the appropriation, so long the appropriation was completed with due diligence (see Ref.[1] pp. 5–101 to 5–103). Under modern appropriation systems, appropriation applicants are given deadlines within which they must complete their appropriations or else have their application dismissed (see Ref.[1] pp. 5–106 to 5–109).

Priority Administration

One of the most important aspects of state engineer administration is the administration of priorities. When a senior appropriator is not receiving all the water the appropriator is entitled to, the senior appropriator makes a priority call, also referred to as a river call. This involves informing the state engineer's office that the appropriator is not receiving sufficient streamflow to exercise the appropriation. If the inadequate streamflows are confirmed, the state engineer will issue closing orders to junior appropriators upstream from the senior appropriator making the priority call ("priority runs upstream"). When the senior appropriator has completed the appropriator's water use (e.g., the appropriator has completed an irrigation), the senior appropriator will notify the state engineer, who in turn will inform the upstream junior appropriators that they can resume their water diversions (see Ref.[1] pp. 5–53 to 5–55).

Futile Call Doctrine

A major exception to priority administration is the futile call doctrine. If the state engineer determines that the increased water flows generated by issuing closing orders to upstream junior appropriators will not reach the downstream senior appropriator making the priority call in usable quantities and in a timely fashion, the state engineer can refuse to issue closing orders to the junior appropriators despite a downstream river call (see Ref.[1] p. 5–55).

Water-Use Preferences

Another exception to the priority doctrine recognized in some western states is the notion of water-use preferences. Water preferences typically involve an ordering of the importance of water use, such as 1) domestic; 2) agriculture; and 3) industry. The appropriator with the highest use preference is called the superior use; the appropriator with a lower preference is called the inferior use. Under specific limited circumstances, superior uses may in some western states be legally favored over inferior uses regardless of priority (see Ref.[1] pp 5–57 to 5–59).

Preferences are relevant principally when the superior use is a junior appropriation. When the superior water use is the senior appropriation, the superior water use is protected by the priority doctrine. Even when the superior use is the junior appropriation, the senior appropriation will almost always be entitled to exercise its priority without regard to water-use preference.

There are two types of water preferences: absolute and compensatory preferences. Under absolute water preferences, a junior appropriator with a superior use will be entitled to water at the expense of a senior appropriator with an inferior use. Under compensatory water preferences, the senior appropriator with an inferior use has priority over the junior appropriator with the superior use. If the junior appropriator wishes to exercise its superior use preference, it must purchase (or condemn) the senior inferior appropriation. In other words, the junior superior appropriator can obtain the senior inferior appropriator's water only by paying for the water. The vast majority of appropriation water disputes are resolved on the basis of priority.

LOSS OF APPROPRIATIONS

Because water appropriations are based upon beneficial use of the water appropriated, when the water use stops the appropriation may be lost (see Ref.[1] p. 5–152). Unused appropriations may be cancelled by the state engineer when the statutory period for appropriation non-use (e.g., 3 yr) has run (see Ref.[1] pp. 5–156 to 5–159). Appropriations may be legally considered to be abandoned even without administrative appropriation cancellation where the appropriation has not been used for the period of time for losing real estate by adverse possession (e.g., 10 yr) (see Ref.[1] pp. 5–153 to 5–156). The time period for appropriation loss by abandonment is typically longer than the period for administrative appropriation cancellation.

WATER REUSE

Consumptive Use and Return Flows

As noted earlier, under Duty of Water, the appropriation system has been criticized as fostering inefficient water use. To understand this criticism, it is first necessary to understand the concepts of consumptive water use and return flows. Assume that an irrigator diverts 300 acre ft of water to irrigate 100 acres of farmland. (An acre ft of water is enough water to cover an acre of land to a depth of 1 ft, or 325,851 gal.) The crop consumes 175 acre ft of water, and the remaining 125 acre ft return to the stream. Of the 300 acre ft diverted, 175 acre ft are consumptively used in crop production, and the remaining 125 acre ft are return flows.

Appurtenancy Doctrine

In most western states, appropriations may only be used on the land for which the water was originally appropriated (see Ref.[1] pp. 5–122 to 5–125). An irrigator cannot, by improving the irrigator's water-use efficiency, use part of the 300 acre ft diverted on a second field; the appropriator can only irrigate the original field with the 300 acre ft. Thus, the appropriator has less economic incentive to improve water-use efficiency because the saved water cannot be reused. The reason for this policy is that downstream appropriators (both senior and junior) rely on the 125 acre ft of return flows as part of their water supply. Irrigating 150 acres with the 300 acre ft of water instead of the original 100 acres would typically increase the total consumptive use from the original 175 acre ft (unless the crops irrigated were changed). The increased consumptive use reduces the return flows to downstream appropriators, which is illegal under appropriation law. Some states have modified the appurtenancy doctrine to encourage water marketing.

WATER MARKETING

In many western states, irrigators appropriated the natural flow of the state's rivers and streams. Later users who wanted to obtain a secure water supply developed water storage to capture spring runoff for summer use. But where there is no unappropriated water available and water storage options have been fully developed or are too expensive implement, the remaining option for reallocating water from old uses to new uses is water marketing. This typically involves a municipality or industry purchasing a senior irrigation appropriation and using the water for a different purpose, often at a different location. These water right transfers must be approved by the state engineer, who must maintain the return flows to downstream appropriators (see Ref.[1] pp. 5–122 to 5–132). In the hypothetical case where 300 acre ft are diverted for irrigation, 175 acre ft are consumed, and 125 acre ft are return flows, the irrigator could sell and transfer only the 175 acre ft of consumptive use, and not any of the 125 acre ft of return flows. The difficulty is that the relative amounts of consumptive use and return flow may be difficult to determine in particular cases. Appropriation purchasers and downstream appropriators are likely to disagree on the relative quantities of consumptive use and return flows. If the appropriation purchaser takes an aggressive stance regarding consumptive use and return flows, downstream appropriators may be required to hire attorneys and consultants in order to protect their return flows, an expense that many see as unfair. Despite these difficulties, water marketing is an essential tool to allow water to be reallocated from old use patterns to use patterns better reflecting current economic and social needs.

RESERVED WATER RIGHTS

When Indian reservations were created, Congress reserved to the tribes sufficient water to economically develop the reservation. The priority date for Indian reserved rights is the date the reservation was created. Indian reserved rights are not lost by non-use, so a tribe may initiate a water use in 2002 with a priority date of 1850 even if that would displace all appropriations on the stream junior to 1850 (see Ref.[1] pp. 9–69

Soils–Suspended

to 9–79). This has resulted in many conflicts between tribes and appropriators.

Federal reserved water rights are created when Congress or the President establishes a national park, national forest, etc. The priority date is the date the national park is created but the water uses protected are only those uses identified when the national park or forest is created. Typically, fish, wildlife, and recreation uses are not protected under federal reserved water rights (see Ref.[1] pp. 9–92 to 9–110).

PROTECTION OF INSTREAM FLOWS

While most appropriation states have modified their statutes to provide for instream appropriations for fish, wildlife, and recreation (see Ref.[1] pp. 5–47 to 5–48), those instream appropriations will be very junior appropriations. On many western rivers and streams, the instream appropriation will be a paper water right only and will not represent a secure water supply because the stream has been fully appropriated or even over-appropriated. In this circumstance, the better strategy to protect instream flows is through water marketing: purchasing a senior appropriation and converting it to an instream appropriation. The federal Endangered Species Act has also been used to obtain water supplies to maintain federally designated endangered or threatened wildlife species through endangered species regulations rather than through state appropriation laws (see Ref.[1] pp. 9–47 to 9–62).

Suspended-Sediment Transport Measurement

John R. Gray
Office of Surface Water, U.S. Geological Survey (USGS), Reston, Virginia, U.S.A.

Soils–Suspended

INTRODUCTION

Suspended sediment is the material carried in suspension by the turbulent components of a fluid or by Brownian motion. The U.S. Environmental Protection Agency has identified suspended sediment and constituents that sorb to sediments, including metals and pathogens, as major impairments of rivers and streams in the U.S.A.[1] Considering that the annual physical, chemical, and biological damages attributed to fluvial sediment in North America alone total about $20 billion,[2] the need for accurate fluvial-sediment data has never been greater. These data need to be reliable, comparable, cost-effective, and spatially and temporally consistent to accurately quantify the sedimentary content of surface waters.

The reliability, comparability, and applicability of fluvial-sediment transport information should not be taken for granted. A number of factors can affect the quality and usefulness of sediment information, including the instruments and methods used to collect the data; sample processing and analytical methods; sediment-discharge computations and derivation of load estimates; and methods for storing, retrieving, and disseminating the data.

This contribution provides an overview of some of the traditional instruments and techniques used to collect the requisite data for computing suspended-sediment transport. The instruments and techniques developed and produced by the Federal Interagency Sedimentation Project (FISP),[3,4] which are sanctioned by the FISP Technical Committee and the Advisory Committee on Water Data's Subcommittee on Sedimentation,[5] are used to collect the bulk of suspended-sediment data in the U.S.A.[6,7] Although surrogate technologies for measuring suspended-sediment transport show considerable promise for revolutionizing the way that these data are collected, these experimental methods are not described in detail herein.[8–10]

MEASUREMENT OF SUSPENDED-SEDIMENT TRANSPORT

Proper deployment of an appropriate sampler is the first requirement for obtaining the requisite data for computing reliable records of suspended-sediment transport. A suspended-sediment sampler is used to obtain representative samples of the water–sediment mixture in the stream in the vicinity of the sampler intake. Analytical results from these samples often are used to develop a time series of suspended-sediment concentrations. Each concentration value is multiplied by its paired water-discharge value and a units-conversion constant, and the resulting unit-value sediment discharges are summed to compute daily records of suspended-sediment discharges.[11] Additionally, concentration data are sometimes used to develop concentration–water discharge relations—transport curves—which in turn can be used to estimate suspended-sediment discharges.[12]

Sediment concentrations and particle-size distributions tend to vary little at steady flows, but can vary by orders of magnitude over a runoff hydrograph. To compute daily (continuous) records of suspended-sediment discharges, it is important to characterize variations in suspended-sediment concentrations during times of rapidly varying streamflow, and particularly those for higher flows.

Traditional suspended-sediment samplers, including those designed and produced by the FISP,[3,4] can be considered in one of two categories: manually operated samplers[4,6,7] and automatic samplers.[6] The characteristics and limitations of these types of samplers are summarized in the following sections.

Manually Operated Samplers

Manually operated samplers include instantaneous and isokinetic samplers. Instantaneous samplers fill rapidly upon being deployed. They are most appropriate for sampling flows less than about 0.5 m/s, or depths less than about 0.3 m. Examples of such non-isokinetic samplers include open bottles, Kemmerer samplers, and Van Dorne samplers.

Isokinetic samplers, such as those produced by the FISP,[3,4] include those with rigid sample bottles (bottle samplers) and flexible bags (bag samplers). They are designed to ensure that the velocity of water entering the nozzle is within 10% of the ambient stream velocity incident on the sampler nozzle throughout the sampler's operable velocity and depth ranges (Fig. 1). If the velocity of water entering the nozzle differs by

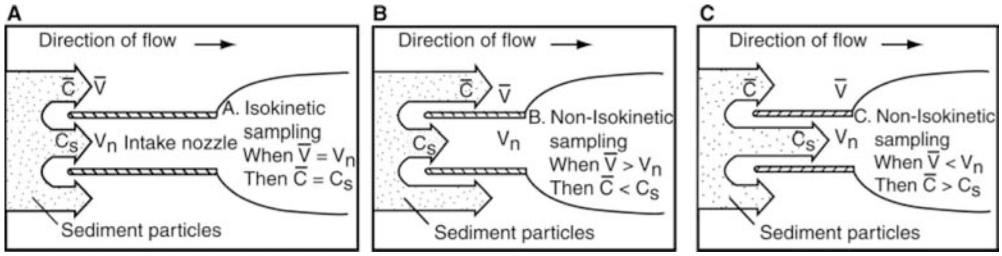

Fig. 1 Relation between intake velocity and sample concentration for: (A) isokinetic and (B, C) non-isokinetic sample collection of particles greater than 0.062 mm. $\bar{v}$ = Mean stream velocity, V_n = velocity in the sampler nozzle, $\bar{c}$ = mean sediment concentration in the stream, and C_s = sample sediment concentration.

more than 10% from the ambient velocity, an unacceptable bias in the concentration and particle-size distribution of the sampled sediment may result (Figs. 1 and 2). This phenomenon is a result of differing momentums associated with the water vs. the entrained sediment, and can be particularly problematic when sand-size material (equal to or larger than about 0.062 mm median diameter) is in suspension (Fig. 2).

A depth-integrating isokinetic sampler collects and accumulates a velocity- or discharge-weighted sample as the sampler descends and ascends through the vertical column of water, provided that the appropriate transit rate is not exceeded, and the sample container does not overfill. Fig. 3 shows three types of depth-integrating samplers developed by the FISP. A point-integrating sampler uses a solenoid valve, enabling the operator to sample isokinetically either at points in the water column or by depth integration in parts of or throughout the entire water column. Rigid-bottle isokinetic samplers can collect a velocity-weighted

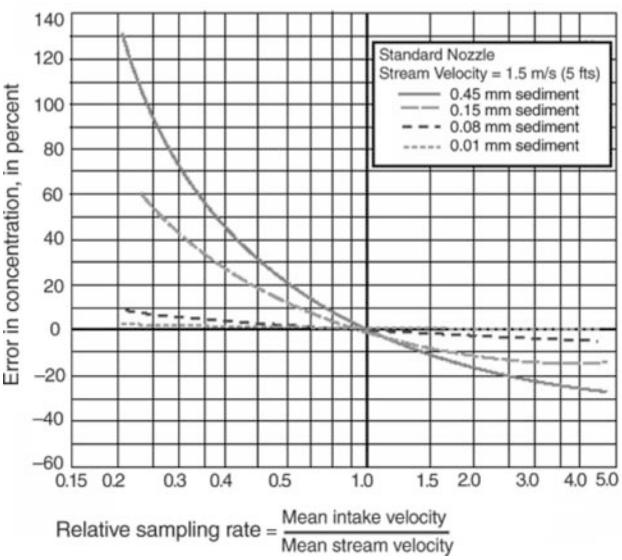

Fig. 2 Effect of sampling rate on measured sediment concentrations for four sediment-size fractions. *Source*: Adapted from Ref.[13].

sample from the surface to within about 0.1 m of the bed, and to depths as great as 4.6 m.[3,4] The U.S. D-99 bag sampler can sample the water column to within 0.24 m of the bed and to depths as great as 67 m.[4]

When deployed in a single vertical from the surface to within about 0.1 m of the streambed (or at selected points in the water column with a point sampler), these samplers provide representative samples for the parts of the stream at which they were deployed. When an isokinetic sampler is deployed using either the Equal-Discharge-Increment or Equal-Width-Increment sampling method,[6,7] the sample is discharge weighted and contains a concentration and particle-size distribution representative of the total discharge.

Although manual samplers have considerable benefits, there are some drawbacks. For example, total costs associated with the acquisition and manual deployment of isokinetic samplers, and subsequent analytical costs, can be unacceptably high.[14] Safety requirements cannot always be met when a hydrographer works in, over, or near a stream, particularly during floods. The sparse temporal distribution of the derivative data—in many cases a single observation per day—requires that daily-load computations be based on estimated concentration values and (or) indexed to another more plentiful data source.

Automatic Samplers

Some sediment-monitoring programs and studies include sites where collection of sediment samples are required at a frequency, time, and (or) under a set of conditions that cannot be accommodated through manual sampling. Safety considerations, remoteness or inaccessibility of site location, flow conditions, operational costs, and other factors may render manual collection of sediment and flow data at a site impractical, dangerous, or impossible. In lieu of manual sampling, automatic samplers may be deployed to accommodate sediment data-collection needs at some sites.

Fig. 3 (A) The U.S. DH-48 suspended-sediment sampler, glass sample bottle shown. (B) The U.S. D-74 suspended-sediment sampler, glass sample bottle in sampler body. (C) The U.S. D-96 suspended-sediment sampler, flexible sample bag in sampler body. *Source*: From Refs.[3,4,6,7].

Automatic samplers are useful for collecting suspended-sediment samples during periods of rapid discharge changes from storm runoff, and in reducing the need for manual measurements associated with intensive sediment-collection programs. Automatic samplers can be categorized as pumping and passive types (Fig. 4). Several types of pumping samplers have the capacity to collect and store multiple samples. Passive samplers, which include single-stage samplers, such as the U.S. U-59 series,[3,6] collect a single sample. Both types normally draw a sample non-isokinetically from a fixed point in the stream.

Automatic samplers enable collection of samples that otherwise could not have been obtained manually because of logistical or safety reasons. Under many circumstances, however, automatic samplers are unreliable for obtaining suspended-sediment samples representative of the mean sediment concentration of the stream cross section, especially in streams with large percentages of sand in suspension. Concentration data from discharge-weighted samples collected from a cross section with isokinetic samplers are required to develop a calibration relation with sediment-concentration values derived from automatic samplers. These calibration relations are used to adjust the concentration data obtained automatically so that these data better represent the mean sediment concentration in the cross section.[11] Additionally, use of automatic samplers may result in reduced data quality owed, in part, to an inability to quantify a stable calibration relation over the full range of flows.

FUTURE PROSPECTS FOR MEASURING SUSPENDED-SEDIMENT DISCHARGE

The limitations associated with traditional means to measure or estimate sediment discharges result in considerable room for improvement. New sediment-surrogate technologies show considerable promise toward providing the types and temporal density of fluvial-sediment data needed to improve sediment-discharge measurements. Potentially useful instruments and methods for inferring the physical characteristics of fluvial sediments are being tested around the world. Through the informal Sediment Monitoring Instrument and Analysis Research Program,[17] the U.S. Geological Survey is testing instruments

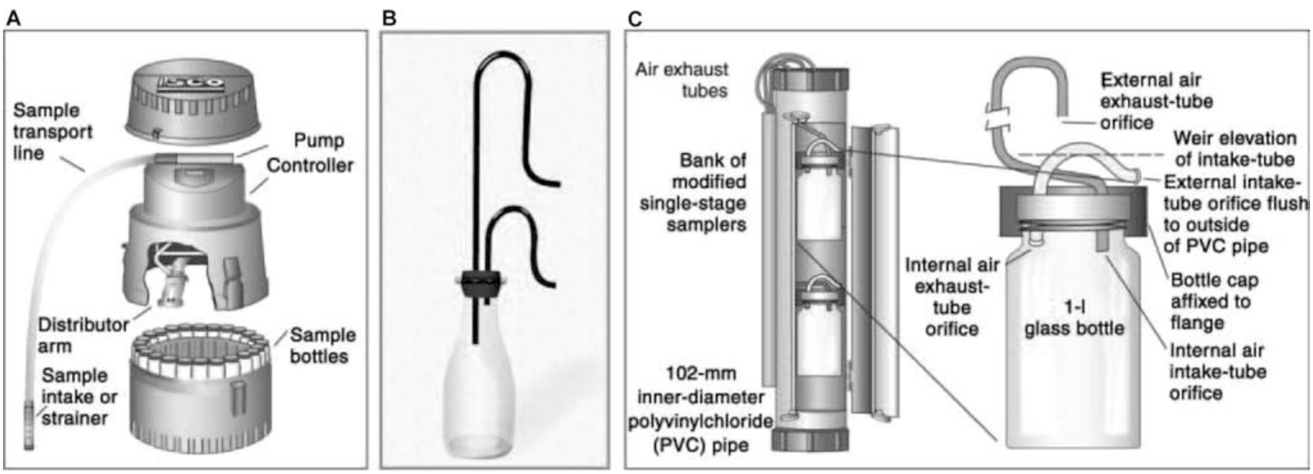

Fig. 4 (A) An automatic pumping sampler; (B) a U.S. U-59B single-stage suspended-sediment (passive) sampler; and (C) a modified single-stage (passive) sampler. *Source*: From Refs.[3,6,15,16], courtesy Teledyne Isco Inc.

operating on acoustic; bulk, digital, and laser optic; and pressure-difference technologies in riverine and laboratory settings for measuring selected characteristics of suspended sediment.[3] Bedload transport is being estimated using passive and active acoustic, magnetic, load-cell sensors, and radio-tracking technologies in addition to bedload traps.[8,10,18] Additionally, a non-contact method for continuously monitoring water discharge has been tested successfully in a limited number of field settings.[19]

To make the transition from research to operational applications, these new technologies must be rigorously tested with respect to accuracy and reliability in different physiographic settings, flow ranges, and sedimentary characteristics, and their performances must be compared to those of traditional techniques. The latter should include concurrent collection of data by traditional and new techniques for a sufficient period—probably years—to identify and minimize changes in bias and precision between the traditional and new technologies.

CONCLUSIONS

Fluvial sediments and associated constituents represent a major source of impairment of U.S. surface waters. The need for accurate data on sediment transport and deposition has never been greater.

A number of factors in the acquisition of sediment data—particularly those related to samplers and sampling techniques—can affect the reliability, comparability, and applicability of those data. The most reliable sediment data are derived from samples obtained manually with FISP isokinetic samplers deployed by the Equal-Discharge-Increment or Equal-Width Increment sampling methods.[3,4,6] Data from samples collected automatically normally require adjustment by empirically derived coefficients to render the derivative data representative of the mean cross-sectional value.[6,11] The benefits of using FISP-approved quality-assured instruments and methods substantially outweighs their associated drawbacks.

Selected surrogate technologies under consideration for monitoring sediment transport, which show considerable promise toward providing the types, temporal density, and in some cases spatial density of fluvial-sediment data needed to improve sediment-discharge measurements, must pass rigorous tests in a variety of physiographic settings, flow ranges, and sedimentary characteristics. Those technologies subsequently approved through the FISP will become available to any user in addition to the current suite of FISP samplers.[3,4,6,17]

Tailwater Recovery and Reuse

C. Dean Yonts
Biological Systems Engineering, Panhandle Research and Extension Center, University of Nebraska, Scottsbluff, Nebraska, U.S.A.

INTRODUCTION

The recovery and reuse of irrigation water are generally associated with surface irrigated fields. When surface-irrigating fields with slope, water must be applied in excess to the needs of the crop in order to irrigate the entire field. As a result, excess water or tailwater collects at the lowest point in the field. The water may percolate into the soil profile or flow as surface drainage away from the field. Either way, the water through the force of gravity can eventually return to a nearby stream or lake. This process is referred to as return flow because water is returned to a surface source to be used again. A tailwater recovery and reuse system can also be used as a way to collect surface water runoff from a field. The reuse system consists of drainage channels to divert water to another site or to a reservoir for storing the water. Many systems will also include pumps and pipelines for delivering water to a new site for distribution and trash screens to remove unwanted debris. The recovery and reuse of tailwater from a surface irrigated field can increase surface irrigation efficiency by approximately 20%.

TAILWATER RECOVERY

Recovering the water that runs off the ends of irrigated fields has long been a method by which available and sometimes limited water supplies could be used more efficiently. Before available electricity, surface water drainage from the end of a field would gravity flow away and could be used again on another field located down gradient. In many cases, the runoff water could not be diverted to another field and would return to a nearby stream as return flow. Water users downstream would then have the opportunity to divert water for irrigation or other purposes. Whether used directly from the field or as return flow, the recovery of runoff water from surface irrigated fields has and will continue as a way to use water efficiently for meeting crop needs.

When electricity became available, pumping water became feasible. Water captured at the end of a field no longer needed to be used on a field down gradient, but could be pumped to irrigate the same field or any farm field within close proximity. The primary purpose was to use available water supplies to irrigate as much land as possible. Surface water users are often a part of a larger irrigation district. These districts in most cases restrict the amount of water that can be diverted or used during the growing season. By recovering runoff water from their fields, irrigators can effectively irrigate more land. Keep in mind not all irrigators using surface water are allowed to collect the runoff water. As stated before, most runoff water will gravity drain to streams and lakes. In many cases, this return flow is vital for downstream users and reuse systems are not allowed.

For ground water users, they pay to pump water to the surface and irrigate. In this case, when the water becomes runoff it can no longer provide a benefit unless a reuse system is installed. Similar to surface water users, laws can define how runoff is to be treated. In some cases, water pumped from the ground is not allowed to enter the surface water drainage system. This means a reuse system must be installed or the water must be allowed to percolate into the soil at the end of the field. Even without this restriction, pumping water to an adjacent field can be much less costly than pumping more water to the surface to irrigate those same fields.

TYPES OF TAILWATER RECOVERY SYSTEMS

There are many different designs for tailwater recovery. Fig. 1 shows two alternatives for irrigating from a reuse system near the runoff site. In Fig. 1(A), a pump system is used to return irrigation water to the field of origin. The example in Fig. 1(B) uses a cycling system and returns water through a storage reservoir to an adjacent field. A brief description of tailwater recovery and reuse systems is given below for some of the more common types being used. For a more detailed description and design, see Refs.[1,2].

Cycling System

Cycling systems use a small sump or pit to store a quantity of water that is enough to allow the pump to operate correctly. It is generally recommended that

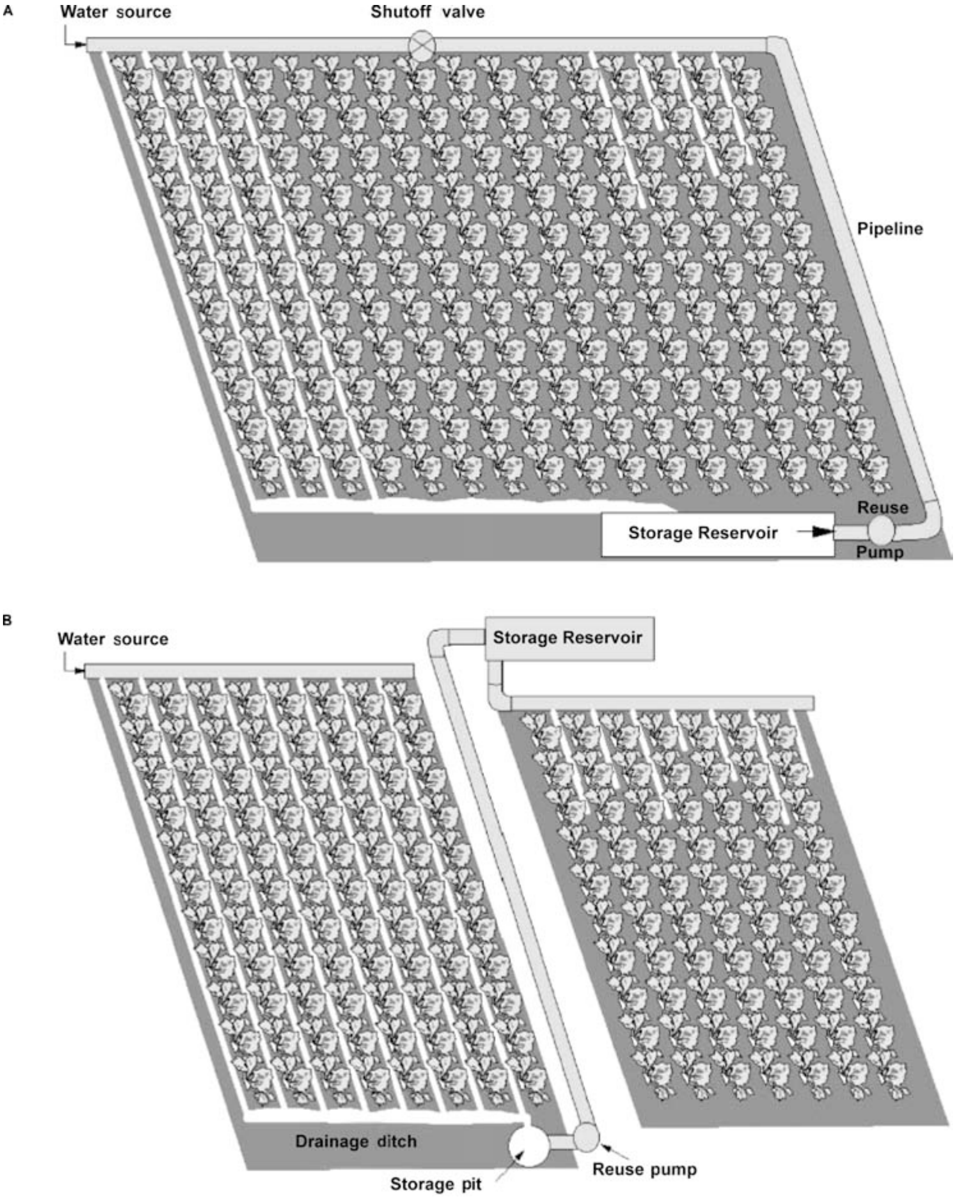

Fig. 1 (A) Runoff recovery and reuse system using a storage reservoir, pump, and pipeline to reuse irrigation water on the field of origin. (B) Runoff recovery and reuse system using a small pit, storage reservoir, pump, and pipeline to reuse irrigation water on an adjacent field.

the pump should operate no more than 15 cycles per hour to maintain pump efficiency. Pit size can be determined based on pumping rate and cycle frequency. Runoff from a surface irrigated field generally begins at a very slow rate and continues to increase until the irrigation set is complete. Because of this variation in runoff flowrate, cycling systems are used primarily for pumping water to a regulating reservoir rather than directly to a field since the constant fluctuation in pumped water flow makes regulation of an irrigation set difficult.

Pump System

In contrast to a cycling system, the pump system will often collect reuse water at the end of the field in a large storage reservoir. The reuse water stored in the reservoir is normally of sufficient volume to allow for a complete irrigation set to be made once the reuse pump is turned on without the need for additional water. When filled to the desired level, the pump will deliver water either back to the same field, independent of a current irrigation set, or to an irrigation set on an adjacent field. For systems that do not provide adequate storage capacity to complete a single irrigation set, labor will be increased along with a decrease in the water use efficiency.

Sequence System

Sequence systems are those systems that have been used for many years. These types of systems simply deliver the reuse water by gravity through open ditch or pipeline to fields down gradient without the use of a pump. These systems can increase water use efficiency but labor will also be increased due to the variability in the rate of water runoff from a field as explained for the cycling systems.

OPERATION OF TAILWATER RECOVERY SYSTEMS

Most reuse systems can be adapted to automation by controlling pump operation based on water level in the storage reservoir or simply controlled based on time. Water level controls automatically start the pump when the water level increases to a predetermined level and shuts the pump off when the water level falls to a predetermined level. Water level controls would most often be found on reuse systems with pumps that are designed to cycle on and off. Timing mechanisms for automation are normally used on large storage reservoirs. When adequate water has been recovered, the pump may be started manually. A timer is then used to shut the pump off after the desired irrigation set time is complete.

Because tailwater carries sediment with it, reuse pits should be designed to accommodate the collection and removal of sediment. This collection area should be in advance of the major storage portion of the pit. In the case of recycling pumps, storage is minimal and sediments should be removed prior to entering the reuse system. Some sediment will be carried with the recycled water, however, larger sediment particles can be removed by the use of grass filters. Keep in mind sediment will build up in the grass filter and must be mechanically removed periodically.

As water enters the pit whether it is large or small, flow velocities should be maintained below erosive levels. In pits, the inlet structure may be a part of the reuse structure (Fig. 2). In reservoirs, placement of a pipe through the bank of the pit will allow water to enter the reuse system without eroding soil banks (Fig. 3).

When using runoff water, the water should be applied to a succeeding irrigation set or to a different field (Fig. 1). Applying reuse water to the same irrigation set that is producing the runoff is ineffective and is generally not recommended. For example, when using a cycling system runoff is not available until water has started to reach the end of the field. As runoff increases, cycle frequency increases. Because additional water is applied after water advance is nearly complete, the result is pulsing inflows and increases in erosion without improving overall irrigation uniformity.

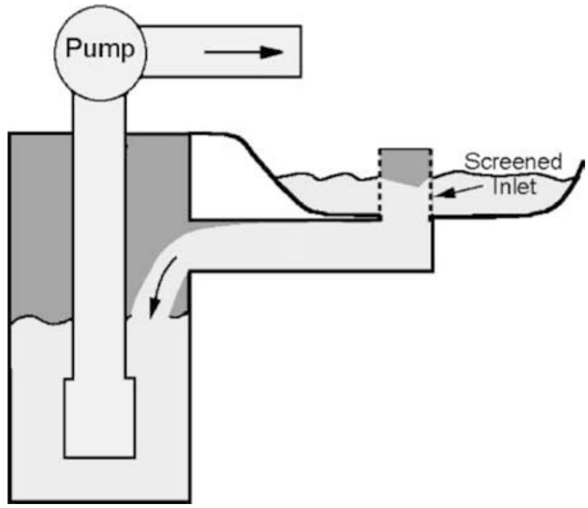

Fig. 2 Design for a cycling system inlet structure.

Pumping from a reservoir will be similar to the cycling system, but without the pulse flows. Once runoff begins and reuse water is added to the irrigation set, flowrate increases to a level greater than needed. The increased flowrate will likely further increase soil erosion. Using runoff from a reservoir system can function better if runoff is collected but not used until the beginning of the next irrigation set. This will allow greater flowrates to be used during the initial stages of water advance. Once runoff begins, the reuse system pump is shutdown and water is again stored for use at the beginning of the next irrigation set. Because the water has already advanced across the field, a reduction in inflow to the field at this time can be beneficial by improving application uniformity and increasing water use efficiency. Using a reuse system in this fashion will require more exact design in sizing the reservoir, determining reuse pump capacity, and determining irrigation set size.

Performance of surface irrigation is dependent upon many factors when it comes to designing a runoff recovery and reuse system. The rate of water infiltration into the soil can increase or decrease the rate

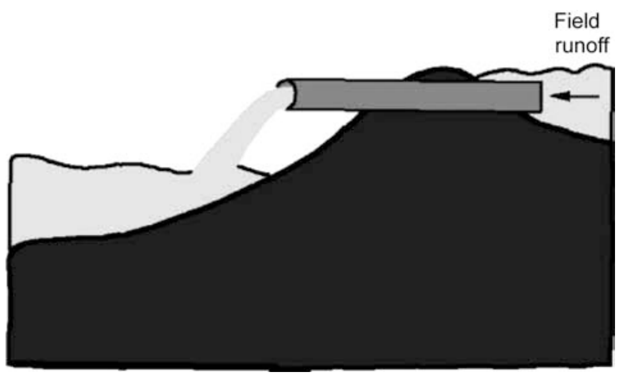

Fig. 3 Design for a pump system reservoir inlet structure.

Tailwater–Virtual

of water advance to the end of the field and greatly influence irrigation set time. This in turn influences total runoff volume. The soil infiltration rate will change not only from field to field and year to year but from one irrigation set to the next making design of a reuse system challenging. Other factors that influence runoff rate and volume are changes made to set size, system inflow rate, and weather conditions. In many cases, it may take two or three irrigation sets to determine the preferred set size and inflow rate. Once established, the management of the runoff water can be fully determined.

WATER QUALITY

Tailwater recovery systems can provide a mechanism through which water quality can be maintained. Surface irrigation field runoff often carries sediment that can have traces of chemicals and fertilizers used for producing crops attached to the soil particles. By capturing the water for a brief period of time much of the sediment in the water will settle out. During the off season, the sediment should be removed and placed back on a production field.

Fertilizer and chemicals can also be held in suspension and carried in the water. By installing a tailwater recovery and reuse system, chemicals can be reapplied to fields during irrigation, keeping unwanted material from entering the surface water drainage system.

SAFETY OF TAILWATER RECOVERY SYSTEMS

Anytime water is collected and stored in a reservoir, safety should be of concern. In some cases, reuse pits or reservoirs are constructed with the goal of taking as little land as possible out of crop production. This may mean deep pits or reservoirs that have steep side slopes. This type of situation offers the potential for a hazard if children can be expected within the vicinity. Keeping side slopes that allow for mowing will also allow for easier escape if someone would find their way into a reservoir. If this is not possible, then fencing may be needed to insure small intruders do not have access to the area.

CONCLUSION

Tailwater recovery and reuse offers an alternative that can increase on-farm water use efficiency. At the same time, water quality can be maintained by keeping sediment and agricultural chemicals near the point of application. Finally, irrigating with reuse water can save both time and labor when properly designed. The end result will be irrigation that is environmentally friendly while still producing food and fiber for the world.

Tailwater–Virtual

Tamarisk

Tom L. Dudley
Marine Science Institute, Santa Barbara, California, U.S.A.

INTRODUCTION

Invasive, non-indigenous plants are increasingly serious resource concerns in wetlands and riparian ecosystems because of their potential to displace native plant species, degrade habitat quality for wildlife, and alter physical properties of ecosystems, including the potential to retain water resources. One of the most serious plant invaders in western North America is tamarisk or saltcedar (*Tamarix* spp.), a fast-growing shrub or small tree that now dominates many arid-zone riparian systems throughout the region.[1] Fig. 1 illustrates the abundances that can be attained, in this case at the Virgin River in southern Nevada. While tamarisk has colonized numerous wildland ecosystems, the most severe infestations occur along regulated rivers and reservoirs where it benefits from altered hydrologies and other anthropogenic influences, and may place severe demands on limited water supplies.[2] A variety of control technologies exist or are being developed to control tamarisk, and substantial financial resources are directed to managing this invasive weed. However, controversies continue over the nature of its economic and environmental impacts and whether control or eradication will provide the benefits anticipated.[3–5]

BACKGROUND

Tamarisk is the common name for shrubs and trees of the genus *Tamarix*, which along with the *Myricaria* and *Reaumuria* comprise the Tamaricaceae, a family associated with arid and semi-arid, frequently saline, environments of the Old World (Europe, Africa, and Asia). At least 54 species of *Tamarix* are known, and it is often a dominant element of the vegetation in low-lying basins and river corridors where heat, salt, and irregular water availability limit the number of other riparian plants that can tolerate these conditions.[6] These trees can use saline groundwater and excrete excess salt from glands on the leaves and green stems. Leaves consist of cedar-like bracts, and these two traits suggest the other common name for genus, saltcedar. Many members of the genus are deciduous and frost-tolerant, losing their foliage during the winter months, while some species, particularly *T. aphylla*, commonly known as athel, are evergreen and are associated with warmer frost-free regions. Plants produce long racemes of insect- and wind-pollinated pink to white flowers producing copious quantities of small (ca. 0.5 mm length), short-lived windblown seed.

Numerous species of *Tamarix* have been imported into North America and other temperate or subtropical regions and planted since the early 1800s for horticulture, windbreaks, and erosion control, especially in the southwestern U.S.A. Tamarisk was reported as naturalized in riparian areas by 1877, and has come to dominate riparian vegetation along many major rivers.[7,8] The deciduous tamarisks now occupy an estimated 1–1.6 million acres from northern Mexico to central Montana and from central Kansas to coastal California.[8,9] The potential distribution of this group is illustrated in Fig. 2, based on biogeographic studies conducted by Morrisette et al.[34] Currently, tamarisk is the third most abundant woody plant in western riparian areas,[10] and its potential distribution is illustrated. Several taxa are involved in this complex, including *T. ramosissima, T. chinensis*, *T. parviflora, T. canariensis, and T. gallica*, while the most common invasive form in the arid West is a hybrid between *T. ramosissima* and *T. chinensis*.[11] The evergreen *T. aphylla*, a species used extensively in the region as a shade tree, was previously thought to be non-reproductive in North America despite its invasiveness in Australia. More recently, it has been found as invading sites in the lower Colorado River drainage, and also now hybridizes with the deciduous forms.[12]

WHY IS TAMARISK A SUCCESSFUL INVADER?

The success of this invader is related to its capacity to take advantage of unpredictable periods of favorability to colonize sites, and its ability to tolerate harsh conditions once established. Colonization typically follows unusually high run-off events that scour substrates and remove existing vegetation. Because seed production can occur over a period of several months (basically mid-spring to late-summer), there are often ample propagules that germinate on the fine particle substrates (silt and sand) left as flooding recedes and the sustained moist conditions facilitate survival by the

Fig. 1 Virgin River, Clark County, Nevada. This tributary to the lower Colorado River is heavily dominated by *Tamarix ramosissima*, although substantial native vegetation remains in some river reaches. *Source*: From Ref.[20].

relatively slow-growing seedlings. Young plants are poor competitors against native species,[13] but the scoured surfaces offer competitor-free space for establishment. Seedlings are more susceptible to repeat flooding than are native cottonwoods and willows, so establishment is most successful where flood events are rare, which is why infestations are less common in non-regulated riverways that experience natural

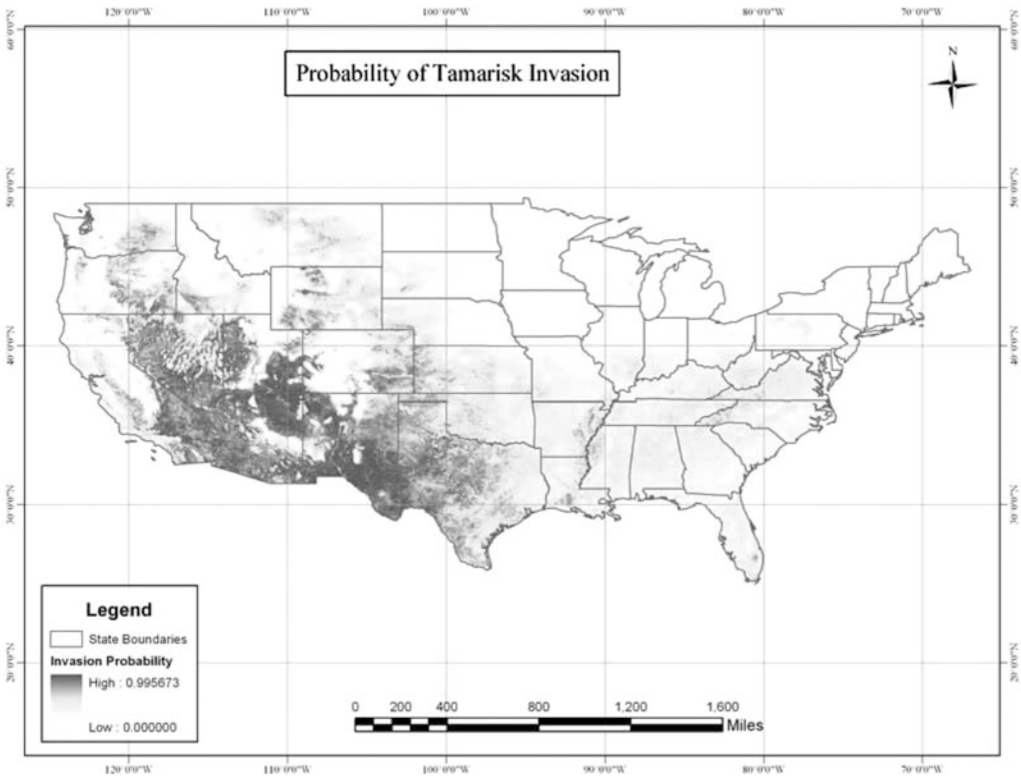

Fig. 2 Illustration showing the likelihood of occurrence of tamarisk based on ecogeographic characteristics of its current distribution. Darker green indicates where tamarisk is most likely to occur, and is, in fact roughly its current distribution. *Source*: From Ref.[34].

flood disturbances every 2 or 3 yr.[14] Once established, plants are resistant to infrequent disturbances such as flood and fire, and if above-ground material is removed, the plants readily re-grow from below-ground basal crowns.[15]

Tamarix invasion is often facilitated by river management that has altered natural hydrologic and geomorphic processes.[1,16] Its greatest expansion occurred in the early- to mid-20th century following the widespread construction of dams and other water projects in the western U.S.A. Water diversions reduce availability of moisture to native obligate phreatophytes that require nearly constant contact with free water, unlike tamarisk, which continues metabolic activity below saturation levels (facultative phreatophyte) and tolerates long periods of drought.[17] Diversions and lack of flushing flows also result in salinization of riparian soils to levels that inhibit native plants.[18] Land uses such as livestock grazing and groundwater pumping further facilitate replacement of native plants by tamarisk in altered habitats; however, *Tamarix* has invaded many relatively pristine sites as well, particularly in smaller watersheds where natural flooding is infrequent.[19] Although tamarisk frequently exists as small patches within a diverse vegetation mosaic, the above dynamics often lead to the establishment of extensive, dense, monospecific stands that inhibit the re-colonization of native riparian species.[20]

IMPACTS OF TAMARISK INVASION

The impacts of tamarisk invasion are both economic and environmental. In some situations it may be considered beneficial, for example, to control erosion, provide wooded habitat on sites too salty or dry for native forest, and provide nectar for bees, but generally its impacts are detrimental.[2]

Water Resource Depletion

The most frequently cited concern is the lowering of ground and surface water levels resulting from high evapotranspiration (ET) rates, which is presumed to desiccate streams channels, has caused springs to dry up, and places demands on scarce water resources in arid regions. ET estimates for tamarisk in the Southwest U.S.A. range from 0.7 to 3.4 m^3/m^2 of ground area/year (typically abbreviated to m/yr), depending on the technique used, site and climatic conditions, and the duration of measurements.[2] The higher estimates are primarily from lysimeter studies, in which water use rates are measured in tanks with continuous water supply. More realistic estimates using a variety of methods, especially micrometeorological approaches (Bowen Ratio Energy Balance and eddy covariance) are in the range of 0.7–1.7 m/yr. This still translates to very high rates of water escape from floodplain environments (e.g. 7000–17,000 m^3 entering the atmosphere each year from a hectare of infested landscape, or approximately 4.6–6.7 million gallons per acre).

''Salvage'' of such water is the goal of many tamarisk control programs, but depends on replacement vegetation using less water. On a leaf area basis, tamarisk transpires roughly equivalent amounts of water as other riparian species such as willows and cottonwoods, but under good growth conditions, the leaf or photosynthetic area of tamarisk can substantially exceed native plants, and thus, more water is transpired per unit land area.[17,21] Greatest ET can take place where tall canopy trees co-occur with a dense tamarisk understory.[22] Furthermore, because tamarisk is a facultative phreatophyte that can use adsorbed water, ET continues during dry periods when other species have ceased water uptake. Anticipated water savings from replacement of tamarisk by cottonwood-willow vegetation vary from nil to 0.6 m/yr, but in many locations, the replacement native species, e.g. mesquite (*Prosopis* spp.), saltbush (*Atriplex* spp.), or forage grasses (*Distichlis spicata*, *Spirobolus* spp.), are better adapted to xeric conditions and offer less water consumptive alternatives.[2]

Physical Impacts to Riparian Systems

Tamarisk also alters the physical features of channels, with potential increased risk of flood damage and channel erosion.[23] Dense vegetation causes water flows to slow, not only forcing flood flows upward and occasionally outside of the streambanks, but also promoting deposition of entrained sediments that would otherwise be flushed from the system. In turn, the active channel can be narrowed by weed encroachment with corresponding downcutting erosion, further lowering water tables as channel elevations are lowered. Streambanks may also be at greater risk of erosion because tamarisk is deeply rooted, but its shallow roots are relatively simple with little bank-stabilizing influence when compared with native woody plants. The bare substrates commonly found underneath tamarisk also increase bank erosiveness.

Another physical alteration is the increased frequency of wildfires in tamarisk-infested systems. Riparian areas are traditionally considered to be barriers to wildfire spread, but tamarisk foliage turns them into pathways for fire movement because it is quite flammable both while green on the plant and when the deciduous foliage remains in the canopy or falls to the substrate.[15] Native woody plants are frequently killed by these fires, leaving tamarisk to re-sprout and dominate post-fire landscapes.[24,25]

Ecological Impacts of Invasion

Biodiversity impacts of tamarisk are also numerous, a serious concern in desert riparian areas, which provide habitat to many of the threatened and endangered species of the region. Even though young plants are poor competitors, once established tamarisk inhibits establishment and growth native plant species.[1,20] The salts excreted from the foliage and contained in the litter when it falls tend to salinate underlying soils and discourage germination of some native species. Its tolerance of drought and aggressive growth behavior give tamarisk a competitive advantage, and removal has been shown to allow renewed growth by native willows.[26] The combination of anthropogenically degraded environmental conditions and competition often leads to vegetative domination by this single taxon. Wildlife habitat is diminished because structural diversity and food resources are poorer in tamarisk stands when compared with native vegetation.[2,27]

Migratory and nesting birds depend on plant-associated arthropods (insects, spiders, etc.), but these food resources are relatively scarce on tamarisk, as is typical for non-indigenous plants that arrive in new landscapes without the associated organisms found in their native regions. Generalist pollinators (butterflies, wasps, flies) are common when plants are flowering and are used by birds,[27] but cannot develop on tamarisk so depend on nearby host plants for larval foods; hosts that are lost with increasing domination by tamarisk. Interestingly, the introduction of biological control insects specific to tamarisk has resulted in increasing avian occupation of this habitat through provisioning of food resources.[5] Herpetofauna and other wildlife that are less mobile than birds are generally found in lower numbers and diversity in tamarisk stands.[2,28] Presumably, many reptiles require habitat features that are not available in tamarisk, but some small mammals such as deermice (*Peromyscus* spp.) may respond positively to the dense woody cover provided by tamarisk.[29]

Besides general reduction in wildlife habitat quality and associated biodiversity, threatened and endangered species also have appeared to decline when tamarisk invades riparian areas.[5,19] These include sensitive species such as yellow billed cuckoo (*Coccyzus amaericanus*), southwestern willow flycatcher (*Empidonax traillii extimus*), least Bell's vireo (*Vireo bellii pusillus*), western pond turtle (*Clemmys marmorata*), desert slender salamander (*Batrachoseps major aridus*), and numerous rare plants such as Pecos sunflower (*Helianthus paradoxus*). Conflicts have arisen, however, because the southwestern willow flycatcher now nests to some extent in tamarisk, so control efforts now must take this unanticipated wildlife relationship into account.[30]

Finally, recreational use of riparian areas and water bodies is impeded by tamarisk infestation, and these habitats tend to be avoided by sportsmen and wildlife observers alike, possibly reducing recreation-based income in western communities. The economic costs of tamarisk invasion have been estimated at $127–291 million per year, primarily resulting from water resource and erosion.[9] Efforts to control tamarisk have been taken for several decades, and currently millions of dollars are spent each year to control saltcedar to increase water yield and enhance ecosystem health.

CONTROL MEASURES

Saltcedar has been controlled using mechanical, chemical, and biological methods.[2] Simple removal of above-ground biomass is ineffective, as is burning, because of the rapid re-sprouting which occurs, but by bulldozing surface material, removing the root crowns from the soil, and burning the slash, reasonable efficacy can be achieved.[31] Chemical control technologies are similarly improving, from small-scale manual application of herbicides (typically imazapyr or triclopyr compounds) to aerial applications to large infestations with little native plant component, and fire is often subsequently used to remove remaining debris.

Because of the high costs (ranging from approximately $300 to $6000 per hectare) of, and collateral damage (unintended heribiciding of native plants, physical damage to streambanks) resulting from traditional control methods, and because control is not sustainable, recent approaches use natural enemies imported from the regions where tamarisk naturally occurs to suppress weed infestations (classical biological control).[32] Several specialist insects have been tested and show potential for control, and the saltcedar leaf beetle (*Diorhabda elongata*) has been released into most western states where it is causing very substantial defoliation of tamarisk.[5] "Biocontrol" offers the potential for low-cost and sustainable reduction in weed abundance, and with proper safeguards to ensure that the risk of unintended negative consequences to native species or valuable resources is low, this will certainly be the preferred approach to tamarisk management in the future.

Restoration of infested riparian ecosystems remains an important goal of most control programs, and this requires not only improvements in the methods for promoting recovery of native woody plants but also active management of critical natural processes, which are often key to successful restoration efforts. In particular, increasing attention is given to managing river-flows in regulated watersheds to inhibit establishment of pest plants and to promote native species, and such ecosystem management approaches should improve the success rate for riparian restoration.[2,33]

CONCLUSIONS

Arid and semi-arid riparian areas of the western U.S.A. are increasingly infested by non-native tamarisk, despite many programs intended to reduce its abundance and impacts. Its impacts are environmental (e.g. displacing native plants, degrading wildlife habitat) as well as economic (e.g. promoting wildfire and channel erosion, reducing recreational value, reducing water resources). Human land uses have had an important, but not exclusive, role in promoting these infestations. Resolving this natural resource problem is complex, requiring active intervention to control infestations as well as restoration of hydrological conditions that encourage native riparian plants and discourage tamarisk establishment. The recent introduction of natural enemies to reduce populations (biological control) offers excellent potential to improve the cost-effectiveness of tamarisk control, and to reduce its impacts region-wide while enhancing riparian biodiversity.

Timber Harvesting: Influence on Water Yield and Water Quality

C. Rhett Jackson
Warnell School of Forest Resources, University of Georgia, Athens, Georgia, U.S.A.

INTRODUCTION

While the chemical, physical, and biological qualities of waters draining commercial forest lands are generally quite good, harvesting and planting of trees can temporarily alter streamflows, water chemistry, and biotic communities. The magnitude and duration of water quality effects vary with environmental setting but can be controlled to a large degree by implementing best management practices (BMPs) to protect water quality. Minimization of bare and compacted soil areas and dispersal of road runoff are critical for protecting water quality in commercial forests.

FOREST HYDROLOGY

In general, continuing commercial production forestry is practiced in humid climates where annual precipitation exceeds potential evapotranspiration (ET) but where soils or market conditions do not support more valuable agricultural commodities. Example areas include temperate forests of Europe and North America, tropical forests of Brazil and Southeast Asia, and boreal forests of Canada and Russia. While commercial forests cross many geologic, topographic, and climatic conditions, biogeographic zones where forestry is practiced feature sufficient commonality to generalize about hydrology and water quality of streams draining forest lands.

Harvesting and planting of trees can alter hydrologic behavior of watersheds with resulting impacts to streamflow, water quality, and aquatic life. Fig. 1 illustrates dominant hydrologic processes in forest environments and compares these processes between mature forests and clearcuts. Dense canopies of intact forests capture some rainfall before it hits the ground. Water evaporated from the canopy before it drips to the ground is called canopy interception and can account for 10–30% of annual precipitation. Interception depends on the leaf area index (ratio of total leaf surface area to underlying land surface area), which varies between 6 and 15 in forests of different types and between summer and winter in deciduous forests. After clearcutting, leaf area index and canopy interception are greatly reduced. Therefore, more rainfall reaches the ground. As trees regenerate, full canopy interception returns over time.

Deep and well-developed root systems of mature forests efficiently extract soil moisture for tree growth. Evapotranspiration from soil storage returns a large portion of annual rainfall to the atmosphere before it reaches the water table or a stream. Shallow and limited root systems of young plantations extract far less water from soil storage. Therefore, percolation of soil water to the water table and shallow subsurface flow to streams both increase after clearcutting. Yield, or proportion of rainfall that becomes streamflow, is therefore greater in clearcuts and young plantations. Much of the increased yield reaches streams as dry season baseflow, improving habitat conditions for aquatic life during low-flow seasons.

Soils beneath mature forests usually feature well-developed litter layers, low bulk densities, high porosities, and dense macropore networks due to roots and soil fauna activity, so infiltration rates are very high. Most rainfall reaching the forest floor infiltrates, and overland flow occurs only during very intense rainfall events. Surface runoff occurs only as variable source area runoff from low lying areas such as floodplains, wetlands, and ephemeral streams where the water table rises to the soil surface during rainfall. These areas comprise only 5–15% of most forest landscapes. In clearcuts and areas prepared for tree planting, bare soils may be exposed by harvest and site preparation equipment. Without the physical protection of litter layers, bare soils often form crusts during rainfall, and such crusts greatly reduce infiltration rates. Surface runoff is common from bare soils, and surface runoff mobilizes soil particles and transports them to streams. Storm runoff volumes, sediment loads, and sometimes peak flow rates are increased if clearcutting or site preparation creates significant bare soil areas. In addition, variable source areas are enlarged in clearcuts and young plantations due to higher water tables.

Roads are usually required to access and remove timber, and roads impact hydrology and water quality. Logging roads are surfaced with compacted native soil and sometimes covered with gravel. Surface runoff is

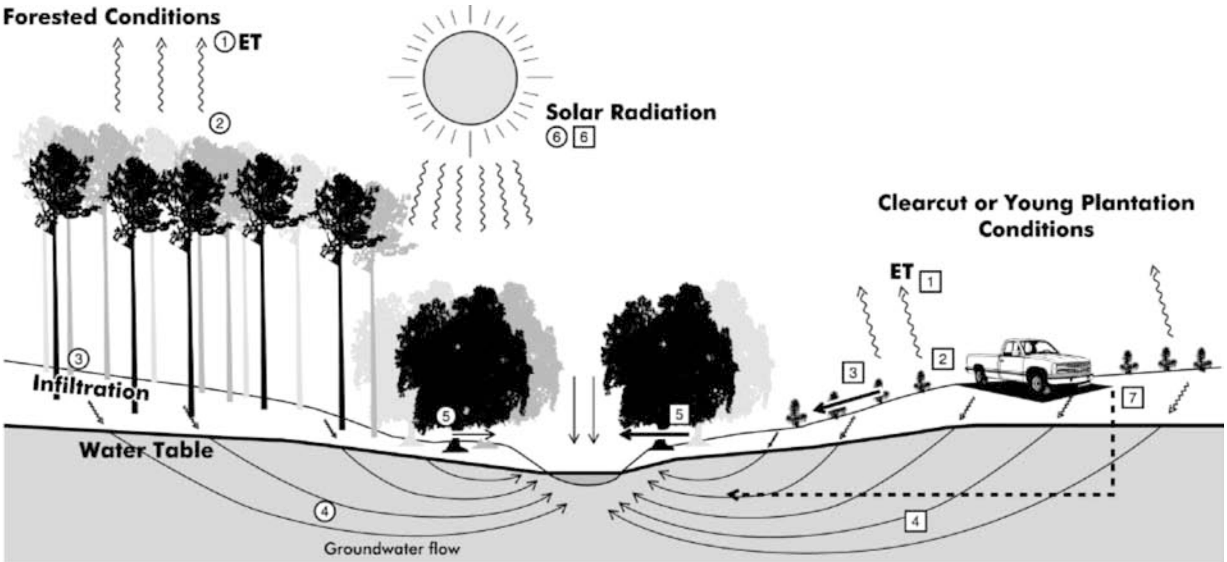

Fig. 1 Process schematic of silvicultural impacts on watershed hydrology; Forested conditions: (1) Evapotranspiration rates are greater in forests, so a large portion of rainfall is returned to the atmosphere from soil storage. (2) In forests, canopy interception returns some of the rainfall back to the atmosphere before it ever reaches the ground surface. (3) Infiltration rates are very high. Therefore, surface runoff is rare. (4) Subsurface flow paths are the dominant contributor to streamflow. (5) Surface runoff is common only in low areas near the channel where water tables are near the surface (variable source area runoff). (6) An intact forest canopy provides maximum shade to streams and maintains a cooler humid microclimate in the valleys. Clearcut or Young Plantation Conditions: (1) Evapotranspiration rates are significantly lower in first 4–10 yr after harvest and planting. (2) Canopy interception is much lower in clearcuts and young plantations, so more rainfall reaches the ground. (3) When soils are left bare, overland flow is common until vegetation is re-established. Overland flow on bare soils transports sediment and other contaminants to the stream system. (4) Due to the reduced ET and interception, water tables are higher and baseflows are increased. (5) Due to the higher water tables, variable source areas may be enlarged, thus increasing surface runoff. (6) If SMZs do not sustain sufficient shade, stream temperatures may increase due to greater solar insolation. (7) Without water bars and filter strips, road runoff increases streamflows and sediment production.

common from roads due to low infiltration rates. Road runoff typically carries high amounts of fine sediment and is often collected in roadside ditches and transported to streams. In small basins, road runoff can substantially increase peak flows and volumes. If roads are cut into hillside subsoils, road cuts can serve to collect shallow groundwater flow from the hillside above. Logging roads are responsible for many, if not most, water quality problems associated with forestry.

While general hydrologic processes apply to all forested landscapes, hydrologic behavior varies greatly with geology, soils, topography, solar aspect, and climate. These landscape factors control absolute and relative magnitude of forest hydrologic processes and also affect watershed response to forestry activities.

VARIATION IN SILVICULTURAL PRACTICES AND THEIR HYDROLOGIC EFFECTS

In any given watershed, hydrologic effects of forestry activities depend greatly on how timber is harvested and planted. If harvest and site preparation maintain organic litter layers, avoid soil compaction, disperse road runoff, and maintain vegetated buffers along streams and wetlands, hydrologic and water quality effects of forestry can be minimal and often below levels of detectability. If harvest and site preparation activities create large areas of bare soils, gouge ruts up and down the slopes, concentrate road runoff and deliver it to streams, and extend operations to stream banks, hydrologic and water quality effects can be large and deleterious to aquatic life. Understanding and mitigating hydrologic effects of forestry requires some understanding of possible silvicultural activities.

In steep terrain, trees are cut manually with chain saws and yarded to roads via high lead (one end of the log is picked up) or full suspension (log is completely lifted off ground surface) cable systems. High lead yarding can leave bare soils but full suspension yarding leaves most of the litter soil surface intact. In flat and moderate terrain, it is now more efficient to use tractor-based equipment, such as feller-bunchers and skidders, to cut and yard trees. If tractors operate along the same tracks, and especially if they operate in wet conditions, they can create continuous tracks of compacted bare soils that may transport flow and sediments to streams.

Site preparation and tree planting methods vary considerably more than harvest methods. Intensive forest management, potentially involving plowing or ripping of soils, bedding of soils, ditching of hydric soils, burning of organic debris, and applying herbicide and fertilizer, is becoming more common, although hand planting of trees without silvicultural enhancements is still widely practiced. Hydrologic and water quality impacts of site preparation depend on how much bare soil is created, the duration of bare soils, and on timing, location, and amount of chemical application.

Effects of road runoff can be greatly reduced by routing water off roads at regular intervals onto hillslope locations where flow can be reinfiltrated. Water bars, broad-based dips, and cross-drains are typical methods by which road runoff is shed from roads onto hillslopes. Depending on slopes and native soils, surfacing roads with gravel or rock can also reduce surface erosion.

Streamside management zones (SMZs), also called riparian buffers, are strips of uncut trees and undisturbed soils left along water courses, and they greatly reduce ecological and water quality effects of forestry operations. SMZs perform multiple functions including: 1) maintaining bank stability; 2) providing shade; 3) filtering runoff from upslope; 4) denitrifying shallow groundwater; 5) maintaining woody and organic debris recruitment to channels; 6) providing wildlife habitat; and 7) maintaining valley microclimates. While SMZs are commonly applied to modern forestry operations, appropriate widths are still matters of research and debate.

HYDROLOGIC EFFECTS—ANNUAL YIELD, STORM FLOW PEAKS, AND STORM VOLUMES

The effects of timber harvest and site preparation on storm flows vary with amount of bare soil exposed, amount and locations of road surfaces, connectivity of road runoff to streams, time since harvest, season, size of watershed, and size of storm. The storm flow effect is the greatest for early fall storms due to reduced summer ET in clearcuts and young plantations. In forests, early fall storms produce little to no runoff because very dry soils store most precipitation. In comparison, soils on clearcut sites are wetter and thus become more responsive earlier in the fall. Therefore, for early fall flows, clearcuts can produce flow peaks and volumes that are three times greater than mature forest flows.[1] However, fall flow events are usually small when compared with winter events. By the time the larger winter runoff events occur, there is little difference between soil moisture levels in clearcuts and forests, and studies have revealed little difference in flow peaks for large and infrequent flow events. For storms in the range of the two year flow, timber harvest effects on peak flow rates are generally less than 20% and often statistically undetectable.[2,3]

As basin area increases, the percentage of recently clearcut area diminishes. In large basins, the effects of timber harvest and roads on flow peaks are usually imperceptible. However, increases in storm flow volumes due to timber harvest are observed in larger basins, usually manifested as a lengthening of recession limbs of storm hydrographs. Peak flow rate changes are difficult to discern in basins larger than 1000 ha.

Reduced ET in clearcuts and young plantations increases annual water yield and dry season baseflows from forested basins.[4] Magnitudes of mean annual flow and baseflow increases depend on the climate and the type of forest vegetation. Only in areas where fog-drip contributes significantly to the hydrologic cycle does forest clearing result in a reduction in yield and baseflows.

The hydrologic effects of forest removal are temporary and diminish as forest cover is re-established. Most of the hydrologic effects disappear after about 7 yr of regrowth, although some studies have found some hydrologic effects lasting as long as 20 yr.

WATER QUALITY

The chemical, physical, and biological qualities of waters draining commercial forest lands are generally quite good.[5] The major water quality concerns for forest management activities are 1) increased sediment loads due to surface erosion, road runoff, and landslides; 2) increased nutrient loads due to fertilizer washoff; 3) stream temperature increases from inadequate channel shading; 4) decreased woody debris recruitment from inadequate SMZs; and 5) pesticide runoff from intensively managed plantations. Again, the water quality effects of forestry activities are quite variable, depending on site conditions, intensity of activities, and application of BMPs. Without BMPs and maintenance of SMZs, timber harvest and site preparation can have large deleterious effects on water quality and aquatic biota. Recent studies of forestry activities that implement BMPs have found good water quality and biotic conditions downstream. Logger education and encouragement of BMPs are critical for maintaining good water quality in commercial forests.

Time Domain Reflectometry: Salinity and Solute Measurement

Jon M. Wraith
Department of Land Resources and Environmental Sciences, Montana State University, Bozeman, Montana, U.S.A.

INTRODUCTION

Time domain reflectometry (TDR) has a unique and potentially very useful ability to concurrently measure both water content (θ)[1] and electrical conductivity (σ)[2] in soils and other porous media. Both θ and σ are important physical/chemical attributes that have substantial impact on the behavior and transport of mass and energy, are critical to plant growth, and may be used to infer salinity or concentration of certain solutes in porous media. The TDR can also accurately measure σ and, thus, indirectly solute concentration in water, but it is a relatively expensive tool in relation to other available methods for this application.

Solutes are substances that can dissolve in water. Some solutes, those that dissociate into ions, confer water the property of electrical conductance. The relative ability of water or variably water-saturated porous media to conduct electricity is related to the concentration of ionic solutes and, in the case of porous media, to the wetness and the geometry of solid, liquid, and air phases. Air does not conduct electricity, and the solids found in common porous media (e.g., soil) conduct electricity very poorly. (The electrical conductivity of soil solids is related to the ions held at exchangeable surface charges rather than to the solids themselves.) Hence, the measured electrical conductivity may be directly related to the concentration of solutes in the liquid water phase, which depends in turn on its ionic composition. The SI units for electrical conductivity are Siemens per meter (S/m). Because common measurement ranges found in soils and waters may result in inconveniently high or low values, fractional units such as dS/m and mS/cm are commonly used. (Note 1 dS/m = 1 mmho/cm, with mmho/cm being the formerly common non-SI unit for σ.)

MEASUREMENT PRINCIPLES

Electrical Conductivity Measurements Using TDR

Measurement of electrical conductivity by using TDR is based on attenuation of the voltage signal as it travels along a transmission line probe embedded in the medium of interest. Media with higher electrical conductivity lead to increased attenuation (loss) of the electrical signal, and this may be inferred from analyzing the TDR trace. The Giese and Tiemann[3] method is commonly used with TDR to measure the apparent electrical conductivity (σ_a, S/m):

$$\sigma_a = \frac{\varepsilon_0 c}{L}\frac{Z_0}{Z_u}\left(\frac{2V_0}{V_f} - 1\right) \qquad (1)$$

with ε_0, the permittivity of free space (8.854×10^{-12} F/m), c, the speed of light in vacuum (2.997×10^{8} m/sec), L, the probe length (m), Z_0, the probe impedance (Ω), Z_u, the characteristic impedance of the cable tester (usually 50 Ω), and V_0 and V_f, the relative voltages of different parts of the TDR waveform (Fig. 1). This analysis is easily performed on the digital waveforms obtained from a TDR instrument, and is used in many available software programs. The probe impedance must be calibrated; this may conveniently be done by immersing in deionized water[4,5] and using

$$Z_0 = Z_u \varepsilon_w^{0.5}\left(\frac{V_1}{2V_0 - V_1}\right) \qquad (2)$$

where ε_w is the known dielectric constant of water, and the location of V_1 is illustrated in Fig. 1. Alternatively, a TDR probe cell constant $K = \varepsilon_0 c Z_0/L$ may be used,[4,5] with substitution into Eq. (1). The temperature-dependent ε_w may be determined using tables or equations found in references including Refs.[6–8]. Because σ increases with increasing temperature, a correction factor[8,9] is used to compensate measurements obtained at a given ambient temperature to a base temperature such as 25°C.

Some of the signal from the TDR instrument is lost as it moves through transmission cables and connectors leading to the probe. To obtain accurate measurements, these signal losses must be considered in cases where σ exceeds about 3 dS/m or where combined cable lengths exceed about 3 m.[9,10] A combined

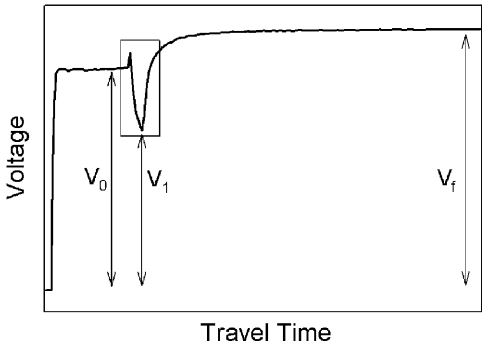

Fig. 1 TDR waveform illustrating voltage heights V_0, V_f, and V_1 used in calculating electrical conductivity. Region within box represents approximate portion of waveform used in travel-time water content analysis. *Source*: Modified from Ref.[8].

solution, σ_w, is commonly the attribute of interest in practical applications. The σ_w arises from the total ionic solute concentration, but may be related to the concentration of specific solutes under some conditions. Under constant θ and temperature, a linear relationship may be assumed between σ_a and σ_w. Several approaches have been utilized to estimate σ_w or solute concentrations using this direct calibration approach (e.g., Refs.[10,13,14]). However, under typical conditions where θ varies in time and space, models describing the relationship among the σ_a, σ_w, σ_s, soil water content θ, and the tortuous soil geometry in terms of electrical flow paths, are required. Because of the inherent complexity of the physical properties and processes governing electrical flow in variably

cable plus connector series resistance, Z_{cable}, may be determined and included in Eq. (1) as

$$\sigma_a = \frac{\varepsilon_0 c Z_0}{L(Z_L - Z_{cable})}\left(\frac{2V_0}{V_f} - 1\right) \tag{3}$$

where $Z_L = Z_u/(2V_0/V_f - 1)$, and Z_{cable} may be measured using a series of solutions having known σ[9,10] or by analyzing signals resulting from electrically shorting the cables and probes[11]. Excellent agreement between σ measured by using TDR and electrodes has been repeatedly documented (Fig. 2; e.g., Refs.[9–12]).

Electrical Conductivity Calibration Models and Methods for Soils and Porous Media

Soils are complex mixtures comprising solid, liquid, and gas components. The TDR measures the apparent electrical conductivity of the bulk soil, σ_a, integrated over all these components. However, the σ of the soil

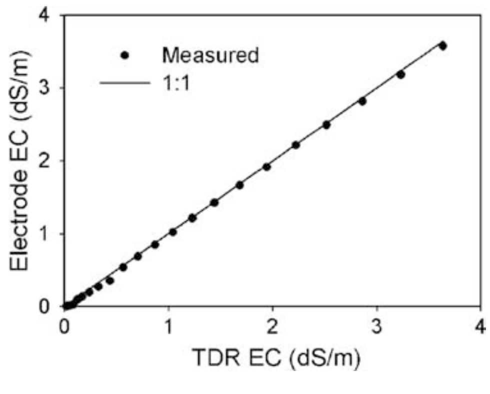

Fig. 2 Comparison of electrical conductivity measured in KCl solution using TDR and electrode. *Source*: J. M. Wraith, unpublished data.

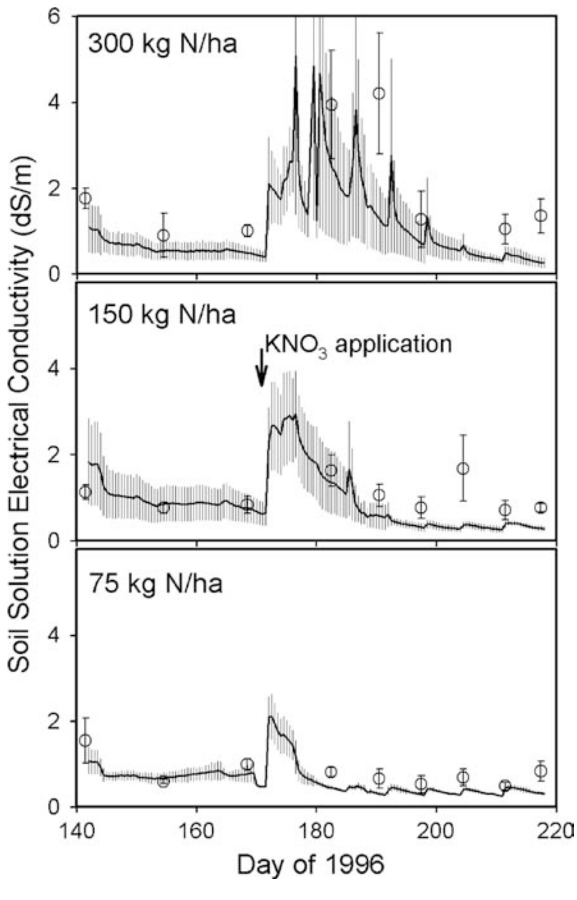

Fig. 3 Mean soil solution electrical conductivity measurements using replicate soil cores and TDR probes, under different KNO_3 application rates. Three TDR probes were permanently installed at 15 cm depth in each plot, and five soil cores were collected from 10 cm to 20 cm depth increment at random locations in each plot on each sampling date. Periodic irrigation events during the abrupt increase in σ_w following KNO_3 application (most evident in top panel) reflect water addition by irrigation events. Error bars are ±standard f means, and reflect spatial variation among field measurement locations. *Source*: Modified from Ref.[20].

saturated soils, simple conceptual models are typically applied. In many models, the bulk soil electrical conductivity is linearly related to σ_w as

$$\sigma_a = \theta F_g \sigma_w + \sigma_s \tag{4}$$

with F_g a geometry factor describing the dependence of the electrical flow pathways on the tortuous soil matrix. The bulk soil electrical conductivity σ_a is thus seen to be a result of the combined influences of σ_w, wetness, and soil geometry, along with contributions of the exchangeable ions at the solid clay and organic matter surfaces σ_s. The σ_s may be neglected due to its small magnitude relative to the other components under some conditions (i.e., coarse soils, or $\sigma_w >$ about 0.5–1 dS/m).[16] The F_g changes substantially with changing wetness for a given soil, since water and air have very dissimilar conducting properties. Hence, the F_g is often characterized as a function of θ.[15–17]

Conceptual models that have been most commonly applied to the measurement of solutes and salinity in soils by using TDR include those of Rhoades et al.[15,16] and Mualem and Friedman.[17] The two- and three-conducting pathway models[15,16] use calibrated empirical constants to describe the dependence of F_g on soil properties and wetness, while Mualem and Friedman[17] relate the F_g to the soil hydraulic conductivity relationship. F_g may also be estimated using analogy to simple gas diffusion models.[18] Calibration of all the models mentioned here is required to obtain suitable results for most applications. Development and testing of calibration methods and models is an ongoing area of inquiry, and is discussed in many of the papers cited as well as in Ref.[19].

CONCLUSION

The use of TDR to measure solutes and salinity is particularly appropriate in applications where high temporal or spatial resolution or unattended measurements are desired, and under conditions of changing water status. Because TDR can provide detailed time series measurements with no ongoing labor requirement and is non-destructive, it may be preferred over alternative methods. Many past applications have focused on evaluating transport of soluble chemicals through soils or other materials, monitoring water and salt distributions in the root zone of plants (e.g., Fig. 3), evaluating solute transport models, and related issues. These and a number of other practical problems may be amenable to study or to an improved management through the use of TDR and appropriate calibration models and methods.

Total Maximum Daily Load (TMDL)

Robin K. Craig
College of Law, Florida State University, Tallahassee, Florida, U.S.A.

INTRODUCTION

This article explains what a "total maximum daily load" (TMDL) is and how TMDLs help to implement the Federal Water Pollution Control Act, more commonly known as the Clean Water Act. In 1972, Congress significantly amended this Act in order to better "restore and maintain the chemical, physical, and biological integrity of the Nation's waters."[1] To achieve this goal, Congress relied upon three main mechanisms: two federal permit programs that regulate the discharges of pollutants from point sources; state non-point source control programs that manage more diffuse sources of water pollution, such as agricultural runoff; and state-set water quality standards, which define the more particularized water quality goals for individual water bodies, based on the existing and/or desired uses of the particular water body.

The TMDL is the calculation that the Clean Water Act prescribes in order to coordinate these three mechanisms for restoring and maintaining desired levels of water quality. A TMDL is, literally, the "TMDL"—that is, the maximum amount of a given pollutant that can be added to a particular water body on a daily (or, occasionally, weekly, monthly, or yearly) basis and still have that water body meet its state-set water quality standards. Individual states and the federal Environmental Protection Agency (EPA) use TMDLs when the national technology-based effluent limitations and the standard state non-point source control requirements are not stringent enough to allow a water body to achieve its water quality standards. Proper employment of a TMDL can require adjustments to the discharge permits, adjustments to the non-point source control requirements, or both.

BASIC STRUCTURE OF THE CLEAN WATER ACT

The TMDLs cannot be understood outside of the general regulatory structure of the Clean Water Act. The Act prohibits any "discharge of a pollutant" except as in compliance with the Act.[2] "Discharge of a pollutant" is a defined term and refers to the "addition" of any "pollutant" to "navigable waters" from any "point source."[3] The Act further defines each of these terms broadly, so that the Act essentially prohibits any addition of almost any substance to almost any surface water from a human-controlled source.[3] More specifically, a "point source" is "any discernible, confined and discrete conveyance," like a pipe.[3]

In order to comply with the Clean Water Act, point sources that discharge pollutants must get a permit. The most generally applicable permit program under the Clean Water Act is the National Pollutant Discharge Elimination System (NPDES) permit program.[4] The EPA has the primary authority to implement this permit program, although it has delegated much of its permitting authority to the individual states.[4] When a point source gets an NPDES permit, the requirements governing its discharge initially will be based on national effluent limitations.[2] Effluent limitations are "end of the pipe," numerical limitations on the concentrations of pollutants that a discharger can discharge.[2] The EPA generally sets effluent limitations on an industry-wide basis. Moreover, the effluent limitations are technology based. For example, the EPA currently sets most effluent limitations on the basis of the "best available technology economically achievable" for each category of industry.[2] Where the EPA has not issued national technology-based effluent limitations, states write equivalent limits into individual permits.

Nevertheless, the federal permit programs apply only to point sources of water pollution. A "non-point source" of water pollution is any source that is not a point source—that is not a discernible, confined, or discrete conveyance. Common non-point sources are uncontrolled and contaminated runoff or snowmelt or deposition onto water of air pollution. The Clean Water Act leaves the states in charge of managing non-point source water pollution.[5]

In addition, the states also received the primary authority to set water quality standards.[6] Water quality standards establish the ultimate goals of water pollution regulation for individual water bodies. Specifically, water quality standards "consist of the designated uses of the navigable waters involved and the water quality criteria for such waters based upon such uses."[6] Congress directed states to consider waters' uses for public water supply, fish and wildlife support, recreation, agriculture, industry, and navigation, but states are free to consider other uses, as well.[6]

THE ROLE OF TMDLs IN ACHIEVING THE ACT'S GOALS

As noted, Congress intended the regulatory mechanisms in the Clean Water Act "to restore and maintain the chemical, physical, and biological integrity of the Nation's waters."[1] The state-set water quality standards define such integrity for particular water bodies and hence are the measure of whether the Act's goals have been achieved for a particular water body.

Nevertheless, the exact conditions of and sources of pollution into particular water bodies varies from state to state and even location to location within a state. Moreover, states may set particularly stringent water quality standards for certain kinds of water bodies, such as pristine mountain lakes or Outstanding Natural Resource Waters. In other words, water quality standards are an inherently *local* requirement. However, the EPA does have authority to ensure that state water quality standards meet the Act's minimum requirements and to issue standards for states that fail to do so.

In contrast, the two primary mechanisms for achieving desired levels of water quality—the permits and the non-point source control requirements—are, respectively, inherently national and state wide in focus. As a result, the standard effluent limitations in NPDES permits and the standard non-point source control requirements in state non-point source management programs may not be sufficient to ensure that some individual water bodies meet their water quality standards.

The Clean Water Act's TMDL process provides a means for adjusting both permit requirements and the non-point source management requirements for the particular sources that contribute pollution to a water body that cannot achieve its water quality standards when only the standard effluent limitations and non-point source controls are applied. At the start of this process, each state identifies water bodies or segments within its boundaries for which the effluent limitations "are not stringent enough to implement any water quality standard applicable to such waters."[6] Each state then establishes a priority ranking of these "water quality impaired" water bodies.[6] Finally, taking the impaired waters in order of priority, the state establishes a TMDL for each of the pollutants that is causing a water quality problem for a

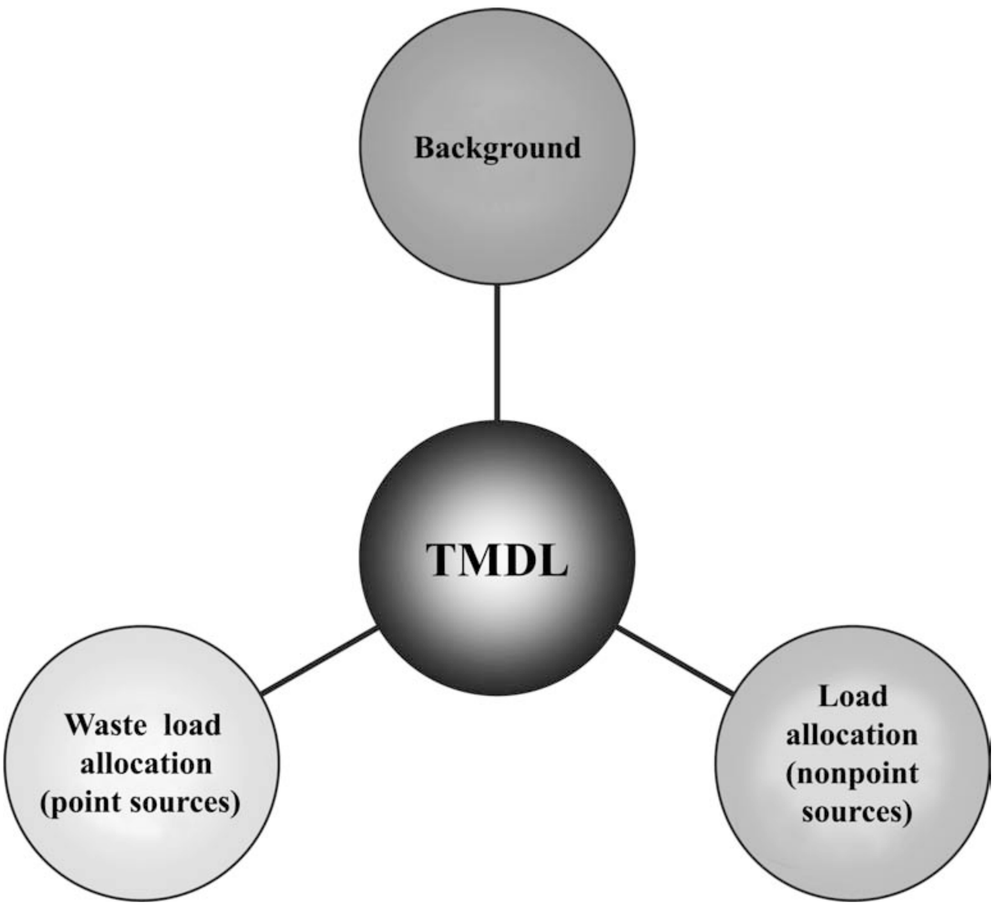

Fig. 1 Allocation of the TMDL.

Table 1 Sources of sediment in the Blue river and Green river in state A

Source	Blue River	Green River
Background/natural	5 kg per day from cliff erosion	10 kilograms per day from upstream erosion
Point sources	500 kg per day from 4 confined animal feeding operations, each of which has an NPDES permit	NONE
Non-point sources	10 kg per day from runoff over a small farm	600 kg per day from 3 large timber operations along the river

particular impaired water, ‘‘at a level necessary to implement the applicable water quality standards,’’ taking into account ‘‘seasonal variations’’ (such as wet and dry seasons) and including a ‘‘margin of safety’’ to account for uncertainties.[6] The EPA then reviews the list of impaired waters and the TMDLs established; moreover, the EPA can establish TMDLs if the state fails to do so.[6]

Once established and approved, TMDLs become part of the state’s continuing planning process for water quality.[6] The total daily load of a pollutant established in a TMDL must then be allocated among the sources that contribute that pollutant to the impaired water. The EPA recognizes that the TMDL’s total pollutant load must be allocated among three sources (Fig. 1): background or ‘‘natural’’ sources of the pollutant; non-point sources of the pollutant (the ‘‘load allocation’’); and point sources of the pollutant (the ‘‘waste load allocation’’).

For example, suppose that State A has designated both the Blue River and the Green River as cold-water rivers to support native trout populations. To support this designated use, State A establishes water quality criteria for sediment. However, it discovers that both rivers are violating their water quality standards for sediment, causing harm to the trout populations. Through the TMDL process, State A calculates that 100 kg of sediment can be added to each river each day without violating the water quality standard for trout. It then identifies the sources contributing sediment to each river (Table 1).

Given these sources, State A should take a different approach to implementing the sediment TMDL on the Blue River than it does to implementing the sediment TMDL on the Green River. To ensure that the Blue River will meet its water quality standards, State A will need to adjust the *waste load allocation*, which it can accomplish by changing the sediment effluent limitations in each of the point sources’ NPDES permits. In contrast, to ensure that the Green River will meet its water quality standards, State A will have to address the *load allocation* by imposing additional non-point source control requirements on the timber companies. Such requirements will probably take the form of best management practices, such as requiring buffer zones and/or selective logging instead of clear cutting. States have authority under the Clean Water Act to take either, or both, of these actions.[6]

In contrast, the state has only limited authority to relax requirements once a TMDL is established for a water quality-limited water body. As long as the water body still violates the applicable water quality standard, the state cannot change effluent limitations that are based on the TMDL unless ‘‘i) the cumulative effect of all such revised effluent limitations based on such TMDL will assure the attainment of such water quality standard, or ii) the designated use that is not being attained is removed.’’[6]

CONCLUSION

Congress designed the TMDL process to ensure that every ‘‘water of the United States’’ would eventually achieve chemical, physical, and biological integrity, as defined by the states in water quality standards. The focus of TMDL implementation was initially concentrated on adjusting the effluent limitations in point sources’ permits. However, as it becomes clear that non-point source pollution is the most significant remaining source of water quality impairment, TMDLs are increasingly providing the mechanism to encourage states to adequately control those sources of water pollution, as well.

Transpiration

Thomas R. Sinclair
Crop Genetics and Environmental Research Unit, U.S. Department of Agriculture (USDA), University of Florida, Gainesville, Florida, U.S.A.

INTRODUCTION

Nearly all water evaporated from vegetated surfaces to the atmosphere originates from leaves. Water is vaporized from cell walls inside leaves and diffuses from the leaf interior to the bulk atmosphere around plants. This process is called transpiration, and this section discusses the regulation of and methods to estimate transpiration rates. While transpiration involves basically the vaporization of water and the diffusion of the vapor into the bulk atmosphere, transpiration is complex because the water vapor must move from the leaf interior, through pores in the leaf epidermis called stomata, and finally into the atmosphere. Stomata are under active control so that transpiration rates are dynamic and rapidly respond to the environment. An understanding of the influence of stomata regulation on both carbon dioxide and water vapor flux density leads to various approaches to calculate plant canopy transpiration rates.

BACKGROUND

Carbon dioxide (CO_2) assimilation in photosynthesis was greatly facilitated, and thereby allowing rapid plant growth, when plants invaded the earth's land masses. No longer was it necessary for CO_2 to diffuse at very slow rates through the water surrounding aquatic plant life, but rather CO_2 could be absorbed directly from the atmosphere into individual cells. While photosynthesis rates and plant growth were enhanced substantially by allowing direct exposure of photosynthetic cells to the atmosphere, a potentially fatal consequence was that water could be evaporated at very high rates from exposed cell surfaces.

The problem of rapid evaporation from cell surfaces can be solved by having either an especially effective plant structure to rapidly transport large quantities of water in order to replenish each cell with water, or mechanisms to substantially inhibit water loss (and also CO_2 assimilation rates) from cell surfaces. While evolution ''experimented'' with each of these approaches, an innovative third, anatomical solution dominates. The photosynthetic cells are packaged inside thin broad tissues, i.e., leaves, that can throttle water vapor diffusion between the cells inside leaves and the atmosphere outside the leaves (Fig. 1).

The exterior of leaf epidermal cells is coated with a cuticle containing waxy materials that effectively block water loss directly from epidermal cells to the atmosphere. Consequently, virtually all water lost by leaves must move through stomatal pores that are scattered in the leaf epidermis (Fig. 2). Stomata regulate gas diffusion through the epidermis by adjustments in the dimension of the stomatal pore. The apertures of stomatal pores adjust to maintain a fairly stable CO_2 concentration inside leaves. When leaf photosynthetic rates are high, stomata adjust to increase the size of the pore aperture for rapid diffusion of CO_2 into leaves. On the other hand, when photosynthetic rates are low, aperture size decreases. Since water vapor diffuses through the same stomatal aperture, adjustments to accommodate photosynthesis cause changes in transpiration rate.

STOMATA

Stomata are embedded in the leaf epidermis and are formed by a pair of cells called guard cells. The guard cells in monocots plants, as shown in Fig. 2, tend to resemble barbells with bulbous structures at each end. The guard cells of dicot plants shown in Fig. 3, have a kidney shape. In both cases, the pair of guard cells is attached to each other at both ends. Swelling of the bulbous end of guard cells in monocots causes the cylindrical midsections to move apart increasing the aperture of the pore. The entire kidney-shaped cells of dicots swell and, as a result of a specialized cell wall structure bordering the pore, the aperture of the pore increases. Conversely, a decrease in the size of guard cells in both cases results in a decrease in pore aperture.

The shrinking and swelling of guard cells are under active control by plants as a result of changes in the concentrations of specific compounds in guard cells and neighboring cells. An increase in solute concentration in guard cells causes water to flow into the cells so that guard cells swell. There appears to be two mechanisms in guard cells that result in changes in

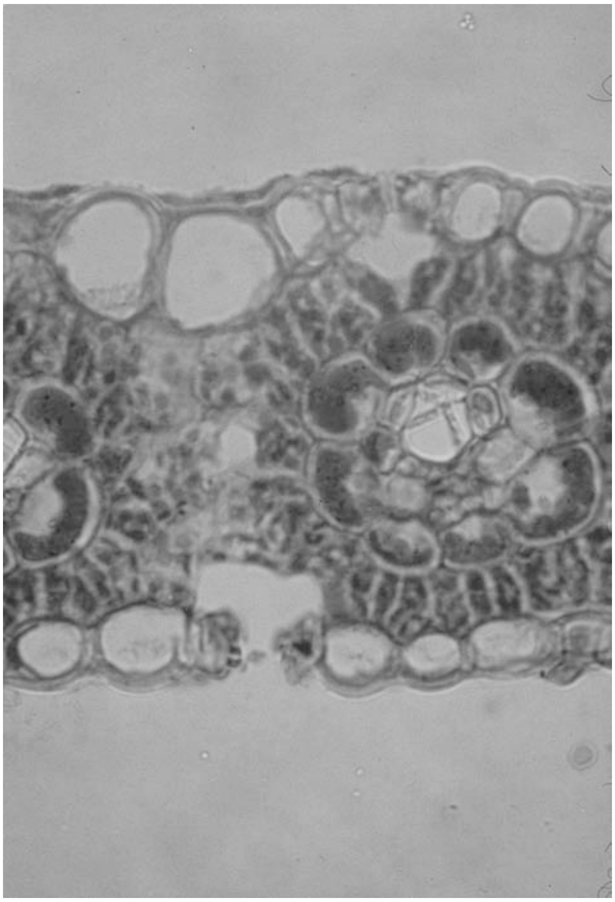

Fig. 1 Cross-section of monocot leaf showing stomata in epidermis of both sides of the leaf.

solute concentration.[1] One mechanism is based on potassium-malate transport and appears to be particularly involved with stomata opening in response to light at sunrise. The second mechanism involves sucrose accumulation in guard cells and is associated with maintenance of stomata aperture during the day. Both mechanisms are potentially sensitive to changes in the CO_2 environment of the leaf interior.[1] The sucrose mechanism seems especially sensitive to leaf photosynthetic rates so that stomata aperture can be fine tuned throughout the day as the photosynthetic rate of the leaf responds to changing environmental conditions. Of course, changes in aperture to match CO_2 diffusion to leaf photosynthetic capacity also results in changes in transpiration rate.

LEAF TRANSPIRATION RATE

Leaf transpiration involves the diffusion of water vapor through stomatal pores, so transpiration rate is dependent on conductance of vapor through and above the pores, and on the gradient of water vapor across the pores. Not surprisingly, conductance of an individual stomatal pore (g_p, $cm^3 sec^{-1}$) is directly dependent on the dimensions of the pore aperture and can be expressed quantitatively[2] as

$$g_p \approx \pi abD/d \qquad (1)$$

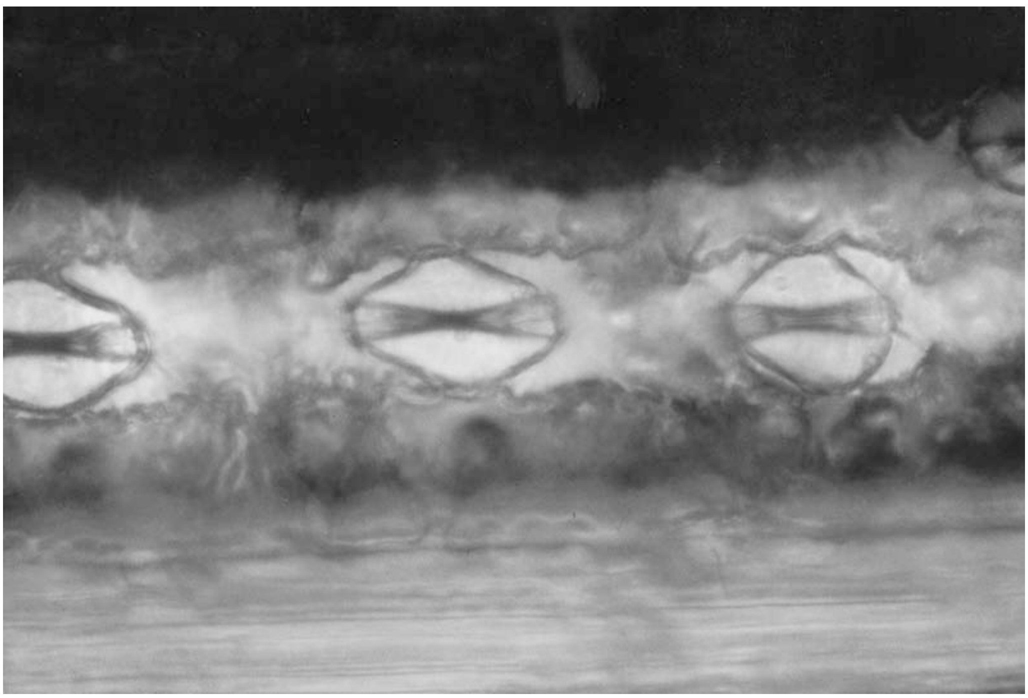

Fig. 2 Photograph showing stomata in the leaf surface of sorghum.

Tailwater–Virtual

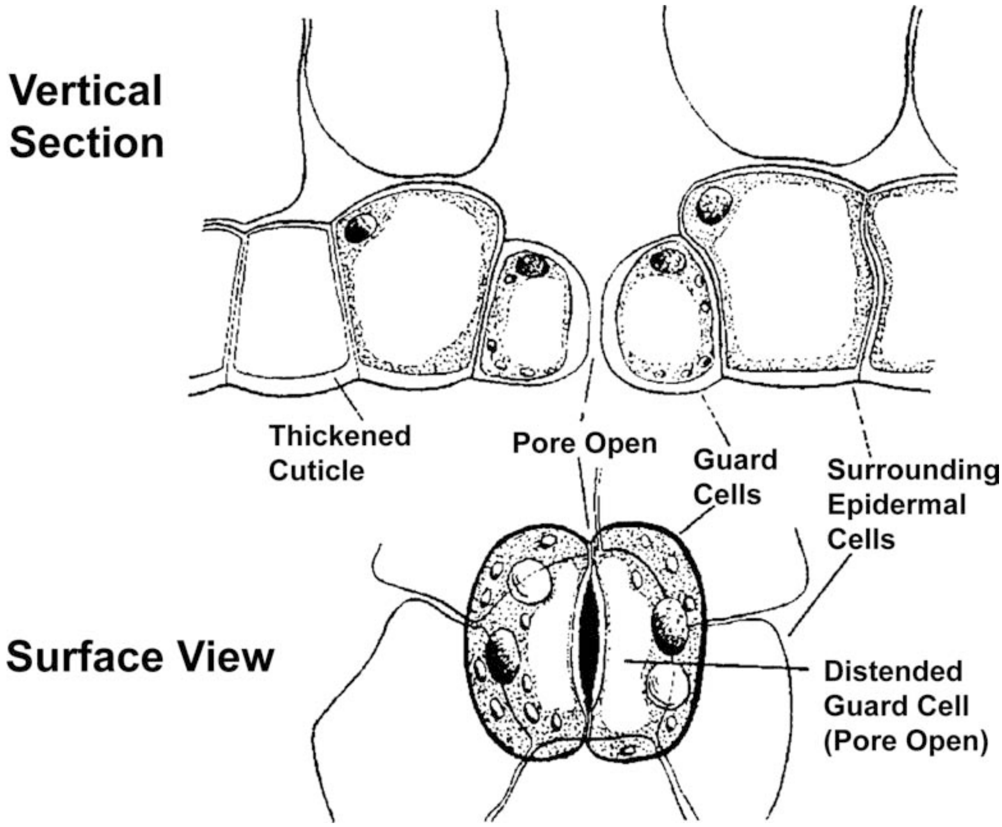

Fig. 3 Drawing of cross-section and surface view of a dicot stomata. *Source*: From Ref.[10].

where a is the semilength of the major axis (cm), b, the semilength of the minor axis (cm), d, the depth of the pore (cm), and D, the molecular diffusion coefficient of water vapor ($0.24\,cm^2\,sec^{-1}$ at 20°C).

The semilength and depth of the pore usually remain fairly stable, so the main variable influencing g_p is the semilength of the minor axis of the pore.

The overall stomata conductance of the leaf (g_s, $cm\,sec^{-1}$) is calculated by incorporating into Eq. (1) stomatal density (n, $stomata\,cm^{-2}$) and the influence of "end effects" exterior to the leaf.[2] Consequently,

$$g_s \approx n\pi abD/(d + b/2\ln(4a/b)) \qquad (2)$$

An estimate of maximum g_s can be calculated for fully open stomata ($b \approx 3 \times 10^{-4}$ cm) by assuming that $a = 8 \times 10^{-4}$ cm, $d = 10 \times 10^{-4}$ cm, and $n = 10 \times 10^3$ stomata cm^{-2}. Eq. (2) gives $1.3\,cm\,sec^{-1}$ for a leaf with stomata on only one side, and $2.5\,cm\,sec^{-1}$ for a leaf with stomata on two sides. Of course, when the stomatal pore is closed ($b = 0$), Eq. (2) gives a conductance of zero.

In addition to the restriction on water vapor diffusion resulting from stomatal conductance, there is also a limitation on water loss resulting from the aerodynamic boundary layer around leaves (g_{bl}, $cm\,sec^{-1}$). The value of g_{bl} is dependent on wind speed and leaf dimensions. In the case of a $100\,cm\,sec^{-1}$ wind speed and 8 cm wide leaf, the value of g_{bl} is approximately $2.5\,cm\,sec^{-1}$.[3] Consequently, in this case, the value of g_{bl} is equal to that of g_s.

As g_s and g_{bl} are in series, the inverse of the two conductances are added together to calculate leaf transpiration rate, Tr_L ($g\,cm^{-2}\,sec^{-1}$). The combined conductance is multiplied by the vapor pressure difference between the interior of the leaf, which is calculated as the saturated vapor pressure at leaf temperature (P_L^*), and atmospheric vapor pressure (P_a).[3]

$$Tr_L = \varepsilon(g_s g_{bl}/(g_s + g_{bl}))(P_L^* - P_a)/H_v \qquad (3)$$

where ε is the molecular weight of water ($18\,g\,mol^{-1}$) and H_v the heat of vaporization ($44\,kJ\,mol^{-1}$ at 25°C).

CANOPY TRANSPIRATION RATE

In principle, the transpiration of a leaf canopy (Tr_C) can be calculated by summing Tr_L for all the individual leaves in the canopy. This is a formidable task,

Tailwater–Virtual

however, because values of g_s, g_{bl}, and leaf temperature are required for each individual leaf. Consequently, "summary" expressions have been developed in an effort to express the transpiration rates of the entire canopy.

One of the more popular approaches relies on predictions of the energy balance of the leaf canopy. The Penman–Monteith equation[4] gives an explicit solution for canopy transpiration rate based on the energy balance of the entire canopy. The difficulty with this approach is that it requires an estimate of the canopy boundary layer conductance and the "canopy conductance" for the entire canopy, which must be appropriately weighted to represent vapor transfer through all the stomata distributed in the canopy. There is really no independent method for measuring canopy conductance, and estimates are obtained only by back-solving the energy balance equation. In practice, the Penman–Monteith is often applied as an empirical equation where boundary layer and canopy conductances are estimated from empirical functions.

A recent innovation has been developed to calculate Tr_C based on the water use efficiency of leaf canopies. Water use efficiency has been a topic of research since at least 1699[5] giving it a longer history of study than virtually any other plant trait. Roughly 100 yr ago, there was a particularly intensive period of study in both Europe and the United States on plant water use efficiency, culminating in the classic investigations by Briggs and Shantz.[6,7] In an analysis of much of the data from this period, deWit[8] found a highly stable relationship within each species between accumulated plant mass and cumulative transpiration over a wide range of conditions when normalized by "atmospheric demand" (Fig. 4).

Tanner and Sinclair[9] extended the analysis of deWit[8] by deriving a mechanistic expression for transpirational water use efficiency of canopies. Their derivation defined a specific transpirational water use efficiency coefficient (k, Pa) for each crop species dependent on the photosynthetic pathway and the biochemical composition of the plant products. Their estimates of k for maize, wheat, and soybean were 12 Pa,

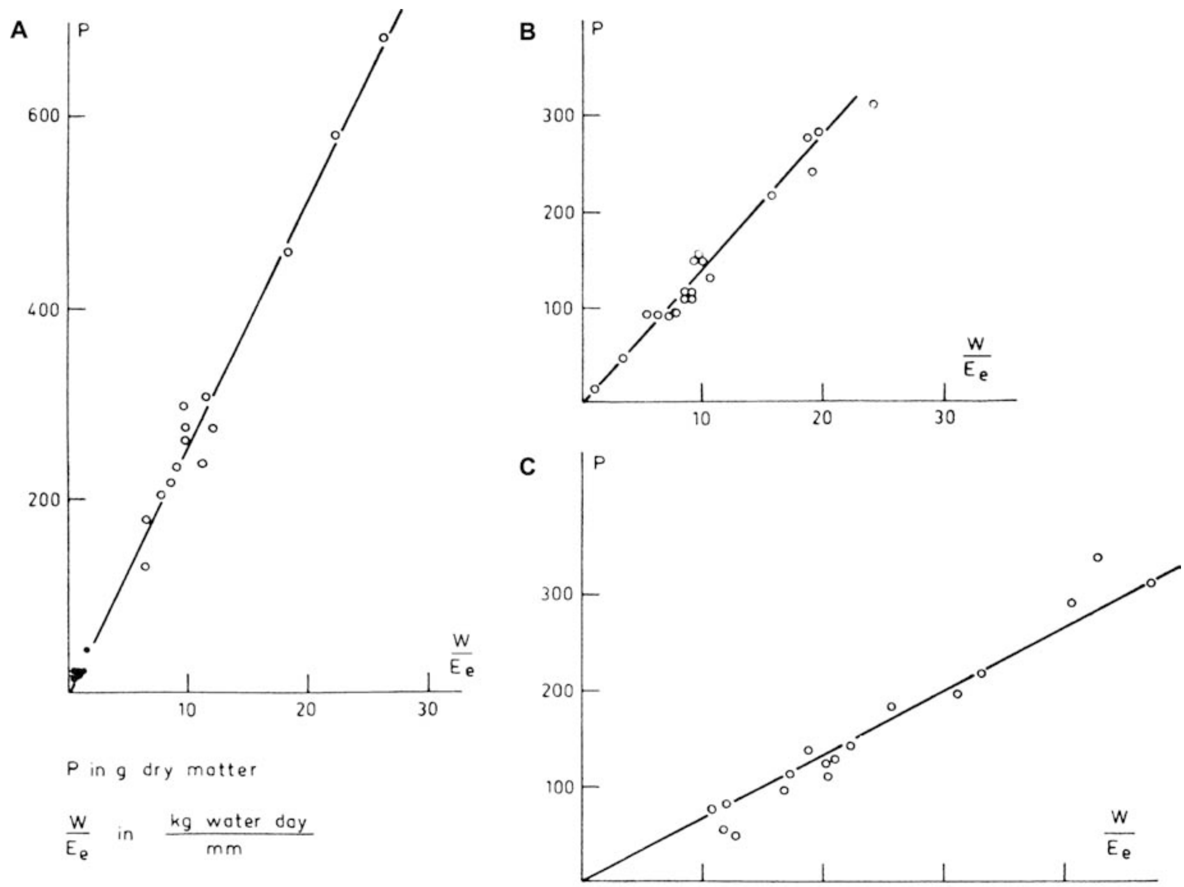

Fig. 4 Plot of crop growth (P) against transpiration water loss (W) divided by pan evaporation for (A) sorghum, (B) wheat, and (C) alfalfa. *Source*: From Ref.[8].

5 Pa, and 4 Pa, respectively. Then, for each species, water use efficiency based on accumulated plant mass (M) was stable when expressed in the following equation:

$$M/\mathrm{Tr_C} = k/(P_a^* - P_a) \quad (4)$$

Tanner and Sinclair[9] approximated ($P_a^* - P_a$) for daily transpiration by assuming this value was 75% of the maximum atmospheric vapor pressure deficit calculated at the daily maximum temperature.

A solution for $\mathrm{Tr_C}$ is obtained directly by the rearrangement of Eq. (4):

$$Tr_C = M(P_a^* - P_a)/k \quad (5)$$

This equation can be readily used based on estimates of M, which in turn can be calculated based on the interception of solar radiation and the radiation use efficiency of the canopy. Consequently, Eq. (5) is consistent with the energy balance approach in that it is sensitive to the amount of solar radiation intercepted by the canopy.

Not only is Eq. (5) easier in principle to implement that an energy balance approach, but it is conceptually much more compatible with the understanding of stomata regulation of transpiration. That is, Eq. (5) is calculated from a direct dependence of $\mathrm{Tr_C}$ on CO_2 assimilation, which is consistent with the fact that stomata are regulated for CO_2 assimilation and the rate of water loss from leaves is simply a consequence of this process. Eq. (5) has been used very effectively to calculate transpiration rates and evaluate limitations of water availability on crop yields.

INTRODUCTION

Atmospheric carbon dioxide (CO_2) concentration has varied throughout the life history of the earth. During the last two million years of cyclic formation and partial melting of ice caps, the CO_2 concentration has ranged from as low as about 180 ppm (mole fraction basis) during the coldest periods to as high as about 300 ppm during interglacial warm periods.[1] The atmospheric CO_2 concentration increased from about 280 ppm in pre-industrial times to 315 ppm in 1958 when the first careful continuous measurements were made at Mauna Loa, Hawaii.[2] Since then, CO_2 has continued to increase and the concentration is about 370 ppm currently. This increase has been due primarily to burning of fossil fuels and secondarily to deforestation and land-use changes. This increase of CO_2 (and other greenhouse-effect gases) is expected to cause global warming and other climate changes, but rising CO_2 will also affect plants directly.

Carbon dioxide is the first molecular link in the food chain of most life on Earth. Through the process of photosynthesis in green plants, carbon of CO_2 is incorporated into simple sugars which enter eventually into other biochemical reactions in the creation of living matter. There are three primary types of photosynthetic metabolism pathways used by green plants; C_3, C_4, and crassulation acid metabolism (CAM). The most abundant in terms of number of plants is the C_3 photosynthetic biochemical pathway, in which CO_2 binds onto the enzyme ribulose 1,5-bisphosphate carboxylase/oxygenase (Rubisco) in the chloroplasts, and enters into a biochemical cycle in which a 3-carbon sugar, phosphoglyceric acid, is the first product. Wheat (*Triticum aestivum* L.), rice (*Oryza sativa* L.), pulses (various bean and pea species), and most vegetable crops, fruit crops, and trees have the C_3 pathway of photosynthesis. In the C_4 photosynthetic pathway plants, CO_2 first binds with phosphoenolpyruvate carboxylase (PEPcase) in mesophyll cells of leaves, thereby forming a 4-carbon sugar (e.g., malic acid) that is translocated to bundle sheath cells surrounding vascular tissue. Photosynthesis is then completed via the C_3 pathway. The most familiar C_4 plants are maize (*Zea mays* L.), sugarcane (*Saccharum officinarium* L.), sorghum (*Sorghum bicolor* [L.] Moench), and many tropical and subtropical grass species. The CAM plants typically open their stomata at night and take up CO_2 by incorporating it into phosphoenolpyruvate via PEPcase and sequestering CO_2 as 4-carbon compounds such as malic acid.[3] As a group, CAM plants have less economic importance than C_3 and C_4 plants, but they are prevalent in arid and semiarid tropical zones. Pineapple (*Ananas comosus* [L.] Merr.) is the best known CAM plant, but *Agave* species are used for leaf fibre and prickly pear cactus (*Opuntia ficus-indica* [L.] P. Mill) and other *Opuntia* species are important as feed material for cattle and other uses.

Photosynthetic plants are found in habitats ranging from aquatic to xerophytic environments. Responses to increasing atmospheric CO_2 can vary among these habitats, so the focus of this discussion will be on mesophytic terrestrial green plants where rising atmospheric CO_2 and predicted concomitant climate changes are likely to have important impacts.

PLANT GAS EXCHANGE

Photosynthesis

The quantitative effects of CO_2, light, and temperature on leaf photosynthetic carbon assimilation were established about 100 years ago.[4] Plant scientists developed renewed interest in these effects, especially CO_2 effects, when it became apparent that carbon dioxide concentration of the atmosphere was increasing. Carbon dioxide has two direct effects on plant leaves. Increased CO_2 both increases rates of photosynthesis and decreases stomatal conductance of CO_2 and water vapor. Studies of photosynthetic rates of most C_3 plants show that leaves increase their uptake of CO_2 when concentrations are increased to at least 1000 ppm and beyond. Increases in CO_2 uptake of C_4 plants rise rapidly and flatten out above 400 ppm because of their CO_2-concentrating mechanism. Using a Michaelis–Menten type rectangular hyperbola model fitted to a set of C_3 plant, soybean (*Glycine max* [L.] Merr.) responses to a wide range of CO_2 concentrations, Allen et al.[5] predicted that canopy net photosynthetic rates would increase about 53% with a doubling of CO_2 concentration. Increases in leaf photosynthetic rates as external CO_2 concentrations increase result from higher influx rates of CO_2 through the stomata of leaves and on to the sites of carboxylation in the leaf chloroplasts.

Transpiration

Leaves are porous inside, occupied by cells with air gaps and passageways to the leaf stomata. Transpiration is the process whereby liquid water evaporates from the surface of cells within the leaf into the leaf air-space and diffuses to the outside through stomata. Stomata are pores on the surface of the leaf that are formed by two guard cells. These guard cells distort to cause the stomata to open in the presence of light and decreased intercellular leaf concentration of CO_2.

Morison[6] reported that leaf stomatal conductance of many plants decreased about 40% with a doubling of atmospheric CO_2 concentration. However, most experiments have shown that whole plants or plant communities decrease transpiration rate (TR) only to about 10% with a doubling of CO_2. The explanation of this difference is related to the energy balance in a real-world environment. As the stomatal conductance decreases with increasing CO_2 concentration, the TR decreases. However, as TR decreases, leaf temperature will begin to rise because of less evaporational cooling. As leaf temperature rises, the vapor pressure of water inside the leaves increases, and thus increases the driving force for evaporation of water. The resultant effect of these processes is that, although stomatal conductance decreases as CO_2 concentration is increased, the energy balance feedback effects cause the vapor pressure to increase, and thereby largely counterbalances the expected reduction in transpirational water use by plants, as described below.

Energy Balance of a Leaf

The coupled energy and mass exchange of a leaf can be expressed in an energy balance equation:

$$R_n = H + \ell E + \lambda \ell$$

where R_n = net radiation flux density; H = sensible heat flux density; ℓE = latent heat flux density, where ℓ is the latent heat of evaporation and E is the water vapor flux density in mass units; $\lambda\ell$ = photochemical heat flux density, with λ being the heat of CO_2 fixation and ℓ being the CO_2 flux density in mass units. Note that $\lambda\ell$ can be ignored to simplify the energy balance equation.

Sensible heat flux density can be expressed in a resistance and temperature difference form, and latent heat flux density can be expressed in a resistance and vapor pressure difference form, as:

$$\begin{aligned} R_n = {} & \rho C_p(T_L - T_A)/r_{a,h} \\ & + (\rho C_p/\Gamma)(e*[T_L] - e_a)/(r_{a,v} + r_{s,v}) \end{aligned}$$

where ρ = air density; C_p = air heat capacity; T_L = leaf temperature; T_A = ambient air temperature; $r_{a,h}$ = aerodynamic boundary layer resistance for heat transfer; Γ = psychometric constant for converting vapor flux density to energy flux density; $e*[T_L]$ = saturation vapor pressure at leaf temperature; e_a = ambient air vapor pressure; $r_{a,v}$ = aerodynamic boundary layer resistance for vapor exchange and $r_{s,v}$ = stomatal diffusion resistance for water vapor.

Decreasing stomatal conductance caused by elevated CO_2 would decrease latent heat flux density and create an unbalance in the energy balance equation. (Note: $r_{s,v}$ is the reciprocal of stomatal conductance.) Evaporative cooling would decrease, but this would cause T_L and $e*[T_L]$ to increase and thus increase the driving force for transpiration. The resultant effect is that a 40% decrease in leaf conductance will result in about 10% decrease in whole-crop transpiration.

Water-Use Efficiency (WUE)

WUE is defined here as the ratio of net photosynthetic CO_2 exchange rate (CER) to TR.

$$\mathrm{WUE} = \mathrm{CER/TR}$$

The WUE is impacted by increasing atmospheric CO_2 in two primary ways. First, decrease of stomatal conductance caused by the effects of increasing CO_2 will decrease TR to a limited extent. Secondly, and more importantly, elevated CO_2 increases plant photosynthetic CER. The ratio of WUE at elevated CO_2 ($\mathrm{WUE_e}$) to ambient CO_2 ($\mathrm{WUE_a}$) is given by:

$$\begin{aligned} \mathrm{WUE_e/WUE_a} &= (\mathrm{CER_e/CER_a})(\mathrm{TR_a/TR_e}) \\ &= (1 + \Delta\mathrm{CER/CER_a})(1 + \Delta\mathrm{TR/TR_e}) \end{aligned}$$

where ΔCER and ΔTR are the differences, $\mathrm{CER_e} - \mathrm{CER_a}$ and $\mathrm{TR_a} - \mathrm{TR_e}$, respectively. Furthermore, the percentage contribution of CER changes to WUE ratios is:

$$(\Delta CER/CER_a)/(\Delta CER/CER_a + \Delta TR/TR_e) \times 100$$

and the percentage contribution of TR changes to WUE ratio is:

$$(\Delta TR/TR_e)/(\Delta CER/CER_a + TR/TR_e) \times 100$$

Allen[7] reported that the contribution of CER to the increase in WUE ratio ranged from 60% to 90% for several C_3 plants, but was only about 25% for a C_4 plant (maize).

Respiration

There have been reports of direct suppression of plant respiration by elevated CO_2. However, this effect is not always found. Regardless of the putative direct effect of CO_2 on respiration, plants grown in elevated CO_2 are frequently found to have greater respiration rates because they are larger plants. Probably the best statement is that respiration is directly proportional to the amount of plant nitrogen or the amount of proteinaceous metabolic components of the plant.

PLANT GROWTH AND DEVELOPMENT

Vegetative Growth Responses

Most plants, both C_3 and C_4 species, show an increase in vegetative growth when exposed to elevated CO_2.[8,9] The largest responses seem to be from legume species that can fix their own nitrogen symbiotically. These increases are generally 30% or greater for C_3 species (Table 1) and about 10% for C_4 species. The exact nature of the biomass growth responses will depend on how the study is implemented and the state in the life cycle when the measurements are made. The greatest relative responses occur in isolated plants in early stages of growth.[9,10] In cropping systems, the space available for individual plant expansion becomes limited when complete ground cover is achieved, and responses to elevated CO_2 become somewhat limited by available light per unit land area.

Plants generally accumulate photoassimilates (nonstructural carbohydrates) in leaves and other vegetative structures under elevated CO_2 treatments. In addition, some plants acclimate to elevated CO_2 by down-regulating the synthesis of Rubisco, which can lead to less response to elevated CO_2. The combination of these two effects tends to increase the carbon-to-nitrogen ratio in the aboveground biomass. The acclimation response to elevated CO_2 has been clearly shown for rice, whereas soybean has little down-regulation response.[11]

Reproductive Growth and Seed Yield

Reproductive growth and seed yield increase with increasing CO_2, but generally not as much as biomass accumulation. Most crop plants do not appear to be adapted to take full advantage of the increased photosynthetic rates under elevated CO_2. For example, Allen and Boote[12] reported that soybean seed yields increased by about 30% with doubled

Table 1 Total biomass yield and seed yield response of soybean plants (21 plants per square meter at final harvest) to temperature and CO_2 with day/night, maximum/minimum cycles of 28/18, 32/22, 36/26, 40/30, 44/34, and 48/38 °C. The CO_2 concentrations were maintained at 700 ppm for each temperature treatment and at 350 ppm for 28/18 and 40/30 °C

	Temperature, day maximum/night minimum (°C)					
CO_2 concentration (ppm)	**28/18**	**32/22**	**36/26**	**40/30**	**44/34**	**48/38**
Biomass yield (grams per plant)						
700	23.0	24.1	27.0	25.5	26.1	1.7
350	15.1			16.6		
Ratio	1.52			1.54		
Seed yield (grams per plant)						
700	10.0	11.4	12.3	8.7	0.5	0.0
350	7.6			6.7		
Ratio	1.32			1.30		
Harvest index						
700	0.43	0.47	0.45	0.34	0.02	
350	0.50			0.40		
Ratio	0.86			0.85		

Source: Allen and Boote.[12]

Tailwater–Virtual

CO_2 concentration although total biomass increased by about 50% (Table 1). Thus, the harvest index (the ratio of seed yield to total above-ground biomass accumulation) was decreased from 0.50 at 350 ppm to 0.43 at 700 ppm for a harvest index ratio of 0.86 when plants were grown at day/night maximum/minimum temperatures of 28/18 °C. When grown at 40/30 °C, harvest index values were lower with 0.43 at 350 ppm and 0.34 at 700 ppm, with a ratio of 0.85. In general, the evidence for $CO_2 \times$ temperature interaction on either vegetative biomass accumulation or seed yield has been weak, although there are some reports of a strong interaction.[13,14]

TEMPERATURE AND DROUGHT EFFECTS

Along with the direct effects of increasing atmospheric CO_2, there may be indirect effects on plants because of associated global warming and other climatic changes. First, increasing temperatures would increase the TR of plants. Both experimental data and crop models indicate that TR would increase from about 4% to 8% per 1 °C rise in temperature (the specific increase depends on other environmental and plant conditions). The Third Assessment Report of the Intergovernmental Panel on Climate Change (IPCC) predicts that global warming could be 1.4EC–5.8 °C between now and 2100.[15] Using a midrange value of 6% increase in TR per 1 °C, these data indicate that TR could increase from 8% to 35%, depending on the global warming scenario. Thus, global warming might override any savings in plant water use that would arise from a doubling of CO_2 concentration. On a local scale, drought is harder to predict, but decreases in rainfall could make climate change stresses on plants even more severe.

Increases in temperature would generally not cause serious reductions in photosynthesis or vegetative biomass growth. However, increases in temperature can cause serious problems with reproductive development and seed yield (Table 1). Generally, pollen development and pollination (fertilization) are decreased seriously by temperature increases above the optimum for seed production.[16] In general, seed productivity appears to decrease about 10% per °C from the optimum temperature to essentially zero seed production at about 10EC above the optimum. Again, using the IPCC estimates of 1.4–5.8 °C warming, seed productivity might be decreased from 14% to 58% depending on the severity of global warming.

Recently, the International Rice Research Institute, Philippines[17] found that rice cultivars carry on pollination processes over a 9–12-hr period during the daytime, and that "early pollinators" are more successful than "late pollinators" in rice seed production under elevated daytime temperatures. Plant selection and incorporation of early morning pollination is thus a strategy that might be employed in adapting to global warming that might be induced by increasing atmospheric CO_2 concentration.

CONCLUSIONS

Increasing atmospheric CO_2 concentration will likely increase plant photosynthesis, growth, and seed productivity. A doubling of CO_2 is expected to increase seed yields about 30% and decrease transpirational water use about 10%. However, global warming and climatic changes could alter this scenario (Table 1). Predicted levels of global warming might increase plant transpiration by 8–35% and override the small water savings due to decreased stomatal conductance. Furthermore, predicted levels of global warming could decrease seed yield by 14–58%, unless progress can be made in plant selections to avoid the detrimental effects of high temperature on pollination, seed development, and growth processes.

Transpiration: Efficiency

Graeme C. Wright

INTRODUCTION

A prevalent problem for plant and crop production is shortage of water, which is an essential component in all biological functions. For every kilogram of biomass produced, several hundred kilograms of water is lost from the leaf surfaces via the processes of transpiration (T), or both leaf and soil surfaces via evapotranspiration (ET).

An important concept used to define the efficient use of water derived from rainfall and irrigation is water-use efficiency (WUE). In most agricultural systems, the WUE is used to express the amount of either total biomass (Tbio) or grain yield (Yg) produced per unit of ET, and is a pivotal factor in achieving high productivity when water is limited. The Tbio or Yg can also be expressed as a function of transpiration efficiency (TE), where water used by the plant or crop is only by transpiration. The TE has also been expressed as the reciprocal form, transpiration ratio, defined as the amount of water lost through transpiration per unit of dry matter produced. However, in this chapter, we use "TE" as the efficiency of an organism (leaf, plant, and crop) to use water under specific environmental conditions. Readers are referred to a number of excellent reviews on TE in various crops.[1–4]

CAUSE OF VARIATION IN TE

The term TE is often applied at the leaf, whole-plant, and ecosystem level. The cause of variation in TE becomes complex as the level of organism increases from a single leaf to plant and crop canopy.

At the leaf level, TE is referred to as the "instantaneous or intrinsic" TE, expressed as mmol of CO_2 fixed per mol of H_2O transpired through stomata, and is calculated as

$$TE = A/g_s = (p_a - p_i)/\nu(1.6) \quad (1)$$

where A is the CO_2 assimilation rate ($\mu mol\,m^{-2}\,sec^{-1}$), p_a and p_i (ppm) are the partial pressures of CO_2 in ambient air and in the intercellular space, respectively, g_s is the stomatal conductance ($\mu mol\,m^{-2}\,sec^{-1}$), ν is the water vapor pressure gradient between intercellular space and ambient air, and 1.6 is the diffusivity constant between CO_2 and H_2O.

Eq. (1) suggests that TE can be regulated either by the leaf to air CO_2 pressure gradient (p_i/p_a) or leaf to air H_2O gradient (ν). The leaf to air CO_2 pressure gradient is a direct reflection of the CO_2 assimilation rate, which in turn is governed by the efficiency of carboxylating enzymes, whereas ν is controlled by the stomatal conductance. The closing of stomata in response to drought conditions to prevent excessive water loss through transpiration is a well-known drought adaptation mechanism. Stomatal closing reduces CO_2 uptake as well as water loss, thus decreasing the photosynthetic rate. Under conditions of elevated CO_2 concentration, the CO_2 gradient between the atmosphere and the leaf is higher and CO_2 can pass through partially closed stomata at a rate similar to that under conditions of lower CO_2 and open stomata. The water vapor gradient remains the same at higher CO_2, and the transpiration is impeded. The net result is improved transpiration efficiency by some plants. Under low ν conditions, there is very little water vapor flux from leaf to air, and gas exchange can occur through open stomata with minimum loss of water. Under these conditions, the net result is also improved transpiration efficiency.

The advantage of intrinsic TE as a term is that it allows a direct comparison of intrinsic physiological considerations without confounding effects of differences in temperature and humidity that may exist in a canopy situation. On the contrary, the disadvantage is that it only represents a "snap shot" of A/g_s, and may not necessarily scale up to long-term considerations related to overall canopy productivity and growth.

Transpiration efficiency at the entire plant level is defined as plant biomass (DM) accumulated per unit of water transpired (T) over a specified time interval, expressed as $g\,kg^{-1}$. At the entire plant level, TE can be more accurately determined by cumbersome and labor intensive gravimetric methods.[5–7]

Variation in TE can occur due to both genetic and environmental factors. The following expression illustrates the potential sources of variation in TE:

$$TE = A/g_s = [p_a(1 - p_i/p_a)]/1.6(e_i - e_a) \quad (2)$$

where e_i and e_a (mbar) are intercellular and atmospheric water vapor pressures.

It can be seen from Eq. (2) that a reduction in p_i/p_a at a given $e_i - e_a$, (i.e., the vapor pressure deficit (VPD) will increase TE.

At the crop level, TE is influenced by a range of physiological factors and processes associated with production of dry matter (i.e., photosynthetic capacity, water extraction ability of roots, stomatal movements, leaf area regulation, etc.), which are in turn influenced by environmental and soil factors. Indeed, Fischer[8] and Tanner and Sinclair[9] argued that inter- and intra-specific variation for TE is small and can mostly be accounted for by soil fertility (particularly N) or environmental VPD factors. These studies concluded that TE was inversely proportional to the average VPD during the growing season, with k being the constant of proportionality, i.e.,

$$TE = k/(e_i - e_a) \quad (3)$$

Eq. (3) allows the evaluation of TE (as k) independent of VPD, and hence the comparison of the genotypic variation in TE.

INTER- AND INTRA-SPECIES VARIATION IN TE

Historical Perspective

The first report of intra-species differences in TE occurred nearly a century ago when Briggs and Shantz[10] produced evidence in pot studies showing a significant variation among genotypes of the same species. These authors speculated that it should be possible to develop high TE lines through genetic selection. Despite these early findings, little research was subsequently conducted on TE variation within species until the mid-1980s. There are a number of reasons for this lack of follow-up research. First, the early work of DeWit[11] which showed a strong linear relationship between dry matter production and water implied a constant ratio between dry matter and water use, and hence TE. This led to the widely accepted belief that p_i/p_a among genotypes of species with a C_3 or C_4 photosynthetic pathway were invariant, and that TE could be considered a crop species constant, known as "k."[8,9,12] Second, there are substantial difficulties in accurately measuring TE variation in plants or crops. Both CO_2 assimilation and transpiration from single leaves vary markedly during the day and according to leaf age and plant age. As mentioned earlier, these instantaneous measurements of A and g_s may not represent integrated performance throughout the life of a plant or crop. As well, these measurements cannot assess the impact of morphological or physiological adaptations in response to drought that can influence the integrated measure of TE.[13] Similarly, pot studies by using gravimetric techniques for water measurement although providing accurate time integrated measures of TE, were considered time consuming, laborious, and resource intensive.[1] It was not until the mid-1980s, when Farquhar and Richards[14] reported a twofold variation in TE among wheat genotypes, that physiologists began to "research" and demonstrate significant intra-species variation in TE in many crops.

Since the mid-1980s, there have been voluminous reports of inter- and intra-species variation in TE, particularly for C_3 plants including cereals, legumes, pasture species, and numerous horticultural crops. Significant genotypic differences in TE have also been reported in C_4 crop species, including sorghum and sugarcane. Readers are referred to review papers by Richards and Condon,[2] Turner,[3] and Subbarao et al.[13] for a more complete set of references on the species variation in TE.

Selection Tools for TE

Measurement of carbon isotope discrimination (Δ) in plant tissue has been shown to be an extremely effective technique to identify genetic variation in TE. Theory[15] has demonstrated that C_3 plants should exhibit an association between the extent of their discrimination against ^{13}C compared with ^{12}C during CO_2 fixation, and their leaf intrinsic gas exchange efficiency (A/g). The use of Δ to select for improved TE was proposed following the experimental confirmation of the theory in wheat genotypes.[14] Its measurement has opened up new opportunities for the genetic improvement of TE, as it provides a time-integrated estimate of TE and is easier and faster to measure than total growth and water use. The Δ technique therefore provides a ready screen for plants growing under identical conditions.

Pot studies in which growth (including roots) and water use have been measured precisely, have consistently shown a negative relationship between Δ and TE, as summarized by Richards and Condon,[2] Turner,[3] and Hall et al.[16] It is important for breeders and physiologists alike to be confident that the genotypic variation for TE and Δ measured in pots translate to the field. There have only been a limited number of studies conducted to confirm that the negative relationship observed between Δ and TE in pots will occur under field conditions. The lack of reports in the literature relates to the difficulty in accurately measuring crop transpiration (after accounting for soil evaporative losses) and biomass (including roots) under field conditions for a range of contrasting genotypes.[17] Using a mini-lysimeter system located within a rain-out shelter facility,[5,7] the negative relationship between Δ and TE under field conditions has been confirmed in a number of crop legumes including peanut[6] (Fig. 1), soybean,[18] common bean,[19] and cowpea.[20] It has also been confirmed for wheat genotypes when accurate techniques for measuring the crop water balance were employed.[21]

Genotypic differences in TE that are independent of VPD differences due to environment and location, calculated as *k*, have been demonstrated in a range of grain legume crops (Fig. 2, adapted from Ref.[22]).

The discovery of a strong relationship between Δ and TE has also made it possible to understand the physiological basis of variation in TE within species,[23] as well as the exploitation of TE in some crop improvement programs.[24,25]

Recent studies have shown that in C_3 crops such as cowpea,[20] cotton,[26] and chickpea,[27] TE is predominantly controlled by g_s, i.e., stomatal factors. In contrast, photosynthetic capacity (A) has been shown to be the major cause for variability in TE in crops such as peanut,[6] sunflower,[28] and spruce.[29] Udayakumar et al.[23] argued that C_3 crops could be grouped into two distinct categories, depending on whether TE is controlled predominantly by stomatal factors or photosynthetic capacity. These findings have major implications for using TE as a selection tool in the crop improvement programs (discussed in the following section). Udayakumar et al.[23] and Ashok et al.[20] argue that in C_3 crops where TE is controlled by stomatal factors (and hence affecting transpiration),

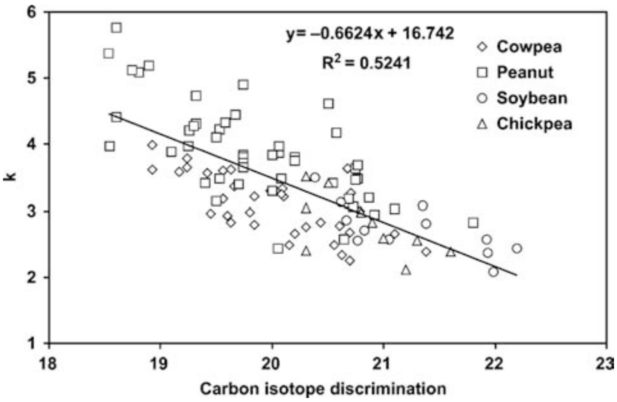

Fig. 2 Relationship between ''k'' (TE adjusted for VPD) and carbon isotope discrimination in different grain legume crops. *Source*: From Ref.[22].

selection for high TE is likely to result in genotypes with low total dry matter productivity. In contrast, in those crops where variation in TE is brought about by higher unit leaf rates of photosynthesis, or greater mesophyll efficiency, selection for high TE is likely to result in genotypes with higher dry matter productivity.[6,23,30]

While the use of Δ as a rapid and reliable selection tool for TE clearly has advantages over other cumbersome and labor intensive measurements of TE, there are several factors that need to be considered before recommending its use as a tool in large-scale genetic enhancement programs, include the following:

- A limited understanding of the value of TE for genetic enhancement in a specific environment.
- Complex genotype × environment interactions for TE in different crops due to differences in growth phenology among germplasm.[2,30,31]
- A lack of information on sampling procedures in different crops. For example, Δ can vary with leaf

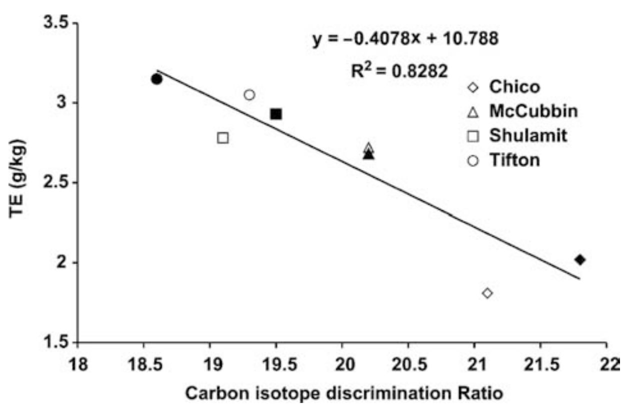

Fig. 1 Relationship between TE and carbon isotope discrimination (Δ) in four peanut genotypes grown under irrigated (filled symbols) and drought (open symbols) conditions. *Source*: From Ref.[6].

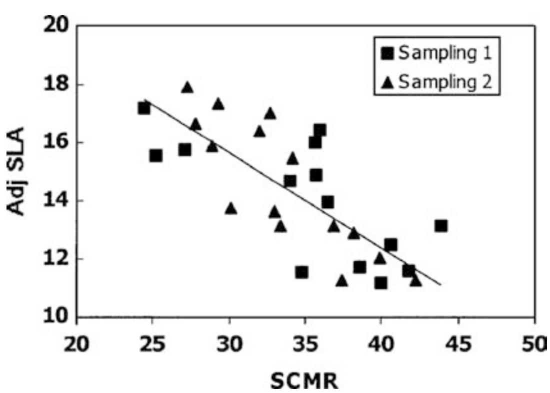

Fig. 3 Relationship between specific leaf area adjusted for radiation and VPD parmeters (Adj SLA) and spad chlorophyll meter readings (SCMR) in 15 peanut genotypes measured at two sampling times. *Source*: From Ref.[36].

age within the canopy and may confound interpretation of results.[32]

- The high cost of Δ analysis.

Recent research in peanut has shown that specific leaf area (SLA)[33–35] or the SPAD-Chlorophyll Meter Readings (SCMR)[36] can be used as rapid and low cost surrogate measure for TE (Fig. 3). Richards et al.[37] discuss the value of using various selection tools such as SLA, ash, and molecular methods for genetic enhancement using the TE trait. The use of these methods will however depend on cost, degree of association with TE, and the relative ease of measurement of the trait.

SCOPE FOR GENETIC ENHANCEMENT OF TE IN AGRICULTURAL CROPS

Plant breeding programs have historically increased grain yield in crops from increases in partitioning of biomass to the reproductive component, or harvest index. Relatively little progress has been made in increasing plant biomass production per unit of water.[38–40] With the improved understanding of factors influencing water use and transpiration efficiency, there is now however greater opportunity to more precisely target improvement in TE.

A useful model for describing avenues for improvement in crop yield (Yg) in water limited environments in the aforementioned context is provided by the identity.[21,41]

$$\mathrm{Yg} = E \times (T/E) \times \mathrm{TE} \times \mathrm{HI} \qquad (4)$$

where E is the total water use, T/E is the proportion of this water that is transpired (T), TE is the transpiration efficiency, and HI is the partitioning of biomass to grain. Implicit in the use of Eq. (4) is the concept that the various components are relatively independent so that increases in any of them will increase yield. In reality, numerous physiological and genetic interactions between model components can occur, thus complicating the expected response to selection of traits such as TE. The following section presents some case studies of approaches adopted for genetic enhancement for TE in different crops. It highlights some potential complications, which need to be kept in perspective when recommending whether plant breeders should launch into a large-scale selection program targeting TE improvement.

In peanut, development of surrogate tools for TE[33] and simple methodologies to analyze genotypic yield within the water model framework given in Eq. (4)[30,42] made it possible to select elite genotypes with high levels of model components (T, TE, and HI) (Table 1. Recent studies by Nigam et al.,[43] have shown that additive gene effects were important in the expression of SLA (i.e., a surrogate measure of TE) and HI in peanuts and suggested that in some crosses selection for SLA and HI can be effective in early generations. Positive correlations between Δ and HI have been observed in some peanut genotypes, and progeny from crosses of parents with similar maturity.[30] Similar responses have been observed in cowpea[44] and wheat[45] genotypes. These correlations suggest that breeders will need to be aware of such associations when selecting solely on the basis of low Δ.

Table 1 Performance of selected peanut genotypes for T, TE, and HI relative to experimental mean (as %) in 1994–95 rainy seasons in an international collaborative project involving the International Crops Research Institute for Semi-Arid Tropics (ICRISAT), the Indian Council for Agricultural Research (ICAR) and the Queensland Department of Primary Industries

Exp. mean	2.23	290.5	2.7	0.31

In other C_3 crops, preliminary genetic and breeding studies using Δ as a selection trait have shown different relationships with crop growth, final biomass, and/or grain yield.[16] These responses have been further analyzed to indicate genetic associations between Δ and other important yield component traits, including earliness, HI, rooting depth, and rate of leaf area development. Early flowering has been associated with high leaf Δ in common bean,[46] cowpea,[16] wheat,[2] and barley.[31] Here, the negative association between Δ and days to flowering could constrain breeding for adaptation to specific water limited environments where both early maturity and high TE could be beneficial. The challenge for breeders in this situation is to identify whether germplasm is available with both low Δ and early flowering so that concurrent selection for both traits could be achieved.

In common bean, a positive association between Δ and Yg under water limited conditions was observed.[46] It was shown that Δ and the extent of rooting were positively correlated, indicating a possible genetic or physiological association among genotypes. Clearly, such a correlation would tend to constrain selection for those environments where deep rooting and high TE are desirable.

In barley, carbon isotope discrimination (Δ) was closely correlated with TE,[31] but it was either positively or negatively related to grain yield depending on the growing environment. Selection for high Δ at postanthesis or at maturity resulted in selection for high yields in water limited Mediterranean environments.[31] However, the prospect of selecting for Δ in early generations (e.g., F_2) is unclear. Voltas et al.,[47] also observed that barley genotypes with low Δ (i.e., high TE) performed better in low-yielding environments, whereas those with high Δ performed better in medium and high-yielding environments. This observation supports the assumption that drought tolerance and high yield potential under non-limiting growing conditions may be antagonistic concepts in barley.

In bread wheat, it was concluded that a selection for low Δ in early generation (e.g., F_2) was successful in improving TE, plant total dry matter and root dry matter under water-limited conditions.[45] A positive association between Δ and early canopy growth has been observed in wheat genotypes.[2,21] In environments with high water availability, low Δ genotypes were slower growing, had higher soil evaporative losses, lower T and hence lower Yg. In contrast, in environments with severe drought conditions, Yg and Δ were negatively associated according to theoretical expectations, as soil evaporative losses were minimal.

It is evident from all the earlier reports that low Δ, and hence higher TE, may not always translate into higher Yg. It is critical for breeders to understand the potential trade-offs between Δ and growth in specific environments, and not expect that direct yield benefits will result from sole selection for Δ.

CONCLUSION

Although there is extensive information published on the variability in TE both between and within species, the challenge remains to establish whether TE (via measurement of Δ or other surrogate) is a sufficiently reliable trait to select for in plant breeding programs. At this early stage, the evidence from a number of different crops suggests that Δ has considerable potential. A number of experiments in cereal and legume crops have shown that Δ is correlated either positively or negatively with a wide range of attributes, including physiological (TE and HI), phenological (plant height and days to anthesis), and growth (TDM and yield) characters. These correlations also seem to depend on the crop and level of water stress prevailing in the growing environment. Thus, it is highly unlikely that the selection for TE alone will bring significant yield improvements across all environments. The understanding of yield constraints in the growing environment is vital to assess the value of TE among other yield limiting constraints in that environment. This assessment on the need and scope for improving TE can be made by analyzing grain yield of locally adapted genotypes within the framework of the water yield component model [Eq. (4.)[30,41]] The authors conclude that if TE is to be used effectively in breeding programs, it will be one of multiple criteria used by the breeder to improve the adaptation of the crop.

Transpiration: Scaling from Leaves and Canopies

Matthias Langensiepen
Department of Modeling Plant Systems, Institute of Crop Science, Humboldt University of Berlin, Berlin, Germany

INTRODUCTION

Transpiration is the vapor loss from living surfaces to the atmosphere. When a leaf of a well-watered plant is exposed to dry air and solar radiation, it starts to transpire through its stomatal pores. The rate of vapor transport from the leaf into the atmosphere E_l can be determined from the product of leaf vapor conductance g_{lv} and the vapor pressure difference between the leaf mesophyll and the adjacent atmosphere:

$$E_l = g_{lv}(e_{mv} - e_{av}) \quad (1)$$

where e_{mv} and e_{av} are the water vapor partial pressures in the mesophyll and at the leaf surface, respectively. As the mesophyll cells lose water, they experience an increase in solute concentration and a reduction in water potential. Since plants are continuous hydraulic systems, changes in leaf transpiration are transmitted to other plant tissues and to the soil and atmosphere boundaries. Physiological control of stomatal vapor diffusion and turbulent transport are the dominating processes controlling the intensity of canopy transpiration. They take place on distinctive spatial and temporal scales that must be integrated to facilitate a quantitative understanding of canopy transpiration.

SCALING AS A PROCESS

A scale is defined as a spatial or temporal dimension of an object or a process, characterized by both grain (finest level of spatial resolution) and extent. Numerous processes and relationships constitute the soil–plant–atmosphere system. To make the system manageable, it must be decomposed into hierarchical structures, which are organized in terms of spatial, temporal, and organizational levels.

Using information from finer scales to explain phenomena at a broader scale is called ‘‘bottom-up scaling.’’ Bottom-up scaling entails mechanistic information from lower system levels such as roots, single leaves, leaf patches, or even individual guard cells. Bottom-up scaling is particularly useful, when the physiological and physical processes do not transfer linearly between different levels of system organization. Yet, increasing levels of observation will also introduce noisiness in the quantification process. To overcome the statistical difficulties associated with this so-called complexity paradox,[1] the lowest scaling level (granularity) must be carefully chosen.

Inferring phenomena on a finer scale from information on a broader scale is termed ‘‘top-down scaling.’’ Top-down scaling is typically applied when detailed information about processes taking place on lower system levels is difficult to obtain. A popular example shown below is the inversion of a canopy transpiration model for estimating the underlying process of canopy regulation. Top-down scaling must necessarily be based on a priori assumptions that are often untestable.

To avoid spurious or noisy results, any scaling attempt must be based on a thorough understanding of the processes considered in the scaling framework. For the same reason, it is also important to limit the scaling range to adjacent levels of system organization. Considering the extraordinary variability of plant physiological responses to the environment, it is hardly possible, however, to attain such goals. Quantitative relations between plants and environment, which serve as foundations of any scaling structure, must therefore always be regarded as approximations of reality.

BOTTOM-UP SCALING

Bottom-up scaling of transpiration from leaves to canopies requires an understanding of the regulation processes underlying plant–environmental interaction. Stomata play a key role in coordinating liquid and vapor phase fluxes through the soil–plant–atmosphere system.[2] They function as pressure regulators preserving hydraulic contact between leaves and soil.[3] Many interacting mechanisms influence the regulation of stomatal vapor conductance, which are not yet fully understood. Stomatal modeling thus remains an active field of research (see elsewhere in this encyclopedia).

Scaling Transpiration from Leaves To Canopies

Leaf transpiration can be calculated with Eq. (1) by employing any model simulating stomatal conductance and using leaf surface temperature and humidity data.

However, since such data are hardly accessible under practical conditions, simplified concepts like the combination equation must be applied that eliminate the need for surface information:[4]

$$\lambda_e E_i = \frac{\varepsilon_s A_i + \lambda_e \rho_a \Delta_i * g_{bvi}}{(\varepsilon_s + 1) + g_{bvi}/g_{lvi}} \tag{2}$$

where λ_e is latent heat of vaporization at air temperature, E_i the vapor flux density from an individual leaf i, A_i the energy available for conversion into latent and effective heat (predominantly net radiation), ρ_a the density of air, ε_s the slope of saturated specific humidity with air temperature ($\varepsilon_s = 2.2$ at 20°C), and Δ_i the vapor saturation deficit at the edge of each leaf boundary layer (see Ref.[5] for calculation procedures). g_{lvi} and g_{bvi} are the leaf and boundary layer vapor conductances of the ith leaf, respectively.

Theoretically, leaf transpiration could now be scaled to canopy transpiration by integrating (2) over the entire canopy. However, the statistical uncertainties and instrumentation required for scaling turbulent air flow to each individual canopy element render such an endeavor almost impossible. The problem can be simplified by dividing the canopy into multiple horizontal layers and by determining the fluxes of momentum, heat, and mass from these layers over suitable time intervals using appropriate micrometeorological techniques.[6] An even simpler approach can be applied that treats the canopy as one giant transpiring leaf located at a mean height of momentum absorption, which also represents the center of mass and heat exchange. The logarithmic portion of the wind profile above a canopy can be extrapolated to this exchange level, provided atmospheric conditions are near neutral. Further treating eddy diffusivity in analogy to its molecular counterpart and assuming similarity between the fluxes of heat, mass, and momentum, the logarithmic profile can serve as a scaling framework for determining the canopy vapor flux. The approach is known as the ‘‘K-theory’’ or ‘‘first-order closure approach’’ and relates the fluxes of trace species to the gradient of mean quantities through the eddy diffusivity (denoted as ‘‘K’’—see Refs.[4,7] for further theoretical information and procedures for correcting the profile under unstable or stable exchange conditions).

Based on this simplification, Eq. (2) can be rearranged to account for the bulk vapor transport by assigning canopy variables to their corresponding leaf counterparts: First, A_i is replaced by A_c, which is the net-radiation energy absorbed by the bulk transpiring canopy minus soil heat flux (see Ref.[5] for calculation procedures). A canopy radiative transfer model[8] is needed for this procedure, which is also required for the second step of determining photosynthetically active radiation loads on the canopy. Based on this information, canopy conductance g_{canopy} can be estimated using any stomatal light response function, and by serially integrating the responses of the leaf classes g_{lvi} according to their reception of direct, diffuse, and penumbral radiation.[9]

Leaf boundary layer conductance g_{bvi} in Eq. (2) is replaced by an aerodynamic canopy transport conductance term g_a, which is defined as

$$\frac{1}{g_a} = \frac{1}{g_b{}'} + \frac{1}{g_t} \tag{3}$$

where $g_b{}'$ is the parallel sum of all boundary layer conductances ($\sum g_{bvi}$) and g_t the turbulent resistance, which can be estimated on the basis of the K-theory:[10]

$$g_t = \frac{k^2 u_z}{\ln[z - d/z_m] \ln[z - d/z_h]} \tag{4}$$

where $k = 0.41$ is the von Karman constant, u_z the wind speed measured at height z, $d = 0.7h$ the average height of heat, mass, and momentum exchange within a uniform canopy of height h, $z_m = 0.12$h-the momentum roughness length, and $z_h = 0.2z_m$ the heat roughness length.

Finally, Δ_i is replaced by a corresponding air saturation vapor deficit term Δ_a, and soil evaporation is subtracted from $\lambda_e E_c$ to allow the quantification of actual transpiration (methods for estimating soil evaporation are not shown here, since they can be found elsewhere[11]).

Basing leaf to canopy scaling on the flux-gradient relation is attractive for the simplicity of its theoretical basis. However, the K-theory is only strictly valid for relatively short plant canopies, which experience sufficient turbulent mixing under neutral exchange conditions. In the absence of sufficient mixing, as it is the case under buoyant exchange conditions or in tall canopies such as forests, heat transfer becomes strongly ejection dominated, while momentum transfer is still related to sweeps or gusts. Such countergradient conditions lead to the invalidation of the K-theory. Experiments treating canopy elements as independent point sources of fluid particles have additionally shown that the K-theory can only describe the far-field regime, but will fail whenever near-field effects become important (see Refs.[4,12] for a detailed discussion). Unfortunately, alternative higher-order closure or Langrangian solutions require complicated instrumentation and extensive parameterization that prevent the practical implementation of these methods.

TOP-DOWN SCALING

Given the lack of practical methods for scaling stomatal conductance from leaves to canopies, top-down approaches may serve as useful alternatives. One of the most widespread solutions is the inversion of the combination equation:[12]

$$\frac{1}{g_{\text{canopy}}} = \frac{1}{g_{\text{a}}}\left[\frac{\varepsilon_{\text{s}} A_{\text{c}}}{\lambda_{\text{e}} E_{\text{c}}} - (\varepsilon_{\text{s}} + 1)\right] + \frac{\Delta_{\text{a}}}{E_{\text{c}}} \tag{5}$$

where the symbols are the same as in the canopy version of the combination Eq. (2) explained above. Usage of Eq. (5) is restricted to situations, where fluxes of heat, mass, and momentum are similar, and the canopy can be treated as a large homogenous plane.

A_c can be determined with a canopy radiation model and measurements of soil-heat flux, provided the latter becomes an important component of the energy balance. Lysimeters serving as surrogates for their surrounding conditions are often used for directly measuring $\lambda_e E_c$. It is also possible to determine $\lambda_e E_c$ using flux-gradient or eddy-correlation measurements (see Ref.[4] for procedures and instrumentation). The application of remote sensing techniques should be regarded with caution, because a large gap exists between canopy and regional scales, which cannot be surpassed without employing untestable assumptions.

Once g_{canopy} is parameterized, Eq. (5) can be rearranged to its original form for predicting canopy transpiration on the basis of standard meteorological measurements. It must be noted, however, that such a solution is only valid in the range of its empirical parameterization and can thus not be extrapolated to other conditions.

CONCLUSIONS

When comparing the bottom-up and top-down scaling approaches, it is difficult to recommend which is best. They often fulfill different purposes. Bottom-up or reductionist approaches provide insight into the complexity of the various principles underlying canopy transpiration but are often not suitable for practical application. However, they form the theoretical basis for simplified approaches. Top-down approaches, in turn, are straightforward, simple, require little experimental information, and are therefore highly attractive for practical application. Yet, their validity is restricted to the conditions under which they were derived that prevent widespread application.

Reductionist scaling is a measure for our ability to understand the complex mechanisms underlying canopy transpiration. Limited knowledge on topics like the plant sensing of environmental conditions, signal-transduction, and hormonal regulation of plant water relations make canopy scaling remain an active field of research.

Transpiration: Water Use Efficiency

Miranda Y. Mortlock
Office of Economic and Statistical Research (OESR), Brisbane, Queensland, Australia

INTRODUCTION

The balance between carbon assimilation (net photosynthetic production) and the throughput of water by transpiration (resource use in terms of water) results in a benefit–cost ratio of interest to eco-physiologists and crop physiologists, known as water use efficiency. The differences in concentration of CO_2 and water vapor between the intercellular surfaces of the leaf mesophyll and the atmosphere drive the fluxes of carbon dioxide and water through the plant. Hot dry environments provide conditions of high evaporative demand. CO_2 concentrations are low in the atmosphere, and this gas diffuses through the stomata, which need to be open to allow gas exchange. There is a need under most environments to conserve water, and under drought stress stomata close which conserves water. Water use efficiency is an expression of the benefit–cost ratio for a plant and integrates the physiology of photosynthesis and plant water relations over a particular growth period or cropping season.

DEVELOPMENT OF THE CONCEPT OF WATER USE EFFICIENCY

Early last century, Briggs and Shantz studied the water requirements (WRs) of crops by weighing containers and working out WR per plant; however, they did not use an area basis.[1] Water requirement is the inverse of water use efficiency. Viets confined his definition of water use efficiency to the ratio of plant production to ET measured on the same area.[2] Tanner and Sinclair summarized some early studies and defined water use efficiency as the biomass of water accumulated per unit of water transpired and evaporated per unit crop area.[1] Biomass is expressed as total yield or economic yield. To compare species with different chemical composition (protein vs. carbohydrate products), grams of glucose *equivalents* are used. In irrigation studies, water use efficiencies may be referring to a broader definition of water, with efficiencies comparing situations where soil water drainage, surface run-off, or soil evaporation are considered. These types of water use efficiency are not included in this discussion.

WATER USE EFFICIENCY ON AN EVAPOTRANSPIRATION BASIS

Water use can be defined per unit of evapotranspiration (ET), and under field conditions, this is more practical than the narrower definition using just transpiration. Measures of ET integrate both soil and crop factors for the season, which confound the respective efficiencies of the plant and soil evaporation. Timing and frequency of irrigations and rain, the soil type and plant or mulch cover can affect soil evaporation. The transpiration part of ET use is a measure of crop performance.

WATER USE EFFICIENCY ON A TRANSPIRATION BASIS

Another definition of water use efficiency is in terms of transpired water only. Measuring the transpiration component is hard to do in practice, as it is difficult to prevent soil evaporation. Deep soil drainage also needs to be measured or prevented. It is only possible to measure transpiration on an experimental basis with the use of weighing lysimeters. Typically, the lysimeter is a large pot in the greenhouse and may weigh up to 80 kg. The lysimeter is weighed frequently over the crop season, and known quantities of water are added which is, both costly and limits the practical size of the trial. When extended to field studies (lysimeters within a growing crop), a limited numbers of comparisons are made due to the setup cost and expense of rainout facilities at sites.

TRANSPIRATION EFFICIENCY UNITS

Water use efficiency can be expressed as $g\,kg^{-1}$ of water transpired. Typical values may be 1.6–2.4 $g\,kg^{-1}$ for sunflower or around 9 $g\,kg^{-1}$ for sorghum. It can also be expressed by using a molar scale. Transpiration may be typically 1–5 $mmol\,m^{-2}\,sec^{-1}$ and photosynthetic rates for C_3 20–25 $\mu mol\,m^{-2}\,sec^{-1}$ or 40 $\mu mol\,m^{-2}\,sec^{-1}$ for C_4 plants. Hence, C_4 plants have higher transpiration efficiencies than C_3 plants.

TRANSPIRATION EFFICIENCY AND COMPARISON ACROSS SEASONS

As the evaporative demand of the atmosphere will vary from place to place and from season to season, transpiration efficiency (TE) from particular trials are adjusted for the vapor pressure deficit (VPD) of the atmosphere:

$$Y/T = k/(e^* - e_i)$$

where Y is the yield, T, the transpiration, k, the transpiration coefficient, e^*, the saturated vapor pressure, and e_i, the vapor pressure of the atmosphere.[1] The coefficient (k) is estimated as 9 kPa for sorghum.

Typically, a mean value of VPD for hours of daylight over the stress period season can be used. The mean daily value of the 9.00 hr VPD and VPD at the time of maximum temperature can been used to compute a seasonal VPD over the stress period.[3]

INSTANTANEOUS TRANSPIRATION EFFICIENCY MEASURED AT AN INDIVIDUAL LEAF LEVEL

Transpiration and photosynthesis measured by using a canopy gas exchange system are used to compute an instantaneous measurement of TE at the leaf level. This rarely correlates with TE computed for a season as there are many processes integrated within the plant alone and over the cropping season.

Water use efficiency is the molar ratio of CO_2 uptake (A) to transpiration (E) and can be written as

$$A/E = (c_a - c_i)/1.6\Delta_w$$

where c_a is external and c_i is the internal partial pressure of CO_2, respectively. Δ_w is the leaf-air VPD.[4]

This shows that the internal partial pressure of CO_2 is linked to water use efficiency.

PHYSIOLOGY OF TRANSPIRATION EFFICIENCY

C_3 and C_4 plants vary in TE as the carboxylation pathways give rise to different efficiencies.[5–7] C_4 plants such as maize and sorghum, have higher transpiration efficiencies than C_3 plants. Legumes have a lower TE than cereal crops due to the metabolic cost of symbiotic N fixation. Variations in TE for wheat correlate with carbon isotope discrimination.[8] Carbon isotope discrimination (Δ) as determined on dried leaf tissue of C_3 plants has shown to be correlated to TE. This is useful, but is not necessarily practical as carbon isotope discrimination is a costly measurement and therefore not ideal as a selection criterion. Progress has been made in C_3 crops, towards obtaining a selection index for high TE lines. In peanut, the carbon isotope discrimination was linearly related to the specific leaf area of the leaves. Thus, a surrogate for Δ is available and has been used to breed high TE lines.[9]

ENVIRONMENTAL INFLUENCES ON TRANSPIRATION EFFICIENCY

Water Deficit Effect

Under moderate water deficits, TE increased in grain sorghum.[3,10] Leaf area index is irreversibly reduced under stress, cell density is maintained but cell enlargement is irreversibly affected.[11] Some plants may be able to adjust osmotically which may contribute to resistance to water deficits.

Rising CO_2

As the CO_2 concentration doubles, transpiration will decline and photosynthesis will increase.[12]

TRANSPIRATION EFFICIENCY IN DROUGHT RESEARCH

If this trait can be identified as significant and suitable selection criteria can be developed, more efficient crops will result through the incorporation of high TE lines in breeding programs. Benefits of high TE lines, anticipated from crop simulation modeling of grain sorghum, suggest a 10% increase in yield from moderate to good environments.[13] Genetic differences in TE appear to be detectable in a range of crops. The combination of C_4 productivity in marginal environments along with improved drought efficiency may have useful economic benefits in the future.

INTRODUCTION

The last few decades have seen increasing interest in enhancing, restoring, and protecting the ecology of wetlands, streams, and watersheds. Achieving these goals requires sound fundamental and applied knowledge, close interaction between scientists and engineers, a systems approach, and a good understanding of spatial and temporal scales. This entry addresses the role and importance of an active floodplain in wadeable two-stage stream systems where the active floodplain plays an important role in sustaining or establishing dynamic equilibrium. Specifically, focus is placed on the size and geometry of the active floodplain (Stage 2) relative to the size of a main channel (Stage 1) that is shaped by channel-forming discharges (Fig. 1). Consideration is also given to floodplains for modified streams and constructed channels such as agricultural ditches. The goal of this entry is to aid the reader in understanding the hydrology, hydraulics, and geomorphology of these systems and to then use this knowledge to protect or size a self-sustaining two-stage channel system.

The term channel-forming discharge is used to describe both the bankfull and effective discharge.[1] Wolman and Miller[2] defined the bankfull discharge as the streamflow that fills the main channel and begins to spill onto the active floodplain; while the effective discharge is the discharge that transports the most sediment over time. Many studies have been conducted on channel-forming discharges and recurrence interval of these flows.[1,3–5] Most studies have suggested that the recurrence interval ranges from 1 yr to more than 5 yr.[4–8] However, in recent studies in Ohio on large rivers[1] and agricultural channels,[9] the authors suggest that flows larger than the channel-forming discharges occur many times annually and the recurrence interval of channel-forming discharges is often less than 1 yr.

The terms floodplain or floodzone, floodprone area, active floodplain, and riparian zone are often considered as synonymous. This causes much confusion as each of these terms can be used to describe different locations on the landscape (Fig. 1) and only occasionally will all these locations coincide with each other. A floodplain or floodzone could be associated with any point on the landscape and is associated with a human concern related to flooding. Rarely are these areas totally flat (as the term plain suggests), and rarely when considering dynamic equilibrium are we concerned with points that are only inundated by very infrequent events (recurrence interval of many hundreds of years). In the Rosgen[10] stream classification system, the width of the floodprone area is measured at an elevation above the thalweg that is twice the maximum bankfull depth. It is one of the several factors used in this classification system and is not related to a specific recurrence interval flow. An active floodplain is associated with flows that exceed the channel-forming discharges. However, if these flows do not immediately spill out onto the active floodplain, then the main channel is described as incised or entrenched. A problem

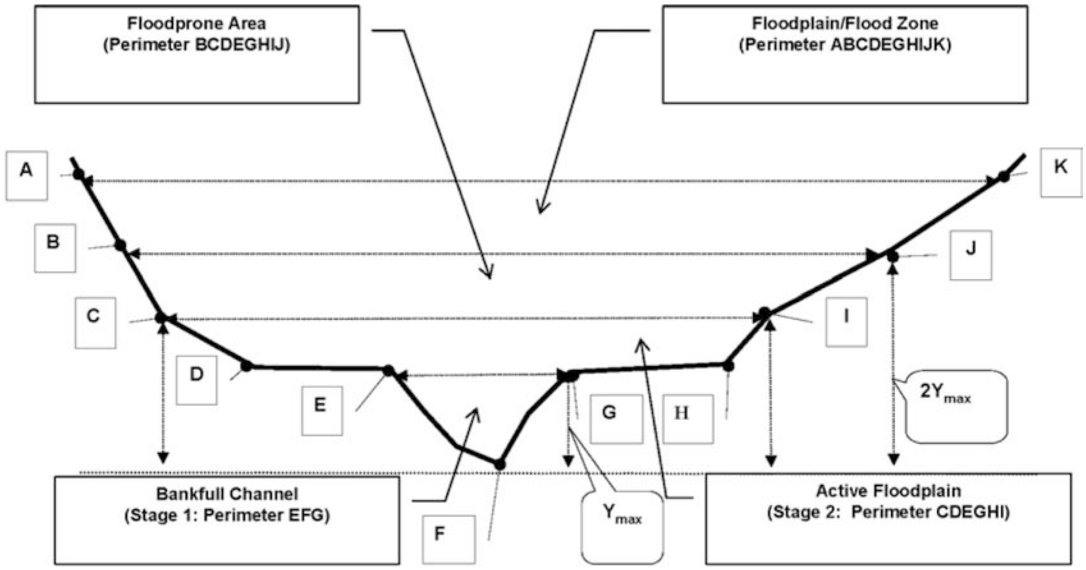

Fig. 1 Illustration of differences between a floodplain, floodprone area, and active floodplain.

with the term active floodplain is that there is no upper limit to the depth or size of the area described by this term. The word riparian means riverbank, so a riparian zone is a piece of land located on the banks of a channel. In the United States, the term riparian zone is generally used to describe areas (such as forests, grasslands, and wetlands) that are beneficial to the riparian ecosystem and function as natural biological filters.

PROCESSES IN CHANNEL SYSTEMS

Dynamic Equilibrium

Flowing water exerts a force on the bed and banks of a channel. If this force exceeds the resistance of the bed and banks to this force, then geomorphic works occur and there is a change in the channel geometry or bed slope. At any point in time, a channel system might be in dynamic equilibrium, failing or recovering. Lane[11] stated that dynamic equilibrium exists between stream power and the discharge of bed material sediments:

$$Q_s d \propto QS \tag{1}$$

where Q_s is the sediment discharge, d is the median sediment size, Q is the discharge, and S is the bedslope. In the context of Relationship 1, if Q exceeds the channel-forming discharge, then equilibrium is achieved if much of the excess stream power, QS, is dissipated across an active floodplain. Sediment transported in a channel might consist of suspended load and bedload. In low-gradient channels, the suspended load might be 95% or more of the total sediment load, while in steep upland channels more than half of the sediment load might be bedload. Sediment movement can be related to a critical shear stress at which particles begin to move, a total sediment transport rate, to discharge or stream power, and numerous bedload transport functions. The average shear stress, or tractive force, on the bed of a straight reach, can be estimated by:[12]

$$T = 1000YS \tag{2}$$

where T is the tractive force (kg force/m^2), Y is the flow depth (m), and S is the bedslope (m/m). Lane[11] found that a tractive force of 1 kg force/m^2 would move bed material with a mean particle size of about 10 mm. The average shear stresses on the banks of a straight channel can be approximated to be about 80% of the bed shear stresses.[13] Eq. (2) is based on several simplifications and is not always consistent with observations. Many scientists have studied and proposed enhancements to tractive force concepts.[14]

If the stream power, for discharges larger than the bankfull discharge, is not dissipated across an active floodplain, the bankfull channel will downcut and/or widen. This creates a domino effect as it will now take larger and larger flows to first fill the channel and to then spill out onto the active floodplain; the channel system is then said to be in a degraded or a failing mode. At some point, a potential might occur for aggradation and/or the building of a new active floodplain, at this point there is potential for channel recovery. Simon[15] presents a channel evolution model that outlines how unstable systems might adjust to achieve equilibrium.

The classic work of Trimble[16] describes how sediment budgets and channel geometry changed for Coon Creek, Wisconsin, during a period of more than 130 yr. His work shows why in evaluating a channel system, it is necessary to consider the interaction between landscape processes and within stream processes. Channel-forming discharges and the geometry of the bankfull channel are a function of many factors, including the drainage area, land uses, watershed topography, sediment supply and transport, within stream and riparian vegetation, the resistance of the bed and banks materials to shear, bedslope, and attributes of the active floodplain such as the geometry and resistance to flow. Spatial and temporal changes in these factors add complexity to an accurate assessment of their effects on the stream system. Montgomery and MacDonald[17] outline a diagnostic approach to making stream assessments. Powell et al.[18] describe a weight-of-evidence approach for sizing a two-stage channel system in agricultural ditches in the Midwest Region of the United States.

Channel-Forming Discharges

Usually, channel-forming discharges cannot be easily measured. Therefore, they are based on calculating either the bankfull discharge based on stream geomorphology measurements or the effective discharge based on measured or estimated sediment and discharge data. Bankfull discharge is calculated based on measuring bankfull features and then using a resistance equation such as Manning's equation or the Darcy–Weisbach equation to calculate the mean flow velocity and discharge.[19] In the United States, survey procedures similar to those described by Harrelson, Rawlins, and Potyondy[20] are commonly used to make the geomorphology measurements. Measurements are made along reaches that are at least 20 times the bankfull width and include measuring bed elevation, water depth, the elevation of bankfull features, azimuth at points of discernable change in geomorphic features in the channel system, cross-section geometry, and bed materials sizes.

Regional curves that relate bankfull attributes and drainage area are often used as an aid in assessing stream morphology. Doll et al.[21] state that regional curves are especially useful in stream restoration projects, where the identification of bankfull features is critical to the design of a stable system. Powell et al.[18] use regional curves as one of the factors in their weight-of-evidence approach. However, regional curves should be used with caution and only provide a general indication of the bankfull geometry. The variability that might occur is illustrated in Fig. 2 where bankfull width measurements versus drainage area are reported for the Olentangy and Upper Scioto River watersheds in Ohio.

The effective discharge is determined from an analysis of suspended or bedload obtained from long-term records or predicted by using sediment transport equation. Approaches for calculation of the effective discharge from measured data are widely published.[1,3] The most common approaches use the Wolman–Miller model.[22] An approach for estimating the effective discharge based on using the Meyer–Peter–Muller bedload transport equation is incorporated in the *Spreadsheet Tools for River Evaluation, Assessment, and Monitoring* (STREAM) modules.[23]

ACTIVE FLOODPLAIN REQUIREMENTS

Channel Hydraulics and Characteristics

Turbulence, vertical vorticity, secondary flows, reverse, and lateral mixing of flows on the floodplain and within the main channel, together with the associated sediment transport and shear stress differences that occur particularly within a meandering channel make the analysis of the system complex. Useful accounts of different approaches are presented in Shiono, Al-Romaih, and Knight[24] and Patra and Kar.[25] Applying resistance (roughness) equations, such as Manning's equation, to compound straight two-stage channels presents a challenge, particularly with low over-bank flow. As the stage initially rises above bankfull, there will be an increase in the wetted perimeter, little change in cross-sectional area, and a decrease in hydraulic radius results in a discontinuity in velocities estimated by Manning's equation. Another problem is accounting for the interaction between the slower over-bank flows with the faster main channel flow.

Posey[26] evaluated a number of commonly used resistance equation methods. He concluded that dividing the main section and two over-bank sections by vertical lines worked well when over-bank flow is shallow, but when over-bank flow is at least half as deep as the bankfull channel depth, then dividing into subsections is not necessary. The method incorporated in the STREAM tools gives similar results to the methods suggested by Posey in the desired respective ranges. The problem of momentum transfer between sections is managed by dividing the sections by "virtual" banks that are perpendicular to lines of equal shear. Also, the hydraulic radius is based on only the physical boundaries of each section and is weighted by the area of each section. Flow velocity is estimated by using Manning's equation with different roughness factors assigned to the main channel and the flood plain. This method is an inexact approximation of the complex hydraulics of a two-stage meandering channel and is only intended to provide estimates of relative values, not to predict actual bedload transport.

Active Floodplain Minimum Size Requirements

Recently in the United States, many local, county, and state organizations have expressed an interest in establishing streamway setbacks to help protect stream systems, particularly in urbanizing watersheds. These efforts are hampered by a lack of published information on how to size active floodplains and streamway setbacks to sustain dynamic equilibrium.

Williams[27] proposed that meander beltwidth (B, m) and the bankfull width (W, m) are to be estimated as follows:

$$B = 4.3W^{1.12} \tag{3}$$

where beltwidth is the width within which a channel moves during a snapshot in time. To account for meander migration over time, we recommend that natural streams be provided a streamway width that is calculated by increasing the coefficient of 4.3 to at least 6.5. This recommendation is based on stream surveys and the use of orthophotos to evaluate meander patterns and meander migrations for several streams in Ohio. For most wadable streams, this approach will estimate a streamway width that is 7–12 times the bankfull width. For incised agricultural ditches in the Midwest Region of the United States, the authors recommend a streamway width that is at least three times the bankfull width.[19] In those applications, the floodplain is depositional or constructed benches located in the lower part of incised ditches. These systems have very low sinuosity and much of the stability depends on the dense grass that grows on the benches and the banks.

A more process-based approach is to consider sediment transport, the shear stresses on the bottom and sides of each stage, and mean velocities in the two-stage system. The following example illustrates how changes in the active floodplain geometry influence these factors. An analysis was performed on an incised trapezoidal channel that is typical of many large agricultural ditches in the Midwest region of the United States (Fig. 3A and 3B). An analysis was performed for a hypothetical 10 km^2 drainage area and a channel with a bedslope of 0.5%. The bed width was 4 m, the side slopes of the main channel were 2:1, the depth of the incised trapezoidal channel was 3 m, and the initial top width of the second stage was 16 m. For simplicity, it was assumed that the bankfull channel had vertical side slopes. Discharge versus recurrence interval relationships were estimated using an empirical procedure, based on streamflow data that was developed by Sherwood[28] for urban areas in Ohio. The basin-development factor (BDF), which is a measure of urbanization in the equation, was set to zero to represent rural conditions. The mean particle size of the bed material was 40 mm. An evaluation was made with Manning's n values of 0.03, 0.045, and 0.06 for the active floodplain.

Shear stresses were calculated using Eq. (2). Bedload transport was determined using the method in the STREAM tools.[23] The two-stage system was proportioned, between the floodplains and the main channel, using the approach described by Posey.[26] Flow velocities and flow depths were determined using Manning's equation. A floodplain ratio (FPR) was

Tailwater–Virtual

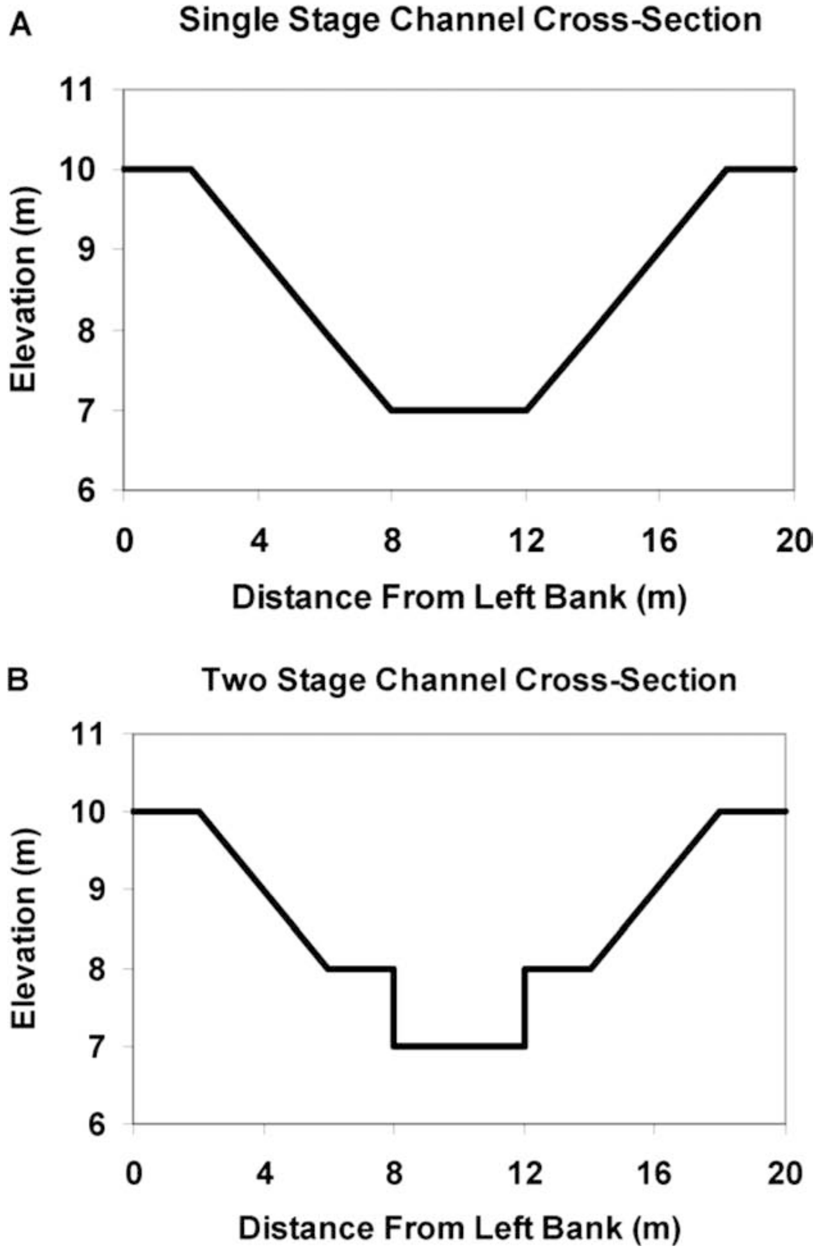

Fig. 3 (A) Single-stage channel geometry used in the process analysis example. (B) Two-stage channel geometry used in the process analysis example.

used to evaluate different active floodplain widths. The FPR was defined as the floodplain width, at the bottom of the second stage, to the bankfull width, which is the channel width at the top of the first stage. The depth of the bankfull channel was 1 m and depositional benches formed to give an FDR of 2 (Fig. 3B). FDR values greater than 2 required widening the second stage of the channel. Shear stresses, total annual bedload transport, and hydraulic properties were related to the bankfull discharge, of $7.2\,m^3/s$, or to the 25 yr recurrence interval flow of $41\,m^3/s$.

A summary of the results is presented in Table 1. For the scenario where small depositional benches (FPR = 2) have developed, there is a 20% increase in the shear stresses in the main channel and an 80% increase in bedload transport when compared with the single-stage channel (FPR = 1). This trend is consistent with our observation in agricultural ditches. The formation of benches and an inset channel (the bankfull channel) results in coarser substrate and a self-flushing system with reduced or non-existent aggradation.

Of particular note is that flows on the floodplain cause shear stresses on the banks of the second stage that are much less than with the single-stage scenario with no floodplain. Even with high roughness on the floodplain (n of 0.06), the mean bank shear stresses in the second stage are lower than they were for the single-stage trapezoidal channel (FPR of 1).

Table 1 Summary results for channel system analysis

		Floodplain $n = 0.03$		Floodplain $n = 0.045$		Floodplain $n = 0.06$	
System Attributes	**Units**	**Channel**	**ActiveFP**	**Channel**	**ActiveFP**	**Channel**	**Active FP**
Bankfull Channel							
Mean velocity	m/s	1.8

Mean velocity	m/s	2.1	1.6	2.2	1.2	2.2	1.0
Max depth of flow	m	1.5	0.5	1.7	0.7	1.8	0.8
Shear stress	kg/m^2	7.7	2.7	8.4	3.4	8.9	3.9
Bedload transport	m^3/yr	51		56		60	
FPR = 13							
Mean velocity	m/s	2.1	1.4	2.1	1.1	2.2	0.9
Max depth of flow	m	1.4	0.4	1.5	0.5	1.6	0.6
Shear stress	kg/m^2	7.2	2.2	7.7	2.7	8.2	3.2
Bedload transport	m^3/yr	48		52		55	

[a]Annual bedload transport is only in the main channel that extends up into the second stage based on Posey partitioning approach. *Source*: From Ref.[26].

For an FPR of 3, the depth of flow, for the 25 yr RI discharge, is at twice the maximum bankfull depth and corresponds to the floodprone area described by the Rosgen classification system.[29] However, the floodplain is undersized to provide the meander pattern that might be expected. An FPR of 5 reduces the shear stresses and velocities of flow in the main channel to values that are similar or less than those in the single-stage trapezoidal channel (FPR of 1). An FPR of 9, and high floodplain roughness, provides lower values than the single-stage channel for all attributes except bedload transport. As might be expected, further increases in the FPR will continue to provide gradual improvements in the system attributes. However, based on these illustrations and other studies by the authors (not shown), it appears that an FPR between 5 and 10 is needed to obtain a self-sustaining system. This is consistent with the empirical approach presented earlier.

DISCUSSION

This entry is not intended as a guide to restoration. Useful discussion on that topic is provided by Shields et al.[30] Procedures that are helpful in stream channel design are present in a new handbook.[31] It is recommended that a bank stability analysis be performed as many channel systems fail owing to mass wasting. A useful tool is the freely available USDA-ARS bank stability model.[29]

In this entry, we have not addressed ecological issues or the debate on designing bankfull channels. Where possible, we recommend an ecological engineering or naturalization approach. Useful discussions on these topics are provided by Palmer et al.[32] and Herricks and Suen.[33] Application of these approaches reduces the amount of initial engineering of the system and focus on assisting nature in developing a more self-sustaining system. We conclude that an important consideration in most stream projects is the availability of an active floodplain. Simple and complex tools, such as the STREAM tools[23] or HEC-RAS,[34] to evaluate two-stage systems on a case-by-case basis are freely available from organizations in the United States.

The approaches described in this entry are relatively simple and represent a minimum level of analysis that should be performed if modifications or protection strategies are proposed for a stream system. Ideally, active floodplains should have FPRs greater than 5 though smaller floodplains will have some beneficial influences on the sustainability of channel systems.

Uptake by Plant Roots

S.G.K. Adiku
Department of Soil Science, University of Ghana, Accra, Ghana

INTRODUCTION

The study of water uptake by plant roots dates as far back as 1727 and continues to attract a great deal of research attention in many disciplines such as botany, agronomy, soil science, meteorology, and hydrology. This is because water flow through the soil–root–stem–leaf pathway to the atmosphere is a major component in the hydrological cycle. Water uptake by plant roots may be defined as the unidirectional transport of water from the soil to the root. Other terms used in the literature to describe the same phenomenon include root water absorption and root water extraction. Water taken up by the entire root system forms the transpiration stream and is terminated by the loss of water vapor from the stomata of leaves to the atmosphere. Many texts have presented details on the mechanisms of root water uptake. A popular view held is that the main mechanism of root water uptake involves a passive transfer of water along a water potential gradient from the soil to the root, whereby the plant simply behaves as a "wick" and plays no role in the uptake process. However, more recent observations suggest that the plant itself plays a role, especially, in determining the patterns of water uptake. Conceivably, an active water uptake may be possible, but strong scientific evidence is still lacking. This article presents a discussion on the subject of root water uptake with emphasis on divergent views regarding the understanding and interpretation of observations. Some areas requiring further research are identified.

BACKGROUND

A survey of the literature shows that research on root water uptake may have formally begun in 1727 with Hales' investigations into the height of rise of water in plant root–stem pathway during transpiration.[1] Many studies on plant water uptake followed, focusing on single aspects such as flow of water into roots, water flow through the stem, or the evaporation from leaves as separate processes, which were hardly interrelated. The unified concept of soil–plant–atmosphere continuum (SPAC), however, recognized the transport of water from the soil through the root–stem–leaf pathway to the atmosphere as a continuum, and emphasized the interrelationship between the various aspects, enabling a holistic study of the phenomenon.[2]

Water uptake by plant roots is determined by evaporative demand of the atmosphere, plant factors such as the root system and soil water conditions. Observations indicate that uptake is generally favored in wet zones of the soil, where both water potential and hydraulic conductivity are also high.[3] But the role of the plant in determining water uptake has been unclear. Subsequently, the debate on root water uptake in the 1970s had centered on whether the plant or soil factors dominated water uptake.[4] The question still lingers on whether or not a plant simply behaves as a "wick" that only passively transmits water from the soil via the soil–root–stem–leaf pathway to the atmosphere. Indeed, the other terms used to describe the phenomenon such as root water *absorption* or root water *extraction* seem to suggest that the plant "makes" some effort involving forces or an expenditure of energy to obtain water from the soil.

Structural Aspects of Roots

Roots are the main organs of water uptake. They consist of a collection of cells specialized in different functions.[5] A schematic representation of the longitudinal and transverse sections of a root is shown in Fig. 1. Water may enter the root through two main paths: 1) through the root hairs, which are outward projections of the epidermal cells (Fig. 1B) and 2) between the epidermal cells. The root hairs, in particular, greatly increase the surface area across which water and nutrients enter the roots of plants.

Once water enters the roots, the upward transport to the stem and leaf is via the xylem vessels (Fig. 1B) which have lignified secondary walls but contain no protoplasm. These vessels are arranged end-to-end and the end walls between the individual members are perforated and therefore serve as low-resistance conduit for upward water transport from the root via the stem to the leaves.

The roots of the plant are often highly branched, intertwined and colonize the soil in three dimensions. This is referred to as the root system. The spatial distribution of the root system is determined by an interplay between the intrinsic development of the root

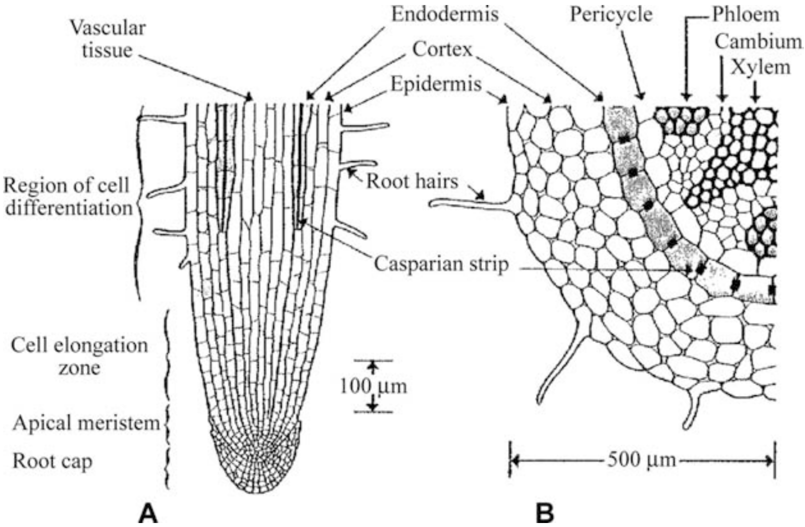

Fig. 1 Schematic diagrams of a root: (A) longitudinal section, indicating the zones that can occur near the root tip, and (B) cross-sectional view approximately 10 mm back from the root tip, indicating arrangements of various cell types. *Source:* From Ref.[5].

system, and external abiotic stimuli such as soil water distribution, soil strength, and nutrient distribution. Lateral root growth is stimulated within water- and nutrient-rich zones of the soil,[6] which many researchers have attributed to the nutritive role of the nutrients. However, it has recently been shown for a small weedy plant, *Arabidopsis thaliana*, that nutrients such as NO_3^-, apart from the nutritive role also act as environmental signals detectable by genes located in the root of the plant.[7] This suggests that the plant is able to detect preferred zones of root growth and can therefore ''influence'' the growth pattern of the root system. Root growth, water and nutrient uptake are, therefore, strongly interdependent and should ideally be studied together.

Mechanisms of Root Water Uptake

It is the popular view that water transport from the soil to the root is in response to a water potential gradient between the soil and the root surface. It is often observed that the water potential declines progressively from the soil through the root–stem–leaf–atmosphere pathway. Typically, the water potential at the soil–root interface of a well-watered soil would lie in the range between -30 kPa and -100 kPa, while that of the intercellular spaces within a leaf at a height of 10 m above the ground may be as low as -1720 kPa.[8] The water potential of air with a relative humidity of about 78% is as low as $-37{,}800$ kPa. Water would, therefore, flow spontaneously from the soil to the root and eventually to the atmosphere, with the plant itself being passive in the uptake process. Such a passive water uptake process requires a continuous column of water in the root–stem pathway, and this is possible up to 10 m due to the cohesive strength of water.[9] However, the fact that water uptake and transpiration continue in plants much taller than 10 m even under dry soil conditions when the water column can be broken by gas molecules, suggests the involvement of an alternative or a complimentary uptake mechanism.

When soil water is limiting, it is known that plants may influence transpiration through physiological changes such as the rolling of leaves which reduces the surface area for transpiration. Also, roots shrink when soil dries, reducing the area of contact between the roots and the soil,[10] and thereby increasing the resistance to the flow across the root surface and minimizing the loss of water from the roots to the soil (the so-called *reverse flow*). These observations indicate that the plant is able to influence indirectly the water uptake and transpiration processes. But, whether the plant can directly determine uptake, thereby providing a basis for an active uptake mechanism is yet to be proven scientifically.

Patterns of Root Water Uptake

Water uptake patterns vary both temporally and spatially. On the temporal scale, uptake varies both diurnally and seasonally. Uptake rates are low in the morning, rise to a peak in mid-afternoon, and decline to zero at night. As for the diurnal variation, uptake rates are low during the early stages of plant growth and reach a peak when the plant is fully established. In many annuals, peak uptake rates often coincide with the onset of the reproductive stage of the plant, when rooting depth and the leaf area index are at their maximum values.

The spatial patterns of root water uptake have been studied extensively over the years, yet views continue to differ, especially regarding the role of root system distribution in determining water uptake patterns. Whereas one school of thought[11] holds the view that root distribution is not an important determinant of water uptake patterns, others[12] are of the view that the spatial distribution of roots has substantial influence on the water uptake patterns.

An important study on water uptake patterns by peach trees, however, provides the much-needed insight into the role of root distribution on water uptake patterns.[13] It was observed that the initial pattern of water withdrawal followed that of root distribution, with more water withdrawn from the top sections of the soil where there were more roots. As the top sections dried out, more water was withdrawn from the deeper sections of the soil where the roots were fewer but the soil was wetter. In the latter case, the uptake pattern did not have any resemblance to the root distribution. It is thus quite clear that whereas both views on the role root distribution on water uptake may have experimental support, neither has general validity. It may also be concluded that even though roots may extend throughout the soil volume, they may not all be active at all times, suggesting that the plant may be capable of "activating" different sections of the root system at different times, depending on soil wetness. But, it is not clear what factors determine the uptake of water by plant roots. How does the plant root system distinguish between a wet or dry zone and how does the plant determine which parts of a root system to activate at a particular time?

Direct answers to these questions are lacking, thus, requiring further research. Even though hormones such as cytokinins and abscicic acids have been isolated from plant roots and are important in determining plant water status, their roles in determining water uptake patterns is unclear. Conceivably, plant roots may also possess *drought-detecting* genes, just as nutrient-detecting genes were isolated from the roots of the weedy plant *Arabidopsis thaliana.* The isolation or identification of such *genes* and a clear understanding of the way plant hormones control them remain crucial to the understanding of the role of the plant itself in determining water uptake patterns.

CONCLUSION

Water uptake by plant roots has and still continues to be an important interdisciplinary research subject. Although a lot of research has been done, much remains to be understood about the process of water uptake by plant roots. In particular, the role of genes in detecting drought and the way they are controlled by hormones merit further research.

Uptake by Plant Roots: Modeling Water Extraction

S.G.K. Adiku
Department of Soil Science, University of Ghana, Accra, Ghana

INTRODUCTION

A great deal of current research on plant-water uptake focuses on modeling water extraction due to the increasing use of such models for crop and water management. The art of modeling root-water extraction is, however, limited by the level of understanding of the processes involved in the phenomenon. Though research on root-water uptake is not new, the lack of complete understanding of the process of root-water extraction has led to the publication of many root-water extraction models as researchers' views on process description differ in detail and scope. By 1981, as many as 18 published models were reviewed.[1] The number of root-water uptake models keeps increasing, especially, due to the increased interest in crop modeling. However, comprehensive models that have wide scope of validity and applicability are still lacking, despite the increased research efforts. This article discusses the concepts behind some of the most common extraction models and seeks to harmonize divergent views where possible. Also, this article presents and discusses a new approach to modeling root-water extraction.

BACKGROUND

Water flow through the soil–root–stem–leaf pathway is a major component of the hydrologic cycle. Every year, about 710 mm of rain falls globally on the soil of which about 57% evaporate back to the atmosphere, often due to plant extraction.[2] A quantitative study of the root-water extraction process cannot be overemphasized as this forms quite a large and important component of the water cycle.

Among the first researchers to describe root-water extraction mathematically was Gardner, who formulated the extraction as a water flow problem from the soil to a single long cylindrical root.[3] This approach, which has become known as the single root model, is also described as microscopic or Type I model.[4] Conceptually, the root-water extraction is considered as a passive process, with water flowing from a region of high to low water potential. But the extension of this model to the complex real root system, where the root architecture and distribution changes in both time and space has met with difficulties.[5] Furthermore, difficulties in measuring and parameterizing the microscopic model have led to the proposal of another class of extraction models that relate extraction to a more easily measurable or predictable soil property, such as the soil water potential.[6] The latter type of models have been described as macroscopic and classified as Type II.[4]

Irrespective of the type of approach, there is a question as to whether or not a plant simply behaves as a mere "wick" that only passively transmits water from the soil via the soil–root–stem–leaf pathway to the atmosphere. If the role of the plant in determining water extraction is not to be ignored, how then would it be formulated quantitatively? A further issue of controversy is the role of root distribution in determining uptake patterns. Opinions are divided, with some researchers indicating that extraction patterns follow root distribution,[7] while others believe otherwise.[6] Apparently, the lack of complete understanding of the phenomenon of root-water extraction continues to be a major handicap to the formulation of root-water extraction models of wide applicability.

Microscopic Water Extraction Models

The microscopic single root model[3] considers the root system that comprises a collection of single long cylindrical roots each surrounded by a soil cylinder (Fig. 1). By using the cylindrical coordinate system, the radial flow of water from the surrounding soil to the root cylinder can be formulated as[3]

$$\frac{d\theta}{dt} = \frac{1}{r}\frac{d}{dr}\left(rk(\Psi)\frac{d\Psi}{dr}\right) \tag{1}$$

where θ is the soil water content, r the spatial coordinate, Ψ the soil water potential, k the hydraulic conductivity, and t the time. A solution of this water flow problem can be obtained under the appropriate boundary conditions, leading to the estimation of the water uptake per unit root length and time at soil depth z, q_z ($m^3\, m^{-1}\, sec^{-1}$), as

$$q_z = 4\pi k \frac{(\Psi_{zs} - \Psi_{r_z})}{\ln \frac{c^2}{r_1^2}} \tag{2}$$

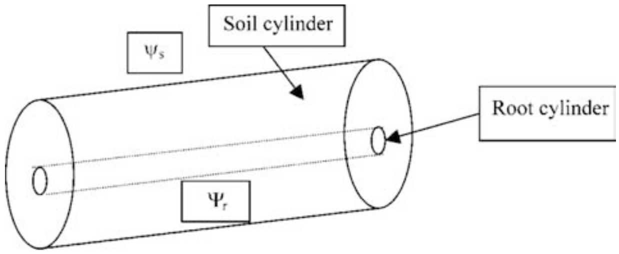

Fig. 1 Schematic representation of the single root model.

where Ψ_s is the soil water potential, Ψ_r the water potential at the soil–root interface, r_1 the root radius, and c the path length or one-half the distance between two roots.

The single root model has been used extensively in the literature to model water extraction. To account for the role of the plant, further development of the model is necessary. Noting that not all roots of a root system are active in water extraction at all times,[8] then the root-water potential may not be constant along the entire length of each root. Some researchers have shown that variations of the root xylem potential with distance from the base of the root can indeed be calculated,[5] but the mathematical formulations are not only complex but the computer implementation is also cumbersome.[9]

Generally, when root distribution is considered as an important factor in determining water uptake patterns, then extraction is weighted towards soil sections with more roots,[7] even though this is not entirely correct since water uptake patterns do not always follow root distribution.[8,10]

Macroscopic Water Extraction Models

A typical macroscopic water extraction model is formulated by establishing a simple often empirical relation between the extraction at a given depth and the soil water potential at that depth z,[6] e.g.,

$$S_z = \alpha(\Psi) S_{\max,z} \tag{3}$$

where S_z is the uptake from depth z (sec^{-1}), $S_{\max,z}$ the maximum water extraction from depth z for no-stress conditions, and $\alpha(\Psi)$ the non-dimensional stress response function equivalent to the ratio between the actual extraction S_z, and the maximum uptake $S_{\max,z}$. The factor $S_{\max,z}$ is related to the potential transpiration, T_p (m sec^{-1}) of the plant by

$$S_{\max,z} = \frac{T_p}{z_r} \tag{4}$$

where z_r is the root depth (m). The basic concept of this model is that each rooted depth makes an equal contribution to the total plant uptake, irrespective of the number of roots at that depth. This model, therefore, predicts equal extraction from each rooted depth even under uniformly wet soil conditions, contrary to the observations that extraction indeed follows root distribution under such conditions.[8] In view of this, some researchers have introduced factors that are used to discriminate uptake in relation to root distribution.[4]

Macroscopic water extraction models are easier to parameterize and have found practical applications for crop and water management and incorporated into many crop models. But after an extensive review, it was concluded that these types of models seem to work only for the particular circumstances for which they were developed, and their extrapolation to other conditions is limited.[2]

A New Concept for Modeling Root-Water Extraction

The need to develop root-water extraction models with wide applicability has led to the re-examination of the subject of modeling root extraction. A new concept of energy minimization was proposed as the basis of modeling root-water extraction.[11] The *minimum energy* hypothesis assumes that root-water uptake involves energy expenditure which is related to the action of the plant, and that the plant, as a survival strategy seeks to minimize the overall energy expenditure. The concept generally accepts the validity of Eq. (2), but further proposes that the role of the plant can be expressed in terms of the energy expenditure.

The examination of Eq. (2) indicates that water flow from the soil to the roots at any depth requires that there is a potential gradient towards the root. This drop in potential, $\Delta\Psi(=\Psi_s - \Psi_r)$ is the work done per unit quantity of water transferred across the potential drop. The root-water uptake process must therefore involve energy expenditure by the plant. To formulate the energy expenditure, q_z in Eq. (2) is expressed first as the rate of water uptake per unit volume of soil at depth z, Q_z (m^3 m^{-3} sec^{-1}) $= q_z. Lv_z$; where Lv_z is the local root density (m m^{-3}). The value of Q_z can also be easily converted to the uptake rate per unit soil area, U_z (kg m^{-2} sec^{-1}) as

$$U_z = Q_z \rho_w dz \tag{5}$$

where ρ_w is the density of water. The rate of energy expenditure in extracting water at any depth, dE_z/dt can then be obtained as the product of U_z and the potential drop, yielding

$$\frac{dE_z}{dt} = U_z(\Psi_{z_s} - \Psi_{r_z}) \tag{6}$$

Tailwater–Virtual

With the potentials expressed in $\mathrm{J\,kg^{-1}}$, the unit of Eq. (6) is $\mathrm{W\,m^{-2}}$, which is clearly the unit for the rate of energy expenditure. The total rate of energy expenditure in extracting water from the entire root zone of the soil profile, z_r, can be calculated as

$$\int_0^{z_r} \frac{dE_z}{dt}\, dz = \int_0^{z_r} U_z(\Psi_{zs} - \Psi_{r_z})\, dz \qquad (7)$$

If the plant minimizes energy expenditure during water uptake, then root-water uptake phenomenon can be considered as a minimization problem. The constraints for this minimization problem can be derived by considering that the actual uptake from a given depth, say r_z ($\mathrm{m^3\,m^{-3}\,sec^{-1}}$), can be zero when the roots at that depth are temporarily non-active, and its maximum value will be Q_z ($\mathrm{m^3\,m^{-3}\,sec^{-1}}$). The actual rate of energy expenditure in extracting water at depth z will then be, say $e_z[=r_z\rho_w\, dz(\Psi_s - \Psi_r)]$. To minimize the total rate of energy expenditure, then the summation of e_z over z_r must be less than any other energy summation calculated over the whole rooted profile. Furthermore, the summation of $r_z\, dz$ over all rooted layers cannot exceed the total transpiration rate. An objective function can, therefore, be formulated that minimizes the total energy expenditure subject to the above constraints.

As can be deduced from Eq. (6), the energy required for extracting water from any depth derives from the product of U_z and the potential drop ($\Psi_s - \Psi_r$). Note that U_z is obtained from q_z (Eq. (2) whose calculation entails ($\Psi_s - \Psi_r$). Therefore, the energy expenditure in water extraction from any depth depends on the square of the potential drop, so that a slight decrease in water potential at any depth increases energy requirement at that depth considerably. The energy model can, therefore, be used to ''identify'' zones within the soil where water would be preferentially taken up in seeking to satisfy the atmospheric water demand.

The minimum energy hypothesis has received only a limited testing. A simulation of the water uptake patterns from an initially uniformly wetted soil profile during a 20-day drying cycle is shown in Fig. 2. In this simulation, a hypothetical root distribution, which declines exponentially with depth (Fig. 2A) was assumed. The measured leaf water potential data of maize during a drying cycle[12] was used as a surrogate for the water potential at the root surface. As shown in Fig. 2B, water uptake begun initially from the top

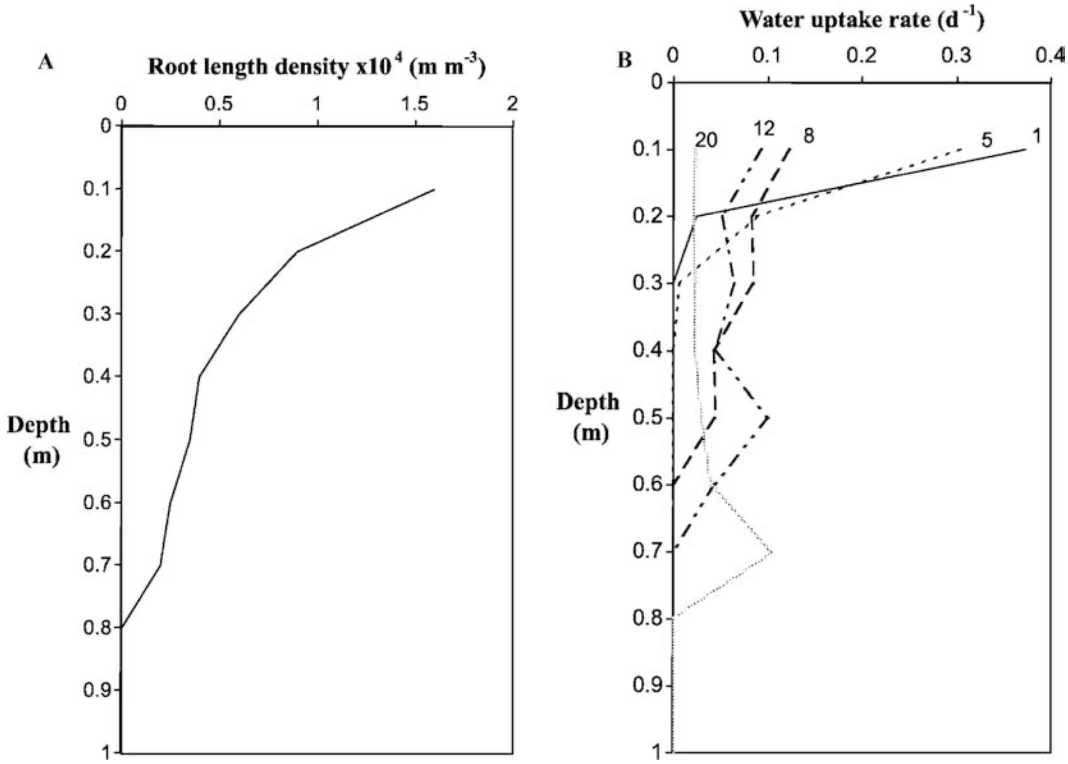

Fig. 2 Root distribution (A) and (B) simulated patterns of root-water uptake ($\mathrm{day^{-1}}$) during a 20-day drying cycle numbers on the curves: days of drying cycle).

sections of the soil (day 1). With time, more water was withdrawn from the deeper sections of the soil profile. By day 20, no water was withdrawn from the upper sections although the root distribution remained unaltered. These types of water uptake patterns are reported in the literature. An important advantage of the minimum energy model is that it avoids the need to make any prior assumptions about the root-water uptake pattern and provides a useful tool for analyzing water uptake patterns under varying soil and root distribution conditions. In its present form, the minimum energy model assumes that the root-water potential is spatially non-variant, a weakness inherent in Eq. (2). Including a spatially variable root-water potential term, however, would not negate the hypothesis, but improve the model.

CONCLUSION

Modeling root-water extraction continues to be an important research subject, as models are increasingly used for crop and water management. Although a lot of research has been done on the subject, much more research is still required to help formulate the roles of the plant and root distribution in determining uptake patterns. The concept of energy minimization is an attempt to formulate the role of the plant in water extraction. The minimum energy models is capable of simulating realistic water uptake patterns under varying soil water conditions, but further development is necessary to account for varying root-water potential.

Urban Hydrology

C. Rhett Jackson
Warnell School of Forest Resources, University of Georgia, Athens, Georgia, U.S.A.

INTRODUCTION

Since the passage of the 1972 Clean Water Act, the water quality of most United States rivers and streams has improved markedly, but urban streams have been an exception. Given the importance of flow to channel geomorphology and aquatic biota, the permanent and severe hydrologic changes wrought by urbanization make it difficult to restore good water quality conditions to previously urbanized streams.

ALTERATION OF HYDROLOGIC PROCESSES

Urbanization—broadly defined as all aspects of converting natural or agricultural land to residential, commercial, and institutional land—radically alters the hydrology of local streams, principally by reducing infiltration rates over most of the landscape. The infiltration rate is the depth of water per unit of time that can enter the soil from the surface. When infiltration rates are lowered, rainfall that formerly infiltrated into the ground and reached streams by relatively slow subsurface pathways instead runs over the ground surface, picks up pollutants spilled or applied to the ground or paved surfaces, typically enters engineered conveyance systems, and rapidly reaches streams during storms.

The influence of urbanization on local hydrologic systems can only be understood in comparison to the hydrology of natural watersheds. In a forest or grassland, soil structure and hydrologic behavior are strongly influenced by biological activity, the presence of leaf litter, and carbon accumulation from plant matter. Root growth, root decay, cracking due to freeze/thaw and wetting/drying processes, animal burrowing, the windthrow of weak trees, subsurface erosion, and other natural processes all increase soil porosity (the ratio of void space to total soil volume), the number and size of macropores, and the conductivity of the soil to water. Leaf litter on the soil surface dissipates raindrop energy and allows rainfall to drip into the soil. Relatively high organic contents of natural soils increase the stability of soil aggregates, and stable aggregates prevent soil crusting during rainfall, reduce detachment of small soil particles, and maintain high surface infiltration rates. For all of these reasons, almost all rainfall infiltrates into the ground surface except during extremely intense rainfall events. When rainfall rates exceed infiltration rates, excess precipitation runs downhill over the ground surface. This type of surface runoff is called Horton overland flow and is rare on natural upland soils.

During the process of urbanization, lands are cleared of native vegetation; slopes and soils are graded to improve the topography for building; impervious surfaces (rooftops, parking lots, roads) are constructed; and typically curbs, gutters, and storm drains are created to hasten the flow of surface water off the landscape (Fig. 1). The process of clearing and grading compacts the soil, reducing porosity and macropore density and thus decreasing infiltration rates. Urban soils typically lack litter layers and have low carbon contents, so they are susceptible to surface sealing during rainfall. Horton overland flow occurs at lower rainfall rates on these urban soils. Impervious surfaces have infiltration rates approaching zero and thus convert nearly 100% of incident rainfall into overland flow.

Forests and grasslands have high leaf area indices—the ratio of vegetative surface area to the underlying ground area—and therefore a significant portion of rainfall is captured by the canopy and evaporated before ever reaching the ground. Urbanization typically reduces leaf area indices, increasing the amount of rainfall reaching the ground. Additionally, vegetative canopies provide temporary storage of rainfall, reducing precipitation intensities at the ground surface. Between storms, some water held by soils in the natural landscape is used by plants for transpiration and the rest moves by subsurface pathways to the water table and to streams, lakes, or wetlands at the base of the slope. Depending on hillslope position and the structure of the soils, travel times through these subsurface flow paths range from days to years, as opposed to minutes and hours for Horton overland flow. Because of interception and transpiration, a significant portion of rainfall on natural watersheds evaporates before reaching surface waters. The fraction of rainfall that becomes runoff is called the yield of a watershed, and yields increase in urbanized areas because of increased Horton overland flow and decreased transpiration. Furthermore, because of reduced evaporative cooling, reductions in soil water storage and canopy cover also increase urban heat island effects.

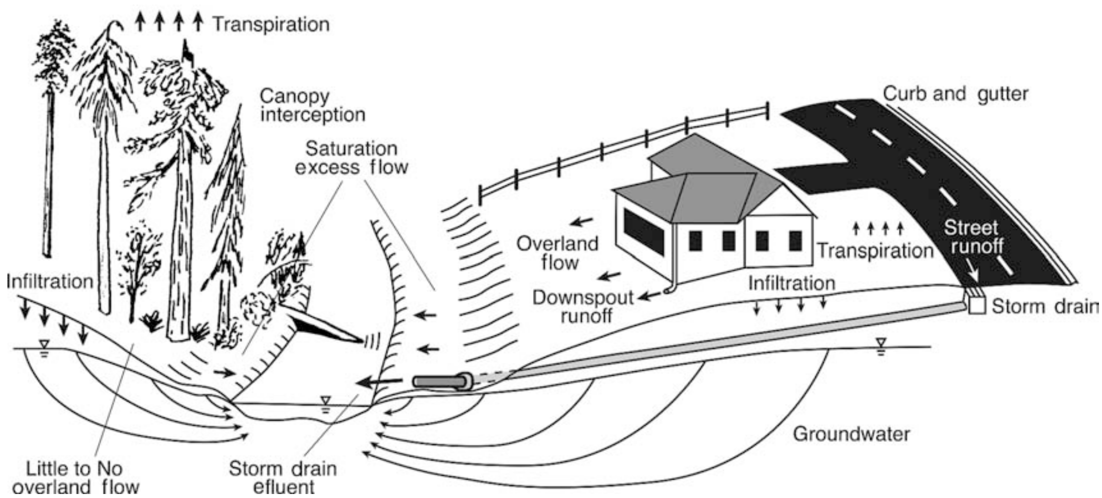

Fig. 1 Schematic illustrating multiple hydrologic changes wrought by urbanization including loss of forest cover, grading of soils, construction of impervious surfaces and stormwater conveyance facilities, occurrence of frequent overland flow, and reduced interception, infiltration, and evaporation.

Where water tables occur near the ground surface, typically at the base of slopes and around the margins of streams, wetlands, and lakes, water tables may rise to the surface during rainfall. When the soil saturates from below, additional rainfall runs over the ground surface as saturation excess flow.[1] The areas that produce saturation excess flow are called variable source areas because they expand during wet periods and contract during dry periods.[2] These areas, along with direct precipitation on channels, are responsible for stormflow response in natural basins. Urbanization has relatively little effect on variable source areas but adds impervious surfaces and compacted soils to these rapidly responding areas. Thus, in relatively small basins, stormflow volumes and peak flow rates increase almost linearly with increasing impervious surface coverage and also increase strongly with increasing coverage of compacted soil.

HYDROGRAPH EFFECTS

Within relatively small basins, the hydrologic alteration caused by urbanization can increase peak flow rates more than five times over their pre-development levels—with greater increases for frequent storm events and smaller increases for low frequency events[3]—and therefore increase flooding costs and problems. Stormflow volumes and cumulative durations of high flows also increase.[4] The additional erosive power leads to cycles of channel erosion and degradation[5,6] and to channel widening and simplification.[4,7] Channel erosion associated with flow increases in urban basins can contribute two-thirds of the sediment yield of an urban watershed.[8] These hydrologic and geomorphic alterations, along with changes in water chemistry associated with urbanization, are manifested in reduced diversity of aquatic organisms.[9,10] In addition to its direct hydrologic effects, increased percentages of impervious surfaces have been associated with increased nutrient loads and bacteria concentrations, higher summer stream temperatures, and reduced plant diversity in wetlands receiving urban runoff.[10]

Urbanization alters streamflow response to larger storms much less than the response to smaller storms because, in undeveloped watersheds, variable source areas expand and produce surface runoff over large areas during very large storms. The additive effect of impervious surfaces becomes less important during such storms (Fig. 2). Furthermore, the effects of peak flow alteration diminish going downstream as hydrograph phasing and channel routing progressively dampen flood flows as basin area increases. A city located on a large river has little effect on the large river flows; rather, it affects the tributaries draining the city into the river and also affects the river's chemical and biological quality.

Stormflows in urban streams also increase in frequency. In natural basins, when soils are dry, rainfall events are absorbed by the soils and streams respond very little. In most of the humid United States, natural streams experience very few large flows in late summer and early fall when soils are dry. Impervious surfaces provide no such buffering and produce stormflows during all rainfall events regardless of soil moisture conditions. Cumulative hydrologic alterations of an urban basin can also dramatically affect wetland hydropatterns (the time series of water levels), causing

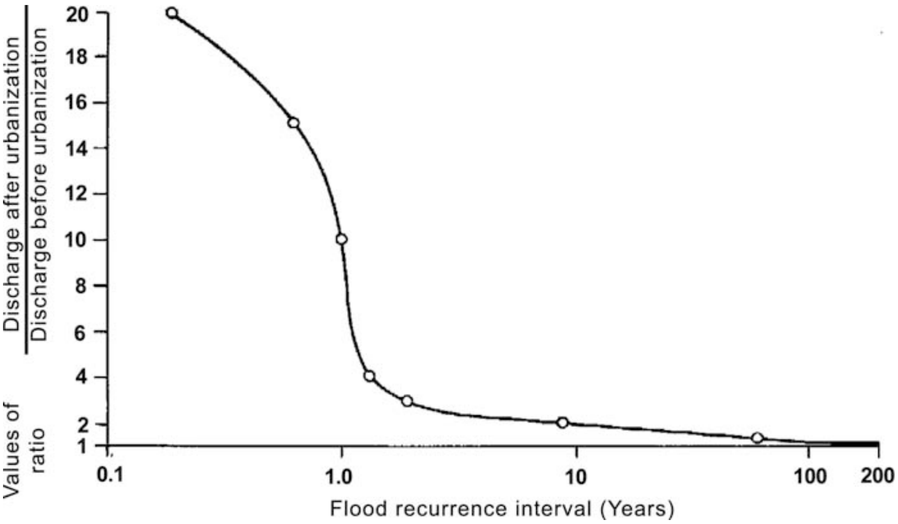

Fig. 2 Relationship between the relative increase in flood discharge due to urbanization (for watersheds with 20% pavement) and the flood recurrence interval. Urbanization has a very large effect on frequent floods and progressively less effect on large, low-frequency floods. *Source*: Graph taken from USGS (see Ref.[3]).

shifts in the composition of vegetative and amphibian communities. Urbanization reduces recharge rates over much of the landscape, thus reducing local sources of stream baseflow; but urban areas often import water from other basins, and groundwater and baseflows in urban streams may be supplemented by leakage from the water and sewage distribution system, lawn watering, and car washing. Thus, different studies have found both increases and decreases in baseflows as a result of urbanization.

The hydrograph of Peachtree Creek, Atlanta, when compared to the hydrograph of a nearby forested stream, clearly illustrates the multiple hydrograph effects of urbanization (Fig. 3). Peachtree Creek begins in the highly developed eastern suburbs of Atlanta and flows through Atlanta's urban core, draining 86.8 mi^2. Compared to a nearby forested stream on a unit area basis, Peachtree Creek has larger peak flows, greater stormflow volumes, more frequent high flow events, and greater total streamflow.

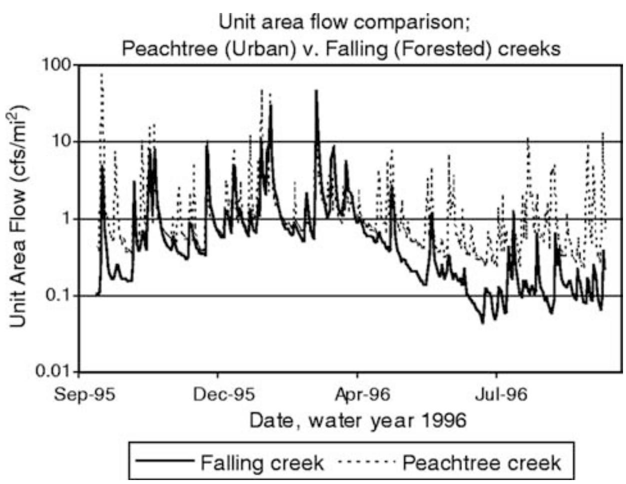

Fig. 3 Comparison of unit area runoff (cubic feet per second per square mile) between a highly urbanized stream (Peachtree Creek in Atlanta, Georgia) and a nearby forested stream (Falling Creek near Juliette, Georgia). Data are United States Geological Survey daily flow measurements shown for water year 1996 (October 1, 1995 through September 30, 1996).

MITIGATION

Mitigating the potential hydrologic effects of urbanization involves maintaining infiltration rates and soil storage to the degree possible and creating artificial storage for runoff from impervious surfaces and compacted soils. The complete suite of stormwater mitigation strategies includes clustering development to reduce impervious surfaces and maintain forest cover, using pervious pavements where feasible,[11] employing low-impact development principles at the site scale (e.g., downspout infiltration, rain gardens, infiltration/biofiltration, and swales), incorporating green roof technology into commercial developments, constructing infiltration or detention basins, and maintaining riparian buffers around streams.[12,13] Detention facilities collect water from developed areas and release it at slower rates than it enters, whereas infiltration facilities are sited over soils that allow infiltration of a substantial portion of the collected waters. Riparian buffers provide little hydrologic benefit, but they increase the physical and biological resiliency of channels to hydrologic alteration. Structural solutions alone have been inadequate to mitigate urbanizations hydrologic alterations,[12] and protecting urban streams requires full integration of structural, non-structural, and site design strategies.[12,14]

In conventional structural stormwater mitigation, simple hydrologic models of runoff from single rain events are used to estimate stormflow peaks and volumes for pre- and post-development conditions. Then, a hydraulic routing model is used to design detention or infiltration ponds to reduce post-development peak flow rates to pre-development levels for various storms of interest, typically the 2-year, 10-year, and 25-year 24-h rainstorms. There are two main problems with this design protocol: (1) matching only the peak flow rates still allows the duration of high flows to increase, thus the so-called peak matching design standards do not protect receiving streams from increased erosion[4] and (2) single rainfall event models are inherently incapable of matching peak flow rates because they do not account for problems associated with successive storms.[15] To protect receiving channels, detention and infiltration ponds should be sized to match durations of erosive flows. Development and acceptance of continuous rainfall/runoff models for stormwater design will result in better stormwater mitigation design and analysis.[15]

Because it takes years of post-development monitoring to evaluate hydrologic and water quality responses of streams to urbanization and because developments incorporating all modern concepts of stormwater mitigation have only recently been built, the cumulative effectiveness of modern stormwater management techniques for protecting the hydrology and water quality of urbanizing watersheds is unknown.

CONCLUSIONS

Urbanization reduces the volume of water storage provided by soils and vegetation, increases the fraction of rainfall that becomes surface runoff during storms, hastens the movement of runoff to streams, reduces evaporation, and increases watershed yield. Protecting the hydrology and water quality of streams in newly urbanizing basins requires comprehensive implementation of structural and non-structural mitigation, including but not limited to the retention of natural vegetation, the minimization of impervious surfaces, low-impact site designs, rain gardens, detention and infiltration facilities, and water quality treatments. However, the maximum possible extent of urbanization that can be accommodated while protecting the hydrology, geomorphology, and biota of receiving waters is uncertain.

Urban Water Quality

Linda Schweitzer

Environmental Science and Engineering Program, University of California–Los Angeles, Los Angeles, California, U.S.A.

INTRODUCTION

Urban water quality is affected by nearly all anthropogenic activities, and is generally a function of population and land usage, both of which influence the type and mass of pollutant discharges entering surface waters. Examples of urban land uses include residential, industrial, commercial, retail, and parkland. Land uses that lead to an increase in percentage of impervious surfaces result in greater peak flows (discharge) of urban runoff, decreased soil infiltration, increased soil erosion, and a focusing of pollutants into surface waters.

POINT OR NON-POINT SOURCES OF POLLUTION?

The USEPA[1] states that non-point source pollution is the largest source of water quality impairments in the U.S.A. and is the main reason that 40% of US lakes and streams are non-swimmable or fishable. Point sources are from a single point, or conveyance, of discharge into surface waters, whereas non-point sources of pollution are from releases distributed over a portion of the watershed, such as air deposition or stormwater runoff. Non-point sources in the U.S.A. are regulated by the National Pollution Discharge Elimination System (NPDES) permitting process. Many water quality problems are believed to come from non-point source runoff. As the solution to the pollution will be different depending on the nature of the problem, studies should be conducted to determine sources of pollutants and establish cause-and-effect for the degraded water quality.

Pollutants that enter our waterways from wet or dry atmospheric deposition are considered non-point sources. However, if the source of emissions to air is from a point source, the solution to the problem should be focused at the site of release, rather than the receiving waters. This approach has worked in the case of mercury that cycles between air, water, and sediments. After passage of the US Clean Air Act, atmospheric deposition of mercury decreased from a high of 20-fold preindustrial levels in 1984 to 11-fold preindustrial levels between 1986 and 1993, according to ice core data from the Upper Fremont Glacier, Wyoming.[2] Mercury levels in surficial lake sediments decreased as atmospheric inputs decreased.[3–5] Further reductions are needed, however, as levels are significantly above background. Also, resuspension of contaminated sediments can release mercury into the water column. Hot spots of contaminated sediments, if found, could also be considered a point source of pollution that should be remediated.

An unidentified source of contaminants should not necessarily be construed as a non-point source. For example, high bacterial counts resulting in beach closures may be falsely attributed to non-point sources, such as runoff from wildlife or pet waste. Sewage effluent is a major point source of nutrients, solids, organic enrichment, and bacterial and chemical contamination even though secondary municipal wastewater treatment plants are now used for all metropolitan areas. Part of the problem is from combined sewer overflows (CSOs)—point source discharges of stormwater and wastewater from combined sewer systems—and from sanitary sewer overflows (SSOs)—point source discharges of wastewater from the sanitary sewer system—usually during wet weather, when the sanitary system exceeds its capacity to receive and treat large flows. Bacterial contamination may also be from illicit connections or leaking septic systems. An illicit connection, i.e., a waste system that has been connected to a storm system rather than sanitary system, is considered a single point source of bacterial contamination. Leaking septic systems, a problem at the urban–rural fringe, are considered non-point sources because of the distance the contamination has to travel to reach surface waters and because of their numbers (e.g., in Michigan, up to 23% of home septic systems failed inspection at time of sale, according to the Michigan Department of Environmental Quality.[6]).

Source identification may determine the relative contribution of point and non-point sources of pollutants. There are a number of forensic tools that can be employed for source identification.[7,8] Sediment toxicity tests such as Toxicity Identification Evaluations under NPDES[9] can help determine the relative contribution of the various pollutants on the health of the ecosystem. For any water body that is impaired, i.e., not meeting applicable water quality standards, a total maximum daily load (TMDL) must be established according to 303(d) of the Clean Water Act. The TMDL is the maximum amount of pollutant that a waterbody can receive from all point and non-point sources and still meet its water quality criteria. Total maximum daily loads have been established for a number of water quality parameters such as temperature, dissolved oxygen, nutrients, pathogens, and sometimes for specific chemicals or classes of chemicals such as mercury, polychlorinated biphenyls (PCBs), and pesticides. The TMDL may also include a margin of safety for uncertainty. The difficulty in determining TMDLs on an individual pollutant and waterbody basis is currently being addressed by the EPA to streamline the process.

SOURCES OF IMPAIRMENTS IN URBAN WATERSHEDS AND POSSIBLE SOLUTIONS

Table 1 presents the specific water quality problem, source of impairment, and suggested mitigation. Because contaminants are carried on particles, one major approach of mitigation is to reduce the transport of particles in the urban environment to surface waters. Particle sources include erosion (of soil) mainly from construction sites, incinerators and other industrial facilities, vehicular exhaust, and pieces of car tires, road, and parking lot pavement.

Microbiological Contaminants

Bacteria and other waterborne pathogens such as Giardia and Cryptosporidium parasites from CSOs, SSOs, and illicit connections are major concerns to water quality leading to impairments of surface waters. Infrastructure improvements to mitigate CSOs and SSOs include separating combined stormwater and septic systems and installing impoundments to capture overflows during storm events that can later be treated. Ordinances to inspect leaking septic systems upon sale of the property and/or a mandatory certification program can lead to corrective action for unsuspecting homeowners who generally are unaware of the problem. Efforts to reduce runoff will also mitigate some of the problems.

When all known point sources of bacteria are eliminated, sources within the natural environment should be evaluated. Human enteric bacteria that were once

Table 1 Water quality problems in the urban environment

2. Nitrogen		Implement fertilizer ordinances

[a](From Ref.[10].)

released from sewage spills can grow in the sediments of shallow waters and in soil along stream banks.[11,12] Thus, bacteria levels may increase in shallow waters during the summer from the biologically favorable conditions even when no new sources are entering the water.

When the receiving waters for sewage and other effluents are the same as source waters for drinking, our surface waters are imperiled. Backup power systems should be installed at water treatment plants in the event of power outages. More frequent monitoring of water quality can reduce disease outbreaks.

Heavy Metal and Organic Chemical Contaminants

The EPA's Toxic Release Inventory shows the relative contribution of organic and metal contaminants that are released into the urban environment from various industries. Coal burning power plants are a major contributor to water quality impairments. Toxic metals are released into the atmosphere from coal burning. Stormwater runoff can leach carbon and metals from coal piles stored open at power plants into nearby surface waters. Boiler blowdown is water waste with the impurities that concentrate in steam boilers. It contains heavy metals and other chemicals that are added to reduce scaling and corrosion. Process wastewater from power plants and other industrial facilities contributes organic and inorganic chemical loading to surface waters.

Polyaromatic hydrocarbons (PAHs), products of incomplete combustion of fossil fuels from mobile and stationary sources, are often a significant contributor in urban watersheds to river, lake, and estuarine sediment toxicity. Rubber car tires are a major source of particulate matter, zinc, and other chemicals such as benzothiazole in urban runoff. Automobiles also contribute to metal contamination from their use and manufacture. Steel plants are a major source of toxic metal emissions into air, which attach to particles that settle out.

Pesticide and other biocides used in residential, park, retail, or commercial properties can add to the contaminant loading of surface waters, especially in stormwater runoff. The first flush effect occurs during the beginning of a wet weather event following a dry period; oil and grease from cars, chemicals depositing to the ground from atmospheric deposition, and any other type of pollutants on surfaces will suddenly be washed into local receiving waters. Thereafter, as the storm continues, the pollutants will be diluted to lower concentrations. The best mitigation approach is to reduce impervious surfaces within the watershed. There is a new movement to reduce the size of parking lots in shopping malls. Wetland and other green space protection and, in general, natural habitat restoration, are included strategies in most stormwater plans. Wetlands, in particular, filter contaminants and cycle nutrients.

Other chemicals of concern in urban runoff include historic contaminants such as PCBs that, although banned, continue to cycle between air, water, sediments, and soil and the ecosystem food chain.

Sewage effluent is a major source of all pollutant types. Pharmaceutical compounds such as analgesics, antibiotics, hormonal compounds, antiepiletics, antidepressants, and blood lipid regulars have been identified in outflows from sewage treatment plants and surface waters worldwide.[13,14] Some are endocrine disruptors—chemicals that either mimic hormones or interfere with the endocrine system or hormonal signaling. Sewage effluent containing natural and synthetic hormones excreted by humans and industrial waste containing chemicals such as alkylphenolic compounds may contribute significantly to the estrogenic activity of the wastewater.[15]

Nutrients and Other Concerns

Other concerns to water quality include nutrients (phosphorus in particular) resulting in algal blooms and reduced dissolved oxygen which impact fish populations, increased turbidity from soil erosion, and increased conductivity usually because of road salt runoff in winter climates. Even sand, which is used to remove icy spots on roads, can add particle loading to streams affecting nutrient quality of the sediments. Fertilizer ordinances may have to be considered to reduce unnecessary usage of nitrogen and phosphorus. During development, measures must be taken to reduce soil erosion, such as employing silt screens in a manner that is effective (and not to forget removing them once a project is complete, so that the material does not enter the aquatic environment, impacting fish).

Cooling water from coal and nuclear power plants and industrial facilities contributes to thermal pollution. Thermal pollution results from water that runs off paved surfaces during warm seasons. While some aquatic species thrive better in warmer waters, the unnatural temperature fluctuations can be detrimental to aquatic life. A solution to the problems associated with power plants and fossil fuel industries is to develop and expand renewable sources of energy such as solar, wind, geothermal, and new alternative forms of energy.

Aesthetic issues of water quality include trash and debris buildup and log jams in streams. Mitigation includes community cleanup and education programs. In urban watersheds, many sources of contaminants remain unknown because of lack of monitoring and enforcement. Industrial spills still occur, but may go undetected in the absence of monitoring. Monitoring can also reveal when pollutants from historic landfills and toxic waste dumps leach contaminants into surface waters.

Watershed management plans include technological, legislative, and other best management practices (BMPs) to reduce pollutant loading into surface waters. However, many of the current strategies and BMPs are largely ineffective. Structural measures are costly and often cannot accommodate large flows. The strategy should consist of pollution prevention and source reduction plans to reduce pollutant loadings, and improved urban planning to address sustainability issues and a return to the natural flow regime of the watershed, including natural sediment fluxes. Although this can be dismissed as being impossible, it may also be a limitation of our creativity. For example, water may be treated in closed-loop processes for point sources. To achieve sustainability, wastewater would ideally be treated to a potable level in a continuous closed loop with the drinking water but that would require a complete elimination of all chemical and biological contaminants (i.e., removal efficiency of 100%).

As water resources become more valuable, the concept of zero discharge may become acceptable as a goal. Finally, with global climate change expected, water resources must be more carefully managed with future forecasting in mind.

Vadose Zone and Groundwater Protection

Charalambos Papelis
Michael H. Young
Division of Hydrologic Sciences, Desert Research Institute, Las Vegas, Nevada, U.S.A.

INTRODUCTION

This section will familiarize the reader with natural processes and anthropogenic activities that protect soil and groundwater qualities. First, the vadose zone is defined as the aerated region of soil or geologic material above the permanent water table and below ground surface. Vadose zone and groundwater protection is defined here in terms of quality, rather than quantity, because the increasing stress on worldwide water supplies is often viewed in terms of water that is potable or of high enough quality for use in agricultural or industrial uses. We will discuss the types and sources of soil and groundwater contamination, describe geochemical characteristics of soil or aquifer material that affect contaminant levels, and then describe methods to control or reduce subsurface contamination through the use of containment structures (e.g., landfills), and active and passive treatment technologies.

TYPES AND SOURCES OF CONTAMINATION

Types of Contamination

Waste material comes in many forms and toxicity levels, and from a variety of sources. Solid wastes range from municipal waste, such as household trash, to hazardous materials, including some mining and industrial wastes. Liquid wastes range from municipal wastewaters, which are typically not considered hazardous, to industrial wastewaters containing organic contaminants, acids, or high concentrations of metals. Finally, sludges contain between 3% and 25% solids,[1] and could contain a variety of hazardous solids or liquids. Each of these waste forms is subject to control through State or Federal regulations, or both.

Each potential waste form can contain a variety of contaminants. Organic contaminants (e.g., fuels, chlorinated solvents, and pesticides) vary widely in their chemical properties and mobility in the subsurface environment. For example, a straight chain hydrocarbon with an OH^- group (e.g., hexanol) and a benzene ring with an OH^- group (i.e., phenol) have the same number of carbon atoms, but are structurally different. Consequently, they will have different affinities for the same soil or aquifer material. Inorganic contaminants, which occur naturally or as a byproduct of industrial processes, also take many forms depending on the oxidation–reduction state of the subsurface environment. Their migration characteristics are highly variable and affected by time, redox environment, the nature of the soil or aquifer material, and the presence or absence of other contaminants. Finally, biological contaminants, which can be present in groundwater due to improper disposal of human or animal wastes, are often reactive and subject to mechanical filtering and biodegradation. Moreover, bacteria or parasites have activation periods, so their toxicity levels change with time. Clearly, the differences in contaminant characteristics must be evaluated on a contaminant-specific basis to better understand risks to the soil and groundwater.

Sources of Contamination

Protecting soil and groundwater resources requires an understanding of how contaminants are released into the environment. Sources can be broadly classified as point and non-point. Point sources are typically related to industrial processes, and releases often occur while temporarily storing materials used in manufacturing or chemical operations. Fluid storage tanks, below- and above-ground plumbing, and impoundments can leak and contribute to contamination. Concentrated feedlot operations, a livestock-based industrial source, are sources of nitrate, phosphorus, and fecal coliforms.[2] Municipal storm flow might also be a point source of these nutrient and biological contaminants.

Non-point sources are typically related to agricultural practices, because of the widespread application of pesticides and fertilizers, and some mining operations, where large swaths of land are disturbed during mineral extraction. Contemporary agricultural practices in many countries rely heavily on the application of organic and inorganic fertilizers, which have high concentrations of nitrogen and phosphorus. Downward migration of these fertilizers away from plant roots can increase concentrations of nitrogen and phosphorus in groundwater to levels that can exceed water quality criteria. In some instances, water from a large numbers of water wells was rendered non-potable. Urban runoff also can contribute to non-point source pollution; e.g., runoff from streets can contain oils and salts, and runoff and downward drainage from parks, lawns, and golf courses can be a source of sediment, pesticides, nitrogen, and phosphorus.

ATTENUATION PROPERTIES OF SOIL

Soil material, composed of fragments of rock that have undergone physical, chemical, and biological weathering, has potentially a very high capacity to attenuate (or reduce) the concentration of contaminants migrating through it. Biogeochemical processes that could be responsible for the reduction of contaminant concentrations in soil include biological or abiotic transformation, sorption, precipitation–dissolution, oxidation–reduction, complexation, and mass transfer processes.[3] The attenuation capacity of soil depends on many factors, including the soil physicochemical characteristics, the type of contaminant, and the geochemical conditions in the soil pore water.

For non-porous particles, particle size is inversely proportional to specific surface area.[4] Particle surface area is typically related to the number of reactive sites and therefore the attenuation properties of the soil. In addition, particles on the order of 1 μm or less (colloids) can substantially enhance the transport of constituents associated with them[5] thereby affecting the extent of natural attenuation. The mineralogy of soil particles can also have a dramatic effect on the surface area. For example, non-weathered quartz and feldspar particles have an insignificant surface area compared to zeolites, smectite clay minerals, and disordered iron and aluminum oxide phases with high porosity.

The surface charge properties of particles are also a function of particle mineralogy and can dramatically affect the sorption of inorganic contaminants on mineral surfaces and therefore the potential for immobilization. Surface charge properties are described by the point of zero charge (PZC) of a mineral, or the pH value at which a particle has no net surface charge. The PZC for common soil minerals can vary from approximately 2 for quartz to approximately 8–9 for iron and aluminum oxides. Sorption of metals and other cations is favored at higher pH values where particles tend to be negatively charged, whereas sorption of oxy- and other anions is favored at lower pH values where particles tend to be negatively charged. It should be kept in mind, however, that strong, specific sorption on mineral surfaces is possible against electrostatic repulsion.

The organic content fraction of soil can also have significant implications for the natural attenuation of organic and inorganic contaminants. The partitioning of organic contaminants at the soil–water interface is directly proportional to the organic fraction content of the soil.[6] In addition, natural organic materials can complex metals and other inorganic ions, thereby immobilizing them. Organic compounds in soil particles can be used by microorganisms as a carbon or energy source, a prerequisite for biotransformation of organic compounds.

Finally, the redox conditions in a soil environment can dramatically affect attenuation properties. For example, the reductive dehalogenation of organic chemicals has been frequently observed.[7] This reduction process is sometimes catalyzed by the oxidation of reduced soil components (e.g., iron and manganese oxides or sulfides). Another example involves the oxidation or reduction of oxyanions, producing species with substantially different properties. The sorption properties of oxyanions of selenium and arsenic, two elements of significant environmental concern, are a strong function of oxidation state, leading to substantially different sorption affinities for mineral surfaces.

METHODS TO PROTECT VADOSE ZONE AND GROUNDWATER

The vast majority of groundwater contamination problems involve the vadose zone because, unless contaminants are introduced directly into the saturated zone, soil contamination will almost always precede groundwater contamination. Steps taken to reduce vadose zone contamination can thus reduce groundwater contamination.

Improving Waste Disposal Practices

Landfilling of waste is still the most common mode of disposal for those materials that are not recycled or reused. For example, as of 1992, 67% of municipal solid waste (MSW) generated in this country was landfilled.[8] The technology behind landfilling of waste varies significantly. In the past, landfills were not equipped with adequate covers or liners (Fig. 1A), and they were often located without regard to the proximity to groundwater resources. As a result, water from precipitation often percolated into the waste material, leached potentially harmful chemicals, and transported them into deeper soil layers and groundwater.

Current landfill designs are more sophisticated, and have a stronger appreciation for the need to reduce downward percolation of precipitation and generation

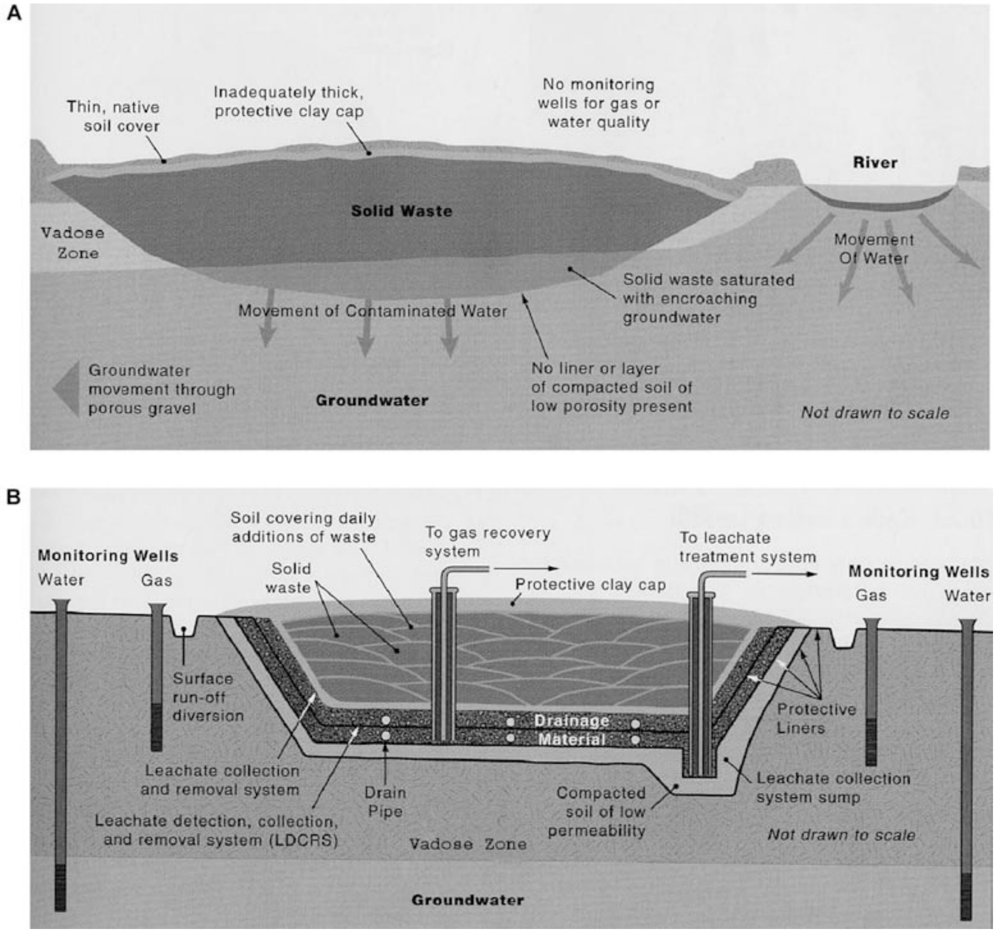

Fig. 1 Cross-sections of two landfills: (A) Old-style sanitary landfill without many design features commonly used today; (B) Modern sanitary landfill showing monitoring, containment, and gas recovery systems. *Source*: From Ref.[1] and reprinted with permission.

of leachate. Fig. 1B shows some design features required in modern sanitary landfills. Hazardous waste disposal facilities have these and other design features required by the U.S. Environmental Protection Agency, including multi-layered covers and liners, leachate collection systems, and groundwater monitoring programs.[9] A key design goal is to divert water away from the disposal cell, thereby reducing the potential for leachate generation.

Recently, some new design components have shown promise in reducing leachate generation at lower costs. Depending on the climatic conditions, plants can remove the majority of precipitation falling onto the disposal site cover, substantially reducing the potential amount of water that would percolate through the waste.[10] Other developments include the conversion of MSW landfills into bioreactors, where microorganisms consume waste material for their life energy. Careful control of environmental conditions inside the cell (e.g., water content, pH, temperature, etc.) is needed to enhance the bioremediation.[11]

Active Remediation of Existing Contamination

Protecting the vadose zone and groundwater from future contamination is easier than remediating existing contamination. However, where contamination exists, removing it enhances vadose zone and groundwater protection. Engineered remediation strategies for reducing existing vadose zone and groundwater contamination fall into several broad categories: containment, removal, and treatment.[12]

Containment focuses on restricting or redirecting the movement of contaminants with either physical or hydraulic barriers. Physical barriers are structures designed to direct groundwater or soil water flow away from a contaminated area, thereby containing the plume size. Physical barriers can include sheet piling, slurry walls, grout curtains, and engineered covers (synthetic or natural). Hydraulic barriers are used to capture contaminated water through the manipulation of hydraulic gradients, and subsequently to treat, store, or otherwise dispose of the water.

Removal strategies include excavation, ex-situ pump and treat, and in-situ treatment. Excavation is a brute-force method of remediation, where contaminated soil or aquifer material is physically removed from the site. Though this method has some disadvantages (higher potential worker exposure, higher transportation cost), it has proven effective for areas with shallow, localized contamination. Pumping and treating contaminated water is probably the most widely used remediation technology. Contaminated groundwater is pumped from the aquifer and then treated at ground surface. If the primary concern is soil contamination, then clean water can be applied at ground surface and allowed to percolate through the contaminated area, leaching the contaminants and removing them from the vadose zone. The newly contaminated water is then captured using hydraulic control and treated.

Natural Attenuation

Natural attenuation is defined as the use of unenhanced natural processes as part of a site remediation strategy,[3] and is being used in conjunction with or as an alternative to engineered remediation systems.[13] The reliance on natural attenuation in the vadose zone and groundwater comes in part because of the high costs of active remediation at thousands of sites around the United States. Natural attenuation relies on biogeochemical degradation of contaminants through interactions with soil and aquifer material in the vadose or saturated environments. The degradation leads to contaminant destruction, immobilization, or transformation to innocuous byproducts. Biological transformation requires the presence and activation of a specific microorganism or a consortium of microorganisms that consume the contaminant in question. Chemical reactions that can attenuate contaminant concentrations include acid-base, redox, precipitation, sorption, and complexation.[3] In any biogeochemical reaction pathway, conditions in the substrate and the contaminant concentrations must be within a specific range, or the reaction rates can decrease. Natural attenuation must be coupled with an aggressive monitoring program to ensure regulators and the public that the processes are effectively reducing contaminant levels. Furthermore, the likelihood of success of natural attenuation is contaminant-specific; some contaminants (e.g., BTEX) have a high likelihood of success, while others (e.g., polycyclic aromatic hydrocarbons) have a lower likelihood. The choice of using natural attenuation is therefore complicated and must be made after careful consideration of subsurface conditions, the contaminant, and the regulatory and public acceptability.

Vapor Transport in Dry Soils

Anderson L. Ward

Glendon W. Gee
Battelle Pacific Northwest National Laboratory, Richland, Washington, U.S.A.

INTRODUCTION

Water-vapor movement in soils is a complex process, controlled by both diffusion and advection and influenced by pressure and thermal gradients acting across tortuous flow paths. Wide-ranging interest in water-vapor transport includes both theoretical and practical aspects. Just how pressure and thermal gradients enhance water-vapor flow is still not completely understood and subject to ongoing research. However, in unsaturated soils, it is now well accepted that the rate and direction of water flow may be completely misinterpreted if vapor movement is ignored. Practical aspects include dryland farming (surface mulching), water harvesting (aerial wells), fertilizer placement, and migration of contaminants at waste sites. The following article describes the processes and practical applications of water-vapor transport, with emphasis on relatively dry soil systems.

PROCESSES CONTROLLING VAPOR TRANSPORT

Diffusion

Water-vapor transport in fine-textured soils (e.g., silts and clays with little or no macroporosity) is often described as a simple diffusion process where Fick's law applies. In this type of assessment, the vapor flux is expressed in terms of a diffusion coefficient multiplied by a concentration gradient. The diffusion coefficient, in turn, is the product of the binary diffusion coefficient of pure water vapor in air, multiplied by a tortuosity factor and a term that is empirically related to the air-filled porosity of the soil. As soils dry out, the diffusion coefficient increases as a power function of the air-filled porosity. Recent work over the entire water-content range by Moldrup et al.[1,2] indicate that reasonable agreement occurs between observed and predicted values when the modeled vapor-transport equation includes a term for the air-filled porosity raised to a power of three.

Advection

In well-drained, coarse soils, and similarly in fine-textured soils containing a significant number of large (macro) pores, advection can control the transport of water vapor. Often the advection is temperature assisted, since seldom is the process isothermal. Kemper, Nicks, and Corey[3] studied advective transport of water vapor through dry gravels and developed a working equation for water-vapor flow that includes both diffusive and advective flow, which can be written as:

$$q = (D_f + D_s)(P - \theta 2)(L/L_e)^2)[C/Z] \quad (1)$$

where q (g cm^{-2} sec^{-1}) is the vapor flux, D_f (cm^2 sec^{-1}) is the diffusion coefficient for water in still air, D_s (cm^2 sec^{-1}) is the dispersion coefficient that is affected by wind speed, turbulence, and pore size, $P - \theta$ (m^3 m^{-3}) is the air-filled pore space, L/L_e is the straight line distance through the mulch over the average tortuous path length; C (g cm^{-3}) is the water-vapor concentration difference across the mulch (from the soil–mulch to the mulch–air interface), and Z (cm) is the mulch thickness.

The combined diffusive and advective coefficients control the flow and the relative influence of each term is dictated by the characteristics of the porous media, being a function of the macroscopic properties including tortuosity and volumetric water content. As soil becomes coarser, advective flow can equal or exceed the diffusive flow.

Non-Isothermal Flow

Over the years, there has been considerable interest in the non-isothermal flow of water vapor in soils.[4–15] The classic work by Philip and de Vries[4] has been the framework upon which most non-isothermal water-flow models have been developed and tested. Fig. 1 shows the basic concept of enhanced vapor transport in a soil pore aided by a temperature gradient.[4] Numerous observations over the years have demonstrated that there is an enhanced vapor transport in the presence of a

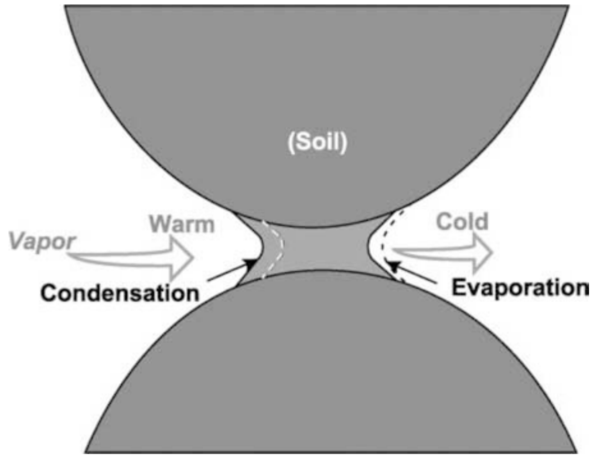

Fig. 1 Thermally enhanced water-vapor transport in a pore. Water condenses on the warmer side the liquid island and evaporates from the cooler side of the island creating a short circuit and enhancing vapor flow. *Source*: From Ref.[4].

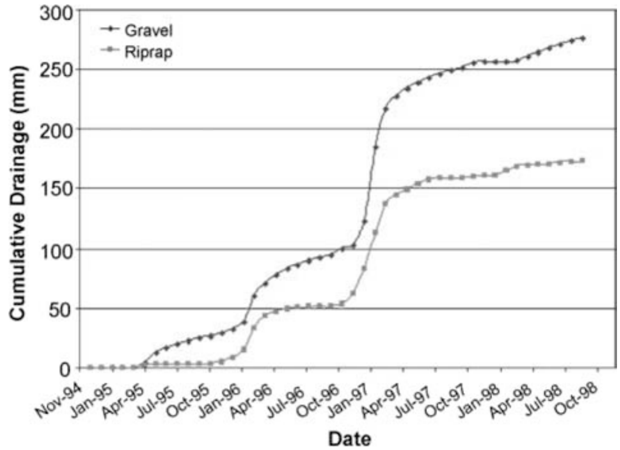

Fig. 2 Cumulative drainage from a rock side-slope of a surface barrier compared to drainage from an adjacent gravel side-slope. The lower drainage from the rock side-slope is attributed to thermal advection.

thermal gradient that cannot be derived directly from first principles. Cass, Campbell, and Jones[11] measured enhanced water-vapor diffusion that ranged from a factor of 1 to 15 over a range of temperatures and saturations. Nassar, Horton, and Globus[12] studied flow under a combination of thermal and solute gradients and found that water-vapor transport was underpredicted by a factor of four. The working hypothesis for the enhancement is that there are liquid islands that exist in porous media and that as the water vapor moves through the porous system, the vapor condenses on the warm side of the island and evaporates on the cool side of the island (Fig. 1). This short circuit is believed to cause the enhanced transport. For each soil, there is an optimal water contents area between saturation and air dry at which liquid islands are prominent in the flow pathway, and enhanced vapor flow is maximized.[16]

Convective Flow

There is mounting evidence that thermal pulses can cause enhanced vapor flow in soil, particularly near the soil surface. Measured flow in the field has been found to be an order of magnitude or more higher than that computed by invoking diffusive flow mechanics.[13] Parlange et al.[14] demonstrated that the agreement between theory and measurement could be improved substantially when both diffusion and convection were included explicitly in the analysis. These authors assumed that the mechanism responsible for the large vapor flux is convective transport driven by the diurnal heating and cooling of the soil surface and the corresponding thermal expansion and contraction of the soil air. This analysis and the corresponding conclusions are similar to those of Rose and Guo,[17] who demonstrated via computer modeling that thermal convection could accelerate the movement of soil air in hillsides. Field evidence of thermal convection, resulting in accelerated evaporation, was obtained by Ward and Gee,[18,19] who reported on water losses from a 2 : 1 (horizontal/vertical) rock riprap side-slope located on a monitored landfill cover. Evaporation from the rock side-slope was about twice that of an adjacent gravel-side slope that had a lower slope (10 : 1) and a lower porosity (Fig. 2).

PRACTICAL ASPECTS OF VAPOR TRANSPORT

Mulching and Dryland Farming

The basic concept of mulching is that water stored in the soil during winter months (or periods of low evaporation) can be kept in the ground longer if there is a way to limit vapor losses from the soil surface. In arid-climate regions, farmers have tried various methods to conserve water using a variety of mulching materials. The Anasazi, ancient dwellers of the America southwest, used cobble mulch in their gardens as early as the 14th century A.D.[20,21] It is hypothesized that cobble surfaces stimulated crop production by increasing water storage, controlling weeds, and mitigating temperature extremes in an environment of limited moisture and elevated temperatures. White, Dressen, and Loftin[21] tested the theory of increased water storage using cobble mulch at test sites adjacent to the ancient gardens in New Mexico. Water storage in soils covered with 7-cm-thick gravel mulch was increased by as much as 50%. This is very similar to

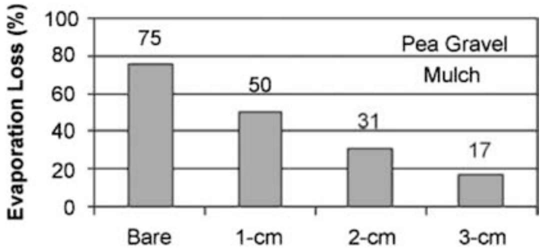

Fig. 3 Evaporation losses from pea gravel mulch layers of various thicknesses.

results reported by Kemper, Nicks, and Corey[3] in studies conducted earlier in Ft. Collins, Colorado, to evaluate the benefits of gravel mulches for enhanced water storage. Fig. 3 shows the results of one of Kemper's experiments (as reported by Hanks and Ashcroft[22]) using pea gravel (i.e., coarse material with a particle-size distribution ranging from 2 mm to 10 mm) as the mulch. The Kemper field study extended over 13 months during which 589 mm of precipitation fell on the test plots. The data show that evaporation losses were reduced by a factor of more than 3, and water storage increased by a similar amount as the thickness of the pea gravel mulch increased from 0 cm to 3 cm (about three complete layers). It is clear that coarse gravels provide a capillary break to upward liquid flow. The resultant vapor barrier then limits water transfer to the soil surface, causing a significant reduction in evaporation from soils under the gravel mulch.

A simple farming practice, known as fallow farming, requires that a farmer till his field to loosen the topsoil, but he does not plant. The loosened soil acts as a diffusion or vapor barrier to the already stored moisture, and in areas where there is insufficient precipitation to sustain a crop, the stored moisture from the previous year is used the next season to produce the crop. The application of mulch breaks the liquid continuity and increases diffusion resistance, thus limiting the rate of water loss from the soil surface. Mulches made of various materials have been used successfully to create a diffusion barrier. Over the past 50 years, studies have been conducted on various mulches, including dry soils, straw, and gravel or stones of various sizes and colors.[3,21,23–28] In general, clean gravel or stone mulches tend to retard evaporation losses more than mulches containing finer materials. Kemper, Nicks, and Corey[3] developed a formula for estimating the efficiency of gravel mulch based on particle diameter and thickness of the barrier.

Aerial Wells

On the Crimean peninsula, on the shores of the Black Sea in central Asia, are porous stone remnants of what

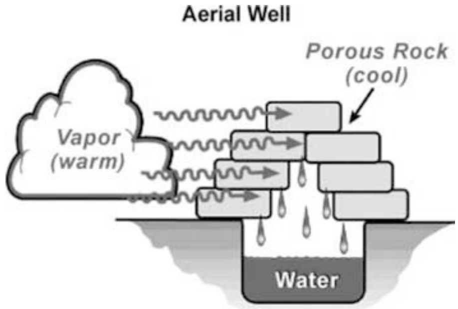

Fig. 4 Aerial well. Water vapor from fog condenses on cooler rock surfaces and is collected in underlying cistern.

are believed to have been aerial wells used by the ancient inhabitants to condense and collect water from fog-laden air. Thermal differences caused warm, most air to condense on cool rock surfaces (Fig. 4). The water drained to above-ground cisterns, connected to aqueducts that carried water to nearby gardens and municipalities and had the capacity of supplying Theodosia with 721 m^3 (190,000 gal) of water daily.[29] While it appears that such structures could be constructed at a number of locations throughout the world, the climatic conditions apparently have to be nearly perfect for significant quantities of water to be collected. Such a system would be impractical except for very limited use in arid areas where there is persistent fog. All modern attempts to replicate such a system for water production have failed.[29,30]

Fertilizer Placement and Waste Management

When deliquescent salts, like many fertilizers, are emplaced in partially saturated soils, differences in solute concentrations develop across the air-filled pores, and significant vapor movement can occur.[31] Under these conditions, the air–liquid interface acts as a semipermeable membrane from which ions are excluded but across which water vapor can freely migrate in response to the osmotic potential gradient. The presence of salt causes a lowering of the vapor pressure, and water vapor is transported from regions of lower solute concentration to regions of higher concentration. Eventually, the migrating water condenses, the salt slowly dissolves, and the liquid continues to move under forces of gravity and capillarity.[32,33] This mechanism of moving salt in soil is of practical significance in agriculture. The placement of seeds or seedlings near fertilizer bands must account for this movement to minimize impacts on germination and seedling survival since high-salt concentrations can adversely affect plants. There are also implications for managing saline wastes in the vadose zone.

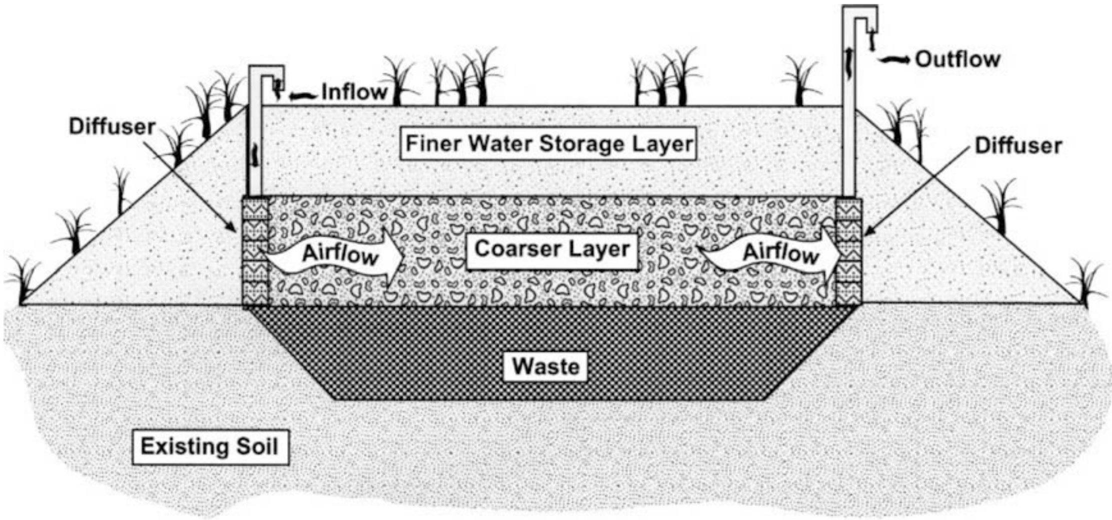

Fig. 5 Schematic of a dry barrier for an arid site landfill.

An analysis of vapor condensation at a waste site, where high concentrations of sodium nitrate salts are stored in tanks, showed that one mechanism for long-term leakage of fluid is vapor condensation.[34] Vapor-transport analyses, using a number of design parameters including the thickness of the concrete tanks and the gravel packs around the tanks, indicated that rates of water loss from vapor condensation ranged from 0.1 mm yr^{-1} to 0.5 mm yr^{-1}. For storage periods of up to 10,000 yr, this amounts to as much as 5 m of fluid that could be lost from a storage tank continuously exposed to soil water vapor. One proposed engineering solution is to design a passive thermal gradient using a specially constructed rock chimney surrounding the waste tank. The rock chimney would create a thermal shield around the waste tank and could help isolate the vapor transport from surrounding wetter soil. In addition, the chimney could be used to drain the condensation water harmlessly away from the waste tank.[34]

Dry Barriers

Stormont, Ankeny, and Kelsey[35] proposed the use of coarse rock placed at depth in a landfill cover. In their design, the rock is exposed to the surface either at a side-slope exposure or by way of vent tubes that protrude to the surface (Fig. 5). Wind action, blowing over the vent tube or the side slope, causes convective gas movement similar to that observed in animal burrows.[36] In arid regions, such a barrier could be used to dry the subsurface sufficiently to prevent drainage to lower layers in the profile, thus preventing recharge at the waste site. The so-called dry barrier has been tested successfully at a landfill near Boardman, Oregon.[37]

CONCLUSION

How water vapor moves in dry soils is still a research topic. It is known that both diffusion and convection are important in the water-vapor transport process. Practical aspects include dryland farming, aerial wells, fertilizer dissolution, and deployment of dry barriers to limit water infiltration at arid waste sites.

Dennis Wichelns
Rivers Institute at Hanover College, Hanover, Indiana, U.S.A.

INTRODUCTION

We describe the concept of virtual water and demonstrate how the metaphor enhances the understanding of water scarcity, food security, and international trade. Virtual water silently and invisibly enables some politicians and public officials to avoid discussing politically sensitive water scarcity issues. Many water-short countries achieve food security by importing large amounts of crops and livestock products. Consumers generally do not observe the water used to produce the goods and services they purchase in local markets. International trade enables public officials to satisfy domestic food demands without discussing issues regarding water scarcity.

We demonstrate the empirical importance of virtual water in expanding a nation's food supply by examining crop production and international trade information for Egypt. Although rice, wheat, and maize production have increased substantially since 1970, Egypt still relies on substantial imports of wheat and maize to satisfy its increasing demand for food.

BACKGROUND

The term 'virtual water' began appearing in the water resources literature in the mid-1990s in discussions of water scarcity and international trade in the Middle East and North Africa (MENA), where national water supplies had become inadequate to achieve food self-sufficiency. Despite concerns of imminent violent conflict in the MENA region induced by water scarcity, there had been no such conflicts since those of the early 1960s in the Upper Jordan.[1] The absence of conflict was explained by the growing reliance of MENA economies on agricultural imports. Large amounts of food grains were imported each year, and the amounts were increasing with population growth. In a sense, the water used to produce imported crops was enabling several water-short countries to achieve food security, even as the water available per person in those countries was declining.

'Embedded water' was used originally to describe the role of imports in achieving food security in water-short countries, but that term did not generate substantial interest in the topic.[2] Switching to 'virtual water' brought greater attention from public officials, academicians, and other experts. The virtual water metaphor is now used widely to describe how water-short countries achieve food security by importing crops and livestock products from water-abundant countries.[3] No Minister of Water in the MENA region is unaware of this concept and its significance. The virtual water process is strategically very effective in solving MENA water scarcity problems. However, reliance on virtual water contradicts the preferred self-image of the peoples of the region. They have been water self-sufficient for thousands of years. No politician can publicly identify with the new insecure water circumstances.

VIRTUAL WATER IS INVISIBLE, SILENT, AND VITAL

Empirical estimates of virtual water are obtained by calculating the volume of water used to produce imported crops. For example, the estimated world average volume of water required to produce 1 t of wheat is 1334 m^3.[4] Multiplying this by the estimated 50 million tonnes (mt) of grain imported annually by countries in the MENA region suggests that those countries rely on 66.7 billion m^3 of virtual water, a volume that is 20% larger than the 55.5 billion m^3 of Nile River water flowing into Egypt each year.[5] Because the importing countries do not have adequate water supplies to produce all of their food requirements, virtual water plays a vital role in their ability to achieve food security.

The role of virtual water is also silent and invisible. Consumers of food crops and livestock products do not see the water used in production, regardless of whether the crops and livestock are produced domestically or imported. Many consumers are also only partially informed about national issues regarding water

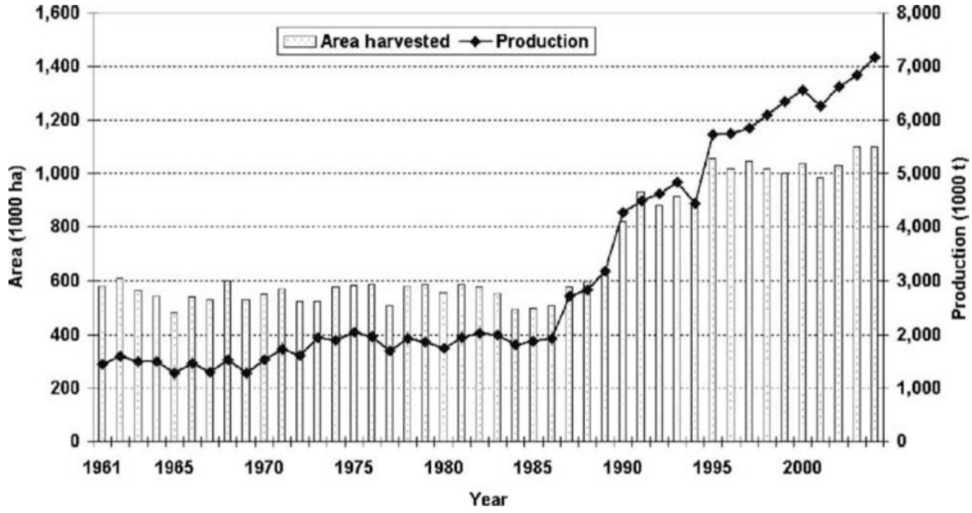

Fig. 1 Area harvested and production of wheat in Egypt, 1961–2004.

scarcity, food security, and international trade. Their inadequate knowledge is due, in part, to a desire among public officials and politicians to avoid discussing the true scope of water scarcity and food security issues. In many countries, politicians prefer not to acknowledge that the national food supply depends largely on imports. They describe their nations as secure in both food and water, noting that water supplies are sufficient to support economic activities and that food products are generally available in local markets.

Politicians in the MENA region benefit from the silent role of virtual water in providing food security and sustaining their economies. As long as food crops and livestock products are available at reasonable prices in world markets, public officials can delay addressing water scarcity issues that otherwise might be controversial and costly.[6] Reforming water policies, revising allocations, and establishing water markets often are contentious issues that consume substantial public attention and political capital. Patterns of water use and water rights have evolved over many years in most countries, making change a cumbersome process. Virtual water silently and invisibly enables public officials to invest their financial and political capital in other pressing priorities.

The benefit that politicians gain in the near term by avoiding or delaying serious discussion of water scarcity might be offset by long-term costs. The paucity of discussion regarding water scarcity can be harmful if public officials and legislators fail to implement the policies and programs needed to manage water demands or enhance supplies over time. In some countries, it might be wise for public officials to discuss openly the topics of resource endowments and food demands, and the role virtual water plays in achieving

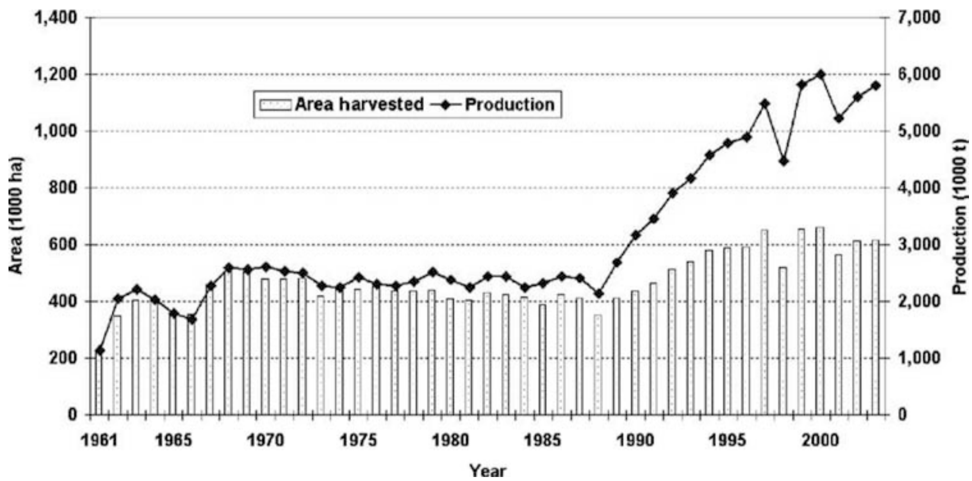

Fig. 2 Area harvested and production of rice (paddy) in Egypt, 1961–2003.

Tailwater–Virtual

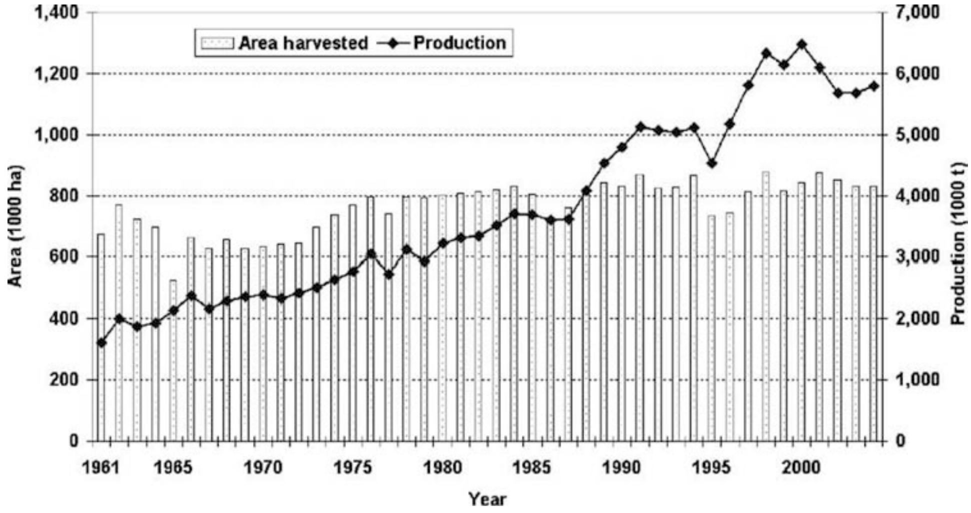

Fig. 3 Area harvested and production of maize in Egypt, 1961–2004.

food security. That discussion might be helpful in creating awareness among residents about the importance of international trade and it might increase the likelihood that countries will develop cooperative relationships regarding scarce water resources rather than engaging in transborder conflicts.

VIRTUAL WATER ENHANCES FOOD SECURITY IN EGYPT

The population of Egypt has increased from about 30 million persons in 1962 to 72 million in 2003.[7] The increasing demand for food in Egypt has been met with increases in domestic agricultural production and substantial imports of food crops. Domestic production has increased due to improvements in technology and increases in irrigated area. The area planted in wheat has increased from about 600,000 hectares (ha) before 1990 to about 1 million ha since 1995 (Fig. 1). Annual domestic production of wheat has increased from less than 2 mt to more than 6 mt since 1985. The area planted in rice has increased from about 400,000 to 600,000 ha, while production has increased from about 2.5 mt to more than 5 mt (Fig. 2). The area planted in maize has remained at about 800,000 ha since 1975, while production has increased from about 3 mt in 1975 to more than 5 mt in recent years (Fig. 3).

Even with these increases in production, substantial imports have been needed to meet food demands. Imports of wheat follow an upward trend in recent

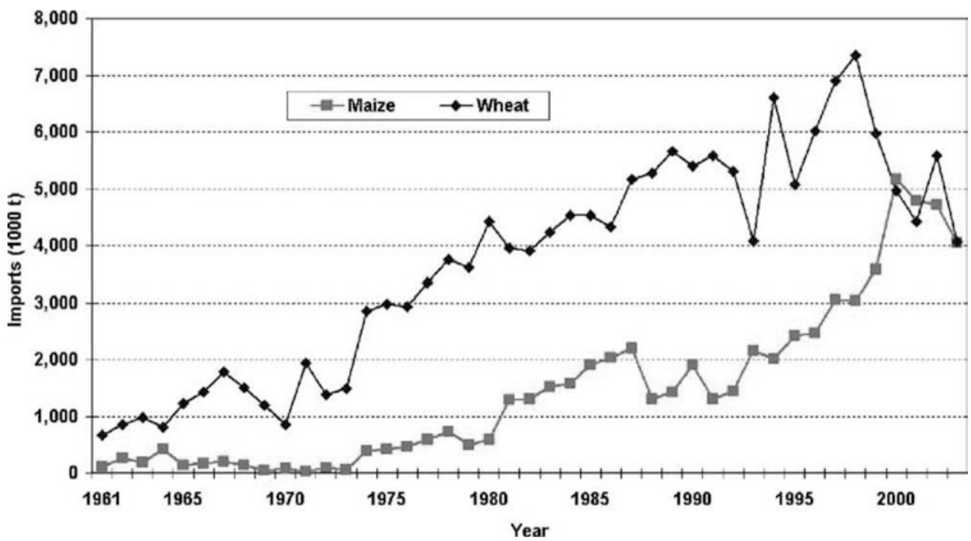

Fig. 4 Maize and wheat imports to Egypt, 1961–2003.

decades, rising from less than 1 mt in 1961 to more than 7 mt in 1998 (Fig. 4). Wheat imports have declined to about 5 mt in recent years. Annual maize imports have increased from less than 1 mt in 1980 to more than 4 mt since 2000. At 5 mt per year, wheat imports increase the amount of wheat available for consumption in Egypt by about 71% (5/7 mt). Maize imports increase the amount of maize available by about 67% (4/6 mt). It is not likely that Egypt could produce this additional wheat and maize at acceptable costs and without a substantial shift in land and water allocations.

Assuming that 1 t of grain requires 1334 m^3 of water,[4] domestic production of the imported wheat and maize would require 12 billion m^3 of additional irrigation water or about 22% of Egypt's supply of water from the Nile River. The opportunity cost of reallocating that water from other uses in Egypt would be substantial. The virtual water embedded in Egypt's wheat and maize imports enables the country to achieve food security at a much smaller cost than what would be required to produce all of its food using only domestic resources.

LOOKING FORWARD

Virtual water will continue to play a vital role in enabling water-short countries to achieve food security. As the demand for water continues to increase while the supply is limited, public officials, private firms, and individuals will continue to seek innovative methods to maximize the values obtained from scarce resources. New technologies and improvements in institutions such as water prices, allocations, and markets will be helpful in those efforts. Nations also will continue enhancing the benefits they receive from international trade. One of those benefits is the ability to achieve food security by importing crops and livestock products while using domestic water resources for higher valued endeavors.

Virtual Water: Economic Perspective

Dennis Wichelns
Rivers Institute at Hanover College, Hanover, Indiana, U.S.A.

INTRODUCTION

The virtual water metaphor was originally created to gain the attention of public officials who choose policies that influence the use of water resources in arid regions. Over time, the metaphor has been used in both empirical and conceptual settings, primarily to describe the water used to produce crop and livestock products that are traded in international markets. Several authors have described how water-short countries can enhance food security by importing water-intensive food crops.[1–3] Others have calculated the 'volumes' of virtual water moving between nations that trade crop and livestock products.[4]

The focus on international trade has led some authors to describe similarities between the virtual water metaphor and the economic theory of comparative advantage. That observation is enticing, but it is not accurate. The virtual water metaphor is not sufficiently broad in scope to be considered the same concept as comparative advantage. The goal of this article is to describe the difference between the virtual water metaphor and the economic concept of comparative advantage. Understanding the difference might enable water resource experts to make better recommendations regarding water resource policies in water-short and water-abundant countries. Two examples involving hypothetical countries with different production technologies and resource endowments demonstrate the importance of considering comparative advantages.

VIRTUAL WATER AND COMPARATIVE ADVANTAGE

Comparative advantage is a fundamental component of international trade theory. In essence, nations can gain from trade if they concentrate or specialize in the production of goods and services for which they have a comparative advantage while importing goods and services for which they have a comparative disadvantage. Comparative advantages are determined by examining resource endowments and production technologies and evaluating the opportunity costs of production in countries that can engage in trade. Opportunity costs must be considered to determine the optimal allocation of scarce resources. Understanding comparative advantage can be helpful in appreciating the value of the virtual water metaphor in policy discussions.[5]

A useful definition of opportunity cost is that it is the value of one input or product that must be given up or foregone in order to obtain some other input or product. For example, the opportunity cost of 1000 m^3 of water used to produce cotton might be the wheat that could be produced by using the 1000 m^3 to irrigate wheat instead of cotton. Opportunity costs can involve cross-sectoral considerations. The opportunity cost of using water to produce wheat or cotton might be the value foregone by not using the water to support an urban housing development. In general, the opportunity cost of water will be higher in water-short countries than in water-abundant countries, but that is not a sufficient criterion for determining an optimal trade strategy. Countries must compare their opportunity costs to those of their trading partners to determine the optimal plan.

Example 1: Comparative Advantage with the Same Water Endowment

Suppose a small nation (Country A) has 10 million m^3 of water available for irrigation. Suppose that volume is sufficient to irrigate 1000 ha of cotton and produce 1200 t of lint, or to irrigate 1500 ha of wheat and produce 4800 t of grain. Assuming linear production technology, the opportunity cost of producing each tonne of cotton in Country A is 4 t of wheat. Similarly, the opportunity cost of producing each tonne of wheat is 0.25 t of cotton lint. These opportunity costs can be compared to those for a potential trading partner.

Suppose another small nation (Country B) also has 10 million m^3 of irrigation water available. Suppose Country B also could irrigate 1000 ha of cotton or 1500 ha of wheat, but its soils and seeds are not as productive as those in Country A. Hence, the total production opportunities in Country B are only 800 t of lint or 4000 t of grain. The production opportunities for Countries A and B and the opportunity costs in each country are summarized in Table 1.

Country A can produce more cotton or more wheat than Country B. Hence, Country A has an absolute advantage in producing both crops. Still, both nations

Table 1 Production opportunities and opportunity costs when Countries A and B have the same water endowment

	Country A	Country B
Production opportunities		
Cotton	1200 t	800 t
Wheat	4800 t	4000 t
Opportunity costs		
Cotton	4 t of wheat	5 t of wheat
Wheat	0.25 t of cotton	0.20 t of cotton

can gain from trade if they consider their opportunity costs and evaluate their comparative advantages. The opportunity cost of cotton is smaller in Country A while the opportunity cost of wheat is smaller in Country B. Hence, Country A has a comparative advantage in cotton production, while Country B has a comparative advantage in wheat production. Consumption opportunities in both countries can be enhanced if Country A specializes in cotton production while Country B specializes in wheat production.

Suppose the two countries specialize in the manner suggested above. Country A produces 1200 t of lint and Country B produces 4000 t of grain. The nations can then trade with each other to obtain units of the commodity they choose not to produce. The international prices will be within the range of opportunity costs shown in Table 1. The price of cotton might become 4.5 t of wheat and the price of wheat might become 0.22 t of lint. Both countries could enhance their consumption of cotton and wheat by specializing in one commodity and trading to obtain units of the other at those prices. Country A might send 400 t of the cotton it produces to Country B in exchange for 1800 t of wheat. The consumption bundles would become those shown in Table 2.

It is easy to verify that neither country could achieve these trading bundles without specialization and trade. If Country A produced 800 t of cotton on 667 ha of land, it could produce only 1600 t of wheat. That result is determined by subtracting the water used to irrigate cotton (6.67 million m^3) from the 10 million m^3 available, calculating the number of hectares of wheat that can be irrigated with the remaining volume (500 ha), and multiplying that area by the average yield of wheat

Table 2 Examples of consumption bundles that might develop when Countries A and B engage in trade

	Consumption bundles with trade	
	Country A	Country B
Cotton	800 t	1200 t
Wheat	1800 t	2200 t

Table 3 Examples of consumption bundles that might develop when Countries A and B do not engage in trade

	Consumption bundles without trade	
	Country A	Country B
Cotton	800 t	360 t
Wheat	1600 t	2200 t

in Country A (3.2 t per ha). Suppose Country B produced 2200 t of wheat and used its remaining water supply to irrigate cotton. Wheat production on 825 ha would leave 4.5 million m^3 for cotton production. That volume would enable Country B to irrigate only 450 ha of cotton and produce only 360 t of lint. Clearly both countries have smaller consumption bundles without trade (Table 3).

This example demonstrates how two countries with the same water endowment can gain from specialization and trade, even if one country has an absolute advantage in producing both commodities. The gains are possible because each country has a comparative advantage in one of the commodities—Country A in cotton and Country B in wheat.

Example 2: Comparative Advantage with Different Water Endowments

A second example is helpful in demonstrating why a water-short country might gain by exporting water-intensive crops and importing crops that require less water per unit of production. Such a scenario seems counterintuitive and inconsistent with the virtual water metaphor. The inconsistency arises because virtual water considers only resource endowments while not accounting for comparative advantages.

Suppose Country A has only half the water supply described in Example 1, while all other parameters of the example remain the same for Countries A and B. If Country A has only 5 million m^3 of water available, its production opportunities are reduced by 50%.

Table 4 Production opportunities and opportunity costs when Countries A and B have different water endowments

	Country A	Country B
Production opportunities		
Cotton	600 t	800 t
Wheat	2400 t	4000 t
Opportunity costs		
Cotton	4 t of wheat	5 t of wheat
Wheat	0.25 t of cotton	0.20 t of cotton

Tailwater–Virtual

Country B's opportunities are not affected. The opportunity costs of production within each country remain the same as in Example 1, as shown in Table 4.

Given the same opportunity costs, the comparative advantages also are the same as in Example 1. Country A will gain by specializing in cotton, even though it requires more irrigation water per hectare than wheat in these examples ($10{,}000\,m^3$ vs. $6667\,m^3$). If the two countries engage in trade, Country A will sell cotton to Country B in exchange for wheat, just as trade occurred in Example 1. An observer using only the virtual water metaphor for guidance may have suggested that Country A should specialize in wheat production and import cotton.

POLICY IMPLICATIONS

The virtual water metaphor, by highlighting the role of embedded water in crop production, can be helpful in motivating public officials to consider policies that will encourage improvements in the use of scarce resources. At some point, discussions with public officials must include consideration of opportunity costs and comparative advantages to ensure that appropriate policy alternatives are examined. The virtual water metaphor does not consider production technologies or opportunity costs; hence it is not analogous to the concept of comparative advantage.

Virtual Water: Measuring Flows around the World

Arjen Y. Hoekstra
Department of Water Engineering and Management, University of Twente, Enschede, The Netherlands

INTRODUCTION

It is generally argued that the river basin is the appropriate unit for analyzing freshwater availability and use. However, it becomes increasingly important to put freshwater issues in a global context due to the increasing water demand and scarcity throughout the world and the inherently global effects of climate change.[1,2] Another reason for taking a global perspective is the effect of global trade on the distribution of water resources use in the world. International trade of commodities implies large-distance transfers of water in virtual form, where virtual water is understood as the volume of water that is required to produce a commodity and that is thus virtually embedded in it.[3,4] One obtains a more realistic picture of water demand and scarcity of a country if one does not only look at actual water use in the country, but also at the virtual water flows entering and leaving the country. Jordan imports about 5 billion cubic meter of virtual water per year,[5] which is in sheer contrast with the 1 billion cubic meters of annual water withdrawal from domestic water sources. Egypt, with a total water withdrawal inside the country of 65 billion cubic meters per year, has an estimated net virtual water import of 11 billion cubic meters per year. The aim of this entry is to show how water requirements of products and international virtual water flows can be estimated and to summarize current knowledge on the size, the relevance, and the consequences of global virtual water flows.

THE VIRTUAL WATER CONTENT OF PRODUCTS

The virtual water content of primary crops is a function of crop water requirements and yields. Crop water requirements can be estimated with the Penman–Monteith equation, as promoted by the Food and Agriculture Organisation.[6] The term 'virtual water' includes both blue water use (the use of abstracted surface or groundwater) and green water use (the use of soil water originating from infiltrated rainwater). The virtual water content of live animals can be estimated based on the virtual water content of their feed and the volumes of drinking and service water consumed during their lifetimes. The procedure for assessing the virtual water content of a processed product (e.g., flour, cotton clothes, milk, cheese, eggs, or meat) is first to obtain the virtual water content of the input product (e.g., the primary crop or the slaughtered animal) and the water necessary to process it. The sum of these two components is then distributed over the various output products based on their product fraction (ton of processed product obtained per ton of input product) and value fraction (the market value of one output product divided by the aggregated market value of all output products).[5]

Based on the above methodology, the total water requirements of all sorts of products can be calculated. One cup of coffee requires, for instance, 140 liters of water, while a cup of tea takes 34 liters. Producing one hamburger requires 2400 liters of water. Wearing a cotton pair of jeans requires more than 11,000 liters. These are global average estimates. There are large differences as a result of production circumstances such as climate and applied technology.

INTERNATIONAL VIRTUAL WATER FLOWS

Virtual water flows between countries ($m^3\,yr^{-1}$) can be calculated by multiplying commodity trade flows ($ton\,yr^{-1}$) by their associated virtual water content ($m^3\,ton^{-1}$). The latter is taken as the volume of water required to produce the commodity in the exporting country.[7]

The sum of international virtual water flows during 1997–2001 was $1625\,Gm^3/yr$.[5] The major share (61%) was related to international trade of crops and crop products. Trade in livestock products contributed 17% and trade in industrial products contributed 22%. These estimates have been based on an analysis of trade between 243 countries for which international trade data are available through the International Trade Center. In total, 285 crop products (covering 164 primary crops) and 123 livestock products (covering 8 animal categories) were considered. Trade in industrial products was dealt with all-inclusively as well, but in a more crude way—the average virtual water content per dollar of traded industrial product was a key parameter.

The total volume of international virtual water flows includes virtual water flows that are related to re-export of imported products. The global volume

Table 1 International virtual water flows and global water use per sector. Period 1997–2001

	Related to trade in agricultural products(Gm^3/yr)	Related to trade in industrial products(Gm^3/yr)	Related to trade in domestic water(Gm^3/yr)	Total(Gm^3/yr)
Gross virtual water flows				
Virtual water export related to export of domestically produced products	957	240	0	1197
Virtual water export related to re-export of imported products	306	122	0	428
Total virtual water export	1263	362	0	1625
	Agricultural sector	**Industrial sector**	**Domestic sector**	**Total**
Water use per sector				
Global water use (Gm^3/yr)	6391	716	344	7451
Water use in the world not used for domestic consumption but for export (%)	15	34	0	16

of virtual water flows related to export of domestically produced products is 1197 Gm^3/yr (Table 1). With a total global water use of 7451 Gm^3/yr, this means that 16% of the global water use is not meant for domestic consumption but for export. In the agricultural sector, 15% of the water use is for producing export products; in the industrial sector, this is 34%.

The major water exporters are the United States, Canada, France, Australia, China, Germany, Brazil, the Netherlands, and Argentina. The major water importers are the United States, Germany, Japan, Italy, France, the Netherlands, the United Kingdom, and China. Table 2 presents the virtual water flows for a number of selected countries. Import of water in virtual form can substantially contribute to the total water supply of a country. The Netherlands imports, for instance, a net amount of (virtual) water equivalent to the annual net precipitation in the country.

VIRTUAL WATER FLOWS BETWEEN WORLD REGIONS

The biggest net virtual water flows between thirteen world regions are shown in Fig. 1. The figure also shows the regional virtual water balances from 1997 to 2001. The green colored regions in the map have a net virtual water export and the red colored regions have a net virtual water import. The regions with the largest virtual water export are North and South America. The largest importers are Western Europe and Central and South Asia. The single most important intercontinental water dependency is Central and South Asia (including China and India), annually importing 80 Gm^3 of virtual water from North America. This is equivalent to one-seventh of the annual runoff of the Mississippi. Ironically, the African continent, not known for its water abundance, is a net exporter of water to the other continents, particularly to Europe.

DISCUSSION

Globalization of freshwater brings both risks and opportunities. The largest risk is that the indirect effects of consumption are externalized to other countries. Because about 16% of global water use is for making export products, a substantial part of the water problems in the world can be traced back to production for export. Water in agriculture is still priced far below its real cost in most countries so that costs associated with water use in the exporting countries are not included in the prices of the products consumed in the importing countries. Efficient and fair trade would require restoring the link between consumers on the one hand and production costs and impacts on the other hand.

Another risk is that the national water security of many countries increasingly depends on the import of water-intensive commodities from other countries. Already today, Jordan annually imports a virtual water volume that is five times its own annually renewable water resource. Although saving their own domestic water resources, it increases Jordan's dependency on other nations. Other countries in the same region, such as Kuwait, Qatar, Bahrain, Oman, and Israel, but also European countries such as the

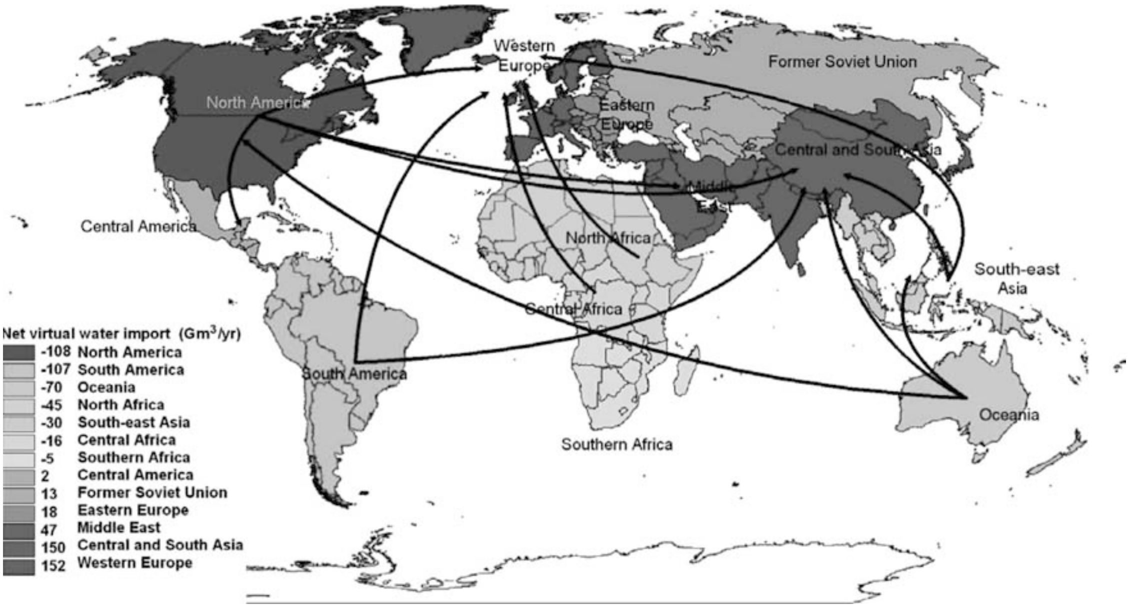

Fig. 1 Regional virtual water balances and net interregional virtual water flows (>10 Gm^3/yr) related to the trade in agricultural products. Period: 1997–2001.

United Kingdom, Belgium, the Netherlands, Germany, Switzerland, Denmark, Italy, and Malta, have a similar high water-import dependency.

An opportunity provided by reduced trade barriers is that virtual water can be regarded as an alternative source of water. Virtual water import can be used by national governments as a tool to release the pressure on their domestic water resources. In an open world economy, according to international trade theory, the people of a nation will seek profit by trading products produced with resources that are abundantly available within the country for products needing resources that are scarcely available. People in countries where water is a comparatively scarce resource could thus aim at importing products that require a lot of water in their production (water-intensive products) and exporting products or services that require less water (water-extensive products).

Finally, global virtual water trade can physically save water if products are traded from countries with high water productivity to countries with low water productivity. For example, Mexico imports wheat, maize, and sorghum from the United States, which require 7.1 Gm^3 of water per year in the United States. If Mexico would produce the imported crops domestically, they would require 15.6 Gm^3/yr. Thus, from a global perspective, the trade of cereals from the United States to Mexico saves 8.5 Gm^3/yr. Although there are examples where water-intensive commodities flow in the other direction—from countries with low water productivity to countries with high water productivity—the resultant of all international trade flows works into the positive direction. Global water saving as a result of international trade of agricultural products has been estimated at about 350 Gm^3/yr. This volume is equivalent to 6% of the global volume of water used for agricultural production.[8]

INTRODUCTION

The demographic trends and future growth projections suggest that more than 60% of the global population may suffer water scarcity by the year 2025.[1] Despite improvements in water-use efficiency techniques, water scarce countries will have to increasingly rely on irrigation with marginal-quality water resources. Wastewater generated by domestic, commercial, and industrial uses is an important component of marginal-quality waters. In many developing countries, wastewater is used for crop production in treated, partly treated, diluted, and untreated forms.[2] Estimates suggest that at least 3.5 million ha are irrigated worldwide with different forms of wastewater;[3] the acreage will increase in future as more freshwater will be diverted to household and industrial sectors, which will generate greater volumes of wastewater.[4]

Many small-scale farmers in developing countries use wastewater in urban and peri-urban areas to produce vegetables as a market-ready product. In addition, rice, fodder, and industrial crops are produced. In developed countries, treated wastewater is mostly used for landscaping, particularly in cities though extensive use in agriculture occurs as well.[5]

The protection of consumer and farmer health and environment are the main concerns associated with uncontrolled wastewater irrigation.[6] Thus, sustainable use of wastewater depends largely on appropriate measures, which address three major aspects: pertinent regulatory policies and institutional arrangements; wastewater treatment per intended reuse option; and agronomic management practices that minimize the health and environmental implications. The focus of this entry is on the agronomic considerations.

AGRONOMIC CONSIDERATIONS FOR WASTEWATER USE

The implementation of suitable agronomic practices for wastewater irrigation is the key to sustainable production systems while taking into account the health and environmental implications. Such agronomic considerations can be divided into four major categories: crop selection and diversification in terms of market value, irrigation requirement, and tolerance against ambient stresses; irrigation management based on water quality, and irrigation method, rate, and scheduling; soil-based considerations such as soil characteristics, soil preparation practices, application of fertilizers and amendments if needed, and soil health aspects; and other considerations such as crop harvesting measures, human health protection while working in the field, and awareness of the farmers about the best agronomic practices. The agronomic considerations are interrelated and implicate each other (Fig. 1).

CROP SELECTION AND DIVERSIFICATION

Crop selection in terms of irrigation requirement is particularly important in water scarce areas where major dependency is based on the nature of the crop, the growth period, and the climatic conditions in the area such as rainfall, and ambient temperature and relative humidity. Since crop evapotranspiration is determined by the climatic factors, it can be estimated by using the meteorological data. Computer models are available that assist in computation of crop water use.

In addition to some metals and metalloids, most treated wastewaters contain appreciable concentrations of salts, which may affect growth and yield. The growth of crops irrigated with saline wastewater is influenced by the osmotic and ion-specific effects, and ionic imbalance leading to deficiency and/or toxicity of some nutrients. In such cases, there would be a need to select crops that can tolerate the salt and ion-specific effects. Guidelines are available that suggest yield potentials of a range of grain, forage, vegetable, and fiber crops as a function of average root zone salinity (see the entry *Wastewater Use in Agriculture: Saline and Sodic Waters*).

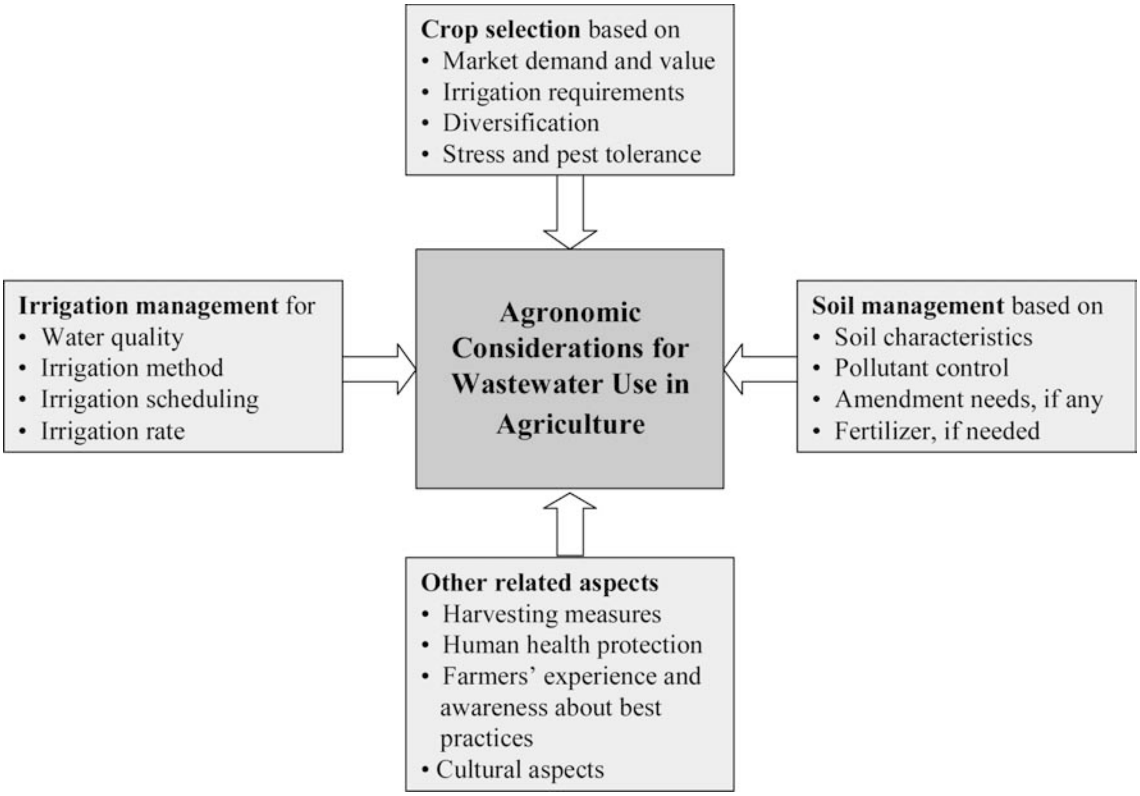

Fig. 1 Schematic illustration of the four main categories of agronomic considerations, which are interrelated and implicate each other.

The selection of crops for irrigation with wastewater also depends on the cost of inputs and the subsequent economic and/or on-farm benefits. However, care should be taken to select the crops that while providing financial benefits to the farmers should not contain excessive levels of metals, metalloids, and biological contaminants, which may have deleterious health effects. The restrictions on crops are feasible and particularly facilitated under the following conditions: strong law enforcement on crop selection; control of public body over water allocation; irrigation project with strong central management; and market demand of the crop(s) promoted for irrigation with wastewater.[7] In general, the highest risk involves consumers and farmers when irrigation with untreated, or inadequately treated, wastewater is practiced for crops that are eaten uncooked such as fresh vegetables. The cultivation of industrial crops such as cotton provides the lowest risks to the consumers, but protection of farmers is still needed.[8] The implications relating to irrigation with untreated or partly treated wastewater can be reduced if agroforestry species are grown for non-edible products such as fuel and timber.[9]

IRRIGATION MANAGEMENT

In addition to water supply conditions, climate, soil characteristics, candidate crops, irrigation cost, and farmer's skill, the choice of irrigation method with wastewater depends on water quality, possible contamination of the harvest material, and health and environmental implications. Based on possible risks of contamination by different metals and metalloids, water quality guidelines for wastewater irrigation are available (Table 1).

Wastewater irrigation can be accomplished by the following approaches: surface or flood irrigation where water is applied directly on the soil surface by gravity; furrow irrigation; high pressure sprinkler irrigation; and micro-irrigation such as drip and trickle irrigation. Flood irrigation is the lowest cost method with low water use efficiency and low level of health protection for the farmers and consumers. With medium level of health protection, furrow irrigation needs land leveling. It is suitable when there is a greater leaching need to remove high levels of salts. Without the need of land leveling, irrigation with sprinklers involves medium to high cost and medium water use efficiency. It has low levels of health protection because of aerosols. Irrigation scheduling aspects such as irrigation during night and no irrigation under windy conditions are important considerations while using sprinklers. Drip irrigation systems are costly, but highly efficient in water use along with the highest levels of health protection. However, filtration is needed to prevent clogging of emitters.[9]

Table 1 Recommended maximum concentrations (RMC) of selected metals and metalloids in irrigation water

Element	RMC ($mg\,L^{-1}$)	Remarks
Aluminum	5.00	Can cause non-productivity in acid soils ($pH < 5.5$), but more alkaline soils at $pH > 7.0$ will precipitate the ion and eliminate any toxicity
Arsenic	0.10	Toxicity to plants varies widely, ranging from $12\,mg\,L^{-1}$ for Sudan grass to less than $0.05\,mg\,L^{-1}$ for rice
Beryllium	0.10	Toxicity to plants varies widely, ranging from $5\,mg\,L^{-1}$ for kale to $0.5\,mg\,L^{-1}$ for bush beans
Cadmium	0.01	Toxic at concentrations as low as $0.1\,mg\,L^{-1}$ in nutrient solution for beans, beets and turnips. Conservative limits recommended
Chromium	0.10	Not generally recognized as an essential plant growth element. Conservative limits recommended
Cobalt	0.05	Toxic to tomato plants at $0.1\,mg\,L^{-1}$ in nutrient solution. It tends to be inactivated by neutral and alkaline soils
Copper	0.20	Toxic to a number of plants at 0.1 to $1.0\,mg\,L^{-1}$ in nutrient solution
Iron	5.00	Non-toxic to plants in aerated soils, but can contribute to soil acidification and loss of availability of phosphorus and molybdenum
Lithium	2.50	Tolerated by most crops up to $5\,mg\,L^{-1}$. Mobile in soil. Toxic to citrus at low concentrations with recommended limit of $<0.075\,mg\,L^{-1}$
Manganese	0.20	Toxic to a number of crops at a few-tenths to a few $mg\,L^{-1}$ in acidic soils
Molybdenum	0.01	Non-toxic to plants at normal concentrations in soil and water. Can be toxic to livestock if forage is grown in soils with high concentrations of available molybdenum
Nickel	0.20	Toxic to a number of plants at 0.5 to $1.0\,mg\,L^{-1}$; reduced toxicity at neutral or alkaline pH
Lead	5.00	Can inhibit plant cell growth at very high concentrations
Selenium	0.02	Toxic to plants at low concentrations and toxic to livestock if forage is grown in soils with relatively high levels of selenium
Zinc	2.00	Toxic to many plants at widely varying concentrations; reduced toxicity at $pH \geq 6.0$ and in fine textured or organic soils

The maximum concentration is based on a water application rate, which is consistent with good irrigation practices ($10000\,m^3\,ha^{-1}\,yr^{-1}$). If the water application rate greatly exceeds this, the maximum concentrations should be adjusted downward accordingly. No adjustment should be made for application rates less than $10000\,m^3\,ha^{-1}\,yr^{-1}$. The values given are for water used on a long-term basis at one site.
Source: Adapted from Ref.[10].

Financial consideration is an important factor that drives the choice of irrigation method. Nevertheless, the health risks associated with different methods as well as water savings should also be considered.[8] Recently revised guidelines by the World Health Organization provide complementary options for wastewater treatment and control of human exposures (see the entry *Wastewater Use in Agriculture: Empirical Evidence*).

SOIL-BASED INTERVENTIONS

Good management practices play a crucial role in the preservation of the soil properties while irrigating with wastewater. Soil-based interventions are important, particularly in case of inorganic contaminants, which usually accumulate in the upper part of the soil because of strong adsorption and precipitation phenomena. For moderate levels of metals and metalloids in wastewater, there is no particular management needed if the soils are calcareous, i.e., contain appreciable levels of calcite. However, metal ions may be a problem in acid soils, which need specific management measures such as liming, avoiding use of fertilizers with acidic reactions, and selection of crops that do not accumulate the metals of concern.[10] In case of irrigation with wastewater containing elevated levels of sodium, care should be taken to avoid soil structure deterioration. Application of a source of calcium such as gypsum is desirable. Procedures are available to determine the rate of gypsum application to mitigate the effects of sodium resulting from sodic wastewater irrigation.

The quality and depth of groundwater prior to wastewater irrigation determine the detrimental effects of salts, nitrates, and metals reaching groundwater. The deeper the groundwater, the longer it will take to have such effects. In case of shallow groundwater or coarse-textured soils—sandy soils that are highly permeable—care must be taken to prevent groundwater pollution.

Table 2 Contribution of irrigation with recycled wastewater (treated urban wastewater) in terms of nutrient addition to the soil

		Fertilizer contribution ($kg\,ha^{-1}$)	
Nutrient	**Concentration ($mg\,L^{-1}$)**	**Irrigation at $3000\,m^3\,ha^{-1}$**	**Irrigation at $5000\,m^3\,ha^{-1}$**
Nitrogen	16–62	48–186	80–310
Phosphorus	4–24	12–72	20–120
Potassium	2–69	6–207	10–345
Calcium	18–208	54–624	90–1040
Magnesium	9–110	27–330	45–550
Sodium	27–182	81–546	135–910

Derived from the data on nutrient concentrations in recycled wastewater and volume of applied irrigation. *Source*: From Ref.[7].

Although the fertilizer value of wastewater is of great importance, as nutrients in wastewater contribute to crop requirements, periodic monitoring is required to estimate the nutrient loads in wastewater and adjust fertilizer applications.[7] Excessive nutrients can cause nutrient imbalances, undesirable vegetative growth, delayed or uneven maturity, and can also reduce crop quality and pollute groundwater and surface water. The amount of nutrients applied via wastewater irrigation can vary considerably if it is raw, treated, or diluted with stream water. The contribution of irrigation with recycled wastewater in terms of nutrient addition to the soil is given in Table 2.

OTHER CONSIDERATIONS

Farmers who use untreated, or inadequately treated, wastewater are exposed to health risks, which can be reduced by implementing protective measures such as wearing boots and gloves, and washing their arms and legs after immersion in wastewater to prevent the spread of infections (see the entry *Wastewater Use in Agriculture: Public Health Considerations*). For certain crops, farmers also can suspend application sometime prior to harvest, to reduce potential harm to consumers. Vegetables can be washed (with good-quality water free of pathogens, viruses, and contaminants) before sale or consumed along with improvement in the storage methods. The awareness and education of the farmers about the best agronomic interventions is an essential step in sustainable wastewater irrigation.

Wastewater Use in Agriculture: Empirical Evidence

Liqa Raschid-Sally

INTRODUCTION

Agriculture is the largest consumer of freshwater resources, currently accounting for about 70% of global water diversions. With increasing demand from municipal and industrial sectors, competition for water will increase and it is expected that water now used for agriculture will be diverted to the urban and industrial sectors. One *planned* response in *developed* countries to increasing competition and water scarcity is to promote greater use of treated urban wastewater for various purposes, including agriculture.[1] In water short arid areas like the Middle East, this contribution can represent as much as 25–55% of irrigation water use.[2]

On the other hand, in *developing* countries the use of untreated wastewater for agriculture is already an unplanned reality as rapid urbanization outpaced the development of appropriate treatment infrastructure. Especially in Africa and Asia, there is hardly a city where more than 30% of the generated wastewater is collected and/or at least partially treated. The common situation is a non-point disposal across the city in gutters and storm water drains. These drain into and pollute natural waterways traditionally serving the downstream population.[3] In some instances seasonal streams become perennial owing to the continuous flow of wastewater into them, like the Musi River in Hyderabad, India. In most cases a large portion of the wastewater is of domestic origin although industrial wastewater can be part of the wastewater flow (Box 1).

This entry summarizes information on extents and practices and the challenges faced in addressing the health risks associated with the agricultural use of *untreated* wastewater in low-income countries.

Box 1: Terminology as used in this entry

Wastewater components and origin: Wastewater can comprise one or more of the following components: domestic water from kitchens and bathrooms (so-called ‘‘gray’’ water), from toilets (‘‘black’’ water), urban run-off (storm water), and (agro) industrial return flow.

(Continued)

Wastewater quality: The most common pollutants comprise pathogens, organic matter, and chemicals. The degree of pollution can vary widely in time and space (upstream, downstream) and depends largely on the percentage of urban liquid and solid waste collected, in particular of human urine and feces, treatment capacities, presence and type of industry, etc. To capture the variability, the term ‘‘wastewater’’ as used here, *refers to insufficiently treated wastewater, including polluted stream water with a pollution level considered inappropriate for irrigation of crops likely to be eaten uncooked*. The most common microbiological (health) indicators are fecal coliform bacteria, which should be less than 10^3 (=1000) in 100 ml of the water. However, in most urban streams in the developing world, the values range between 10^4 and 10^9.

Wastewater use in agriculture: Treatment is recommended before such use. When farmers choose to use it untreated, it is usually because there is no alternative cleaner, more reliable, or cheaper water source available. But they also appreciate its nutrient content, which might allow reducing fertilizer application, though concentrations of nutrients vary with the degree of dilution and are not controllable at farmers' end.

EXTENTS AND LIVELIHOOD BENEFITS

Irrigation with ‘‘wastewater’’ (see box) is a common reality in three-fourths of all cities, as a recent survey of 53 cities across Africa, Asia, and Latin America showed.[2] The underlying reason is the urban demand for perishable food, where supply is constrained by lack of refrigerated transport and storage. Farming in market proximity becomes profitable, and the most important physical factor for selecting a farm plot is access to water throughout the year. Streams in or close to the city provide this. Although total areas under irrigation might be small, continuous cultivation with up to 10 harvests per year often satisfies the total urban demand for specific crops like lettuce.[4] The use of polluted irrigation water is most prevalent in Asian cities with Vietnam, China, and India taking the lead. Vegetables and cereals (especially rice) are the two most common commodities cultivated.

The same survey showed that approximately 0.4 million ha are cultivated with wastewater by a farmer population of over one million in the cities studied. Global estimates, though fragmentary, give a figure of at least 3.5 million hectares worldwide with the largest share probably in China.[5] In Vietnam, the two major cities account for 120,000 ha under irrigation with polluted water. Raw sewage irrigation takes place, for example, on 10,000 ha around Pakistan's major cities and 90,000 ha in the Mezquital valley in Mexico. Mexico accounts probably for half of the 500,000 ha irrigated with wastewater in Latin America. In some countries, the area under irrigation with polluted water can far exceed that in official irrigation schemes using conventional water sources.[4]

Cash crop cultivation in city proximity can provide significant livelihood opportunities and have other positive impacts.[6] In Ghana, dry-season irrigation allows an average extra-income of US$150 while year-round irrigation in urban areas keeps families above the poverty line.[4] Around Kumasi, more than 60,000 people depend on these water sources for their living, and in Mexico's Mezquital valley the irrigation area supports more than 450,000 people. In other places, wastewater farmers have higher returns on investments than farmers using conventional water sources, which often are less reliable, lack nutrients, and are more expensive.[7]

POSSIBLE HEALTH IMPACTS AND RISKS

Crop contamination levels vary with the methods of water application and amounts. While in Asia and Latin America, flood and furrow irrigation can be observed, most smallholders in Africa fetch and apply the water with watering cans. Especially, spray application on the crop leads to high contamination levels. But besides the consumers (of crops eaten raw), farmers in contact with the water, and traders in contact with the produce are also at risk. Shuval, Yekutiel, and Fattal[8] ranked the pathogens in the following descending order of risk:

1. High: **Helminths** [the intestinal nematodes (*Ascaris, Trichuris*), hookworm (*Ancylostoma*), and cestodes–(*Taenia*)].
2. Lower: **Bacterial infections** (i.e. cholera, typhoid, and shigellosis) and **Protozoan infections** (i.e. amebiasis, giardiasis).
3. Least: **Viral infections** (viral gastroenteritis and infectious hepatitis).

Many studies confirmed that irrigation with wastewater use could increase farmers' risks of skin infection and helminth infections, mainly *Ascaris* and hookworm.[9] Corresponding recommendations on how farmers could protect themselves are seldom applied for various reasons, often related to the inconvenience of using protective clothing, especially in hot climates. Other studies have shown that consumption of vegetables irrigated with wastewater can increase the risk of worm infections in the general public as well as outbreaks of typhoid fever, etc.[9] However, too few studies have combined epidemiological investigations with water and crop quality analysis and quantitative microbial risk and exposure assessments. Especially in developing country contexts, the risk from exposure to food and water rendered unsafe owing to other sources of contamination, as well as unhygienic conditions, may be far in excess of risks related to the intake of vegetables irrigated with wastewater; and clear cause–effect relationships are difficult to establish.[10]

Table 1 The effectiveness of selected health-protection measures that can be used to remove pathogens from wastewater if possible in combination

Protection measure (examples)	Pathogen reduction (log units)
Wastewater treatment (to different degrees)	1–6
Localized (drip) irrigation (with "low-growing" crops, e.g. lettuce)	2
Localized (drip) irrigation (with "high-growing" crops, e.g. tomatoes)	4
Pathogen die-off on the surface of crops after the last irrigation	0.5–2 per day
Washing of produce with clean water	1
Disinfection of produce (using a weak disinfectant solution)	1–2
Disinfection of produce (using recommended products and concentrations)	3–4
Peeling of produce (fruits, root crops)	2
Cooking of produce	6–7

Source: Modified from Ref.[9].

Wastewater–Yellow

The studies in Accra, Ghana, where vegetables produced with polluted irrigation water reach 200,000 urban dwellers every day demonstrate, however, the potential risk of spreading epidemics if risk reduction measures are lacking.

RISK REDUCTION

In low-income countries where comprehensive wastewater treatment is not feasible, strict water quality guidelines serve little purpose, as farmers do not have much choice in the selection of the irrigation water source and its quality. Pollution control measures are required but often hard to finance and enforce given the fact that the majority of pollution is non-point. Other regulations, including crop restrictions, are seldom economically feasible for farmers. Although in most countries the use of untreated wastewater is banned, it remains often tolerated, as enforcements are hardly possible given the large numbers of dependent farmers. Thus, other approaches to risk reduction have to be implemented.

The latest guidelines[9] for the safe use of wastewater in agriculture moved the discussion from water quality-based targets to health-based targets. In addition, governments in developing countries have been given greater flexibility in applying the guidelines using a combination of treatment and/or non-treatment options for health risk reduction (Table 1). This should allow them to reduce possible health risks as much as possible under their circumstances, even if common water quality thresholds cannot be reached.

CONCLUSIONS

In many developing countries, the use of wastewater to irrigate vegetables is particularly common in urban and peri-urban areas. Considering the gap between population growth and urban infrastructure development, it can be assumed that this practice will remain a reality in the decades to come. The related health risks are an increasing concern of authorities as neither comprehensive wastewater treatment nor banning its use appears possible. In finding appropriate solutions, the trade-offs between the benefits and risks of irrigation with wastewater have to be considered. The new WHO guidelines for wastewater use in irrigated agriculture[9] offers increased flexibility in options for health risk reduction tailored to this context. The applicability of these guidelines is now being tested in Africa, the Middle East, and Latin America.

Wastewater Use in Agriculture: Public Health Considerations

Blanca Jimenez
Environmental Engineering, Universidad Nacional Autónoma de México, Mexico City, Mexico

INTRODUCTION

By and large, the use of wastewater for agricultural irrigation is the most important reuse of wastewater around the world. It is actually an old practice dating from 4000 B.C. At present, some countries use treated wastewater, while others still use raw wastewater for many reasons. In principle, if treated wastewater is used and properly managed during irrigation, no health effects should occur. But, if polluted or non-treated wastewater is used, negative health effects would be observed. This entry describes such effects. The different groups of population at risk are presented and it is explained how such risks are scientifically measured. Observed effects caused by biological and chemical pollutants are discussed together with different ways to control them.

AFFECTED POPULATION GROUPS

There are four population groups at risk due to the different exposure pathways to wastewater: (a) farmers and their families, (b) crop handlers, (c) produce consumers, and (d) people living near the places where irrigation takes place. Exposure may be direct through contact with the wastewater or indirect through contact with sick people or the ingestion/contact of polluted crops, meat, or milk. The elderly and children are the most vulnerable groups. Health problems may also arise if wastewater irrigation activities result in increased vector breeding, promoting the spread of vector-borne diseases. Crops are polluted by their contact with wastewater during irrigation or, in the case of metals, through absorption from soil. Pollution of the edible parts of food crops depends not only on the quality of water, but also on the quantity of wastewater applied, the irrigation method, and the type of crop. For example, zucchini, when spray-irrigated with wastewater, accumulate on their surface higher levels of pathogens than other crops. Zucchini have a hairy, sticky cover and grow close to the ground, thus favoring pathogen attachment. Crop contamination can occur not only as a result of wastewater irrigation but also during washing, packing, transportation, and marketing, which are problems frequently not addressed, giving the impression that irrigation is the only source of pollutants. Meat and milk are contaminated if cattle graze on pasture polluted with wastewater and subsequent ingestion of these products may affect human health.[1]

HEALTH RISKS

The most important negative health effects are due to the presence of pathogens and toxic chemical compounds in the wastewater. To determine the extent of the impact, two approaches are used: epidemiological and quantitative risk assessment studies. The first consists of measuring the number of additional sick people in a population exposed to wastewater during irrigation, compared with a similar (socially and economically) unexposed population. In other words, these studies measure the health effects that actually occur. Quantitative risk assessment studies use data on the pollutant content in wastewater, different scenario exposure (types or crops, quantity of wastewater involved, ingestion modes, etc.) and the infective or toxic dose to determine the risk of disease–that is to say, they estimate the health effects.

BIOLOGICAL POLLUTANTS

There are four groups of biological pollutants in wastewater: viruses, bacteria, protozoa, and helminth eggs. Each group is composed of several types of organisms, some of which are pathogenic to humans. The type and concentration of each group in a wastewater depends on the number of sick people contributing to the wastewater. This is because wastewater

Table 1 Comparison of the disease rate in an area using wastewater to irrigate with an area using treated wastewater

		Rate of morbidity		
Organism	**Population affected by age**	**Zone irrigated with untreated wastewater (A)**	**Zone irrigated with treated wastewater (B)**	**A/B ratio**
Helminth *(Ascaris lumbricoides)*	0–4	15.3	2.7	5.7
	5–14	16.1	1.0	16.0
	>15	5.3	0.5	10.6
Protozoan *(Giardia lamblia)*	0–4	13.6	13.5	1.0
	5–14	9.6	9.2	0.9
	>15	2.3	2.5	0.9
Protozoan *(Entamoeba histolytica)*	0–4	7.0	7.3	1.0
	5–14	16.4	12.0	1.4
	>15	16.0	13.8	1.2

Source: From Ref.[2].

mirrors public health conditions, reflecting by its composition the magnitude and type of local diseases.

Not all of the biological groups represent the same risk. This can be explained with the help of Table 1, which summarizes the results from an epidemiologic study comparing observed effects on two similar populations. In the population using wastewater to irrigate, disease caused by a helminth was increased 6–16 times more than that in the unexposed population. However, for protozoan diseases, no difference was observed.

In 2006, the World Health Organization (WHO) stated that the major risk for all exposed groups to wastewater was caused by helminths. Following helminths, the next causes of risk are bacteria and viruses. Cholera, typhoid, shigellosis, salmonellosis, nonspecific diarrhoeal disease outbreaks, as well as *Helicobacter pylori* infections causing gastric ulcers, have been reported when untreated wastewater is used. Different viral infections have also been reported. For neighboring communities, bacterial (but not viral) infections are increased if wastewater is applied using sprinklers. Concerning protozoa, there is no evidence of an increase in disease transmission for any except amebiasis in farm workers and their families if they are in contact with wastewater. Using quantitative microbial risk assessment studies, it has been demonstrated that risks caused by viruses are higher than those caused by protozoa.[3]

MAIN INFECTIOUS DISEASES

Helminthiases (worm diseases) are the major diseases transmitted. They are very common in developing countries, where the affected population is 25–33%, reaching up to 90% in populations living in poverty and with poor sanitary conditions.[4] In developed countries, helminthiases reach 1.5% of the population at most. There are several kinds of helminthiasis; ascariasis is the most common and is endemic in Africa, Latin America, and the Far East. There are 1.3 billion infections globally. And, even though it is a disease with low mortality rate, most of the people affected are children under 15 years with problems of faltering growth or impaired fitness or both. Approximately 1.5 million of these children will probably never catch up, even if treated.[5] Another important helminthiasis is schistosomiasis, which particularly affects African and Asian countries. Other diseases related to the use of wastewater are cholera, typhoid, shigellosis, gastric ulcers, giardiasis, amebiasis, and skin diseases. Koilonychia (spoon-shaped nails disease) has been also reported in farmers as a result of the anemia caused by helminths.

CHEMICALS

Regarding chemical compounds, the major health concern is due to heavy metals, followed by toxic organic compounds. Some heavy metals, such as cadmium, copper, molybdenum, nickel, and zinc, accumulate in crops to levels that are toxic to consumers. But fortunately, most of them cause damage in the plants before reaching harmful levels in humans and cattle. Cadmium is the metal displaying the greatest risk. It is toxic to humans and animals in doses much lower than those that visibly affect plants; furthermore crop uptake can increase with time.[6] Maximum tolerable soil concentrations of various chemical compounds (heavy metals and organics), based on human health protection, are given by the WHO.[3] Heavy metal contents in municipal wastewaters

Table 2 Health protection measures to control the risks caused by pathogens

For all exposed groups		
• Wastewater treatment • Access to safe drinking-water and sanitation facilities • Chemotherapy and immunization • Health and hygiene promotion		
Product consumers and produce handlers	**Workers and their families**	**People living in the nearby areas**
• Crop restriction • Wastewater application techniques that minimize contamination • Withholding periods to allow pathogen die-off after the last wastewater application • Hygienic practices at food markets and during food preparation • Produce washing, disinfection, and cooking	• Use of personal protective equipment • Disease vector and intermediate host control • Reduced vector contact • Reduced vector contact	• Restricted access to irrigated fields and hydraulic structures • Access to safe recreational water, especially for children and adolescents • Disease vector and intermediate host control

are generally within acceptable levels; however, if industrial wastewaters are dicharged to municipal sewers, metals might reach dangerous levels.

There are no epidemiological data on the effect of organic compounds. Based on quantitative risk assessment studies, they appear to be minor. Most of the toxic organic compounds have a large size and high molecular weight, so they are not absorbed by plants and they tend to remain in the soil.[3] In fact, the major risk is caused by pesticides remaining on the surface of fruits and leaves that are applied directly to crop fields, rather than due to their introduction through wastewater irrigation.

BENEFICIAL EFFECTS ON HEALTH

The use of wastewater can also have positive effects on health. These are recently acknowledged and relate to food security in poor areas. Thanks to wastewater, it is possible (and frequently the only way) to produce food and increase income in poor areas and thus this way nutrition and thus health are improved. Malnutrition plays a significant role in the death of 50% of all children in developing countries, with nearly 10.4 million children under the age of 5 dying from it every year.

CONTROL

Although it could be thought that to control risks, the use of wastewater should be simply banned, in many regions this is not an option. What is needed is first to set appropriate and affordable standards in each country to progressively control the use of untreated wastewater. In doing this, it is important to identify different methods (Table 2).

According to WHO (2006), treated wastewater with 10^3–10^4 thermotolerant coliforms (that are indicators of bacterial fecal pollution) and <1 helminth egg/L should not pose any threat. Thus, it is important to disinfect wastewater. This can be done for all pathogens but for helminth eggs by using chlorine, UV-light, or ozone. For helminth eggs, the only efficient methods consist in removing them from wastewater by methods that remove particles,[7] such as sedimentation and filtration. That is why, stabilization ponds, sand and gravel filtration, and even coagulation–flocculation processes have been successfully applied. Removal of Helminth eggs is only relevant in developing countries where their content in wastewater is 7–80 times higher than in that from developed ones.

CONCLUSION

The use of wastewater for irrigation provokes negative and positive effects on health. Negative effects are due mainly to pathogenic diseases, the most important ones being those caused by helminths, bacteria, and viruses, in that order. To obtain maximal benefits from using wastewater, it is important to apply methods to control these negative impacts. The methods are very varied and do not only refer to wastewater treatment, but also to those presented in Table 2.

INTRODUCTION

In dry areas, water of marginal quality is a crucial segment of the overall water management in irrigated agriculture. As an important component of marginal-quality water, urban wastewater is used to irrigate a range of crops. Wastewater is more saline than freshwater because salts are added to it from different sources.[1] There are no economically viable means to remove the salts once they enter wastewater because of the prohibitively expensive techniques such as cation exchange resins or reverse osmosis membranes, which are only used to produce high-quality recycled water.[2]

Saline wastewater contains excess levels of soluble salts while sodic water is characterized by excess levels of sodium (Na^+). In many cases, both salts and Na^+ are present in excess concentrations (saline–sodic wastewater). In addition, wastewater may contain excess levels of metals, metalloids, detergents, pesticide residues, and medical waste. Salinity in wastewater is characterized by its electrical conductivity (EC) expressed in terms of deciSiemens per meter ($dS\,m^{-1}$). Sodicity is assessed by sodium adsorption ratio (SAR), which is expressed as the relative amounts of Na^+ to that of calcium (Ca^{2+}) and magnesium (Mg^{2+}). This entry addresses sources of salts in wastewater, their potential environmental implications, relevant preventive measures, and management strategies for agricultural use.

SOURCES OF SALTS IN WASTEWATER

Major sources of salts and other inorganic contaminants in wastewater originate from the industries, which are generally divided into two broad categories. The first category includes those industries that generate wastes with high salt concentrations. The examples are rayon plants, and the chemical manufacturing industry (caustic soda, soap, and detergents), among others. The second category consists of industries that generate varying levels of toxic wastes; for example, pesticides, fertilizers, steel plants, smelters, pharmaceuticals, and tanneries.[3] The amount and type of salts used in an industry and the relevant treatment affect its wastewater quality. In addition, the implications are complex when industrial or commercial brine waste streams are not discharged into separate waste sewers, rather into main urban sewers that convey wastewater to the treatment plants or to disposal channels leading to farmers' fields. There are no limits on salt concentrations for discharge of industrial wastewater into urban sewers.[4] Salinity and sodicity related characteristics in wastewater generated in different areas of the Indian sub-continent are given in Table 1.

ENVIRONMENTAL IMPLICATIONS

In addition to metals and metalloids and other pollutants, excess salts in irrigation water have negative effects on crops, soils, and groundwater. Plant growth is affected by the osmotic and ion-specific effects, and ionic imbalance leading to deficiency and/or toxicity of some nutrients. Osmotic effects depress the external water potential, making water less available to the plants. Excess levels of certain ions, such as Na^+, chloride (Cl^-), metals, and metalloids cause ion-specific effects leading to toxicity or deficiency of certain nutrients in plants.[5]

Excess salinity levels in irrigation water do not adversely affect soil structure and its physical and hydraulic properties. Rather, saline conditions may have favorable effects on soil structure stability.[6] However, in case of sodic water irrigation, the excess levels of Na^+ and bicarbonate (HCO_3^-) gradually result in the development of sodicity problem in soils, thereby exhibiting structural problems created by certain physical processes (slaking, swelling, and dispersion of clay) and specific conditions such as surface crusting and hardsetting.[7] Such problems may affect water and

As a salinity parameter, EC refers to electrical conductivity. Sodicity parameters consist of sodium adsorption ratio (SAR) and residual sodium carbonate (RSC).

air movement, root penetration, seedling emergence, runoff, erosion, and tillage operations.

Irrigation with saline and/or sodic wastewater may impact groundwater quality. In case of well-drained soils, there is a possibility of movement of salts and other contaminants through the soil profile into unconfined aquifers.[8] The quality of wastewater, soil characteristics, and the initial quality of the receiving groundwater are the important factors that determine the extent to which salts in wastewater impact groundwater quality.

PREVENTIVE MEASURES AND MANAGEMENT STRATEGIES

Source Control

Controlling the source from where salts are added to wastewater is an important step to protect wastewater quality for beneficial reuse. The sources of salts in wastewater can be reduced by using technologies in industrial sector that reduce salt consumption vis-à-vis discharge into the sewage system. In addition, restrictions can be imposed on the use of certain products for domestic use that are major sources of salts in wastewater.[4] Other measures consist of rehabilitation or repair of leaky sewers infiltrated by saline effluent.

Crop Selection

An appropriate selection of crop or crop variety capable of producing profitable biomass is vital while irrigating with saline and/or sodic wastewater. Such selection is generally based on the ability of the crop to withstand ambient levels of salinity and sodicity in the growth medium.[9] The salt tolerance of a crop is not an exact value because it depends on several soil, crop, and climatic factors. It reflects the capacity of a crop to endure the effects of excess root zone salinity. The capacity of crops to withstand salinity is described in relative terms and generally divided into four classes, i.e., sensitive, moderately sensitive, moderately tolerant, and tolerant. Salt tolerance threshold values of a range of crops as a function of average root zone salinity are given in Table 2. The genetic diversity among these crops provides a range of cropping options. In the case where production of field crops is not feasible owing to high salinity, salt-tolerant trees and halophytes can be planted.

In case of long-term wastewater irrigation, there may be toxicity of certain ions if taken up by the plants in excessive concentrations. The degree of such damage depends on ambient concentrations of the toxic element, crop sensitivity, and crop water use. In terms of their effects, the main toxic ions in municipal effluents are boron (B) > Na^+ > Cl^-.[4] Classification of crops as a function of tolerance for these ions is available elsewhere.[9] Since wastewater mostly contains high concentrations of nutrients such as nitrogen (N), the crops may not require N-fertilizer application except for the basal dose in some cases to meet the initial high demands. However, effective management of nutrients in wastewater is case-specific.

Irrigation and Water Management

Wastewater irrigation can be accomplished by different methods such as surface or flood irrigation, furrow irrigation, sprinkler irrigation, and micro-irrigation such as drip or trickle irrigation. Among them, sprinkler irrigation may cause injury to crops from the salts absorbed directly through wetted leaf surfaces. Several factors affect salt accumulation in leaves: leaf age, shape, angle, and position on plant; type and concentration of salt; ambient temperature; air velocity; irrigation frequency; and length of time the leaf remains wet.[9] Since injury is related more to the number than the duration of sprinkler irrigation, infrequent and heavy irrigations should be preferred over frequent and light irrigations.

Consistent with all irrigation approaches, care should be taken that water is applied in excess of crop water requirement (evapotranspiration) or that predictable rainfall occurs to leach excess salts from the root zone. Salinity control by effective leaching of the root zone becomes more important under conditions where wastewater and/or soil contain high concentrations of salts. Leaching can be accomplished at each irrigation event, alternate irrigation, or less frequently as the leaching frequency depends on the salinity status in water or soil, salt tolerance of the crop, and climatic conditions. The amount of rainfall should be taken

Table 2 Yield potentials of some grain, forage, vegetable, and fiber crops as a function of average root zone salinity

Crop at specified yield potentials		Average root zone salinity ($dS\,m^{-1}$)

These data serve only as a guideline to relative tolerances among crops. Absolute tolerances vary and depend on climate, soil conditions, and cultural practices.
Based on the salt tolerance data of different crops and percentage decrease in yield per unit increase in root zone salinity in terms of $dS\,m^{-1}$ as reported by Maas and Grattan.[9]

into consideration while estimating the leaching requirement and selecting leaching method. Although leaching is essential to prevent root zone salinity, leaching under saline wastewater irrigation may result in the movement of nitrates, metals and metalloids, and salts to the groundwater. Therefore, monitoring of groundwater level and quality is an essential indicator of environmental performance.[4]

Saline wastewater can be used for irrigation in conjunction with freshwater, if available, through cyclic, blending, and sequential approaches. Several studies have evaluated different aspects of these approaches on a field scale. These approaches allow a good degree of flexibility to fit into different situations.[10] Guidelines pertaining to water quality for irrigation are available in Table 3.

Seedbed Preparation and Planting Techniques

Since most crops are salt-sensitive at germination stage, their establishment is most critical with saline wastewater. Under field conditions, it is possible by modifications of planting practices to minimize salt accumulation around the seed and to improve the stand of crops that are sensitive to salts during germination. For example, sowing near the bottom of the furrows on both sides of the ridges, raising seedlings with freshwater and their transplanting, using mulch to carry over soil moisture for longer period, and increasing seed or seedling rate per unit area (plant

Wastewater–Yellow

density) to compensate for possible decrease in germination and growth.

Soil and Water Treatment

Irrigation with sodic wastewater needs provision of a source of Ca^{2+} to mitigate Na^{+} effects on soils and crops. Gypsum ($CaSO_4{\cdot}2H_2O$) is the most commonly used source of Ca^{2+}; its requirement for sodic water depends on the Na^{+} concentration and can be estimated through simple analytical tests. Gypsum can be added to the soil, applied with irrigation water by using gypsum beds, or placing gypsum stones in water channel. In case of calcareous soils, containing precipitated or native calcite ($CaCO_3$), the dissolution of calcite can be enhanced through plant root action to increase Ca^{2+} levels in the root zone. Therefore, a lower rate of gypsum application may work well on calcareous soils. Plant residues and other organic matter left in or added to the field can also improve chemical and physical conditions of the soils irrigated with sodic wastewater. In addition, biological treatment of salt-prone wastewater by standard activated-sludge culture can be triggered by the inclusion of salt-tolerant organisms to improve treatment efficiency. Other amendments such as lime, kaolin, and zeolite can also be used to immobilize heavy metals in wastewater-irrigated soils.

CONCLUSIONS

Irrigation with urban wastewater is a popular alternative to its discharge into rivers or other water bodies. In addition to organic solutes, wastewater may contain appreciable amounts of inorganic salts, metals, metalloids, detergents, pesticide residues, and medical waste. Major sources of salts in wastewater originate from industrial sector. Salt-prone wastewater can be saline or sodic. Saline wastewater contains excess levels of soluble salts while sodic wastewater is characterized by excess levels of sodium. Irrigation with salt-prone wastewater may result in negative impacts on irrigated crops, soils, and groundwater. Therefore, long-term wastewater irrigation needs special management strategies, which are determined by the crop grown, water quality, rainfall pattern, climate, soil characteristics, groundwater level and quality, and provision of a drainage system.

INTRODUCTION

The correct timing and ideal amount of irrigation water to apply depends on many factors including soil properties, plant physiology, and the climate. On the other hand, optimal irrigation management also requires efficient water application to achieve the best production and/or economic efficiency. The estimation and use of evapotranspiration-based scheduling to achieve optimal water use efficiency and production will be discussed.

WATER BALANCE OF A FIELD

The objective of irrigation scheduling is to maintain the water content of a crop root zone within an acceptable range that is conducive to the optimal growth, production, and quality for the existing climatic conditions. The goal of good irrigation management is to apply water to the field so that the water losses are mainly to transpiration and yet to supply water with the correct timing and amount to achieve high production and crop quality. The application efficiency (A_E) is commonly defined as the ratio of water stored in the root zone, which can contribute to evapotranspiration, to the amount of water applied. One goal of irrigation application is to make the value for A_E as high as possible while supplying sufficient water to the entire field to minimize production losses due to non-uniform application. This is generally done by maximizing how evenly water soaks in across a field, minimizing runoff, and applying sufficient water so that the soil water content is increased to field capacity or higher over most of the field.

YIELD THRESHOLD DEPLETION (Y_{TD})

When the soil water depletion or S_{WD} (i.e., field capacity minus the soil water content) exceeds the yield threshold depletion (Y_{TD}) the yield or quality is likely to decrease. For practical purposes, the Y_{TD} is determined as the product of the crop-specific allowable depletion (A_D) and the plant available water (P_{AW}) within the effective root zone ($Y_{TD} = A_D \times P_{AW}$), where P_{AW} is the water held between field capacity and the permanent wilting point. Characteristics associated with low A_D (35–50%) include: 1) harvesting the whole plant; 2) slow root growth rates; 3) high ET rates during midseason; 4) shallow soil depths; 5) poor soil structure; 6) low water infiltration rates; 7) root pest problems; 8) water or soil salinity; 9) high topsoil fertility; and 10) high soil temperature for shallow-rooted crops. Crops with the opposite characteristics tend to have higher A_D values (50–65%).

MANAGEMENT ALLOWABLE DEPLETION

Although the Y_{TD} is an important factor in scheduling, the management allowable depletion (M_{AD}) is the depletion that is commonly used to time irrigation. The M_{AD} is the soil water depletion that best fits the growers' needs, and irrigation events are timed so that applications are made on or before the day that S_{WD} exceeds the M_{AD}. For a well-designed irrigation system, the Y_{TD} is the upper limit for the M_{AD}. The M_{AD} accounts for factors including: optimization of application efficiency, cultivation, pruning, water delivery restrictions, etc., that often control scheduling more than the Y_{TD}. The gross application to an irrigated crop is calculated as

$$G_A = R_T \times A_R \tag{1}$$

where R_T is the irrigation runtime in hours and A_R is the application rate in mm hr^{-1}.

The corresponding net application (N_A) is

$$N_A = G_A \times A_E \tag{2}$$

For efficient irrigation, the M_{AD} can be determined using these relationships. For example, if a surface-irrigated crop with application rate 20 mm hr^{-1} has optimal $A_E = 80\%$ given an $R_T = 8$ hr set, the $G_A = 160$ mm, and $N_A = 128$ mm. Whenever the soil water depletion reaches about 128 mm, an irrigation with $R_T = 8$ hr can be applied to refill most of the soil to field capacity. For a microsprinkler system with $A_R = 0.65$ mm hr^{-1} and $A_E = 90\%$ that is operated at $R_T = 48$ hr at each irrigation, $G_A = 31.2$ mm and $N_A = 28.1$ mm, so $M_{AD} = 28.1$ mm. In all cases, M_{AD} should be smaller than Y_{TD}.

EVAPOTRANSPIRATION

Well-watered crop evapotranspiration (ET_c) is calculated as the product of reference evapotranspiration (ET_o) and a crop coefficient (K_c), where ET_o is the evapotranspiration of a reference crop an estimate of the evapotranspiration of a 0.12-m tall, well-watered, cool-season grass and the K_c is a crop factor. It is assumed that ET_o responds only to weather factors, and the variation in ET_o rate is used to estimate the weather effects on ET_c. Since the relative ET_c of the crop varies with growth and management, the K_c factor accounts for differences between the crop ET_c and ET_o.

Reference Evapotranspiration

The most commonly used equation for estimating ET_o using daily weather data is the Penman–Monteith equation.[1] In many locations, automated weather station networks are used to estimate ET_o using hourly weather data and the equation from Ref.[2]. Readers are referred to the original publications for details on calculating ET_o. The equations and Excel programs for calculating ET_o with the Penman–Monteith equation are also available on the internet at http://biomet.ucdavis.edu.

Crop Coefficients

Crop coefficient (K_c) factors change during a season as the crop develops and management changes. When the crop canopy or the foliage is small, evaporation from the surface is often a larger component of evapotranspiration than evaporation from other surfaces. As the canopy develops, the relative contribution of transpiration increases relative to evaporation until it becomes the dominant part of ET_c. For annual crops, the leaves senesce in the fall and the transpiration decreases as the leaves age. Thus, for most annual crops, the K_c values are low in the spring, reach a peak during midseason, and decline in the fall. For perennial crops, the transpiration part of ET_c tends to be fixed all year, with some changes in ET_c due to differences in soil evaporation due to wet soil.

A linear approximation for the general shape of a seasonal K_c curve for field and row crops is shown in Fig. 1. Annual tree and vine crops have a similar curve, but without the initial growth period between dates A and B. The K_c curve for tree and vine crops starts on date B. Subtropical horticultural crops have relatively fixed K_c values all year. A crop K_c curve is never expected to fall below the K_c of bare soil based on ET_o rate and rainfall frequency (Fig. 2). The dates in Fig. 1 are A (planting), B (10% ground cover), C (75% ground cover), D (onset of senescence), and E (when transpiration ceases or the crop is harvested). For tree and vine crops, date C corresponds to about 70% ground cover.

One problem is that it is difficult for growers to identify the date when senescence begins. To overcome the problem, percentages of the growing season rather than growth dates can be used. In general, the percentage of the season until the onset of senescence is relatively fixed regardless of the planting date or climatic conditions. Using percentages of the season until various growth dates has simplified scheduling software so that growers only need to enter the start and end dates, and all other dates are computed from the percentages. A listing of percentages of the season to dates B, C, and D and the K_c values for dates C and E for major crops from several sources is given in Table 1.[1,3–6] The estimates of K_c values during initial growth based on bare soil evaporation as a function of the ET_o rate and rainfall and/or irrigation frequency is provided in Fig. 2.[7]

Irrigation Scheduling

Irrigation is used to replace soil water losses that are not replaced by natural means (i.e., rainfall, fog interception, and water table). Applications are normally timed to replace water before yield-reducing water stress occurs. Water losses occur mainly through evapotranspiration and accurate estimates of ET_c are needed to determine soil water depletion; especially for drip and microsprinkler irrigation systems. Often a schedule based on historical ET_o provides considerable benefit for little effort, and derivation of historical ET_o schedules is highly recommended; especially for surface and sprinkler irrigation methods. For frequently irrigated crops, near-real time or forecast ET_o can improve management. For example, the California Irrigation Management Information System (CIMIS) provides near-real-time ET_o for growers in California.

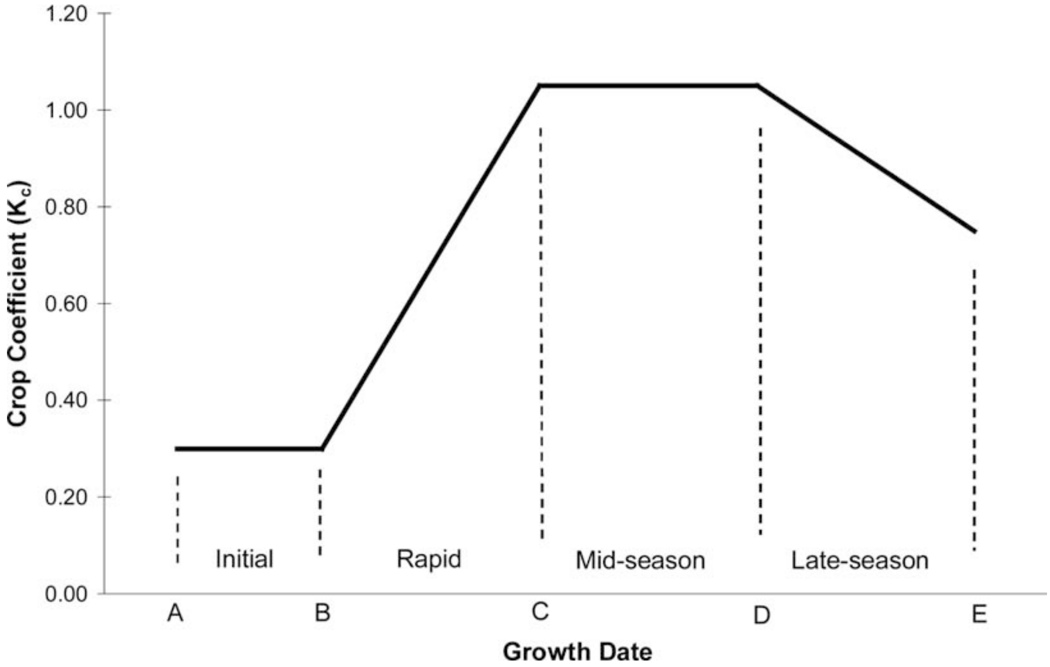

Fig. 1 Generalized crop coefficient curve for field and row crops.

A sample water balance calculation for a crop starting with the water content at field capacity (i.e., the soil water depletion is $S_{WD} = 0$) on 2 July and an $M_{AD} = 60$ mm is provided in Table 2. The daily ET_c is calculated as the product of corresponding ET_o and K_c values. The current day S_{WD} is calculated as S_{WD} from the previous day plus the ET_c minus effective rainfall and any net application on the current day. Effective

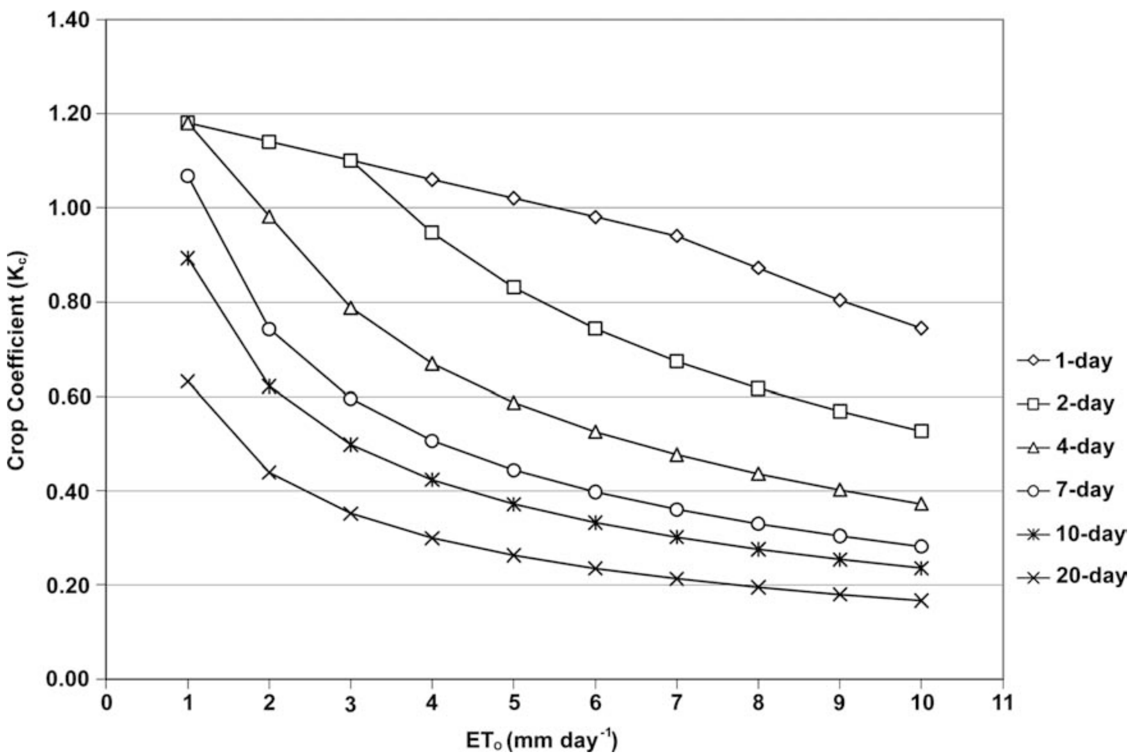

Fig. 2 Crop coefficient (K_c) for near-bare soil (less than 10% ground cover) as a function of daily mean ET_o rate and days between significant rainfall or irrigation (>5.0 mm).

rainfall equals the smaller of the rainfall or S_{WD}. On the irrigation date, G_A is calculated as N_A divided by the A_E fraction, and R_T equals G_A divided by A_R. Following the irrigation, the calculation procedure is repeated and the next irrigation is applied when the S_{WD} again exceeds $M_{AD} = 60$ mm.

CONCLUSIONS

Proper irrigation scheduling is needed to insure that water is used efficiently and to maximize crop production in arid environments. An arid environment is typified by a lack of water for plant growth and development, and, therefore, irrigation is commonly used to produce crops in arid lands. Water balance, determining yield thresholds, selecting managed allowable depletions, reference evapotranspiration, and crop coefficients were discussed to provide irrigators with the basic concepts of irrigation scheduling. Sample crop coefficients and growth information for major crops were provided. A sample irrigation schedule was presented as an example of the procedure.

Water Footprints

Arjen Y. Hoekstra
Department of Water Engineering and Management, University of Twente, Enschede, The Netherlands

INTRODUCTION

Worldwide, water demand studies have traditionally taken the perspective of production. Databases and literature on water demand generally show the water withdrawals in the domestic, agricultural, and industrial sector.[1–3] Though providing useful information, these datasets do not tell much about the water needed by people in relation to their consumption. Many goods consumed by the inhabitants of a country are produced in other countries, and this means that the real water demand of a population can be much higher than the national water withdrawals suggest. The reverse can be the case as well—national water withdrawals are substantial, but a large amount of the products are being exported for consumption elsewhere.

The water footprint concept was introduced in 2002 in order to have a consumption-based indicator of water use that could provide useful information in addition to the traditional production-sector-based indicators of water use.[4] The water footprint of a nation is defined as the total volume of freshwater that is used to produce the goods and services consumed by the people of the nation. The concept has been developed in analogy to the ecological footprint concept.[5,6] The ecological footprint of a population represents the area required to produce the resources used and to assimilate the wastes produced by a certain population at a specified material standard of living, wherever on Earth that land may be located. Whereas the ecological footprint thus quantifies the area needed to sustain people's living, the water footprint indicates the volume of water required. A similar type of analysis, not focussing on area or volume of water but on volume of energy, is known under the term ''embodied energy analysis'' or—in an alternative form—''emergy analysis.''[7] Although integration of ecological footprint analysis, water footprint analysis, and embodied energy or emergy analysis into one coherent analytical framework is an obvious challenge, efforts in this direction have not yet been undertaken.

This entry shows how the concept of water footprint can be quantified and mapped and also summarizes current knowledge on the actual water footprints of nations.

ASSESSING THE WATER FOOTPRINT OF A NATION

There are two ways of quantifying the water footprint of a nation. In the bottom-up approach, one multiplies all goods and services consumed by the inhabitants of the nation by their respective virtual water content. Virtual water is the volume of water required to produce a commodity or service (see the entry *Virtual Water: Measuring Flows around the World*). It is termed ''virtual'' because the water is not really embedded in the commodity or service. The real water content of commodities is generally very small if compared to their virtual water content.

In the top–down approach, the water footprint of a nation is estimated as the national water use plus the virtual water flows that enter the country minus the virtual water flows that leave the country. A nation's water footprint has two components—the internal and the external water footprint. The first component is defined as the use of domestic water resources to produce goods and services consumed by inhabitants of the country. It is the sum of the total water volume used from the domestic water resources in the national economy minus the volume of virtual water export to other countries insofar related to export of domestically produced products. The external water footprint of a country is defined as the annual volume of water resources used in other countries to produce goods and services consumed by the inhabitants of the country concerned. It is equal to the so-called virtual water import into the country minus the volume of virtual water exported to other countries as a result of the re-export of imported products. Virtual water flows (m^3/yr) between nations can be estimated by multiplying commodity trade flows (tn/yr) by their associated virtual water content (m^3/tn).

WATER NEEDS BY PRODUCT

Total crop production in the world requires 6390 billion m^3 of water per year at field level.[8] This volume includes both the use of blue water (ground and surface water) and the use of green water (moisture stored in soil strata). Adding irrigation losses, which globally

Wastewater–Yellow

Table 1 Global average virtual water content of some selected products, per unit of product

Product	Virtual water content (litres)
1 sheet of A4-paper ($80\,g/m^2$)	10
1 tomato (70 g)	13
1 potato (100 g)	25
1 microchip (2 g)	32
1 cup of tea (250 ml)	35
1 slice of bread (30 g)	40
1 orange (100 g)	50
1 apple (100 g)	70
1 glass of beer (250 ml)	75
1 slice of bread (30 g) with cheese (10 g)	90
1 glass of wine (125 ml)	120
1 egg (40 g)	135
1 cup of coffee (125 ml)	140
1 glass of orange juice (200 ml)	170
1 bag of potato crisps (200 g)	185
1 glass of apple juice (200 ml)	190
1 glass of milk (200 ml)	200
1 cotton T-shirt (250 g)	2300
1 hamburger (150 g)	2400
1 pair of shoes (bovine leather)	8000

add up to 1590 billion m^3/yr, the total volume of water used in agriculture becomes 7980 billion m^3/yr. About one-third of this amount is blue water withdrawn for irrigation and the remaining two-thirds is green water (soil water). Rice is the largest water consumer. It takes about 1359 billion m^3/yr, which is about 21% of the total volume of water used for crop production at field level. The second largest water consumer is wheat (12%). Although the total volume of the world rice production is about equal to the wheat production, rice consumes much more water per ton of production. The difference is due to higher evaporative demand for rice production and lower yields in comparison to wheat production. As a result, the global average virtual water content of rice (paddy) is 2291 m^3/tn and the average for wheat is 1334 m^3/tn.

The virtual water content of rice (broken) that a consumer buys in the shop is 3420 m^3/tn on average. This is larger than the virtual water content of paddy rice as harvested from the field because of the weight loss as paddy rice is processed into broken rice. Table 1 shows the virtual water content of a few consumer products. In general, livestock products have higher virtual water contents than crop products. This is because a live animal consumes a lot of feed crops, drinking water, and service water in its lifetime before it produces some output. The higher up in the product chain the greater the virtual water content of the product. For example, the global average virtual water content of maize, wheat, and rice (husked) is 900, 1300, and 3000 m^3/tn, respectively, whereas the virtual water content of chicken meat, pork, and beef is 3900,

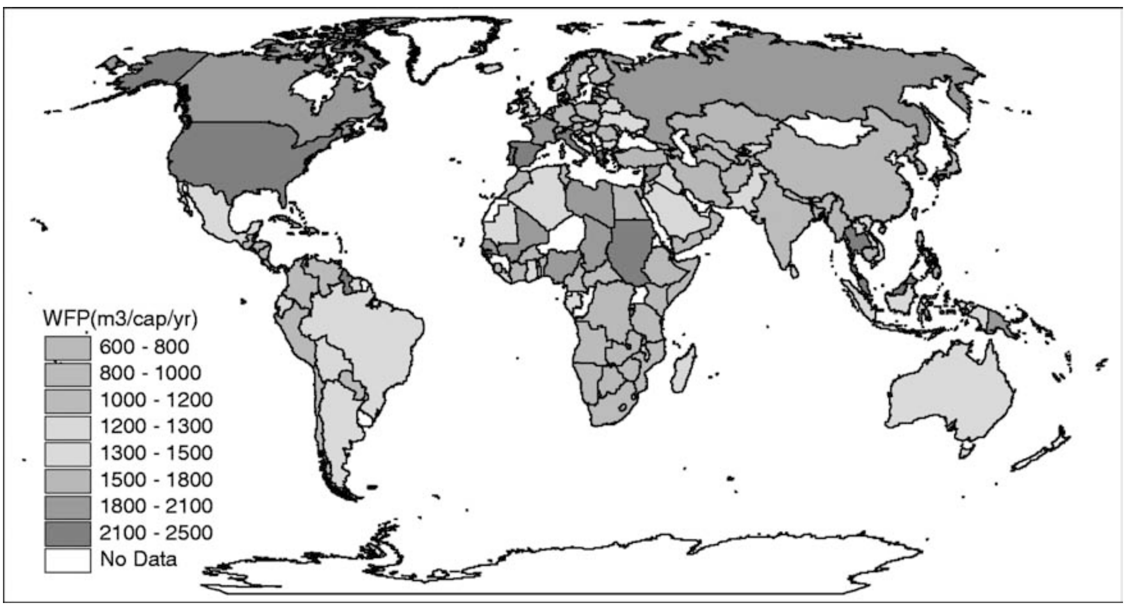

Fig. 1 Average national water footprint per capita (m^3/capita/yr). Green means that the nation's water footprint is equal to or smaller than global average. Countries with red have a water footprint beyond the global average.

4900, and 15,500 m^3/tn, respectively. However, the virtual water content of products varies greatly from place to place, depending upon the climate and technology adopted for farming and corresponding yields.

WATER FOOTPRINTS OF NATIONS

The global water footprint is 7450 billion m^3/yr, which is 1240 m^3/cap/yr in average.[8] About 86% of the global water footprint relates to the consumption of food and other agricultural products. Eight countries—India, China, the United States, the Russian Federation, Indonesia, Nigeria, Brazil, and Pakistan—together contribute 50% to the total global water footprint. In absolute terms, India is the country with the largest footprint in the world, with a total footprint of 987 billion m^3/yr. But on a relative basis, the United State's citizens have the largest water footprint, with 2480 m^3/yr per capita, followed by the people in south European countries such as Greece, Italy, and Spain (2300–2400 m^3/yr per capita). Large water footprints can also be found in Malaysia and Thailand. The Chinese people have a relatively low water footprint, with an average of 700 m^3/yr per capita. The average per capita water footprints of nations are shown in Fig. 1. Table 2 shows the composition of the water footprint for a few selected countries.

The explanatory factors behind the size of a national water footprint are the volume of consumption, consumption patterns, climate, and agricultural practice. In rich countries, people generally consume more goods and services, which immediately translate into increased water footprints. This partially explains the high water footprints of, for instance, the United States, Italy, and Switzerland. The composition of the consumption package is relevant, too, because some goods (bovine meat, rice) require more water than others. The high consumption of meat significantly contributes to larger water footprints in countries like the United States, Canada, France, Spain, Portugal, Italy, and Greece. The average meat consumption in the United States is, for instance, 120 kg/yr—more than three times the world average. In regions with unfavorable climatic conditions (high evaporative demand), the water requirement per unit of crop production is relatively large, lending to higher water footprints in countries such as Senegal, Mali, Sudan, Chad, Nigeria, and Syria. A fourth factor that determines larger water footprints is water-inefficient agricultural practice that increases water requirements in production, as evident in countries such as Thailand, Cambodia, Turkmenistan, Sudan, Mali, and Nigeria. In Thailand, for instance, rice yields averaged 2.5 tn/ha in the period of 1997–2001, while the global average in the same period was 3.9 tn/ha.

CONCLUSION

The water footprint of a nation is a rough indicator of the effects of national consumption on worldwide water resources. The ratio of internal to external water footprint is relevant because externalising the water footprint means externalising the environmental impacts. Some European countries (Italy, Germany, the United Kingdom, and the Netherlands) have external water footprints, contributing 50–80% to the total water footprint.[8] The ratio of blue to green water footprint is relevant because blue water abstractions affect the environment generally more than green water use.[9] Finally, some components of the water footprint involve the use of water for which no alternative use is possible, while other parts relate to water that could have been used for other purposes with higher value added. There is a difference, for instance, between beef produced in extensively grazed grasslands of Botswana (use of green water without alternative use) and beef produced in an industrial livestock farm in the Netherlands (partially fed with imported irrigated feed crops).

Water Harvesting

Gary W. Frasier
U.S. Department of Agriculture (USDA), Fort Collins, Colorado, U.S.A.

INTRODUCTION

A significant portion of the world's land surface is too dry for intensive agriculture without supplemental water, usually in some form of irrigation using surface water diversion or pumped groundwater. There are many parts of these same arid and semiarid lands where irrigation water is inadequate, unavailable, or unsuitable. Yet, many of these lands have in the past, or currently, supported some form of cultivated agriculture, even in areas that receive less than 200 mm of rainfall per year. How can there be intensive agriculture in areas where rainfall quantities are less than 200 mm/yr? The answer is; the crops are grown using a technique of water supply called water harvesting. Even most arid lands have relatively large quantities of water available in the form of precipitation that is potentially available for some beneficial use if it can be collected or concentrated and stored.

What is water harvesting? Water harvesting is a technique of water supply that can be used where conventional surface or groundwater sources are unavailable or unsuitable. The basic premise of water harvesting is the collection of precipitation from a specific area for some beneficial use. Precipitation runoff is collected from a relatively large area and stored or concentrated onto a smaller area. This provides a multiplication factor for maximizing the benefits of the limited precipitation. The water collection area may be a natural undisturbed hillslope or some type of prepared impermeable surface. The collected water can be used for growing crops, drinking water for human and animals, or other domestic uses. The collected water may be used immediately by placement in the soil (infiltration) or stored in an appropriate container for later use.

BACKGROUND

There is evidence of water harvesting structures being used over 9000 yr ago in the Edom Mountains of Southern Jordan.[1] The people of Ur practiced water harvesting as early as 4500 BC.[2] Studies have shown that extensive agricultural systems using water harvesting techniques existed in some areas 3000–4000 yr ago. One such area is the vast arid zone adjacent to the "Fertile Crescent" of the Middle East. The Fertile Crescent stretches from Israel through Lebanon and Syria ending in Mesopotamia along the Tigris–Euphrates Valley. In historical times this was a major agricultural area utilizing water from various streams and rivers in the area for irrigating crops. With increasing population pressures there was an exodus of the population from within the "Crescent" into the adjacent arid deserts outside the Crescent.[3] These desert areas were considerably less desirable for agricultural production than the areas the people had left. There were no perennial surface water supplies, streams, or groundwater.[4] Even so, extensive agricultural communities were developed in the desert lands that, in some areas, still flourish today.[3] There is evidence that similar techniques were used over 400 yr ago in Southwestern United States where Mesa Verde National Park is located.[5]

A common concept is that water harvesting has only been used in, or is most suitable for, arid lands. In reality water harvesting can be used almost anywhere where other water sources are inadequate, unavailable, or unsuitable. In recent times water harvesting has been used for growing crops in many places in the world such as Israel, Egypt, Jordan, Mexico, Australia, and the United States. It has been used to supply drinking water for domestic use and animals in places such as Hawaii (United States), Thailand, Mexico, Australia, and Egypt. It is most effective where there is a predictable quantity and timing of precipitation during the period when the water is needed.

TYPES OF WATER HARVESTING FOR CROPS

Crop production using water harvesting techniques is commonly referred to as runoff farming. In runoff farming the collected water can be applied directly to fields from the catchment area during the precipitation event or stored for later application using some system of irrigation.

One method of runoff farming is called floodwater farming. The precipitation runoff flowing down a channel during a storm event is directed or diverted onto a field or cropping area. A second method is called microcatchment farming. With microcatchments, each plant or small group of plants has a small runoff contributing area directly upslope of the growing area. Typically the runoff area is 5–20 times larger than the cropping area. This technique has been used very extensively for various tree crops such as pistachio, olives, and almonds (Fig. 1).

A third method of runoff farming encompasses a combination of both direct application of the runoff water and later irrigation with excess runoff water from a stored source. The land is formed into a series of large ridges and furrows. Crops such as fruit trees or grapes are planted in the bottom of the furrows. Water from the side slopes of the ridges drains onto the crop area in the bottom of the furrows. Runoff water that is not directly infiltrated into the planted area continues down the center of the furrow into some storage pond or container. At some later date the water is pumped back onto the crop area as needed using some form of an irrigation system (Fig. 2).

Fig. 2 Ridge and furrow water harvesting system for growing pistachios near Saltillo, Coahuila, Mexico. Excess precipitation runoff is collected in a storage pond at the lower edge of the field for later application to the trees by a drip irrigation system.

POTENTIAL OF WATER HARVESTING

If all the water that falls as precipitation on a given piece of land can be collected and put to beneficial use, there is usually adequate water to sustain life and support some form of agriculture. This can be illustrated using an example from the Negev desert of Israel. While historical precipitation records are not available from prehistoric days, various experts believe there have been no major changes in the past 2000 yr.[6] Current yearly precipitation records for a typical area in the Negev desert show that precipitation ranges from 28 mm/yr to 168 mm/yr, with an average of about 86 mm/yr. Most of the precipitation occurs during the winter months, November–March, with about 16 rainy days/yr, 12 days with precipitation greater than 1 mm, 3 days with precipitation greater than 10 mm, with only a single storm event greater than 25 mm/day every 2 yr. Average hourly intensities are relatively low, less than 5 mm/hr, but for short periods of 5 min to 10 min, precipitation intensities up to 20–50 mm/hr have been recorded.[7] These precipitation characteristics are similar to other arid lands in the world.

Fig. 1 Microcatchment water harvesting for growing jojoba near Phoenix, Arizona, USA in a 230 mm annual precipitation zone.

Even with a low annual precipitation occurring as infrequent storms, considerable water can be collected and utilized. One millimeter of precipitation per square meter is equal to 1 L of water. Using the Negev desert data; if all the annual precipitation (85 mm) occurring on 10 m^2 of land can be collected and used to irrigate 1 m^2, it is equivalent to 850 mm of water of precipitation. Collecting the precipitation runoff from large areas for use on smaller areas can provide adequate quantities of water for growing crops, even if it occurs only on a few days each year. Table 1 gives some estimated quantities of water from other areas of the world, which can potentially be collected from precipitation. All that is necessary is to have some means for storing the collected water until it is needed.

Even if only a portion of the total precipitation is collected and effectively used, crops can be grown in areas that would normally be considered unsuitable. Researchers have been able to re-construct some of the ancient farms in the Negev desert and grow various fruits and nuts, like olives, pomegranates, figs, almonds, pistachio, apricots, peaches, plums, and vegetables-like onions, peas, artichokes, and asparagus. Fields of wheat and barley have produced adequate food grain crops.[8]

To maximize the benefits of water harvesting for growing crops under limited precipitation conditions, several other factors are desirable. These include:

Soil type—in the cropping area, it is desirable to have deep soils with a high water-holding capacity that

will retain the water within the plant rooting depth. The water collecting area (catchment) should have impermeable soils or a surface that prevents the water from infiltrating and maximizes the runoff. Catchment areas should have sufficient slope and a topography that rapidly carries the runoff water from the area.

Precipitation—maximum benefits of water harvesting are achieved if the precipitation occurs during cooler weather when evapotranspiration rates are the lowest. Precipitation intensities must be greater than the infiltration rate of the catchment area. When growing crops there is an added benefit if the precipitation occurs during the cropping season. This reduces the period of time necessary to store the collected water.

Crop type—crop species must be drought tolerant or capable of surviving extended dry periods. Cropping practices must include plants that are capable of utilizing the available water efficiently yet can withstand prolonged time intervals when water may be limited or non-existent. Good cropping practices must also recognize that water requirements for plant establishment are frequently different than the water requirements for mature established plants. During the plant establishment phase, rooting systems are usually shallow, which necessitates the water be available in the upper layers of the soil profile. Under these conditions there is also the potential for significant losses of the soil water by evaporation from the unprotected (non-shaded) soil surface.

ADVANTAGES AND DISADVANTAGES OF WATER HARVESTING

If there is some precipitation, water harvesting can be a method of water supply. In most instances the collected water is of a very good quality (pure).

While water harvesting can supply water in most areas, it should not be considered an inexpensive means of water supply. There are appreciable costs of preparing catchment areas and water storage facilities. Maximum runoff efficiency is obtained by sealing or covering the soil surface. These techniques are relatively expensive and may not be cost effective in many locations. At sites where land area and labor are relatively inexpensive and readily available, smoothing of the soil surface may be the most effective means of collecting the required quantities of water. Runoff per unit area from a smoothed soil catchment surface may be relatively low. Using a larger catchment area can offset the lower runoff efficiency.

In many locations, the cost of the water storage can represent the major expense of a water harvesting facility. In these instances it may be desirable to design the storage supply to meet the needs even if there is excess water during part of the year.

For maximum long-term effectiveness, water harvesting systems must have scheduled and timely maintenance and repair. Many systems have been adequately designed and constructed, and yet have failed to supply the anticipated quantities of water within a relatively short time interval because of inadequate maintenance. Usually the required maintenance or repair can be accomplished in a relatively short period of time without a lot of expense.

Water Properties

James D. Oster
Department of Environmental Sciences, University of California–Riverside, Riverside, California, U.S.A.

INTRODUCTION

Water's physical and chemical properties are uniquely different from other substances in ways that determine, to a large extent, the nature of the physics and biology of the earth. Individual water molecules can link with each other through hydrogen bonds. The degree of hydrogen bonding between water molecules changes with temperature that causes changes in the density of water and its heat content. These changes are uniquely important to the sustainability of life on earth. The dissociation of water into hydrogen and hydroxyl ions, although very small, is important in reactions of acids and bases. These topics, which were chosen as the focus of this article, are only the "tip-of-the-iceberg" as is evident when one peruses the references cited here.

> Water's large heat capacity [75.2 J(mol K)$^{-1}$] plays a key role in providing an environment that makes life possible, as we know it. The Gulf Stream, which flows from the Gulf of Mexico to the Arctic Ocean, cools about 20°C releasing, in the process, energy at a rate equivalent to that released by burning 175 million metric tons of coal per hour. All the coal mined annually would supply energy at this rate for only 12 hr. Thus the heat released from the cooling of warm ocean currents is responsible for the temperate climate over much of the earth's surface.[1]

The physical properties of water are used to define the following physical constants and units: 1) the freezing point of water is taken as 0°C and the boiling point at atmospheric pressure is taken as 100°C; 2) the unit of volume in the metric systems is chosen so that 1 mL of water at 3.98°C weighs 1.000 g; 3) the unit of heat, the calorie, is the amount of heat required to raise the temperature of 1 g of water by 1°C at 15°C.

MOLECULAR STRUCTURE

The water molecule, H_2O, consists of two atoms of hydrogen (H) and one atom of oxygen (O). The orientations of the electron orbitals in the oxygen atom and the location of the hydrogen atoms result in a water molecule that can be visualized as a pyramid (Fig. 1). Simplistically, the water molecule can be thought of as an O atom with two hydrogen atoms attached near its surface on one side causing this side of the molecule to have a small positive charge that is matched with a small negative charge on the other side. This resulting separation of the positive and negative charges on the water molecule is called an electric dipole: water has a large electric dipole moment.

HYDROGEN BONDING AND ITS ROLE IN THE STRUCTURE OF ICE, WATER, AND STEAM

Each hydrogen in one water molecule can bond with the negatively charged oxygen side of another in what is known as a hydrogen bond. Each water molecule can form four hydrogen bonds that extend in four directions. This resulting structure, known as a tetrahedron, is illustrated in Fig. 2. This arrangement exists among all water molecules in ice: the tetrahedrons form a lattice with others that can be represented as sheets of hexagonal rings (Fig. 3). This structure is a very open, more open than what exists in water. As a result, ice is less dense than water.

> An interesting consequence of this difference in density occurs as lakes cool during the winter. Ice forms on the surface of lakes rather than on the lake bottom. This provides insulation slowing the rate of freezing and makes it less likely that all the water in lakes will freeze during the winter. Another consequence is that when water freezes in plants, the accompanying expansion can cause cell walls to break, killing the cell. For example, oranges when ripe can be ruined for the fresh fruit market by prolonged temperatures below freezing. As the juice within an orange freezes, the edible portion of the orange becomes mushy because the cell walls are broken. When this occurs oranges must be harvested quickly for the juice market.

When ice melts, the hexagonal rings are partially degraded because some of the hydrogen bonds are broken. Consequently, water molecules are packed more closely together, causing water to have a greater density than ice. With an increase in temperature from 0 to 4°C, further ring degradation and breaking of hydrogen bonds occur, causing a further increase in the density of water. Only at temperatures greater

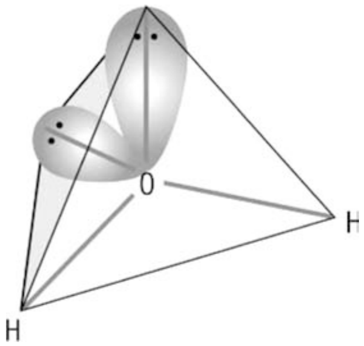

Fig. 1 Geometric shape of the water molecule.

than 4°C does water begin to show the usual decrease in density with increasing temperature: normal expansion occurs because molecular agitation increases the distance between water molecules and overcomes the effect of hexagonal ring degradation.

Water vapor at 100°C, or steam, consists of mostly single water molecules. Because high temperatures increase the ability of molecules to move, the chances are small that two or more molecules in steam remain together due to H-bonding.

WATER AS A SOLVENT FOR SALTS

The reasons that water is so effective in dissolving salts are due to its dipolar character and its shape. Because of the former it hydrates the ions of salts. Because of a combination of ionic character and shape, the attractive force between solvated ions are reduced making them less likely to precipitate out of solution.

Due to its dipolar character, water molecules tend to combine with ions to form hydrated ions. This hydration process releases enough energy to overcome the lattice energy holding the ions together in a salt

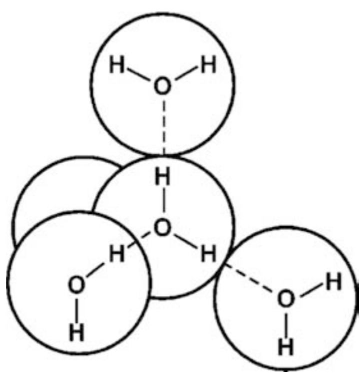

Fig. 2 The tetrahederal arrangement between four water molecules resulting from hydrogen bonds, shown as broken lines, between individual molecules.

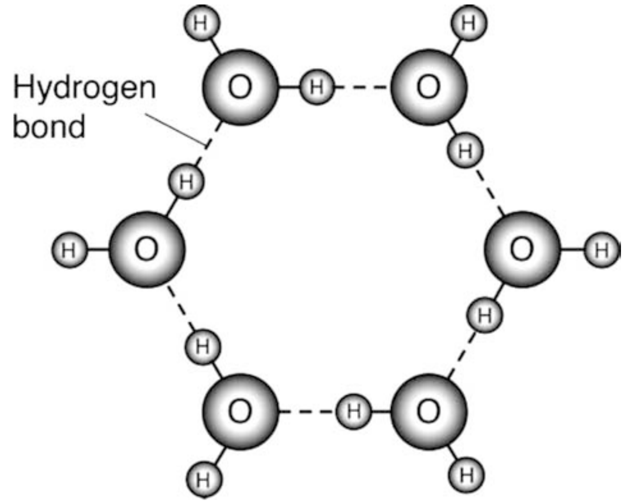

Fig. 3 The lattice of hexagonal rings of water molecules that exists among all water molecules in ice.

crystal. Salt crystals consist of negative and positive ions. For example, table salt consists of negatively charged chloride ions and positively charged sodium ions. Each negative ion attracts the positive ends of water molecules, and holds several water molecules to itself. Positive ions, which are usually smaller than negative ions, show this effect more strongly; each positive ion attracts the negative ends of the water molecules and binds several molecules to itself. Generally speaking, the greater the ratio of an ion's charge to its surface area, the more heavily hydrated it will be. Hydration is least significant for singly charged anions such as chloride and nitrate, which are considerably larger than most cations.

The dissolution of salts by water is also related to it dielectric constant, another aspect of its shape and electric characteristic. When water molecules are subjected to electrostatically charged plates, they align their positive ends toward the negative plate and their negative ends toward the positive plate. This partially neutralizes the applied field: the dielectric constant of water at room temperature is about 80. This compares to a dielectric constant for air of one. The force of attraction, or repulsion, of electric charges is inversely proportional to the dielectric constant of the medium surrounding the charges. This means that two oppositely charged ions in water attract each other with a force of 1/80 as strong as in air. Salts are not as soluble in solvents with low dielectric constants, such as gasoline or acetone as they are in water.

Thus not only does water tend to hydrate both the positive and negative ions in a salt crystal releasing enough energy to overcome the lattice energy, the force of attraction between the solvated ions is low because of water's high dielectric constant.

DISSOCIATION OF WATER

In addition to its role as a solvent, water also plays a significant role in reactions of chemical species known as acids and bases. This stems from the dissociation of water into hydrogen (H^+) and hydroxyl (OH^-) ions according to the reaction

$$H_2O \rightleftarrows H^+ + OH^-$$

The equilibrium expression for this reaction is

$$K_w = [H^+] \times [OH^-] = 1.0 \times 10^{-14}$$

where K_w is known as the dissociation constant of water, and the ions within brackets represent their molar concentrations.

According to the dissociation constant of water, only a few H_2O molecules dissociate. In 1 L of pure water, there are about 55 moles of H_2O and 0.0000001 (1×10^{-7}) mol each of H^+ and OH^-. The product of these ion concentrations equals 1.0×10^{-14} as it should according to the equation for the dissociation constant of water.

A solution where the concentration of both $[H^+]$ and $[OH^-]$ equals $1 \times 10^{-7}\,\text{mol L}^{-1}$ is known as a neutral solution. A water solution where $[H^+]$ exceeds $[OH^-]$ is said to be acidic. On the other hand, where $[OH^-]$ exceeds $[H^+]$, the water solution is said to be basic. Using such small numbers to characterize acidity and basicity is difficult. In 1909 Sorensen proposed an alternative method by introducing a term known as pH, where

$$\text{pH} \equiv -\log_{10}[H^+] = \log_{10} 1/[H^+]$$

The pH of a neutral solution is $-\log_{10}[1 \times 10^{-7}]$ which equals 7. For acidic solutions the hydrogen ion concentrations will be greater than 1×10^{-7} and their pH will be less than 7. For basic solutions the hydrogen ion concentrations will be less than 1×10^{-7} and their pH will be greater than 7 (Table 1).

Table 1 pH of some common liquids

Tomato juice	3.0	Human saliva	6.5–7.5
Beer	4–5	Wine	2.8–3.8
Cow's milk	6.3–6.6	Drinking water	6.5–8.0

Source: From Ref.[2], Table 19.2.

CONCLUSION

The combination of one oxygen atom with two atoms of hydrogen results in a molecule with a small negative charge on one side and a small positive charge on the other. This distribution of charges results in bonding between water molecules. This bonding, known as H-bonding, causes water to have unique changes in density upon freezing and a high heat capacity. Both are important to the sustainability of life on earth. The small negative and positive charges on the water molecule play a key role in its ability to dissolve salts. Although the bonds between the oxygen and hydrogen atoms in water are strong, in a liter of water, a very small fraction of the water molecules dissociate into OH^- and H^+ ions. This dissociation is the key to the definition of pH and to the understanding of acid and base reactions.

Water Quality: Modeling

Richard Lowrance
Southeast Watershed Research Laboratory, Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Tifton, Georgia, U.S.A.

INTRODUCTION

Largely because of the difficulty of monitoring and predicting non-point source pollutants from large areas, water quality modeling has been an important area of water science since the late 1960s. Water quality modeling plays many roles in evaluating and improving the quality of our environment. Models have a major role in helping management and regulatory agencies determine how water quality standards can be met, especially when water quality problems are due to non-point sources. Water quality models are used to compare different management strategies designed to control non-point source pollution. Models are used to estimate the effects of inputs (including pollutants) on the internal dynamics of water bodies. Water quality modeling is also used to summarize and estimate the various sources of pollutants, especially nutrients, in large basins in order to provide a basis for geographic targeting of pollutant sources.

Water quality models are based on some representation of hydrology and may include movement of surface water, groundwater, and mixing of water in lakes and water bodies. Based on the hydrology, water quality models then simulate some combination of sediment, nutrients, heavy metals, and xenobiotics such as pesticides. Some water quality models, especially those that deal with nutrients, may contain substantial detail related to biological processes including algal growth, nutrient transformations, and respiration. Most water quality models that portray the movement of water within a landscape or landscape components (e.g., fields, forests, streams) portray the interaction of water with soil in a variety of ways. Newer water quality models and add-ons to older water quality models are able to portray the effects of water quality parameters on the biota of lakes and streams or incorporate stream bank, riparian zone, and/or channel functions to understand the effects of these areas on chemical and sediment transport. Other water quality models are used to simulate the effects of critical inputs on the biological communities of lakes and rivers. These aquatic ecosystem models may or may not be tied to watershed models that provide simulated loading to the aquatic ecosystem under varying land use and management.

CLASSIFICATION OF WATER QUALITY MODELS

Water quality models are either built on hydrologic models, are used in conjunction with hydrologic models, or use empirical hydrologic data. Although water quality models can be physical representations of the real world such as channels and ditches built to scale, mathematical or formal models are more common.[1] Mathematical water quality models are quantitative expressions of processes or phenomena that are known to occur in the real-world. The expressions are simplifications of real-world systems through a series of equations governed by conservation of mass. Mathematical water quality models are often a combination of theoretical and empirical representations of the real-world system. Empirical models use water quality observations to provide estimates of water quality parameters through regression analysis. Process based or theoretical representations use physical, chemical, and biological causal relationships to describe the workings of a conceptual system.

Although the real world is subject to random occurrences of weather and management that drive hydrology and water quality, many models ignore the randomness of inputs and spatially distributed attributes and assume that there is a known value for all model parameters. Conversely, stochastic (or random) models use probability distributions of parameters in time or space and can provide outputs based on the distribution. Most water quality models are deterministic models in the sense that one set of inputs will provide only one set of outputs. The difference in a stochastic and deterministic model can be illustrated by how models deal with something simple like how fast water moves in a soil. A deterministic model would use one value for each soil while a stochastic model would vary the movement rate based on the range and distribution of measured water movement rates. Deterministic models are often used with a range of key parameters in order to produce a range of outputs that would better represent real world conditions. Another critical distinction among water quality models is whether they provide continuous or event-based simulations. Continuous simulation models generally provide at least some representation of groundwater/

surface water interactions, while event-based models are more likely to provide only representations of hydrologic processes that take place during rainfall events.

A final distinction among models is whether they are lumped or distributed parameter models. A lumped parameter model contains little or no spatial realism and represents landscape units as homogeneous with respect to the parameters and inputs that drive the model. A distributed parameter model represents certain aspects of the landscape structure, typically by representing areas that are homogeneous with respect to soils, vegetation, and/or land use. Each of these discrete areas is modeled separately and then outputs from all the discrete areas are put together and routed through the system. Because most water quality models are tied to hydrologic models, the water quality outputs from source areas in the model are typically routed through either surface flow pathways, subsurface flow pathways, or both. Models that deal only with events are typically routed through surface flow pathways. Models that simulate continuous or daily water quality in a watershed or field generally must deal with both subsurface or groundwater routing and surface water routing.[2]

USES OF WATER QUALITY MODELS

Risk Assessment of Pesticides

Knowledge of fate and transport of pesticides in the environment is essential to the assessment of risk due to dietary and drinking water exposure. The passage of the Food Quality Protection Act (FQPA) lead to a pressing need to quantitatively predict ranges and magnitudes of expected environmental pesticide concentrations in drinking water. Health-based safety standards mandated by FQPA require USEPA to consider drinking water exposures of humans to pesticides during the risk assessment process. Some state agencies and USEPA use screening models to estimate pesticide concentrations in groundwater and surface water to identify those food-use pesticides that are not expected to contribute enough exposure via drinking water to result in unacceptable levels of aggregate risk.[3] The models are used to guide regulatory agencies such as USEPA to identify where more detailed field data are needed.

Evaluation of Best Management Practices (BMPs)

Water quality improvement from extensive land uses such as agriculture and forestry depends largely on the use of BMPs. Agricultural water quality modeling attempts to adequately represent the differences among various management practices in order to compare and choose which BMPs lead to the least transport of pollutants. These models are typically structured to represent homogeneous landscape units such as fields or portions of fields in order to compare management features such as tillage, fertilizer sources, manure use, and pesticide use and predict the relative impacts on local transport of pollutants such as sediment, nitrogen, phosphorus, and pesticides. Existing models may be used to test the application of BMPs to areas for which no water quality data are available or to determine the effects of BMPs that are similar to those for which water quality effects have been quantified.

Evaluation of Sources and/or Impacts of Pollutants

Both process based and empirical models have been used successfully to examine the sources of pollutants in watersheds and the impact of pollutants or non-pollutants on aquatic ecosystems. The need to quantify the non-point source contributions for watersheds and small basins is largely driven by Total Maximum Daily Load (TMDL) assessments and implementation plans mandated by the federal Clean Water Act.[4] The TMDL assessments are done with a water quality accounting approach that typically uses water quality models to estimate non-point source pollution. The non-point and point sources of a pollutant that are causing the water quality impairment are then combined and compared to observations in the water body. If the water quality is impaired due to the direct presence of a pollutant, then the model estimates of non-point source pollution are used to design a plan for reducing non-point sources or trading point sources for non-point. If pollutants are tied indirectly to the impairment, for instance nutrient enrichment that causes low dissolved oxygen, then the behavior of the pollutant in the waterbody is modeled in order to determine the necessary pollutant load reduction.

Explanation of Large-Scale Systems Behavior

As the behavior of large-scale systems becomes more of an issue and as water quality monitoring data become more available, attempts have been made to combine monitoring and modeling to predict the transport of water-borne pollutants on large scales—river basins and continents. Regression models are used to relate measured pollutant transport in streams to spatially referenced descriptors of pollutant sources, land surface characteristics, and stream channel characteristics.[5] Although mechanisms of pollutant transport are not modeled directly, coefficients that serve as surrogates for processes are used to achieve substantial explanatory power for observed water quality data.

Water Quality: Range and Pasture Land

Thomas L. Thurow
Department of Renewable Resources, University of Wyoming, Laramie, Wyoming, U.S.A.

INTRODUCTION

Livestock and clean water are two products that can be simultaneously obtained from range and pasture lands. This requires that ecological and hydrological principles be applied when crafting a grazing management strategy that is compatible with *predetermined* water quality goals. Making protection of water quality the starting point of land use planning is a philosophical foundation of 1972 U.S. Clean Water Act and subsequent amendments. This goal is operationalized by management agencies establishing total maximum daily load (TMDL) standards for waterways. A TMDL is a calculation of the maximum amount of a pollutant from all contributing point sources [a specific location such as a confined animal feedlot operation (CAFO)] and non-point sources (pollution that occurs over a wide area such as may originate from grazing).

Major water impairment concerns associated with grazing can be broken down into physical (suspended sediment), chemical (nutrients, dissolved oxygen), and biological (pathogens) aspects of water quality. Design of a grazing system that will protect water quality must consider the interaction between livestock, vegetation, soil, and water. Grazing effects on each of these attributes are discussed later.

PHYSICAL CHARACTERISTICS

Suspended Sediment

Suspended sediment is the most pervasive non-point source pollutant from grazing lands. All waterways naturally contain some suspended sediment attributable to the geologic (natural) erosion influenced by stream type (primarily determined by the geology, topography, and location within the watershed) and ecological factors (e.g., climate, vegetation, soil). Therefore, formulation of TMDL suspended sediment standards must be catchment specific so that geologic erosion can be differentiated from accelerated erosion associated with human activities such as grazing management.

Grazing management can effect the erosion rate of a site primarily by influencing the degree to which livestock impact the soil and vegetation.

Livestock Impacts on Soil

Soil structure is the arrangement of soil particles and intervening pore spaces. The size of soil particles (aggregation) and their stability when wetted determines the porosity of the soil, which governs the rate at which water will enter the soil (infiltration). If the rainfall rate is greater than the infiltration rate, water will run off the site, carrying sediment with it.

Livestock trampling compacts the soil, increasing the bulk density (i.e., the pore volume is reduced resulting in decreased infiltration rate). The degree of damage associated with trampling at a particular site depends on soil type, soil water content, seasonal climatic conditions, and the intensity of livestock use.[1] Compacted trails form on sites where livestock traffic is concentrated. The density of trails tends to increase as the number of pastures is increased within an intensive rotation grazing system. Another common reason for trail formation is repeated movement to and from limited sources of water, mineral supplements, or shelter. The low infiltration rate of trails results in concentrated runoff, which may eventually create gullies. Roads across hilly range and pasture lands are also a serious erosion source, especially since they are often poorly designed and maintained.[2]

Another way livestock trampling causes surficial problems is by churning dry soil to dust. This is very detrimental to infiltration because the disaggregated soil particles are carried by water and lodge in the remaining soil pores making them smaller or sealing them completely. This ‘‘washed in’’ layer where clay particles clog soil pores is a common way that soil crusts are formed. Soil crusts can reduce infiltration by 90%, thereby dramatically increasing runoff and sediment transport.[3] Trampling a crusted soil does break the crust and incorporates mulch and seeds into the soil. However, this benefit is short lived because the subsequent impact of falling raindrops re-seals the soil surface after several minutes. To effectively address a soil-crusting problem, livestock grazing systems must concentrate on addressing poor aggregate stability, which is the cause of crusting. This requires protecting the soil surface from direct raindrop impact through maintaining vegetation cover and facilitating organic matter buildup in the soil via litter deposition.

Livestock Impacts on Vegetation

Direct raindrop impact on soil represents the greatest potential erosive force on grazing land; therefore it is very important that raindrop energy be dissipated by striking some form of cover before reaching the soil.[4] The amount of cover is positively associated with vegetation litter deposition. Litter slows overland flow, resulting in reduced ability to transport sediment. Litter also aids formation of stable aggregates (associated with high infiltration and low erosion rates) by binding soil particles together with adhesive byproducts produced by decaying litter and microbial synthesis.[5]

Grazing impacts on the vegetation community may be manifest by physical removal of standing vegetation through herbivory or through a gradual change in the composition of vegetation. As grazing pressure increases, the amount of cover and the amount of organic matter returned to the soil is reduced, resulting in an increased likelihood of runoff and erosion. Cover and infiltration rate tends to be greatest under trees and shrubs, followed in decreasing order by bunchgrass, shortgrass, and bare ground.[6] There is little impact on species composition with moderate or light grazing but composition change is great in response to heavy grazing, regardless of grazing strategy.[7] Often the change in species composition associated with heavy grazing is toward dominance by annuals or shortgrass species that have more runoff and erosion associated with them.[8] By the time erosion becomes obvious it may be too late to implement economically viable conservation options. Early recognition of a developing degradation pattern requires knowledge of range ecology, for the first signs of an impending erosion problem almost invariably are manifest by changes in plant density, composition, and vigor.[9]

CHEMICAL CHARACTERISTICS

Dissolved Chemicals

Nutrient loss from grazing lands via leaching or runoff is normally negligible, i.e., less than the input of nutrients from rainfall.[10] Most of the dissolved chemical constituents in runoff are contributed from the soil. Nutrients and organic matter adsorbed to the soil particles are also lost via erosion. Therefore, the most important role of a grazing system in nutrient loss is manifest through land use activities that alter the volumes or timing of runoff and erosion.[11]

Most of the nitrogen in urine is lost via volatilization, and most of the nitrogen in feces is sequestered by microorganisms or eventually transferred to soil organic matter. Nitrate is very mobile during heavy rain periods but loss by leaching is probably insignificant on most grasslands.[12] Feces contain almost all of the phosphorus excreted by livestock. Phosphorus is very resistant to leaching as it is rapidly precipitated or absorbed by other soil minerals. Nitrogen or phosphorus contamination of waterways is only of imminent concern when livestock are allowed to congregate near waterways.[13] Because of this concern, the U.S. Environmental Protection Agency interpretation of the Clean Water Act has deemed location of feedlots near waterways an unacceptable practice.

Dissolved Oxygen

Dissolved oxygen decreases when organic matter, such as animal manure, is added to water. This decrease occurs because biological decomposition processes consume available oxygen, as does oxidation of other reduced compounds such as ammonium. Excessive additions to surface water of nutrients such as nitrogen or phosphorus lead to eutrophication, often expressed by enhanced growth of aquatic plants and reduced water transparency (especially due to increases in algae). As the aquatic plants decay the microbes consume oxygen, lowering the concentration of oxygen available needed to support higher forms of aquatic life such as macroinvertrebrates and fish.

BIOLOGICAL CHARACTERISTICS

The primary types of pathogens associated with livestock and wildlife feces are bacteria (e.g., *Campylobacter jejuni*, *Escherichia coli*, *Leptospira interrogans*, *Salmonella* spp.) and water-borne protozoa (e.g., *Cryptosporidia parvum*, *Giardia duodenalis*). These infectious pathogens can pose potential health risks to human drinking water supplies. Environmental fluctuation in temperature and soil moisture of grazing land creates a harsh environment for bacteria and the oocycsts of protozoa. Fecal coliforms can survive for several months in soil but can survive for up to a year within feces.[14] There is a rapid mortality of most oocysts when feces are deposited on land,[15] however, viable oocycsts can be transported overland, especially when fresh feces are washed by an intense storm.[16] Once pathogens reach a water body, the threat of contamination may last from days to months,[17] with freshwater sediments being the site of greatest concentration and survival.[18]

Few detailed studies have explicitly studied the link between livestock grazing and water-borne pathogens. Much of the research has relied upon indicator coliforms that are more easily cultured but have been shown to be poorly correlated with some types of pathogenic bacteria.[14] Furthermore, many wildlife species harbor the same pathogens that livestock do, thus the natural occurrence of pathogens must be considered when analyzing water quality and making the relationship to livestock use of an area. The greatest threat of pathogen contamination of waterbodies occurs when livestock are allowed to concentrate along streams.[19] In situations where risk of bacteriological contamination is unacceptable, it is necessary to restrict livestock access to streams or riparian areas. Livestock use of these sensitive sites can be significantly reduced through development of water supply away from streams.[20]

CONCLUSIONS

Two broad objectives must be achieved to protect water quality associated with range and pasture grazing.

Limit Runoff and Erosion

Suspended sediment is the most common pollutant associated with grazing. Best management practices (BMPs) to limit runoff and erosion rely on maintenance of soil structure. Vegetation provides the organic matter necessary to enhance formation of stable aggregates and provides the cover to dissipate the erosive force of direct raindrop impact. Appropriate range and pasture grazing systems are designed to maintain vegetation cover and composition by adjusting intensity, frequency, and season of use. Flexibility needs to be built into grazing systems to adjust for unexpected fluctuation in the climate or market prices. The underdevelopment of climate and market risk management planning and policy regarding grazing plans is perhaps the most formidable threat to progress in improving water quality since these variables continue to be used as an excuse for water quality deterioration and/or the lack of progress in improving it.[21]

Limit Direct Livestock Use of Waterways and Sensitive Riparian Areas

Contamination of waterways by nutrients and pathogens is a predominant concern only on sites that allow livestock to congregate near water. On sites with limited water distribution, livestock tend to stay in the vicinity of water so long as forage is available. This increases the likelihood of excrement being deposited directly into the waterway. It also causes deterioration of the soil structure and plant community near the waterway, resulting in accelerated runoff and erosion. Streambanks and moist soil around springs and streamside meadows are particularly susceptible to erosion damage and compaction. Livestock impacts to streams and riparian sites can be limited by providing water, mineral supplements, and shelter at locations away from natural water sources. Special fencing or livestock herding may also be needed to protect sensitive areas from excessive use at critical times. Another reason for protecting wetland or riparian sites is that they serve as vegetation buffer strips that slow runoff and trap sediment before it reaches a waterway.

Water Quality: Sampling of Runoff from Agricultural Fields

John M. Laflen
Purdue University, Buffalo Center, Iowa, U.S.A.

INTRODUCTION

Runoff from agricultural fields carries many physical, chemical, and biological constituents that impact water quality. The mass and concentration of these constituents are estimated based on runoff samples. Depending on the objectives, a runoff sample is collected and then analyzed in the laboratory for constituent concentrations. Laboratory data are then combined with flow measurements to estimate the water quality parameter of interest. The water quality parameters might be total mass loss of a particular constituent, the distribution of concentrations and losses over time, average concentration of particular constituents, pathways of loss, or any number of other parameters of interest.

Runoff from agricultural fields is measured and sampled at many scales—ranging from an area of less than a m^2 up to hundreds and perhaps even hundreds of thousands of km^2. Further, runoff can be due to simulated rainfall applied by indoor or outdoor rainfall simulators, natural rainfall, irrigation, and the application of liquid from animal confinements.

Runoff samples due to natural rainfall on agricultural lands must usually be collected and stored automatically due to the unpredictable nature of natural rainfall, large number of treatments, lack of accessibility during runoff events, and footing and lightning hazards to personnel during many runoff events. This limitation is usually removed when man controls the water application, giving a wider freedom to the selection of measuring and sampling techniques and equipment.

Samples must be collected and processed in a manner that insures that concentrations and characteristics of constituents measured in the sample are the same as the concentrations and characteristics of the constituents in the runoff when the sample was collected, and that the constituents and their concentrations in the runoff are identical to those delivered from the field. Depending on the constituents, and on other factors, this may require special control of the environment where samples are stored prior to processing and require particular materials for collecting and storing samples. In some cases, chemicals must be added to samples to stabilize the constituents so that the form of the constituent does not change during storage.

Runoff sampling systems generally can be classified as one of three kinds: 1) those that collect a constant fraction of the total flow over an entire runoff event(s); 2) those that collect a sample at either a given time or flow volume interval (and usually have a flow measuring system that also measures flow rate during an event); and 3) those where samples are collected manually or all flow is collected for sampling. The objective here is to describe some of the standard and innovative ways of runoff sampling and their limitations. Almost every runoff water sampling application requires custom design and construction for that particular application. While standard designs are available, and some commercially available, most require considerable judgment in terms of selection of equipment and its installation. The objective here is to assist those that might wish to select, design, and install runoff sampling equipment to collect water quality samples in runoff from agricultural fields.

CHARACTERISTICS OF SURFACE RUNOFF

The design of the runoff sampling system depends heavily on expected surface runoff flow rates and volumes and on expected delivery of constituents in runoff. Runoff flow rates and volumes can be estimated using readily available techniques.[1] These estimates are critical in designing of runoff conveyance systems, and components of the flow measuring, sampling, and storage systems. Constituent loads, particularly sediment, are important in the selection and design of equipment. Deposited sediment can greatly impact, and in fact totally incapacitate, runoff sampling systems used on agricultural runoff.

Runoff events are generally infrequent and range widely in magnitude (Fig. 1). During an event, runoff rates will vary widely, and depending on contributing area size and topography, runoff rates may react within a minute or so to changes in rainfall intensity. Severe storms are frequently less than an hour in length. Additionally, the average concentration of material transported in runoff may vary by a factor of 10 or more between events (Fig. 2), and even within an event, may vary by a factor of 10 or more.[2,3] Constituent concentrations, particularly sediment and

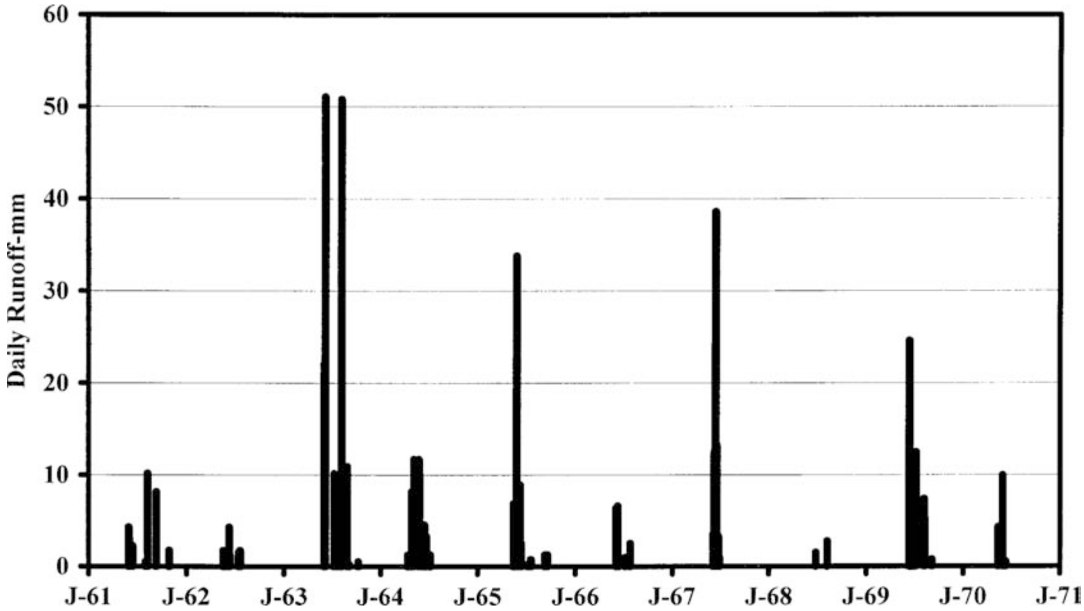

Fig. 1 Daily runoff from a corn–oats rotation erosion plot at Castana, IA between January (J) 1961 and January 1971.

sediment transported constituents, may also vary quite widely.[2–4]

Rare storms are quite important in loss of constituents, and unless systems are carefully designed for these events, system failures are likely to occur. In an 11-yr period near Columbia, MO, over 80% of the soil loss on erosion plots occurred in seven storms, and 50% of the soil loss occurred in only one storm.[5] However, runoff volume from these seven storms was apparently only about 25% of the total runoff during the same period.

A runoff sampling system must be based on expected runoff rates and volumes. In Fig. 3 are shown several dimensionless hydrographs where flow rates as percent of peak are plotted vs. time as percent of runoff duration. The natural runoff and outflow hydrographs shown are idealized, while the rill and interrill plots shown, generated by simulated rainfall, are from measured data.[6]

The rainfall simulation plots illustrate the different response times for different very small areas. Total time during this experiment was 70 min. The long delay

Wastewater–Yellow

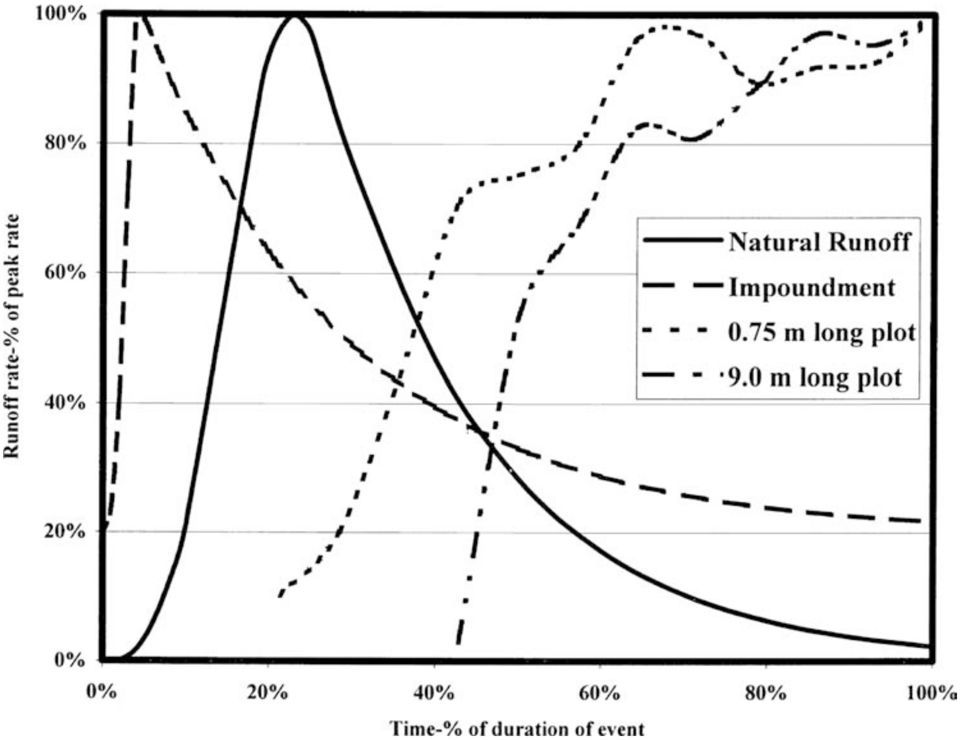

Fig. 3 Dimensionless hydrographs for natural runoff, for areas having impoundments with tile or base flow, and for simulated rainfall with a nominal constant intensity on short plots.

after rainfall began before runoff and the quick rise of the hydrograph affects the design of the sampling system. For a constant rainfall intensity, a constant rise in the hydrograph is expected. In this case, flow rates decreased at times, likely due to minor changes in rainfall intensity because of changes in pump or nozzle performance.

The natural rainfall runoff rates are typical of those with a single burst of intense rainfall. The total time can range from several minutes to several hours, depending on rainfall, topography, and management. It might also be typical of runoff from an ephemeral channel draining a large watershed subjected to a single rainfall event. In that case, the total time might be as much as several days. There is an infinite number of hydrographs that might result from the combinations of storms and topography that exist in nature. Frequently, hydrographs from a single storm contain several peaks due to different periods of intense rainfall.

The outflow from impoundments could represent many cases. Note that in this example, there is a base flow at about 20% of the peak rate. This could represent a small watershed outflow that contained several impoundments and tile drain lines. It might also represent outflow from a watershed with a continuous flowing stream. The total time for the storm runoff to move through the system could be from a few hours for a small watershed with impoundment type terraces and subsurface tiles to several months if the hydrograph represents the Mississippi river.

COLLECTING A CONSTANT PROPORTION OF FLOW

Many sampling schemes require only an estimate of concentration for an entire event. A number of devices have been developed that collect a constant proportion of total runoff throughout a runoff event.[7–10] Limitations for collecting a constant proportion of flow are the size of area and the lack of information about concentrations during an event. Most devices were designed for small areas of only a hectare or less because high flow rates from larger areas require much larger equipment, and it is usually much more feasible to collect needed samples using other technology.

Multislot Divisor Systems

An early device used in sampling surface runoff for soil erosion studies was the Geib multislot divisor.[8] The multislot divisor is constructed so that flow passes through one of a number of parallel rectangular weirs (called slots). Flow is collected from one of the weirs (standard multislot divisors have 13 or fewer slots), with flow from the remainder wasted. The multislot divisor was widely used in erosion studies over much of the United States, and is still in wide use. Maximum flow rates into a standard multislot divisor with 13 slots, each slot of 2.5 cm width, is about $0.10\,m^3\,sec^{-1}$. Divisors could be located in series so that the flow could be split into even smaller parts.

One multislot divisor system was coupled with a Parshall flume[11] for measuring flow rates for a water quality study on flat lands.[9] The system was developed to measure and sample runoff from small plots located on flat lands near the Mississippi river where there was little elevation for measuring and sampling runoff. The hydrograph expected was very similar to the hydrograph for natural rainfall shown in Fig. 3.

A multiweir system that both measured and sampled flow, operating under the same principles as the multislot divisor, was developed for use on terraces with underground outlets.[10] The terrace systems were expected to yield a hydrograph similar to the hydrograph for impoundments shown in Fig. 3, some having base flow and others with no base flow. The duration of the runoff event was expected to be up to about 2 day, but might be longer. In this application, v-notch weirs were used rather than rectangular slots as in the multislot divisor. The v-notch weir gave good precision for measuring and sampling a very wide range of flows. For this application, flow rates were measured continuously, and samples were collected for sediment and plant nutrient analyses. Due to a large range in sizes of watersheds and storm events, the multiweir divisors were used in series with the first multiweir divisor discharging into another divisor, and the lower divisor discharging from one weir into a storage tank. There were 13 weirs in each multiweir divisor, the two in series collected only 1/169th of the total flow. The sampled flow was discharged into a large storage tank, when it overflowed, the flow was again split through a series of small circular orifices whose size depended on the contributing area and expected flow rates. An in-field runoff sampling device similar in concept to the multislot divisor, and used in series was designed to be as unobtrusive as possible, and inexpensive to build.[12] The system worked well, but it was found that the construction and installation were critical to sampling accuracy.

More recently, a 9-slot multislot divisor made of plastic for use in a water quality study was developed and evaluated.[13] A system that uses a tipping bucket flow measuring device and a multitube divisor for collecting runoff samples was also recently described.[14] It has performed well in field studies for several years.

Coshocton Wheel

The Coshocton wheel is a device that samples a constant aliquot of flow from an H-flume.[7] The Coshocton wheel has a series of curved vanes and a single slot, and flow from the H-flume discharges onto the nearly horizontal wheel, with flow entering the slot draining to a storage tank. The flow onto the wheel rotates the wheel with the slot passing under the discharge with each revolution of the wheel. Depending on the wheel chosen, from 0.33% to 1% of the flow is diverted to the storage tank. Flow rates of the Coshocton wheel range up to $0.16\,m^3\,sec^{-1}$.

SAMPLING AT INTERVALS

For many situations, the variation of concentrations of constituents during runoff events is needed. This is usually accomplished by automatically or manually sampling runoff, and by measuring flow rate, either automatically or manually, at the time of sampling. Thus, both the time distribution of concentrations, time distribution of losses, average concentrations and total losses can be computed. This technology can be used on most agricultural watersheds, regardless of size.

For small agricultural watersheds, techniques and equipments are described in Ref.[7]. Numerous samplers are described that collect a sample at various intervals, and one is described that collects samples at varying intervals as dictated by flow rates. Samplers are also commercially available that can collect and store samples at intervals.

An automated water sampling and flow measuring system for runoff and subsurface drainage has coupled a tipping bucket flow measuring device with an automatic sample.[15] It has worked satisfactorily for flow rates from $0.001\,m^3\,min^{-1}$ to $0.12\,m^3\,min^{-1}$ in studies of water quality of tile drain lines in Minnesota.

Sumner et al.[16] describe a rainfall simulator and plot design for studying sedimentation, pesticide and nutrient losses on plots of $600\,m^2$ subjected to simulated rainfall of about $25\,mm\,hr^{-1}$. In this effort, runoff was sampled every 5 min during the first 30 min of runoff, and then at 10 min intervals for the remainder of the 2 hr rainfall event.

MANUAL SAMPLING

Manual sampling has many applications, particularly when runoff is from simulated rainfall, irrigation or application of water for other purposes—including application of animal wastes in liquid form. It is also employed in various monitoring studies where construction is not merited.

Elliot et al.[6] using manual sampling doing a rainfall simulation study, reported consistent sediment concentrations, with occasional wide variations in concentration. They overcame this by regular sampling that determined trends in sediment concentration over time.

All runoff may be collected for small events, during early portions of runoff, or from small areas.

Combinations of total sampling and intermittent sampling can also be used in some applications. This may be important when combining samples to reduce costs of analysis.

SOURCES OF SAMPLING ERRORS

Errors in sampling occur when the sample does not contain the same concentration of constituents as does the flow or when the proportion of the flow sampled is different than expected. There are many sources of such errors. Careful testing will identify many errors.

At very low flows, the multislot divisor did not collect the expected proportion of the flow, even though it was very good at higher flow rates.[12] This was attributed to a 2 mm elevation difference between slots at the outer edge of the divisor and the middle divisor that collected the sample. Others have found the multislot divisor for water quality testing quite precise.[10]

One source of error is deposition of sediment and sediment adsorbed constituents after runoff leaves the contributing area but before it reaches the sampling location.[17] Another source of error is the impact of research methods on the phenomena under study.[18]

CONCLUSION

There are many techniques and equipments for sampling runoff for water quality from studies involving natural rainfall, irrigation, simulated rainfall, and land application of fluid. There are also opportunities for errors and failures in sample collection that careful design, construction, and testing will help avoid.

One of the major problems in sampling runoff from natural rainfall is the operation of systems that are unattended and serviced infrequently. Additionally, for natural rainfall studies, operation during rare events is imperative if valid results are to be obtained.

It is important to evaluate the transport of materials from the area of interest to the sampling point to insure that losses, and perhaps additions, do not occur in channels. Also, one should carefully evaluate the impact of measuring and sampling equipment on the detachment and transport processes.

Wellhead Protection

Babs Makinde-Odusola
Riverside Public Utilities, Riverside, California, U.S.A.

INTRODUCTION

Wellhead protection (WHP) describes the process of managing possibly contaminating activities (PCAs) to protect groundwater quality. The United States Congress established the Wellhead Protection Program (WHPP) as part of the 1986 Amendments to the Safe Drinking Water Act (SDWA).[1] Section 1428 of the SDWA directs every state to develop a program that protects aquifers used as sources of drinking water. This Act defines a wellhead protection area (WHPA) as "the surface and subsurface area surrounding a water well or well field, supplying a public water system through which contaminants are reasonably likely to move toward and reach such well or well field.'' U.S. Environmental Protection Agency (EPA) sometimes refers to WHPA as "groundwater protection area.''[2]

Congress amended the SDWA in 1996 to enhance the nationwide commitment to the prevention and protection of drinking water sources. U.S. EPA is developing a National Source Water Contamination Prevention Strategy.[3] Section 1453 requires each State to establish a Source Water Assessment and Protection Program (SWAPP). SWAPP includes the mandatory Source Water Assessment Program (SWAP) and the voluntary Source Water Protection Program (SWPP). For water systems that rely on groundwater, the SWAPP program builds upon the 1986 WHPP. WHPP is now one of the six major programs within the SDWA related to SWAPP. The other programs are: sole source aquifer, source water assessment, underground injection control (UIC), source water petition, and comprehensive groundwater protection grants. Other Federal laws that protect groundwater quality include the Clean Water Act (CWA), the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA).[3–6] Some states and local governments also have laws or ordinances to protect groundwater quality. This section describes the WHPP for California public water systems.

BENEFITS OF A WHPP

Groundwater is the source of drinking water to about half U.S. population, including 95% of rural communities.[3,7] More than 200 different chemicals have been detected in groundwater including 74 pesticides in groundwater of 38 states.[4] Between 1971 and 1996, contaminated source water was the cause of 86% of waterborne disease outbreaks within the United States.[8] Therefore, Congress established programs to protect groundwater quality. In 1980, Congress established the UIC program to address injection practices that contaminate groundwater.[2] Revisions of 1999 ban locating certain types of UIC wells within WHPA.[2]

In 2000, U.S. EPA proposed a Groundwater Rule (GWR) to address risks of consuming waterborne pathogens in groundwater.[8] About 10% of public water supplies derived from groundwater exceed standards for biological contamination.[8] The proposed GWR does not address the issues of toxic and carcinogenic chemicals but includes hydrogeologic assessments to identify wells vulnerable to fecal contamination—an element of a WHPP.

The California Department of Health Services (DHS) requires source water assessment for new drinking water Sources.[9] By 1998, more than 2800 U.S. communities had completed their WHP.[10] EPA has set a goal of having local SWPPs for at least 30,000 communities by 2005.[11]

U.S. EPA published specific case studies of benefits of WHPP.[12] Potential benefits of a WHPP include more secure and safe drinking water, and the opportunity of reducing costs associated with treating contaminated water. It is much cheaper to prevent contamination than to characterize, monitor, and remediate contaminated groundwater. The National Research Council estimated that as much as $1 trillion may be needed to clean-up contaminated soil and groundwater in the United States over a 30-yr period.[13] Besides, groundwater contamination takes time to cleanup. On average, every gallon of water withdrawn from ground takes 280 yr to replace.[14] Some states allow public water systems to use the SWAP portion of the WHPP to obtain waivers for monitoring some contaminants. Public water systems must include information about the SWAP in the Consumer Confidence Reports distributed to their customers.[9,11]

ELEMENTS OF A WHPP

The SDWA requires each state to develop a WHPP and submit it to the U.S. EPA for approval. States have flexibility to develop programs that suit local needs, but their WHPP must include certain elements such as follows:[1,4,15]

- Delineate a WHPA for each public water system well or well field.
- Identify all Possible Contaminating Activities (PCAs) by location within the WHPA.
- Develop management programs to protect the water supply within WHPA from PCAs.
- Develop contingency plans for the location and provision of alternative water supplies.
- Plan to protect future well(s) from contamination.

States encourage public participation in developing WHPP. As of January 2001, U.S. EPA has approved WHPP for 48 states and two territories.[16] Section 1429 of the SDWA directed U.S. EPA to report the status of groundwater quality in the United States and the effectiveness of State programs for groundwater protection.[7]

Delineation of protection zones by itself does not protect groundwater. It must be coupled with the appropriate management strategies to protect groundwater quality.

DEVELOPING A WHPP

WHPP is usually implemented for existing well(s) or well field(s). However, it is preferable to site a proposed new well away from potential migratory paths of known or expected contaminant sources, and to construct wells in accordance with recommended well standards.[17] A community planning team usually develops the WHPP. Many agencies and professional organizations assist and/or provide resources for developing a WHPP. In the United States, such agencies include the U.S. EPA,[6] the Groundwater Protection Council,[18] National Rural Water Association,[19] and the National Ground Water Association.[20] Using a Geographical Information System (GIS) makes developing a WHPP easier.[21]

Delineating a Wellhead Protection Area (WHPA)

Many criteria had been used to delineate WHPA. Such criteria include distance from the well, time of travel (TOT) of water and/or contaminants to reach the well, assimilative capacity, hydrogeological boundaries and drawdown of the well.[4,9,11,15] Delineation methods range in complexity and costs and may be influenced by local site characteristics such as aquifer settings. Methods often used include the following: the simple arbitrary fixed radius (AFR); Calculated fixed radius (CFR); Modified CFR; analytical methods (AM); hydrogeologic mapping (HM); and the numerical flow/transport models (NFTM).[4,9,15] However, only the CFR method will hereafter be used for illustration.

AFR involves drawing of a specified radius centered and around each of the well(s) to be protected. California DHS approves the use of the AFR method only for non-community water systems.[9] Professional judgment and experience influence the radius chosen. The CFR method is similar to the AFR, except that the radius of the protection zone is based on the estimated radius of the zone of contribution (ZOC) for the specified time-of-travel (TOT), with no further adjustments for groundwater level gradient, hydrogeology, and other factors that may influence the fate of contaminants within the calculated ZOC. The CFR can be determined using the following equation.[9]

$$R_t = \sqrt{(70,267Qt/\pi\eta H)}$$

where R_t = radius of protection zone in feet for TOT t; Q = peak or average pumping capacity of well in gallons per minute (gpm); t = travel time to well in years, chosen based on hydrology and contaminant source; $\pi = 3.1416$; η = effective porosity of aquifer, California DHS recommends $\eta = 0.2$ if unknown; H = open interval or length of well screen interval in feet.

For example, the CFR is 1500 ft for a 500 gpm well with 100 ft of total well screen length, porosity of 0.25, and for a TOT of 5 yr. The calculated radius may need to be adjusted to the minimum recommended radius (MRR) of the jurisdiction.

In the Modified CFR, the radius is calculated as in the CFR except that the center of the circle is shifted upgradient in the known direction of groundwater flow by a distance of 0.5R, i.e., half the radius.[9,15] Shapes other than circles are sometimes used.[15]

AM rely on use of appropriate groundwater flow and transport equations to determine the area of contribution to the well to be protected. For example, the uniform flow equations[22] are used to define a ZOC to a pumping well in a sloping water table. HM uses geological, geophysical, and dye tracing methods to map the flow boundaries and TOT criteria and are appropriate for conduit karst aquifers.[4] NFTM[23] utilize computer-modeling techniques to numerically simulate groundwater flow and contaminant transport. NFTM is usually involved and costly but can be more appropriate for aquifers exhibiting complex hydrogeology.

Protection Zones

States differ as to the number of zones delineated within a WHPA, or how each zone is designated.

It is assumed that the well(s) to be protected had been constructed in accordance with standards.[17] In California, a typical WHPA usually consists of up to five zones that identify and differentiate zones in terms of the degree of contamination threat.[9] The protection zones, based on estimated time of ‘‘contaminant’’ travel (Table 1 and Fig. 1) are classified as follows.

Well Site Control Zone (WSCZ), or ‘‘wellhead,’’ the closest zone, is the area immediately surrounding the well. WSCZ is managed to prevent vandalism or tampering.

Zone A2 or the Microbial/direct Chemical Contamination Zone, is the area above the aquifer that contributes water to well(s) within a 2-yr time-of-travel. This zone was defined by the requirement of the proposed GWR.[8] Research suggests that bacteria and viruses are not likely to survive beyond 2 yr in soil and groundwater.

Zones B5: Chemical Contamination Zone is that surface area overlying the aquifer between the 2 and 5-yr time-of-travel. This zone provides more response time to a chemical spill than Zone A.

Zone B10: Chemical Contamination Zone is that surface area overlying the aquifer between the 5 and 10-yr time-of-travel. This zone provides more response time to a chemical spill than Zone B5.

Buffer Zone: This zone, generally upgradient of Zone B10, offers greater level of protection, and may be extended to include the entire recharge area especially where there are potential sources of significant contamination such as landfills or other hazardous materials.

The delineated zones can be refined in shape and/or size based on professional judgment and/or local knowledge of some site-specific characteristics. Some states may recommend minimum radii different from those shown in Table 1. California requires that the final assessment map be based on a USGS quadrangle 7.5 min series topographic map.[9]

Possible Contaminating Activities

This is an iterative process of establishing an inventory of past and present PCAs, land use, and industries that are considered potential sources of contamination within each of the zones of the WHPA. PCAs include underground storage tanks, improperly abandoned wells, landfills septic tanks, cesspools, pesticides, and fertilizers. Typical resources used in establishing the PCAs include land use maps, business license records, and the Internet.[9,21] Information collected on PCAs is useful in assessing the vulnerability of the drinking water source(s) to contamination.

Vulnerability Assessment

The purpose of Vulnerability Assessment (VA) is to identify PCAs that pose the most significant threats to water quality from the protected well(s). The VA takes into account the type and proximity of the PCA and the presence of any physical barrier that may affect the fate and transport of the PCA. The first step is to determine the Physical Barrier Effectiveness (PBE) using site-specific hydrogeological information.[9] Sources located in fractured rock aquifers are rated low compared to properly designed wells located in deeper confined aquifers. California DHS developed approaches for assessing and ranking vulnerability.[9]

VOLUNTARY SWPP

SWPP is a voluntary program that may be implemented after completion of the SWAP. The goal of the SWPP is to identify, develop, and implement local measures that advance the protection of the water supply.[9] This process begins with a closer review of the SWAP and refinement of the WHPA. The prioritized

Table 1 California WHPA zones

Protection zone	Purpose	TOT (yr)	MRR PA	MRR FRA
WSCZ	Protect from vandalism, tampering, other threats, etc.		50	50
A2	Protect the water supply source from viral, microbial, and direct chemical contamination	2	600	900
B5	Prevent chemical contamination from the water supply	5	1000	1500
B10	Allows time for some natural attenuation of the contaminants and if necessary, development of remedial plans or alternate water supplies	10	1500	2250
Buffer	Added protection for the drinking water source(s)		1500+	2250+

MRR—California Department of Health Services minimum recommended radius in feet; TOT = time of travel in years; PA = porous aquifer; FRA = fractured rock aquifer; WSCZ = well site control zone; AM = analytical method; HM = hydrogeological mapping; NFTM = numerical flow and transport models.
Note that California DHS does not have MRRs for zones A2, B5, B10 if the zones are delineated using AM, HM, and NFTM methods.

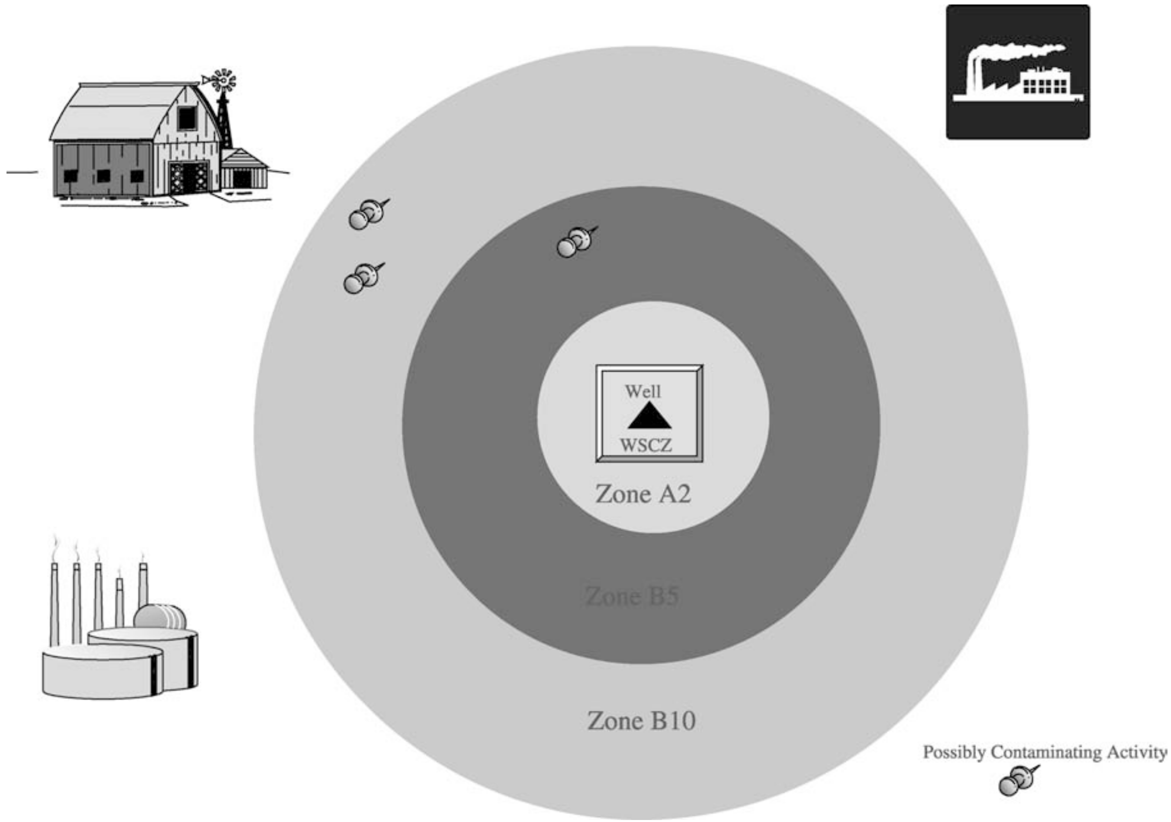

Fig. 1 WHPA using CFR method.

lists from the VA may be used to develop management programs to address PCAs that pose the greatest risk to water quality. It is customary to establish a local advisory committee and provide copies of the SWPP to regulatory agencies, local planning agencies, and the public. Management approaches include designating a lead agency; acquiring technical and financial assistance;[24] land use zoning; permit conditions, land transfer, groundwater monitoring, and establishing performance standards for septic systems. U.S. EPA maintains an electronic Compendium of Groundwater Protection Ordinances.[25]

Contingency Planning

Contingency Planning is the development and implementation of long and short-term strategies for replacing drinking water supply in the event of contamination, chemical spills or physical disruption.[9]

EXAMPLES OF WHPP

Examples of WHPP on the Internet include Yosemite National Park[26] and City of Sebastopol.[27]

Wells: Drilling

Thomas Marek
Texas A&M System Agriculture Research and Extension Center, Amarillo, Texas, U.S.A.

INTRODUCTION

There are many required processes entailed in the proper design and construction of a sand-free irrigation well. This article addresses the typical sequence of operations that should be used in the proper drilling of a new, sand-free irrigation well. Due to the number of operations involved in the process, the owner should outline and agree on them with prospective drillers before the operations begin.

CHOOSING A DRILLER

The first consideration in drilling an irrigation well is selecting a driller. Some drillers have limited knowledge of advanced well design and development. The selection of a driller is most important and should be made from drillers who have kept up with technical advances. Experience does not overcome innovations in technology and should be viewed as complimentary to new, successful advances in drilling technologies.

SELECTING A POTENTIAL WELL SITE

Selection of a potential site(s) may include the relative availability of electricity or natural gas, but should be chosen according to the best available aquifer information. Estimates of the formation and saturated thickness of the aquifer can be made from existing or adjacent wells in relation to the proposed new site(s).

The proposed well site(s) should be located far enough from existing irrigation wells to prevent drawdown interference.[1] Water district or authority rules typically govern the distance between wells. Every well, once pumping is initiated, establishes a drawdown curve and if wells are located too close together, the respective drawdown curves will begin to overlap, causing more drawdown and subsequently requiring more horsepower.

Drilling of the test hole(s) is needed to gather information as to the anticipated production of the well and to provide a vertical formation map.

TEST HOLE PROCESSES

A test hole is required to size the well screen slot size(s) and determine how and where to construct the screened sections in the saturated zone, and for determining the proper sized gravel. This information is required for construction of the well screen prior to the main well drilling activities as the time period from well drilling initiation to gravel installation is limited. Sized gravel must be acquired prior to the main drilling activity. Without a test hole, the driller is essentially guessing at what is beneath the ground. Once the screen and gravel are in the borehole, next to nothing can be done to change either. The test hole drilling fluid should not be that of bentonite as bentonite is a clay-based compound that swells when wetted with water and seals the ''pores'' of the drilled borehole. Reasons for avoiding the use of bentonite is that it can mask the logging characteristics of some aquifer strata(s) and is difficult to remove from the borehole. A strongly suggested, preferred drilling fluid is that of a biological polymer.

It is recommended that the test hole be drilled throughout the water bearing formation and that drilling samples are obtained as drilling progresses. While the number of samples can vary, a determination of the number of samples to be collected should be made based upon the anticipated saturated thickness of the aquifer.

Once the test site borehole is drilled, a series of logs should be conducted to correlate strata data as to the availability and productivity of water within each strata of the formation. The three types of logs recommended are gamma log, specific conductivity, and spontaneous potential.[2]

PROPERLY PLUGGING THE TEST BOREHOLE

Once the borehole logs have been completed, the test hole should be filled and sealed to prevent contaminants from entering the aquifer. Most water authorities have regulations regarding this process.

ANALYSIS OF CUTTING SAMPLES AND LOGS

Analyzing test hole cutting samples consists of placing each sample in a stacked set of progressively smaller sized sieves and shaking them on a mechanical shaker.

The results of the shaker data yield a distribution of curves from each sample zone.[3] The drilling coordinator can then plot the sand-sieved distribution information on a semi-logarithmic paper. In conjunction with the family of curves of the sand-sieved data, the three logs collected from the test borehole provide supplementary evidence as to the specific capacity of the respective formations.

SELECTING A NEW WELL SITE

A comparison of the sets of borehole data should be made and a site chosen as to where the best available water is potentially located. If the difference between the data sets is minimal, other factors such as energy or road accessibility can be considered.

SELECTING A GRAVEL PACK

In a sand-free well, the gravel pack prevents the sand from entering the well casing but allows the water to flow efficiently through the gravel and into the wellbore. Simply put, the gravel stops the sand and the perforated well casing stops the gravel. If one uses an inadequate gravel pack, sand will destroy the pump impellers in a short time. In addition, if one pumps much sand over time and forms a cavity around the perforated section of the well, the potential for the lower part of the formation to collapse onto the casing is possible.

The sieved data collected are necessary to determine the needed gravel size properly. Analysis and gravel sizing requires some expertise as there are "judgment" and experience factors that have to be applied. One should not compromise on the gravel, as the choice to do so is unwise. In addition to size, one wants the gravel to be uniform. Another factor that constitutes "better" gravel is the amount of quartz in the rock of the gravel.

SELECTING A WELL SCREEN

A well screen is strongly suggested in the water bearing regions of the aquifer. It is typically a fabricated, continuously wound type casing reinforced by solid, vertical bars attached to the interior of the wound section. One of the most popular types uses a triangular shape. The smaller or tapered edge of the triangular shaped screen is to the inside of the wellbore. In this manner, any gravel or sand that makes it through the initial outer edge of the screen is allowed to be excavated when the well is being developed and presents no obtrusion to water intake.

Next, using the test hole data, one decides as to where the perforated portion of the well screen needs to be located. In some cases, the screen may be scheduled in a skipped fashion to reduce screen costs and to promote water movement in a more laterally distributed mode. As the well screen location(s) is governed by the test hole strata data, the slot size of the well screen is governed by the size of the gravel selected. The selection is critical to not restrict water flow into the well bore, yet be smaller to prevent any gravel entrance after the well development process.

SELECTING A DRILLING METHOD

There are two basic drilling methods: the direct rotary and the reverse circulation drilling technique, and each has its advantages and application. The rotary method uses a drag type bit with a "centering collar" and can be from 4 in. to 24 in. in diameter. This drilling method involves using a hollow stemmed drilling shaft with drilling fluid being pumped through the interior of the shaft and allowing the drilled materials to be returned to the ground surface around the exterior of the drill stem. The reverse circulation drilling technique suctions the drilling mixture essentially through the drill stem. Thus, the water is returned to the borehole around the outside of the drill stem. This method requires more horsepower than that of the direct rotary method due to the suction pump. The advantages are that this method uses less water and less drilling mixture to stabilize the borehole, and holes greater than 24 in. can be achieved.

SPECIFYING A CORRECT DRILLING FLUID

The use of a biological polymer (organic) compound is strongly recommended. The typical borehole drilling process occurs within 24 hr and coincides with the initiation of the "natural breakdown" period of the organic drilling compound. After drilling and the casing setting process, the driller may use a small amount of chlorine solution to assist in the rapid breakdown of the compound but not damage the well screen slots.

CHOOSING A CASING AND BORE HOLE SIZE

Data indicate that drilling a bigger borehole and installing a bigger diameter well casing results in only marginally better well bore inflow. It should be noted that the aquifer, well pack and well screen, govern the amount of water inflow. Four inches of gravel (radially) is typical around the well screen and adds 8 in. to the diameter of the casing diameter. Thus, if one uses a 16-in. casing, a 24-in. well bore will be required.

MAIN WELL DRILLING AND SAMPLES

It is suggested that cutting samples be obtained during main drilling operations. Although the well screen and most of the materials would already have been prepared from the testhole data, if there is significant difference in formation detected, it is better to substantiate it during the main drilling phase. Also, the main drilling samples can be run later, if desired, to determine how they differ from the test hole stratas.

SETTING CASING, SCREEN, AND GRAVEL

At this point, the borehole will be completed and the well screen assembly, casing and gravel should be on site. The casing should be installed. However, the author strongly encourages one to install a metal airline onto the exterior of the casing and screen to provide the depth to water reading directly with a small jet of compressed air.

WELL DEVELOPMENT

Proper well development is essential and determines whether a well will be sand free and without it, maximum efficiency of the well cannot be achieved. The first operation involves bailing the well. This operation cleans out drilling materials that have settled to the bottom of the hole. It is cautioned that the rate of bailer withdrawal needs to be controlled and should not be excessive, especially in the water bearing portion of the aquifer. This is especially true of bailers that are sized close in diameter to the interior diameter of the well casing and screen. Rapid ascension of a bailer through the water portion of the formation is ''harshly'' pushing the gravel into the aquifer stratas ahead of the bailer (creating a positive pressure wave) and ''slamming'' the gravel back against the outside of the well casing as it passes (creating a negative pressure wave) behind the bailer.

The development process begins with a cable rig utilizing a substantially weighted surge block. Even better is the utilization of a double-flanged surge block. This tool is lowered to the bottom of the hole and worked upward from the bottom to the top of the screened section of the well in short, rapid repetitive steps. This lower-to-upper direction is necessary because the progression of the sequence will draw sand into the well casing and it is unwise to risk getting a surge block ''stuck'' in the screen section due to sand atop the block from a top to bottom sequence. What is desired with this development operation is that the surge block ''puff,'' not ''punch'' by excessive operation rates, the gravel pack. Through this ''upsetting'' and ''closing'' of the gravel pack (created in front and behind the surge block), drilling particles, gravel fines, and fine sands enter the casing. This process also orients the gravel against the casing and sets the adjacent sand of the formation against the gravel.

The range of aquifer addressed in each sequence of the development depends on the saturated thickness of the site. If the thickness is large, a large range for each sequence may be appropriate and acceptable. The rate of the operation is more critical. Rates are typically suggested at 3 ft/sec by the author.

Subsequently, any bailing operations associated with pump reworking later in time can have a significant impact on the gravel pack and formation stability. If a bail operator ''runs'' a bailer at too fast a rate within the screened region of the casing, one runs the risk of upsetting all the previous development efforts and the well may begin to pump sand after the bailing operation is complete.

COMPLETION OF WELLHEAD SITE

After development, the well site should be completed to provide drainage away from the location. Additionally, all well logs should be forwarded to the appropriate water authority for registration of the well.

CLOSING COMMENTS

Due to the number of items entailed in the drilling process, a tabulation of the expected operations should be submitted to potential drillers in the form of a bid. It should also be apparent that drilling a well properly will not produce more water than what is in the ground. It will, however, allow more efficient and feasible extraction of the water over time and provide one with feasible, long-term operation of the well.

Wells: Hydraulics

Mohamed M. Hantush
National Risk Management Research Laboratory, U.S. Environmental Protection Agency (US-EPA), Cincinnati, Ohio, U.S.A.

INTRODUCTION

Water wells have been used and continue to be used as devices for extracting groundwater from aquifers. The importance of wells is not limited to the development of groundwater resources. Wells are used for environmental purposes, among others, the removal of contaminants from groundwater and controlling salt-water encroachment in coastal areas.

CONCEPTS

Hydraulics of water wells deals primarily with the application of Darcy's law and continuity relations to solve problems related to groundwater flow toward wells. Productive wells are those that tap geological formations, called aquifers, which yield groundwater in significant quantities; i.e., capable of yielding (or adding into storage) and transmitting water in appreciable amounts. Wells that tap a confined aquifer, in which groundwater is under pressure greater than atmospheric, are called artesian wells, and whenever the hydraulic head is above the ground surface, they are referred to as flowing wells (Fig. 1). In these wells, groundwater flows freely under pressure without the need for pumping. A well that penetrates an unconfined aquifer (also referred to as a water table or phreatic aquifer) is called a water-table (or gravity) well (Fig. 1). The water level in this well corresponds approximately to the position of the water table (i.e., the surface of atmospheric pressure) at that location.

Groundwater discharged from a well causes drawdown (i.e., lowering of the hydraulic head relative to its prepumping level) around the well, which decreases in the direction away from the well and forms what is known as the cone of depression (Fig. 2A). The hydraulic (or piezopmetric) head gradient formed by the cone of depression induces groundwater flow toward the pumped well, which in extensive aquifers is radially symmetric. This phenomenon is reversed for recharging wells where the hydraulic head buildup around the well decreases outwardly and causes a flow in that direction. The hydraulics of pumping wells applies also to recharging wells.[1] The mechanics of groundwater flow and yield (or storage) due to a discharging (or recharging) well depend on the type of aquifer and the radius of influence of the well. The radius of influence R of a pumping well—the distance from the center of the well at which drawdown is practically zero—generally increases with time until it intercepts an external boundary (Fig. 2A). At which time the well discharge is partially derived from another source, if that external boundary represents an open water body, such as a stream or a lake. Elasticity of aquifers, including compressibility of water, and gravity drainage in unconfined aquifers—water released by drainage from the pore space through which the water table moves—are two primary mechanisms that account for the volumes of water released from or added into storage in aquifers. Leakage across semipervious confining layers (Fig. 4), also called aquitards or leaky units, overlying and/or underlying an aquifer can account for a significant fraction of the volume of pumped groundwater, or even sustains the total groundwater discharge rate when elastic storage is exhausted in seemingly extensive aquifers.

The change of drawdown (or head buildup) with time and space around a pumped (or recharged) well depends on the aquifer hydraulic characteristics, such as its storage capacity and transmissibility. The latter is determined by the transmissivity parameter T [L^2T^{-1}], which measures the ability of a unit section of the aquifer to transmit flow throughout its entire thickness; it is the product of aquifer thickness B and the hydraulic conductivity K [LT^{-1}]. The storage capacity of an aquifer is quantified by the storage coefficient S (also called storativity) [L^3L^{-3}], which is the volume of water released from (or added into storage of) a column of the aquifer of unit horizontal area per unit drop (or increase) of the head. In unconfined aquifers, the storage coefficient is approximated by the specific yield S_y, which gives the yield of an aquifer per unit area and unit drop of the water table. It is also defined as the drainable fraction of pore space in a unit volume of aquifer. An important parameter in the analysis of drawdown in leaky aquifers is the leakage factor $\lambda = \sqrt{Tb/K'}$, which determines the areal distribution of the leakage [L]; where K' and b, respectively, are the hydraulic conductivity and thickness of the semipervious confining layer. Another leaky aquifer parameter is the leakage coefficient[2] $\sigma = b/K'$,

Wastewater–Yellow

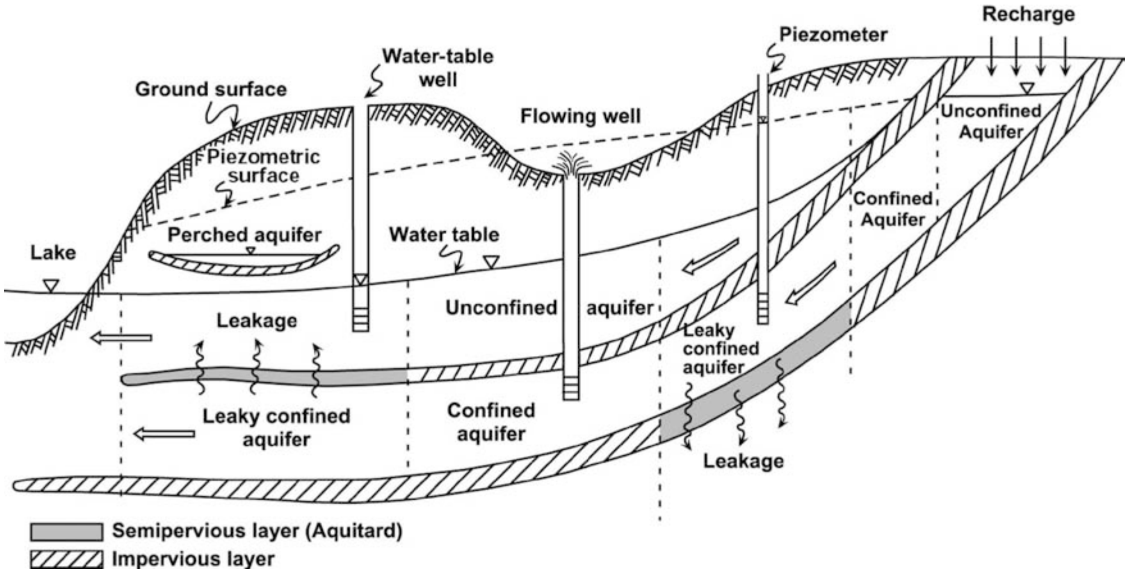

Fig. 1 Illustrative diagram of types of aquifers.

which is defined as the rate of flow across a unit (horizontal) area of the semipervious layer into (or out of) the aquifer under one unit hydraulic difference across the layer [T].

DARCIAN FLOW

Under natural field conditions, groundwater percolates slowly through the porous aquifer material that, for all practical purposes, flow is laminar and provoked mainly by viscous forces. Near the well entrance and inside the well, flow becomes turbulent and inertial forces can no longer be ignored. Darcy's law applies to laminar flow where the specific discharge q [LT^{-1}] (hypothetical flow rate per unit porous area normal to the flow direction) is proportional to the head gradient i and the constant of proportionality is the hydraulic conductivity K:

$$q = Ki \tag{1}$$

Analysis of well hydraulics mainly combines Darcy's law Eq. (1) and continuity relations to derive solutions

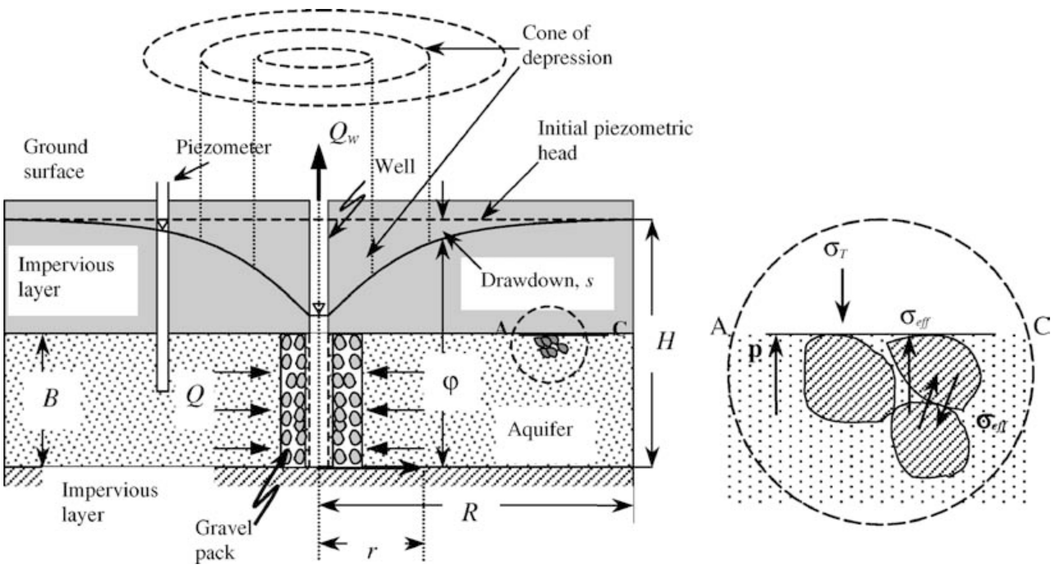

Fig. 2 Illustrative diagram: (A) a confined aquifer and cone of depression, (B) pore-water pressure and inter-granular (effective) stress.

Wastewater–Yellow

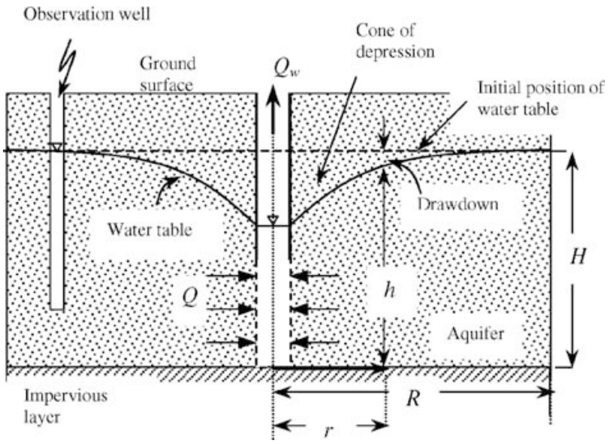

Fig. 3 Illustrative diagram of an unconfined aquifer.

for drawdown in pumped aquifers (or head buildup in recharged aquifers). Based on these fundamental relations, the flow rate Q in an extensive confined aquifer across a cylinder of height equal to the thickness of the aquifer B and radius r is radially symmetric and can be expressed by the relationship (Fig. 2A):

$$Q(r,t) = 2\pi r T \frac{\partial \varphi(r,t)}{\partial r} \tag{2}$$

in which φ is the hydraulic head [L]; $T = KB$ is the aquifer transmissivity; r is the radial distance from the well center; and t denotes time. This equation can also be applied to describe flow toward a well in an extensive water-table aquifer, but with $\varphi = h$ and $T = Kh$, where h is the elevation of the water table above the base of the aquifer at a distance r from the center of the well (Fig. 3). The transmissivity in unconfined aquifers therefore varies with time and distance, as the water table fluctuates in space and time in response to pumpage or recharge. The solution of Eq. (2) under steady flow condition is called the *Thiem* equation,[3]

$$\varphi(R) - \varphi(r) = \frac{Q_w}{2\pi T} \ln\left(\frac{R}{r}\right) \tag{3}$$

in which Q_w is the well discharge rate [L^3T^{-1}]; and H is the hydraulic head at distance R from the center of the well [L]. The solution of Eq. (2) in an unconfined aquifer with $T = Kh$ is known as the *Dupuit–Forchheimer* well discharge formula,[3]

$$h^2(R) - h^2(r) = \frac{Q_w}{\pi K} \ln\left(\frac{R}{r}\right) \tag{4}$$

Eqs. (3) and (4) describe the steady-state hydraulic head at distance r from the center of the well. Eq. (4) is based on Dupuit's assumption[1] that the equipotential lines are nearly vertical and, thus, the flow is essentially horizontal. The hydraulics of gravity wells is largely dependent on this assumption, in which the governing flow equation can be linearized and solved easily.

In most practical problems of flow around wells, the relationship between transient drawdown in the aquifer and rate of discharge of the well Q_w can be expressed by the well-flow equation:[2,4–7]

$$s(r,t) = \frac{Q_w}{4\pi T} W(u) \tag{5}$$

where s is the drawdown in the main aquifer [L] (Fig. 4) at a distance r from the center of the well and time t; and $W(u)$ is called the well function, which is related to aquifer hydraulic characteristics, r and t.

The drawdown caused by wells operating near physical boundaries, such as streams cutting through alluvial valleys and impervious mountain ranges, can be estimated by using the method of images.[1–3,8] The method of superposition can be invoked to solve for the drawdown in a wells field.

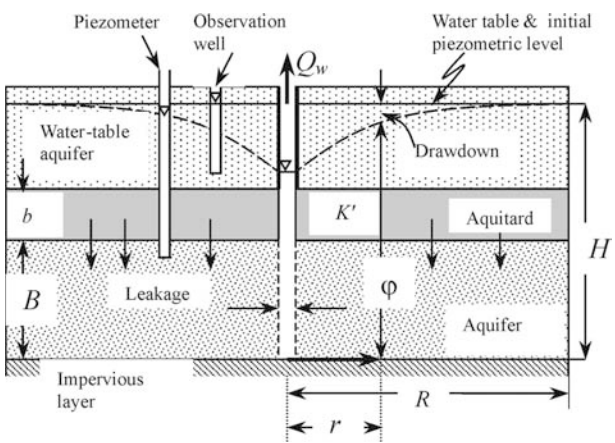

Fig. 4 Illustrative diagram of a leaky-confined aquifer.

MECHANICS OF AQUIFER YIELD AND STORAGE

The elastic properties of the aquifer matrix and water[9] is the primary mechanism for the release and storage of groundwater in confined aquifers. Prior to pumping, the total load (overburden) σ_T [$MLT^{-2}L^{-2}$] above the confined aquifer, including the atmospheric pressure, equilibrates with pore-water pressure p [$MLT^{-2}L^{-2}$] inside the aquifer and the intergranular pressure (or effective stress) σ_{eff} [$MLT^{-2}L^{-2}$] exerted by the sediments on each other at the contact points; i.e., $\sigma_T = p + \sigma_{eff}$ (Fig. 2B). When groundwater is discharged from a well, the pore-water pressure decreases

Wastewater–Yellow

and the effective stress increases by an equal magnitude; i.e., $\Delta p = -\Delta\sigma_{\text{eff}}$, since the overburden σ_T remains constant. Consequently, the decreased pore-water pressure results in the decompression and expansion of the water volume in storage, and the increased effective stress causes the compaction of the aquifer, somewhat reducing the pore space, and thus, the expulsion of additional volume of water. This elastic behavior of the aquifer and water is responsible for the release or taking into storage volumes of water in a pumped (or recharged) aquifer.[5] In wells of large diameters, the storage capacity in the well itself can be significant and impact drawdowns in pumped aquifers.[10]

In water-table aquifers, water is derived from storage primarily by drainage of the pore space above the lowered water table (gravity drainage) and partly from elastic storage as in confined aquifers. The latter is ignored in practical applications and typically characterizes the early response of the aquifer to pumping. When groundwater is pumped from an unconfined aquifer, the well discharge is initially derived from elastic storage and the aquifer behaves as though it is confined. The induced average drawdown therefore creates a head gradient in the vicinity of the water table and causes vertical flow and the subsequent lowering of the water table. In which case, the bulk of the well discharge is accounted by the volumes of water released from storage by vertical displacement of the water table, and the initial decline in the average head, thus, slows down considerably for a period lasting minutes to a few hours. The drawdown appears to be flat during this period, which is referred to as the ''delayed yield'' period.[6,7] The water table can now keep pace with the declining average head and, as in the early stage, the reaction of the aquifer becomes equivalent to that in a confined aquifer where the flow is essentially horizontal, but with the storage coefficient equal to the specific yield.

In a leaky aquifer groundwater is derived from: 1) elastic storage in the main aquifer; 2) gravity drainage if the aquifer is unconfined; and 3) elastic storage in the semipervious confining layers and induced vertical leakage across these units. In most aquifers, the hydraulic conductivity of the semipervious layer is smaller than that in the main aquifer by at least two orders of magnitude so that the flow across this layer can be assumed vertical. For all practical purposes, the flow in the main aquifer is horizontal, except in the vicinity of partially penetrating wells. When water is discharged from a well tapping the main aquifer, it is initially derived from elastic storage, and the average head is thus reduced as drawdown increases toward the discharging well forming a cone of depression. The vertical hydraulic head gradient formed by the drawdown at the interface between the upper and/or lower semipervious layer(s) and the main aquifer induces vertical flow through the semipervious layer derived partly from elastic storage of this leaky layer and partly from leakage due to head differences across the layer(s). Elastic storage of a leaky formation is often neglected, unless it is extensively thick,[2] and leakage across this unit q_l is usually assumed to be proportional to the head difference across the confining leaky unit(s),

$$q_l = -\frac{\varphi - \varphi_0}{\sigma} \text{ or } q_l = \frac{s}{\sigma} \tag{6}$$

in which φ is the head in the main aquifer; φ_0 is the head in the aquifer(s) above the overlying and/or below the underlying leaky confining layer(s) (Fig. 4); and σ is the coefficient of leakage, defined earlier. Contrary to completely confined aquifers, drawdown in leaky aquifers slows down in time and eventually levels off at steady state, as long as the head in the aquifer receiving or supplying leakage φ_0 is kept constant. Steady-state drawdowns occur when the discharge rate is at equilibrium with the total leakage rate through the semipervious layer. This behavior is similar to that displayed by the delayed yield phenomenon in unconfined aquifers, except that in the latter the discharge rate is derived entirely from drainage of the pore space above the water table rather than from leakage.

The time-drawdown relation in fractured rock aquifers shows three distinct stages, which may be similar to the delayed yield response in unconfined aquifers. In fractured-rock aquifers, groundwater flow partly occurs through the interconnected fractures as though it is flowing through pipes, and partly by percolation through the unfractured porous blocks of the rock matrix. Storativity of the fractures (or fissures) accounts for the initial yield of a pumping well, and as pumping continues, the drawdown somewhat slows down as water in the porous matrix reaches the fractures. The delayed yield in fractured aquifers is, thus, the result of the low conductivity of the porous blocks relative to that of the open fractures. At the later stage, the well discharge is derived from both the fractures and the porous blocks as the cone of depression continues to expand.[11]

PARTIALLY PENETRATING WELLS

A well whose screen (water entry section) length is smaller than the saturated thickness of the aquifer it penetrates is called a partially penetrating well. Flow is 3-D and no longer is horizontal in the vicinity of this well and can be turbulent. In fact, the vertical velocity components below and above the well screen can be very large. Partial penetration affects drawdown in the vicinity of the well and for large distances from the pumping well, the flow is essentially horizontal as though the pumped well completely penetrated the aquifer.[2] Anisotropy of the hydraulic conductivity has impact whenever the flow is 3-D. In aquifers where the vertical conductivity is much smaller than the horizontal, the yield of partially penetrating wells may be appreciably smaller than that of an equivalent isotropic aquifer. The effect of the anisotropy increases as the well penetration decreases.[2]

AQUIFER TESTS

Aquifer hydraulic characteristics, such as transmissivity, storativity, leakage factor, and leakage coefficient, are usually obtained from aquifer tests. In these tests, the aquifer is tested under natural field flow conditions, in which a well is pumped at a prescribed rate and the drawdown is measured therein and, preferably, in at least one observation well located at some distance from the pumped well. The Theis Type-Curve method for the estimation of aquifer transmissivity and storativity in a confined aquifer advanced the basic approach of solution to other aquifer flow scenarios.[2,6,7] In this method, a logarithmic plot of the well function $W(u)$ against $1/u$ (called type curve) is superimposed over that of the drawdown s vs. t/r^2 (called data curve) until a best match between the two curves is obtained. The hydraulic properties are then estimated from an arbitrarily chosen matching point and solving simple algebraic relations. In natural aquifers, the transmissivity (also the hydraulic conductivity) change with direction at a given location, in which case the aquifer is referred to as anisotropic. In these aquifers, the transmissivity along any direction can be determined uniquely in terms of its principal values, which are defined along two principal directions in the horizontal plane, and both the values and the principal directions can be estimated from aquifer tests, however, with three observation wells.[12]

WELL LOSSES

The drawdown inside a discharging well s_w is the sum of both formation head loss and well losses, $s_w = C_f Q_w + C_w Q_w^n$, in which C_f is the formation-loss constant; C_w is the well-loss constant relating discharge to the well loss; and n is the exponent due to turbulence.[13] $n = 2$[6] and may exceed 2,[8] and can be as high as 3.5.[14] The formation loss results from laminar flow through aquifer sediments and turbulent flow outside the well screen, and is linearly related to the well discharge Q_w. Well losses are associated with friction losses, which occur when water moves into the well through the screen, and turbulent flow inside the well. Gravel packing (Fig. 2A) and the removal of fine aquifer sediments during well development reduce well losses outside the well. The formation losses and well-loss parameters C_f, C_w, and n can be estimated graphically from a step-drawdown well test, in which drawdown inside the well is measured in time and at incremental well discharge rates.[14,15]

Wetlands and Petroleum

John V. Headley
Aquatic Ecosystem Research Protection Branch, National Water Research Institute, Saskatoon, Saskatchewan, Canada

Kerry M. Peru
Environment Canada, National Hydrology Research Center (NWRI-NHRC), National Water Research Institute, Saskatoon, Saskatchewan, Canada

INTRODUCTION

In recent years, the ecological importance of wetlands has become well established in the scientific community at large. There is growing acceptance to preserve wetlands, wherever possible, as these areas provide support functions for several natural and living resources. Wetlands mediate biogeochemical transformations and serve as buffer zones for assimilation and reduction of toxic petroleum hydrocarbons released to aquatic environments.

DEFINITIONS AND TERMS

The terms "wetlands" and "petroleum" can have a variety of meanings; thus it is important to first define these terms as used in this review. As there is no universally accepted definition for wetlands, it should be noted that the term is used here to denote areas of "emergent land-forming transition zones between uplands and open water."[1] As pointed out by Catallo,[1] some wetlands such as potholes have discrete boundaries and do not provide gradual transitions. However, there are several general defining features of wetlands, including one or more of the following traits: 1) there are at least temporally waterlogged or saturated substrata; 2) there is a dominance of plants adapted to saturated soils; and 3) there is a scarcity of flood-intolerant plants. Examples of natural wetland areas include freshwater swamps and marshes, Prairie potholes, salt and brackish coastal marshes, tidal freshwater marshes, bottomland hardwood forests, and mangrove swamps. In addition to these natural habitats, there are vast regions of man-made lagoons and tailing ponds such as those found in the oilsands region of Alberta, Canada, that also fall under the general category of wetlands. The later and other engineered or constructed wetlands have been fully integrated into some management strategies for treatment and cleanup of petroleum hydrocarbon wastes.[2,3]

Petroleum is used in this article to denote primarily petroleum hydrocarbons—ranging from light gases such as methane, ethane, and butane, to volatile hydrocarbons such as benzene, toluene, ethylbenzene, xylene (BTEX); gas condensates hydrocarbons to heavier molecular weight components in the $C_{5–30}$ range and beyond. The latter would include the asphaltenes and petroleum waxes as high as C_{60}. Particular attention has been given in the literature to BTEX, polycyclic aromatic hydrocarbons, and their alkyl derivatives, primarily because of their importance as environmental contaminants.[4] Although petroleum industrial wastes contain heavy metals and other nitrogen and phosphorous nutrients, along with components with biological oxygen demand (BOD) and chemical oxygen demand (COD), their removal and treatment will not be the main focus of this review. Application of treatment wetlands for the removal of the latter has been well reviewed elsewhere.[3] Likewise, the many chemical reactions to form a diverse range of chlorinated and other halogenated hydrocarbons will not be covered here. Instead, the focus is on naturally occurring petroleum hydrocarbons. Specific attention is given to their fate and transport in wetlands.

CASE STUDIES—ISSUES AND CONCERNS

There are some key questions and issues that the scientific community at large has to face regarding evaluating the effectiveness of wetlands for the treatment of petroleum hydrocarbon wastes. Provided the contaminant loading is not too severe to overload a given wetland's capacity to assimilate and remove petroleum contaminants, wetlands can serve as a sink, rather than a source, for hydrocarbons to the environment. An exception is the offgassing of methane to the atmosphere and other light gases, or combustion of wetland vegetation. However, the majority of petroleum contaminants can be abated in the soil/water/vegetation environment of wetlands. In cases where there is damage to sensitive wetland ecosystems, there are difficult issues to tackle. For example, it is not established what actually constitutes "restoration of contaminated wetlands—and what are considered best management strategies for wetland restoration.''[5] Furthermore, there is the issue of generally accepted endpoints that are suitable for measurement of wetland damage or restoration.[4] These issues are difficult to address fully because of the fact that wetlands are dynamic systems governed largely by: 1) their hydrology; 2) succession of vegetation (types of plants/vegetation best adapted for a particular environment, such as freshwater, saline, or arctic conditions); 3) availability and type of nutrients (whether organic or inorganic); 4) type and physical–chemical characteristics of petroleum oil in contact with the wetland; 5) amount of petroleum exposed to the wetland; 6) whether the contaminants are aged or fresh, as this has major effects on bioavailability; and 7) the extent to which microbial communities at the site are adapted to the degradation of petroleum hydrocarbons.[2,5–8] In favorable cases, petroleum hydrocarbons can increase the abundance of hydrocarbon-degrading bacteria and fungi. Likewise, some wetland vegetations can sequester petroleum hydrocarbons and process chemicals. However, in view of the dynamics of wetland ecology, care and caution need to be exercised when making generalizations from case studies to other wetland systems for treatment of wastes.

The successes and failures of wetlands for the abatement and treatment of petroleum hydrocarbons should be considered within the context of these factors above. It can be argued that the field is still relatively new and that many of the tools for general application of wetlands are still topics of research and development. However, a few case studies are selected below to illustrate how the various petroleum hydrocarbons can be successfully treated in either natural or engineered wetlands, based on reduction in concentration and toxicity in the outflow from wetlands compared with ambient levels in waste streams.

Abatement of Petroleum Hydrocarbons in a Natural Wetland

Results of a 5-year research study were reported by Moore et al.,[9] describing natural attenuation processes in a natural wetland, located downgradient of a sour gas processing plant in central Alberta, Canada. The investigation illustrated the utility of natural wetlands as a management option for the attenuation of condensate, which is primarily composed of C_5 to C_{12} hydrocarbons, including BTEX compounds. The abatement in the natural wetland area (Fig. 1) was considered as a possible favorable remedial solution at the site in question.[9] It was established that both free-phase and dissolved-phase condensates have been discharging to the base of the wetland at 1 m below ground surface, resulting in contamination of the wetland peat and underlying clay till. However, over the past 20 years, the lateral extent of contamination in the wetland has remained stable, and apparent free product thickness and BTEX concentrations have decreased over time. A number of natural processes have contributed to the containment of contaminants, including sorption, aerobic biodegradation, volatilization, and anaerobic biodegradation. Sorption and desorption processes were evaluated by laboratory testing of site soils. There was a significantly higher sorption to the wetland peat compared with clayey silt attributed to the peat's higher organic content (40%) relative to the silt (1%). At this particular wetland, there was no significant resistance to desorption observed, indicating that benzene would remain mobile and bioavailable over time. Aerobic biodegradation and volatilization appeared to be the main removal processes. Anaerobic biodegradation occurred primarily in the clayey silt, based on geochemical indicator parameters, microbial analyses, and soil vapor sampling. Thus, overall, natural attenuation appeared to be a feasible remedial solution for this wetland by facilitating the containment and degradation of condensate components at the wetland site.

Treatment of Petroleum Hydrocarbons in Engineered or Constructed Wetland

There are two general types of shallow vegetated ecosystems or constructed wetlands that are used for the treatment of petroleum hydrocarbon wastes. The wetlands

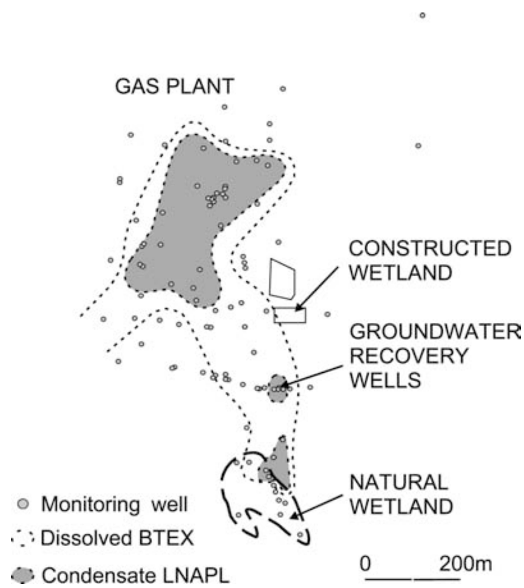

Fig. 1 Abatement of petroleum hydrocarbons in a natural wetland located downgradient of a sour gas processing plant in central Alberta, Canada. *Source*: From Ref.[9]. Courtesy of Marcel Dekker, Inc.

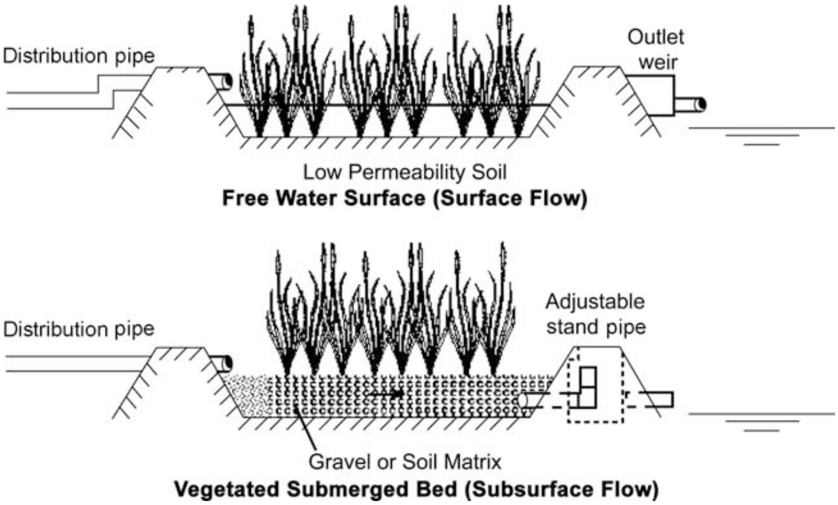

Fig. 2 Application of engineered or constructed wetlands for the treatment of petroleum hydrocarbons. *Source*: From Ref.[3]. ©American Chemical Society, 1999.

have either: 1) free water surface with surface flow; or 2) subsurface flow with vegetated submerged bed systems, as illustrated in Fig. 2. The former more closely mimics the hydrologic regime of natural wetlands, whereas the latter serves to minimize the exposure of humans or wildlife to the petroleum wastewater.

The use of engineered or constructed wetlands (Fig. 2) for the treatment of petroleum hydrocarbons has been well reviewed by Knight, Kadlec, and Ohlendorf.[3] In their review, the authors discussed and illustrated several good examples of treatment wetland applications, including the treatment of refinery effluents, spills and washing, oilsands processing water, and water produced from the processing of natural gas (Table 1).

Several large-scale wetland projects currently exist at oil refineries for treatment of not only petroleum hydrocarbons in wastes but also COD, biochemical oxygen demand, trace organics, metals, toxicity, total suspended solids, nitrogen, and phosphorus. As noted for natural wetlands, the removal of contaminants in the engineered wetlands is also a function of hydraulic loading and influent concentration and, to a lesser extent, is dependent on the diversity and nature of plant communities, water depth, and hydraulic efficiency. As pointed out by Knight, Kadlec, and Ohlendorf,[3] in most cases, data from petroleum industry wetland studies indicate that treatment wetlands are equally or more effective at removing contaminants from petroleum industry wastewaters than from other types of wastewater. However, for cost-effectiveness, it is critical to construct the treatment wetland with the appropriate size as too big a size leads to unnecessary

Table 1 Examples of petroleum industry full-scale and pilot treatment wetlands

Site name/location	Purpose	Wastewater source	Total wetland size (ha)	Average flow (m^3/day)
Amoco, Mandan, ND, USA	Process water polishing	Refinery process water	16.6	5700

Wastewater–Yellow

cost overheads, whereas too small a size leads to the wetland being a source of contaminants rather than a viable treatment option.

CONCLUSION

Although there is growing acceptance that wetlands provide critical buffer zones for the degradation of petroleum hydrocarbons released to aquatic environments, there remain a number of questions on their general use for treatment of wastes from one site to another. For example, there are still a number of knowledge gaps on how chemicals present in petroleum wastes affect microbial activities in wetland soils. Likewise, there is a need to better understand how to manage oil spills in wetland ecosystems. Physical removal of oil from wetlands may not always be advisable as the human foot traffic can cause severe and long-lasting damage. Furthermore, petroleum hydrocarbons mixtures in wetland environment can differ widely in their chemical makeup, toxicity, and metal content, leading to quite diverse and site-specific conditions. These factors, coupled with the dynamics of wetland ecology and the dependence of degradation rates on availability and type of nutrients, likely limit the ability to generalize treatment strategies from one wetland site to other locations.

Wetlands as Treatment Systems

Kyle R. Mankin
Department of Biological and Agricultural Engineering, College of Engineering, Kansas State University, Manhattan, Kansas, U.S.A.

INTRODUCTION

Wetland ecosystems generally can be defined by the presence of saturated soils and plants that grow well under these conditions. These two features promote many processes that trap, transform, and utilize a variety of the materials that flow into a wetland system with the incoming water. Because wetlands possess this capacity to remove contaminants from water, they have been utilized and even constructed for the purpose of treating polluted waters. As constructed treatment wetlands become a more common feature in municipal, rural, agricultural, and industrial settings, it is important to understand the features, processes, and design considerations that make these systems attractive natural-treatment options.

How Do Wetlands Work?

Wetlands can be used to treat wastewater because they process contaminants. However, they treat wastewater more slowly than traditional treatment plants. Oxygen, and the manipulation of oxygen levels, is a primary concern for wastewater treatment because many of the necessary biological and chemical treatment processes require oxygen. Traditional treatment plants can easily manipulate oxygen levels by pumping air into the wastewater. Oxygen enters wetlands by slower, natural processes. Increasing oxygen concentration, by increasing wastewater contact with air, plant roots, or photosynthetic algae, often can enhance the processing ability of wetlands.

When considering wastewater treatment by constructed wetlands, five contaminant groups are of primary importance: sediments, organic matter, nutrients, pathogenic microbes, and metals. Wetlands slow down water movement, allowing sediments to settle out of the water. Organic matter can be processed, or decomposed, by highly competitive microbes. Less competitive microbes called nitrifiers process nitrogen. Both microbe types require oxygen. Because the nitrifiers are less competitive, oxygen levels become very important to insure that both organic matter and nitrogen are fully processed. The other two, pathogenic microbes and metals, are more situational, related to the specific waste being treated. Wetlands treat pathogenic microbes by detaining them until they naturally die off, are eaten by other predatory organisms in the wetland, or are exposed to UV radiation near the water surface. Metals are processed by being adsorbed to other particles and settling out of the water.

The remainder of this entry further explains wetland processes and design considerations. References are provided for more in-depth information.

TREATMENT WETLAND TYPES

Constructed vs. Natural Wetlands

Wetlands constructed as treatment systems differ from natural wetlands in several important ways. Constructed wetlands usually are built with uniform depths and shapes designed to provide consistent detention times and maximize contaminant removal. In contrast, natural wetlands are irregular in depth and shape, which causes irregular flow, allows water to by-pass the shallow treatment zones by moving through the deeper channels, and leads to less effective treatment. In addition, water-quality regulations in the United States dictate that if a natural wetland is associated with an existing water body of the United States, as most are, wastewater discharges into the wetland must meet specific quality standards, similar to other water bodies. Wetlands constructed as wastewater treatment systems typically are located in uplands where wetlands did not exist before and are not subject to inflow water-quality regulations. Natural wetlands are *not* recommended for use as treatment wetlands.

Constructed wetlands increasingly are being used for wastewater treatment in a variety of applications (Table 1). Examples can be found of wetlands being used to treat municipal sewage, urban runoff, onsite residential wastewater, animal feedlot and barnyard runoff, cropland runoff, industrial wastewater, mine drainage, and landfill leachate. Each application takes advantage of a combination of physical, chemical, and biological processes characteristic of natural wetlands to reduce the concentration of contaminants in water. Such contaminants include sediments, organic materials, nutrients (particularly nitrogen and phosphorus), metals, microbial pathogens, and pesticides.

Table 1 North American wetlands as of 1994

Wastewater type	Quantity	Size (ha) Minimum	Median	Maximum
Agricultural	58	0.0004	0.1	47
Industrial	13	0.03	10	1093
Municipal	159	0.004	2	500
Stormwater	6	0.2	8	42
Other	7	3	376	1406

Free-Water vs. Submerged-Bed Wetlands

Constructed wetlands have two common types. Free-water surface (FWS) wetlands (also called surface-flow wetlands) have plants that grow in a shallow layer of water over a soil substrate (Figs. 1 and 2). The location of the plants in the system can vary: the plants can float on the water surface with their roots suspended in the water (free-floating macrophyte systems); they can be rooted in the soil with the entire leaves and stems below the water surface (submerged-macrophyte systems); they can be rooted in the soil having leaves and stems that rise above the water surface (emergent macrophyte systems); or the wetland may use a combination of planted and open-water zones. About two-thirds of existing wetlands as of 1994 were FWS.[1] In vegetated submerged-bed (VSB) wetlands (also called subsurface flow wetlands or rock-plant filters), plants are rooted in a porous media, such as sand or gravel, and water flows through the media in either horizontal or vertical direction (Figs. 3 and 4). About one-quarter of treatment wetlands were VSB systems.[1] However, these systems are currently used in thousands of smaller-scale, onsite residential applications in the United States that do not appear in this database.

TREATMENT PROCESSES

Many wastewaters entering constructed wetlands must be pretreated to avoid excessive contaminant loading, particularly of mineral and organic solids. Pretreatment technologies include septic tanks for onsite systems or anaerobic lagoons for animal waste, municipal, or mine-drainage treatment systems. In each case, the anaerobic condition in the pretreatment process reduces production of additional algae solids. Typical contaminant levels entering treatment wetlands are summarized in Table 2.

The wetland type impacts the processes used to retain or remove contaminants. In a VSB system, wastewater flows through pore spaces of the media and comes into direct contact with the roots of plants. In a FWS system, water flows across the media surface and contacts plant stems and leaves. In either system, solid particles, including sediments (clay and silt particles and colloids) and organic matter (manure particles, organic residues, and algae or other phytoplankton), settle out of the water column or are trapped or filtered as water passes through a wetland. Contaminants that are adsorbed to sediments (e.g., P, NH_4, fecal bacteria) or absorbed within organic solids (e.g., nutrients) are also removed. However, these constituents can be re-suspended or desorbed back into the wetland water. This natural cycling of materials is an important function of wetlands, although it makes system design and interpretation of treatment complex.

Once entrapped, organic materials and associated contaminants are decomposed in wetlands by microbial and chemical transformations. In the degradation process, microbes use oxygen. The amount of oxygen used is related to the amount of organic material in the water. The controlled measurement of biochemical oxygen demand (BOD) is a common way to illustrate the amount of organic matter in water. When wastewater lacks oxygen, or is anaerobic, it requires the addition of oxygen to degrade organic matter. Oxygen is also required for transformation of ammonium to nitrite and nitrate (nitrification), whereas anaerobic conditions are required for transformation of nitrate to nitrogen gas (denitrification). Aerobic wetland conditions often remove metals by aerobic oxidation of iron; subsequently iron hydroxides and other metals precipitate in the wetland.[5] Although some oxygen diffuses into a wetland from the air, a common assumption is that oxygen also is transported through wetland plants and made available to microbes in close

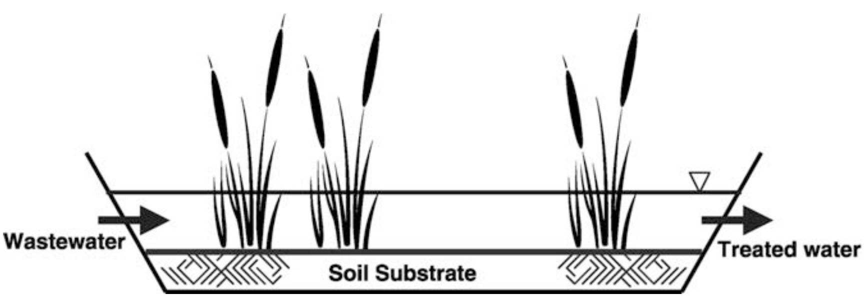

Fig. 1 FWS wetland with emergent macrophytes.

Wastewater–Yellow

proximity to leaky roots.[6] This mechanism may be less important than once thought, though.[2] Treatment wetlands are thought to function effectively because they combine anaerobic zones in the water column with aerobic zones near the water interfaces with air and roots. However, because the microbes that break down organic carbon can out compete nitrifiers for oxygen, nitrogen removal in higher strength wastewaters is often low.

DESIGN CONSIDERATIONS

Design and resulting effectiveness of constructed wetlands (Table 3) depend upon many factors: climate (precipitation, temperature, growing season, evapotranspiration), wastewater characteristics (constituents, loading, flow rate, and volume), topography, and wildlife activity. Wetland designs must specify total area; the number, depth, and size of wetland cells; hydraulic retention times; vegetation types and coverage; inlet and outlet configuration and location; and internal flow patterns.[2] Details for design can be found in numerous references[2,7–11] and some elements are discussed here.

VSB Wetlands

Properly designed VSB systems can achieve high removal rates. Treatment in a VSB wetland is governed by system residence time and wastewater contact with media and plant-root surfaces. Because of this, depth is a critical dimension and is often chosen according to the rooting depth of the selected plant (e.g., cattails: 30 cm; reeds: 40 cm; bulrush: 60 cm). Once depth is chosen, cross-sectional area (and thus wetland width) is selected to assure adequate flow rates. Then, volume (and thus wetland length) is determined from the retention time needed to treat the wastewater to the desired quality. Proper design of inlet and outlet control structures helps maintain uniform flow patterns and depth, avoids problems with clogging and freezing, and minimizes system operation and maintenance (O and M) problems. High loading from influent solids and clogging can lead to surface flows and poor treatment. VSB systems must receive influents that are pretreated

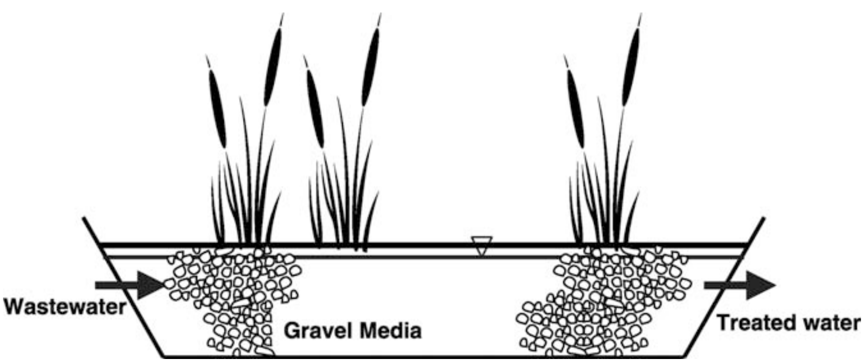

Fig. 3 VSB wetland with emergent macrophytes.

Wastewater–Yellow

to remove solids (e.g., septic tank and effluent filter or anaerobic lagoon).

FWS Wetlands

Properly designed FWS systems also can achieve high removal rates. Design typically follows one of two methods. The areal loading approach allows a designer to select the wetland surface area according to the influent load and the desired effluent quality.[13] Another approach allows a designer to select the wetland area by knowing the biological reaction rate, wastewater concentration, and flow rate along with selected water depth and target outflow water quality.[7,8] Again, depth is a critical dimension and is governed by plant tolerance to standing water and treatment objectives.

FWS vs. VSB Systems

Selection of the most appropriate wetland system depends on wastewater characteristics, treatment requirements, and site constraints. VSB systems generally require less land area, are less susceptible to freezing and mosquito problems, and have no exposed wastewater at the surface (avoiding contact-related health problems). FWS systems are less expensive to construct (without the cost of media), have greater potential for wildlife habitat, and are easier to maintain if solids accumulate.

OPERATION AND MAINTENANCE

O and M of treatment wetlands are relatively simple. The goal of an O and M plan is to assure that the wetland system continues to operate as planned, designed, and constructed. Several sources provide specific O and M guidance,[14] and most design manuals also contain such guidelines. Operation should be consistent with treatment objectives while maintaining structural integrity of the system, uniform flow conditions, and healthy vegetation as well as minimizing odors, nuisance pests and insects. Most maintenance plans require such items as checking water levels, checking for evidence of leaks or wildlife damage, and maintaining plant health on a weekly or monthly basis.

CONCLUSION

Constructed wetlands are complex natural-treatment systems that are well suited for many applications. They are low in cost and maintenance, provide significant reductions of many contaminants, and offer an aesthetic appearance. More work is needed to

Table 2 Wetland influent concentrations

Wastewater type	BOD_5 (mg/L)	TSS (mg/L)	TN (mg/L)	NH_4-N (mg/L)	NO_3-N (mg/L)	TP (mg/L)	FC (per 100 mL)

Wetlands: Ecosystems

Sherri L. DeFauw
University of Arkansas, Fayetteville, Arkansas, U.S.A.

INTRODUCTION

Wetlands perform key roles in the global hydrologic cycle. These transitional ecosystems vary considerably in their capacity to store and subsequently redistribute water to adjacent surface water systems, groundwater, the atmosphere, or some combination of these. Saturation in the root zone or water standing at or above the soil surface is key to defining a wetland. When oxygen levels in waterlogged soils decline below 1%, anaerobic (or reducing) conditions prevail. Most, but not all, wetland soils exhibit redoximorphic features formed by the reduction, translocation, and oxidation of iron (Fe) and manganese (Mn) compounds; the three basic kinds of redoximorphic features include redox concentrations, redox depletions, and reduced matrix.[1] Microbial transformations in flooded soils also impact other biogeochemical cycles (C, N, P, S) at various spatial and temporal scales. Several of the most rapidly disappearing wetland ecosystems in North America are profiled here, in terms of properties and processes.

HYDROLOGIC CONSIDERATIONS

Wetland water volume and source of water are heavily influenced by landscape position, climate, soil properties, and geology. Wetlands may be surface flow dominated, precipitation dominated, or groundwater discharge dominated systems (Fig. 1). Surface flow dominated wetlands include riparian swamps and fringe marshes. In unregulated settings (i.e., no dams or diversions) these ecosystems are subject to large hydrologic fluxes, and vary the most in terms of soil development, sediment loads, and nutrient exchanges. Precipitation-dominated wetlands (e.g., prairie potholes and bogs) reside in landscape depressions and typically have a relatively impermeable complex of clay and/or peat layers that retard infiltration (or recharge) and also impede groundwater discharge (or inflow). Groundwater dominated wetlands (e.g., fens and seeps) may form in riverine settings, at slope breaks, or in areas where abrupt to rather subtle changes in substrate porosity occur. Groundwater contributions to wetlands are complex, dynamic, and rather poorly understood.[2]

Frequency and duration of flooding, and the long-term amplitude of water level fluctuations in a landscape are the three most important hydrologic parameters that "shape" the aerial extent of a wetland complex as well as determine the relative abundance of four intergrading wetland settings (i.e., swamps, wet meadows, marshes, and aquatic ecosystems[3]. Wetland hydrodynamics control soil redox conditions. The hydroperiod-redox linkage, in turn, controls plant macronutrient concentrations (N, P, K, Ca, Mg, S), micronutrient availability (B, Cu, Fe, Mn, Mo, Zn, Cl, Co), pH, organic matter accumulation, decomposition, and influences plant zonation. Oftentimes, the zonation of plants (as determined by competition and/or physiological tolerances) provides key insights into the hydrodynamics and biogeochemistry of an area.[3]

ECOSYSTEM PROFILES

Four of the most rapidly disappearing wetland ecosystems in North America are summarized here in terms of key properties and processes. These profiles include comments on geographical extent, geomorphology, soils, hydrodynamics, biogeochemistry, vegetation structure, and/or indicator species, as well as recent estimates of ecosystem losses and ecological significance.

Riparian Swamps

Bottomland hardwood forests once dominated the river floodplains of the eastern, southern, and central United States. In the Mississippi Alluvial Plain, an estimated 8.6 million hectare area of bottomland hardwoods has been reduced to 2 million forested hectares remaining.[4] Although their true extents are not well-documented (due to difficulties in determining upland edges), these hydrologically open, linear landscape features have been logged, drained, and converted to other uses (predominantly agriculture) at alarming rates. Between 1940 and 1980, bottomland hardwood forests were cleared at a rate of 67,000 ha yr^{-1}.[5]

Riparian wetlands are unique, vegetative zonal expressions of both short- and long-term fluvial processes. A widely used classification scheme relates flooding conditions (frequency and flood duration

Wastewater–Yellow

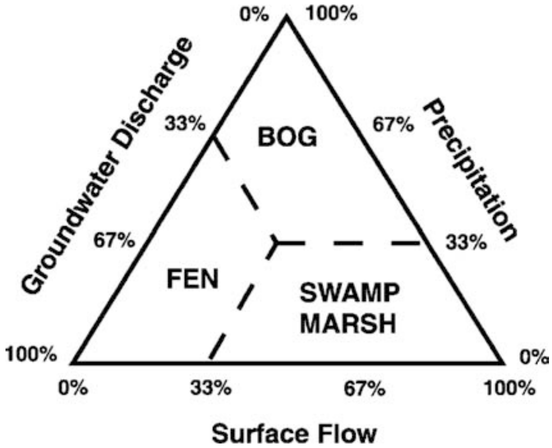

Fig. 1 The relative contributions of groundwater discharge, precipitation, and surface flow determine main wetland types. Swamps and marshes are distinguished by the frequency and duration of surface flows. *Source*: Modified from Ref.[3].

during the growing season) with zonal associations of hardwood species.[6] Zone II (intermittently exposed "swamp"—bald cypress and water tupelo usually dominate the canopy) and Zone III (semipermanently flooded "lower hardwood wetlands"—overcup oak and water hickory are common) are accepted as wetlands by most, however, Zones IV (seasonally flooded "medium hardwood wetlands" that include laurel oak, green ash, and sweetgum) and V (temporarily flooded "higher hardwood wetlands"—typically an oak–hickory association with loblolly pine) have been controversial when dealing with wetland management issues.[7] Typically the complexity of floodplain microtopography abates smooth transitions from one zone to the next, with unaltered floodplain levees oftentimes exhibiting the highest plant diversity.[8]

Riparian wetlands process large influxes of energy and materials from upstream watersheds and lateral runoff from agroecosystems. As a result of these inputs, combined with decomposition of resident biomass, the organic matter content of these alluvial soils usually ranges from 2% to 5%.[8] Clay-rich bottomland tracts have higher concentrations of N and P as well as higher base saturations (i.e., Ca, Mg, K, Na) compared to upland areas. Watersheds dominated by riparian ecosystems export large amounts of organic C in dissolved and particulate forms.[9]

Prairie Potholes

Prairie potholes comprise a regional wetland mosaic that includes parts of the glaciated terrains of the Dakotas, Iowa, Minnesota, Montana, and Canada. Originally, this region encompassed 8 million hectares of wetland prior to drainage for agriculture; an estimated 4 million hectares remained at the close of the 1980s.[10] These landscape depressions are the most important production habitat in North America for most waterfowl.[11]

Most prairie potholes are seasonally flooded wetlands dependent on snowmelt, rainfall, and groundwater. Four main hydrological groupings are recognized: ephemeral, intermittent, semi-permanent, and permanent.[11] Water level fluctuations are as high as 2–3 m in some settings. Measures of soil hydraulic conductivity demonstrate that groundwater flow is relatively slow (0.025–2.5 m yr^{-1}); therefore, the potholes are hydrologically isolated from each other in the short-term.[12]

Long-term ecological studies at the Cottonwood Lake Study Area, NPWRC-USGS[11] have revealed the intricacies of several prairie pothole phases. During periods of drought, marsh soils, sediments, and seed banks are exposed (i.e., dry marsh phase). Seed banks in natural sites have 3000–7000 seeds/m^2. A mixture of annuals (usually the dominant group) and emergent macrophyte species germinate on the exposed mudflats and a wet meadow develops. As water levels increase, the annuals decline and emergent macrophytes rapidly recolonize (i.e., regenerating marsh). If the flooding is consistently shallow, emergent macrophytes will eventually dominate the entire pothole. Sustained deep water flooding results in extensive declines in emergent macrophytes (i.e., degenerating marsh), and intensive grazing by muskrats may culminate in a lake marsh phase as submersed macrophytes become established. When water levels recede, emergent macrophytes re-establish. The rich plant communities that develop in these dynamic marshland complexes are also controlled by two additional environmental gradients, namely, salinity and anthropogenic disturbances (involving conversion to agriculture and extensive irrigation well pumping).[11]

Northern Peatlands

Deep peat deposits, in the United States, occur primarily in Alaska, Michigan, Minnesota, and Wisconsin, and are scattered throughout the glaciated northeast and northwest, as well as mountaintops of the Appalachians. The most extensive peatland system, in North America, is the Hudson Bay lowlands of Canada that occupies an estimated 32 million hectares.[13] The Alaskan and Canadian peatlands are relatively undisturbed, and the least threatened by developmental pressures. Elsewhere, peatlands have either been converted for agricultural use (including forestry) or mined for fuel and horticultural materials.

Bogs and fens are the two major types of peatlands that occupy old lake basins or cloak the landscape.

The most influential, interdependent physical factors shaping these ecosystems include: 1) water level stability; 2) fertility; 3) frequency of fire; and 4) grazing intensity.[3] Northern bogs are dominated by oligotrophic *Sphagnum* moss species, and may be open, shrubby, or forested tracts. These predominantly rainfed (ombrogenous) systems have low water flow (with a water table typically 40–60 cm below the peat surface), are extremely low in nutrients (especially poor in basic cations), and accumulate acidic peats (pH 4.0–4.5).[14] Fens are affected by mineral-bearing soil waters (groundwater and/or surface water flows), and possess water levels at or near the peat surface. Fens may be subdivided into three hydrologic types: soligenous (heavily influenced by flowing surface water); topogenous (largely influenced by stagnant groundwater); or limnogenous (adjacent to lakes and ponds).[14] These minerogenous ecosystems range from acidic (pH 4.5) to basic (pH 8.0); vegetation varies from open, sedge-dominated settings to shrubby, birch-willow dominated associations to forested, black spruce-tamarack tracts. Nutrient availability gradients do not necessarily coincide with the ombrogenous–minerogenous gradient; recent investigations indicate higher P availability in more ombrogenous peatlands, and greater N availability in more minerogenous peatlands.[15]

Northern peatlands represent an important, long-term carbon sink, with an estimated 455 Pg (1 Petagram $= 10^{15}$ g) stored worldwide.[16] An estimated 220 Pg of C is currently stored in North American peatlands, compared to about 20 Pg in storage during the last glacial maximum.[17] High latitude peatlands also release about 60% of the methane generated by natural wetlands.[18] In addition, sponge-like living Sphagnum carpets facilitate permanently wet conditions, and the high cation exchange capacity of cells retains nutrients and serves to acidify the local environment.[19]

Pocosins

The Pocosins region of the Atlantic coastal plain extends from Virginia to the Georgia–Florida border.[20] These non-alluvial, evergreen shrub wetlands are especially prevalent in North Carolina; in fact, pocosins once covered close to 1 million hectare in this state.[21] Derived from an Algonquin Indian word for ''swamp-on-a-hill,'' pocosins are located on broad, flat plateaus and sustained by waterlogged, acidic, nutrient-poor sandy, or peaty soils usually far removed from large streams. Wetland losses are high, with 300,000 ha drained for agriculture and forestry uses between 1962 and 1979.[22]

Pocosins are characterized by a dense, ericaceous shrub layer; an open canopy of pond pine may be present or absent.[21] A typical low pocosin ecosystem [less than 1.5 m (5 ft) tall] includes swamp cyrilla (or titi), fetterbush, bayberry, inkberry, sweetbay, laurel-leaf greenbrier, and sparsely distributed, stunted pond pine.[22] Pocosin soils may be either organic (with a deep peat layer—e.g., Typic Medisaprist) or mineral (usually including a water restrictive spodic horizon—e.g., Typic Endoaquod). As peat depth decreases, the stature of the vegetation increases. High pocosin [with shrubby vegetation 1.5–3.0 m (5–10 ft) tall and canopy trees approximately 5 m (16 ft) in height] usually occurs on peat deposits of 1.5 m (5 ft) or less in thickness or on wet sands.[20] The major natural disturbance to these wetlands is periodic burning (with a fire frequency of about 15–50 yr).

Pocosin surface and subsurface waters are similar to northern ombrogenous bogs, but are more acidic with higher concentrations of sodium, sulfate, and chloride ions.[23] Carbon : Phosphorus (C : P) ratios increase sharply during the growing season; phosphorus availability limits plant growth and probably plays a crucial role in controlling nutrient export. Undisturbed pocosins export organic N and inorganic phosphate in soil water.[23]

CONCLUSIONS

Despite existing preservation policies, U.S. wetland conversions are anticipated to continue at a rate of 290,000–450,000 acres (117,408–182,186 ha) annually.[24] It is widely known that wetlands are the product of many environmental factors acting simultaneously; perturbations in one realm (e.g., hydrology) not only impact local wetland properties and processes, but also have consequences in linked ecosystems as well. Wetlands are major reducing systems of the biosphere, transforming nutrients and metals, and regulating key exchanges between terrestrial and aquatic environments.

Wind Erosion and Water Resources

R. Scott Van Pelt
Wind Erosion and Water Conservation Research Unit, Cropping Systems Research Laboratory, Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Big Spring, Texas, U.S.A.

INTRODUCTION

Wind erosion is the result of wind impacting a dry, bare and loose soil surface. Approximately 500 million ha worldwide are susceptible to wind erosion. Plumes of fugitive dust are the most visible evidence of wind erosion and they may be lifted in the turbulent wind to heights in excess of a kilometer and transported hundreds or thousands of kilometers from the source before returning to the surface. The fine particles that become entrained in the wind and transported great distances contain higher concentrations of organic C, basic cations such as Na, Ca, and Mg, plant nutrients such as N, P, K, and Fe, trace metals, and soil contaminants than the soils from which they originated. Larger particles are often deposited onto surfaces including bodies of water by gravity close to the source area, while smaller particles may remain in the atmosphere for long periods of time and be transported into humid regions where they are often scavenged out of atmospheric suspension by cloud formation and rainfall.

Fine atmospheric particles such as soil dust form condensation nuclei in the presence of near-saturated air. In addition to their role as condensation nuclei in the formation of rain droplets, other particles are intercepted and incorporated by the raindrops falling through the air. The soluble minerals in and adsorbed to the dust particles are dissolved and influence the chemical properties of the precipitation. In addition to the dust that is scavenged from the atmosphere by rainfall, the rain will tend to wash the dust that settled by gravity or by impact from vegetation and other surfaces, further increasing the concentration of dust and dust-borne solutes in the water exiting a watershed. In many nutrient deficient ecosystems, deposited soil dust is a crucial input to the nutrient cycle. Soil dust reacts with and catalyzes reactions with soil gasses and pollutants, thus reducing the deleterious effects of acid rain.

WIND EROSION AND DEPOSITION PROCESSES

As wind blows over a surface, ephemeral gusts move particles in the sand to fine sand size range, which either creep along the soil surface or become entrained in the wind. Most sand-sized particles do not rise more than 30 cm before returning to the surface, accelerated by the wind, with a significant horizontal component of motion. These saltating grains strike the surface with considerable force, releasing more saltating particles and abrading finer soil particles from soil aggregates and crusts resulting in plumes of dust. A thorough treatise on wind erosion processes is presented in Ref.[1].

Finer particles have a higher surface area to volume ratio and are easily entrained into the turbulent eddies to heights often exceeding 2–3 km. The median diameter of entrained particles decreases as altitude increases.[2] As the particles are transported downwind, the higher terminal velocity of the larger particles and shallower transport depth cause them to settle from the atmosphere first and thus closer to the source. Dust may also be deposited in the relative calm air to the lee of surfaces projecting into the wind, or they may impact and deposit on the surfaces. These processes are termed "dry" or "impact deposition," respectively. Dry-deposited particles may be reentrained unless they are deposited on a free water surface. Free water surfaces are regarded as the most effective dust collectors.[3]

Particles $<20\,\mu m$ in diameter have much lower terminal velocities and may remain entrained and transported in the atmosphere for days or weeks. These fine particles tend to be hygroscopic in nature and absorb available water vapor from the surrounding air mass. Dust particles are very efficient condensation nuclei and are the reason for more numerous and smaller cloud droplets over continental areas than over the oceans. Cloud formation and rainfall are very efficient scavengers of fine particles and it is widely held that most of the entrained dust returns to the ground in precipitation. This process is termed "wet deposition." The dust spots on a freshly washed automobile following a rain are evidence of wet deposition. Dust may noticeably color the precipitation close to source regions. In most regions of the world, dust returns to the surface by a combination of dry, impact, and wet deposition termed "bulk deposition." Without sophisticated wet–dry samplers and canopy throughfall collectors, the individual deposition components cannot be accurately quantified.

SOURCES AND MAGNITUDE OF SOIL DUST

The principal source regions of soil dust are arid and semiarid regions of the northern hemisphere (Fig. 1).[4] Large expanses of bare, dry, and often loose soil susceptible to wind erosion exist in these regions. It is estimated that more than a half-billion ha worldwide contribute to the atmospheric dust load. The exact amount of dust that is entrained from these regions remains uncertain owing to the variability among source regions, within individual source regions, among years, and the variability of estimation methods. Estimates of annual dust entrainment vary from 250 to more than 5000 Tg/yr. Deposition rate estimates vary from 10 to 200 t/km/yr for land areas and total deposition flux to the oceans has been estimated at 532–851 Tg/yr.[5] Dust transported from North Africa is deposited in Europe, the Atlantic ocean, North America, South America, Asia, and other locations in Africa. Dust transported from the great source regions of Asia is deposited in the North and Tropical Pacific Basins, North America, Greenland, and Southeast Asia. Evidence from aeolian loess deposits worldwide indicates that the magnitude of dust transport was much greater in the geological past.

CHEMICAL CONSTITUENTS OF SOIL DUST

The chemical characteristics of soil dust are determined by the surface from which they were entrained.[6] As the primary source regions for soil dust are arid and semiarid areas, it is not surprising that the dust from these regions contains an abundance of basic cations such as Ca^{2+}, Mg^{2+}, and Na^{+}, carbonate and bicarbonate minerals, and soluble salts (Table 1). Soil dust also contains enriched concentrations of plant nutrients such as N, P, K, Fe, and trace metals important to biogeochemical cycles of ecosystems.[7] Carbon, in many forms including soluble organic compounds, and pesticides and daughter products, is also transported on soil dust.[8] Simple biological organisms such as algae, bacteria, and fungi[9] including pathogens have been documented on soil dust. These chemical and biological ''hitchhikers'' contribute nutrients to open ocean areas and watersheds that may be deficient

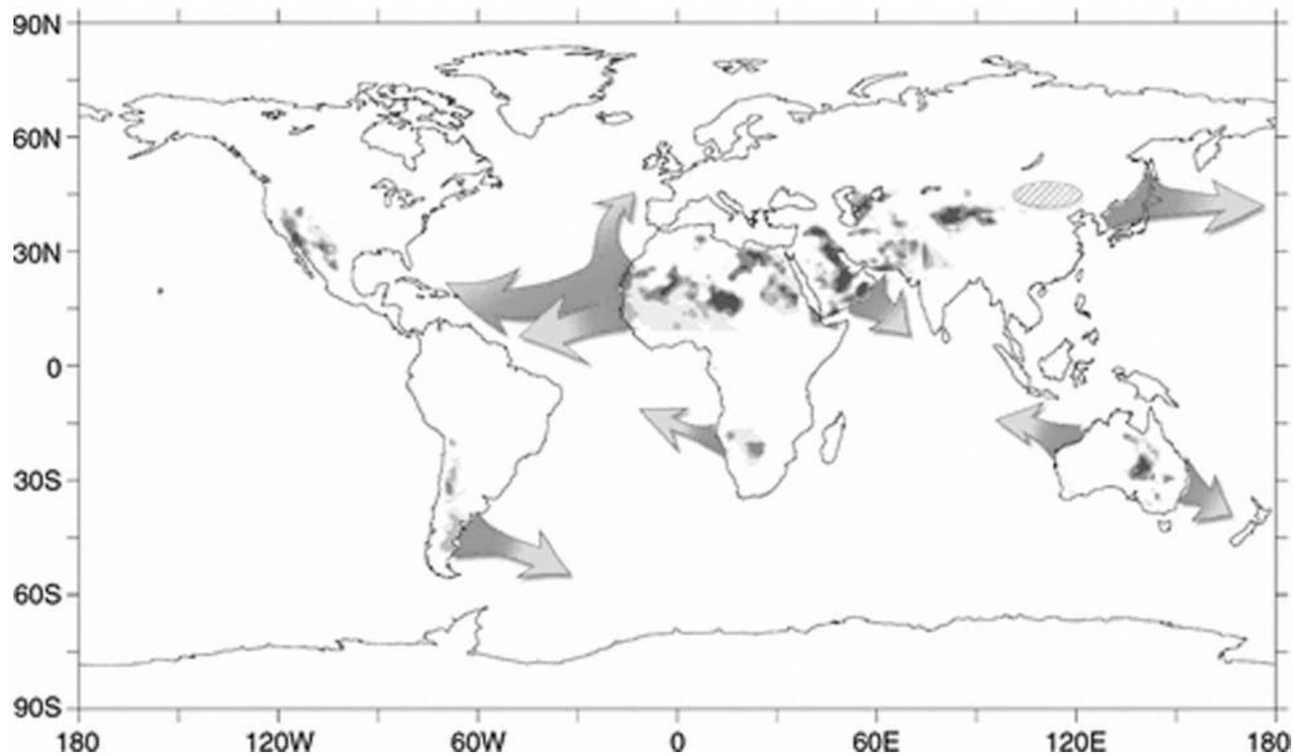

Fig. 1 The global distribution of major dust sources and dust transport paths based on the total ozone mapping spectrometer (TOMS) aerosol product. The darker tones show those regions where substantial concentrations of dust are lifted into the air more than 50% of the time during the dusty seasons of the year. The arrows show the main transport paths over the oceans. The arrow size is neither indicative of the magnitude of the transport nor the distance that dust is carried. *Source*: From Ref.[4].

Table 1 Range of concentrations of chemical and mineralogical constituents of soil dust and range of reported rainfall pH values in documented deposition areas for events with and without atmospheric dust present

Parameter reported	Units	Minimum	Maximum	Number of reports examined[a]
Ca & Mg carbonates	%	0	74	19
Na	%	0	4	10
K	%	0.01	3	13
Fe	%	0.02	14	20
P	mg/kg	90	1074	4
N	mg/kg	5	4700	5
Organic C	%	0	80	14
Rain without dust	pH	3.5	6.7	24
Rain with dust	pH	4.5	8.4	25

[a]Refers to the number of articles in refereed journals reporting the parameters in the units used in the table.

in one or more of these nutrients and to the cycling of these nutrients. However, toxic contaminants may impact organisms involved in biogeochemical cycles. Highly soluble materials that are deposited in humid regions may also be leached to groundwater. Although dust inputs are often small in comparison with soil and organic material eroded by water, they may have a significant impact on the quality of the water leaving the watershed and on downstream aquatic ecosystems.

Soil dust effects on water quality begin in cloud formation processes. As water condenses around the dust particle, soluble salts and organic compounds dissolve. The film of water around the particles in clouds also facilitates chemical reactions between the minerals present and atmospheric gasses and non-soil particulates as well as photolytic valence state transformations of metals such as Fe, making them more soluble. The pH of rainfall in pristine areas is about 5.5 owing to dissolved CO_2 and other gasses. In industrial areas with high fossil fuel use, oxides of S and N are present in larger concentrations and are also dissolved in the rain, resulting in rainfall with much higher acidity. This acid rain has been credited with damage to forest and aquatic ecosystems. In areas frequented by high loads of soil dust, soluble basic minerals, primarily carbonates, partially or totally neutralize the acidity.[10] The pH of rainfall at one location may vary from highly acid to neutral or even basic depending on the atmospheric dust concentration.

CONCLUSIONS

A very large quantity of soil dust is entrained into the atmosphere, transported great distances, and deposited upon the landscape, including water bodies, annually. Of the dust deposited on vegetation and land surfaces, much is washed into surface waters by runoff from rain events. The input of basic cations, plant nutrients, soluble salts, soluble organics, and soil contaminants such as pesticides and pesticide daughter products undoubtedly impacts the quality of surface waters and may have an effect on the quality of groundwater as well. However, dust may positively impact water quality in areas prone to acid precipitation. There is little information available concerning dust's direct impacts on water resources, providing future research opportunities.

INTRODUCTION

The Yellow River is the second longest river in China. The terrain of the Yellow River basin is high in the west, low in the east, thus showing great disparity. The climate along the basin belongs to the arid and the semiarid and semihumid type from west to east, respectively. The Yellow River basin is an important production area in agriculture and is rich in mineral and energy resources. The main crops are wheat, cotton, oil-bearing plants, tobacco, etc. Yellow River provides the major water source for northwest and north China. Compared with other rivers in China, it is characterized by shortage of water, high sand content, and serious loss of water and soil. In the lower reaches of the Yellow River, a large amount of sediment is left behind to raise the riverbed. Thus, the riverbed is higher than the ground outside the river and is called "suspended river." With water consumption increasing rapidly, zero flow occurred in the lower reaches in recent years. Floods and droughts are two major disasters in the Yellow River basin, which caused great losses in people's lives and property.

Since 1949, China has made unremitting efforts to harness the Yellow River. A number of water control projects were undertaken, hydropower stations had been built, and the dykes in the lower reaches had been strengthened and heightened. The eroded land on the Loess Plateau had been harnessed and water and soil loss was restricted. Soil and water conservation improved both agricultural production conditions and the ecological environment. Since 1949, the Yellow River has never been breached, thus ensuring the safety of its people and property and promoting the development of economy and society.

DISCUSSION

The Yellow River originates from the Yueguzonglie Basin, which has an elevation of 4500 m and is located at the northern slope of the Bayankera Mountain in the Qinghai–Tibet Plateau. From west to east, it flows through nine provinces/autonomous regions: Qinghai, Sichuan, Gansu, Ningxia, Inner Mongolia, Shanxi, Shaanxi, Henan, and Shandong, and empties into the Bohai Sea in Kenli county, Shandong Province. The trunk is 5464 km in length and the basin area is 795,000 km^2. Within the river basin, the population is 110.08 million, accounting for 8.7% of the total population in China; the cultivated land is 13.1 million ha.[1] The Yellow River basin is the cradle of Chinese nationality and the birthplace of ancient Chinese civilization. As early as 1 million years ago, the "Lantian Man" had been living in the Yellow River Basin. In this very long historical period, the basin was the center of politics, economy, and culture in China.

The terrain of the Yellow River basin is high in the west and low in the east, thus showing great disparity. The west section of the basin belongs to the Qinghai–Tibet Plateau with an elevation of 3000–5000 m. The middle section is mostly located in the Loess Plateau and reaches the east side of Taihang Mountain, with an elevation of 1000–2000 m. The east section starts from east of Taihang Mountain and ends at the Bohai Sea, lying in the Huanghuaihai Plain, with an elevation of lower than 100 m.[1] Based on the geographical position and the feature of the river, the trunk stream of the Yellow River can be divided into upper, middle, and lower reaches. The upper reaches are from the source of the river to Hekouzhen (Tuoketuo county) in Inner Mongolia, with length of 3472 km and area of 428,000 km^2. The middle reaches are from Hekouzhen, then extend to Taohuayu (Zhengzhou) of Henan province, comprising 1206 km in length and 344,000 km^2 in area. Starting from Taohuayu, the lower reaches run through nearly 800 km, occupy 23,000 km^2 of area, and end at the mouth of the river.[1] Because of the height difference, the climate in the Yellow River basin is very distinct, ranging from arid climate in the west through semiarid to semihumid climate in the east. Average annual temperature is −4°C at the source, 1–8°C in the upper reaches, 8–12°C in the middle reaches, and 12–14°C in the lower reaches. The average annual precipitation of the basin is 452 mm. The maximum is in the southeast part of the basin, reaching 800–1000 mm; whereas the minimum annual precipitation is less than 200 mm in the northwest part of the basin, including Ningxia and Inner Mongolia, which features the inland climate.[1] The Yellow River basin is rich in mineral and energy resources that are of great importance in China. Out of the 45 proved major mineral resources in China, 37 are found in the Yellow River basin.[1] The water energy in the upper-middle reaches of Yellow River, the coal in the middle reaches, and the oil and natural gas in the middle-lower reaches are all quite rich in deposits. Thus the Yellow River basin is called the "energy resources basin," playing an important role in China.[1]

The Yellow River provides the major water resource for northwest and north China, but the amount is comparatively poor. The average annual runoff in the basin is 58 billion m^3, making up only 2% of that in China, whereas the area of the Yellow River basin accounts for 8.3% of the land area of the country.[1] The distributions of runoff in different areas are different. Annual runoff in the upper, middle, and lower reaches contributes 55.6%, 40.8%, and 4.6% of the total annual runoff, respectively. It also varies with seasons. More than 60% of the annual runoff happens during the period from July to October, while less than 40% occurs from November to June.[1] The Yellow River basin is an important production area in agriculture. The main crops are wheat, cotton, oil-bearing plants, tobacco, etc. The irrigation area along the Yellow River basin is about 7.3 million ha,[2] most of which is in the Ningxia–Inner Mongolia Plain at the upper reaches, Fen-Wei basin at the middle reaches, and the irrigation area drawing water from the Yellow River at the lower reaches. Agricultural irrigation consumes 28.4 billion m^3 of water from the Yellow River annually, accounting for 92% of the overall annual water consumption of the river.[2] With high-speed development of the economy and continued population growth, water consumption has increased rapidly and the competition between water supply and demand has become more acute. As a result, zero flow in the lower reaches has resulted in recent years. From 1972 through 1998, zero flow occurred in 21years with accumulated duration of 1051 days. The worst was in 1997, when Lijin, near the river mouth, had zero flow for 226 days; the zero-flow section extended upstream even to Kaifeng of Henan Province.[2]

The Yellow River flows through the Loess Plateau, where the surface is characterized by loose soil and sparse vegetation, and the climate is dominated by dry weather and heavy storms concentrated mostly in the summer. Therefore, it is the largest area affected by water and soil loss and the strongest intensity in erosion in China. Based on the data collected by remote sensor in 1990, the area experiencing water loss and soil erosion is up to 454,000 km^2, which makes up 70.9% of the Loess Plateau's area. The area of water erosion with the annual erosion mean exceeding 8000 Mg/km^2 is 85,000 km^2, accounting for 64% of the congener area in China. The severe water degradation area with annual erosion mean exceeding 15,000 Mg/km^2 is 36,700 km^2, about 89% of the congener area.[1] Average annual amount of sediment and sand washed into the river is about 1.6 billion Mg with sand content of 35 kg/m^3. The maximum sand content is 933 kg /m^3, which was measured at Longmen on July 18, 1966.[3] In the lower reaches of the Yellow River, a large amount of sediment is left behind to raise the riverbed. Nearly 9.2 billion Mg of sediment were deposited in the lower reaches of the Yellow River from 1950 through 1998. Thus, the riverbed is 4–6 m higher than the ground outside the river on an average. At some places, this number could even reach 10 m or more.[2] For this reason, the lower reaches of the Yellow River are called the "suspended river." Because of rainstorms occurring in the middle reaches and the channel in the lower reaches being wider in the upper part and narrower in the lower part, the lower reach area frequently suffers from heavy floods. Records indicated that from 602 BC to 1949 AD, the Yellow River was breached 1590 times and changed its route 26 times, i.e., on the average, "breach twice every three years and changing its route every century."[4] Heavy floods affected a large area from Tianjin City in the north to Huaihe River in the south, crossing 250,000 km^2. On the other hand, drought is another disaster that occurs frequently in the Yellow River basin. In 582 years from 1368 to 1949, severe drought occurred in 107 years, once every 5.4 years.[5] Records show that an extraordinarily serious drought lasted 4 years, from 1875 to 1878, through the whole basin of the Yellow River.

Harnessing of the Yellow River has always been a major issue concerning China's prosperity and the people's peaceful life. Since 1949, China has made unremitting efforts to harness the Yellow River and, therefore, ensured the safety of its people and property, promoted the development of economy and society, and improved the ecological environment. On the trunk of the Yellow River, 15 key water control projects and hydropower stations have been built or are being built, providing a total water capacity of 56.6 billion m^3, a total installed capacity of 11.13 million kW, and an average annual power supply of 40.1 billion kWh.[2] By the end of 2000, 1400 km of dykes along the lower reaches had been strengthened and heightened four times. Large-scale channel improvement had been performed. Reservoirs exceeding 10,000 in number and in different sizes have been built, with a total storage capacity of 72 billion m^3. Among them, 22 of the largest reservoirs are able to hold 61.7 billion m^3 of water.[2] Other projects for irrigation and water supply had also been accomplished and the groundwater had begun to be developed. As a result, the irrigation area has increased from 0.8 million ha in 1950 to 7.3 million ha now, including 2.4 million ha that are located outside of the basin.[2] Until 2000, the area of 180,000 km^2 of eroded land on the Loess Plateau, which is one-third of the land with soil erosion, had been harnessed. To some extent, water and soil loss and desertification have been restricted. The amount of sediment and sand being washed into the Yellow River each year had decreased by about 300 million Mg.[2] Soil and water conservation improved the agricultural production condition and ecological environment. By taking these measures, the average annual grain yield has increased by more than 5 billion kg, which can provide enough food and clothing for more than 10 million people.[2] Since 1949, the Yellow River has never been breached, even when heavy flood with flow of 22,300 m^3/sec occurred in July of 1958.[3]

CONCLUSION

Compared with other rivers in China, the Yellow River is characterized by shortage of water, high content of sand, and serious loss of water and soil. Average annual runoff is only 58 billion m^3, taking up only 2% of that in China, and annual amount of sediment and sand washed into the river is about 1.6 billion Mg with sand content of 35 kg/m^3. The riverbed in lower reaches is 4–6 m higher than the ground outside the river on average. Floods and droughts are two major disasters in the Yellow River basin. Breach occurred frequently in its history. The Chinese government has made great efforts to harness the river. A number of water control projects have been undertaken, hydropower stations have been built, and dykes in the lower reaches had been strengthened and heightened. To a certain extent, the eroded land on the Loess Plateau had been harnessed and water and soil loss was restricted. The implementation of the great-development-of-the-west strategy of China will further prompt the harnessing and exploitation of the Yellow River along with the development of economy and society.
