CONCLUSION

In contrast to the immediate solution provided by traditional containment technologies, living vegetative caps may take 4 to 5 years to become fully functional. However, in suitable circumstances living systems can offer better long-term solutions, which improve with time. This may provide a remediation solution rather than a solution that conceals the problem for others to confront later. Trees have aesthetic and ecological advantage. They enhance the environment and enjoy wide public acceptance. Hydrologic management of contaminated sites using vegetation will not always be a suitable solution; however, increasing public awareness and a demand to "do something" will ensure a steady increase in the use of plants, either alone or in conjunction with more traditional containment solutions.

Hydrologic Process Modeling

Matt C. Smith
Daniel L. Thomas
Department of Biological and Agricultural Engineering, Coastal Plain Experiment Station, University of Georgia, Tifton, Georgia, U.S.A.

INTRODUCTION

Hydrologic process modeling has evolved in two basic forms: physical and numerical. Physical models of hydrologic processes provide a ''scaled'' representation of a particular watershed, field, ground water flow path, and atmospheric condition. These type models are typically used for river hydraulics and hydraulic structure design verification. For example, the U.S. Army Corp. of Engineers maintained a scale model of the Mississippi River on Mud Island near Memphis, Tennessee (U.S.A). The physical model provided a reasonable representation of the impacts of physical stream changes and other conditions (precipitation, snowmelt, flooding, etc.) on the hydrologic response of the river. The implementation of diversion structures and management alternatives were originally based on the physical model.

The advent of fast computers and numerical approaches to represent processes created greater flexibility to test different and new hydrologic conditions. The following discussion emphasizes computer-based process modeling. Many of the examples will be for surface water hydrologic processes, but the same ideas and approaches apply to other components within the hydrologic cycle.

CLASSIFICATION OF PROCESS MODELS

Models may be classified in a number of different ways. Singh[1] and Haan et al.[2] provide excellent descriptions of the different approaches to classifying models. Computer-based models are in two basic forms: lumped or distributed (Fig. 1). Lumped models do not take into account the spatial variability that is normally present in a hydrologic situation (watershed, field, soil, aquifer, atmosphere, etc.). The parameters, relationships, and results are ''lumped'' by averaging or using dominant characteristics in the area of interest. Models may also be lumped on a temporal scale (hour, day, month, year) to allow simpler modeling of dynamic and complicated processes. Distributed models do take into account the variability conditions that occur in the area of interest. For example, a watershed (the area where all runoff water flows to a common outlet) may include farmland, grass, forest, urban areas, streams, and lakes. As precipitation falls on each of these areas, unique processes occur (interception, infiltration, runoff). As a water droplet passes through different areas in the watershed, other processes and conditions will apply (stream and groundwater flow, etc.).

Practically all models that are described as ''distributed,'' have lumped characteristics (input parameters, spatial and boundary conditions, etc.). Rainfall and runoff processes may be distributed, but are likely not ''fully distributed.'' For example, the ANSWERS-2000 model[3] is considered a distributed—parameter hydrologic and water quality model for watershed scale runoff and water quality evaluations. It breaks the watershed into ''elements'' that contain lumped parameters based on dominant characteristics. The size of the elements can be selected based on variability conditions and overall size of the watershed. Water is passed from one element to another in a distributed network.

Models may also be classified by the process approach used in the model. The three basic descriptions are deterministic, stochastic, and mixed (Fig. 1). If all of the variables in the model are considered to be free from random variation, then the model is deterministic.[2] For example, a surface hydrology model may take input from precipitation, determine how much of that water will be associated with storage (surface and subsurface), how much water is associated with flow (surface and subsurface), and how much water is lost (evaporation, transpiration, and interception). Each process component can be represented by a different ''box'' (or submodel), with water coming in, water being stored, and water going out. Bringing all the different ''boxes'' together creates a hydrologic model system.

If any of the variables in a mathematical relationship in a model may be regarded as having random values, then the model system is considered to be stochastic. For example, precipitation over a period of time represents a random sequence. We cannot predict ''actual'' precipitation into the future with any

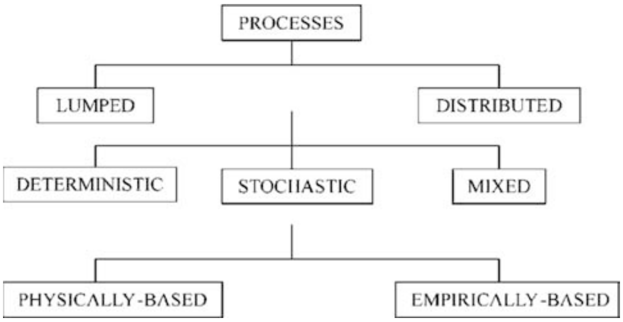

Fig. 1 Basic classification components for hydrologic process models.

degree of certainty. However, precipitation can be described in a distribution with an expected probability of occurrence (based on past history).

Most model systems contain a combination of deterministic and stochastic processes. The direct results from simulation models may not reflect the stochastic nature of the inputs. Many ''continuous'' models are designed to run over a long period of time, so that a range in conditions (such as precipitation) can be simulated to produce a distribution of potential responses.

There are several other classifications of models. A physically based model has relationships that represent actual physical processes. An empirically based model has relationships that are derived from measured data, but have no direct relationship to actual physical processes (Fig. 1).

''Simple'' or ''complicated'' is a classification that applies to the potential user. Originally, simple models tended to require few parameters and therefore yielded simple results. Examples of simple, empirical models are the Rational Method and the SCS Curve Number approach for calculating runoff from rainfall.[2,4] Complicated models are more likely to require extensive and detailed input data and are also more likely to yield more ''detailed'' results. Complicated models may be capable of responding to small changes in parameter values. The desire of most model developers is to make a complicated model easier to use (to increase the potential user-base). The use of interactive interfaces, geographic information systems, and standard data sets has helped ''parameterize'' a complicated model. However, if the user needs only general results, a simple model may suffice.

HISTORICAL DEVELOPMENT OF HYDROLOGIC PROCESS MODELS

One of the earliest computer-based hydrologic process models was the Stanford Watershed Model.[5] This model provided the hydrologic foundation for many later models. The Stanford Watershed Model used a lumped parameter approach, with daily or hourly rainfall and could simulate several years of runoff. The model did require calibration with some existing data to be effective.

The SCS curve number for calculating runoff from daily rainfall is probably the most widely used, empirically based, hydrologic process model within other model systems. Currently available water quality models such as GLEAMS,[6] EPIC,[7] SWRRB,[8] and PRZM[9] all use the SCS curve number to calculate runoff. The SCS curve number calculates runoff based on a ''number'' that reflects surface cover, soil characteristics, and antecedent soil moisture conditions.

CURRENT HYDROLOGIC PROCESS MODELS AND APPLICATIONS

A large number of hydrologic process models are currently available. Most of these models have specific applications (flood determination, river and ground water flow characterization, atmospheric processing, and water quality evaluation). Many of the models that are currently in use have graphical interfaces for improved input of parameters and interpretation of results. One example of a model system that has evolved over time is HEC-1. HEC-1 (a product of the Hydrologic Engineering Center of the Corp. of Engineers; 1) was originally designed to create a river flow hydrograph for a watershed. The model has been modified and enhanced into commercial products with graphical displays. Some versions can evaluate flood hydrographs, breached dam conditions, and even estimates of flood damage. Statistical analysis packages are included in many commercial products to increase the benefits of the model system.

The continual increase in computer speed has created opportunities for more-complicated models to be used by a wider range of clientele. Significant efforts have been expended to convert research-oriented, process models into systems that can be used by essentially anyone. This availability increases the potential for abusing models and their results. If models are used for unintended purposes, or unrealistic parameters are selected, model results will be suspect. It is important to select the model that is most useful to the intended application, to be sure how to use the model, and to not attempt to ''stretch'' the model beyond its' intended range of conditions. Haan et al.,[2] Singh,[1] and Parsons, Thomas, and Huffman[10] provide information on many of the currently available models, including where they can be obtained, their intended use, and what can be expected as a result.

CONCLUSION

Hydrologic process modeling provides an economical approach to representing a hydrologic condition for analyzing the status of water. Computer-based models are available for many of the different processes within the hydrologic cycle and for many different applications.

Hydrology Research Centers

Daniel L. Thomas
Department of Biological and Agricultural Engineering, Coastal Plain Experiment Station, University of Georgia, Tifton, Georgia, U.S.A.

INTRODUCTION

The study of water has been one of the most critical and beneficial needs since man understood the relationship between water and life. From the beginning of recorded history, water-related events (rainfall, snowfall, and runoff), patterns (stream flow, watershed contributions, and groundwater characteristics), and extremes (floods and droughts) have influenced hydrology research. As man impacted the environment and nature continued its process of weathering, approaches have been sought to better understand available resources, their properties, and how to minimize man's impacts on those resources.

Hydrology research encompasses fairly broad spatial and temporal components of water movement. Man has sought knowledge about the movement of water through shallow rivulets in a field to flows and conditions in major rivers and oceans. Man has been concerned about how water moves from melting snow to clouds and water vapor in atmospheric relationships. Research efforts have included attempts to understand water movement around soil particles to larger, more cavernous flows within major underground aquifers. Many of these research endeavors have included the development of physical and computer-based model systems as a way to better understand the phenomenon.

As man continues to influence watersheds and flow paths, research into hydrologic function will continue to be required. Significant research efforts are occurring within existing centers, laboratories, and institutes. This section is designed to identify many of the resource locations for hydrology research. This section will not include extensive listings of different centers for dryland and semi-arid research or centers for water quality investigation.

This document is neither designed to attest to the quality nor breadth of research programs within individual centers. The reader is encouraged to make contacts and determine those characteristics individually. One web-based resource for accessing different centers around the globe that are associated with hydrology is www.spatialhydrology.com/researchcenter.html (accessed October 2001). This resource includes a dynamic resource listing of many different groups since new organizations will continue to emerge while others disappear.

Academic-Oriented Research Programs

Much of the existing hydrology research occurs within academic institutions without a specific designation as a center, laboratory, or institute. These resources should not be excluded from potential access. Obviously, some institutions have extensive hydrology research programs, while others do not. The breadth of the research programs at particular universities is a function of the individual faculty and their interests. The Universities Council on Water Resources[1] provides an extensive listing of many hydrology-oriented programs and is a resource to the member institutions. Also included in their programs is the Universities Water Information Network that allows searching for particular topics and programs of interest.

Research has been coordinated through a variety of organizations that could be classified as "clearing houses" or centers for access to hydrology-oriented information. Some groups are professional organizations while others provide an opportunity to work toward specific goals through regional approaches. The idea is that most organizations do not have all the expertise to address many critical hydrology issues; thus, organizational structures are required to bring experts together. Several organizations that encourage and support hydrology research include the American Institute of Hydrology, the International Association of Hydraulic Engineering and Research (IAHR), the American Geophysical Union (AGU), the American Society of Civil Engineers (ASCE, including the Environmental and Water Resources Institute, EWRI), the Society for engineering in agricultural, food, and biological systems (ASAE), and the Soil Science Society of America (SSSA). The Cooperative State Research, Education and Extension Service[2] also provides coordination of regional projects. Some of these projects encompass hydrology-related research.

Federally Coordinated Research Programs

The U.S. Department of Agriculture (USDA), Agricultural Research Service (ARS),[3] and the United States Geologic Survey (USGS)[4] are two agencies of the United States that have primary missions that include hydrology research. The USDA, ARS have several watershed laboratories, and have been involved in the development of field- and basin-scale models of hydrologic and water quality phenomenon. Most of their work has been limited to surface hydrology and shallow subsurface hydrologic investigation. However, some extensive groundwater work has occurred in the western United States. The designated watershed research laboratories (Tucson, Arizona; Tifton, Georgia; Boise, Idaho; Coshocton, Ohio; Watkinsville, Georgia) are all involved in some aspects of watershed hydrology for soil, topography, and climatic characteristics of the particular region. Additional USDA, ARS laboratories are involved in stream flow hydraulics and structural impacts on flow. In almost every USDA, ARS research location, some aspect of water (quantity and/or quality) is being investigated. For more complete and up-to-date access to current projects, they provide a searchable web site under ''research'' at their primary web site.

The USGS is involved in monitoring and modeling stream flow, groundwater, and their interactions. The USGS also coordinates programs on acid rain and national water use and quality issues. In many states, they are the designated agency providing statewide and regional statistics on water use. The USGS monitoring network provides real-time access to stream flow and groundwater conditions.[4]

Other federal organizations that support research into hydrology characteristics include the Army Corps. Of Engineers and the Bureau of Reclamation (river basin water management), the National Oceanic and Atmospheric Association (NOAA), and the USDA, Natural Resources Conservation Service (NRCS). NOAA has programs associated with atmospheric sciences and global climate conditions, while the NRCS works with small watershed hydrology, dams, and field scale impacts on hydrology and water quality.

Hydrology Research Centers in the United States

The number of centers and laboratories in the United States that have programs that involve hydrology is quite extensive. The listing below is not designed to catalog every one. The primary emphasis is toward indicating the diversity that exists by several examples. The National Institutes for Water Resources (http://wrri.nmsu.edu/niwr/ accessed November 2001) include the different state-level water resources research centers/institutes. These centers may be funded from federal and/or state resources with the primary goal (usually) of initiating water resources projects within that particular state. For example, the Water Resources Research Center at Arizona State University (http://ag.arizona.edu/azwater/ accessed November 2001) has funded research programs investigating riparian systems, flooding, and evaporation effects.

The Stanford Center for Reservoir Forecasting (http://ekofisk.standford.edu/SCRFweb/index.html accessed November 2001) is focused directly on programs that relate to reservoir characterization, performance, and modeling of processes within reservoirs. The Belle W. Baruch Institute for Marine Biology and Coastal Research in Columbia, South Carolina (http://inlet.geol.sc.edu/ accessed November 2001) has programs investigating coastal hydrology issues. The Center for Water Research and Policy in Columbia, South Carolina (http://watercenter.environ.sc.edu/ accessed November 2001) is involved in groundwater systems, contaminant transport processes, and water balance research. The Snow Hydrology Group at the University of California, Santa Barbara (www.icess.ucsb.edu/hydro/hydro.html/ accessed November 2001) is investigating watershed hydrology and modeling under snow conditions. The Florida Center for Environmental Studies in Palm Beach Garden, Florida (www.ces.fau.edu accessed November 2001) represents 10 state universities and four major private universities that are involved in research on river restoration, everglades hydrology, wetland functions, modeling and monitoring, and international programs to address hydrology issues in Central and South America.

International Hydrology Research Centers

The Center for Ecology and Hydrology in Wallingford, U.K. (www.nwl.ac.uk/ih/ accessed October, 2001) is the former Institute of Hydrology. They have very broad areas of interest including flooding, droughts, climate habitats, rivers, plants, and soils. The Center for Science and Environment in New Delhi, India (www.oneworld.org/cse accessed October 2001) has directed their current research emphasis toward the analysis of floods. The Watershed Science Center at Trent University in Ontario, Canada (www.trentu.ca/wsc/welcome.shtml accessed November 2001) has programs oriented toward forest hydrology, structural impacts on fish habitat, and watershed ecosystem management. The Commonwealth Scientific & Industrial Research Organisation (CSIRO, http://www.csiro.au/ accessed November 2001) has programs on natural and managed ecosystems, and weather and climate as they relate to social, economic, and ecological factors.

Centers Studying Drought, Weather, and Climate

Several organizations are involved in the study of drought and weather. The National Drought

Mitigation Center in Lincoln, Nebraska (http://enso.unl.edu/ndmc accessed November 2001) is involved in the development of techniques to improve risk management during droughts and improve the forecasting and understanding of drought. The Global Hydrology and Climate Center in Huntsville, Alabama (www.ghcc.msfc.nasa.gov accessed October 2001) has programs oriented toward the study of the global water cycle. The National Weather Service (www.nws.noaa.gov accessed November 2001) is involved in research associated with forecasts of river levels, floods, and water supply needs. The weather service has regional offices throughout the United States to allow more specific investigation into regional and local weather phenomenon. The Center for International Earth Science Information Network at Columbia University in New York (www.ciesin.org accessed November 2001) is an additional resource for research associated with global climate change.

Centers Studying Pollutant Transport

Pollutant transport is directly associated with hydrology of surface and groundwater resources. The ability of a particular water medium to move pollutants from one place to another and the integrated processes associated with those pollutants are directly tied to the hydrologic characteristics. Besides the many organizations mentioned earlier, Oak Ridge National Laboratory (www.esd.ornl.gov accessed October 2001), the Savannah River Ecology Laboratory (www.uga.edu/~srel/ accessed October 2001), the Center for Environmental Research and Training (CERT, associated with the National Environmental Health Association, www.nehacert.org accessed November 2001), and the Center for Water Research and Policy in Columbia, South Carolina (http://watercenter.environ.sc.edu/ accessed November 2001) all have programs that are directly associated with pollutant transport.

CONCLUSION

Hydrology Research Centers provide an excellent resource to current and future investigation into the characteristics of hydrology. Until man fully understands all hydrologic phenomena and ceases to impact the movement of water, there will need to be research into the future. Centers and institutes provide an appropriate method to focus on particular problems while reducing potential overlaps with other programs.

Hypoxia: Gulf of Mexico

Nancy N. Rabalais
W. J. DeFelice Marine Center, Louisiana Universities Marine Consortium, Chauvin, Louisiana, U.S.A.

INTRODUCTION

Every spring, the dissolved oxygen levels in the coastal waters of the northern Gulf of Mexico decline and result in a vast region of oxygen-starved water that stretches from the Mississippi River westward along the Louisiana shore and onto the Texas coast.[1,2] The phenomenon is known as hypoxia, but has been dubbed the ''Dead Zone'' by environmentalists and fishermen. The low, minimal, or non-existent oxygen levels drive away fish, shrimp, and crabs.

Hypoxia occurs naturally in many parts of the world's ocean, such as fjords, deep basins, open ocean oxygen minimum zones, and oxygen minimum zones associated with upwelling systems. These naturally low oxygen waters have existed throughout geologic time, but the occurrence of hypoxia in shallow coastal and estuarine areas is a recent phenomenon that is related to human alterations within these systems and is on the increase.[3]

DEFINITIONS

Hypoxia is operationally defined for the northern Gulf of Mexico as oxygen concentrations below a level of $2\,mg\,L^{-1}$, or ppm.[1,2] When oxygen levels fall below this point, trawlers do not catch any shrimp or demersal (bottom-dwelling) fishes in their nets. Organisms living in the bottom sediments, such as snails, echinoderms, burrowing shrimp, and worms, often succumb to the low oxygen levels that remain low for extended periods. When the oxygen is completely absent, anoxia occurs ($0\,mg\,L^{-1}$). Anoxic waters are accompanied by the release of hydrogen sulfide (a toxic chemical compound) from the sediments.

CAUSES

Hypoxia in the Gulf of Mexico results from a combination of natural and human-influenced factors, as well as a combination of physics and biology.[1,2] The Mississippi River, one of the ten largest rivers in the world, drains 41% of the land area of the lower 48 United States and delivers freshwater, sediments, and nutrients to the Gulf of Mexico. The fresh water, when it enters the Gulf, floats over the denser saltier water, resulting in stratification, or a two-layered system. The stratification begins in the Spring, intensifies in the Summer as surface waters warm and winds that normally mix the water subside, and dissipates in the Fall with tropical storms or cold fronts (see Fig. 1).

Stratification is a requisite for hypoxia development and maintenance, but the excess organic loading from nutrient over-enrichment drives the reduction of the oxygen.[4] Without excess organic matter, hypoxia would not develop.

The river discharge contains high concentrations of nutrients, such as nitrogen, phosphorus, and silica, which are necessary for the growth of the microscopic algae, i.e. phytoplankton. These nutrients stimulate the growth of the phytoplankton and fuel the marine food web. Excess algae sink to the bottom, or their remains sink to the bottom in fecal pellets of zooplankton or in aggregates of organic debris (see Fig. 2).

The excess organic load from the upper water column is subjected to decomposition by aerobic microbes in the lower water column and on the seabed. The rate of consumption of oxygen in the decomposition process is high and exceeds the rate of oxygen resupply from the upper water column by diffusion and mixing, especially when the water column is strongly stratified.

WHEN AND WHERE HYPOXIA OCCURS

Hypoxic waters are found in shallow depths near the shore (4–5 m) to as deep as 60 m.[1] The more typical depth distribution is between 5 and 35 m. When the hypoxic waters move onto the shore, fish, shrimp, and crabs are trapped along the beach, resulting sometimes in a ''jubilee'' when the stunned animals are easily harvested by beachgoers. A more negative result is a massive fish kill of all the sea life trapped without sufficient oxygen.

Hypoxia occurs on the Louisiana coast from February to November, and nearly continuously from mid-May through mid-September. In March and April, hypoxic water masses are patchy and ephemeral. The hypoxic zone is most widespread, persistent, and

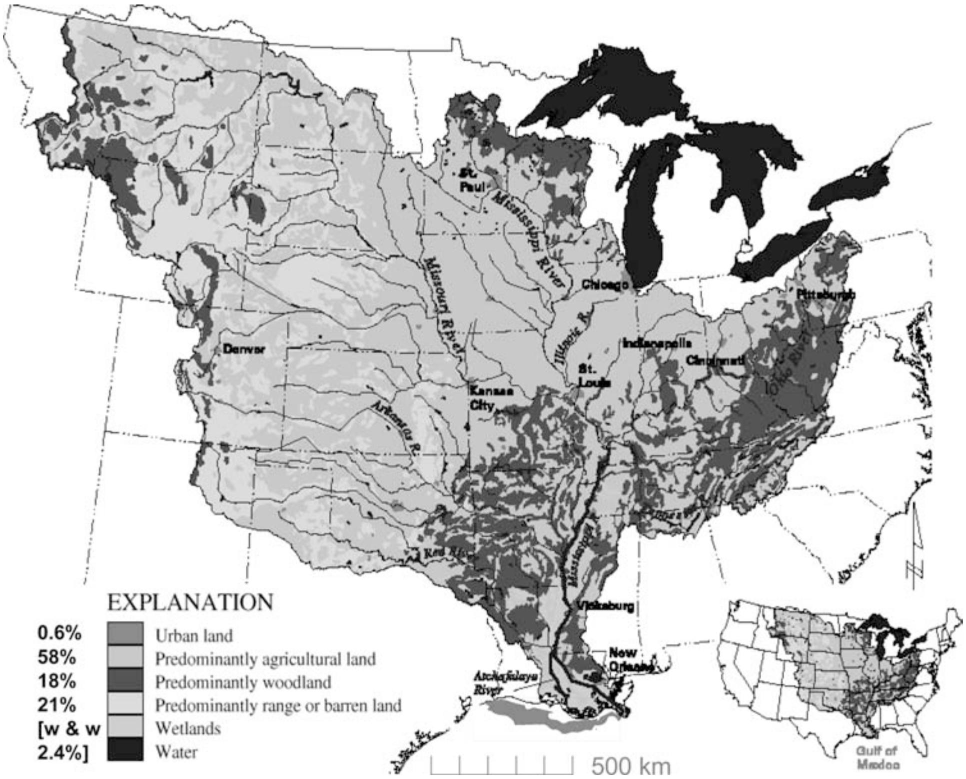

Fig. 1 Mississippi River drainage basin, major tributaries, land use, and general location of the 2002 mid-summer hypoxic zone. *Source*: Map from Ref.[9]; hypoxic area data of Rabalais.

severe in June, July, and August. Anoxic waters occur periodically in mid-summer. The size and distribution of the hypoxic zone is minimal in drought years and has been as large as 22,000 km^2 in July 2002.[2] The average size of the hypoxic zone in the period from 1985 to 2007 equal 13,500 km^2 for the period 2000 to 2007 average area of 15,870 (or 15,900) km^2. The temporal and spatial coverage of the hypoxic zone

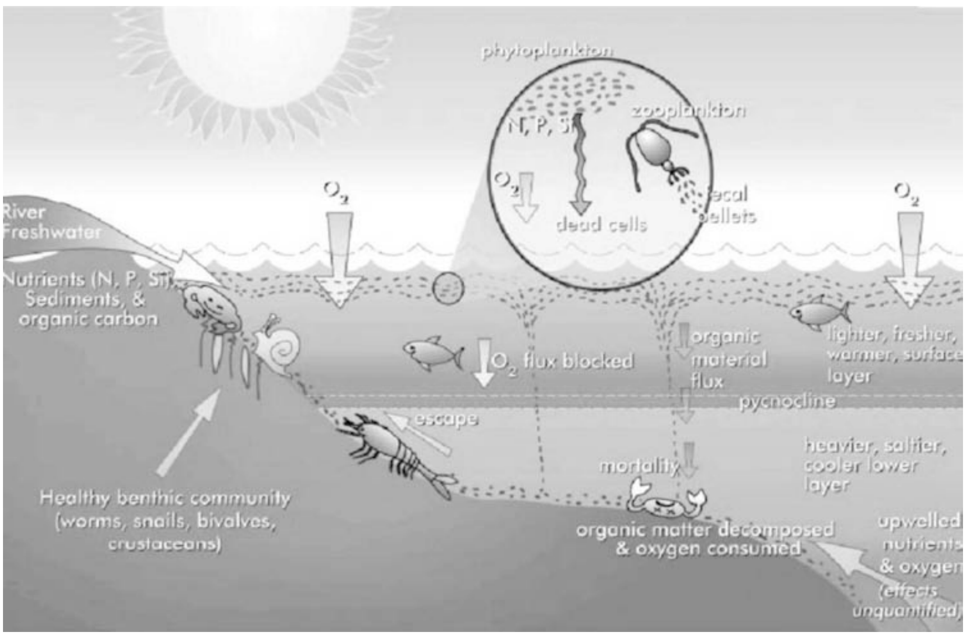

Fig. 2 Description of hypoxic water mass and interacting biological and physical processes important in its formation and maintenance. *Source*: Committee on Environment and Natural Resources (CENR). Integrated Assessment of Hypoxia in the Northern Gulf of Mexico, 2000, National Science and Technology Council: Washington, DC, originally depicted in Ref.[7].

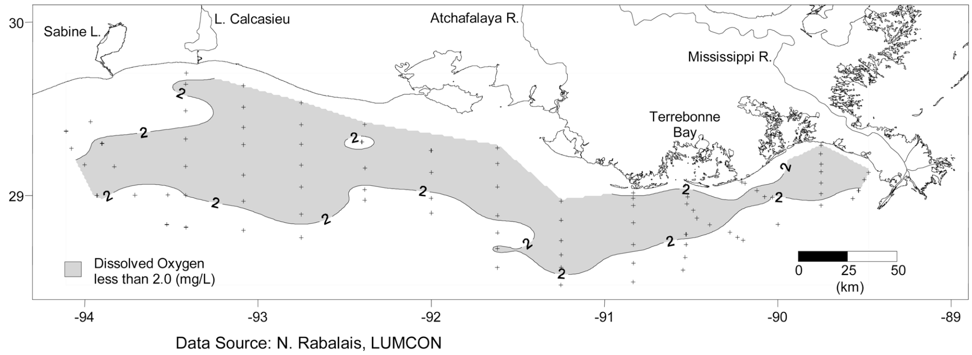

Fig. 3 Expanse of bottom water hypoxia in mid-July 2002.

varies from a continuous band along the coast or disjunct areas on the southeastern and southwestern coasts, to patchy distributions following tropical storms. Hypoxia and the stratified water structure can be broken down by tropical storms or hurricanes in late summer, and the increasing passage of cold fronts through the winter.

The mid-summer size of the hypoxic zone varies annually, and is most closely related to the nitrate load of the Mississippi River in the two months prior to the July mapping exercise.[5] The load of nitrate is determined by the discharge of the Mississippi River multiplied by the concentration of the nitrate, so that the amount of water coming into the Gulf of Mexico is also a factor. The relationship of the size of hypoxia, however, is stronger with the load of nitrate than with the total river water discharge. Changes in the severity of hypoxia over time are related mostly to the change in nitrate concentration in the Mississippi River (80%) and the remainder to changes in increased discharge (20%) (see Fig. 3).[6]

CONSEQUENCES

The obvious effects of hypoxia include the displacement of pelagic organisms and selective loss of demersal and benthic organisms.[1] As the oxygen concentration falls from saturated or optimal levels toward depletion, a variety of behavioral and physiological impairments affect the animals that reside in the water column or in the sediments. Shrimp, fish, and some crabs flee waters where the oxygen concentration falls below $2\,\mathrm{mg\,L^{-1}}$. As the demersal fishes and crustaceans are forced to occupy less suitable habitat, they can be exposed to increased predation, and suboptimal habitats can result in reduced growth. Below $1\,\mathrm{mg\,L^{-1}}$, less mobile organisms, e.g. brittle stars, become stressed and move up out of the sediments, in attempts to find more oxygen. As oxygen levels fall from 0.5 toward $0\,\mathrm{mg\,L^{-1}}$, there is a linear decrease in benthic infaunal diversity, abundance, and biomass (see Fig. 4).

Sensitive marine invertebrates are eliminated, e.g., amphipods, bivalves, gastropods, brittle stars, and sea stars, and only small polychaetes and sipunculans remain. These changes result in an impoverished diet for bottom-feeding fishes and crustaceans once the low oxygen conditions abate and animals move back into the area.

The effects of hypoxia on the highly valuable shrimp fishery should be obvious when a bottom area of the size of Connecticut, New Jersey, or Massachusetts does not support a shrimp population for a portion of the year.[1] The decadal decline in brown shrimp landings could be related to the presence of hypoxia,[7] but also to confounding factors of river discharge, nursery area salinity and acreage, and fishing effort. The effects of hypoxia related loss of essential habitat to production of shrimp or overall fisheries landings is not clear. What is clear is their virtual absence across large areas of the seabed during the peak of hypoxia.

HISTORICAL CHANGE IN HYPOXIA

Hypoxia may have previously occurred under the plume of the Mississippi River, but the database from which to determine long-term trends is minimal. Sediments delivered by the Mississippi River, however, accumulate in an area west of the river delta, and their constituents can be used as surrogates for environmental change. Sediment data indicate that the productivity of marine phytoplankton, and in particular diatoms, has increased, and that oxygen conditions have worsened.[8] Some of the changes date to the turn of the century, but the problems have worsened since the early-1950s, consistent with the increased delivery of Mississippi River nitrogen.

Fig. 4 Dead demersal and bottom-dwelling fishes killed by the encroachment of severely low dissolved oxygen waters onto a Grand Isle, Louisiana beach, in August 1990. [Photo provided by K.M. St. Pé.]

In the last half of the 20th century, the load of nitrogen delivered by the Mississippi River tripled.[5] Nitrogen loads come from industry, urban runoff, atmospheric deposition, fertilizer runoff, animal wastes, and leguminous crops, but well over half of the load is attributable to agricultural activities.[9] In addition, the landscape of the Mississippi River watershed is now highly modified by dams, channels, and straightened rivers, and the conversion of natural flood plains to cleared, drained, and plowed land. The result of all these modifications is that increased nutrient loads to the basin are less likely to be filtered and transformed in the current landscape.[2]

GLOBAL COMPARISONS

The hypoxic zone in the northern Gulf of Mexico is one of the largest hypoxic zones in the world's coastal oceans.[4] Of those that are caused by anthropogenic changes over the last half of the 20th century, the hypoxic zone in the northern Gulf of Mexico adjacent to the Mississippi River is currently the second largest.

The largest human-caused hypoxic zone is in the aggregated coastal areas of the Baltic Sea, reaching 84,000 km^2. Hypoxia once covered 40,000 km^2 on the northwestern Black Sea shelf adjacent to the excess nutrient loads of the Danube River. Reductions in nutrient loads from the Danube post-1990 resulted in a minimization of the hypoxic zone adjacent to it over the succeeding 10 yr.[10] More recently,[11] there are indications that hypoxia could be worsening in the northwestern Black Sea with increased agricultural and industrial activities in the Danube watershed.

The processes of increased phytoplankton production from nutrient over-enrichment and hypoxia development occur elsewhere in the world's estuaries and oceans, e.g., the northern Adriatic Sea, the Kattegat and Skaggerak, Chesapeake Bay, Albemarle-Pamlico Sound, Tampa Bay, the German Bight and the North Sea, Long Island Sound, and New York Bight. The number of estuaries with hypoxia or anoxia continues to rise.[3]

CONCLUSION

The scenario of worsening oxygen conditions in Gulf of Mexico coastal waters adjacent to the nitrogen-enriched effluent of the Mississippi River with consequences to living resources parallels many situations throughout the world's oceans where nutrient pollution is emerging as a new global concern. The continued and accelerated export of nitrogen and phosphorus to the world's coastal ocean is the trajectory to be expected unless societal intervention in the form of controls or changes in culture are pursued.

ACKNOWLEDGMENTS

The hypoxia research efforts are sustained by the collaborations of R. E. Turner, D. Justić, Q. Dortch, B. K. Sen Gupta, W. J. Wiseman, Jr., D. E. Harper, Jr., D. Scavia, D. F. Boesch, G. Stone, N. Walker, and many others through the last 20 years and more, and funding from the NOAA Coastal Ocean Program.

Internet

Janet G. Norris
Sterling C. Evans Library, Texas A&M University, College Station, Texas, U.S.A.

INTRODUCTION

The Internet holds a wealth of water science information sites with free public access. This information can be predominantly found on the World Wide Web (WWW) and although a web search engine can locate millions of web pages related to water, finding specific information can be difficult due to the lack of central organization. The web is further complicated by its dynamism. Web pages change, relocate, and disappear frequently. Fortunately, government, organization and educational web sites have become more stable over the past decade and virtual libraries and subject-specific search engines have been created to assist the searcher. Full text documents, primary data, real-time data, interactive maps, and archived data are available through databases on the WWW, but the databases can be hard to locate. This article outlines methods for locating information in web sites that have moved or changed, describes some effective search engines, and discusses some of the virtual libraries databases that may be of particular value to the researcher who seeks water science information on the WWW.

INTERNET DEVELOPMENT HIGHLIGHTS

The technology developed in 1969 as a U.S. Defense Department project named the Advanced Research Projects Agency Network (ARPANET), which allowed computers to share information simultaneously, gave rise to the Internet. The development of Hypertext Markup Language (HTML) and web browser technology in 1989 gave easy access to the Internet, created the WWW, and with the introduction of the first search engine, Yahoo, in 1994, opened the Internet to the world.[1] The number of available web pages increased phenomenally with the advent of search engines. At the close of the 20th century there were approximately 2.1 billion static web pages[2] with an incredible number of these pages devoted to water science topics.

Water information originating around the world can be discovered and accessed in seconds within the vast library that is the WWW. However, the search for information can be overwhelming and frustrating due to the huge number of web sites and the absence of a central organizing or cataloging mechanism. The nebulous ever-changing nature of web sites is also problematic for Internet users. A 1996 study determined that the half-life of a web site is around 2.9 yr.[3] Fortunately virtual libraries, government sites, and many organizational sites have become relatively stable in recent years.

THE SEARCH FOR WATER INFORMATION ON THE WWW

The WWW, a subset of the Internet, is easily searched and accessed and is a primary location of information available for public access. Public access means that all users have the capability to view the information without having to paying for access. Of course the WWW also contains substantial amounts of information that requires the payment of a fee for access. Fortunately, a multitude of water information is freely available. Important sources of this information include government agencies, educational institutions, and water organizations. However, navigating through the millions of web pages devoted to water topics to find specific information is not easy or fast. Individual web sites can be massive and site navigation can be convoluted. Many sites contain links that lead one out of the site without warning. Web pages continually evolve by changing location within the web site, dividing into a number of pages, or they cease to exist. There are general methods that are useful in determining the contents of a web site or to find the new location of a specific page:

- View the entire page. Many times it is necessary to scroll down the page to locate the site's search engine or index.
- Use the site's help screens.
- Site maps provide a fast way to determine what information a web site contains.
- When a URL does not appear to be correct, reduce the indexing by one level (the next to last slash) until a page is accessed, then look for a hyperlink on that page to the information.
- Enter only the first part of the URL to the domain (.gov, .edu, .com, .org), then use a tool provided by the site to locate the desired information.

Table 1 Selected subject specific search engines (all accessed February 2001)

The WWW consists of sites that can be considered libraries or databases, though there are no uniform protocols that govern how sites are named. Common titles of web sites that organize web pages by subject are Digital Library, Virtual Library, Web Links, Database, Web Directory, Resources, etc. Search engines are actually indexes of web pages but could also be considered libraries.

SEARCH ENGINES

Search engines, metacrawlers, and directories are popular tools (all commonly denominated ‘‘search engines’’) used for locating information on the WWW. However, all three tools may lead to an overwhelming list of web pages if one uses a broad search term, such as ‘‘water.’’ For example, over 8 million web pages were retrieved using the term ‘‘water’’ in the popular search engines Alta Vista, Northern Light, and Excite, supporting the proposition that there are vast resources on the topic to be found on the WWW, but also emphasizing the need for more precise queries. Even directories that provide subdivisions to sites with a more narrow focus, such as Yahoo, Infoseek, and Lycos retrieve hundreds to thousands of links.

Water science information retrieval on the Internet is further complicated by the cross-disciplinary nature of the subject. Water science can encompass the categories of hydraulics, hydrogeology, economics, chemistry, climate, weather, environment, ecology, agriculture, pollution, engineering, etc. Therefore, efficient information retrieval using search engines requires very specific search terms and the use of more than one search engine is required for thoroughness.

Yahoo! Reference Library	http://dir.yahoo.com/Reference/Libraries/

Fortunately, subject-specific search engines have been developed to assist the search for water-related information on the WWW. Selected subject-specific search engines are listed in Table 1. Considering the amount of information generated by the U.S. government, one of the most useful search engines is FirstGov, which provides access to all online U.S. Federal Government resources. This site also provides links for state and local governments as well as interesting topic links for science/technology and agriculture/food and laws. Some of the search engines locate sites relevant to water and/or agriculture such as AgriBiz, Aqueous, Web-Agri, and Wetlands, while others look for full text Adobe Acrobat (PDF) files related to the search. All of the other search engines in the list provide a broader coverage of science or engineering but can be extremely useful in locating water information.

VIRTUAL LIBRARIES AND WATER SCIENCE

There is little distinction between web sites titled "virtual library" and sites that maintain lists of WWW links organized by subject or databases sites. All organize valuable WWW resources. If we consider web libraries to be those sites that organize information and provide access to the information, then subject-specific libraries exist under a variety of names such as gateways, web directories, web links, or personal/organization home pages. Numerous libraries are included within web sites of organizations and government agencies and can be denominated "library," "resources," "reference," etc. Table 2 provides a selection of WWW libraries containing water information along with their URLs.

A standard model for virtual libraries does not exist because they are as varied as the individuals or organizations that have created them. Virtual library web sites include search engines and/or list water topics in sections labeled science, geology, earth science, agriculture, or environment. Some, like the Online Electronic Science Library created by the University of South Carolina, which contains approximately 2500 web resources, are set up and cataloged like traditional academic libraries complete with reference, book, journal, and tool categories. Other traditional library-based models include EEVL, the Edinburgh Engineering Virtual Library; Mel, the Michigan Electronic Library; and BUBL. Virtual libraries, such as the International Association of Hydrogeology site, categorize water information by geographic location, while the Water Librarians' Home Page includes a variety of categories that the author considers important in his or her work as a librarian in a water agency. Each library is designed to provide access to information important to users.

WATER SCIENCE DATABASES

The sharing of information is the primary function of the Internet, and the sharing of data in the world of water science is extremely valuable due to the interdisciplinary nature of water and its global importance. The WWW includes many water-related databases containing real-time data, interactive maps, or historical primary data and presents the scientist, student, and water professional with access to information that was previously neglected due to lack of accessibility or whose existence was unknown. Unfortunately, water data are not conveniently collected in one neat category and may be difficult to locate on the WWW. There is also a question of accuracy and reliability when discussing data. Table 3 presents a selection of fairly stable databases produced by government agencies, water organizations, or educational institutions that should provide accurate, reliable data. The web sites were chosen to provide a broad range of data types and coverage or as major indexes to data sets and are only intended as a starting point for locating data on the web.

THE FUTURE OF WATER INFORMATION ON THE WEB

During the past decade we have witnessed an explosion of information on the Internet. Much of the information is of questionable value or commercial in nature. The virtual libraries have started to organize the web by evaluating and grouping relevant web pages into coherent catalogues, which eliminates the searcher's major frustration of sifting through thousands of irrelevant sites to find information. Searching for resources, then making them useful by cataloging/organizing and continuous maintenance is an extremely labor-intensive process. Librarian Assistants, a software package, currently being developed by one electronic library, may simplify the process[4] and make web organization more feasible. As developing countries' online presence increases over the next few years, new sources of water information will appear on the web. Web-masters will be challenged not only by the sheer volume of information to organize, but also with the daunting task of meeting the needs of searchers in areas with diverse technological capabilities and where change is the only certainty.

Hydrologic–Irrigation

Irrigated Agriculture: Economic Impacts of Investments

Robert A. Young
Colorado State University, Estes Park, Colorado, U.S.A.

INTRODUCTION

Because crop irrigation represents the largest single consumptive user of water in the United States and in the world, and many governments in arid areas have encouraged irrigated agriculture, measures of the economic impacts of changes in irrigated agriculture are of interest for evaluation of proposed irrigation-related public policies. Such policies include potential investments in new irrigation water supplies, transfers of irrigation water to emerging urban, industrial, and environmental demands, and plans for long-term groundwater management policies. Space limitations restrict this discussion to investment issues, although the concepts and evidence are relevant to related topics. This contribution identifies several types of economic impacts of irrigation development, sketches the conventional economic framework for evaluating public policies relating to irrigation, presents evidence on the magnitude of impacts, and concludes with a skeptical assessment of the social returns on public investments in irrigated agriculture and the methods used by public agencies to evaluate such investments.

CONCEPTS FOR EVALUATING NET ECONOMIC IMPACTS OF IRRIGATION-RELATED POLICIES

Standard economic evaluation consists of making estimates in money terms of the beneficial or desired impacts (*benefits*) and the adverse or undesired impacts (*costs*) and balancing the one against the another to determine the net economic impact.[1] Evaluations are necessarily site-specific, because of varying local physical, biological, economic, and policy conditions.

An important initial concept in water policy evaluation is the *accounting stance*, which refers to the point of view or perspective from which the analysis takes place.[2] It can reflect either the *private* individual or the *public* or *social* viewpoint. The social viewpoint is normally from the national perspective, but a regional approach can also be identified. Under the private accounting stance, the private investor is assumed to take the policy environment and hence, prices of productive inputs and outputs as given. From the national social perspective, academic economic doctrine advocates that input and output prices should be adjusted for any distortions from ideal market conditions, such as for public subsidies or unpriced third party impacts.

Another important distinction is between *direct* (or *primary*) and *external* economic impacts.[1] Direct economic impacts accrue to the basic producing unit, the farm. Direct benefits are the *net* monetary value of the output of the water supply initiative, and are measured by the producers' *willingness to pay* for those outputs. Direct costs are the foregone benefits of using those resources in the best alternative use, and reflect the value of resources or inputs used to accomplish the project or initiative. External impacts (also called spillover impacts) arise in addition to the direct project impacts and are those unpriced effects registered on third parties, and can be either positive or negative and either *real* or *pecuniary*. Real indirect effects are due to physical linkages (usually through the hydrologic system) between the activities of two or more affected parties and reflect actual output changes. Pecuniary or *secondary* external impacts reflect income changes occurring via the price system linkages between and among the farms, firms, and households that make up the economy.

Consider now a simple framework (Model 1) that shows the conditions for economic feasibility of a potential investment in irrigated agriculture from the point of view of the private investor. (All benefit and cost elements in the models presented below are assumed to be expressed in annual equivalent terms, employing a consistent interest rate and planning period and reflecting the same general price level.)

Model 1: $DB_p > DC_p$

where the symbols represent the following concepts: The subscript p denotes the private perspective. DB_p is the direct private user benefit (willingness to pay for the initiative) and DC_p is the direct private cost. Direct benefit reflects the economic value of the physical increment in production due to the increment in water supply. Direct benefit is often called the *net return* to or the *value* of water, and is conventionally calculated as the estimated increment in gross revenues from crop sales minus the increment in non-water costs of producing the crops.[2] Direct costs are the costs of bringing the irrigation water supply to the farm, which for example might be the annualized cost of installing and operating an irrigation well and pump or the annual assessment associated with accessing water from a community or public water storage and supply project. Model 1 asserts simply that the contemplated investment is economically feasible if, from the private irrigator's perspective, direct benefits exceed direct costs.

Turning to evaluation of the impacts of an irrigation investment from the public or social accounting stance, three types of adjustments and additions should be made to Model 1. First, benefits and costs are adjusted for subsidies or other government-induced market distortions. For example, crops produced with the aid of government support programs—such as cotton or rice in the southwestern United States—would be valued at lower price levels, derived from estimated free market prices (which task is a challenge itself). Costs would similarly be adjusted for public subsidies (such as low-cost credit, energy, or irrigation water) or penalties (e.g., minimum wage regulations). On balance, these adjustments usually make the social net benefit of added irrigation water less than the private net benefit.

The other adjustments needed for a shift to the public accounting stance are to incorporate monetary estimates of any external effects, both real and pecuniary. These steps are represented in Model 2, in which direct impacts are expressed in social prices (adjusted for market price distortions, denoted by introducing a subscript s) and external impacts (both real and pecuniary) are incorporated in the formula:

Model 2: $\mathrm{DB_s} + \mathrm{IB} + \mathrm{SB} > \mathrm{DC_s} + \mathrm{IC} + \mathrm{SC}$

The terms new in Model 2 are IB, representing indirect (real external) benefits, SB denoting secondary (pecuniary external) benefits, IC standing for real external costs, and SC denoting secondary external costs.

Secondary benefits, the multiplier effects arising from increased purchases of production inputs and consumption goods when a project comes into operation, are typically concentrated in the project region. They are normally measured by specialized economic models (such as regional interindustry models), which simulate the effects of an increment of resources on the economy. Secondary costs (SC) are the pecuniary benefits foregone when a public investment draws funds (via taxes) from the economy at large. Secondary costs typically spread throughout the national economy and are very difficult to measure. The conventional economic wisdom (embedded in public planning manuals) is that from the national accounting stance, secondary or pecuniary costs are at least as large or larger than secondary benefits. Hence, the two effects offset each other and except in special cases, secondary economic impacts can be ignored for national irrigation investment planning purposes.[1]

Indirect costs and benefits, the other class of external effects, should also be incorporated into evaluations adopting a public accounting stance. Indirect benefits are seldom economically important, but indirect costs are typically very significant. Examples of indirect costs of irrigation water diversions include reduced downstream water supplies or adverse effects on water quality downstream for offstream (irrigators, industries, and households) and instream (hydroelectric power plants, recreational water users, and fish and wildlife habitat) water users.

EMPIRICAL EVIDENCE ON ECONOMIC IMPACTS OF IRRIGATED AGRICULTURE

A number of sources suggest that the direct economic benefits of irrigation, even from the private accounting stance, are not as large as assumed by non-specialists or the lay public. One bit of evidence is that farmers are seldom able or willing to pay for public project costs, even if repayment requirements are but a small fraction of actual costs.[3] Econometric studies of land and water rights markets infer that direct benefits of irrigation investments are modest relative to costs.[4] River basin simulation models that adopt a public accounting stance by incorporating indirect costs show that indirect costs to instream water users (such as hydropower producers) may exceed the economic benefits of upstream crop irrigation.[5] Elsewhere, similar evidence is accumulating that when social costs are accounted for, net social benefits of public irrigation developments have been quite unimpressive. The large loss to Aral Sea fisheries and to regional environmental quality from diverting the inflow source for cotton production is one well-known example. Econometric studies in India and China report low rates of economic return to investments in irrigated agriculture (implying negative net social benefits when discounted at conventional interest rates) particularly as compared to the return on expenditures on agricultural research, on education, or on rural road construction.[6]

If the public feasibility studies were correct in concluding that substantial net economic benefits would flow from water resource developments, regional economic studies of ex post impacts would be expected to show corresponding positive impacts on economic growth indicators. Several statistical studies of the role of water investments in regional economic growth in the United States conducted over two decades ago were unable to find statistically significant positive effects of water development on regional incomes.[7] More recently, a regional economic model of the Sacramento Valley (a California agricultural region comprising nearly 2 million irrigated acres) simulated the effect of hypothetical drought scenarios which would reduce water availability by up to 25%. Even the most drastic scenario, and measuring both direct and secondary effects, was predicted to reduce employment by only 300 jobs and reduce total regional income by less than 1%.[8]

The large regional secondary (multiplier) effects from irrigation development sometimes assumed by non-economists are not substantiated on careful study. And, because labor-saving technologies have reduced the labor requirements in agriculture and related industries (dramatically so in the developed world), direct and secondary employment impacts of irrigated agriculture are found to be modest. These ex post studies have of necessity used private prices. If the data had permitted adjustments for subsidized product and input prices, and acknowledged the downstream indirect costs, the conclusions would be even more pessimistic from the social accounting stance.

CONCLUSION

Many early public investments in irrigated agriculture likely yielded an adequate social return. However, conceptual and empirical reasons combine to make it difficult to avoid the inference that the net economic benefits of investments in irrigated agriculture over, say, the last half century, have not been large in the United States and even elsewhere. This conclusion is particularly firm when a social accounting stance is adopted, so that negative indirect effects are accounted for and impact measures are adjusted for input and output subsides. By making overoptimistic assumptions on crop productivity and prices, by ignoring the opportunity costs of certain inputs, or not properly accounting for public subsidies and external costs, public irrigation planning agencies have tended to systematically overstate net economic benefits of public investments in irrigated agriculture.

Irrigated Agriculture: Endangered Species Policy

Norman K. Whittlesey

Joel R. Hamilton
Department of Agricultural Economics, University of Idaho, Moscow, Idaho, U.S.A.

INTRODUCTION

Irrigated agriculture in the western United States (the West) holds the most senior appropriative water rights allocated pursuant to state statutes, and accounts for about 90% of the consumptive water use in the West.[1] Appropriation of the dependable flow of regional rivers into irrigation has altered natural flow regimes to the detriment of aquatic habitats, and consequently has contributed to the listing of several species relying on aquatic habitats as endangered or threatened pursuant to the federal Endangered Species Act (ESA).[2] Notable examples are the listings of several anadromous salmon species in the Columbia River Basin,[3] and of waterfowl and fish species in the Platte River Basin.[4]

The curtailment of state appropriative water rights pursuant to ESA-sanctioned species recovery plans has placed federal and state law on a collision course whose resolution will establish the legal parameters governing policy tradeoffs in allocating water between irrigated agricultural and endangered species protection. Our objective is to illuminate what these legal parameters might be. We begin with brief reviews of the ESA and of the prior appropriation doctrine that provides the foundation of state water law.

THE ENDANGERED SPECIES ACT

The Endangered Species Act (ESA) elevates the conservation of endangered species to the highest level of federal policy objectives, and sets forth a legal procedure affording them extensive protection. Section 1533 authorizes two federal agencies to ''list'' imperiled species as ''endangered'' (defined as species in danger of becoming extinct through all or a significant portion of their range) or ''threatened'' (defined as species likely to become endangered in the foreseeable future) based on solely biological criteria. The Secretary of Commerce—acting through the National Marine Fisheries Service (NMFS)—lists marine species, and the Secretary of the Interior—acting through the Fish and Wildlife Service (FWS)—lists all other species. The listing agencies are required to designate the species' critical habitat, and to prepare ''recovery plans'' detailing strategies to revive populations to healthy levels. Species recovery receives top priority in the formulation of recovery plans if conflicts arise with construction, development, or other economic activities.

Section 1536 directs federal agencies to consult with listing agencies to ensure that proposed federal actions do not jeopardize the continued existence of a listed (or proposed to be listed) species or adversely modify its critical habitat. If the proposed action is deemed to have an ''incidental'' impact, the listing agency can require that the consulting agency take ''reasonable and prudent measures'' to minimize the impact. A consulting agency is banned from making any ''irreversible or irretrievable'' action that would foreclose the implementation of such measures.

Section 1538 bans the ''taking'' (e.g., harassment, killing, or capturing) of listed species, and applies to all persons within the jurisdiction of the United States, with exceptions for ''incidental takings'' (defined as takings that are ''incidental to, and not the purpose of, the carrying out of an otherwise lawful activity'').

THE PRIOR APPROPRIATION DOCTRINE

Water allocation generally is governed by state law in the West. Variations of the prior appropriation doctrine provide the foundation of most western water law. Briefly, a person acquires the right to use some quantity of publicly owned water by diverting it to a beneficial use on a fixed tract of land (the ''water duty''). The priority of the right is established by the date of first diversion. During water shortages, the longest-term (senior) appropriators receive their full water duties until no water remains at the source. The water rights of shorter-term (junior) appropriators are curtailed completely. Water that is not beneficially used is forfeited and available for re-appropriation by another person (''use it or lose it'').

The prior appropriation doctrine ideally protects water-right holders from encroachment by other water-right holders taking water out-of-priority or enlarging their rights in a manner not prescribed by statute. This protection depends on the security of complicated interrelationships or ''use-dependencies'' created among water users due to the fugitive nature of water resources. Actual consumption of water (''consumptive use'') in irrigation is often less than the full amount diverted from the stream (''diversion''). Unconsumed water may return to the stream (''return flow''). Return flows, along with natural stream flows, supply water available for appropriation by other irrigators, and thus constitute a portion of their water rights. Appropriators who modify water use from that prevailing when their water rights were granted may shift the timing, location, quantity, or quality of return/escape flows, and consequently may impair other use-dependent water rights.

CONFLICT

The extent to which federal environmental programs such as the ESA authorize federal regulators to disrupt state-created appropriative water rights is controversial. At one extreme, some observers contend that such programs establish ''federal regulatory rights'' that empower the federal government to ''cancel the historic *de facto* assignment of property rights in commons to exploiters and reassign them to the government as agent for the public generally.'' (See Ref.[5], p. 3.) At the other extreme, some federal courts have held that the federal government must defer to state-created water rights in the absence of explicit congressional intent to pre-empt them.[6]

So far, the federal government has not used the ESA as authority to establish a new brand of ''federal regulatory rights.'' However, it has curtailed state-created water rights under two sections of the law. Federal agencies supplying or distributing water to private irrigators have curtailed state-granted water rights for varying lengths of time in compliance with a Section 1536 consultation with the listing ESA agency. For example, the U.S. Forest Service shut down irrigation ditches operating on agency land in the Methow Valley in Washington State for much of the 1999 irrigation season.[7] In another example, the U.S. Bureau of Reclamation cut-off water to 90% of the 220,000 acres in the Klamath Project in Oregon for much of the 2001 irrigation season.[8] The potential for further curtailment of state-granted water rights under Section 1536 consultations is great because the Bureau of Reclamation is the largest supplier and manager of water in the West.[1]

The federal government also has relied on Section 1538 (banning the taking of listed species by private parties) to threaten the curtailment of state-created water rights of irrigators using non-federally developed or delivered water. For example, NMFS officials warned the Methow Valley Irrigation District that water would be cut-off during the 2002 irrigation season for about 250 irrigators unless the district switched to a more efficient, fish-friendly means of distributing water.[9]

The Methow Valley and Klamath Project water curtailments, and the ensuing losses to the local agricultural economy, understandably have generated substantial ill-will toward the federal government among irrigators, irrigation districts, rural communities, and state governments. For example, the Klamath Project curtailment is estimated to have cost farmers approximately $200 million in lost crops.[10] Business in local communities also has suffered.[10] The prospect of these losses drove about 100 irrigators to risk arrest when they ran an irrigation line to divert water around a canal head gate that the federal government had closed to protect listed fish in Upper Klamath Lake.[11] Could the federal government avoid such confrontation by evolving toward the extreme of deferring to state prior appropriation statutes to satisfy ESA mandates? Unfortunately, the prior appropriation doctrine is not designed to protect aquatic habitat, and thus would be an ineffective replacement for the legal protection that endangered species receive under the ESA.[12] Non-diversionary water uses were not recognized as beneficial uses when traditional appropriative rights were being locked into irrigated agriculture in the late 19th and early 20th centuries. Consequently, irrigated agriculture currently has priority regardless of how little water remains for non-diversionary uses. For example, Wilkinson noted that, under the prior appropriation doctrine, the most senior water-rights holders need not share the water with emerging new water needs, but can ''with impunity, flood deep canyons and literally dry up streams, as has happened with some regularity.'' (See Ref.[13], p. 21.)

Are there policies available for protecting endangered aquatic habitats while mitigating adverse impacts on state-created water rights? Economists have long recommended water marketing as a means of shifting water from prior appropriative uses to competing private and public uses. Unfortunately, while most state water statutes permit public interest groups to purchase water rights for the purpose of augmenting instream flows, state protection of such rights from appropriation by other water-rights holders generally is difficult. Moreover, states impose moderate to severe limits on water transfers to protect third-party water-rights holders from impairment due to changes in return flows. Perhaps the best policy for accommodating endangered species protection and state-created water rights is the use of specialized water transfers designed to limit the extent and duration of impairment to use-dependent rights. Examples are ''trial transfers'' (transfers that can be modified or revoked if actual impairment results), ''one-time temporary transfers'' (transfers whose short-term nature makes injuries short-lived), and ''contingent transfers'' (transfers that occur intermittently and are triggered only by some predetermined contingency such as instream flow below some critical level).[12,14]

Irrigated Agriculture: Historical View

Lyman S. Willardson
Department of Biological and Irrigation Engineering, Utah State University, Logan, Utah, U.S.A.

INTRODUCTION

There is no known record of the beginning of irrigated agriculture. It was most likely started on a very small scale by someone trying to keep a wilted plant alive by pouring water on the soil around its base. Then, ways were found to keep more plants supplied with water when they were remote from the water supply. However, carrying water from a spring or a stream to supply many plants is heavy work. By scraping small furrows from a stream to the plants, irrigation could be practiced with a greatly reduced labor input. The practitioners soon realized that they could produce more food by keeping an adequate supply of water available to their plants at all times. The availability of more food from irrigated plants meant that more people could live in a smaller area and communal living could be practiced. Communities could grow into cities and cities could grow into nations. When governments were organized, public resources were available to construct the necessary infrastructure to supply water to all suitable lands. It is certain that irrigation became a necessity as population increased in arid or semiarid areas. In many areas, the season of limited rainfall corresponds to the season of maturity of food crops. If the crops are short of water at that time, yields are severely depressed. It therefore became important to develop irrigation systems that could supply water to crops in seasons of rainfall shortage. With irrigation, it is possible to grow crops in areas of very low rainfall or areas where nearly all the precipitation falls in the non-growing season. Irrigation is a means of taking advantage of the productive capacity of suitably fertile soils which lack only adequate water for crop plants in their normal growing season.

IRRIGATION IN ANCIENT TIMES

One of the earliest written records of irrigation practice was found in the Code of Hammurabi.[1] Various translations of the Code exist that include references to laws related to irrigation. Irrigation in Babylonian times was very important. One article in the law says "If the irrigator neglects to repair his dyke, or leaves his runnel open and causes a flood, he has to make good the damage done to his neighbor's crops, or be sold with his family to pay. The theft of a watering-machine, water-bucket, or other agricultural implement was heavily fined." This law was in effect in approximately 1750 B.C.

Another famous historical irrigation development occurred between the Tigris and Euphrates rivers in what is modern Iraq. A very large civilization developed in that area and then disappeared. Originally, it was thought that the developing population denuded the watersheds and the canals filled with silt from erosion of the watersheds, making continued irrigation impossible. It is more likely that a rising water table in the area caused salinization of the soils being irrigated. The loss of food production on the salt-affected soils caused the civilization to disappear. Another possible explanation is that the area was overrun by conquerors who had no appreciation for the need to maintain the irrigation systems. The irrigation works were allowed to deteriorate until they could no longer feed the population.

In a book, copyrighted in 1898 by King,[2] the author reported extensive irrigation developments in many areas of the world. He references a paper presented by Mr. Frederick S. Gipps before the Royal Society of New South Wales in 1887 claiming that the first authentic lake or reservoir was Lake Maeris. It was constructed by King Maeris or King Amenemhet III of the 12th Dynasty in 2084 B.C. Water was stored at the time of flooding on the Nile to relieve some flooding and was later released back into the river. Sesostris in 1491 B.C. built many canals in Lower Egypt for irrigation and transportation. Egypt claims the world's oldest dam[3] built in about 3000 B.C. The Phoenicians, about 1100 B.C.[2] were irrigating the "African shore" and had gardens and large plantations "abounding in canals." The Bible mentions many ditches in Second Kings 3:16–17.

In more modern times, the Romans built extensive aqueducts to supply water to cities. They therefore had the technology necessary to develop and transport water for irrigation and food production. The valley of the Po River in Italy is currently irrigated with many old, if not ancient, canals.

China[2] also has some ancient irrigation works on a grand scale. The Great Imperial Canal has a length of more than 1000 km (650 mi) and connects two rivers. The canal even crossed some lakes on elevated dikes.

One of the most significant democratic institutional arrangements in the history of irrigation is the "Tribunal of Waters,'' which still exists, after more than 1000 yr, in the irrigation districts of eastern Spain.[4] Each Tribunal, which consists of locally elected canal presidents, meets at a fixed time every week to hear farmers' complaints about water use offenders and applies appropriate sanctions.

When the Spaniards began their conquest of Mexico and Peru, they found irrigation being practiced on a relatively large scale. In the ruins of older cities, they found evidence of irrigation canals that had long been abandoned. In Peru, in a district named Condesuyos, they found a comprehensive canal that passed through a number of basins and had a length of approximately 600 km.

In recent historical times, as engineering and science progressed, irrigation was practiced extensively in many of the countries of Europe, not considered to be arid or even semiarid. Much of the irrigation water was applied to pastures. Water wheels were used to lift water out of streams. By 1800, the total irrigated area of the world was about 8 million ha.[5]

The British, during their commonwealth period in the late 1800s, developed large irrigation systems in the areas that are now India and Pakistan. Water was diverted from rivers and carried in large canals for long distances. Many wells were also developed to irrigate localized areas. More than 2,000,000 ha were brought under irrigation. In Ceylon (Sri Lanka) at the same time, irrigation systems consisted of a system of tanks (reservoirs) that served as small an area as one farm. Runoff water from rainstorms was captured, stored, and used in times of water shortage, primarily for irrigation of paddy rice. Irrigation was just beginning in southeast Australia, which was under British rule during this same period. By 1900, the total irrigated land in the world was about 48 million ha.[5]

Extensive irrigation in the United States of America began in the mid-1800s in the West. At that time, there was limited irrigation of small gardens by native Mexicans living in the southern area of California. When the Mormons migrated from the humid east and central part of the United States and the rainfed areas of Europe to the arid valleys of the Rocky Mountains, the settlers found themselves in a low rainfall environment that would not support agricultural crops without irrigation. With limited information about irrigation gained from explorers of the West, they began diverting water from perennial streams onto the soil to make it possible to plow, cultivate, and plant food crops. Diversion of water from natural streams became a common practice and new settlements were established wherever there was a dependable water supply. The arid west was settled rapidly and extensively and a modern civilization was quickly established, based on irrigated agriculture. Ancient civilizations grew as a result of irrigation. Western American civilization developed based on irrigation. Without irrigation, the arid western United States could only support a limited population of hunters and gatherers.

As the number of settlers in the West increased, the competition for water increased and it became necessary to determine how the water should be divided equitably among the potential users. Some crops needed more water than others and some soils needed more frequent irrigation to keep plants growing properly. New laws had to be developed specifically for management of the limited water supply. The system of law defining Riparian Water Rights, common to humid areas, gave legal use rights to the landowner touching the streams. This law was not appropriate for water-short areas where the water had to be taken away from the stream to non-riparian land. A new system of water law, called Prior Rights, was developed. The doctrine of prior rights states that first in time of use is first in right and that beneficial use of the water determines the right. The first person to use the water has a legally superior right to use the water and can maintain that right as long as he uses the water beneficially. Since the land was essentially worthless without a water right, water rights normally were sold with the land.

The establishment of the Land Grant University system by President Abraham Lincoln in 1862, gave emphasis to the development of agriculture. In the arid and semiarid areas of the country, agriculture depended on irrigation water management. Universities in those areas gave special emphasis to research on soil–plant–water relations. This information was very important to the effective and efficient use of water. In ancient times, water was applied to the soil until the irrigator felt that the soil was wet enough. He also learned that too much water was damaging to the plants. His only means of applying water was to carry water to the individual plants or bring the water from the source in a small ditch or furrow. He could also build a small dike around an area containing plants and flood irrigation water into the resulting basin. Rice can be irrigated by continually flooding it in a basin area. From ancient to modern times, the majority of the irrigation taking place in the world is by surface irrigation methods. Irrigation that uses the soil surface to transport as well as absorb the water is called surface irrigation. As a result of research, mostly at land grand universities, irrigation water can now be applied using mechanical systems. The water is transported in pipes and is applied to the soil using sprinklers or drip-irrigation systems. Surface irrigation, to be successful, requires a lot of hand labor and the good judgment of the irrigator. Mechanized irrigation can be accomplished by complete automation, including the decisions of when to irrigate and how much water to apply.

Irrigation on a large scale developed in the American West soon after the passage of the Reclamation Act in 1902. The U.S. Bureau of Reclamation of the U.S. Department of the Interior, backed by the U.S. Government financing, was able to build large dams that provided water for reclaiming many western desert lands. In recent years, controversy[6] has arisen over the environmental changes caused by using rivers to generate electric power, to supply water to remote cities in other drainage basins, and to make desert lands agriculturally productive, rather than leaving the rivers in their natural ecological state. Similar objections have not been raised in India, Pakistan, and China where there are even larger expanses of irrigated land.

CONCLUSION

There is an International Commission on Irrigation and Drainage headquartered in New Delhi, India. This organization maintains statistics about irrigation and encourages more efficient and effective use of irrigation water. There are 25 countries in Africa, 16 in the America, 29 in Asia and Oceana, and 28 in Europe that have significant areas under irrigation. In the year 1998, there were more than 271 million ha of land being irrigated in the world. At least 22 persons depend, in some degree, on the food produced on each hectare of land irrigated in the world. Irrigation plays a more important role in food production in the modern world than it did in the ancient world. During the 21st Century, most of the world's increased food supply will have to come from the higher agricultural productivity of existing irrigated lands.

INTRODUCTION

Water management improvements in an irrigated valley improve productivity, reduce the environmental impacts of irrigation, enhance the environment of rivers, and usually provide additional water that can be used for other purposes. Long-standing traditional beliefs are that water cannot be saved by improving water management in an irrigated valley. These beliefs are shown to be based upon erroneous assumptions. Improving water management increases yields, area affected by waterlogging and salinity is reduced, return flows and salinity are lowered, and water saved in the reservoir improves the environment of the river when released. Organizations and individual actions need to be changed for successful water management improvements.

Irrigated agriculture plays an important role in food production. Commonly, irrigated agricultural production averages nearly twice the production of rainfed agriculture per unit area. Actually, effective irrigated agriculture easily produces 3–5 times rainfed production. The reduced level of average production under irrigation is a measure of the inadequacy of performance of irrigation.

The Food and Agricultural Organization (FAO)[1] has shown that water shortages are currently an issue in many countries. By 2030, these shortages will cause serious food shortages in many countries. Therefore, a key strategy for irrigated agriculture is to develop water conservation programs to conserve and enhance water supplies and substantially increase productivity worldwide.

IRRIGATION WATER MANAGEMENT STATUS

Irrigation water management practices need significant improvement worldwide.[2,3] Fig. 1A shows an irrigated valley with major waterlogging and salinity problems caused by poor water management practices. Fig. 1B shows evaporation from standing water and excess evapotranspiration from crops supported from a high water table. Poor or non-functioning drainage systems also cause excess evapotranspiration as shown in Fig. 1C. Water use for irrigation is often 2–4 times as much as good management achieves. Encroaching salinity and waterlogging remove millions of hectares from production each year. Worldwide, the irrigated area severely or moderately affected by waterlogging and salinity equals 30% of the irrigated area, and it increases by 1–2% per year.[1] Poor water management practices throughout an irrigation project cause the waterlogging and salinity. With high water tables, from 15% to 85% of the rainfall plus irrigation supplied can evapotranspire. Evaporation and evapotranspiration losses from waterlogged areas represent a major source of water that can be conserved. Thus, water management improvements to increase productivity, reduce the impacts of waterlogging and salinity, and conserve water supplies are urgently needed practices.

Farm Water Management Assessment

Crop yields under irrigated agriculture can be assessed using many different strategies. Comparing average yields to record yields for a country or an irrigated valley is one strategy for assessing the potential yields. Often, average yields are one-third to one-fifth and even less of the record yields.

Causes of these lower yields are varied. Basic to yield improvement under surface irrigation is a precision-leveled field especially when level basins are the field system. Level basins should be within 15 mm of the average elevation for good water management and to achieve potential yields. Because fields are usually designed and leveled by farmers, most are not adequately leveled. Over application of water to fields or parts of fields is often the major factor causing waterlogging in irrigation projects. Farmers in Pakistan were thought to use lower than recommended levels of fertilizer. More careful evaluation showed

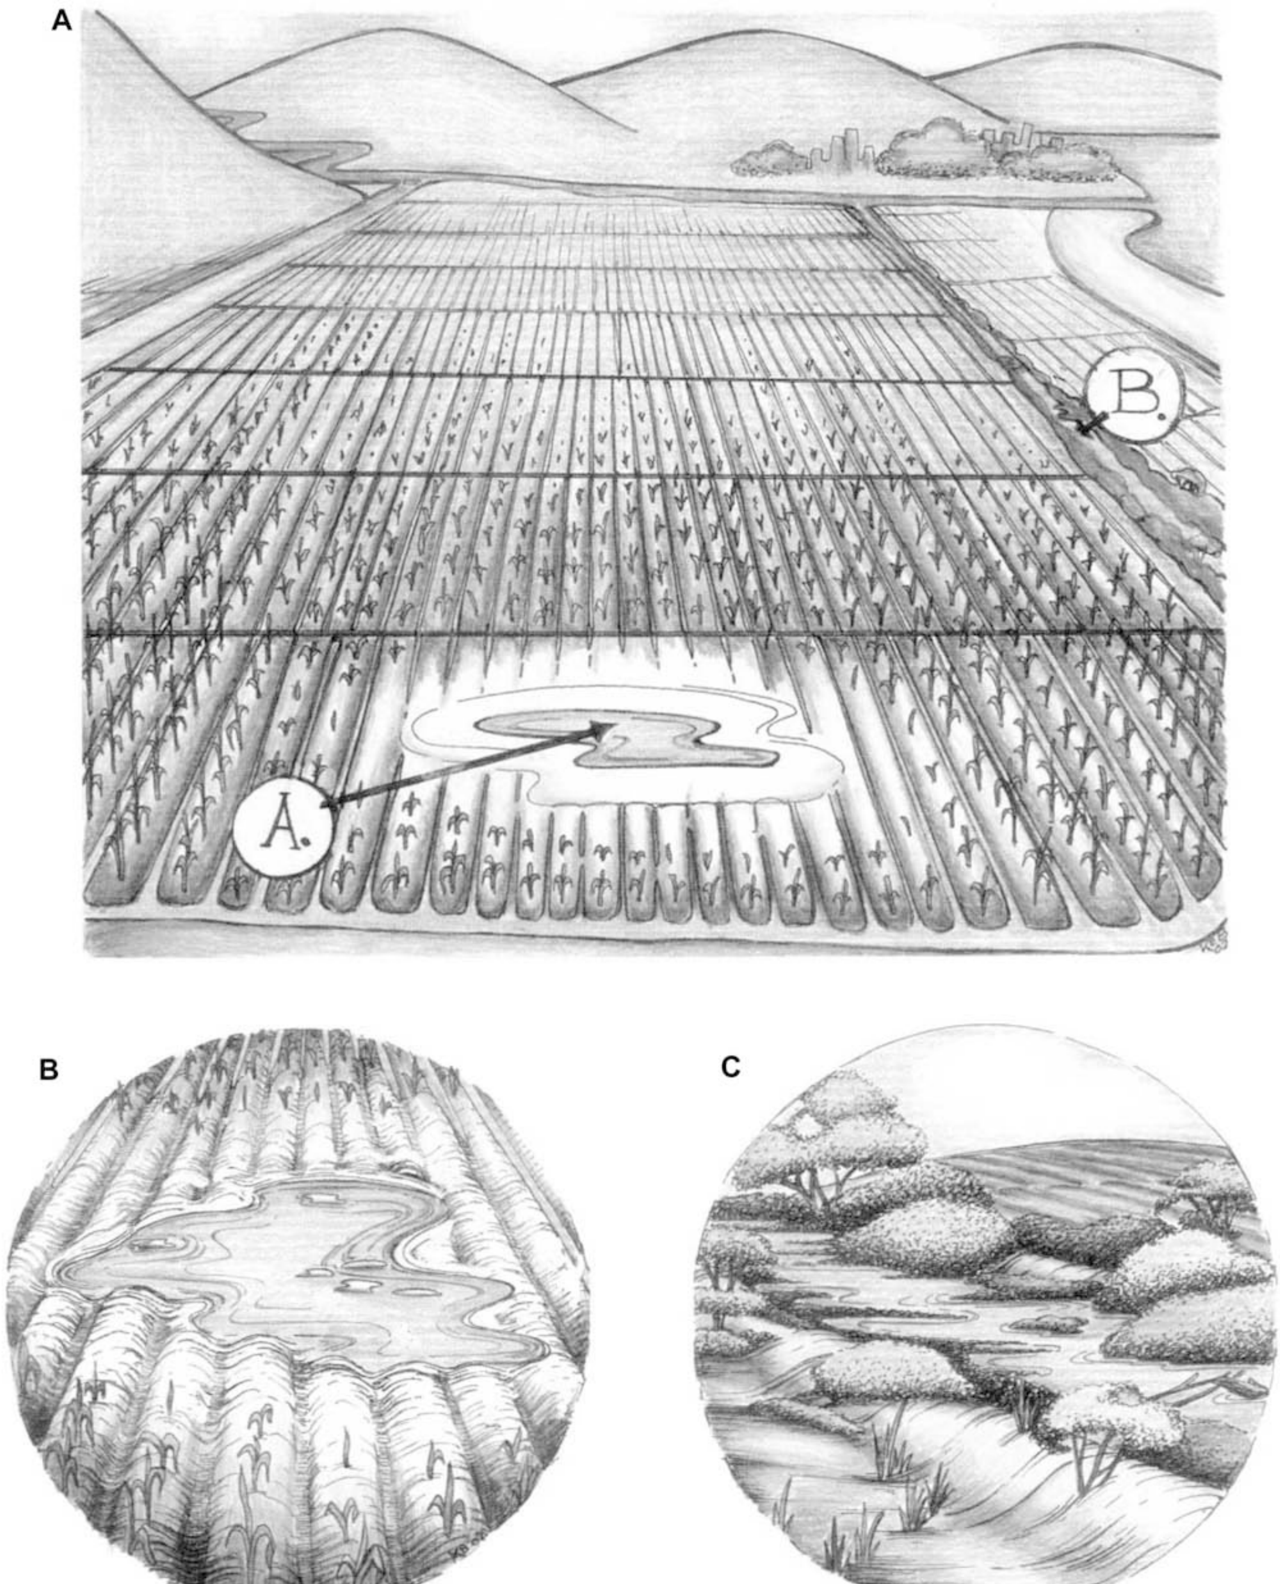

Fig. 1 (A) Irrigated valley with waterlogged area and poorly defined surface drainage system. (B) Waterlogging and salinity is an integral part of irrigated agriculture in most projects and the water evaporated or evapotranspired is a non-beneficial use. (C) Drainage systems for many irrigation projects cause non-beneficial use and reduce return flows. *Source*: From Ref.[12].

that the level of fertilizer used was near the optimum for the fields' potential yields.

Studies in several countries have shown that precision leveling (precision conventional leveling or laser leveling) with appropriate inputs contributed to many-fold yield increases while water requirements were reduced substantially, often by half or even more. Thus, water management improvements at the field level increase productivity while reducing the water required for irrigating the field. Water management and input improvements generally increase yields sufficiently to more than pay for the services when quality service is provided at an effective cost with credit available when needed. Productivity improvements and increases in the effective use of water supplies are often the highest priorities for a country.

Delivery of Water Supplies

Field studies in irrigation projects around the world have shown that adequacy, dependability, and equity are important, but often unattained, goals of water delivery. Canals and watercourses usually do not provide a target discharge of necessary duration for farmers to irrigate adequately. Undependable water supplies can cause farmers not to plant any crop, or to use traditional seeds with little or no fertilizer instead of high yielding varieties with adequate fertilizer. They also may not follow appropriate cropping practices, and limit the use of adequate weed and pest controls.[4] Therefore, undependable water supplies often create greater constraints on productivity and potential productivity than just those caused by inadequate water. Assessments of productivity in canal commands in many countries have shown that yields under undependable, inadequate water supplies are fractions of adjacent fields with dependable, adequate water.[4]

Farmers irrigate too frequently and apply too much water when supplies are undependable but available. They use the water when available because experience has taught them that it may not be available when they next need to irrigate. Frequent irrigations cause excess evapotranspiration and increase waterlogging. Inadequate water supplies reduce actual yields, and teach farmers that investments in inputs for higher yields are not profitable. Studies in India showed that the intensity of cash value crops was directly correlated with distance from the canal outlet with the type of crop grown determined by water supply.[5] In Nepal and Sri Lanka, when farmers were not adequately advised about expected water supplies, they planned for inadequate water supplies as described earlier.

Every extensive water distribution system studied had head to tail inequities in the adequacy and dependability of water supplies. Inequities in water delivery have been measured in India, Egypt, Sri Lanka, Nepal, Pakistan, Thailand, Somalia, and the United States of America to name a few countries. Upper reaches of most delivery systems or branches with influential farmers often have three or more times the target water supply while those at the end of the canals, laterals, and watercourses receive half or zero of the target.

Water Quality Management

Irrigation water management in recent decades has focused on salinity management—now urgently needed. Irrigating a field supplies water to be used by the crop through evapotranspiration. Since the water changes to vapor as it leaves the soil or plant surface, the salts it carries remain in the soil. All irrigation leaves salts in the soil that must be controlled by adding additional water. The additional water travels through the rootzone and removes salts by a process called leaching. The excess water becomes deep percolation that goes to groundwater or to a substratum. Some excess water, carrying the leached salt, often travels to the river as return flow. Additional salts can be in the return flow because the groundwater was more saline to start with or because the substratum had excess salts that were added to the water. Sometimes, natural return flows to the river are not sufficient and rapid enough, and drainage must be provided to remove the excess water and salts. Erosion of the fields during irrigation may cause sediment pickup. Erosion damages the irrigated fields, and the sediment may damage lands and waterways where the sediment is deposited. Sediment that remains in suspension in the water limits the value of the water for reuse.

Return flows from irrigation may also contain nitrogen, phosphorus, and other agrochemicals, used to control weeds or pests, from agricultural operations that contaminate the water for other uses. Small amounts of selenium, boron, or other elements toxic to plants (and humans) in low concentrations may also limit the value of the return flows for subsequent irrigation or other uses. Excess chloride, which causes foliage damage when the water is used in sprinkle irrigation, can be a serious problem especially on vegetable crops. Excess sodium in the irrigation water may cause difficulties with infiltration of the water into soils and thus limit the usefulness of the water. Reductions in water quality lower the value of water or increase the costs of using the water.

Traditional Views of Water Management

Water conservation is a widely misunderstood concept. Placed in an irrigated valley context, even greater misunderstandings exist. First, many believe that improving low irrigation efficiencies automatically make large amounts of water available. They believe the conserved water is available for the improved farm, the irrigated valley, or other water uses as an additional water supply. This understanding is not valid when the excess water returns to the river. The value assigned to the water saved must be reduced by the value of the return flows for reuse.

Second, another common misunderstanding, shared by the public and many professionals, is that water conservation has almost no place in irrigated valleys. They believe water can be conserved only when direct flows to salt sinks, such as saline water bodies and the ocean, are prevented. This view is supported by often erroneous assumptions that 100% of the excess irrigation water is available and 100% of this available water returns to the river as return flow.[6] The reduced value of the return flow caused by reductions in water quality is often not considered. This concept seriously hampers efforts to reduce the impacts of waterlogging and salinity and control the environmental effects of irrigation. A more balanced concept for achieving water conservation in an irrigated valley is the focus of the following section.

SUSTAINABLE WATER MANAGEMENT FOR IRRIGATED AGRICULTURE

Sustainable water management must achieve effective water management improvements and manage to limit salinity impacts. Institutional and attitudinal changes are essential to achieve such improvements.

Sustainable Water Management

A farmer irrigating a field is the focus of water management improvements. Reducing the volume of water required for irrigating the field is the objective. Water not supplied for irrigating the field is water saved. Water not released from a reservoir or diverted from the river is water conserved. When the reduced supply for irrigation results in reduced return flows to the river, then an appropriate volume of the saved water may be made available to replace the reduction in return flow. Water released to replace return flows was conserved because the water has a greater value since it was not used initially for irrigation. The remaining water is available for reallocation, whether in reservoir or groundwater storage, or is continuing flow in the river. Water available for reallocation can be allocated for other uses such as industrial, municipal, environmental, or even irrigation.

Water available for reallocation comes from reduction of non-beneficial evapotranspiration within the irrigation project. The water conserved also can result from water supplies stored in groundwater systems or from returns to the river with major increases in salinity that materially reduces the value of the water. Water seriously contaminated when used for irrigation by one of the previously defined contaminants also can be conserved. Excess irrigation water that returns to salt sinks, such as the ocean or saline water bodies, also can be conserved.

Water conservation accomplished by improving water management that reduces non-beneficial evapotranspiration, as an example, is now illustrated for a waterlogged irrigation project. Table 1 summarizes approximate data for an irrigation project in the central part of the Punjab in Pakistan.[7] Within the irrigation project, beneficial use comes from crop evapotranspiration. Non-beneficial use comes from areas waterlogged, areas with a high water table that increases evaporation at the soil surface, poorly leveled fields with low areas where standing water evaporates, and poor drainage systems. Water is available for evaporation at the potential rate when water stands on the land surface as in a waterlogged area.

Total water supply is an important variable and rainfall is important particularly in monsoon climates. With the lower water supply (Table 1), waterlogging developed from irrigation in Pakistan over more than a 100 yr period because water losses persisted although the total water supply was less than potential evapotranspiration. Eighty-six percent of the lower water supply is lost to non-beneficial evapotranspiration (Table 1) when waterlogging developed. When water supplies were increased because dams were completed, waterlogging continued because beneficial and non-beneficial uses did not exceed the water supply. With the high water supply, as much as 34% of the total water supply is lost (Table 1). The key point is that large volumes of the water supply are lost through non-beneficial evapotranspiration. These data do not

Table 1 Depletion of total water supply from non-beneficial evapotranspiration from a waterlogged area in an irrigation project

Waterlogged area (%)	Total water supply (irrigation + rainfall) ($m^3 m^{-2}$)	Depletion (%)
15	0.63	42
30	0.63	86
15	1.69	16
30	1.69	34

Project area is 500,000 ha, annual potential ET is 1.88 $m^3 m^{-2}$, irrigation water supplies are 0.16 $m^3 m^{-2}$ and 1.22 $m^3 m^{-2}$, and rainfall is 0.47 $m^3 m^{-2}$.

Hydrologic–Irrigation

assess the impacts of unlevel fields, and ineffective drainage systems. Improving water management can achieve major results through water conservation by eliminating non-beneficial uses.

Water Quality Management

Irrigated agriculture is not sustainable unless salinity is managed. A strategy for improving management of salinity should include reducing leaching fractions to a minimum.[8] This strategy is consistent with the water management improvement focus because when irrigation efficiencies are 40% or less, then attempting to target a 5% or less leaching fraction is not appropriate. Lower leaching fractions reduce the total salts that return to the river in return flows, and may sometimes precipitate some salts before they enter the river.[9] More careful control of leaching can precipitate salts below the rootzone and minimize the pick up of salts from saline strata.

A useful strategy is to use good quality irrigation water to grow salt sensitive crops such as lettuce. Then, as salinity increases down an irrigated valley, to grow more salt tolerant crops such as wheat and cotton, and further down the valley even more tolerant crops such as barley.[8] Continuing to use water from the river for irrigation that increases in salinity reduces the return flows to the river and lowers the volume of saline water that must be managed for disposal. Evaporation ponds and pipelines to salt sinks such as the ocean are appropriate disposal alternatives.[8] These strategies for managing salinity are a key part of the water management improvements for increased water conservation.

A critical need is a system for costing and valuing changes in water quality. Traditionally, reductions in water quality are neither assigned a cost nor are improvements in water quality assigned a value. Keller, Keller, and Seckler[10] suggested that return flow volumes be reduced by the volume of additional water required for leaching because of the salinity increases in the return flow. While this is an important step, the result is an inadequate approach for costing and valuing increases in salinity, and does not evaluate other important quality changes. A strategy for costing and valuing water quality changes is further described.

The amount of water used to replace the reduced return flows from water conservation should be based upon an effective volume or value assessment. Clyma and Shafique[6] suggest that the effective value of the return flow be determined. Then, the reduction in return flow is replaced by a volume from storage that equals the reduction in effective value caused by water conservation, if any. Keller and Keller's[10] approach does not consider reductions in yield or crop changes that result from increased salinity, or other reductions in value such as lifting costs for pumping. Clyma and Shafique[6] allow for increased value of the replacement water and decreases in value from salinity, energy costs, impacts of other contaminants, and other factors. An important consideration is the trade-offs between water stored in a reservoir, water in groundwater storage, and return flows that vary in amount and the time when available in the river.

The valley water management strategy starts at the farm with improvements in water control that cause water applied to approach crop needs and minimum leaching requirements. Using minimum leaching requirements does reduce salt loads. Minimum return flows also reduce the total salt load in the river but may increase the concentration of salts in the return flows. Salinity increases down the river are reduced because of the lower total salts. Water releases from the upstream reservoir or remaining in the river provide additional flow volume for the river further reducing salinity in the river. Additional good quality water is made available for subsequent canal commands. When the return flow salinity reaches a critical level approaching zero value for the return flows, then disposal of the water from evaporation ponds or with a pipeline to the ocean or another salt sink can be considered. Such a management strategy approaches achieving a permanent irrigated agriculture.

Institutional and Attitudinal Changes

Farmers change their water management when they understand and experience the value of change. Supporting organizations and their professional personnel must appreciate the changes needed to enable them to support farmers in accomplishing such changes effectively. Institutions must modify their policies and programs to define and then support farmer needs for change. Then, they must support personnel that effectively provides the needed support to farmers.[11] Changing individuals and organizations—farmer, private, and local, county, state, and federal units—is difficult but can be successfully accomplished.[11] Changes to water laws will often be needed if water is to be conserved. Farmers must benefit financially when water conservation increases the effective water supply. Water banks, begun recently in some Western States in the United States, offer some of the changes needed. Water rights in many countries will need major redefinition.

CONCLUSIONS

Water management improvements provide major opportunities for increasing productivity, reducing the environmental impacts of irrigation, and increasing water supplies by accomplishing water conservation. Poorly managed water supplies and field irrigation limit productivity and create major increases in waterlogging and salinity. Water quality for irrigation decreases down a valley further reducing productivity.

Water management improvements reduce the amount of water required to irrigate a field. Water not supplied to the field is water saved. When return flows are reduced because of improvements, water saved can be released to replace the return flows. The remaining water saved is water available for reallocation. It is available for a variety of uses such as industrial, municipal, environmental, or even expanded irrigation.

Improvements in water management reduce waterlogging and salinity. Because leaching volumes are reduced, total salt returning to the river is often reduced. Water released to replace return flows further improves the quality of water in the river and provides more water for fish and wild life at an improved quality. Careful management may achieve a permanent irrigated agriculture.

Irrigated Agriculture: Social Impacts

Gaylord V. Skogerboe
Utah State University, Ogden, Utah, U.S.A.

INTRODUCTION

Ancient hydraulic civilizations had absolute power, including strong organizational coordination and complete control of resources, elaborate postal communication and intelligence networks for social control, along with the dominant religion being under the authority of the state.

In sharp contrast, small indigenous farmer-managed hydraulic societies have existed for centuries in many countries. These irrigation systems are operated by using democratic principles wherein all farmers participate in managing their system.

During the past century, the world's irrigated land has increased fivefold, but there will be limited expansion in the future. These systems are commonly managed by government agencies. But, water scarcity will require that some of the irrigation water supplies be transferred to meet increasing municipal and industrial water needs. In order to feed growing populations, much higher levels of irrigation water management will be required. This will necessitate transferring these government-managed irrigated systems to farmers so that they become more self-reliant and innovative. To significantly increase crop yields with less water requires: 1) a clearly defined water rights system; and 2) sustainable farmers organizations.

NATURE OF SOCIAL IMPACTS

The degree of productivity in irrigated agriculture is highly dependent upon the degree of cooperation among farmers and with the individuals responsible for managing the irrigation system. In addition, each farmer is impacted by the actions occurring upstream, such as unreliable water deliveries and water theft. Farmers who are more self-reliant are more likely to maintain their irrigation facilities. Cooperation and independence also foster innovations that lead to increased agricultural productivity, possibly more employment and better health. The dominant factor impacting these traits is the type of social organization employed for managing an irrigation system.

Worldwide irrigated agriculture has grown from 8 Mha in 1800 to 48 Mha a century later,[1] with the United Nations[2] estimating 255 Mha in 1995, which is most likely an overestimate. More importantly, the amount of irrigated land is expected to increase very little in the future. About 17% of the world's agricultural land is presently irrigated, which accounts for about 40% of the world's food production.[2]

For the future, planners place heavy emphasis upon 75% or more of increased food production coming from irrigated agriculture. A good case has been made[3] for doubling the productivity of water in order to feed 8 billion people within the next three decades, while protecting the world's ecosystems. With increasing water scarcity in many global locations, some of the present irrigation water supplies must be transferred to meet future urban and industrial water demands. This will necessitate much higher levels of water management, with a major emphasis on significantly improved social organization of irrigation systems in many parts of the world.

CENTRALLY-ADMINISTERED HYDRAULIC CIVILIZATIONS

Wittfogel[4] reports on the administrative management of numerous irrigation systems around the globe, but especially Asia, over many thousand of years. Small-scale irrigation is called a "hydraulic society," while a large-scale and government-managed irrigation network is a "hydraulic civilization." There are three paramount characteristics of a hydraulic civilization: 1) involves a division of labor; 2) intensifies cultivation; and 3) necessitates cooperation on a large scale.

Hydraulic civilizations used corvee forced labor, which was conscripted on a temporary, but recurring, basis. In Imperial China, every commoner family was expected on demand to provide labor for hydraulic and other public services. The writings of India, as well as the Incas and Aztecs, indicate a similar claim on corvee labor.

In terms of social control and natural resources development, the master builders of hydraulic civilizations had no equal in the non-hydraulic world because of control over the entire country's labor and materials. The dispersed castles of Medieval Europe are clear evidence of feudal society, just as huge administrative cities and colossal palaces, temples and tombs of Asia, Egypt, and ancient America express the organizational coordination and resources mobilization of the hydraulic civilizations.[4]

Administrators and officers were placed in all major settlements, which virtually everywhere assumed the character of government-controlled administrative and garrison towns. In addition, almost all hydraulic civilizations enhanced their power by elaborate systems of postal communication and intelligence, which became a formidable weapon of social control. The masters of the empire in China combined state roads and man-made waterways in establishing a postal and intelligence system that lasted for more than 2000 yr, but with some disruptions.[4]

The government of a hydraulic civilization was an integral part of the irrigation management bureaucracy, with the dominant religion being closely attached to the state. Nowhere in hydraulic civilizations did the dominant religion place itself outside the authority of the state as a national or international autonomous church.[4] This formidable concentration of vital functions gave the government its genuinely absolutist power, where its rule was not effectively checked by non-governmental forces.

Egypt was an important deviation. The central government imposed a tax on the farmers of 10–20% of their harvest, but the administration of the irrigation system remained local.[3] An observation[5] is that "Egypt probably survived for so long because production did not depend on a centralized state; the collapse of government or the turnover of dynasties did little to undermine irrigation and agricultural production at the local level."

INDIGENOUS FARMER-MANAGED HYDRAULIC SOCIETIES

For many centuries, farmer-managed irrigation systems (FMISs) have existed at various locations around the world. In Asia, the systems in Nepal, Thailand, and the Philippines have been partially investigated. The social organizational arrangements are a sharp contrast with the despotic hydraulic civilizations described previously.

Two-thirds of the irrigated agriculture in Nepal is farmer-managed; mostly, these thousands of systems are autonomous, self-governing entities ranging in cultivated area from 10 ha to 15,000 ha. A comparative study of 21 FMISs has been reported,[6] along with institutional arrangements consisting of social organization and property rights in water.[7] These irrigation organizations perform tasks of water acquisition, water allocation and distribution, resource mobilization (people and tools), system maintenance, decision-making, communication, and conflict resolution.

Decisions regarding irrigation water management are made by the irrigators as a whole at their annual meeting, where the farmers review the performance of the previous year, audit and settle accounts, decide on the plan and program for each major task, and elect officeholders. An irrigation management committee is elected to carry out the decisions of the general body of irrigators. Remuneration to committee members often consists of cash or kind, but sometimes nothing.

Resource mobilization (such as channel cleaning and replacement of low-cost structures that failed due to floods), may be based on the size of landholding, water shares, water outlet size, village units, or the number of households in the command area. Water allocation may be based on the size of landholding, labor contributions for maintenance, original investment, water shares, or the type of land. Water distribution needs intensive supervision, particularly when the water supply is barely sufficient to meet the crop needs.

When traveling throughout Thailand, it is readily apparent that the best agriculture occurs on roughly 2000 small FMISs located in the North (two-thirds of cultivated area), where irrigation has been practiced for at least 700 yr. A 10-yr multidisciplinary study of five FMISs[8] shows there is a high degree of acceptance among the farmers of the water rules and regulations, which in earlier times were considered sacred because they provided rice for everyone; thus, water theft was considered a severe crime against society.

In Thailand, the farmer leaders for a FMIS receive much respect because they are trusted by the farmers, which results from the leaders diligently doing what they promised, along with being very fair in their dealings, and placing a strong emphasis on bettering the community. These traits result[8] in equitable water distribution.

GOVERNMENT AGENCY-MANAGED IRRIGATION SYSTEMS

From the mid-19th century through the 20th century, about three-fourths of the developed irrigated lands are administered by government irrigation agencies. Majority of these irrigation systems in developing countries are not properly maintained, so they are unable to increase agricultural productivity for feeding a growing population. Rehabilitation is often considered a remedy, but usually results in another costly cycle of improvement and decay with no long-term benefits.[9] There is a growing perception that these public irrigation agencies lack the incentives and responsiveness to improve management performance and that a management system which is more accountable to farmers will be more equitable and responsive.

The argument can easily be made that farmers under these agency-managed irrigation systems (AMISs) are oppressed. Certainly, they have limited control of their destiny. They are not organized for administering their irrigation system, and they do not have meaningful water rights. Increasing agricultural productivity over time is highly dependent on farmers being empowered so that they become more self-reliant and innovative, thereby benefiting socially and economically from their ingenuity.

SELF-RELIANCE AND INNOVATION

The degree of independence and innovation demonstrated by the farmers in an irrigation system is a good indicator of social impacts. A healthy agricultural environment relies on farmers being innovative, which in turn is dependent upon farmers being able to benefit socially and economically from their inventive behavior. A major goal of agricultural development should be to establish an institutional environment that strongly supports innovations by farmers.

In order for farmers to become more confident, a highly participatory approach is required from all types of agricultural support services. Farmers must not only be treated as equals, but they must be recognized as the local experts. Thus, the attitudes and behavior by those individuals providing support services is crucial to successful agricultural development. The most underutilized resource for improving irrigated agriculture, the farmers, can only be effectively strengthened by using participatory approaches that strongly emphasize farmers first.[10]

The most significant determinant of self-reliance will be the degree that farmers manage their own irrigation system. Farmers recognize the significance of controlling the entire canal network, including the canal headworks. This can be readily envisioned for relatively small irrigation systems, but farmer management is even more important for the much larger canal systems such as encountered in China, India, and Pakistan.

INSTITUTIONAL EMPOWERMENT

The major lesson from past hydraulic civilizations, numerous FMISs over many centuries, as well as Australia, Canada, and the American West in the last 150 yr, is that locally managed irrigation enterprises are to be preferred for long-term sustainability. The critical ingredients to highly productive agriculture for such systems are having the power to assess the beneficiaries for making improvements, along with water rights to encourage long-term investments. The success of irrigated agriculture requires fitting many pieces of the puzzle together, including social cohesion, but certainly institutional measures should lead, not follow technology, in this continual struggle for progress.

CONCLUSION

Entering the 21st century, there were about 25 countries experimenting with the transfer of irrigation system management from government agencies to farmers, which is encouraging. This is a time-consuming task requiring decades. The American West generally required three decades, or more, to develop effective irrigation institutions.

The necessity for doubling the water productivity of irrigated agriculture over the next three decades is strongly dependent upon enhancing the social impacts by having a clearly defined water rights system in each irrigated region, as well as sustainable farmers organizations as measured by: 1) equitable water distribution throughout the irrigation system; and 2) farmers feeling free to report offenders (such as stealing water) and their organization is capable of applying sanctions.[11]

Irrigated Water: Market Role in Reallocating

Bonnie G. Colby
Department of Agricultural and Resource Economics, University of Arizona, Tucson, Arizona, U.S.A.

INTRODUCTION

Market transactions are an important strategy for responding to water scarcity and the conflicts among water users, communities, and governments that can be stimulated by water scarcity. This article outlines the policy and economic issues raised by water markets, drawing on several decades of experience with marketing water in the western United States.

WHY HAVE MARKETS DEVELOPED?

Market acquisitions of irrigation water rights are increasingly common worldwide in regions where existing water supplies are fully appropriated and development of new supplies is costly. Those needing additional water must bid supplies away from current water users, primarily irrigators. In the American West, urban growth, environmental disputes, and Native American water claims, all create incentives for acquisition of agricultural water supplies and a few active regional markets have developed. While market acquisitions of additional water supplies often are essential to economic development, they also are the subjects of controversy and complex regulatory systems exist to govern market transactions in water.

A water market consists of the interaction of individuals and organizations which buy, sell and lease water rights, use of water supplies, and access to water-related infrastructure (canals, pumps, reservoirs). The degree of market activity varies among and within the western United States in terms of numbers of buyers and sellers, frequency of transactions and prices. Only a few areas have well-developed water markets with many transactions occurring every year. In other areas, sales of water rights largely involve water exchanges among neighboring farmers, transactions occur sporadically and price information is difficult to obtain. The Southwest generally is perceived to be the most active region of the United States, with respect to market activity, although drought in the Pacific Northwest is stimulating transactions there.[1]

In the western United States throughout the 1900s, water development projects diverted vast amounts of water from streams in order to irrigate crops. Water quality, recreation, and wildlife benefits associated with water left instream were largely unacknowledged, as were Native American claims to water. Irrigation districts, farmers, ranchers, and towns were accorded property rights in the resource.

Water supplies are renewed by nature in a stochastic and seasonal manner so that policymakers and water users cannot predict river flows far in advance. This uncertainty has prompted investment in infrastructure to store and convey surface water and to recharge groundwater so that supplies are available in a more predictable manner. Public and private expenditures to reduce variability in water supplies have been immense. Federal subsidies for irrigation projects in the western United States have covered approximately eighty percent of the capital costs of providing irrigation water to farm lands receiving water from federal projects.[2,3]

The West's economic transition from ranching, irrigated farming, and mining to urban growth, services, tourism, and industry has brought strong pressure to transfer water out of agriculture. Agriculture still accounts for 85–95% of water use in most western states, and the cost of reducing irrigated acreage so that water can be available for other uses generally is far less than the cost of developing new water supplies. Western U.S. cities pioneered water marketing by purchasing irrigated land, sometimes entire irrigation districts, to acquire water rights for urban development.[4] While urban growth still is the driving force behind water markets, water transfers to support wildlife, fisheries, and recreation have become more common.[5] Transfers have become more complex and innovative in order to respond to drought, and to environmental and community concerns.

PUBLIC GOODS AND EXTERNALITIES

The term "public good" refers to resources characterized by non-excludability, meaning it is difficult or impossible to exclude those who do not pay from enjoying the benefits of the resource. Water for recreation and wildlife habitat provides public benefits for which beneficiaries cannot readily be charged a user fee. Streamflows also provide public good benefits through dilution and water quality enhancement. Many individuals who benefit from streams and wetlands may be "free riders," enjoying these resources but making no payments—because payments are not required. Due to non-excludability and free rider tendencies, market transactions alone are unlikely to ensure that adequate flows remain in streams to preserve habitat, water quality, and recreational opportunities. Therefore, public agencies sometimes assume the task of protecting streamflows.

Water transfers can generate externalities, including reduced water supplies for other water right holders, diminished economic activity in areas from which water is taken, lower river flows and degradation of water quality, fish and wildlife habitat, and recreation. While water transfers create positive externalities in the area to which water is being moved, it is the negative impacts that create controversy and pressure to carefully regulate transactions.

Western U.S. state laws specifically exclude some parties who may experience significant externalities from formally objecting to water transfer approval. In general, only water right holders can force their concerns to be accounted for. Recreationists and environmental advocates typically have little bargaining power in the regulatory process. Broader access to property rights in water and to the transfer approval process can allow a wider array of externalities to be considered.

MARKETS AND LITIGATION: COMPLEMENTARY FORCES

Voluntary transfers of water are not the only mechanism used to move water out of agriculture. Complex legal proceedings, termed adjudications, are taking place in many areas to quantify and prioritize the competing claims of Native Americans, wilderness areas, cities, and farms. Litigation based on the Endangered Species Act, the Clean Water Act, federal reserved rights and the public-trust doctrine has successfully forced reallocation of water to enhance streamflows for recreation, fish, wildlife, and water quality. Voluntary and involuntary pressures for reallocation often work in a complementary manner. There is no incentive quite so effective in stimulating voluntary transfers as the looming threat of a protracted and costly court battle. The threat of judicial and administrative reallocations has provided impetus for numerous voluntary reallocations among parties embroiled in conflicts over water.[6]

DEVELOPING COST EFFECTIVE POLICIES

The key challenge in developing policies to govern water markets is to utilize the flexibility that markets offer, while protecting third parties and public interests that can be impaired by water transfers. The complex nature of water rights and the changing social values associated with water make instantaneous, faceless and standardized transactions in water improbable and undesirable. Nevertheless, market incentives should play a significant role in water allocation; to move water to uses where it generates higher economic returns and to give water users incentives for efficient water use. A "command and control" bureaucratic allocation system is undesirable due to its inflexibility as new demands arise and water values change. While government policies must play a primary role in evaluating proposed water transfers to prevent uncompensated third party impacts, bureaucracies should not dictate how much water must be used by whom and for what purpose.

Every western U.S. state imposes conditions on water transfers and there is no "free market." Market transactions sometimes resemble complex diplomatic negotiations rather than commodity exchanges. Regulatory policies generate uncertainties and costs for transferors and these costs sometimes are perceived as unnecessary impositions on the market. However, public policies should not necessarily seek to minimize the cost of reallocating water because appropriately structured transaction costs may facilitate efficient reallocation, by giving transacting parties an incentive to account for social costs of transfers.[7]

Transaction costs are the costs of making a market system work. In western U.S. water markets, parties incur transaction costs in searching for water supplies, contacting willing buyers and sellers, ascertaining the characteristics of water rights, negotiating price, and obtaining legal approval for the proposed change in water use. This latter category of transactions costs can include attorneys' fees, engineering and hydrologic studies, court costs, and fees paid to state agencies.

Transaction costs incurred to comply with regulatory policies reflect the substantial and multiple economic benefits associated with water in various uses, benefits which can be impaired by a transfer. Transactions costs are an important issue in western water reallocation. If the costs of implementing a water transfer become too high, many beneficial transfers will not take place and water supplies will remain locked into suboptimal use patterns. On the other hand, the ability to impose transactions costs on those proposing to transfer water represents bargaining power in the water allocation process. Some transaction costs are necessary, justified by the need to better account for externalities and public goods. Transaction costs also reflect the absence of "free" information and the need for hydrologic, legal, and economic data to address externalities in an efficient manner (see Ref.[8], for a detailed discussion of balancing transactions costs and consideration of third-party impacts).

CONCLUSION

In summary, market transactions are an essential response to water scarcity. Without the flexibility provided through voluntary transfers, water supplies would remain locked into outdated patterns of use. Markets allow water to move permanently out of agriculture and to be leased to alleviate temporary scarcities (as during drought). Water scarcity creates tensions worldwide and voluntary transactions are one important strategy for addressing such conflicts. However, to provide flexibility and increased economic returns from regional water supplies, markets must be governed by policies that carefully weigh the advantages of a proposed transfer against externalities, impairment of public goods, and the concerns of affected communities and governments.

INTRODUCTION

In the past decade, water-soluble polyacrylamide (PAM) was identified as an environmentally safe and highly effective erosion preventing and infiltration enhancing polymer when applied in furrow irrigation water at 1–10 mg L^{-1}, i.e., 1–10 ppm.[1–9] Various polymers and biopolymers have long been recognized as viable soil conditioners because they stabilize soil surface structure and pore continuity. The new strategy of adding the conditioner, high molecular weight anionic PAM, *to irrigation water* in the first several hours of irrigation implies a significant costs savings over traditional application methods, in which hundreds of kilograms per hectare of soil additives are tilled into the entire (15 cm deep) soil surface layer. By adding PAM to the irrigation water, soil structure is improved in the important 1–5 mm thick layer at the soil/water interface of the 25–30% of field surface contacted by flowing water.[7]

In 1995, the U.S. Natural Resource Conservation Service (NRCS) published a PAM-use conservation practice standard for PAM-use in irrigation water.[10] A 3-year study[2] applying these standards showed that PAM at dosage rates of 1–2 kg ha^{-1} per irrigation eliminated 94% (80–99% range) of sediment loss in furrow irrigation runoff, while increasing infiltration 15–50%. Seasonal application rates using the NRCS standard typically total 3–5 kg ha^{-1}.

As PAM-use is one of the most effective and economical technologies for reducing soil-runoff, it has branched into stabilization of construction sites and road cuts, with formal statewide application standards set in Wisconsin and several southern states. Recent studies with biopolymers such as charged polysaccharides,[11–14] whey,[15] and industrial cellulose derivatives[11,14] introduce potential biopolymer alternatives to PAM.

POLYACRYLAMIDE

The term polyacrylamide and acronym "PAM" are chemistry jargon for a broad class of acrylamide-based polymers varying in chain length, charge type, charge concentration, and the number and types of side-group substitutions.[16–20] Typically, PAM for erosion control is a charged copolymer with one in five acrylamide chain segments replaced by an acrylic acid entity (Fig. 1), which generally exhibits a negative charge in water. Molecular weights of PAM used for irrigated agriculture range from 12 million g mol^{-1} to 15 million g mol^{-1} (over 150,000 monomer units per chain). As a result of its structure, PAM attracts soil particles via coulombic and Van der Waals forces.[11,17,21,22] Ionic bridging creates large stable aggregates of PAM and soil, in which charged entities on both the polymer and multiple soil particles are thought to interact with the aid of calcium counterions.[11,22–24] Chain bridging further stabilizes aggregates, whereby the long polymer chain spans between separate soil particles. Despite their large size, PAM copolymers used for erosion control are formulated to dissolve in water, although this sometimes requires vigorous agitation.

PAM Erosion Control

Lentz and Sojka[2] reported a 94% reduction in runoff sediment loss over 3 yr using the NRCS application standard.[10] The 1995 NRCS standard calls for dissolving 10 ppm (or 10 g m^{-3}) PAM in furrow inflow water as it first crosses a field—typically the first 10–25% of an irrigation duration—then halting PAM dosing when runoff begins. Under many circumstances, applying PAM continuously at 1–2 ppm for the full irrigation cycle can be equally effective, although continuous application at 0.25 ppm PAM was a third less effective.[25–27]

PAM and Infiltration

The infiltration rate of PAM-treated furrows on medium to fine textured soil is usually higher than untreated furrows—typically 15% higher than for untreated water on silt loam soils and up to 50% higher

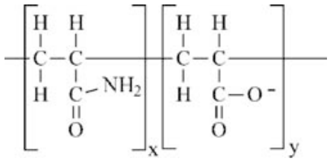

Fig. 1 PAM: Poly(acrylamide-co-acrylic acid).

on clays.[28] Bjorneberg[29] reported that in tube diameters >10 mm, the PAM–water viscosity did not rise sharply until the PAM concentration in the water was >400 ppm. However, in small soil pores, "apparent viscosity" increases significantly, even at the low PAM concentrations used for erosion control.[30] Most likely, PAM infiltration effects are a balance between prevention of surface sealing and apparent viscosity increases in soil pores.[30–34] In medium to fine textured soils, maintenance of pore continuity via aggregate stabilization is more important. In coarse textured soils, where PAM achieves little pore continuity enhancement, infiltration effects are nil or even slightly negative, particularly above 20 ppm.[28]

Because PAM prevents erosion of furrow bottoms and sealing of the wetted perimeter, water moves about 25% further laterally in silt loams compared to non-treated furrows.[1,2] This can be a significant water conserving effect for early irrigations. Farmers should take advantage of PAMs erosion prevention to improve field infiltration uniformity by increasing inflow rates two to threefold (compared to normal). This reduces infiltration opportunity time differences between inflow and outflow ends of furrows.[28,35]

Sprinkler Application of PAM

Farmers and agronomists are showing interest in PAM for sprinkler irrigation.[5,6,36–40] PAM may prevent runoff/runon problems and ponding effects on stand establishment and irrigation uniformity. Polyacrylamide sprinkler application rates of 2–4 kg ha^{-1} reduced runoff 70% and soil loss 75% compared with controls.[36] However, the effectiveness of sprinkler-applied PAM is more variable than for furrow irrigation because of application strategies and system variables that affect water drop energy, the rate of water and PAM delivery, and possible application timing scenarios. Multiple groups[6,36–40] report improved aggregate stability from sprinkler-applied PAM, leading to decreased runoff and erosion. Flanagan, Norton, and Shainberg[5,6] increased sprinkler infiltration with 10 ppm PAM, which they attributed to reduced surface sealing. Polyacrylamide effects under sprinkler irrigation have been more transitory, less predictable and have usually needed higher seasonal field application totals for efficacy. However, farmers with sprinkler infiltration uniformity problems (runoff or runon), e.g., with center pivots on steep or variable slopes, have begun to use PAM. Testimonials claim that PAM-use improves stands because of reduced ponding, crusting and damping off (a plant seedling disease complex).

ENVIRONMENTAL IMPACT OF PAM

The overriding environmental impact of PAM is reduced erosion-induced sediment runoff,[1,2] with corresponding reductions of entrained chemical residue reaching riparian waterways.[41–43] For example, PAM prevents yearly topsoil runoff of up to 6.4 tn acre^{-1}[2] and at least three times that as on-field erosion.[34] Since toxic pesticides and herbicides are transported via soil sediment to open water and then eventually into the air there is an increasing need to prevent soil-runoff. Recently, PAM was shown to sequester biological and chemical contaminants of runoff, providing significant potential for reduced spread of phytopathogens, animal coliforms, and other organisms of public health concern.[44,45]

The main environmental concerns in PAM-use revolve around polymer purity,[46,47] and issues related to biodegradation/accumulation;[48–53] i.e., since PAM degrades slowly, the long-term, unknown effects on organisms must be considered. Biological degradation of PAM incorporated into soil is about 10% per year.[50] However, low application rates and shallow surface application is thought to accelerate degradation via various pathways, including deamination, shear-induced chain scission, and UV photosensitive chain scission.[50–53] Even at 10% annual degradation, PAM accumulation is insignificant at these application rates. Sojka and Lentz[26] showed that only 1–3% of applied PAM leaves fields in runoff and that this is quickly adsorbed by entrained sediment or ditch surfaces. Barvenik[16,50] noted that anionic PAM is safe for aquatic organisms at surprisingly high concentrations, with LC_{50} > 50 times the inflow dosage rates. Water impurities further buffer environmental effects by quickly deactivating dissolved PAM.

Care must be taken by PAM supplies to ensure polymer purity, since the acrylamide monomer (AMD) used to synthesize PAM is a neurotoxin. The EPA recently reviewed the use of PAM with USDA and PAM industry scientists, and concluded that the AMD concentrations of <0.05% found in products for use during furrow irrigation are acceptable, with minimal amounts of monomer released into the environment.[26,53] The first step in the biodegradation of PAM is early removal of the amine group from the polymer backbone,[46,47,54–56] with reversion to AMD thermodynamically unfavorable.[53] Although these environmental issues about PAM are raised, PAM is widely recognized as a safe, environmentally friendly, hygenically safe, and cost-effective flocculating agent. It has been used industrially for decades as a soil conditioner, in food processing, and in various water treatment processes.

BIOPOLYMER ALTERNATIVES TO PAM

PAMs successful use in irrigation water to reduce erosion and improve infiltration has raised questions of whether it is the ''best'' polymer for the application. There is increasing anecdotal and scientific evidence[57,58] that PAM efficacy varies with different soils and waters. Variations include sodicity, texture, bulk density, and surface charge-related properties. It would be beneficial to have a wide array of polymers with potentially different soil-stabilizing mechanisms, applicable to different soil types.

Of course, any reduction in price would also benefit farmers. The market price of PAM, i.e., several dollars per kilogram, is high relative to many commodity polymers, such as polyethylene, polypropylene, and polystyrene. Treatment for 1 year can cost up to $25 per hectare, which is still cost competetive with conventional erosion abating technologies such as straw bales, settling ponds, and underground or drip irrigation systems.

The increasing market pull of organic farming techniques is a strong reason to explore alternatives to PAM. Polyacrylamide cannot be used during organic farmering because it is a synthetic polymer derived from non-renewable resources. Natural polymers, which often degrade via relatively benign routes, may be more suitable. Biopolymer alternatives to PAM would likely have marketing advantages due to public *perception* of being safer.

Cellulose and starch xanthates were among the first industrial biopolymers shown to stabilize soil.[11,14] Menefee and Hautala[14] reduced sediment runoff by nearly 98% by surface treating 20° sloped plots with cellulose xanthate solution (0.4%). Orts, Sojka, and Glenn[11] added cellulose xanthate to the irrigation water of lab-scale mini-furrows, and reduced erosion 80% when xanthate was applied at concentrations of 80 ppm or greater, which is well above the standard PAM application rate of 10 ppm and even 5 ppm.

Chitosan, the biopolymer derived from crab and shrimp shells, was shown to reduce erosion losses as effectively as PAM in lab-scale mini-furrow at concentrations of 20 ppm.[22] With such favorable lab test results, chitosan was further tested in a series of field tests at the USDA Northwest Irrigation and Soil Research Lab, Kimberly, Idaho.[22] In the field tests, chitosan reduced erosion-induced soil losses by, at best, half of the control, but far less effectively than PAM. Such poor comparative results, however, do not mean that chitosan had no effect on the irrigation. Observations of the furrows treated with chitosan revealed remarkable results in the first ~20 m of the furrow. In fact, chitosan acted as such an effective flocculating agent that it removed fine sediments, and even algae from the irrigation water. Perhaps chitosan binds so readily with sediment that it flocculates out of solution near the top of the furrow. The major drawback of chitosan is its market cost of over $\$3\,kg^{-1}$, roughly twice the price of PAM.

Hydrologic–Irrigation

CONCLUSION

U.S. agricultural PAM-use for erosion control and infiltration improvement reached 400,000 ha in 1999,[59] with U.S. and worldwide markets expected to grow as farmers recognize PAMs efficacy, and as government-mandated water quality legislation is realized. The success of PAM in agriculture opens the possibility to explore other Ag-related uses for PAM,[45] as well as the potential to find alternatives to PAM. For example, modified polysaccharides[11–14] and cheese whey, the protein concentrate from cheese processing, are particularly interesting natural soil stabilizers, and could be used to treat irrigation water.

Irrigation Design: Steps and Elements

Gary A. Clark
Department of Biological and Agricultural Engineering, College of Engineering, Kansas State University, Manhattan, Kansas, U.S.A.

INTRODUCTION

In general, the primary objective of most irrigation systems is to provide water to a crop to meet the evapotranspiration demands in the absence of rainfall. While irrigation systems can be used for other purposes such as chemigation, cold protection, or heat stress relief, this discussion will focus on the design steps and elements associated with the objective of meeting crop water requirements.

An irrigation system typically includes a pump, various pipes, valves, and water emission or discharging devices such as sprinklers or drip emitters. Fig. 1 shows an example layout that could apply to a sprinkler irrigation or microirrigation system with a control head that shows many of the components that may or may not be used. The inclusion of filters or strainers and chemical injection systems will be dependent on the type of irrigation emission devices used, and characteristics of the water quality. In the design process, these components along with the other pipes and valves are sized, arranged, and connected together using a variety of fittings to create a working system that will transport water from a supply source to the water storage system (soil, potting media, etc.) for a crop in an efficient, timely, and cost-effective manner. Because many design scenarios are possible, the designer must be knowledgeable about the land or field characteristics, the cropping system, the water supply, the pipeline hydraulics, and the operational characteristics of different irrigation systems and associated components. While design texts and other references are available[1–8] and provide much greater detail and background on the design process, this discussion provides an overview of the elements of the irrigation system design process and recommended steps to follow. As an additional reference source, standards[9–13] have been developed to assist the designer with recommended practices and procedures for system design and evaluation.

INITIAL ASSESSMENT

The initial stages of the design process require some basic knowledge of the various elements that will influence the design and operation of the irrigation system. Thus, an initial assessment should be conducted to answer the following general questions:

1. What is the intended use and desired goal for the irrigation system? While many irrigation systems are used to meet the full, supplemental irrigation requirements of the crop, other systems are used to make reasonable use of limited water supplies. Another aspect to assess is whether the system is to be dedicated to a single field within a production season, or if the system needs to be portable.
2. Where is the water source located; what is the availability of the water source; and what is the quality of the water source?
3. What are the characteristics of the land area that is to be irrigated as well as climatic conditions of the geographic region?
4. What are the production system characteristics of the crop (or crops) that is (are) to be grown and irrigated, and what is the crop value?
5. Are irrigation supplies and services locally available?

With answers to the above questions, the designers use their engineering and general knowledge to synthesize the information into rough drafts of one or more design scenarios that can be presented to the client. During this initial phase, the designer and the client meet and discuss the proposed design scenarios identifying additional desired outcomes or system constraints that may be subsequently incorporated into a new design scenario. After an acceptable design scenario is identified, the more formal steps of the design process are conducted. The following sections discuss the elements of design and selection of components as influenced by the water source, field and cropping system characteristics, and the water supply system.

WATER SOURCES—QUANTITY AND QUALITY

The design process must include an assessment of how much water is available from the source for use (quantity and capacity or rate), and then to quantify how

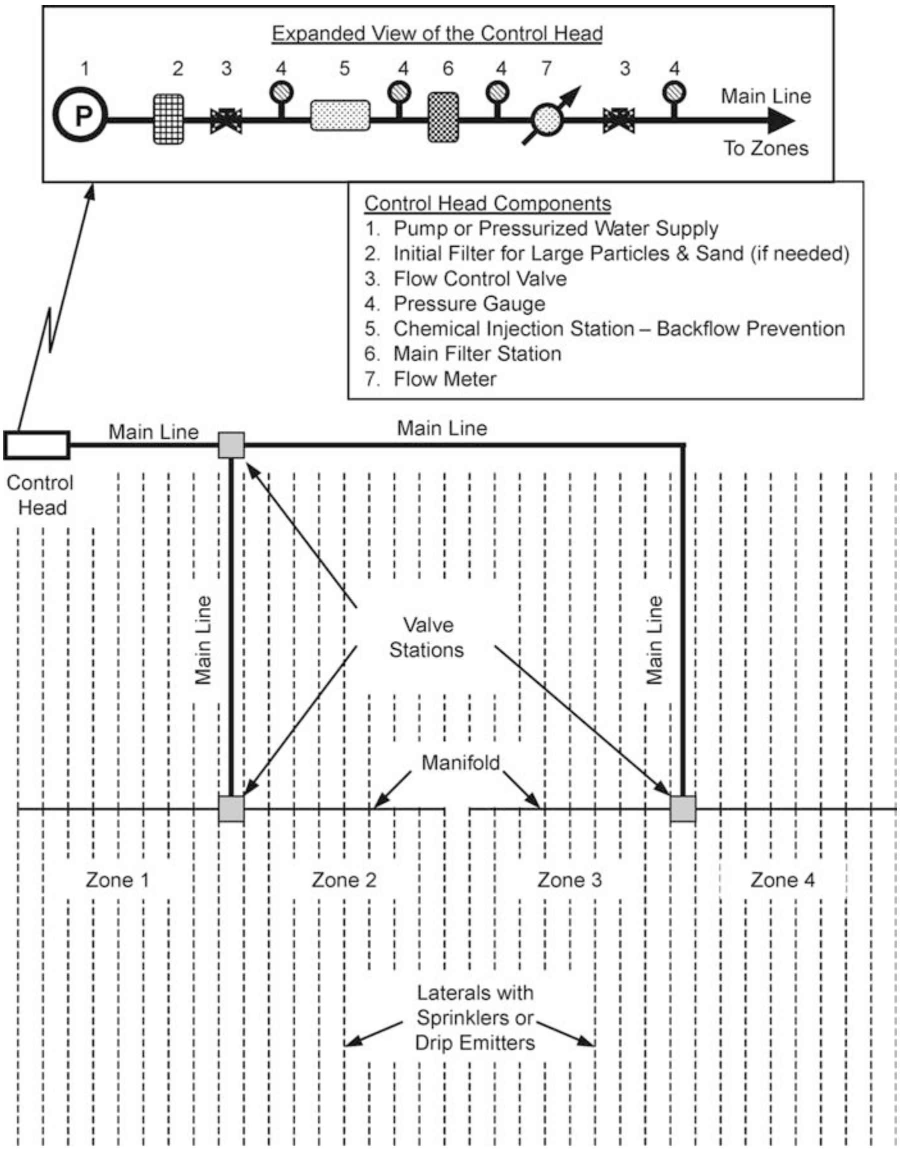

Fig. 1 General layout of a solid-set sprinkler irrigation system or micro-irrigation system showing the control head and associated components, main supply lines, manifold supply lines, and lateral lines that would contain sprinklers, microsprinklers, or drip emitters.

much water is needed or must be used for the desired goal. The total quantity of available water will depend on applicable laws or allocation procedures and the size and physical characteristics of the source. Water availability limitations, use restrictions, ownership, and uncertainty in water supply amounts will influence the total irrigated area, the irrigation scheduling decision process, and perhaps the choice of components and ''permanency'' of the system. For example, a limited water supply may be used to adequately irrigate a limited irrigated area or may be used to ''deficit'' irrigate a larger crop production area. While most irrigation systems are designed for long-term use (>10 yr) on a single site, some systems may have some ''portability'' included into the design in order to accommodate uncertainty in a local water source or land-lease agreements. These situations are not necessarily the norm, but can provide some unique and challenging design scenarios.

The following equation represents a basic mass balance approach and is used to determine any one of the components given the values of the other three.

$$(Q_{\mathrm{sys}})(T_{\mathrm{c}}) = C(A)(I_{\mathrm{gr}}) \tag{1}$$

where Q_{sys} is either the flow rate of the irrigation system or the water system supply rate from the source (L/sec); T_{c}, the operational time (hr) of the system per cycle or period of time needed or desired to apply I_{gr}; A, the size of the area to be irrigated (ha); I_{gr}, the gross depth of irrigation water that is to be applied (mm) as a daily or seasonal amount and must correspond to T_{c}; and C, a constant of proportionality to adjust and properly cancel the units in the other four variables ($C = 2.78$ for these SI units).

The gross irrigation depth is related to the net irrigation depth, I_{net}, with the irrigation system efficiency as:

$$I_{gr} = \frac{I_{net}}{E_{sys}} \quad (2)$$

Irrigation system efficiency, E_{sys}, can range from as low as 20% to over 90% and characterizes water that is "lost" in the conveyance system (canals or pipes), the distribution system (sprinklers, emitters, orifices, etc.), and water that is lost in the field due to runoff and/or deep percolation below the root zone of the crop. The net irrigation depth, I_{net}, represents the amount of water that is needed for and directly useable by the crop. This may be expressed as the amount of water to refill the soil profile from a certain deficit level to the field capacity level, it may represent a daily peak or design evapotranspiration depth, or it may represent a seasonal (or specific time period) depth of water that is to be applied. For example, the last condition may represent the amount of water that needs to be applied from a lagoon to a cropped land area in a certain window of time, T_c. It may also represent the result of a seasonal water balance:

$$I_{net} = ET_c - P_e - ASW \quad (3)$$

where I_{net} is the seasonal net irrigation water requirement; ET_c, the seasonal crop evapotranspiration; P_e, the seasonal effective precipitation; and ASW, the available water in the soil profile at the beginning of the irrigation period that can be used by the crop during the irrigation period.

The quality of the water source must be assessed as to how physical, biological, and/or chemical constituents in the water may affect or interact with components of the delivery system (pump, pipes, valves, and emitters), the soil, and crop. Water treatment and amendment practices may need to be incorporated into the design to avoid clogging of certain irrigation components. The required level of treatment will depend on the quality of the water and the sensitivity of components to the various constituents in the water.

Water quality from both groundwater and surface water sources can range from excellent to very poor, and typical quality concerns include suspended solids, dissolved solids, and biological organisms. Poor well screening and/or well development problems can result in suspended sand, silt, or clay particles. Surface water sources may have suspended particles of silt and/or clay, aquatic plants, small fish, algae, larvae, or other organic debris. While these physical constituents can generally be controlled with proper filtration, chemical treatment may be necessary to neutralize related organic growths.

Dissolved solids such as calcium, iron, or other elements can precipitate under certain conditions and subsequently clog some microirrigation emitters. Biological growths include slimes (associated with iron and/or hydrogen sulfide), fungi, and algae. Such organic growths can grow within and clog pipelines, valves, and irrigation emission devices (sprinklers, drip emitters, etc.). Chemical treatment of the water is often necessary under these conditions in addition to filtration to prevent or "clean-up" these organic growths. Severe instances of several of the above water quality problems may require expensive remediation components and/or management practices to ensure proper and continual operation of the irrigation system. Because such conditions may result in a financially impractical design, or poor system performance or failure, a thorough assessment of the quality of the water source must be performed prior to completion of the final design.

Recycled water sources (municipal wastewater, livestock wastewater lagoons, industry wastewater sources) should be thoroughly assessed for their physical, chemical, and biological constituents. Key concerns will include pH, salts, nitrogen, and phosphorus. Some "contaminated" water sources may contain heavy metals or organic compounds that may be of concern when applied to agricultural crops and fields. Water application and/or loading rates may need to be assessed with respect to the concentrations of certain key elements or compounds in the water. Allowable water application amounts may not be sufficient to meet peak or design crop water demands and supplemental "clean" water sources may be needed to augment the water supply.

FIELD AND CROPPING SYSTEM CHARACTERISTICS

The site for the planned irrigation systems needs to be assessed for dimensions, topography, physical features, soil characteristics, and climatic characteristics. The size and shape of the field must be measured and include lengths of boundaries, interior angles of adjoining sides, and any on-site, physical obstructions (trees, power poles, buildings, etc.). Obstructions should be identified as to whether they can be removed. It is also beneficial to identify on-site or nearby electrical power sources. Because land slope and surface conditions influence the type of irrigation systems that can be used and the design of the selected system, those elements should be characterized. A contour map can be very helpful for these purposes.

Soil characteristics should include physical and chemical assessments. Soil texture in the surface and subsoil components of the profile influence water holding capacity and can also influence rooting characteristics of the crop. Surface conditions should be assessed for infiltration rates and subsurface conditions should be assessed for high water table conditions or restrictive soil horizons. A chemical analysis of the soil should be conducted to evaluate the pH, salinity, and nutritional characteristics.

Climatic conditions have several impacts on system selection and design. The utilization, selection, spacing, and placement of sprinklers and microsprinklers will be influenced by local wind characteristics of speed, duration, and direction. While most systems are designed to meet the evapotranspiration demands on the crop, some systems may have heat stress relief or cold protection incorporated into the design. For example, if a citrus irrigation system needs to be used for general crop evapotranspiration-based irrigation requirements and for freeze protection, then the entire field must be irrigated simultaneously rather than sequentially in zones. Thus the resulting pump system and pipe network must be substantially larger.

Irrigation is used for a variety of crops and cropping systems that include traditional field crops (corn, cotton, etc.), tree crops (citrus, apples, cherries, etc.), vine crops (grapes and other berries), vegetable crops (tomatoes, melons, etc.), ornamental plants (flowers, shrubs, trees, etc.), and turf (landscapes, golf courses, and commercial production). These crops have various heights, plant densities, row spacing, plant spacing, sensitivity to water stress, bedding or soil tillage practices, artificial or natural mulches, and other cultural practices. These characteristics need to be considered by the designer and incorporated into the design. In addition, crop value and irrigated yield potential will also influence the type and complexity of the irrigation system.

WATER SUPPLY SYSTEM

The water supply system includes a pump and a network of pipes, valves, and fittings (Fig. 1) to deliver water to the infield distribution system, which may be a center pivot system, solid-set sprinklers, microirrigation laterals, or other distribution devices. The pump has two primary purposes: 1) it moves water at a desired flow rate; and 2) it provides energy to the water. Eq. (1) was discussed and presented as a method to determine the required pump capacity (Q_{sys}). The energy requirements of the pump are often referred to as ‘‘pump head’’ and expressed in units of a height (m) of a column of water.

Required pump head has three components that include elevation head, friction head, and pressure head. Elevation head refers to the vertical elevation difference between the pumping water level and the level of the highest irrigation system outlet (sprinklers, etc.). As water flows through the pipes and other fittings, friction reduces the energy level of the water and is characterized as friction head. Finally, the irrigation system will have a specified water pressure for proper operation of the discharge devices and this is characterized using pressure head. Because most water-discharging devices provide different flow rates of water with respect to operational pressure, one of the design goals is to minimize pressure variations within the pipe network and to maintain variations within allowable design limits. Therefore, while the designer is sizing and configuring the main lines, header pipes, laterals, associated fittings and components, material costs, pipeline flow velocities, and pressure head variations due to elevation changes and friction head losses are also being computed and analyzed to achieve an economical, hydraulically balanced and uniform irrigation system.

CONCLUSION

Irrigation system design involves an assessment of the intended use and desired goal for the system; the location, availability, and quality of the water source; physical and climatic characteristics of the site; and production system characteristics of the crop. The designer sizes and configures the pump system, pipelines, water discharge devices, and the associated fittings and components into a system that will uniformly distribute water to meet the desired goals within the economic, cultural, and physical constraints associated with the site, the crops, and the production system. The final design and installed system should be evaluated to ascertain proper performance and operation.

ACKNOWLEDGMENTS

The author would like to acknowledge the following individuals for their mentorship, collaboration, and professional feedback, which have all contributed to his professional growth and development in the area of irrigation system design and management: Dr. Allen G. Smajstrla (deceased), Professor, Agricultural and Biological Engineering Department, University of Florida; Dr. Freddie Lamm, Professor, NW Research and Extension Center, Kansas State University; Dr. Dorota Haman, Professor, Agricultural and Biological Engineering Department, University of Florida;

Mr. James Prochaska, P.E., President, JNM Technologies, Inc.; Dr. Danny Rogers, Professor, Department of Biological and Agricultural Engineering, Kansas State University; Dr. Muluneh Yitayew, Associate Professor, Department of Agricultural and Biosystems Engineering, University of Arizona; and the many students, in the United States and abroad, who have participated in my irrigation system design courses, workshops, and seminars.

Irrigation Districts and Similar Organizations

David E. Nelson
Irrigation Engineering, P.E., Billings, Montana, U.S.A.

Anisa Joy Divine
Resources Planning and Management Department, Imperial Irrigation District, Imperial, California, U.S.A.

INTRODUCTION

Irrigation canal systems are typically managed either by a government agency or by an organization run directly or indirectly by irrigators. Organizations run by irrigators are often referred to as water user associations (WUAs). WUAs can be further divided into two major types: irrigation districts that are similar to local governments, and canal companies that are typically non-profit corporations. Irrigation organizations deliver water; drain excess water; construct, maintain, and improve the system; and collect fees. They develop plans and budgets, hire and manage employees, and are increasingly involved in environmental stewardship. They may provide water to urban, industrial, commercial, and environmental users as well as farmers.

IRRIGATION ORGANIZATIONS

Government Agencies

Worldwide, roughly half of all irrigation canal systems are managed by government agencies.[1] Often, this managing agency also designed and constructed the original canal and drainage system. Such an agency may be staffed with professionally trained employees who understand the system and the principles underlying its construction.

Although agency systems can be well managed, one or more of the following problems may develop. Agency employees, not being responsible to the users, may lack incentives to perform well. The agency may have more employees than needed. If insufficient fees or taxes are collected, the system may become a financial burden to the government. Sometimes income is diverted to activities other than managing the irrigation and drainage system. Finally, when an irrigation system is managed by a government agency, the irrigators often develop the attitude that ''it is the government's system'' rather than ''our system.''

Water User Associations

WUAs may be run directly by the users, or indirectly by people employed by the users or their representatives. A WUA can be created as a government entity (irrigation district), or a private canal company (typically a non-profit corporation). For legal recognition, an irrigation district or canal company may be required to have the support of more than half the landowners within its boundaries.

Irrigator-Controlled Government Entities

This type of WUA has the legal status of a local government and, in the United States, is called an irrigation district. In the United States, irrigation districts are organized under state laws. State laws are adapted to that state's conditions, and are often very specific as to how the district is to be run. Districts may establish their own bylaws, which further specify how they will be managed.

Irrigator-Controlled Canal Companies

A canal or ditch company is typically formed as a non-profit corporation under corporation laws. Irrigators own shares in the company, usually in proportion to the amount of irrigated land each owns. Canal company bylaws specify how the corporation will be managed. Canal companies generally have more flexibility in how they operate than irrigation districts because corporation law is less restrictive. Canal companies are similar to—or may even be—cooperatives because they are owned by and managed for the benefit of their members.

Informal Associations

Irrigators may also establish informal associations, without legal status. Informal associations use social pressure or refusal of water to ensure cooperation and support. Irrigators on agency-managed systems may form informal associations to represent their interests and promote changes and improvements.

Other Groupings

Combinations of organizational types may be found on large irrigation systems. For example, a government agency may be responsible for the dam, storage reservoir, and main canal, with water user organizations managing secondary and tertiary canals that make up the delivery system and the drainage system.

Sometimes WUAs establish a Joint Board of Control, comprised of representatives from each WUA, to manage the main canal. Such boards typically operate under a contract with specific provisions. Costs are shared by the participating organizations under the terms of a negotiated contract. WUAs may also contract with a private service company for system management.

Irrigation organizations in the same region often form larger associations to share ideas, make plans, solve problems, and provide input regarding government policy.

FUNCTIONS OF IRRIGATION ORGANIZATIONS

Water Delivery and Drainage

Water delivery is the primary function of canal system management. Each irrigator should receive a fair share of the irrigation water. Some organizations measure water deliveries at each farm turnout, whereas others measure water only at main sections or major laterals. Efficiency and flexibility are also major objectives, so that water can be delivered to crops at the proper time and in proper amounts.

A ditchrider patrols a section of a canal system and distributes water to the users in that section. Ditchriders are commonly required to keep written records of their water deliveries, to promote fairness in water distribution and to protect the organization from unfair complaints or lawsuits.

Sometimes drainage water is managed by a separate agency. However, the water delivery organization usually has this responsibility.

Maintenance

The physical system used to deliver irrigation water and to remove drainage must be adequately maintained. But frequently, this is not the case. When systems are built, maintenance needs are low for the first few years, so organizations are slow to develop good maintenance programs. Even after a program is established, maintenance is often postponed in an effort to remain within the organization's budget. Three guidelines can help prevent this from happening:

1. Separate operating funds from maintenance funds.
2. Devote some staff entirely to maintenance.
3. Establish specific annual maintenance goals, such as rehabilitating or replacing a specific number of structures (based on the total number of structures and their average useful life), and cleaning a specific length of canals and drains.

Finances

Ideally, all irrigation organizations should be financially self-supporting, but many rely on external sources of funds.[2] Usually, irrigators are charged assessment fees, which vary in proportion to the area they irrigate, the amount of water they receive, or a combination of both. If fees are not paid, water delivery is terminated. In some systems, voting is not allowed until all fees have been paid. Penalties may be charged for failure to pay fees on schedule.

Systems managed by government agencies often have difficulty collecting irrigation assessments because irrigators regard the system as belonging to the government. In some cases, irrigators invest time and effort to obtaining government subsidies rather than paying their fair share, often resulting in systems that are inadequately financed and poorly maintained.

Irrigation organizations sometimes keep some money in a separate reserve account for unexpected large expenditures. The amount typically ranges from about one-third to the full amount of the average annual operation and maintenance expenditures.

Oversight

Irrigation organizations often conduct two or more meetings with the irrigators each year to discuss accomplishments, expenditures, and plans for the coming year. For WUAs, these meetings may be used for electing or selecting leaders, setting irrigation fees, deciding on rules and policies, and approving or modifying plans. The meetings also provide an opportunity for irrigation training programs.

Fair and clear voting procedures are necessary for an effective WUA. Some examples of voting methods are as follows:

1. *One vote per member*: This method is simple. But it may not be fair to give a small landowner's vote the same weight as that of a large landowner because it can lead to domination of the organization by small landowners. In the United States, for example, small landowners are often not farmers, and may not be interested in the performance of the system.
2. *One vote per unit of irrigated land or per share of stock owned*: This proportionality is generally fairer than one-vote-per-member, but it makes voting more difficult. This is the most common system in the United States, and is favored because it better reflects the costs borne by individual irrigators.[3] In some situations, it can lead to domination by a few large landowners.
3. *A structured voting system*: In the United States, Oregon irrigation district law[4] provides one vote for irrigators with up to 40 acres (16 ha); two votes for 40–160 acres (16–65 ha); and three votes for more than 160 acres (65 ha). This simplifies voting, but still partially reflects the amount of irrigated land owned on the system.

Voting is often done by secret ballot, particularly for election of directors or leaders.[3] This reduces the chance of a director being hostile to those not supporting him or her.

Secrecy can be difficult to maintain when votes are proportional to the number of shares owned, or area of land irrigated. In this situation, colored ballots can help maintain confidentiality. For example, one color of ballot may count for one vote and another color may count for 10 votes. Each irrigator is given the proper number of ballots of each color to match one's vote entitlement.

Membership and voting power are usually limited to owners of irrigable land in the service area. However, where an organization also provides water for non-irrigation uses, all residents in the area served may be entitled to vote. Decisions are normally made by simple-majority vote, but a two-thirds majority may be required for borrowing money or changing bylaws.

Elections are sometimes conducted by an outside organization, or at least monitored by outside observers, to reduce the chance of election fraud.

The number of people on a leadership body or board of directors commonly varies from three to nine. Directors may be elected for staggered terms, so that only a portion of the board can be replaced in a particular election. This ensures that there are always some experienced members on the board.

Once elected, the leaders or board members usually meet at least monthly to conduct business and to solve management problems. The board usually hires a manager to supervise day-to-day operation and maintenance. The board and/or the manager also hire ditchriders, maintenance workers, and other needed staff.

Most managing organizations are primarily concerned with system operation and maintenance. Others get involved in associated activities such as technical assistance to the farmers, sale of seeds and fertilizer, and marketing of crops. Some organizations also manage the generation and sale of hydroelectric power. With increasing population and intensified use of water, managing organizations are increasingly involved in water conservation and environmental stewardship.

Irrigation districts are often required to have outside supervision of elections and an annual independent audit of the district's financial records, and all meetings and records must be open to the public. Another desirable but rare component is an outside audit of the water distribution records.

As with all organizations, an outside evaluation of performance should occasionally be done, perhaps once every 5–10 years. The Bureau of Reclamation in the United States requires such evaluations at least once every 6 years.

Hydrologic–Irrigation

Irrigation Economics: Global

Keith D. Wiebe
Noel Gollehon
Resource Economics Division, U.S. Department of Agriculture (USDA), Washington, District of Columbia, U.S.A.

INTRODUCTION

Irrigation involves complex interactions among ecological, social, and economic processes at a variety of scales, with important implications for agricultural production, income generation, poverty reduction, and environmental quality. No simple measure can fully capture the global economic importance of irrigation. Nevertheless, a review of historic trends in agricultural demand and resource use indicates that irrigation has contributed to dramatic increases in global crop yields and production over the past four decades. Given projected trends in demand for agricultural commodities and in the availability and condition of land and other natural resources, irrigation will continue to play a critical role in the future. Improved management will be necessary, however, to balance public and private economic and environmental objectives.

TRENDS IN DEMAND FOR AGRICULTURAL COMMODITIES

Global demand for agricultural commodities has increased rapidly since the mid-20th century as a result of growth in population, income, and other factors. Based on continued growth in these factors, the Food and Agriculture Organization (FAO)[1] and the International Food Policy Research Institute[2] project that global demand for cereals will increase by 1.2–1.3% per year over the next several decades, while demand for meat will increase slightly faster. Most of the increased demand is projected to come from developing countries, especially in Asia (most of which are already highly dependent on irrigation). Although demand growth rates are slowing and remain within the range of crop production growth rates achieved over the past several decades, demands on natural resources—including water—will increase.

TRENDS IN USE OF NATURAL RESOURCES

Land

The Food and Agriculture Organization reports that the total area devoted to annual and permanent crops worldwide has increased by about 0.3% per year since 1961, to 1.5 billion ha in 1998. Growth has slowed markedly in the past decade, to about 0.1% per year, as a result of weak grain prices, deliberate policy reforms (in North America and Europe), and institutional changes (e.g., those in the former Soviet Union). The Food and Agriculture Organization estimates that an additional 2.7 billion ha currently in other uses are suitable for crop production, but this land is unevenly distributed and includes land with relatively low yield potential and/or significant environmental value. Therefore, cropland area is expected to expand only slightly over the next several decades.

Genetic Resources

About half of all gains in crop yields over the past century are attributable to genetic improvements through scientific plant breeding.[3] By the 1990s, most developing countries' (and all the developed countries') cropland in wheat, rice, and maize was planted to scientifically bred varieties. Gains from genetic improvements will continue in future, but likely at slower rates and increasing research costs.[3]

Climate

The Intergovernmental Panel on Climate Change,[4] representing a broad scientific consensus, projects that the earth's climate will change significantly during the 21st century because of increasing concentrations of carbon dioxide (CO_2) and other "greenhouse" gases in the atmosphere. Given the adjustments that farmers would likely make in response to these climatic changes, aggregate global crop production may not be dramatically affected, but regional impacts may be significant: agricultural production would tend to increase in temperate latitudes and decrease in the tropics due to projected changes in precipitation and temperature (and thus in the spatial and temporal distribution of water).

Water

Fresh water is abundant globally, but only a small portion—about 10,000 $km^3 yr^{-1}$—is renewable and available for human use. Furthermore, this portion is distributed unevenly between countries, within countries, and across seasons and years. Of this portion, about a third is currently withdrawn for human use.[5] Agriculture accounts for about 70% of water withdrawals worldwide, and over 90% of withdrawals in low-income, developing countries.[6]

TRENDS IN IRRIGATION

The extent of irrigated cropland worldwide has grown at an average annual rate of 1.8% since 1961 (six times the rate of total cropland expansion), from 139 million ha in 1961 (10% of total cropland) to 274 million ha in 1999 (18% of total cropland).[7] Growth in irrigated area has been especially rapid in India, West Asia, North Africa, Latin America and the Caribbean, and about two-thirds of the world's irrigated area is in Asia (Table 1).

Irrigation expansion has slowed significantly in recent decades, from 2.2% per year during 1967–1982 to 1.5% per year during 1982–1995, due to declining cereal prices, the lower quality of land available for new irrigation, and the increasing economic, social, and environmental costs of large-scale irrigation systems.[2] The Food and Agriculture Organization[1] projects that irrigation expansion will slow further to an average increase of 0.6% per year through 2030.

Water withdrawn for agriculture averaged about 1 m in depth over all irrigated area in 1990 in 118 countries studied by Seckler et al.[5] Wood, Sebastian, and Scherr[8] note that global estimates of irrigation efficiency (i.e., the proportion of water withdrawn for irrigation that is actually consumed by crops) average about 43%, with most of the remainder being returned to the river or to the groundwater aquifer.

TRENDS IN AGRICULTURAL PRODUCTION

Growth in publicly-funded surface irrigation and in largely privately-funded tubewell irrigation contributed significantly to the food production increases and real food price declines of the Green Revolution.[9] Food and Agriculture Organization data indicate that cereal yields have increased in developing countries by an average of 2.3% per year since the early 1960s. Some of this increase is due to increased use of irrigation water (along with fertilizer and scientifically bred crop varieties); in developing countries, cereal yields are more than twice as high in irrigated areas (3.8 Mg ha^{-1}) as they are in rainfed areas (1.7 Mg ha^{-1}). Irrigated cropland now produces 30–40% of the world's crop output, including nearly two-thirds of all rice and wheat; at international agricultural prices for 1989–1991, the irrigated share corresponds to a total value of roughly $400–530 billion per year.[8]

Over time, however, subsidized water delivery (whether via public infrastructure or subsidized fuel for private tubewell operation) and inadequate property rights in water have led to excessive and inefficient exploitation of water resources in some countries.[10] Barker and van Koppen[9] argue that these trends will adversely affect food production in key grain-producing areas (including India and China) in the coming decades. Waterlogging and salinization of irrigated land threaten crop yields in some areas, and are likely to become an increasing problem in the absence of appropriate management.

Table 1 Irrigation indicators, 1990

Region	Total irrigated area (million ha)	Area growth rate (% yr^{-1})	Irrigation depth (m)	Irrigation efficiency[a] (%)
World	243.0	1.6	1.0	43
Asia	154.4	1.9	1.0	39
China	48.0	1.3	1.0	39
India	45.1	2.7	1.1	40
Other Asia	61.3	1.7	0.9	32
West Asia and North Africa	22.6	2.5	1.2	60
North America	21.6	0.9	0.9	53
Europe	16.7	0.6	0.9	56

[a]Irrigation efficiency is a complex concept, but is generally defined as the ratio of water actually used by crops (i.e., returned to the atmosphere via transpiration) to the gross amount of water extracted for irrigation use. *Source*: For further discussion, see Ref.[13]. From Ref.[8].

Meanwhile, population growth and the increasing cost of developing new sources of water will place increasing pressure on world water supplies in the coming decades. Even as demand for irrigation water increases, farmers face growing competition for water from urban and industrial users, and from demands to protect in-stream ecological functions by imposing minimum in-stream flows. In light of these conditions, Rosegrant et al.[2] argue that water will likely become a major constraint on increased food production and improved food security in many developing countries, especially in Central and Western Asia and in Africa. Seckler et al.[5] assert that in a growing number of countries, water has become the single most important constraint to increased food production.

OPTIONS FOR INCREASED SUPPLY AND IMPROVED MANAGEMENT OF WATER

Water storage is a key component of strategies to overcome spatial and temporal variability in precipitation and river flows. National governments, multilateral agencies, and local communities have invested heavily in dams over the past century, but such investments are becoming increasingly expensive in financial, environmental, and political terms.[6] Groundwater has been withdrawn at rates in excess of recharge and degraded through contamination in many areas. Interbasin transfers may be appealing in some areas, but are characterized by the same costs that limit new investment in dams. Water recycling and desalination remain too costly for extensive use.

Given limitations on increased supply, a variety of options for improved water management become important. Serageldin[11] notes that because of water's unique characteristics, governments have generally assumed central responsibility for its management. In seeking to assure access by all, however, governments generally price water as though it were an abundant resource rather than a scarce one, thereby encouraging excessive use in many countries.[12] As the costs of excessive use are recognized, e.g., in terms of groundwater depletion and salinization, increasing attention is being paid to policies that address market and government failures and provide incentives for more efficient water use. Key among these are efforts to price water at levels that better reflect costs, and to establish tradable water rights. Policy and technology also play a role in changing management practices to improve water infiltration and moisture-holding capacity on agricultural lands.

Seckler et al.[5] estimate that about half of the projected increase in global demand for water by the year 2025 can be met by reducing losses to evaporation and sinks, controlling salinity and pollution, reallocating water from lower-valued to higher-valued crops, and investing in genetic improvements that increase crop yields per unit of water. It is important to note, however, that reducing runoff or deep percolation to groundwater may affect the water supply for other water users or for environmental purposes, resulting in unintended and undesirable impacts.[13]

CONCLUSION

In considering strategies to improve irrigation supplies and management, it is essential that the full costs and benefits to all affected parties are recognized. Ultimately, the extent to which crop production keeps pace with future increases in demand at acceptable economic and environmental cost will depend on the institutions, market incentives, policy measures, and investments in research and infrastructure that influence how water and other resources are used.

Irrigation Economics: United States

Noel Gollehon
Resource Economics Division, U.S. Department of Agriculture (USDA), Washington, District of Columbia, U.S.A.

INTRODUCTION

Irrigation is the defining characteristic of crop production in the American West and an increasingly important feature of crop production in the Eastern United States. The irrigated cotton fields of the Southwest, corn farms of the Plains, and citrus groves of Florida, all attest to the magnitude, extent, and importance of irrigation. This article provides an overview of the contribution of irrigation to crop production in the United States. It also focuses on the sales value of crops produced, but provides a context for those values by first considering irrigated area and water use in irrigation. Readers will gain insight into irrigation's importance both from an economic and a resource use perspective.

IRRIGATED AGRICULTURAL AREA

The National Agricultural Statistics Service (NASS), USDA conducts the Census of Agriculture on a 5-yr interval.[1] The 1997 Census data are the latest available; with the next Census of Agriculture due to be collected in 2003 for the 2002 calendar year. The long history, consistent methodology, and statistical reliability of the Census data series makes these data especially useful for capturing irrigation trends.

According to the 1997 Census of Agriculture,[1] 55.0 million acres of agricultural land were irrigated in the United States. This represents a new census-year high, with an additional 5.6 million acres (over 11%) over levels reported in the 1992 Census of Agriculture. The distribution of irrigated lands (both cropland and pastureland) shows that 78% (43 million acres) were located in the 19 Western states with the remaining 22% (12 million acres) in 31 Eastern states (Table 1).

Some cropland is irrigated in all 50 states. In 1997, irrigated land area ranged from about 2500 acres in Vermont, New Hampshire, and Alaska to about 8.7 million acres in California. Irrigated areas have historically been concentrated in the West (89% of U.S. irrigated area in 1969) because arid conditions required irrigation to supplement inadequate growing season rainfall. The West still retains the bulk of the irrigated land, but irrigated area is expanding in the more humid East. Since 1969, irrigated land in the East has increased by almost the same number of acres as in the West, with a much faster rate of growth (187–23%). More recently (1987–1997), irrigated land in the West increased by about 5.3 million acres (14%) compared with 3.3 million acres (38%) in the East.

Of the 55 million irrigated acres reported in the 1997 Census, there were 50 million acres of "Cropland Harvested," and 5 million acres of "Pastureland and other land." Nationally, irrigated cropland represented about 16% of all harvested cropland. In the West, irrigated cropland harvested comprises a greater share of total cropland acres (about 27%), representing about 76% of the nation's total harvested irrigated cropland. While irrigation in the East accounts for the remaining 24% of the nation's total, only a small share (7%) of the harvested cropland in the East was irrigated (Table 1).

WATER USED FOR IRRIGATION

The U.S. Geological Survey, U.S. Department of the Interior, estimates both water withdrawals and consumptive use every 5 yr.[2] Estimates are made at a local level based on locally available information, including theoretical estimates of crop water use, crop area, delivery records of off-farm water suppliers, and details on conveyance losses, water application rates, and return flows.

Three measures can be used to characterize water use for agricultural irrigation: withdrawals, applications, and consumptive use. Withdrawals represent total water diverted from surface water sources and extracted from groundwater aquifers.[2] Applications measure that portion of the water withdrawn that is delivered to the field, excluding off-field conveyance system losses and gains.[3] Water applications represent the portion of withdrawals that are directly under producers' control and are thus impacted by on-farm irrigation management and technology choice decisions.

Views expressed are the author's and do not necessarily represent those of Economic Research Service or USDA.

Hydrologic–Irrigation

Table 1 Irrigated area in the United States, by region, 1997

Region	Harvested cropland irrigated (million acres)	Pastureland irrigated (million acres)	Total irrigated area (million acres)
United States	50.0	5.0	55.0
Western states[a]	38.2	4.8	43.0
Eastern states	11.8	0.2	12.0

[a]Western states includes HI, AK, WA, OR, CA, ID, NV, MT, WY, UT, CO, AZ, NM, ND, SD, NE, KS, OK, and TX.
Source: Ref.[1].

Consumptive use refers to that portion of water withdrawn and applied that is actually consumed for plant needs.[2,4] Consumptive use is usually estimated based on plant water requirement models, and does not include excess water lost to percolation, runoff, or evaporation, other than that required for plant growth.

Measures of irrigation water use may be used to describe the impact of irrigation on hydrologic conditions. Withdrawals are the best indication of the water quantity impacts of irrigation water diversions. While withdrawn water that is not consumptively used may be available for future use, the location, quality, and timing of availability are often affected. Consumptive use is an indicator of the water quantity lost to the immediate hydrologic cycle. Irrigation withdrawals, as well as withdrawals for other out-of-stream uses, may be quantified and compared. None of these measures consider in-stream water uses, such as hydroelectric power generation, navigation, recreation flows, or flows to maintain ecosystems. In-stream uses may be more significant than off-stream uses in many locations, but specific quantities are difficult to measure.

Irrigated agriculture withdraws and consumes the most freshwater of any economic sector in the United States Irrigation accounts for withdrawals of 150 million acre feet (maf) nationally, almost 40% of total freshwater withdrawals (Table 2). When measured by consumptive use, irrigation uses about 91 maf of water, or more than 80% of the total consumptive use. Comparing across sectors, irrigation consumes about 60% of irrigation water withdrawn—a much greater share relative to the average consumption rate of 9% in other sectors.[2]

The water use picture varies substantially between the 19-state western and 31-state eastern regions. In the West, irrigated agriculture accounts for 133 maf or 75% of total freshwater withdrawals in the region. The average water quantity withdrawn per acre of irrigated crop and pastureland is 2.7 acre ft. When measured by consumptive use, irrigation uses about 79 maf of water, or almost 90% of total water consumed in the West. Roughly two-thirds of the irrigation water in the West is supplied from surface water sources with groundwater accounting for the remaining supply. California has more than double the irrigation withdrawals of any other State (32 maf), while Idaho, Colorado, and Texas—all have withdrawals greater than 10 maf. Of these four states, only Texas withdraws more groundwater than surface water.[2]

By comparison, irrigation withdrawals in the 31 Eastern states account for 17 maf, or about 8% of total regional withdrawals. Withdrawal rates were substantially lower than in the West, at 1.3 acre ft per acre of irrigated crop and pastureland reflecting the greater natural precipitation in agricultural areas. Irrigation consumptive use (12 maf) accounts for 52% of total water consumed in the East. (Thermoelectric power generation, which withdraws a large quantity of water but consumes little, accounts for most Eastern withdrawals.) Groundwater is the primary source of irrigation water in the East. Arkansas withdraws the largest quantity of irrigation water (6.6 maf) among eastern states, primarily from groundwater sources. Florida (almost 4 maf) and Mississippi (almost 2 maf) are also major irrigation withdrawal states in the region.[2]

Table 2 Irrigation and water withdrawals and consumption in the United States, 1995

Region	Sector	Water withdrawals (maf)	Consumptive water use (maf)
United States	All	382	112
	Irrigation	150	91
Western states[a]	All	179	88
	Irrigation	133	79
Eastern states	All	203	24
	Irrigation	17	12

[a]Western states include HI, AK, WA, OR, CA, ID, NV, MT, WY, UT, CO, AZ, NM, ND, SD, NE, KS, OK, and TX.
Source: Ref.[2].

Several factors will influence the extent of future increases or continuation of current withdrawal levels of water for irrigation use. Increasing demands from other sectors for both out-of-stream and in-stream use have recently limited irrigation water withdrawals in some areas, particularly under drought conditions. Increasing capital costs for new projects and recognition of environmental impacts have combined to limit large-scale new water developments to augment irrigation water supplies. It is unlikely that these trends will reverse, at least in the near future, implying that expansions in irrigated area will likely occur primarily through more efficient use of the water already dedicated to agricultural production.

VALUE OF IRRIGATION

Crop sales reports from the Census of Agriculture provide the basis for current estimates of irrigated crop values. Individual Census of Agriculture farms were classified into one of three irrigation groups for each commodity group: only irrigated, only non-irrigated, and combined irrigated and non-irrigated. Irrigated commodity sales was calculated as the sum of the only irrigated farms plus an apportioned share of the sales on combined farms in the 1997 Census of Agriculture.[1]

Crop sales, which measure the value of commodities leaving the farm gate, also serve as an indication of economic activity associated with farming and related income flows through rural areas. Preferred measures of irrigation's contribution to crop production would be profitability of irrigated agriculture or the direct value of total crop production, but those estimates are not available. The Census of Agriculture reports the amount of crop sales at the farm market gate, but does not capture the value of crops that are produced and consumed on-the-farm without entering a market channel, most prevalent with irrigated forage and feed crops used on the farm. Although this value adjustment is not known for 1997, the underestimation was about 15% of sales value in 1987.[5]

Based on calculations from the 1997 Census of Agriculture information, there were 309 million acre of harvested cropland that produced crop sales of \$98 billion. Irrigated crops occupied 16% of that area, but accounted for 49% of the total value of sales from U.S. farms and ranches (Fig. 1, top row). Average sales per harvested acre were \$950 for irrigated cropland compared with \$200 for non-irrigated cropland. Irrigated crop sales were highest for orchards, vegetables,

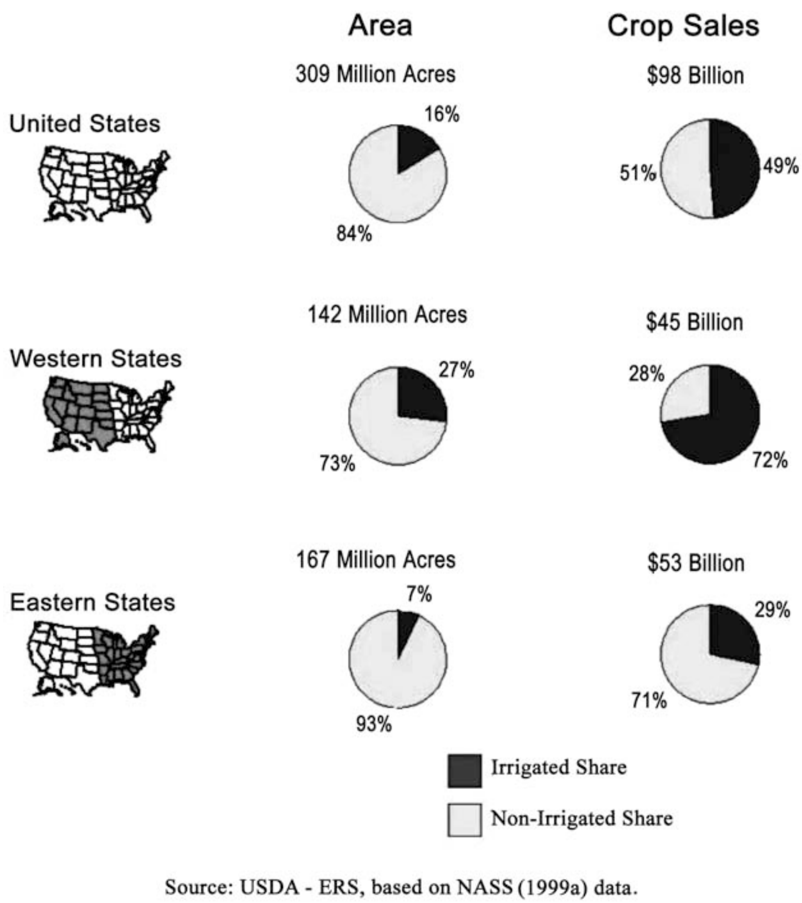

Fig. 1 Irrigated crop area and sales as a share of total, 1997. *Source*: From Ref.[1].

Hydrologic–Irrigation

and nursery crops while irrigated cropland area was dominated by grain and forage crops, primarily corn for grain and alfalfa hay.

In the West, the 1997 Census reported 142 million acre of harvested cropland that produced total crop sales of $45 billion. Irrigated crops in the West accounted for 27% of the area, but produced 72% of the total value of sales in the region (Fig. 1, middle row). The sales of Western irrigated crops totaled about $32 billion in 1997, or roughly one-third of all U.S. crop sales. Average sales per harvested acre in the West were $850 for irrigated and $122 for non-irrigated cropland. As was the case when examining the national values, irrigated crop sales were led by orchards, vegetables, and nursery crops while irrigated cropland area was dominated by grain and forage crops.

In the East, the 1997 Census reported 167 million acres of harvested cropland with total crop sales of almost $53 billion. Irrigated crops in the east occupied only 7% of the harvested cropland area, but produced $15 billion or 29% of the region's total value of sales (Fig. 1, bottom row). Average sales per harvested irrigated acre were greater than the national average at over $1200, while non-irrigated cropland averaged sales of $200 per acre. The greatest contribution to sales totals were made by irrigated nursery crops, orchard crops, and vegetables. Rice, soybeans, and corn for grain dominated irrigated cropland area in the region.

The wide differences in crop sales values, coupled with the fact that most of the crop sales comes from high-valued crops, provides significant flexibility for irrigated agriculture to adjust to changes in water availability. Farmers can adjust to physical water shortages by improving irrigation technology and/or adjusting cropping choices to maintain production of the higher-valued crops. This ability to substitute crops is an important response to water shortfalls. In addition, innovative water markets have increased the ability of farmers and water suppliers to transfer water, enabling maintenance of higher-valued crops during droughts.[6]

CONCLUSION

This article examined three measures of irrigation: irrigated agricultural area, water used in irrigation, and the sales value of crops produced. By all three measures, irrigation is an important contributor to the value of crop agriculture. In 1997, irrigated lands produced 49% of crop sales on only 16% of the harvested crop area, providing an important input to most of the nation's higher-valued crop production. Irrigation is also an important component in the nation's hydrologic picture by virtue of the spatial extent and volume of water involved. In 1995, irrigation accounted for 40% of the nation's water freshwater withdrawals from lakes, rivers, and aquifers. Irrigation accounted for over 80% of the total consumptive use by all sectors of the economy. In future increased competition for water will affect irrigated agriculture's ability to withdraw and consume water at current levels.

INTRODUCTION

Irrigation management includes deciding how much irrigation water to apply, and when to start and stop the irrigation. For any management decision, the choice of operation depends on what one wants to do. The simple answer may appear to be "put on some water," but the choice is often more complex. For instance, one can attempt to maximize net return, minimize operating costs (especially labor), maximize yield, optimize limited water supply, minimize environmental risk, or optimize production under a limited irrigation system capacity. All of these may be constrained by regulations. In general, water supply and irrigation costs control the economics, so the best result is obtained by maximizing yield on all irrigated land, usually called the land-limiting case. In simple terms, one irrigates to avoid crop water stress.

Important irrigation system parameters for consideration include the irrigation application rate per unit area, the total system supply rate, and for moving systems, the velocity. At a given pumping rate, moving machines cover their entire irrigated area in a given return time. If more application depth is required, the system can be set for a slower velocity, which trades increasing depth for longer operating times. For solid-set systems, including sprinklers and drip, increasing application depth is achieved by operating the system longer.

All these considerations apply for both arid and humid areas, and are covered briefly here so that the reader may interpret the article without referring elsewhere. For the following, the discussion concentrates on the particular case of humid areas, contrasting with the conventional, more-arid case.

CONTEXT OF HUMID AREAS

Humid area climate differs from arid area climate in several ways. First is the defining characteristic, humidity. In humid areas, the dew point often equals the early morning air temperature, unlike most arid areas, and the difference in vapor pressure deficit affects crop temperature. Along with higher humidity comes, generally, more clouds. These reduce the total daily solar radiation, which reduces the evaporative demand. Finally, humid areas generally receive more rain than arid areas. The possibility of rain occurring just after an irrigation can complicate an irrigation manager's decision in two important ways beyond applying unnecessary water. One is the risk of waterlogging a crop and causing damage by lack of aeration. The other is risk of leaching nutrients or other chemicals.

On the other hand, during periods without rain, the weather in humid areas can be similar to that in arid areas. Rain-free days are generally less cloudy, which then means more nearly clear-sky solar radiation and higher evaporative demand. Also, air temperature may be higher and humidity lower than averages, which include the cooler wet days. Similarity between humid and arid regions during periods of drought, which can occur in as little as two rainless weeks, creates additional challenges for irrigation managers in the humid region. Strategies optimized assuming the next rainfall is imminent can fail if the next rain occurs four or six weeks later.

Another consequence of higher rainfall amounts in humid areas is a radically different water supply system than in arid regions. There are few large water projects with objectives to provide irrigation water, and no extensive water districts to manage the allocation. Therefore, most water supplies must be farmer-developed. Historically, these were farm ponds retaining runoff or streams from either of which farmers pumped directly. Where groundwater was available, wells were added to provide backup to ponds, and where extensive aquifers existed, irrigation expanded using high-capacity wells. Since they were developed individually, farmer water supplies were not regulated, or if so, minimal information was required for permits.

As a direct result of this history of irrigation development, little knowledge exists regarding the water withdrawals, irrigation capabilities, or area irrigated in most humid areas. A useful case study of the difficulties caused by this lack of information can be found in southwestern Georgia.[1]

IRRIGATION SCHEDULING EMPLOYED IN HUMID AREAS

As mentioned earlier, in the usual (land-limiting) case, one achieves the optimum economic return by maximizing yield on all irrigated land, which is achieved by irrigating to avoid crop stress. This can be done in several ways, all of which have been used in humid areas of the eastern United States. One can sense the water status of the crop, measure soil moisture, or compute the soil water balance. There are many variations on these three approaches. Even the fixed time-clock control of lawn and other turf irrigation systems (if adjusted properly) is an attempt to maintain soil moisture in a range suitable for plant health.

Plant Stress Methods

The most well-known indicators of plant water stress are visual: rolled or drooping leaves and color change. However, by the time these conditions occur in crops, yield has already been reduced. Therefore, scientists looked for earlier indicators of water stress. One early stress measurement is the infrared thermometer, which is a non-contact device and is sensitive to longwave ($\sim$10 μm) radiation, that measures the average temperature in the field of view. For theoretical reasons, the difference between the canopy and the air temperature is the important measure, but the vapor pressure deficit is an important factor in the interpretation of the temperature difference. In humid areas, the canopy temperature may be somewhat higher relative to the air temperature than in arid areas. Both air temperature and vapor pressure deficit are taken into account with the crop water stress index, or CWSI, but research in the humid southeastern United States indicates that additional work is needed before this method can be widely applied.

Other plant stress monitors have been proposed and are included here for reference. Near-infrared (NIR, $\sim$1 μm) photography and remote sensing have been used in research environments, but other stresses, such as disease or poor nutrition, can also cause NIR responses. Some research has monitored leaf water potential using the pressure chamber or the leaf press. Sap flow devices have been used to measure water movement into plants, particularly for perennial plants. Since water flow is in response to plant water needs and soil water supply, the device can detect periods when these are limited. A recent report from Israel suggested that minute changes in leaf thickness could be sensed as an indication of plant water status. All of these devices have been useful in research for assessing plant water stress, but expense and/or complexity have limited their application in production.

Successful use of any plant water status measure depends on being able to identify some trigger point at which to initiate irrigation. For the infrared-thermometer-based CWSI method, some have determined responses to initiation at one value or another, say 0.5 in the range 0 (no stress) to 1.0 (complete stress). However, as mentioned earlier, using any absolute value of the CWSI in humid areas requires additional research or possibly local calibration. In addition, scheduling irrigation based on observing stress is subject to an inherent limitation in that it cannot successfully predict what time in the future one needs to irrigate. In practice, experience can overcome this limitation.

These local calibrations may be avoided using an innovative approach to initiating irrigation using an indicator of the variation in soil water that exists across a field. In this approach, an infrared thermometer is read as it is moved across a field, as from the window of a moving vehicle. Irrigation is triggered when the variation in temperature in the series of measurements exceeds a certain amount. Basically, this approach uses the driest area of the field as an indicator; when it gets dry, the rest of the field would not be far behind, so irrigate soon. Because the air temperature, vapor pressure, and other factors are all reasonably constant during the scan, this method can use the actual crop temperature.

Soil Moisture Methods

Research has shown that plants can extract water from soil when it is held somewhere between the field capacity, which happens after free drainage following rain and is between -0.01 MPa and -0.03 MPa soil water potential, and the permanent wilting point, usually assumed to be at -1.5 MPa soil water potential. These concepts have been debated, but use has shown them to be useful approximations. Most of the water contained in the soil is held between the field capacity and -0.1 MPa. For this reason, tensiometers, which can measure water between 0 MPa and -0.08 MPa, can monitor soil water over a range important to irrigation.

Researchers in the southeastern United States have employed tensiometers, with irrigation being triggered when the potential at 0.3-m depth gets drier from -0.02 MPa to -0.05 MPa. Important considerations include the depth, the position of the sensor relative to the plant row and roots, and also the crop species. Tensiometers must be serviced periodically to remove air and ensure that they have not gotten out of range, which causes unpredictable readings. They must also be monitored frequently in sandy soils because the water removed from the soil in a day might cause the readings to go out of range.

Electrical resistance devices have been embedded in the root zone to measure soil water potential indirectly, using the known relationship between water content and electrical resistance of gypsum. Advantages of these devices are low maintenance and adaptability for reading with simple meters or data loggers. With experience, managers can use these simple devices to indicate that the soil is becoming too dry for continued plant growth.

The other measure of soil moisture is water content. As mentioned earlier, the water content and potential are related through the water-holding capacity function, which may differ for each soil and soil layer. If this relationship is known, soil water content (SWC) sensors can be used to sense soil moisture for irrigation purposes, by determining the water content corresponding to the field capacity and wilting point. Water content can be expressed per unit volume or per unit weight. The only practical method that produces a value per unit weight is the gravimetric technique, in which a sample is weighed, dried, and weighed again. If this technique is used, the mass of soil per unit volume in the original state, or bulk density, must be known to convert to a volume basis. Knowing the water content on a volume basis adds to the irrigation manager's tools because the difference between the water content and the wilting point is an indication of how much water remains, and the difference between field capacity and the water content is how much can be applied at the time of the measurement. Clearly, soil moisture measurements must represent the water content of the effective root zone for this technique to be useful, and the root zone thickness changes with type and usually increases with age of the crop.

Water Balance Techniques

The checkbook-type water balance method has been known for nearly 50 yr. This direct analog to a bank checkbook uses rain and irrigation as credits and evapotranspiration (ET) as a debit to maintain a water content between the field capacity and wilting point for the root zone. One can adjust the rainfall for runoff and drainage below the root zone. Availability of ET data has been the main problem using this technique in the southeastern United States. Evaporation pans have been used, with research testing whether screened or open pans are most reliable.

A physical model of the checkbook method has been implemented using an evaporation pan directly. For this, a calibrated scale is placed on the pan (usually a screened pan) with indications for a full and an empty rooting zone. An inexpensive, recent implementation uses a large washtub specially fitted with a float attached to a flag visible from some distance. When the water level has dropped to a point equivalent to the soil water refill amount, the flag passes a preset mark and irrigation is indicated. An overflow hole is set at a level representing full SWC. Since the device is placed in the field of sprinkler irrigated crops, it receives both irrigation and rainfall, filling to the overflow mark with excessive rain or simply adding to the pan as rain and irrigation partially refill the soil and pan.

A computer model of the water balance is simply an automated version of the manual and physical methods mentioned earlier. Usually, ET is calculated from weather station data for temperature and solar radiation, but if ET data were available in published reports, it could be entered. Some computer-based methods use the best available information, starting with measurements, then calculations from weather station data, then calculations from forecast weather, and for predictions beyond the forecast period, historical data. Fig. 1 illustrates the water balance technique. Note the increased water-holding capacity of the profile as the root zone expanded during the season. Up to ~85 days after planting, the irrigation in this case was scheduled to successfully control the SWC above the CL line. After that time, the SWC fell below the control limit, and the computer program flagged the line with triangles to indicate the need for irrigation.

Common Considerations

In all of the previous soil-based methods, some decision must be made about the allowable range of soil moisture. Seldom does an irrigator want to allow the soil moisture to drop very close to the wilting point; most trigger points are approximately 30%–50% depletion of available water-holding capacity, for the sake of insurance. Conversely, if irrigation fills the soil rooting zone to field capacity, and rain falls soon after, then the root zone can be subject to aeration problems, and this free water (rain) is lost through runoff or drainage. This choice of management-allowed depletion depends on the probability of rainfall and the likely amount that could be tolerated or used. In this regard, humid-area management is different than arid-area management. The range over which the manager can control soil moisture may need to be restricted to allow for the higher chance of rain.[2]

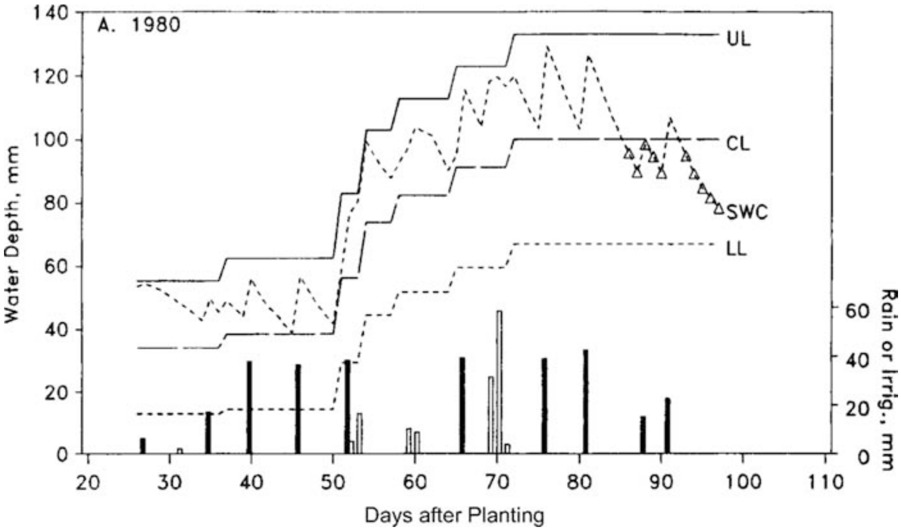

Fig. 1 Water balance technique illustrated. Source was computer-based method in Camp and Campbell, 1988. The lines labeled UL and LL are the upper and lower limits of available water within the root zone. The line CL was the irrigation control point, here at 50% management-allowed depletion. The line SWC is the computed SWC, with triangles flagging the need to irrigate. Solid bars indicate irrigation; open bars indicate rain.

These requirements, a narrow range for deficit irrigation and inherent limits of the soil water storage, support using frequent, small irrigations rather than less-frequent, large ones. This can lead to a higher fraction of water evaporated directly from the soil surface, which is wet more frequently in the case of sprinkler irrigation, and to increased disease incidence when susceptible crops are frequently wetted. The combination of these considerations brings more interest in buried drip irrigation, which can, if so designed, irrigate frequently, yet keep the soil surface mostly dry.

All measurements represent the area where the measurements are made, but spatial variation will cause any measurement to be unrepresentative of the entire area in most fields. Assuming the field is irrigated the same throughout, how many measurements are needed to represent the entire field? There is no simple answer to this question, nor is there one for the trade offs when distinctly dissimilar soils exist all in one irrigation management unit.

Comparisons

A multi-state study of irrigation scheduling methods concluded that, if properly employed, tensiometers, evaporation pans, and computerized water balance methods, all could be used in the southeastern United States. Tensiometers had one advantage in that they were fairly universal, requiring little calibration. On the other hand, they required significant labor for reading and maintenance. Evaporation pans were also labor-intensive. Computerized water balance models were data-intensive and occasionally needed adjustment of the SWC to eliminate accumulated errors, but were much more amenable to forecasting future irrigation needs.

TECHNICAL ABSTRACT

During the long history of irrigation, management of irrigation systems, which includes deciding how much irrigation to apply and when to do it, has been the subject of much study. Most of this work has been done in primarily arid areas, where the development of irrigation started earlier. However, current trends include increasing irrigated areas in humid regions, for which the contrasting climatic conditions require correspondingly different management techniques. In addition to having higher humidity, humid areas are generally more cloudy (lower solar radiation and thus lower evaporative demand), receive more rainfall, and tend to be cooler on average. However, during even short droughts, the conditions may be quite similar to those in arid regions. Dynamic weather complicates the management of irrigation systems in humid regions, forcing managers to trade off the possibility of rain against the need to leave storage space for potential rain by controlling a relatively narrow range of management-allowed depletion. Doing so can be achieved more easily using frequent, light irrigations instead of less-frequent, heavy ones commonly used in arid regions. Case studies of irrigation management in the southeastern United States serve to illustrate the common management methods, which include tensiometers, evaporation pans, and computer-based water balances. Continuing trends of increasing irrigated area and increasing interest in precision agriculture may combine to focus on spatially variable irrigation management in humid regions.

Interpretive Summary

Irrigation management includes deciding when to apply irrigation, and also how much to apply. Making these choices in humid regions is somewhat more complicated than in arid ones, primarily because of the possibility of receiving rain shortly after an irrigation. Besides being wasteful, this possibility also carries a risk of drainage and runoff carrying nutrients to groundwater or streams. Managing irrigation to save some room in the soil for possible rain requires a careful balance between crop needs and soil capacity, which can be limited by sandy soils or shallow rooting depths. Management methods leave storage space for potential rain by controlling a relatively narrow range of management-allowed depletion. Doing so in humid regions can be achieved more easily using frequent, light irrigations instead of less-frequent, heavy ones commonly used in arid regions. Case studies of irrigation management in the southeastern United States showed that common methods, which include tensiometers, evaporation pans, and computer-based water balances, can all work. Increases in irrigated area and interest in precision agriculture may combine to focus on spatially variable irrigation management in humid regions.

CONCLUSION

At the current time, two trends in irrigation are apparent. While they may also exist elsewhere, they are somewhat recent in the southeastern United States. The first is the simultaneous increase in irrigated area and increased competition with nonfarm users for water resources. This leads to both a less-than-optimal water supply and higher valuation of the water resource. Therefore, additional questions arise. If one cannot irrigate all the land, where should the water be used to greatest advantage? Should it be used only on high value crops? Should it be applied suboptimally to all the land? Or should the second trend, interest in precision (site-specific) agriculture, be extended to irrigation, so that each individual soil in a field could be irrigated optimally, or less-productive soils be left rainfed while productive soils are irrigated optimally? These questions are currently of increasing interest to researchers. Should the southeastern drought of 1998–2002 continue, they will likely be of increasing interest as well to producers.

Irrigation Management: Tropics

R. Sakthivadivel
Hilmy Sally
International Water Management Institute (IWMI), Colombo, Sri Lanka

INTRODUCTION

The tropics refer to "that part of the world located between 23.5 degrees north and south of the equator." The tropics make up 38% of the earth's land surface (approximately 5 billion ha) and 45% of the world's population, estimated at 6.1 billion in 2000,[1] live there. About 75 countries, most of them "developing," lie wholly or mostly in the tropics.* The data and statistics that will be presented in this article are based on entire countries. Hence, even though some parts of southern China are within the latitudinal definition of the tropics, China has not been included. On the other hand, India, Bangladesh, Mexico, and Brazil have been taken into account although parts of these countries lie outside the boundaries. With this provision, the major irrigated countries such as China, Iran, Pakistan, the Russian Federation, Turkey, and the United States of America fall outside the tropics.

This article will first present the climate and other key features of the tropics, with special emphasis on water, irrigation, and food production. Trends in irrigated agriculture and changes in land–water–people balances are then shown. Finally, strategies and conditions to promote effective and sustainable management of irrigation and water resources are discussed.

The need to adopt a holistic approach, integrating the technical, social, and institutional aspects of irrigation and water resources management, is highlighted.

*The main countries include: Angola, Bangladesh, Benin, Bolivia, Brazil, Burkina Faso, Burundi, Cambodia, Cameroon, Central African Republic, Chad, Colombia, Congo (Democratic Republic), Congo (Republic of), Costa Rica, Côte d'Ivoire, Cuba, Djibouti, Dominican Republic, Ecuador, El Salvador, Eritrea, Ethiopia, Gabon, Gambia, Ghana, Guatemala, Guinea, Guinea Bissau, Haiti, Honduras, India, Indonesia, Kenya, Korea (North), Korea (South), Liberia, Madagascar, Malawi, Malaysia, Mali, Mauritania, Mauritius, Mexico, Mozambique, Myanmar, Namibia, Nicaragua, Niger, Nigeria, Oman, Panama, Papua New Guinea, Paraguay, Peru, Philippines, Réunion, Rwanda, Sao Tome & Principe, Senegal, Sierra Leone, Somalia, Sri Lanka, Sudan, Swaziland, Tanzania, Thailand, Togo, Uganda, Uruguay, Venezuela, Vietnam, Yemen, Zambia, Zimbabwe.

CLIMATE AND CROPS

Tropical temperatures remain fairly constant throughout the year with a mean monthly temperature variation of 5°C or less between the average of the three warmest and the three coldest months.[2] Annual rainfall varies from 0 mm to 10,000 mm, decreasing with increasing latitude, with a high year-to-year and monthly variability. Indeed, the climate of the region is largely determined by the distribution of rainfall rather than the total amount. Three main zones can be delimited on this basis: 1) permanent humid zone, experiencing 9.5–12 mo of rain, located very close to the equator, and occupying roughly one-fourth of the tropics; 2) seasonally humid zone (4.5–9.5 mo of rain), covering one-half of the tropics and where most crops (including rice in the monsoon region of Asia) are grown; 3) semiarid zone, receiving 2–4.5 mo of rainfall and providing good growing conditions for crops such as maize and cotton.

Although agriculture is the main economic activity in the tropical regions, the proportion of cultivated lands (about 10%) is virtually the same as in the temperate region. But tropical soils tend to be more fragile and failure to replace soil nutrients can ultimately undermine their productive capacity. Rice, cassava, corn, wheat, sorghum, and millet are among the main crops grown in the tropics. Ninety percent of rice production comes from tropical Asia.

IRRIGATION SYSTEMS AND RESOURCE ENDOWMENTS

Irrigation systems in the tropics are subject to both shortage and surplus of water at different times, posing special problems for managing irrigation water efficiently and productively. Differences in rainfall regimes can have a significant impact on irrigation management and irrigation performance. For example, in a situation where rainfed cropping is possible, farmers may cultivate extents of land beyond what the irrigation system had been designed to support. This would complicate management in the event of a drought because all the crops could need water irrespective of whether they were authorized for irrigation or not; while in more favorable rainfall conditions, little or no irrigation water may be needed even for authorized crops.

In contrast, farmers in arid areas would plan their activities in expectation of irrigation rather than depending on rainfall. As irrigation is more predictable and the demands relatively stable, management is simplified. Producers in such low-rainfall areas know what to expect by way of water supply in the rainy season and would accordingly limit the extent of high-value, water sensitive crops with the balance area under low-value crops or kept fallow. If there is ample rainfall, it will benefit all the planted crops. But if the rains fail, low-value crops would probably be lost, whereas high-input crops would survive due to irrigation. Access to alternate sources of water such as a well could allow high value crops over the whole farm. Given the costs associated with pumping, producers would also tend to make effective use of the surface water supply (subject to any legal constraints) and rainfall. Indeed, how well irrigation systems make use of rainfall will have decisive implications for water management and for efficiency of water use.

Land and labor endowments can also affect irrigation development and management, and the relative prosperity of a region. The eastern and western Gangetic plains in India, lying in two different climatic zones, provide a good example.

Population density in the eastern Gangetic plain has always been higher than in the west, with most suitable land farmed. Higher population pressure has resulted in extension of cultivation to less favorable areas with an attendant decline in farm size. But the persistence of yield-limiting constraints means that even in a good year there is little surplus. In contrast, in the western Gangetic plain, irrigated agriculture has greatly expanded, cropping patterns changed, and higher yields are obtained. This illustrates the fact that favorable shifts in the relative endowments of land and labor in association with technologies that improve the reliability and predictability of agricultural conditions can greatly enhance regional and national productivity.

TRENDS IN IRRIGATED AGRICULTURE

Population and its growth are crucial factors that drive water development strategies whether for food production, or for domestic or industrial purposes. In this section we will examine the trends in irrigation, food production and food consumption, and assess the impacts on water availability and water use in the tropics.

Fig. 1 shows the past and projected trends in population growth and per capita internally renewable water resources (IRWR) in the tropics for the 60-year period 1965–2025. Between 1965 and 1995 the population has nearly doubled and the per capita IRWR halved. If population growth in the tropics follows the United Nations (UN) medium projection path, this will result in a further 20% decrease in IRWR. The per capita IRWR available in 2025 is projected to be 5000 m^3 (kiloliters), which is still considered enough to meet the water needs of each person in the tropics. However, this aggregate figure masks substantial spatial and temporal variations between countries and regions on one hand, and between different times in the year on the other.

Table 1 shows that in 1995, the average per capita calorie supply in the tropical countries was 2456 kcal.

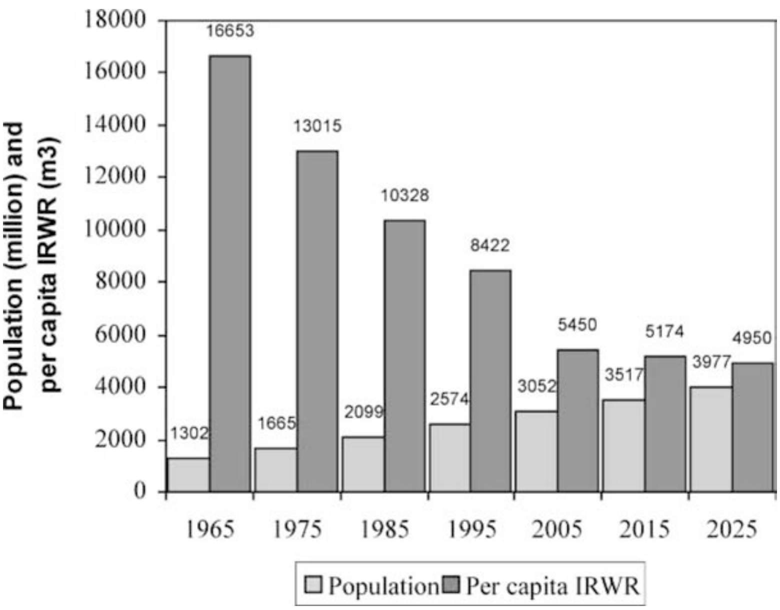

Fig. 1 Trends in population and internally renewable water resources in the tropics. *Source*: Adapted from Ref.[3].

Hydrologic–Irrigation

Assuming that a calorie supply of 2700–3000 kcal per person per day is needed to meet most of the nutritional requirements of people in developing countries, this indicates that a substantial number of poor people in this region suffer from nutritional deficiencies. Table 2 shows the production and productivity statistics for the same 30-year period between 1965 and 1995.

In 1995, the total cereal consumption was 529 million metric tons (Table 1, against a total cereal production of only 470 million metric tons (Table 2, indicating a production deficit of 59 million metric tons. According to IWMI,[3] this shortfall would increase to 98 million metric tons to meet a targeted calorific requirement of 2747 kcal in 2025, even though this is still lower than the global average. The above analysis brings to light the urgent need to increase cereal production in the tropics in the next few decades to meet the food and nutritional requirement of its people.

Table 1 also shows that although the total amount of cereal consumed increased by 147% during the 30-year period 1965–1995 (at an average annual growth rate of 3.1%), there has not been a commensurate increase in per capita calorie supply, which has recorded an overall increase of only 19% in the same period.

From Table 2 it can be observed that cereal production in the tropics has increased by 137% in the 30 yr since 1965 (at nearly 2.9% per year), largely as a result of the near doubling of both irrigated area and yield. While the cereal irrigated area in the tropics is only 30% of the cultivated area, it provides nearly 50% of the cereal production.

In terms of the water resources situation, the total water diverted in the tropics is 1057 km^3, of which the total primary water diverted is only 685 km^3. The rest is return flow. This 685 km^3 represents only 8% of potentially utilizable water resources (PUWR) of the tropics. But 89% of this water is used for irrigation. Hence, improving the productivity performance of existing irrigation systems must be given high priority in efforts to overcome the food and nutritional deficits confronting the tropics. Possible irrigation management strategies to help achieve this goal are discussed in the following section.

STRATEGIES FOR IMPROVING AND SUSTAINING IRRIGATED AGRICULTURE

While irrigated agriculture has made significant contributions to the food security of growing populations, concerns have also been expressed about its performance and some of its less desirable consequences: the poor returns to irrigation investments, the environmental impacts (such as waterlogging and salinization) brought about by poor design and operation of irrigation schemes, and the lack of attention paid to the needs of the poorer sections of society. So, the challenge is to find ways of improving and sustaining food security and livelihoods that make optimum use of available resources and do not degrade the productive capacity of land and water.

While increasing cropped area, either by expansion of irrigation facilities or increasing crop intensity remains a possibility, there must also be emphasis on improving land and water productivity through the adoption of appropriate agricultural and water management practices. Measures will include: developing high yielding crop varieties, promoting innovative low-cost techniques for water harvesting and water application, conjunctive use of surface and groundwater, and implementation of institutional and policy reforms to enable integrated water resources management at the basin level, recognizing the multiple uses and users of water.

The Basin Perspective and Water Savings

It is generally recognized that the river basin is the appropriate unit of analysis to assess water availability,

Hydrologic–Irrigation

Table 1 Total population, calorie supply, and cereal consumption in the tropics

	Population		Per capita calorie supply		Cereal consumption	
Year	Population (million)	Annual growth (%)	Total (kcal)	Annual growth (%)	Total (M Mt)	Annual growth (%)
1965	1302	—	2061	—	214	—
1975	1665	2.5	2114	0.3	289	3.1
1985	2099	2.3	2277	0.7	399	3.3
1995	2574	2.1	2456	0.8	529	2.9
Growth 1965–1995	97.6%	2.3%	19%	0.6%	147%	3.1%

water use, and thereby, the scope for water savings. Essentially, water saving means diverting water from non-beneficial or less beneficial uses and making it available for other more productive uses. For example, flows to saline sinks or unrecoverable water bodies can be minimized through interventions that reduce irrecoverable deep percolation and surface runoff. Similarly, the pollution caused by the movement of salts into recoverable irrigation return flows can be reduced by minimizing the passage of these flows through saline soils or saline groundwater.

Decreasing non-beneficial depletion of water can also be achieved by: 1) reducing evaporation from water applied to irrigated fields by adopting appropriate precision irrigation technologies such as drip irrigation, or agronomic practices such as mulching, or by changing the crop planting dates to match the period of lower evaporative demand; 2) reducing the evaporation from fallow land; 3) decreasing the area of free water surfaces; 4) decreasing the amount of non- or less-beneficial vegetation, and controlling weeds; and 5) by diverting saline or otherwise polluted water directly to sinks without having to dilute it with fresh water.

Projects are quite often justified on the basis of water savings. But this is misleading because, the commonly used term ‘‘irrigation efficiency’’ ignores water recycling and reuse, phenomena that are prevalent in many irrigation systems. Therefore, one has to be careful in assuming that apparent water savings at field level will automatically result in real water savings. Only proper basin-level analysis will reveal if there are uncommitted outflows available and whether water savings are really possible.[4]

Hydrologic–Irrigation

Role of Storage

Different annual rainfall regimes result in different levels of availability of fresh water resources. In the permanent humid climatic zone there is water surplus but because the rainfall distribution is regular, the run-off is quite stable and there are few problems with floods. In many parts of the seasonally humid and semiarid climates, river run-off is irregularly distributed within the year. Heavy rain alternates with dry spells resulting in alternating flood and drought periods. This is particularly serious in monsoon Asia and in the semiarid areas of Africa and India. In such areas, suitable measures to capture and store excess water for irrigation, industry, and domestic use must be adopted. In Sri Lanka and southern India, this has been done over thousands of years through the construction of small storage reservoirs (called ‘‘tanks’’) by building a bund at a strategic location in a catchment area.

In fact, much of the growth in irrigation in the last three decades has been made possible by water development projects ranging from multipurpose storage reservoirs to extensive groundwater extraction from underground aquifers. Storage, whether in reservoirs, small tanks, farm ponds, or groundwater aquifers helps to match water demand and supply especially in drier periods, in the face of spatial and temporal variations in natural water supply. A recent development in India has been the concept of ‘‘watershed-based systems for resource conservation, management and use,’’ which involves the optimum use of precipitation through improved water, soil, and crop management. This is accomplished through improving infiltration of rainfall into the soil, run-off collection, and by recovery from wells after deep percolation resulting in the improvement and stabilization of agriculture in the watershed.

As stated in the preceding section, planning for storage is best done on the basis of water resources analysis in a basin perspective. One of the first steps is to ascertain whether the basin in question is open, closed, or semiclosed.[5] Current water use and productivity in the basin must be assessed to determine the extent to which increased demands for irrigated agricultural production can be met by increasing water productivity, and the degree to which increased demands will require increased consumption of water. Then plans to capture and use any uncommitted discharge from open or semiclosed basins can be drawn up. Combinations of small and large surface water storage and groundwater recharge are generally the best systems where they are feasible. In monsoon Asia, research and development are needed on how to manage water under monsoonal conditions, particularly on how to develop effective irrigation management responses to rainfall.

Increasing the Productivity of Water

Not only is per capita water availability decreasing in many developing countries but agriculture's share of water is also declining while water demands are increasing from the industrial and urban sectors. When managing water for agriculture, especially in areas where water rather than land is the limiting resource, it is useful to shift the focus from increasing the productivity of land to increasing the productivity of water. That is, to identify and adopt agricultural and water management practices that achieve more output per unit of water consumed. On one hand, these will include selecting crops or crop varieties that are less water-consuming, or which yield higher physical or economic productivity per unit of water, and improved land preparation and fertilization practices. On the other hand, techniques such as deficit, supplemental, or precision irrigation that allow better control, timing, and reliability of water supplies will enable farmers to apply limited amounts of water to their crops in the time and amount that help realize optimum crop response to water. Any water thereby freed up can, in turn, be reallocated to other uses with potentially dramatic increases in overall economic productivity of water.

Such techniques do not always imply high-tech options but will include simple bucket and drum kits for drip irrigation, pitcher irrigation, small sprinkler systems, level basins, as well as conventional drip and sprinkler systems. Innovative and affordable water management systems such as these are especially important for small farmers in situations where rainfall is limited and uncertain, and where one or two irrigation applications can have a big impact on crop yields and household food security and income.

Sustainable Management of Groundwater

In many tropical countries with high levels of rural poverty, groundwater development offers major opportunities for promoting food and improving livelihoods. Affordable innovations in manual irrigation technologies such as the treadle pump (costing US$ 12–25 per unit and which can be operated even by children) have dramatically improved poor people's access to groundwater in Bangladesh, Eastern India, and Nepal.[6] The capital requirements to develop groundwater irrigation are generally low and its productivity higher compared to surface irrigation. It offers farmers irrigation water "on-demand" and responds slower to drought. Farmers also tend to exercise more care in using it because of the costs involved in lifting water, thus maximizing application efficiencies.

The undoubted benefits of groundwater development have to be balanced with the risks of overexploitation and contamination. One of the most serious effects of groundwater depletion is seawater intrusion in coastal aquifers as in the Tamilnadu coast near Madras in India and in the Saurashtra coast of the Western Indian State of Gujarat. While there are only rough estimates of the amount of unsustainable groundwater use, the 1–3 m per year decline in water tables occurring in pump intensive areas of India and China clearly highlights the gravity and magnitude of the problem.

While reducing pumping for irrigation is an obvious response, this will have adverse effects on the outputs from this highly productive form of agriculture and ultimately affect the food security of the concerned countries. More desirable solutions are groundwater recharge and increasing water productivity to achieve the same production with less water.

Regulating groundwater overdraft is a far more complex and difficult issue compared with stimulating groundwater use where it is abundant. Enforcing groundwater laws in developing regions present formidable difficulties given the sheer numbers involved (for e.g., the total number of private tubewells in South Asia is thought to exceed 20 million, largely unregistered and unlicensed, and growing at a rate of 1 million per year). The challenge therefore is to identify appropriate institutional and legal frameworks compatible with the local environment through a careful learning process approach to combat the problem of groundwater overdraft.

Effective Irrigation Management Institutions and Policies

Sound institutions and policies are vital for effective irrigation management and increasing food production while sustaining land and water quality, especially in light of growing demands and competition for water from other sectors. Irrigation management must therefore be viewed within the overall context of an integrated and sustainable approach to water resources management that is sensitive to the requirements of all uses and users of water. This not only entails the formulation of adequate laws, institutions, and policies, but also the development of the requisite organizational capacity and skills for enforcement and regulation.

Key institutional attributes include the demarcation of the roles, rights and responsibilities of the various actors in the water sector, the promotion of new forms of public and private partnerships for investment, operation and maintenance, and the emergence of financially self-reliant service delivery organizations that are responsive and accountable to water users. In fact, the overarching concern must be to ensure meaningful participation of all stakeholders in the whole gamut of planning, operation, maintenance, and management of irrigation schemes.

Improving Irrigation Services

The level of irrigation services provided to farmers is influenced by the physical design of the system, its operation and maintenance, as well as the underlying institutional environment. When farmers are provided with reliable irrigation services, they would be more likely to invest in improved technologies and practices, generally resulting in increased production, higher incomes, and improved irrigation performance. But it is useful to remember that, in general, more flexible and sophisticated technology will require levels of management capability that are not always readily available in rural environments. Thus, in seeking to provide a stable and predictable water supply to farmers, it is quite important to find ways and means of doing so that are commensurate with the available skills and resources. The dilemma of rigidity vs. flexibility in irrigation design, and the interactions between design and system management have been discussed in detail by Horst.[7]

In discussing the large public irrigation schemes of monsoon Asia, Burns[8] has pointed out that structuring such systems to formalize the allocation of sporadic wet season scarcity, while protecting the civil works from producer damage, is a necessary task. He further states that unless these schemes are run as regulated and monitored public utilities, actual system performance will bear little resemblance to design intentions due to the rent-seeking activities of system designers, operators, and individual farmers.

Ensuring reliable irrigation services also implies the establishment of: 1) clear rules and agreements between providers and users giving details of the nature of the service and the compensation arrangements for providing and receiving such services; 2) mechanisms for monitoring and control of obligations; 3) modalities for conflict-resolution; and 4) procedures for modifying and updating agreements. These aspects take on added significance in light of the progressive disengagement of public agencies from irrigation management with attendant transfer of responsibilities to the beneficiaries.

CONCLUSION

Feeding the world's population presents a formidable challenge: there are more mouths to feed, less arable land available, increasing competition for water resources, and major concerns about deteriorating ecosystems. Irrigated agriculture makes undeniable contributions to the food security of people in the tropics, providing nearly 50% of its cereal production. But there is a gap between supply and demand and it is urgent to find sustainable ways to improve the performance of the irrigation sector and to satisfy the nutritional requirements of a growing population. The management of natural resources, especially water, takes on added significance as population increases and changes in resource utilization place greater pressures on land and water.

With fewer opportunities to expand irrigated areas by the development of new systems, and growing demands and competition for water from other sectors, the emphasis must shift to practicing more effective methods of management with particular focus on improving the productivity of water. A vital prerequisite is for irrigation management to be viewed within an overall framework of an integrated, holistic approach to water resources management. This is best done on the basin scale, taking into account the needs of all uses and users but also considering the conjunctive use of surface water, groundwater, and rainfall.

Given the multiple facets of irrigation development and management, a piecemeal and uni-dimensional focus on individual components is bound to produce outputs that fall short of expectations. For instance, concentrating only on the technological aspects of an innovation while neglecting other aspects such as maintenance, institutional support, training, and skills development, will yield disappointing overall results, however, well that individual component has been addressed. Hence, the need to take a holistic view and move towards service-oriented irrigation management with meaningful participation of all interested parties.

INTRODUCTION

The return flows from irrigated agriculture (i.e., Irrigation Return Flows, IRF) are considered the major diffuse or "non-point" contributor to the pollution of surface and groundwater bodies.[1] This off-the-farm discharge ("off-site" contamination) is inevitable since irrigated agriculture cannot survive if salts and other constituents accumulate in excessive amounts in the crop's root zone ("on-site" contamination), and so they must be reached and exported with the drainage waters.[2] Thus, the major task concerning the viability and the long-term sustainability of irrigated agriculture is the attainment of a proper balance for optimizing crop production while minimizing both the "on-site" and the "off-site" environmental damages or impacts and, ultimately, finding an acceptable disposal of the IRF.[3,4]

As a consequence of this increasing "off-site" environmental problem, water pollution standards and emerging policies regulating the discharge of the IRF are being implemented in developed countries. The key policies for mitigating the negative environmental impacts of irrigation are incorporated in the Water Pollution Control Act in United States,[5] and in the Nitrates, Habitats and Environmental Impact Assessment, and Water Framework directives in European Union.[6]

The degree of the "off-site" irrigation-induced pollution depends on the hydrogeological characteristics of the irrigated land and substrata, the agricultural production technologies used, and the water supply and drainage conveyance systems.[1] This article reviews these issues in IRF, describes the main components and chemical constituents of IRF, and summarizes recommended management practices aimed at reducing the off-site water quality impact from irrigated agriculture.

COMPONENTS OF IRF

Fig. 1 gives a schematic diagram of a typical irrigation-crop-soil-drainage system, composed of the water delivery, the farm, and the water removal subsystems.[2] The water removal subsystem (i.e., the IRF) may be divided into the surface drainage, consisting of the overflow or bypass water and surface runoff or tailwater, and the collected subsurface drainage components. Since IRF are mixtures of these components, their proportions determine the final quality of IRF. Table 1 summarizes the expected water quality changes of the three IRF components (overflow, tailwater, and subsurface drainage) relative to the quality of the applied irrigation water.

Overflow is the result of operational spill waters from distribution conveyances that are directly discharged into the drainage system and its quality is generally similar to that of the irrigation water (Table 1).

Tailwater is the portion of the applied irrigation water that runs off over the soil and discharges from the lower end of the field directly into the drain system. Because of its limited contact and exposure to the soil surface, its quality degradation is generally minor. Even so, these waters may increase slightly in salinity and may pick up considerable amounts of sediments and associated nutrients (phosphorus in particular) as well as water-applied agricultural chemicals such as pesticides and nitrogen fertilizers (anhydrous ammonia in particular) (Table 1).

Subsurface drainage is the portion of the infiltrating water that flows through the soil and is collected by the under drainage system. Because of its more intimate contact with the soil and the dynamic soil–plant–water interactions, its quality degradation is generally substantial. These subsurface drain waters carry any anthropogenic chemicals present in a soluble form in the soil water as well as any salts and other soluble elements present in the soil and parent geologic material and intercepted shallow groundwaters. The salinity and agrochemicals in subsurface drainage are the primary source of pollution associated with irrigated agriculture (Table 1).

WATER QUALITY CONSTITUENTS IN IRF

Irrigation return flows provide the vehicle for conveying the pollutants to a receiving stream or groundwater

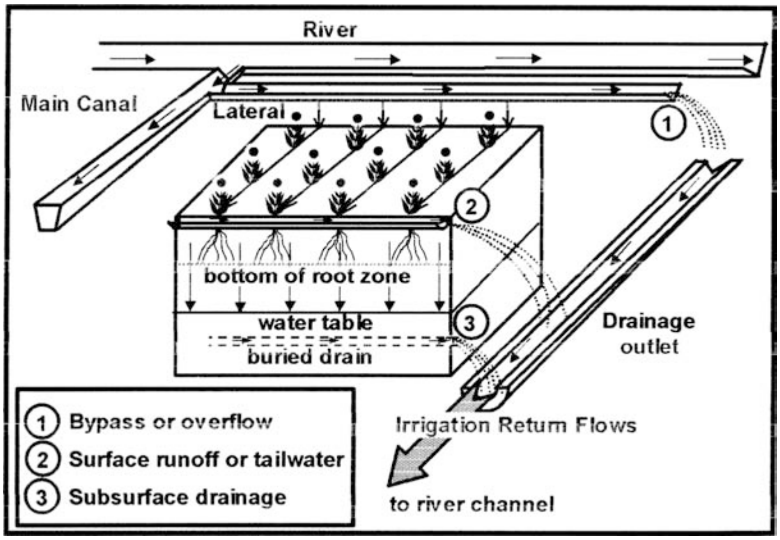

Fig. 1 Idealized sketch showing the diversion of irrigation water through a main canal, its distribution through a lateral, and its application to croplands. The three main components of the irrigation return flows (IRF) to the river channel are shown. The deeper groundwater zone, a second receiving water system, is not shown.

reservoir. It is therefore necessary to characterize their most important water quality constituents (namely, inorganic salts, agrochemicals and trace elements) and to develop management strategies aimed at alleviating their detrimental effects on the receiving water bodies.

Salts

Salts are a major quality factor since they can restrict the municipal, industrial and agricultural uses of water and can dramatically decrease the productivity and sustainability of irrigated agriculture in arid zones.

The primary source of dissolved mineral salts (also referred to as salinity) is the chemical weathering of rocks, minerals, and soils. Salinity is reported in terms of total dissolved solids (TDS in $mg\,L^{-1}$) or Electrical Conductivity (EC in $dS\,m^{-1}$ at 25°C). The main solutes contributing to salinity are the cations calcium (Ca), sodium (Na), and magnesium (Mg), and the anions chloride (Cl), sulfate (SO_4), and bicarbonate (HCO_3). These solutes are reactive in waters and soil solutions participating, among others, in cation exchange and mineral solubility. The excessive accumulation of Na (i.e., sodicity, generally expressed by the Sodium Adsorption Ratio or SAR) in the soil solution and exchange complex may impair poor soil physical

Table 1 Quality parameters of the three irrigation return flow (IRF) components and their expected quality changes as related to the quality of the irrigation water

	Components of IRF		
Quality parameters	**Overflow**	**Tailwater**	**Subsurface drainage**
General quality degradation	0	+	++
Salinity	0	0, +	++
Nitrogen	0	0, +, ++	++, +
Phosphorus	0, +	++	0, −, +
Oxygen demanding organics	0	+, 0	0, −, −−
Sediments	0, +, −	++	−−
Pesticide residues	0	++	0, −, +
Trace elements	0	0, +	0, −, +
Pathogenic organisms	0	0, +	−, −−

0: Negligible quality changes expected.
+, −: Expected to be slightly higher (i.e., pick up), lower (deposition).
++: Expected to be significantly higher due to concentrating effects, application of agricultural chemicals, erosional losses, pick up of natural geochemical sources, etc.
−−: Expected to be significantly lower due to filtration, fixation, microbial degradation, etc.

properties and is a critical factor in the sustainability of irrigated soils.[7]

Growing plants extract water through evapotranspiration and leave behind most of the dissolved salts, increasing its concentration in the soil water ("evapoconcentration effect"). Irrigation also adds to the salt load in IRF by leaching natural salts arising from weathered minerals occurring in the soil profile, or deposited below ("weathering effect").[2] As a consequence of both effects, it follows that the salinity and chemical composition of IRF depend basically on the characteristics of the irrigation water, the soil and subsoil, and the hydrogeology, as well as on the management of the irrigation water or Leaching Fraction (LF) defined as the fraction of infiltrated water that percolates out of the root zone. Thus, high LFs promote the weathering effect and the salt load carried out with the IRF (i.e., increased "off-site" pollution) whereas low LFs promote the evapoconcentration effect and the concentration of salts in the crop's root zone (i.e., increased "on-site" pollution).

In conclusion, the mass of salts or salt loading in IRF depends mainly on the salinity of the irrigation water, the minerals present in the soil and subsoil, and the water management (LF). The salt loading values may vary widely, from values similar to those of the irrigation water to values one order of magnitude higher. Thus, typical salt loading values in IRF from arid-land irrigated agriculture vary between $2\,Mg\,ha^{-1}\,yr^{-1}$ and $20\,Mg\,ha^{-1}\,yr^{-1}$.[1,2,7] The quantification of salt loading is critical to ascertain the "off-site" contamination of irrigated agriculture, since the prediction of the resultant salt concentration in a body of water after mixing with the IRF requires knowledge of the mass of salts (i.e., concentration and flow) in each contributing body.

Nitrogen

Nitrogen can be in either the organic or the inorganic (ammonium, nitrate and nitrite) form. Organic N is predominant in surface drainage (although it is not usually an issue in arid areas), whereas inorganic N is predominant in subsurface drainage water. Although nitrite is considered more hazardous than nitrate, it is in general a transient form of N present in small quantities. Nitrate is thus the dominant form of N in IRF and should be the focus of the water quality evaluation.[3]

High nitrate (NO_3) concentrations in IRF are a major concern since they may cause eutrophication (excessive algal growth) and hypoxia (decline in dissolved oxygen from decay of algae) problems. When nitrate is ingested in substantial amounts by humans and animals, it may cause methemoglobinemia (blue-bay like symptoms from oxygen starvation exhibited by infants and elderly) and certain cancers.[7] Thus, USEPA has set the maximum allowable concentration of nitrate in public water supplies at $45\,mg\,L^{-1}$,[5] whereas the European Union has limited it to $50\,mg\,L^{-1}$.[6]

The three major sources of nitrate found in IRF are leaching from croplands, land disposal of urban sewage, and concentrated animal feeding (beef feedlots, dairies, swine, chicken houses) wastes. The potential for nitrate leaching is a function of soil type, weather conditions and crop management system. In general, the higher the N application rate, the greater the amount of N available to be lost, since fertilizer N recovery by harvested crops averages about 50% and tends to be even lower when high N application rates are used. In addition, mineralization of organic N, followed by nitrification of NH_4 may also increase the N losses.[4]

Drainage has a large influence upon losses of nitrogen. The N loss from poorly drained soils is generally much less than from soils with improved drainage systems. As previously indicated, much of the N transported in surface runoff is organic N associated with the sediment, although the amount lost is usually small and poses little threat to the environment except in pristine waters. On the other hand, nitrate concentrations in subsurface drainage water are much higher and variable, depending on the N fertilization rates and time of applications, and on water and soil management.[4]

Phosphorus

Phosphorus (P), present in both organic and inorganic forms, is a relevant water quality constituent in IRF because of its contribution to eutrophication of surface waters. Most of the P in surface drainage is in particulate (i.e., sediment and organic matter-bound) form whereas most of the P in subsurface drainage water is in soluble phosphate form.

The release of P depends on such biogeochemical processes as adsorption/desorption of phosphate, precipitation/dissolution of inorganic P forms, and mineralization of organic P forms.[7] Phosphorus in subsurface drainage waters is typically low in concentration because of its strong adsorption in arid zone soils. Thus, although P discharge from agricultural fields vary considerably, it is usually in the range of $0.2\,kg\,P\,ha^{-1}\,yr^{-1}$ to less than $3\,kg\,P\,ha^{-1}\,yr^{-1}$. Even though P loading in IRF is minor, the P concentrations measured in many agricultural IRF may be orders of magnitude above the soluble ($10\,\mu g\,P\,L^{-1}$) and total

Table 2 Summary of recommended management practices at the water delivery, farm, and water removal subsystems to reduce off-site water quality impacts from irrigated agriculture

Water delivery subsystem
Designed to meet the farm water requirements while reducing undesirable water losses
Canal lining and/or closed conduits and reservoir lining: prevent seepage losses, phreatophyte ET losses, soil waterlogging, and groundwater recharge; improve irrigation water quality (i.e., suspended solids).
Installation of flow measuring devices: water control; appropriate water charges and penalties; reduce bypass losses; attain high water-conveyance efficiencies.
Construction of regulation reservoirs at the irrigation district level to increase flexibility in water delivery.
Implement an efficient institutional framework, service-oriented besides its regulatory character; scheduled maintenance programs.
Farm subsystem
Designed to maintain or increase crop productivity while improving source control
Improve cultural practices: rate and timing of fertilizers; slow-release fertilizers; fertigation; pest control; seeding and tillage practices.
Adopt less environmentally damaging agricultural practices: integrated management systems; mixed cropping practices; organic farming.
Increase irrigation application efficiency and uniformity: proper design of the farm irrigation layout; choice of irrigation system; optimum irrigation scheduling; reduce evaporation through mulching and reduced tillage.
Minimize the Leaching Fraction according to the leaching requirement of crops: reduce drainage volume; maximize mineral precipitation; minimize pick up of salts.
Provide training and technical services to farmers; eliminate institutional constraints.
Water removal subsystem
Designed to improve sink control and minimize loading in IRF
Constraints in disposal of IRF to meet quality objectives in the receiving water body.
Reuse for irrigation drainage waters, municipal wastewaters and sewage effluents; integrated on-farm drainage management (i.e., on-farm cycling of drainage waters through biological materials-agroforestry systems).
Ocean and inland (i.e., evaporation ponds; solar evaporators; deep well injection) disposal of drainage waters.
Design and management of drainage systems: include water quality as a design parameter; depth and distance of placement of drains; integrated drain flow and irrigation management; crop water use from shallow watertables (i.e., subirrigation); controlled drainage (i.e., management of the water level in the drainage outlet); reduce nitrate effluxes by maintaining a high water table to increase denitrification losses.
Pumping and disposal of groundwater to reduce intercepted groundwater by the drainage network.
Flowing of surface drainage water through vegetated filters and riparian vegetation (removal of sediments and sediments-associated contaminants), flowing of subsurface drainage water through riparian zones (removal of nitrate due to plant uptake and denitrification); flowing of drainage water through constructed wetlands (sink for sediment, nutrients, trace elements, and pesticides).
Physical, chemical, and biological treatment of drainage waters: particle removal; adsorption, air stripping; desalination (membrane processes and distillation); coagulation and flocculation; chemical precipitation; ion exchange; advanced oxidation processes; biofiltration (irrigation of specific crops that accumulate large quantities of undesirable constituents such as Se, Mo, B, NO_3, etc.); algal–bacterial treatment facilities (removal of NO_3 and Se).

($20\,\mu g\,P\,L^{-1}$) critical levels assumed to accelerate the eutrophication of freshwater aquatic ecosystems.[5]

Pesticide Residues

Pesticide contamination in IRF is of concern in some agricultural areas, although it is in general less significant than the salinity or nitrogen pollution problem.[3]

Pesticides used in irrigated agriculture include herbicides, insecticides, fungicides, and nematicides. These various types make it difficult to assess their potential impacts on water quality. Pesticide concentrations in surface drainage are usually much greater than those in subsurface drainage due to the filtering action of the soil. Thus, the total loss of pesticides via subsurface drainage is usually 0.15% or less of the amount applied, whereas losses via surface drainage can be up to 5% or more.[4]

The environmental fate of pesticides is quite complex. Chemical-specific properties influence the reactivity of pesticides. Pesticides can be degraded by microbes, chemical and photochemical reactions, adsorbed on to soil organic matter and clay minerals, lost to the atmosphere through volatilization, and lost through surface runoff and leaching.[4] Once a pesticide enters into the soil, its fate is largely dependent on sorption (evaluated by use of a sorption coefficient based on the organic carbon content of soils) and persistence (evaluated in terms of the half-life or the time it takes for 50% of the chemical to be degraded or transformed). Pesticides with low sorption coefficient (such as atrazine, DBCP, and aldicarb) are likely to leach readily, whereas pesticides with long half-lives (such as DDT, lindane, and endosulfan) are so persistent that many of them banned various decades ago are still found in stream sediments or are now being detected in the groundwaters.[7]

Trace Elements

High concentrations of trace elements in soils and waters pose a threat to agriculture, wildlife, drinking water, and human health. The trace elements of most importance, documented as pollutants associated with irrigated agriculture, are barium (Ba) and lithium (Li) (alkali and alkali earth metals), chromium (Cr), molybdenum (Mo), and vanadium (V) (transition metals), arsenic (As), boron (B), and selenium (Se) (non-metals), and cadmium (Cd), copper (Cu), lead (Pb), mercury (Hg), nickel (Ni), and zinc (Zn) (heavy metals).[3] Those trace elements such as As, Cd, Hg, Pb, B, Cr, and Se are especially harmful to aquatic species because of biological magnification.[5] Due to the generally narrow window between deficiency and toxicity of trace elements, it is essential to have an adequate information on their concentrations in soils and waters.

The sources of trace element contamination may be divided into natural (i.e., geologic materials) and agricultural-induced (i.e., fertilizers, irrigation waters, soil and water amendments, animal manures, sewage effluent and sludge, and pesticides). Increases in trace element concentrations in surface runoff are generally not expected, whereas the presence of trace elements in groundwaters is influenced by the nature of the sources, the speciation and reactivity of the trace elements, and the mobility and transport processes. Thus, high concentrations of trace elements in subsurface drainage water appear to be strongly associated with the geologic setting of the irrigated area and may be affected by the same processes that affect the soil and groundwater salinity.[3,7]

An illustrative example of trace element contamination is the selenium toxicosis of waterfowl at Kesterson reservoir (California, U.S.A.), a terminal evaporation pond for drainage waters high in Se (300 ppb average) originating from the Moreno shale, a geologic formation of the Coast Range Mountains in the west side of the San Joaquin Valley.[7]

MANAGEMENT OPTIONS TO REDUCE OFF-SITE WATER QUALITY IMPACTS FROM IRRIGATED AGRICULTURE

The basic idea behind the control of irrigation-induced environmental problems is the change in focus from a ‘‘water resource development’’ to a ‘‘water resource management’’ approach. This new ‘‘thinking’’ involves both policy changes, such as reducing the applied water through economic and regulatory policies (i.e., water metering, water pricing, licenses and time-limited abstraction permits), and developing farmer's incentives for promoting best management practices (i.e., compensation and agri-environment payments for irrigated crops), and a variety of technical measures.[5,6,8]

Since a detailed description of the technical measures is too lengthy for this article, Table 2 summarizes some of the recommended strategies aimed at reducing the off-site water quality impacts from irrigated agriculture. However, it should be cautioned that these measures should be applied in a ‘‘case-by-case’’ basis, since some of them could aggravate the ‘‘on-site’’ pollution problems. Typical examples will be (i) the ‘‘minimum leaching fraction concept,’’ that could promote soil sodification and structural stability problems due to the precipitation of calcium minerals such as calcite and gypsum; (ii) the reuse of drainage water for irrigation, which is only sustainable if it is of sufficient good quality; and (iii) the disposal of drainage water in evaporation ponds, which may eventually lead to other environmental problems.

The reader is referred to the references given at the end of the entry for further information on the myriad of technical management options developed in the last decades and on details of their advantages and limitations.

Irrigation Sagacity (IS)

Charles M. Burt
Ken H. Solomon
BioResource and Agricultural Engineering Department, California Polytechnic State University, San Luis Obispo, California, U.S.A.

INTRODUCTION

Throughout the Western United States, water rights are granted for *reasonable* and *beneficial* purposes. Engineers require an irrigation performance parameter that embodies the reasonable and beneficial standard to assess irrigation systems, practices, and competing uses, whether against each other, or against benchmark targets. Irrigation sagacity (IS), initially proposed by Solomon,[1] is such a parameter. The term *sagacity* comes from *sagacious*, meaning wise or prudent.

IS is fundamentally different from irrigation efficiency (IE), long used to quantify beneficial use of irrigation water.[2] Water is used beneficially if it contributes directly to the agronomic production of the crop. However, due to physical, economic, or managerial constraints, and various environmental requirements, some degree of non-beneficial use is generally reasonable. IS goes beyond IE to incorporate quantification of reasonable uses: those uses that may not contribute to agronomic production, but are nonetheless justified under the particular circumstances at hand.

BENEFICIAL USES

Both IE and IS credit those portions of the irrigation water that are judged to be beneficially used. Examples of beneficial uses include: crop evapotranspiration (ET), water harvested with the crop, water used for salt control (leaching), climate control, seedbed preparation, softening the soil crust for seedling emergence, and ET from beneficial plants (windbreak, cover-crop, habitat for beneficial insects). Evaporation during regular and reclamation leaching, and evaporation during necessary irrigations are beneficial, because an agronomic objective is achieved during those events.

Examples of non-beneficial uses at the farm level include: overirrigation due to non-uniformity, uncollected tailwater, deep percolation beyond that needed for salt removal, unnecessary evaporation from wet soil outside cropped area, spray drift beyond field boundaries, and evaporation associated with excessively frequent irrigations. At the irrigation district level, non-beneficial uses include: spills, seepage, evaporation from canals or reservoirs, and ET from non-beneficial plants such as weeds and phreatophytes.

REASONABLE USES

IS quantifies that portion of irrigation water going to sagacious (either beneficial or reasonable) uses.[1,2] Reasonable uses are those that, while not directly benefiting agronomic production, are nonetheless reasonable under prevailing economic and physical conditions. Examples of reasonable, though not beneficial, water uses include the following.

Losses that cannot be economically avoided are considered reasonable. For example, canal seepage may be reasonable if canal seepage rates are low and it is not economical to line the canal to avoid that seepage. No irrigation system can be designed to apply water with perfect uniformity, so some deep percolation due to non-uniformity is reasonable.

Losses tied to technical requirements may be reasonable. Reservoirs in the distribution system add flexibility and reduce canal spills. Evaporation from such reservoirs constitutes a reasonable use. Microirrigation systems generally require filtration, and filters need to be flushed periodically. Filter flush water may be a reasonable use. If sprinkler irrigation is the appropriate technology, spray evaporation and wind drift losses are an inevitable consequence of using that technology to irrigate, and hence are a reasonable use.

Losses due to the uncertainties associated with many aspects of water management may be reasonable. Exactly how much water is held in the soil? Exactly how much crop ET since the last irrigation? Exactly how much water is necessary for maintenance leaching? In the face of such uncertainties, it is reasonable for the farmers to err on the side of overapplication, so some deep percolation due to uncertainty may be reasonable.

Losses that contribute toward environmental goals may be reasonable. If canal seepage feeds a wetland or wildlife habitat area in a timely manner, that seepage may be deemed a reasonable use. (Even though feeding a wetlands/habitat area meets environmental goals, it is not considered a beneficial use because it does not directly aid the production of the crop being irrigated.) If tailwater blends with drainage water to meet water quality standards in receiving waters, then that tailwater may be a reasonable use.

Non-sagacious uses (neither beneficial nor reasonable) are those uses without economic, practical, or other justification. An example of a non-sagacious use is wet soil and spray evaporation associated with excessively frequent irrigations. No agronomic objective is served by irrigating more frequently than needed, and it is difficult to imagine an economic justification for doing so. Hence, these losses are without justification. They are unreasonable and non-sagacious.

CONSERVATION IMPLICATIONS

It is a common misunderstanding that (1 − IE) represents the fraction of the applied irrigation water that is wasted, and therefore, the fraction that may be conserved or reallocated. However, as noted above, some degree of non-beneficial use is generally reasonable, so the potential for conservation and reallocation consists only of water uses that are both non-beneficial and unreasonable.

DETERMINATION OF SAGACITY

As with other irrigation performance parameters, application of the IS concept requires that boundaries be specified, flows into and out of the bounded area be quantified, fractions of the irrigation water flowing to various destinations be estimated, and judgments be made about whether those fractions are beneficial or reasonable. Whereas the determination of beneficial use involves only an agronomic criterion—direct contribution to the agronomic production of the crop—the determination of reasonable use involves more varied criteria.

Feasibility

Identifying a particular non-beneficial water use as unreasonable requires that an alternate practice be identified that uses less water, and is practically, technically, economically, and environmentally feasible.

Practical feasibility considers physical constraints such as limitations due to climate, soil, terrain, water delivery schedules, or water travel time. Required resources, which can include labor (sufficient quantity and with suitable experience), infrastructure (maintenance of specialized equipment, extension advice on proposed crops, etc.), and information (precise knowledge, facts, data available when needed), are available. Even after identifying the benefits of a new practice, there will be a lag time before implementation is possible. Decision-makers need to be convinced, approvals obtained, plans drawn, and financing arranged. Thus, a realistic time schedule for implementation is also required.

Technical feasibility has not only hardware but software and operational aspects. Equipment must be available, affordable, and perform reliably in an agricultural environment. It must satisfy requirements for accuracy and precision of flow, time or other quantities to be measured or controlled. Local, farm scale demonstration projects may be necessary to prove that equipment and plans are reliable, and operations feasible. A phased transition into any new practice should be planned.

Economic feasibility is an obvious but complex test. It is not enough to compare the costs of operating one way to the costs of operating another way. The proposition facing a farmer is to change from one practice to another. The costs involved in abandoning an old practice and adopting a new one, or converting from the old to the new, may well be greater than the cost if the new practice were started from scratch in a new operation. Further, even if the annualized cost of an alternate practice is favorable, it may not be possible for farmers to implement it unless additional resources such as financing and credit are available. Economic feasibility must also consider risk. It is not reasonable to ask farmers to undertake a large risk to actualize the potential of a small benefit.

Economic feasibility must include plans and mechanisms for properly allocating the costs of alternate practices to those who will ultimately reap the benefit. This may be particularly difficult in the case of alternate practices whose ultimate beneficiary is the environment, because it is often not clear who ‘‘ought’’ to pay on behalf of an environmental common good.

Environmental feasibility requires that the alternative practice must be environmentally benign or beneficial, or that the costs of any required environmental mitigation are considered.

If no alternate practice using less water meets all four feasibility tests, the current practice is reasonable. The current practice is unreasonable if a feasible alternate using less water exists. The amount of unreasonable (non-sagacious) use due to the current practice is the difference between the current use and the (reduced) use of the preferred alternate.

CONCLUSION

The results of a sagacity determination may vary with location, geographic scale, or time. Because sagacity includes economics, which can change as markets and prices do, sagacity can change with place and time. Technology and the availability of resources are also factors influencing sagacity that can change with place and time.

Results of the various feasibility checks can depend on scale. To a farmer, the district's water delivery policies and schedule are given. At the district level, these things may be considered adjustable. Districts can and should consider options that individual farmers cannot consider. Economics and the ability to absorb risk change with scale as well. What may not be economical to an individual farmer could be economical to a district, region, or to another competing water user, if there is a way for them to share in the costs as well as the benefits. While individual farmers are less able to bear risks due to uncertainty or reduced water use, the shift to a district or societal level offers the potential to "average" individual outcomes and pool risks.

So sagacity is very much a site-, scale-, and time-specific quantity. Therefore, a necessary preliminary to the determination of sagacity described above is to specify the boundaries and geographic extent of study area, the time frame for economic and technological determinations, and the perspective for feasibility checks (individual farmer, district, region, or society).

For a more complete discussion of IS and its application, the reader is referred to Ref.[3].

Irrigation Scheduling: Plant Indicators (Field Application)

David A. Goldhamer
Kearney Agricultural Center, University of California, Parlier, California, U.S.A.

INTRODUCTION

While there has been extensive research in measuring plant water status and its impact on plant processes and aspects of crop production, relatively little work has been published on giving specific protocols for using plant-based measurements in irrigation scheduling. This is likely the result of plant water status being very dynamic since the plant is coupled to both its soil water and atmospheric surroundings. Thus, no single value can be used to indicate the onset of water stress. Plant water status changes diurnally and over the season, and its dynamic nature makes it difficult to identify threshold values for practical use. Plant water measurements, by themselves, mean little if they are not considered relative to the equivalent measurements representing fully irrigated plants in the same environment. This has been accomplished by developing "reference" or "baseline" values, representing the behavior of plants under non-limiting soil water supply.

APPLICATIONS OF PLANT INDICATORS FOR THE MANAGEMENT OF WATER STRESS IN IRRIGATION

It is well documented that virtually all plant processes are affected by a reduction in plant water status.[1] Plant water deficits decrease leaf growth and thus, leaf area. With field and row crops, where the goal is to achieve a full canopy as soon as possible, early season water deficits translate into lower field photosynthesis and ultimately lower total biomass production. Thus, with crops harvested for biomass, such as alfalfa and silage corn, any water stress will reduce yield. The linear nature of the classical production function relating yield to crop water use illustrates this fact clearly.[2]

The effect of water deficits on production of crops where only the reproductive organ is harvested is much less straightforward. One example is cotton; an indeterminate row crop. Severe water stress can reduce leaf area, photosynthesis, the number of fruiting sites, and thus reduce lint yield.[3] On the other hand, mild water stress, enough to significantly reduce vegetative growth, did not reduce yield.[4] There are few documented cases of water stress increasing crop yields. Fereres[5] reported that mild water deficits increased yields of cotton and sorghum over those under full irrigation. This was attributed to the increase in harvest index due to a greater partitioning of assimilate from vegetative to reproductive sinks. Chalmers, Mitchell, and van Heek[6] reported that regulated deficit irrigation (RDI) significantly reduced unwanted vegetative growth in peach and consequently, an increase in harvest fruit size, again due to greater assimilate partitioning. It should be noted that others have tried to reproduce these results, specifically, increased fruit size in response to water stress, and failed.[7–9] However, these experiments occurred under different soil and atmospheric conditions and with different cultivars. There are far more instances reported of water stress improving some aspect of fruit quality than fruit size. For example, Goldhamer et al.[9] found that RDI can significantly reduce peel creasing in navel oranges without negatively affecting other yield components, thus increasing grower profit.

The interactions between irrigation and pest and disease management offer opportunities for the use of plant indicators for beneficial purposes. While water stress is usually associated with higher insect pressures, there are cases where water stress had beneficial effects. Leigh et al.[10] found that lygus bug levels in cotton were reduced by 50% by the imposition of water stress compared to fully irrigated plants. Goldhamer et al.[11] found that epicarp lesion on pistachio nuts, believed to be the result of feeding by leaf-footed plant bugs, was significantly reduced in severely stressed trees. Reduced insect pressures in response to water stress are usually attributed to a less favorable feeding environment due to higher canopy temperatures. However, high temperatures are also related with greater pest pressures due to higher insect development rates.[12] Teviotdale et al.[13] noted that preharvest water deficits in almond trees significantly reduced the fungal disease of hull rot in almonds. Further work resulted in a recommendation that water stress be imposed for a two-week period about 1 mo prior to harvest not to be less than a predawn leaf (Ψ) water potential of -1.5 MPa.[14] Although this approach provided a great amount of disease control, the authors advised that water stress

Irrigation–Journals

could reduce kernel size (3–5%) and thus, the grower must decide on whether the impact of the disease would be worse than that of water stress.

INTERPRETATION OF MEASUREMENTS FOR IRRIGATION DECISION MAKING

The fact that plant species and plant processes differ in their sensitivity to water stress complicates the issue of applying indicators of plant water status to irrigation management. For example, predawn water Ψ of leaves in fully irrigated pistachio tress in the central valley of California is from −0.8 MPa to −1.0 MPa compared with −0.15 MPa to −0.20 MPa for walnut trees in the same environment. Mild to moderate water stress from mid-May to early July has a little impact on any pistachio yield component while it reduces the size of harvested walnuts. In order to use plant Ψ in production agriculture, it is of paramount importance that both accurate measurements of normalized water stress and how they impact yield be known for successful application of any plant-based scheduling program. This two-phase knowledge is rare. Nevertheless, some workers have developed plant-based protocols that have achieved varying degrees of success in on-farm water management. Examples of the most promising of these approaches for tree crops are highlighted in the following discussion.

Shackel et al.[15] proposed using stem Ψ for irrigation scheduling of prunes. This crop is an ideal candidate for plant-based scheduling that accurately identifies stress in that it is a dried product and thus, lower fruit hydration at harvest resulting from water deficits during the season is actually beneficial. The influence of evaporative demand was addressed by providing a table showing stem Ψ for a range of relative humidity and air temperature conditions (Table 1). Additional work had identified periods of the season, which were most stress tolerant[16] resulting in specific, recommended protocols of desired stem Ψ over the season (Table 2). These protocols have been adopted by numerous prune growers in California.

One short coming of plant-based scheduling approaches is that they do not provide quantitative information on how much water should be applied at each irrigation as is possible with soil water monitoring and atmospheric-based methods. Thus, protocols for using plant Ψ should somehow address this issue. Here, both measurement and irrigation frequency are important; the more frequent the monitoring, the greater is the opportunity to adjust the irrigation amount. It is difficult to conduct frequent manual stem Ψ monitoring, and this measurement cannot be automated currently. There is little chance of coupling these manual measurements to irrigation electronic controllers.

Goldhamer and Fereres[17] presented protocols based on experimental data for using trunk diameter measurement to schedule irrigations in almond trees. They suggested maximum daily trunk shrinkage (MDS) as the stress indicator parameter. These data were normalized for vapor pressure deficit (VPD) using reference values obtaining either from fully irrigated trees or relationships previously developed between VPD and fully irrigated trees. They used the term “signal” (ratio of measured to reference value) to represent the stress magnitude and suggested target signals for irrigation scheduling based on how much stress the grower desired during the season. If the measured signal consistently exceeds the target threshold, the irrigation rate is increased by 10% for the next cycle.

Table 1 Values of midday stem Ψ in MPa expected for fully irrigated prune trees under different air temperature and relative humidity conditions

	Air relative humidity (RH) (%)

If the measured signal is below the threshold, the irrigation rate is lowered by 10%. Their goal was to have the actual signal oscillate as close as possible around the selected threshold level. This approach was recently validated in a field study comparing different target threshold values.

Goldhamer et al.[18] conducted an analysis of the sensitivity of these scheduling approaches to progressively greater water deficits on mature peach trees under high-frequency irrigation. Reference values were determined using control trees under non-limiting soil moisture conditions (irrigation based on a weighing lysimeter). Stem Ψ and MDS measurements during both the deficit irrigation period and when full irrigation was reintroduced to the stressed trees tracked each other well (Fig. 1A, B). Both stem Ψ and MDS were equal in identifying the onset of stress but after the first few days, the MDS signal was clearly higher than the stem Ψ signal for the remainder of the stress period (Fig. 1C). Following the return to full irrigation, both indicator signals remained well-above, 1.0, reflecting the fact that the soil water reservoir was not refilled.

In addition to signal strength, the variability of the indicator values will determine the usefulness of the signal in irrigation scheduling. There have been reports that MDS is more variable than SWP in tree crops.[17,19,20] High measurement variability (''noise'') would require more tree measurements to decrease the uncertainty, increasing the monitoring costs. Goldhamer et al.[18] found that MDS variability was higher than that of SWP under mild to moderate stress but lower than MDS under severe water stress (Fig. 1D, E). During the entire stress range, SWP variability remained unchanged. The signal/noise ratio, which integrates both the indicator strength and variability, was equal for both stem Ψ and MDS under mild to moderate stress (Fig. 1F). In other words, even though the MDS signal was higher than stem Ψ in this stress range, the increased variability reduced the usefulness as a scheduling indicator. However, under severe stress, the MDS signal/noise ratio was about five times higher than the peach stem Ψ value. This example clearly illustrates that a multitude of factors must be taken into account in evaluating which plant-based monitoring technique performs best under a given set of conditions.

OVERCOMING BARRIERS FOR GROWER ADOPTION

While scientists may disagree over which plant-based monitoring approach provides the most sensitive indicator of water stress and how stress impact yield, on-farm personnel responsible for irrigation scheduling have much simpler question that requires an affirmative answer for method adoption to occur: ''Will it make their jobs easier?'' A secondary issue is whether it is cost effective and the time profitably used. It is believed that the current state-of-the-art in plant-based monitoring is stem Ψ for the following reasons: 1) it is grounded in proven scientific principles; and 2) it has been adopted by some growers. Its primary shortcoming is that the measurement is manually taken, requiring the technician to make trips to the field. Moreover, the measurements must be made within a 2 hr or so period around midday. Additional negatives are that a relatively bulky pressure chamber must be hauled to the field (although a lighter ''pump-up'' version is now commercially available), and data processing is manual. Continuously recorded trunk diameter measurements overcome the logistical problems and labor requirements of the stem Ψ measurements. Since they are electronically recorded, graphical representation, which is a powerful incentive for grower adoption, is relatively easy.

Electronically recorded measurements also facilitate data analysis. One can envision algorithms in a computer/controller that not only derive indicator parameters, such as MDS, but also generate and execute system-operating times. Additionally, the rapid availability and ease of data transfer on from local to global networks offer the prospect of irrigation control and consultation from remote locations. To be sure, there are trade-offs associated with using trunk diameter measurements in irrigation scheduling. The data are most variable (''noisy'') than corresponding stem Ψ values.[18] The special LVDT mounts currently cost

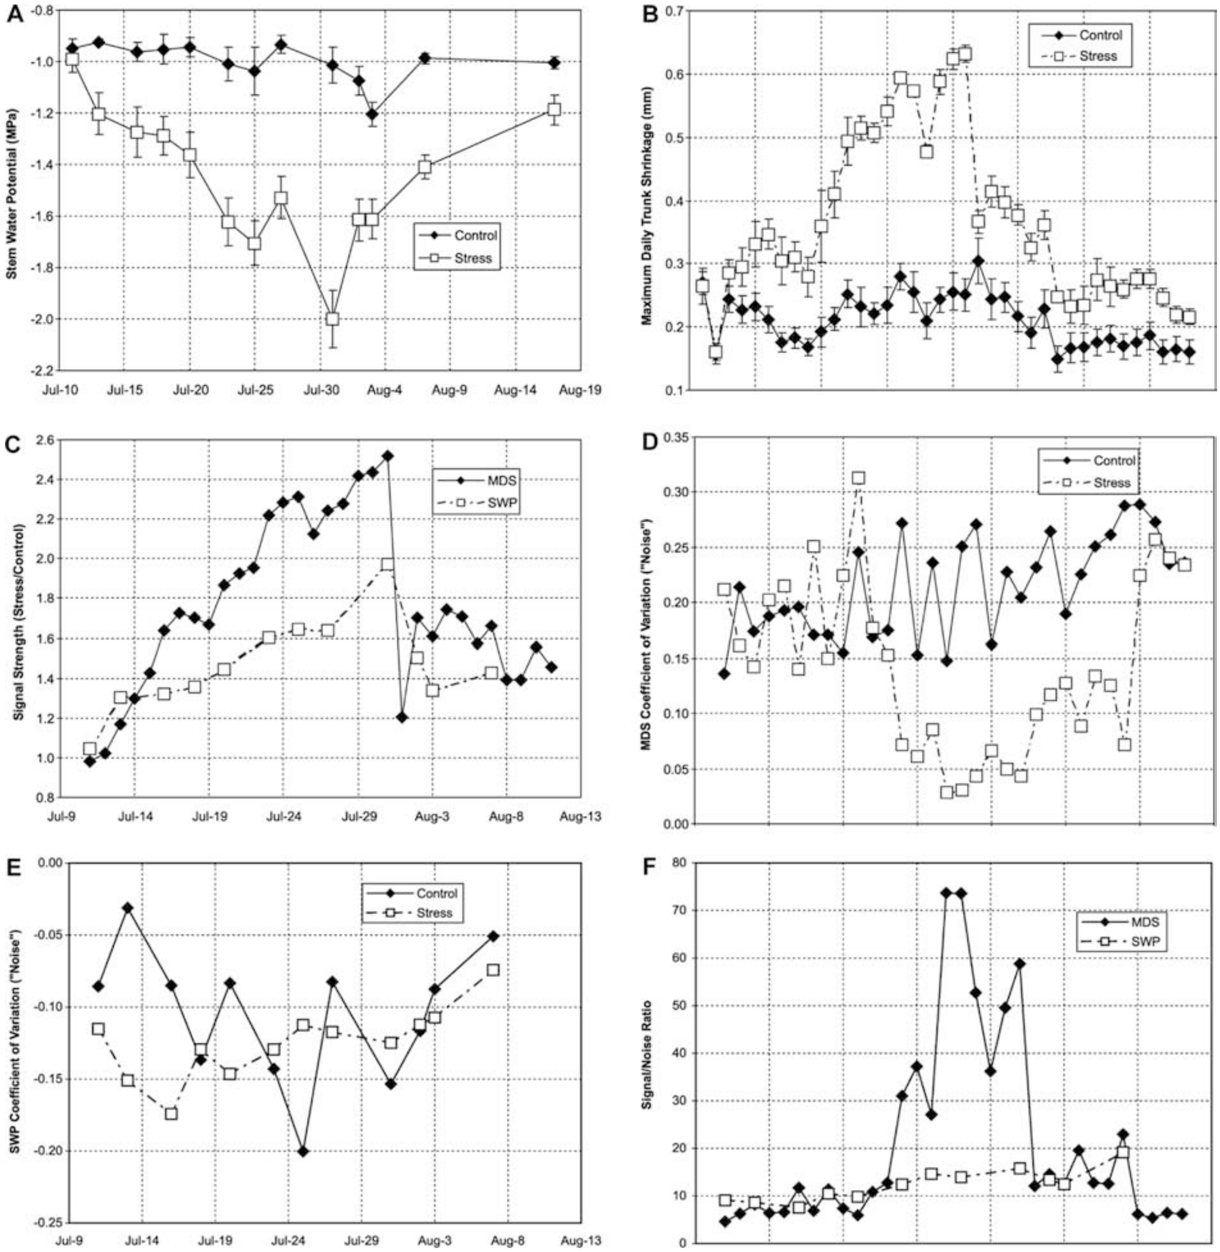

Fig. 1 For mature peach trees under both full (Control) and deficit irrigation (Stress) through July-31 followed by a return to full irrigation: A) stem water potential (SWP); B) maximum daily trunk shrinkage (MDS); C) MDS and SWP signal strength (Stress/Control); D) MDS coefficient of variation (noise); E) SWP coefficient of variation (noise), and F) MDS and SWP ''signal/noise'' ratio. Vertical bars are two standard errors. *Source*: From Ref.[18].

$US 40–80 and LVDTs are $US 150–250. Repairing electronic devices is beyond the ability of most on-farm personnel. Additionally, dataloggers located in the field require periodic trips by a technician to download data unless wireless communication has been established.

The decreasing availability and increasing cost of water for agriculture will be incentives to improve irrigation management that growers will be unable to ignore in the future. Using plant-based methods to quantify stress and adjusting irrigation schedules accordingly should become more prevalent, especially in high water cost areas and with high value crops. They can be used as stand-alone methods or more likely, to augment and fine tune the more widely available types of atmospheric-based approaches. Indeed, a combination of scheduling techniques may prove optimal, especially for cropping situations where early season stress is desirable. For example, the quality of wine grapes has been shown to improve with deficit irrigation prior to veraison (berry color change).

Williams (personal communication) recommend that leaf water Ψ be maintained at $-1.0\,MPa$ (mild stress) early in the season and then irrigated at 60% ET_c from veraison to harvest. Imposing early season stress based on irrigating at certain percentages of ET_c is difficult since it is necessary to accurately characterize and account for the amount of water available in the soil moisture reservoir. Early season plant-based monitoring overcomes this problem. As growers become more sophisticated in their irrigation programs, especially those that utilize water stress beneficially (RDI), plant-based monitoring, whether they taken manually or recorded electronically, will become a more valuable tool for use in production agriculture.

Irrigation Scheduling: Plant Indicators (Measurement)

David A. Goldhamer
Kearney Agricultural Center, University of California,
Parlier, California, U.S.A.

INTRODUCTION

Even though optimizing plant biomass or fruit production is the goal of irrigation, the plant is rarely the primary focus in irrigation scheduling techniques. Atmospheric techniques, where the plant is considered only tangentially when evapotranspiration (ET_c) is estimated, and soil moisture monitoring with a wide variety of instruments are by far the dominant scheduling approaches in use today. The plant sits midway in the soil, plant, and atmospheric continuum and is the integrator of both the water status of the soil and the atmosphere. Moreover, virtually all plant processes that ultimately affect productivity are directly or indirectly linked to plant water status.[1] Although there are a variety of methods to measure or infer plant water status, few references in the literature propose the use of directly measured or inferred plant water status measurements in irrigation scheduling.[2–5] The primary reason for this may involve the difficulties in interpreting plant water status measurements due to their interactions with evaporative demand and crop specific physiological factors. On-farm use of plant-based scheduling is exceedingly low. However, the increasing importance of agricultural water productivity and recent advancements in equipment and sensors for plant-based monitoring focus renewed interest in this scheduling approach.

MEASURING PLANT WATER STATUS

The most common parameter used for characterizing the water status of plants is the water potential (Ψ). There are a variety of instruments that have been used to measure plant water potential that are covered in detail by Hsiao.[6] The instrument that best fit the requirements for use in irrigation programming is the pressure chamber. In addition, there are other techniques best suited for laboratory conditions such as thermocouple psychrometry[7] and the Shardakov dye method.[6]

The Pressure Chamber

The pressure chamber requires that a leaf be excised, placed, and sealed in a chamber with the cut petiole end sticking out, and then the chamber is pressurized with nitrogen gas until xylem sap just appears at the end of the petiole.[8] The "balancing pressure" created by the compressed gas in the chamber is, under reasonable assumptions, a measure of the leaf Ψ.

There are a variety of techniques used and precautions recommended when using the pressure chamber to determine leaf Ψ. Of particular importance is to minimize water loss from the leaf between excision and placement in the chamber. This can be accomplished by covering the leaf with damp cheesecloth or a small plastic bag prior to excision and placing the leaf/cloth/bag combination in the chamber. Some pressure chamber operators blow into the plastic bag just before placing it over the leaf in order to create high enough humidity to minimize transpiration. The rate that the chamber is pressurized also can influence the reading.[9] Hsiao[6] recommends pressurizing at a rate of less than $0.1\,\mathrm{MPa\,sec^{-1}}$ at the beginning of the measurement and $0.02\,\mathrm{MPa\,sec^{-1}}$ as the balancing pressure is approached. Turner[10] suggested a pressurization rate of $0.025\,\mathrm{MPa\,sec^{-1}}$. Fast pressurization rates can also cause adiabatic heating in the chamber. This also can be controlled by using the aforementioned rates of pressurization and by covering the leaf with a plastic bag.

A variant in measuring leaf Ψ is stem Ψ. Here, an interior, shaded leaf is covered by a small plastic bag overlaid with aluminum foil for a period of time prior to excision. Shackel et al.[4] suggested that this period be a minimum of 2 hr while Fulton et al.[11] indicate that transpiration ceases with 15 min of bagging. The elimination of transpiration results in an equilibrium in Ψ between the leaf and the adjacent stem and presumably in a tree, the trunk. Thus, stem Ψ should be higher than leaf Ψ, less coupled to the aerial environment, more representative of the whole tree water status, and less variable than leaf Ψ measurements, that are influenced by stomatal behavior and leaf shade history. Naor[12] found that stem Ψ was a better plant water stress indicator than predawn or midday leaf Ψ.

Leaf and stem Ψ change with time over the day. Highest values occur at predawn, become more negative during the morning, sometimes reaching a "plateau" for 2–3 hr just after solar noon, and then increasing in the late afternoon and evening. Thus, readings are usually taken during the plateau period for day-to-day comparisons.

Indirect evaluation of plant water status may be accomplished by numerous plant-based parameters that are related to plant Ψ. Many of these parameters have logistical and operational advantages over direct measurement techniques. Following is a description of those considered most relevant for irrigation programming.

Stomatal Opening

Current models of steady-state porometers can accurately measure stomatal conductance, which is directly related to photosynthesis, and linked to plant water status. However, water deficits need to be moderate to severe to cause stomatal closure; thus, this parameter is not considered as a sensitive indicator for use in irrigation management.

Plant Organ Size Variations

Both herbaceous and woody plant stems undergo diurnal oscillations in size due to both hydration and growth.[13] In the short term, size variations due to changing levels of hydration within various plant tissues greatly exceed those resulting from growth.[14] It is generally agreed that the living cells of the phloem, cambium, and parenchyma that surround the xylem provide most of the stored water contributing to size variations.[15] While Irvine and Grace[16] believe that contractions occur within the xylem in response to varying xylem Ψp, the consensus is that xylem tissues are almost totally rigid and contribute very little (10–30%) to daily stem size variations.[15,17] It is generally agreed that stem diameter fluctuations are directly related to changes in plant water status.[18,19] While most of the attention in using plant organs as indicators of water status has been on stems, leaf, and fruit size daily fluctuations also occur. However, there is no known commercial use of these techniques. In the case of leaves, this may be due to having to calibrate thickness against an independent measure of Ψ for each leaf.[20] Recent advancements in the size-measuring sensors and mounting hardware for large, well attached fruits bode well for future research in fruit size oscillations' relations to Ψ as well as simply using fruit growth as a scheduling indicator.

Linear variable displacement transducers (LVDTs) and strain gauges are the most common types of organ size measuring devices. Since daily stem diameter oscillations are very small (generally less than 300 μm in mature fruit tree trunks), care must be taken to prevent temperature effects on the sensors and mounting hardware. Measures include shading the instruments and using mounting materials with low thermal expansion properties. Stem diameter oscillations are identified by continuously recording organ size using dataloggers. Data are downloaded manually in the field or transmitted by cellular phone or radio signals to computers.

Canopy Temperature

This technique relies on the fact that water-stressed plants undergo stomatal closure and consequently higher canopy temperatures due to lower transpirational cooling. The development of the infrared thermometer (IRT) made the canopy temperature measurement possible without physically contacting the plant and signaled the start of a high level of research on using the measurement in irrigation management.[21] Theoretical analysis[22] and experimental work[23] evolved the concept of the crop water stress index (CWSI). The CWSI is based on the temperature difference between the canopy (T_c) and surrounding air (T_a), normalized for the vapor pressure deficit of the air. It is calculated based on the ratio of where the measured $T_c - T_a$ value falls between equivalent values for a fully irrigated canopy (lower baseline experimentally determined) and severely stressed canopy (upper baseline empirically determined) under equivalent evaporative demand conditions. Protocols for use involve irrigating as to not exceed CWSI threshold values during specific periods of the season.

The CWSI method has been tested primarily on field and row crops. The technique requires that canopy temperature be accurately determined with the IRT and thus, soil within the view of the instrument must be avoided, although a method for correcting for soil effects has been developed.[24] This method is not sensitive to detect water deficits so mild that do not reduce crop transpiration.

Expansive Growth

The growth rate of leaves and stems is one of the most sensitive of all plant processes to water stress.[1] With indeterminate crops such as cotton, growth rate evaluation is likely the most popular, and certainly the oldest, plant method used to time irrigations. This is facilitated by the fact that any reduction in the distance between the growing terminal of the main stem and the reddish color associated with mature main stem tissue is visually very apparent. In addition to visual observations of growth, sensors may be placed on vegetative or reproductive organs to quantify growth. Goldhamer and Fereres[5] reported that this is a viable technique in young peach trees. Regardless of whether the approach is visual or mechanical, physiological and environmental factors other than water status can affect expansive growth. For example, growth with determinate crops ceases shortly after the onset of anthesis.

Sap Flow

Sensors using both heat pulse[25] and heat balance[26] techniques have been developed to estimate transpiration in individual plants. Both techniques involve a heat source placed on the stem or trunk of the plant and then thermocouples either inserted into the conducting tissue or placed along the surface of the stem or trunk. One major difference in the techniques is that the heat pulse measures flow velocity and an estimate of the cross sectional area of flow is required to calculate transpiration. Quantifying flow cross sectional area is usually done by visually evaluating conducting tissue, which in the case of trees, requires a core taken with a trunk boring tool. This is difficult and can result in significant errors.[27] Nevertheless, sap flow measurements can be qualitatively useful in identifying differences in transpiration between plants of similar size and the same species. The primary drawback with using sap flow measurement for irrigation scheduling is the same as with stomatal conductance and canopy temperature—transpiration is not affected under mild stress levels likely to affect expansive growth. Many techniques have been developed in plant physiological research to characterize the water status of plants, but only a few, such as those discussed above, have promise in the development of relevant applications for irrigation scheduling.

Irrigation Scheduling: Remote Sensing Technologies

Stephan J. Maas
Texas Tech University, Lubbock, Texas, U.S.A.

INTRODUCTION

Remote sensing is a method of quantifying physical characteristics of an object through measurements that do not require physical contact with the object. The physical characteristics of the object are determined from measurements of electromagnetic radiation, often in specific wavelengths, reflected or emitted by the object's surface. Although we usually associate remote sensing with satellites or aircraft, some types of remote sensing involve measurements made with ground-based sensors.

Researchers have suggested that there are two main characteristics that favor the use of remote sensing as part of a procedure for scheduling the irrigation of agricultural crops. First, remote sensing provides a quantification of the degree of crop water stress derived from measurements made directly on the crop canopy. This is in contrast to inferring crop water stress from measurements of properties of the soil, such as soil water content or soil water potential, in which the crop is grown. Second, remote sensing imagery can show the detailed variability of crop water stress within a field. When field conditions are variable, basing an irrigation strategy on a limited number of measurements may lead to over- or underwatering some parts of the field. Remote sensing imagery can provide a depiction of the variability in crop water stress across a field with a spatial resolution much greater than what can typically be achieved through conventional field measurements, such as water content or leaf water potential.

APPROACHES

Attempts to use remote sensing in irrigation scheduling have concentrated on the observation of two physical characteristics of the plant canopy: leaf temperature and leaf water content. Each of these characteristics has given rise to distinct approaches in measuring and utilizing remote sensing data in this application.

Leaf Temperature

The temperature of the leaf surfaces in a plant canopy is the result of the balance between the energy gained from the surrounding environment and lost to the surrounding environment.[1] During the daytime, when most irrigation-related remote sensing observations are made, the energy balance of a plant canopy can be expressed,

$$R_{ab} + C = E + R_{em}$$

In this expression, R_{ab} is the longwave and shortwave radiant energy absorbed by the leaf canopy from the sun, the sky, and surrounding soil and plant surfaces. C is the sensible heat gained or lost to the surrounding air through convection. If the surrounding air is warmer than the plant canopy, the canopy will gain heat energy from the air. The opposite is true if the surrounding air is cooler than the plant canopy. E is the latent heat energy lost by the plant canopy through transpiration, i.e., the evaporation of water from the leaves. R_{em} is the longwave radiant energy emitted by the plant canopy, and is a function of the temperature of the leaf surfaces,

$$R_{em} = \varepsilon\sigma T^4$$

In this expression, ε is the emissivity of the canopy (approximately 1 for leaves), σ is the Stefan–Boltzmann constant, and T is the absolute temperature of the leaf canopy (in K). It is through this expression that remote sensing systems can measure leaf temperature, by measuring the longwave radiant energy emitted by the plant canopy.

In the energy balance for the plant canopy, the magnitude of E is determined by the ambient micrometeorological conditions (air temperature, humidity, and wind speed) and the degree to which the leaf stomata are open. As crop plants deplete the soil water below the level necessary for optimum growth, the stomata close to restrict the further loss of water from the plants through evaporation. As the magnitude of E is reduced through stomatal closure, the magnitude of R_{em} must correspondingly increase to maintain the energy balance. This increase is observed through remote sensing as an increase in leaf temperature.

Several different approaches have been described for using remote sensing observations of leaf temperature in irrigation scheduling. The most well-documented of these are described in the following three sections.

Thermal Kinetic Window

As in most organisms, the biochemical reactions leading to the growth of crop plants are controlled by enzymes. The temperature dependence of enzyme function helps establish the growth rate of a crop plant in a given environment. If the environment is too warm or too cool, enzyme activity will be inhibited and the potential rate of growth will be reduced. A range of temperature has been identified for each of several crops within which the activities of many important enzymes are at optimum levels.[2] This range is called the Thermal Kinetic Window (TKW). In arid and semiarid regions, leaf temperatures may exceed the range specified by the TKW during part of the day, particularly if soil water is limited.[3] Under these circumstances, irrigating the crop can cause leaf temperatures to fall within the TKW by increasing the loss of heat energy from the canopy through evaporation (Fig. 1). Maintaining leaf temperatures within the TKW by this strategy insures that biochemical reactions proceed at optimum rates.

Field studies in the Texas High Plains demonstrated that cotton yields could be maximized by irrigating the crop when the observed leaf canopy temperature exceeded 28°C.[4,5] Canopy temperatures were sensed with infrared thermometers, the signals from which could be used to control an automated irrigation system. A refinement of this procedure involved using the time that the crop was above 28°C (the Temperature–Time Threshold, or "TTT") to control irrigation application.[6] Using a TTT of 4 hr resulted in crop yields equaling those achieved with shorter values of TTT, but with less irrigation.

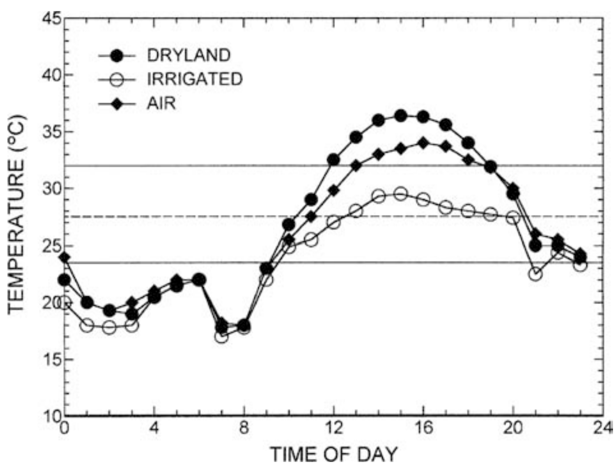

Fig. 1 Diurnal air temperature and foliage temperatures of irrigated and dryland cotton. The solid horizontal lines delimit the TKW and the dashed line illustrates the temperature providing optimum enzyme function. *Source*: From Ref.[3].

This concept was commercialized in a system called the Biologically Identified Optimal Temperature Interactive Console, or "BIOTIC."[7] In BIOTIC (Fig. 2), the leaf canopy temperature is measured with an infrared thermometer, and the time that the canopy temperature is above a specified threshold is accumulated by the control unit. When this time accumulation exceeds another predetermined threshold, and taking into account ambient humidity conditions, a signal is sent to turn on the irrigation system. A limitation to BIOTIC is that, early in the growing season when plants are small, measurements of leaf canopy temperature made by the infrared thermometer may be confounded by the higher temperature of the soil surrounding the plants. This might result in the irrigation system being turned on more often than necessary. This problem disappears when the plants reach a size to completely fill the field of view of the infrared thermometer. Since the time accumulation used in BIOTIC is based on essentially continuous measurements of canopy temperature, this approach is limited to ground-based, in-field sensor systems.

Crop Water Stress Index

In environments with a high evaporative demand, the temperature of a fully irrigated crop canopy is typically below the ambient air temperature during the day. Thus, the difference between canopy and air temperature has been recognized as an indicator of crop water

Fig. 2 A BIOTIC system set up in a cotton field. (Photo courtesy of J. Mahan, USDA-ARS.)

Irrigation–Journals

stress. Theoretical and experimental work led to the development of the Crop Water Stress Index, or "CWSI."[8,9] The CWSI expresses the degree to which the evapotranspiration (ET) of the crop approaches the maximum possible value of ET determined by ambient environmental conditions (the potential ET, or "PET"),

$$\mathrm{CWSI} = 1 - (\mathrm{ET}/\mathrm{PET})$$

In practice, PET can be calculated from ambient meteorological conditions or estimated from measurements of ET from a well-watered grass or alfalfa surface. CWSI is related to the difference between the canopy temperature T_c and air temperature T_a through the expression,

$$\mathrm{CWSI} = [(T_c - T_a)_{min} - (T_c - T_a)_{obs}] / [(T_c - T_a)_{min} - (T_c - T_a)_{max}]$$

In this expression, $(T_c - T_a)_{obs}$ is the observed temperature difference, and $(T_c - T_a)_{min}$ and $(T_c - T_a)_{max}$ are the minimum and maximum differences to be expected based on ambient environmental conditions. Empirically derived expressions relating $(T_c - T_a)_{min}$ and $(T_c - T_a)_{max}$ to the ambient saturation vapor pressure deficit have been reported for a number of crops.[10]

A limitation of the practical application of CWSI is that its strict derivation does not include soil temperature effects. For aircraft or satellite observing systems, which are usually pointed straight down at a field, the measured surface temperature will be a combination of plant canopy temperature and soil temperature when the canopy does not completely cover the soil surface. An adaptation of the CWSI has been developed that accounts for incomplete vegetation cover.[11] In this approach, called the "Vegetation Index/Temperature(VIT) Trapezoid," measured surface minus air temperature is plotted vs. a measure of ground cover derived from remote sensing observations in the visible and near-infrared wavelengths. This point should lie within a trapezoid, the vertices of which represent the surface–air temperatures of a well-watered complete canopy, a severely water-stressed complete canopy, a saturated bare soil surface, and a completely dry bare soil surface (Fig. 3). In this figure, the ratio of the line segments AC/AB represents a Water Deficit Index (WDI) analogous to CWSI, but accounting for the degree of vegetation cover. In practice, the ordinate in the VIT Trapezoid is usually evaluated in terms of a vegetation index, like the Soil-Adjusted Vegetation Index,[12] that is derived from remote sensing observations and is proportional to vegetation cover.

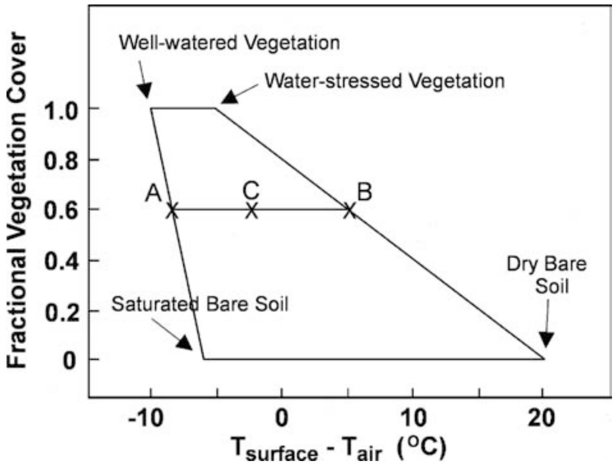

Fig. 3 The VIT Trapezoid. *Source*: From Ref.[11].

The use of WDI in detecting crop condition in support of irrigation management was demonstrated at the Maricopa Agricultural Center in Arizona.[13,14] It was concluded from these studies that satellite observations were too infrequent to support operational irrigation scheduling based on WDI. Aircraft observations could be obtained with sufficient frequency for this application.

To accommodate infrequent remote sensing observations, the VIT Trapezoid was utilized in conjunction with a mathematical model of daily crop growth and water use. In this approach, the model (called "ProBE") provides a daily description of the water status of the crop based on weather and soil conditions, while the model simulation is calibrated through the evaluation of the actual water status of the crop on days with remote sensing observations.[15,16] A desirable feature of this approach is the capability to predict crop water status beyond the current day using weather forecasts or climatological data. In this way, the onset of water stress can be anticipated prior to its occurrence, allowing advance preparations to be made for irrigating the crop.

Spatial Variability in Canopy Temperature

When crop plants in a field are adequately watered, their transpiration rates are determined more by the evaporative demand of the ambient atmosphere than by soil conditions. As the plants deplete the soil water in the field to the point of becoming stressed, their transpiration rates become more dependent on soil conditions. As soil conditions typically are more spatially variable across a field than atmospheric conditions, one would expect to see more spatial variability in observed canopy temperature for a water-stressed crop than for an adequately watered crop.

Studies involving corn in the U.S. Great Plains suggest that irrigation should be applied when the range of six measurements of canopy temperature made within a field exceeds 0.7°C.[17] Researchers in Arizona have developed a "Histogram-derived Crop Water Stress Index" (HCWSI) that measures the departure of the distribution of measured canopy temperatures in a field from a normal distribution.[18] This approach is based on the observation that the distribution of canopy temperature measurements becomes skewed as the crop becomes stressed.

An advantage of scheduling irrigation based on this approach is that the variability in observed temperature, and not the precise measurement of temperature, is used as an indicator of the onset of stress. Thus, uncalibrated thermal images of a field might be sufficient for this application. Previous studies have been conducted on fields where the crop completely covers the soil surface. Observed surface temperature variability resulting from the variability in crop ground cover might seriously confound the measurements used in this approach.

Leaf Water Content

The interaction of electromagnetic radiation with water contained in plant tissues provides another mechanism for possibly detecting crop water status using remote sensing. Leaf water content is observable in leaf reflectance measurements particularly in near-infrared wavelengths (0.8–2.5 μm), where a systematic decrease in leaf reflectance is noted with decreasing leaf water content.[19] Several strong water absorption bands (particularly at 1.45 μm and 1.95 μm) are observable in leaf reflectance spectra in the near infrared. Radar backscatter at microwave frequencies in the range 5–10 GHz is also affected by plant canopy and soil water content.[20]

While leaf water content can be observed using remote sensing, there are several factors that limit its potential effectiveness in irrigation scheduling. First, leaf transpiration rate is physically related to leaf water potential, not to leaf water content. Thus, there is no direct connection between the observed remote sensing data and crop water status, as is the case with leaf temperature. Second, because leaf water is contained within plant tissue, remotely sensed leaf water content is affected by not only the water content of the tissue, but also how much tissue is present in the observation. Thus, remote sensing observations at near-infrared or microwave wavelengths cannot unambiguously discriminate between the amount of vegetation and the water status of the vegetation. In part because of these reasons, there are currently no widely recognized approaches for irrigation scheduling based on remotely sensed leaf water content.

CONCLUSION

Several irrigation scheduling approaches based on remotely sensed plant canopy temperature have been demonstrated to be operationally feasible. The TKW approach can be effective in maintaining crop canopy temperatures within the range conducive to optimal enzyme activity and growth. The WDI can compensate for incomplete crop ground cover in remote sensing observations of surface temperature, and can be used with a crop model to predict the onset of water stress. Other procedures involving spatial temperature variability and leaf water content await further development and testing.

Irrigation Scheduling: Soil Water Status

Philip Charlesworth
Davies Laboratory, Commonwealth Scientific and Industrial Research Organisation (CSIRO), Townsville, Queensland, Australia

Richard J. Stirzaker
Commonwealth Scientific and Industrial Research Organisation (CSIRO), Canberra, Australian Capital Territory, Australia

INTRODUCTION

There are three methods for matching irrigation with crop water requirements. The first is to measure how much water the soil contains. The second is to monitor some attribute of the plant that is related to water deficits. The third is to calculate how much water the atmosphere can extract from a well-watered crop. This article is about the first method, irrigation management by soil water status. Successful irrigation by this method requires more than just the ability to measure soil water status. We need to know how to relate measurements of soil water status to the amount and timing of irrigation, and how this ultimately affects crop yield.

DEFINITIONS OF SOIL WATER STATUS

Soil consists of a range of different sized particles from fine clays (<2 μm diameter) through silts and sands to gravels (>2 mm). Water adheres to the surface of these particles, so soils with a finer texture (more clay) can store more water than soils with a sandier texture. The soil particles are also arranged so as to produce aggregates and pores or voids, giving the soil the property termed structure. Pores with a diameter in the range of 0.5–50 μm are important for storing water. Pores larger than these are normally air-filled and water in pores smaller than this is usually not available to plants.

For the purposes of irrigation, the water status of the soil is usually expressed as the volume of water in a given volume of soil. Thus, if a cubic meter of soil contained 300 L of water the volumetric water content would be $0.3\,m^3$ of water per cubic meter of soil ($0.3\,m_w^3\,m_s^{-3}$) or 30%. Since rain and irrigation are measured in depths (mm) it is often easier to express $0.3\,m^3\,m^{-3}$ as a depth equivalent, i.e., 300 mm of water in 1-m depth of soil.

Plants can easily extract water from wet soil because the water is held in large pores. As soil becomes drier, water is held more strongly in smaller pores or closer to the soil particles themselves. To obtain water, the roots must be in contact with the water films around the soil particles and in effect, the roots must be "drier" or exert more "pull" on the water than the soil. The size of this "pull" can be expressed in energy terms and is called soil water or matric potential. It is usually measured in kilopascals (kPa) and this gives a measure of the force needed to extract water from the soil matrix. When the soil is wet, little force is needed, as it dries, more force or pull is needed.

A soil water retention curve (SWRC) is used to convert the amount of water in a soil (volumetric water content) to its availability (energy status as given by the matric potential). As the clay content of a soil increases, the SWRC curve is displaced towards higher water contents (Fig. 1).

MEASURING SOIL WATER STATUS

Field monitoring of soil water potential began in the 1930s with the development of the tensiometer.[2] Routine, non-destructive measurements of soil water content were made possible by the development of the neutron scattering technique.[3] The last 20 yr have seen the rapid development of new tools for measuring soil water content, particularly measurements based on time domain reflectometry, capacitance, and heat dissipation.[4] A description of 25 commercially available products for measuring matric potential and soil water content and their mode of operation has been produced.[5]

USING SOIL WATER MEASUREMENTS

During irrigation the soil water potential rises close to 0 kPa. If the application rate exceeds the infiltration rate of the soil, then the soil water potential rises to 0 kPa and water ponds on the soil surface. Immediately after irrigation large pores drain rapidly, so the wetted

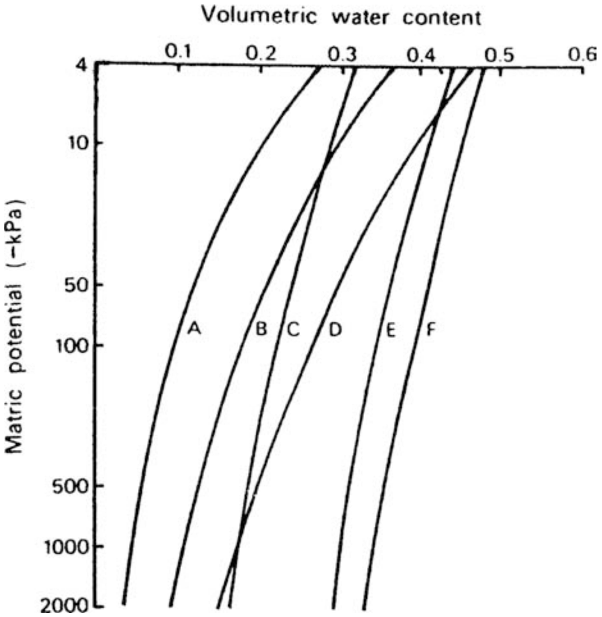

Fig. 1 Soil water retention curves for a range of soils from A—sand, to F—heavy clay. *Source*: From Ref.[1].

depth of soil increases and the average water content of the topsoil falls. The rapid drainage phase is usually completed within 2 days and the soil water content at this stage is termed the drained upper limit (DUL) (Fig. 2). In reality, drainage continues indefinitely, although at slower and slower rates, so the DUL is not an intrinsic property of the soil. However, the drainage rate at the DUL is generally very much lower than the other source of water loss from soil, evaporation, so for practical irrigation purposes DUL is a convenient measure of the full point.

A plant will extract water from the full profile until the soil is so dry that the plant wilts, even if the relative humidity around the leaves is near 100%. The soil water content at this stage is called the lower limit (LL). The amount of water between the DUL and LL is called plant available water (PAW), a term first used in 1949.[6] The main assumptions, errors, and remedies in deriving these terms have been summarized.[7] The terms ''Field Capacity'' and ''Wilting Point'' are also used to describe the range of soil water availability.

In practice, water becomes increasingly less available to plants between the DUL and LL. Some studies have shown that growth can be sustained until 70–80% of the PAW has been consumed.[8] For practical purposes a more conservative value of 0.5*PAW is often recommended as the depletion amount below DUL at which the profile should be refilled. This amount is referred to as readily available water (RAW). The idea of having this conservative refill point is to avoid the possibility of growth and yield reductions from the drying conditions in commercial crops.

The amount of water readily available to a crop is calculated as the RAW multiplied by the rooting depth. Table 1 gives examples of the average values for the water contents at DUL and the LL and the RAW over 1-m depth of soil for a range of soil textures.

When considering the water availability, a soil water potential of 0 kPa indicates the soil would be saturated or waterlogged. Most soils have sufficient air for root function once the soil water potential drops to

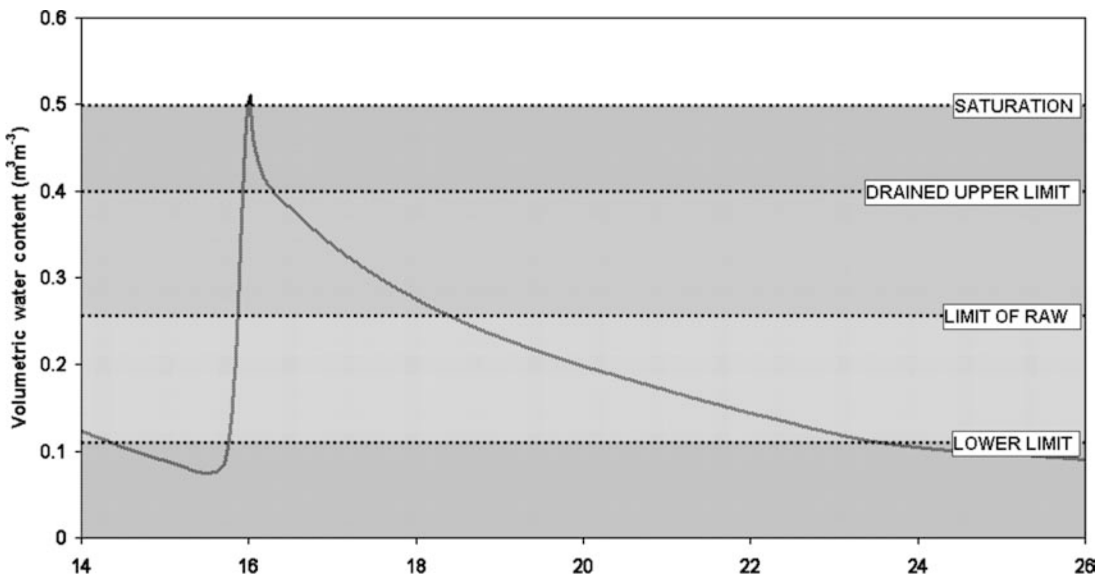

Fig. 2 The change in water content during an irrigation event followed by 10 days of drying. The soil water content falls rapidly immediately after irrigation when drainage dominates, and slows after the readily available water has been transpired. (Assumes constant evapotranspiration.)

Table 1 Representative volumetric water contents ($m^3 m^{-3}$) and the readily available water in 1 m of soil for soils of three textures

	Sand	Loam	Clay
Saturation	0.4	0.5	0.6
DUL	0.06	0.29	0.41
LL	0.02	0.05	0.2
RAW for 1 m root zone	20 mm	120 mm	105 mm

Source: Adapted from Ref.[9].

–5 kPa. Once the soil dries to –50 kPa, many plants will experience some water stress. By –1500 kPa, only small amounts of water can be extracted from the soil and most plants will wilt.

WATER DEFICIT AND PLANT GROWTH

The calculation of RAW above is a useful approximation but belies much of the complexity of soil plant water relations. In reality the rate of water uptake needed to sustain rapid growth is determined by the atmospheric conditions, the leaf area, rooting distribution of the crop and the soil type, and water status.[10–12] More recently, evidence is accumulating that chemical signals produced by roots growing in drying soil affects plant growth. Stomata may close and growth rates fall before there is any detectable change in leaf water potential.[13] These signals could also lead to the root distribution changing to exploit wetter regions of the soil. Such adaptation may be limited by both soil strength and crop growth phase. The majority of crops are most sensitive to water deficits at the time of flowering and fruit set and more tolerant during the vegetative and maturation stages.[14]

OLD VS. NEW CONCEPTS IN IRRIGATION

The calculation of readily available water represents the maximum extraction of water before the crop yield may decline. Such a concept has its roots in flood irrigation and sprinkler irrigation systems where pipes had to be moved from field to field. Flood irrigation is best suited to applying large volumes of water at infrequent intervals, and the method specified how long that interval could be. In the case of sprinkler irrigation, a long interval cuts down the cost associated with moving pipes.

The advent of drip and micro irrigation and center pivot or lateral move sprinkler systems has changed the focus away from refill points. Since these systems allow irrigation to be performed at virtually anytime, there is no need to approach the refill point and the associated dangers of drying the soil out too much. The aim is to keep the soil near the full point by applying water daily, or at most, weekly.

Drip and micro irrigation only wet part of the root zone, so the wetted volume of soil is much smaller than for flood or sprinkler. This means irrigation management must be more precise, as the reduced amount of stored water increases the risk to crop health of, for example, equipment failure. In many cases, these systems have been shown to produce higher yields. Micro irrigation also entails special problems related to the placement of soil water sensors with respect to the emitters.[15]

Interpretation of soil water content measurement is also more difficult for frequent irrigation, where plant uptake, redistribution, and drainage of water can be occurring simultaneously. Few irrigators understand that water can be moving into a layer of soil at the same rate as it is moving out, and make the mistake of interpreting a flat water content vs. time trace as evidence of no drainage.

There is also a much greater understanding of the way in which plants respond to water stress at different growth stages. For example, the practice of regulated deficit irrigation (RDI) can save up to 60% of the seasonal water requirement with little effect on fruit yield or quality.[16] The deficit is allowed to develop after flowering and fruit set at the time vegetative growth is at its maximum, and removed when the fruit size starts to increase. A variant of RDI is partial root zone drying, where half the root zone of a perennial crop is irrigated and the other half allowed to dry.[17] Irrigation is alternated such that the previously dry half is reirrigated and the previously wet half allowed to dry. In this way, half the roots are well watered and half experience drying soil. Roots in the drying soil produce hormonal signals that reduce vegetative growth and provide a more favorable balance between vegetative and fruit production. Again yields are unaffected by the stress or even increased. Of even greater importance is the impact of these controlled stresses on fruit quality, particularly in the wine industry.

ADOPTION BY IRRIGATORS

Irrigation management by soil water status is a method that has been promoted for over 50 yr. However, despite decades of extension work, the uptake by irrigators remains disappointingly low. There are several reasons for this. In most situations water is not a major percentage of the variable costs and many irrigators baulk at the time and expense of collecting, interpreting, and implementing the information soil water sensors provide. In practical terms the cost to the individual farmer of overirrigation is less than the penalty of under irrigating, and there is no doubt large quantities of irrigation water are wasted as a result.[18] Water treatment, algal bloom control, salinity are all examples of off-site impacts of overirrigation, which are generally not included in the cost–benefit analysis.

Point to point variability in soil water content within a field is also a major disincentive for soil water monitoring. This variability is due to changes in soil properties, plant growth, and non-uniformity of water application. To properly account for such variation requires the installation of far more equipment than is practicable.[19] The problem of variability makes the atmosphere-based methods of irrigation scheduling more attractive. However, errors in this method, particularly related to the estimation of leaf area and root distribution, means that some combination of atmospheric and soil based measurement will provide the most robust feedback system. Irrigation scheduling by soil water status should show further improvements through the development of new soil water measuring technology, and particularly the software associated with them that simplifies the interpretation of data for the irrigator.

Irrigation Scheduling: Water Budgeting

Brian Leib
Claudio Osvaldo Stockle
Biological Systems Engineering, Washington State University, Pullman, Washington, U.S.A.

INTRODUCTION

The basic purpose of irrigation in agriculture is to supply plants with sufficient water to obtain optimum harvestable crop yield and quality. For this purpose, irrigation events must be scheduled to provide the right amount of water at the appropriate time. Water stored in the soil explored by plant roots is the main source of water supply for crop uptake, mainly used to meet evaporation losses from plant surfaces. Soil water budgeting is therefore a primary irrigation scheduling approach for agricultural crops.

Why Irrigation Scheduling?

Irrigation scheduling consists of determining when and how much irrigation water to apply to crops growing in the field or greenhouses. The purpose is to supply plant water needs to meet given crop yield and quality targets. Late and/or insufficient irrigation may lead to undesirable crop water stress and yield/quality reduction. Excess irrigation generates undesired water percolation in the soil profile beyond the reach of roots. This not only represents a loss of water otherwise available for plant use, but percolating water also transports nutrients, pesticides, and other chemicals into deeper soil layers, eventually reaching groundwater.

WATER BUDGETING

The approach to be used for proper irrigation scheduling depends on the method of irrigation. High frequency methods such as drip irrigation do not rely much on soil storage of water. Irrigations are applied to meet crop water use, typically on a daily basis, utilizing a small volume of the soil potentially available for root water extraction. Other irrigation methods such as furrow or move-set sprinkler irrigation rely on the soil profile explored by roots as water storage. Plants draw water from this storage until a point where replenishment by irrigation is required. The speed of storage depletion by crop water uptake (and direct soil surface evaporation), the soil water content at any given time, and the critical soil water content (allowable depletion) at which irrigation is required are the central elements of irrigation scheduling by water budgeting.

The general procedure for irrigation scheduling based on water budgeting was summarized in the early 1970s and can be easily implemented in a simple computer program or an electronic spreadsheet.[1] Irrigation scheduling decision support systems that implement computerized water budgeting by linking real-time weather information and soil and crop databases are now commonly available.[2] The daily soil water depletion within the soil profile effectively explored by roots is calculated as:

$$D_i = D_{i-1} + (\mathrm{ET} - P_\mathrm{e} - \mathrm{IR})_i \qquad (1)$$

where D_i is soil water depletion on day i, D_{i-1} is soil water depletion on day $i - 1$, ET is evapotranspiration (water loss by crop transpiration plus soil surface water evaporation) on day i, P_e is effective precipitation (precipitation depth that infiltrates into the soil) on day i, and IR is net irrigation (water depth actually stored in the root zone) on day i. All quantities are expressed as water depth in mm or in. Fig. 1 illustrates the water balance process described by Eq. (1).

Soil water depletion is calculated relative to the upper limit of the soil storage of plant available water (PAW). Soil water may fluctuate from total dryness to saturation, where all porosity is filled with water. The PAW soil storage encompasses a fraction within these two water status extremes. The upper limit corresponds to the water depth equivalent after the soil profile has been fully irrigated and subsequently drained until the drainage rate becomes negligible (24–72 hr after irrigation, depending on soil texture). This is also referred to as the soil field capacity. The lower limit (also known as permanent wilting point) corresponds to the soil water storage level at which plants can no longer remove soil water. The PAW soil storage is the difference between the upper and lower limits.

When the soil water content is equal to the upper limit water content, $D_i = 0$. When $D_i = D_\mathrm{o}$, the allowable depletion for a given crop, an irrigation

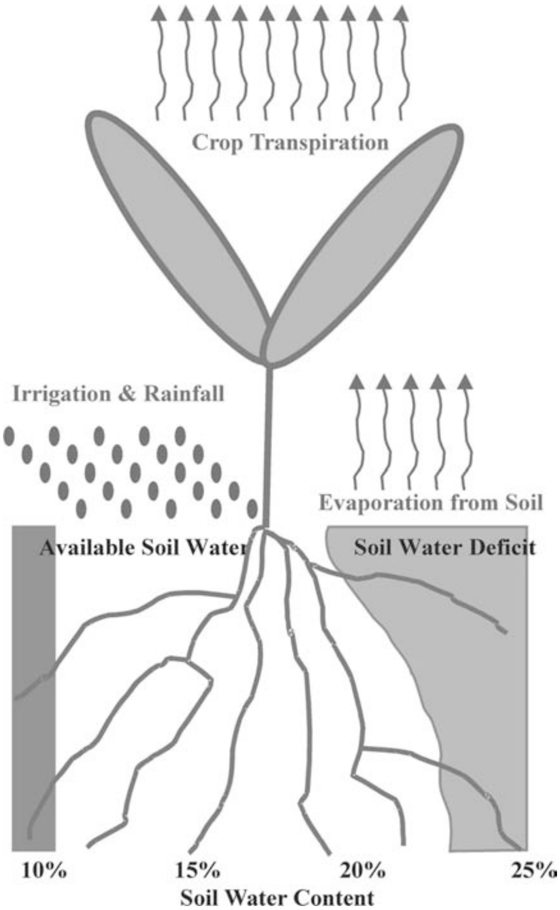

Fig. 1 Soil water balance in irrigation scheduling.

event should be scheduled. D_o corresponds to a water content between the upper and lower limit of PAW. The refill point is closer to the upper limit as the sensitivity of crops to water stress and the atmospheric demand for water evaporation increase. The value of D_o also depends on the size of the PAW soil storage. For more information on soils and irrigation scheduling see Ref.[3].

Evapotranspiration

Soil water evaporation is the process of transformation of liquid water to vapor and subsequent removal from the soil surface. Crop transpiration consists of the transformation of liquid water into vapor inside the plant tissues, and the subsequent removal of vapor to the atmosphere, mainly through stomata. For plants growing under typical field conditions, these two processes occur simultaneously, a phenomenon referred to as evapotranspiration (ET). The ET rate (mm or in per unit time) depends on the energy supply, vapor pressure gradient, and wind as well as on the rate of water supply to plant roots (ultimately to the evaporation sites at the substomatal cavities) and the topsoil. Evapotranspiration depletes the soil moisture in the soil profile explored by roots.

Crop ET can be determined experimentally. However, for irrigation scheduling purposes, ET is normally calculated from weather data. The method consists of the use of empirical equations to calculate ET from a reference crop (ET_o), typically defined as a short healthy grass surface, 12-cm high, fully covering the ground and with ample water supply. Evapotranspiration for the crop of interest (ET_c) is obtained by multiplying ET_o by a crop coefficient (K_c) that fluctuates throughout the growing season based on crop canopy characteristics and its ability to cover the ground. A large number of equations to calculate ET_o are available.[4] Evaluations performed have shown the Penman–Monteith equation,[5] a biophysically based formulation, to be suitable for applications across climatic conditions.[6] A complete description of procedures to calculate ET_o, K_c, and ET_c is given by Allen et al.[7]

Soil Water Content

Soil water sensors can be used in conjunction with a water balance Eq. (1) to help schedule irrigation. Sensors can be used to verify the soil water content estimated from a water balance, to restart a water balance at a known value of soil water content, or to evaluate the upward or downward trend in soil water content from irrigation designed to replace the loss of water from ET. It is important to understand instrument calibration when using a soil water sensor in conjunction with a water balance. Sensor calibration can vary in different soils types.[8,9] However, the relative accuracy of sensors can be useful in irrigation scheduling without the need for absolute accuracy via calibration.[10] Irrigation scheduling is most successfully implemented when ET driven water balances and soil water sensors function as independent checks to compensate for the inaccuracies of both methods. Fig. 2 shows how irrigation was scheduled by calculating the soil water depletion from both a water balance Eq. (1) and soil water sensors.

There are several methods of measuring soil water content and how each type of sensor works is briefly described below. The tensiometer uses a porous ceramic tip in direct contact with the soil to measure soil tension. The granular matrix sensors and resistance blocks measure the change in electrical resistance that occurs as soil water moves in and out of the sensor in response to the surrounding soil moisture. The neutron probe counts the number of neutrons that collide with the hydrogen in water. Tensiometers, resistance sensors, and neutron scattering[11] have a fairly long history of use in irrigation scheduling. Most of the new sensors available on the market today measure

Irrigation–Journals

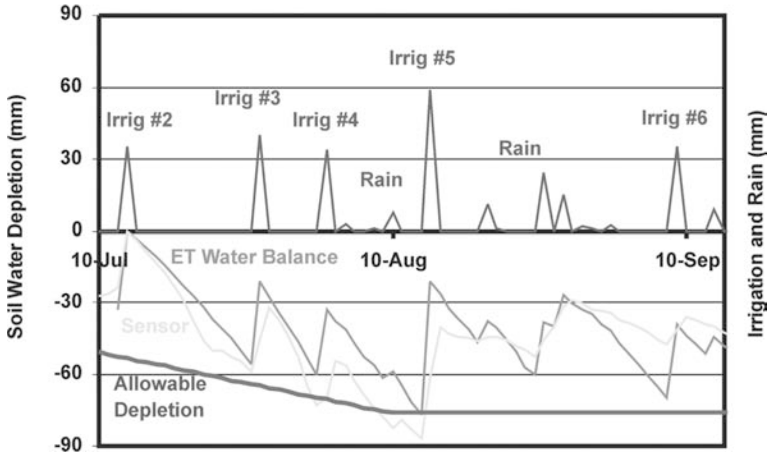

Fig. 2 Example of a water balance used with soil water sensors in irrigation scheduling.

the dielectric constant of the soil. The dielectric constants are of air, mineral soil and water is 1, 3–7, and 80, respectively. Therefore, the overall dielectric constant of bulk soil will vary predominantly in relationship to soil water content. One way to determine the soil's dielectric constant is by measuring the change in a radio wave's frequency as it passes through the soil known as frequency domain reflectometry (FDR) or RF capacitance.[12] Another, way to determine the dielectric constant of the soil is to measure the reflectance pattern of a voltage pulse that is applied to a wire guide known as time domain reflectometry (TDR).[13]

CONCLUSION

Crop, soil, and weather information can be used to calculate components of the soil water balance, which can be used for irrigation scheduling (when and how much irrigation water to apply). Soil water budgeting is a robust approach, widely used in irrigated agriculture. Soil water calculations must be complemented with measurements of water content in the soil profile effectively explored by plant roots. A large array of sensors is available to measure soil water.

INTRODUCTION

A drip irrigation system is a form of localized irrigation that delivers water directly into the root zone of a crop. When properly designed and managed, a drip irrigation system can eliminate surface runoff, minimize deep seepage, and achieve high uniformity of water distribution and irrigation application efficiency. The development of drip irrigation in the late 1960s marked a period of tremendous improvement in irrigation science and technology in which water use is done more beneficially for agricultural production.

With the increasing consequence of limited water resources and the increasing need for environmental protection, drip irrigation will play an even more important role in the future. Drip irrigation systems can be used for many different types of agricultural crops, including fruit trees, vegetables, pastures, specialty crops such as sugarcane, ornamentals, golf course grasses, and high economic value crops grown in greenhouses. An understanding of drip irrigation systems, irrigation scheduling, crop response, and economic ramifications will encourage greater use of drip irrigation in future agricultural production.

UNIFORMITY OF WATER APPLICATION AND DESIGN CONSIDERATIONS

The desired uniformity of water application and the specific crops to be grown guides the creation of drip irrigation systems. There are two types of drip irrigation uniformity: system uniformity and spatial uniformity in the field. The consistency of system distribution of water into the field describes the system uniformity. The spatial uniformity is the regularity of water distribution considering overlapping emitter flow and translocation of water in the soil. For drip irrigation systems designed for trees with large spacing, the system uniformity is equal to the water application uniformity in the field. For high-density plantings, the emitter spacing should be designed considering overlapped wetting patterns and the spatial uniformity in the field. The uniformity of a drip irrigation system depends primarily on the hydraulic design, but must also consider the manufacturer's variation, temperature effects, and potential emitter plugging. The effect of water temperature is generally negligible when using turbulent flow emitters. A combination of proper filtration and turbulent emitters can control emitter plugging. When grouping a number of emitters together as a unit, such as those designed to irrigate an individual plant's root system, the uniformity of water application with respect to the plant will improve.

Many expressions have been used to describe uniformity. The system uniformity, or emitter flow uniformity, can be expressed as the range or variation of water distribution in the field. This term was initially used for hydraulic design of drip irrigation systems given that the minimum and maximum emitter flows could be calculated and determined.[1] When more emitter flows are used or more samples are required for determining variation or spatial uniformity in the field, the Christiansen uniformity coefficient (UCC)[2] and coefficient of variation (CV), which is the ratio of standard deviation and the mean, are used. Each of the uniformity expressions are highly correlated with one other.

HYDRAULIC DESIGN OF DRIP IRRIGATION SYSTEMS

Once selection of the type of drip irrigation emitter is complete, the hydraulic design can be made to achieve the expected uniformity of irrigation application.

The hydraulic design of a drip irrigation system involves designing both the submain and lateral lines. Early research in drip irrigation hydraulic design concentrated mainly on the single lateral line approach,[1,3,4] but in 1985 Bralts and Segerlind developed a method to design a submain unit. The hydraulic design is based on the energy relations in the drip tubing, the friction drop, and energy changes due to slopes in the field. Direct calculations of water pressures along a lateral line or in a submain unit are made by using an energy gradient line approach.[1] All emitter flows along a lateral line and in a submain can be determined based on their corresponding water pressures. Once the emitter flows are determined, the emitter flow variation, q_{var} is expressed by

$$q_{var} = \frac{q_{max} - q_{min}}{q_{max}} \quad (1)$$

where q_{max} is the maximum emitter flow and q_{min} is the minimum emitter flow. Based on these data, other uniformity parameters such as UCC and CV can also be determined. There is a strong correlation between any two of the three uniformity parameters in the hydraulic design of drip irrigation systems, thus any one of the uniformity parameters can be used as a design criterion. This correlation also justifies using the simple emitter flow variation q_{var} for hydraulic design. The emitter flow variation q_{var} is converted to the CV when it is combined with the manufacturer's variation of emitter flow.

The total emitter flow variation caused by both hydraulic and manufacturer's variation can be expressed by,[5]

$$CV_{HM} = \sqrt{CV_H^2 + CV_M^2} \quad (2)$$

where CV_{HM} is the coefficient of variation of emitter flows caused by both hydraulic and manufacturer's variation; CV_H and CV_M are the coefficients of variation of emitter flows caused by hydraulic design and manufacturer's variation, respectively.

The design criterion for emitter flow variation q_{var} for drip irrigation design is arbitrarily set as 10.0–20.0%, which is equivalent to a CV, from 0.033 to 0.076, or 3.0–8.0%. Based on the research of last 30 yr, the manufacturer's variation of turbulent emitters is maintained only in a range 3.0–5.0%, expressed by CV. When this variation is combined with emitter flow variation caused by hydraulic design with a range 3.0–8.0% in CV, the total variation determined by the equation above will be limited to a CV of less than 10.0%. This variation illustrates that the drip irrigation systems are designed to achieve high uniformity and irrigation application efficiency.

Economic return can also be the basis of design criteria for drip irrigation. A new set of design criteria for drip irrigation was developed,[6] based on achieving an expected economic return with various water resources and environmental considerations (Table 1).

DRIP IRRIGATION FOR OPTIMAL RETURN, WATER CONSERVATION, AND ENVIRONMENTAL PROTECTION

When the uniformity of a drip irrigation system is designed with a UCC of 70.0%, 30.0% or less in CV, the irrigation application is expressed as a straight-line distribution,[7,8] as shown in Fig. 1. This figure was plotted using percent of area (PA) against a relative irrigation depth, X, which is the ratio of required irrigation depth to mean irrigation application. The straight-line distribution in the dimensionless plot can be specified by a minimum value, a, a maximum value, $(a + b)$, in the X-scale and a slope b, where b specifies the uniformity of water application.[9]

When a drip irrigation system is designed with fixed uniformity, it is possible to determine the sloped straight line with known value of a and b. A value (X) can then be selected between value a and $(a + b)$ and plotted (Fig. 1). The triangle formed above the horizontal line (X) results in an irrigation deficit and yield reduction. The triangle below the horizontal line results in over-irrigation and deep seepage.

An important irrigation scheduling parameter, the relative irrigation depth, (X) indicates how much irrigation water is applied. The effectiveness of drip irrigation is shown not only by the high uniformity of the drip irrigation system, but also by the irrigation requirement and the strategy of irrigation scheduling. As illustrated in Fig. 1, the irrigation scheduling parameter (X) affects the areas of over-irrigation and water deficit conditions in the field and is directly

Table 1 Design criteria for uniformity of drip irrigation system design

Design consideration	CV (%)	UCC (%)
Water is abundant and no environmental pollution problems	30–20	75–85
Water is abundant but with environmental protection considerations	20–10	80–90
Limited water resources but with no environmental pollution problems	25–15	80–90
Considerations for both water conservation and environmental protection	15–5	85–95

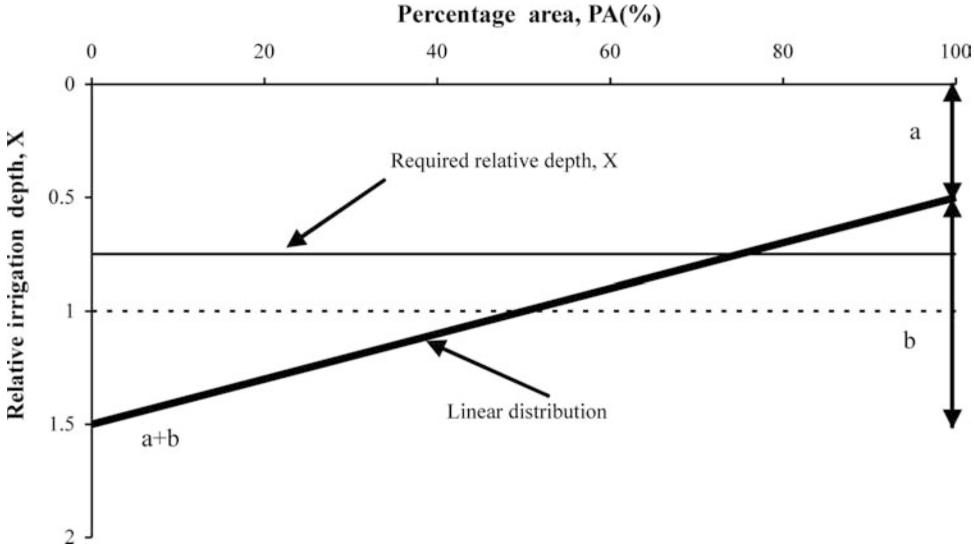

Fig. 1 A linear water application model for drip irrigation.

related to the economic return. Practically speaking, the X parameter is selected in a range from a to $(a + b)$, as shown in Fig. 1. Three typical irrigation schedules can be expressed by X and are as follows:

$X = a$	This schedule is a conventional irrigation schedule, which is based on the minimum emitter or minimum water application. The field is fully irrigated and whole field is over-irrigated except the point of minimum irrigation application.
$X = X_0$	For an optimal return there is a value of X for the irrigation scheduling parameter between a and $(a + b)$.
$X = (a + b)$	This irrigation schedule is based on the maximum emitter flow or maximum irrigation application. The whole field is under deficit condition except the point of maximum water application. There is no deep percolation.

An optimal irrigation schedule for maximum economic return was determined[9] based on cost of water, price of the yield, and damage such as environmental pollution and groundwater contamination caused by over irrigation. Different irrigation strategies require different amounts of water application. Water conservation and environmental protection are realized by comparing any two of the irrigation strategies.[10]

CONCLUSION

Drip irrigation is an irrigation method that can distribute irrigation water uniformly and directly into the root zone of crops. It is one of the most efficient irrigation methods and can be designed and scheduled to meet the water requirement of crop and produce maximum yield in the field.

When the drip irrigation system is designed with high uniformity, the slope b of the straight line of water application function (Fig. 1) can be controlled to achieve the desired variation. In this case the conventional irrigation schedule, $X = a$, optimal irrigation schedule, X_0, which is a location between a and $(a + b)$, and the irrigation schedule for environmental protection, $X = a + b$, are in close proximity. This closeness shows that the drip irrigation system can achieve optimal economic return, water conservation, and environmental protection.

Irrigation Systems: History

Wayne Clyma
Water Management Consultant, Fort Collins, Colorado, U.S.A.

INTRODUCTION

Irrigation as a technology probably has existed since 6000 B.C. rather than 3000 B.C. as determined from recorded history. Irrigation started with individual farmers experimenting with carrying water to individual plants or cropped areas and expanded to diversions from streams or building bunds for flooded areas. Surface irrigation began the process of irrigation, but sprinkle and microirrigation have evolved and expanded to present day management with computer managed controls and precise application of water to crops often on a daily basis.

Prehistoric man has survived from the food provided from fruits, grains, vegetables, and animals as early as 10,000 B.C. Farming or crop cultivation is believed to have started about 8000 B.C. The first irrigation (Table 1) in Mesopotamia and Northern Africa is believed to have begun as early as 6000 B.C. This early date perhaps more nearly represents the beginning of irrigation rather than the beginning of large scale irrigation.[1] These dates reflect anthropological assessments of the beginning of irrigation rather than the first recorded history or physical evidence of the existence of canal irrigation. The recorded history of large-scale irrigation is reviewed more thoroughly by Willardson. Thailand, and the Yangtze Valley in China are estimated to have started irrigation about 5000 B.C. while the Indus Valley in what is now Pakistan started irrigation about 3500 B.C. Irrigation in Europe is believed to have begun as early as 4500 B.C. while irrigation started about 2500 B.C. in Japan at the influence of China. North and South America, represented by Mexico, started irrigating in about 1500 B.C. Many historians believe irrigated agriculture supported, but also required the development of advanced civilizations. Other historians believe that declines in irrigated agricultural capability led to the decline of civilizations. Others believe the decline of civilizations caused the decline of irrigation.

INVENTING IRRIGATION

Irrigating crops likely started as a trial and process with perhaps some container used to carry water to individual fruit trees or small patches of grain or vegetables. The Pueblo Indians in New Mexico are believed to have irrigated all their corn by such a method. Studies in Mesopotamia showed that early irrigation efforts involved building canals that took water from the river, which was the irrigation supply source, to areas where trees and crops were growing. The form that these early field units took has never been described to my knowledge.

Irrigation from the Nile River in Egypt is believed to have started by planting crops in the area where flood waters had receded. Subsequently, dikes were formed to control both entry of water to an area and the time an area was inundated. Studies of areas where farmers have developed small diversion canals to divert water from streams suggest farmers used small basins to control the water supplied to crops. Informal inspections of ancient sites in India suggest hand labor was used to carry and apply water to small areas in a castle when irrigation was needed.

Informal reviews of the evolution of irrigation in the North America, South America, Asia, and Africa suggest that initial diversions of water through canals were used to irrigate crops by wild flooding. In the United States, India, and Chile, wild flooding was accomplished by spreading water over large areas without the use of dikes to control the spread of the water. For the United States and Chile, because of the larger field equipment, larger units for farming were used. No such goal was identified in India, but apparently transfer of water control concepts from other irrigated areas never occurred. In Afghanistan, Ethiopia, India, Kenya, Nepal, Somalia, Pakistan, Sri Lanka, and Thailand, small bunded units were constructed to control the water applied to crops. These small units used wild flooding, not the level basins as are frequently assumed, because lateral and longitudinal slopes, and high and low areas occurred in each basin. Even most rice fields are not level basins because within the basin they often have 15 cm or more ranges in elevation.

In Egypt, small bunded units (often less than 10 m^2) are used. The sizes of the units are believed to be related to the small, variable flow rates that are available for irrigation from Shadoofs, Archimedes' screws, and *sakias* (water wheels) using human or animal power. Small units were also used in India where animal power was used for lifting. These units used oxen and a water bag to lift water and supply water to

Table 1 Beginnings of irrigated agriculture in major areas of the world

Area	Years B.C.
Middle East	
Mesopotamia	6,000
Northern Africa	6,000
Asia	
Yangtze Valley in China	5,000
Thailand	5,000
Indus Valley in now Pakistan	3,500
Europe	4,500
Japan	2,500
North and South America	1,500

irrigate a field. The crops were frequently opium poppies and the high cash value seemed to result in more precise leveling and greater care in growing the crop. Studies in Pakistan have shown that farmers adjust the size of their basin to the flow rate available. Farmers changing the size of field as available flow rates vary has also been observed in other countries.

Farmers value fields that are level. Observations and farmer insights repeatedly find that farmers invest considerable labor attempting to level their fields precisely. Those same observations show that precision measuring instruments, surveying levels, or laser guided equipment, are necessary to level basins precisely.

EVOLUTION OF IRRIGATION SYSTEMS

Surface irrigation systems were the first widely used method of irrigation. When soils and topography limited the effectiveness of surface irrigation systems, then sprinkle irrigation was invented. Initial sprinkle systems were pipes with holes to allow water to spray on adjacent crops. When shortages of water and need for precise timing and amounts of water became dominant considerations, trickle irrigation systems were developed and used in farm fields. Some equipment for trickle irrigation was adapted from greenhouse systems in England. Other initial trickle irrigation systems were buried pipes with holes next to the plant row or circular pipes placed around a tree. Both sprinkle and trickle irrigation systems have many additional sophisticated improvements since their initial invention. Both sprinkle and trickle irrigation (drip or microirrigation as more recently named) have the distinct advantage of being suited to non-leveled land and to soils not suited for surface irrigation. They also remove the soil, in a large part, as the hydraulic transport media. Pipes are used to transport the water largely eliminating seepage losses from canals and "over irrigation" at the "head end" of fields and runoff from "tail ends" of fields. In addition, these newer irrigation technologies are better suited to applying smaller application volumes per unit land area reducing longer irrigation intervals typically associated with surface irrigation. All pressure irrigation systems required appropriate maintenance and management or their advantages of higher potential performance are lost.

Evolution of Surface Irrigation Systems

As irrigation projects were observed around-the-world, a sequence for evolvement of field surface irrigation systems was identified. Just as irrigation development follows a sequence, the types of field irrigation systems often follow a sequence. This sequence of evolution of surface systems is as follows:

Wild flooding → Border ditch
→ Graded borders and furrows → Level basins

Initial irrigation efforts are focused on supplying water when drought or lack of adequate rainfall results in low or undependable crop yields. Providing an irrigation water source is initially focused on methods for delivering water to the field. Usually delivery of water is accomplished through a canal from a lake or river by gravity to the field. Field application of water is accomplished by simply diverting water from the source onto the field. Without leveling of the field surface nor dikes to guide the water across the field, wild flooding is the result as shown in Fig. 1. When flow rates are small and large equipment does not dictate larger field units, small bunded units are used with channels constructed to each bunded unit. In rice

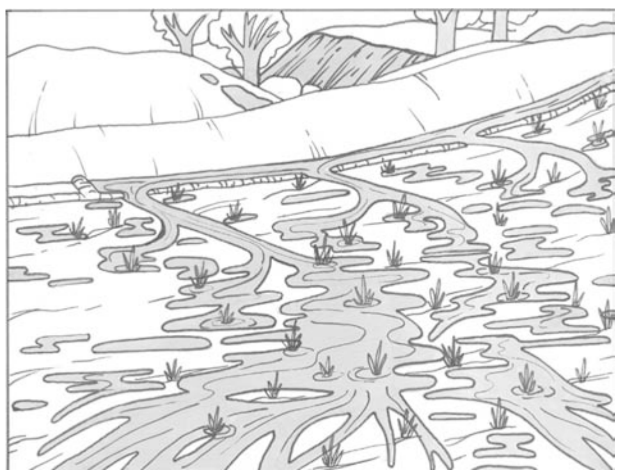

Fig. 1 Wild flooding in surface irrigation of a field. (Water Management Synthesis II Project, Colorado State Univ., Fort Collins, CO.)

Irrigation–Journals

irrigation, channels are often omitted and flow is from bunded unit to bunded unit. Rice irrigation attempts to achieve a continuously flooded condition for weed control not because rice plants must be continuously flooded. Non-rice crops cannot grow with continuous flooded conditions. Therefore, supplying water by allowing it to flow from bunded unit to bunded unit is usually not successful for non-rice crops. Farmers in many countries, including the United States, often repeatedly try to grow non-rice crops with basin to basin flooding with no or limited success. The small bunded unit prevalent in many countries, often incorrectly called level basins, are wild flooded as shown in Fig. 2. Wild flooding is still practiced because within the bunded unit lateral and longitudinal slopes with high and low areas exist.

With time, the surface conditions of the field are improved and channels are constructed to carry water into the field to ensure water is available to all the cropped area of the field. In the mountain west of the United States, these field irrigation systems are called border ditch irrigation systems. Illustrated in Fig. 3, water is carried into the field by ditches, bunds are constructed to guide water down the field, but water is distributed within each bunded unit by wild flooding. In countries with small, variable flows available for irrigation, the small basins for wild flooding are essentially a variation of border ditch irrigation systems.

With land leveling and smoothing, bunds are constructed down the prevailing slope without any lateral slope between the bunds, and an appropriate flow of water is introduced at the upper end (Fig. 4). These field systems are graded border irrigation systems. They improve the uniformity of water distribution over

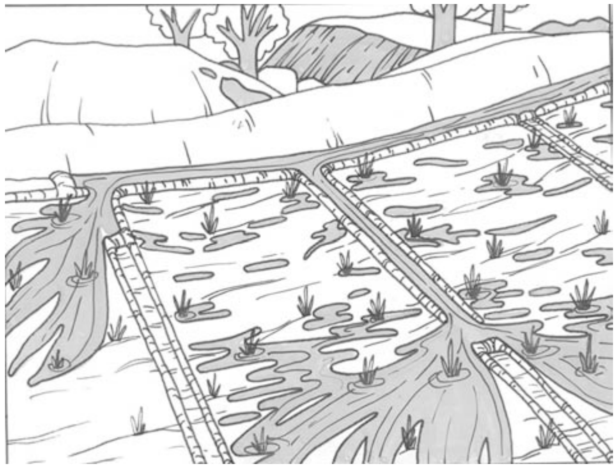

Fig. 3 Border ditch irrigation of larger field units using channels to deliver water within the field by wild flooding the field. (Water Management Synthesis II Project, Colorado State Univ., Fort Collins, CO.)

the field compared with wild flooding. The flow rate must be adjusted according to the slope and intake rate of the soil or excessive runoff will occur. Continuous flow must be provided until sufficient infiltration is achieved to meet crop requirements. Thus, effective management of graded border irrigation systems by farmers is complex and difficult. Farmers often insist that only trained irrigators or irrigators with experience can manage graded systems.

Graded furrows fall in the same category as graded borders. They are the first development from wild flooding. Furrows are directed downslope between row crops with each furrow or alternate furrows supplied an appropriate flow rate as shown in Fig. 5.

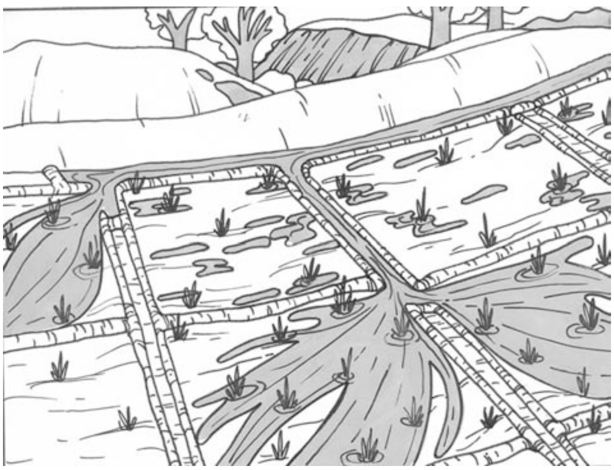

Fig. 2 Border ditch irrigation by wild flooding of a field using small bunded units and channels to deliver water within the field. (Water Management Synthesis II Project, Colorado State Univ., Fort Collins, CO.)

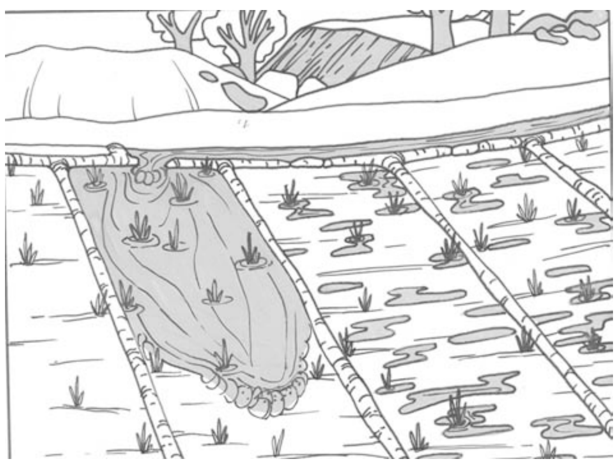

Fig. 4 Graded border irrigation systems with bunds to guide the water down the slope and cross slopes eliminated. (Water Management Synthesis II Project, Colorado State Univ., Fort Collins, CO.)

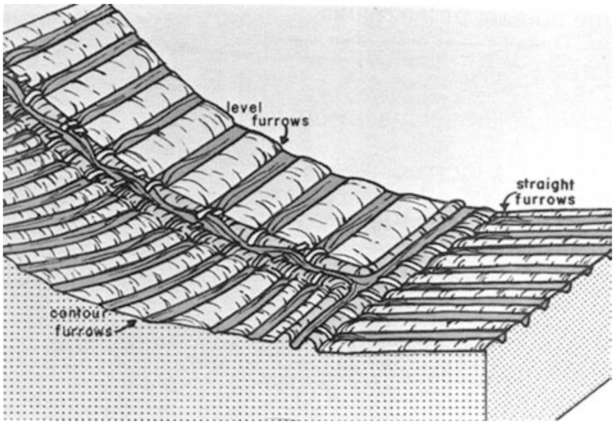

Fig. 5 Furrow irrigation of fields with graded furrows, contour furrows, and level furrows. *Source*: From Ref.[2].

Furrows may also be constructed on contour to limit cross slopes. Flow rates must be adjusted to meet the infiltration requirements of the furrow adequately with sufficient remaining flow to advance down the furrow. If the furrow flow rate is too large, erosion and excessive runoff are the result. If the furrow flow rate is too low, excessive deep percolation may occur at the upper end of the field and the lower end of the field may not receive enough water. Thus, management of graded furrows is complex as are graded borders. Furrows are more adaptable than borders in the sense that they can be constructed on fields with cross slopes if the furrow flow from irrigation or rainfall can be controlled not to exceed furrow capacity. When one furrow breaks, cross slope erosion can be a serious and damaging condition. Furrows can also be constructed in level basins or fields with no slope and result in level furrows. Furrows allow the placement of crops on ridges such that the plants are not covered by water. Vegetables and many field crops produce higher yields when grown on ridges.

Level basins are the final targets of evolution in surface irrigation systems (Fig. 6). They provide the management advantage that farmers add water to the basin within a wide range of flow rates for a time such that the target volume of water is applied. If the basins are appropriately designed and managed, then farmers can use advance distance criteria to apply target amounts of water to the level basin without water measurement. Also, advance distance criteria can be used to shut off the water application to a field when a target amount of water is applied. Farmers around-the-world use advance distance criteria to apply water to fields, but the basins are not adequately level nor designed to apply target amounts of water to a field. Therefore, the technology is available and farmers are already attempting to use the technology. Using the available technology to apply target amounts

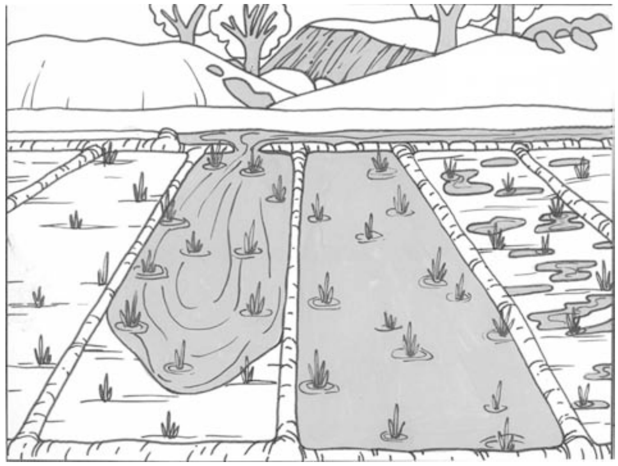

Fig. 6 Level basin irrigation of a field with all slopes removed and precisely leveled. (Water Management Synthesis II Project, Colorado State Univ., Fort Collins, CO.)

of water to a field would achieve quantitative water management with level basins.[3] Level basins came into use in United States when laser leveling was developed. The large basins, often as large as 8 ha, require large flow rates and the very precise leveling achieved with laser-controlled leveling equipment (Fig. 7).

Surface irrigation systems are varied and flexible. They are the most widely used method of irrigation. Level basins can achieve high levels of performance (higher than sprinkle and near the same level as trickle systems) with advantages for farmer management and sometimes system cost. Soils and topography limit the applicability of surface irrigation systems because uniform slopes (level or graded) and medium to lower intake soils of uniform texture are required for

Irrigation–Journals

effective performance. Higher intake rate soils can be irrigated with surface irrigation, but smaller units are required. Surface irrigation systems are applicable to many irrigated areas and are often the most advantageous systems. They often require the lowest investment to become operational, but unless automated, may involve the highest labor costs.

Irrigation was advanced by the coming of mechanical scrappers to form canals and ditches. In addition, canal lining with various materials from concrete to butyl rubber has attempted to reduce canal seepage losses of water. However, canal maintenance remains costly. Also, in the past few years, canal water level control, through Supervisory Control and Data Acquisition (SCADA) systems using computers to remotely access data, and then control canal gates and flow structures, has become widely used in United States to replace less reliable manual and incremental controls. Laser leveling both surveys and precisely levels fields for level basins and other surface systems. More recently, the use of "surge flow" for graded furrows, where flow is "on and off" has been used to reduce runoff losses and provide greater uniformity in the time for infiltration along the furrow length. Surge flow valves are now solar powered and even provide the ability to apply fertilizer into the ending irrigation set times. Cablegation systems have also been developed to automate both on-farm canal and pipeline delivery systems.

Fig. 8 Hand move sprinkler lateral for irrigation of a field. (Courtesy of Natural Resource Conservation Service, USDA; www.nrcs.usda.gov.)

Sprinkle Irrigation Systems

Sprinkle irrigation systems were developed to supply water to crops independent of the transmission capabilities of the soil. Higher intake soils, variable textured soils, and uneven land surfaces limited the appropriate use of surface irrigation systems. The first patented sprinkle irrigation system was developed in 1884.[4] These initial systems used controlled heads to distribute water from pipes. Many initial, key developments in sprinkle irrigation were developed by farmers with manufacturers taking over the development and refining the concept. The Rain Bird impact sprinkler was developed by a farmer and then refined by the Rain Bird Company. These initial sprinkle systems were moved by hand (Fig. 8). Other important developments were quick coupling thin walled pipes, rubber gaskets that supported portable, quick coupling pipes, and aluminum pipe that became economical and available after World War II.[4]

The first mechanical move sprinkle systems were wheel line sprinklers of the lateral move type developed in the 1930s. They use wheels on pipes to irrigate the width of a field in one pass (Fig. 9). These sprinkle systems replaced the expensive solid set sprinklers and the labor intensive hand move systems commonly used. Mechanical move systems were also often more efficient and required less labor than surface irrigation systems.

Center pivots were developed first by a Colorado farmer, Frank Zybach, that used a water drive mechanism. They use wheels and arches to support pipes that travel in a circle as shown in Fig. 10 to irrigate usually square fields. Thus, often the corners of the field are not irrigated. Dr. William Splinter of the University of Nebraska considered the center pivot sprinkle system "the most significant mechanical innovation since the replacement of draft animals by the tractor."[4] Center pivot sprinkle systems now dominate the area irrigated by sprinklers with twice as much area irrigated compared with other sprinkle methods. Large areas (such as shown in Fig. 11) are irrigated in circles with center pivots. Linear move systems provide the ability to irrigate rectangular fields with the equipment capabilities of center pivots (Fig. 12). System costs and management issues are the major detriments to sprinkle systems. Sprinkle irrigation equals about half the area irrigated in United States.[5]

Mechanical move sprinkle systems have been adopted because of their reduced labor requirements,

their adaptability for irrigating rolling topography, and their effectiveness in fields with sandier soils or mixed soil types. Irrigation is accomplished at a higher level of efficiency, but design efficiencies are often misleading. Duke, Heermann, and Dawson[6] found that all the center pivot units in some 60 units evaluated in Colorado could economically have their actual performance improved. Management improvement potential also existed.

Recent advances in center pivot systems include controls that can automate system operation allowing remote controls via radio, cell phones, or infrared (line of sight) linkages from computers or other devices. Currently, the ability to control individual applicators or heads, or groups of applicators offers the potential to use site-specific management or ''prescription'' management of small blocks (10s of m^2). Each block can be managed independently to supply water, fertilizer, or chemicals as required while minimizing any wastes and possibly reducing any environmental impact. These are important developments for the future growth of precision agriculture.

Traveling sprinkle systems use giant single gun-type sprinklers that travel on a chassis down the length of a field and covers an area as much as 400 ft in diameter (Fig. 13). Nozzles operate at 80–100 psi. A cable

winds upon a drum on the self-powered chassis to move the unit down the field. A long hose is used to supply water to the unit from detachable hookups to an underground supply line. Sometimes rotating

booms from 60 ft to 120 ft long are used to cover a large area similar to a boom sprinkler. Because of the high application rates, traveling sprinkle systems are commonly used for supplemental irrigation on sandy soils.

Trickle Irrigation Systems

Trickle irrigation systems include drip, spray, bubbler, and subsurface applications of water to crops. Some have suggested[4] that microirrigation is a more appropriate term. The concept is to apply or make available at each plant or tree the required amount of water for the root zone. Additional area is not irrigated with a reduction in water losses from evaporation and evapotranspiration from weeds. A schematic diagram of a trickle system is shown in Fig. 14.

The first known application of trickle irrigation was in 1860, and used an underground tile line where drainage was accomplished during part of the year, and water was supplied for irrigation during other times.[7] Other major developments include the use of trickle

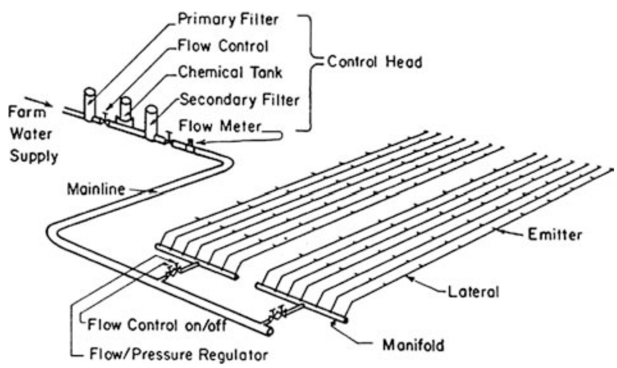

Fig. 14 Schematic diagram of a trickle irrigation system. (Soil Conservation Service, 1984, p. 7–8.)

systems in greenhouses in England during the 1940s.[7] Dr. Symcha Blass, according to Howell,[4] working with greenhouses in England after the war, improved the trickle irrigation systems. Then he transferred the technology to Israel during the 1950s to grow crops in the Negev desert including the use of highly saline waters. Trickle irrigation then spread to Australia, United States, South Africa and to other parts of the world.

Trickle irrigation development in United States started with avocado orchards in California after individuals observed trickle irrigation systems in Israel. A company called Drip-Eze started the manufacturer of emitters for use in trickle irrigation systems.[4] Row crops, primarily vegetables, using trickle irrigation started in New York as new plastic products became available.[4]

Trickle irrigation systems are used for crops that have widely spaced plants, e.g., orchards and vineyards as shown in Fig. 15. High valued vegetable crops are also widely adapted to trickle irrigation systems where careful water control allows increases in yield and improvements in the quality of the produce. Tomatoes are irrigated with an underground trickle system in Fig. 16. Water scarce areas often adapt to trickle irrigation because reduced water requirements result. Because irrigation can be accomplished daily and soil water can be maintained at a high level, irrigation with saline water can also be successful.

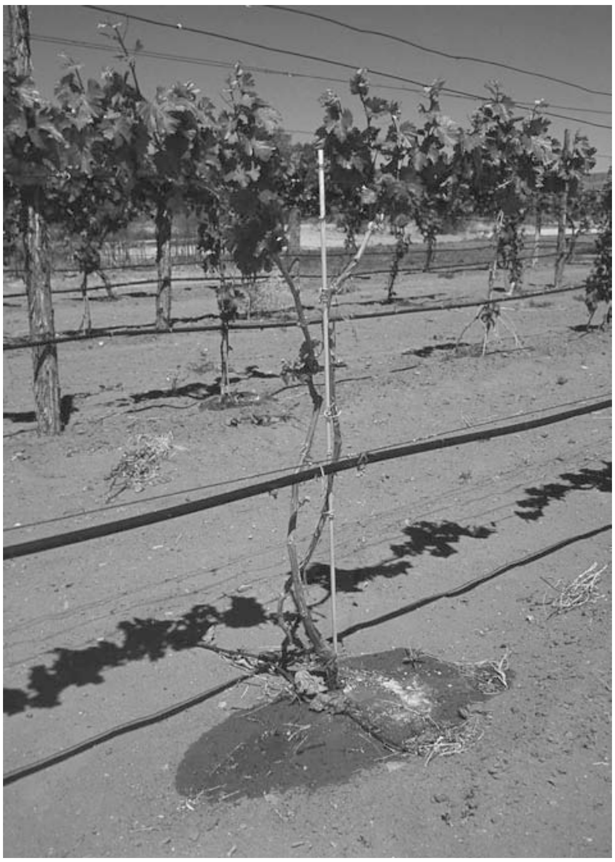

Fig. 15 Trickle irrigation system of grapes showing limited area of water application. (Courtesy of Natural Resource Conservation Service, USDA; www.nrcs.usda.gov.)

The key component of the trickle irrigation system is filtration system. Fine particles, and chemical and bacterial clogging of lines and emitters can rapidly cause irrigation system failure if not carefully managed. Failure of the trickle irrigation system can be catastrophic if the annual crop fails and even the orchard or vineyard dies. Trickle irrigation is used to irrigate about 1,250,000 ha or 4.9% of the irrigated area in United States and irrigates a much higher percentage of the irrigated area in other countries.[8] Israel and other countries have major areas irrigated by trickle irrigation systems.

CRITICAL CONCEPTS IN IRRIGATION

Irrigation as a technology 6000 or more years ago changed society. Civilizations on most continents are considered to have flourished because food production under irrigation allowed education, war, artisans, and a ruling class to develop because everyone no longer needed primarily to focus on finding his family's food. Labor losses from allowing individuals to attend school, participate in a war, and build buildings, monuments, or artistic items are major drains on the food supply. Control of a food supply allows a ruling class to sustain power. Critical concepts in irrigation have supported the continuing important role of irrigation. Water supply management is important in irrigation.

Water Supply

Use of flood waters for irrigation was an important step. Use of channels to divert water for irrigation extended the area that could be irrigated and the time when water was available. Creation of dams to control water and make it available during periods of low flow in the river was another important concept. Dams have been constructed for irrigation to divert water from streams and to store water almost from the first beginnings of irrigation. Dams for irrigation developed the west starting in the late 19th century. Other countries followed the practice with irrigation expanding by 2% per year during the 1960s and 1970s. Costs of irrigation development and concerns about the environmental impacts of irrigation have reduced that expansion to near 1% during the past several decades.[9] Dams also provided flood control along rivers and a power source from early water wheels to modern

Fig. 16 Trickle irrigation of tomatoes using an underground trickle system. (Courtesy of Agricultural Research Service, USDA, www.ars.usda.gov.)

hydroelectric turbines. Recently, in the northwestern United States, dams have raised concern for stream ecology and fish habitats. Occasionally, dams are being removed to satisfy these environmental and societal reasons.

Egypt expanded irrigation along the Nile River greater than many other irrigated valleys because they lifted water by the Archimedes' screw and Shadoof. Pumps provided increased water supply flexibility during the 20th century by lifting water from streams and pumping water from wells. Individual control of water supply by a farmer through pumping is a major advantage in many irrigated areas.

Construction of dams, diversions, and canals became a major part of irrigation development. Managing the delivery of water supplies effectively to meet farm water requirements still needs major improvements. During the 1970s, the importance of effective farm water management facilities began to be recognized. Inadequate farm water management, also constrained by water delivery management, is still a major constraint to effective irrigation in many projects.

Management Concepts

Irrigation scheduling[10] as part of a strategy for water management was one of the most important concepts developed in irrigation. Clyma[11] reviewed status of irrigation scheduling after three decades of application and concluded that the potential of the concept had not been achieved. First, a major part of the technical effort had focused on accurately estimating evapotranspiration for the growing crop. Management decisions were also focused on when and how much to irrigate. Processes for deciding how accurately to apply the target amount of water, and monitoring management decisions of when, how much, and how to irrigate are usually not a part of the irrigation scheduling process. Therefore, irrigation scheduling is not an adequate management process. Perhaps the future will define and apply irrigation scheduling as a strategy for a complete and successful management process.

Farmers commonly do not measure the amount of water applied to a field. Therefore, excess applications of water, and waterlogging and salinity are the common result. Level basins are potentially a major part of surface irrigation systems in the future. A design and management concept, initially defined by Wattenburger and Clyma[12,13] and refined further and integrated into a computer design program,[14] allows farmers to apply a target amount of water to a level basin when the water advances a specified distance into a field.[3] The basin must be precisely leveled and farmers around the world already use advance distance as their criteria for irrigating a field. The technology just needs professionals to supply the needed assistance and appropriate target amounts of water will be applied to each field a farmer irrigates. Perhaps this important concept will be supplied as an urgently needed technology to farmers in the next decade.

CONCLUSION

Irrigation as a technology probably started in 6000 B.C. rather than the 3000 B.C. suggested from recorded history and anthropological evidence of major structures. The intervening time involved the evolution of cities and capability to construct structures such that evidence of irrigation and historical references to irrigation could evolve. Field irrigation systems used by farmers have not been defined from anthropology to my knowledge. Informal information suggesting that Pueblo Indian farmers in Southwest Colorado used pots to irrigate individual plants of corn does suggest a starting point. Observations of field irrigation around the world suggest that wild flooding was the initial surface irrigation system used by farmers. Channels were subsequently constructed to carry water into the field to improve distribution and border ditch irrigation evolved. Graded borders and graded furrows were the next improvements with ridges to control water flow across a field. In all the previous systems, flow rate, infiltration rate for the soil, and slope must be balanced to allow infiltration time for adequate irrigation and management was difficult. Level basins remove all slopes and allow farmers to apply the required amount of water to each field volumetrically.

Sprinkler irrigation systems were developed to allow irrigation of soils with high intake rates, variable soil textures, and uneven land surfaces. Many developments in sprinkler irrigation were invented by farmers, but manufacturers continue to improve existing systems and develop new system components. Mechanical move systems were developed to reduce the labor of hand move systems and the expense of solid set systems. Mechanical move systems were also commonly more efficient than surface systems and required less labor.

Trickle irrigation systems supply water only to the root zone of plants and greatly reduce water requirements for irrigation. Trickle systems also approach 100% efficiencies with good design and management. Labor is greatly reduced because most trickle systems are automated. Yields often increase substantially and the quality of the produce often improves significantly. Trickle systems are expensive, and without good management may fail and cause the loss of the growing crop—a financial disaster.

Water supply management by constructing dams was an important conceptual development in irrigation. Pumps also added greater flexibility and access to adequate water supplies for farmers. Irrigation scheduling after three decades of use does not support adequate management of irrigation systems. Perhaps better management will increase the effectiveness of irrigation scheduling in the future. Appropriate design, precision land leveling of each field, and management of level basins using advance distance criteria should be the future of surface irrigation. Farmers already use advance distance criteria to manage water application. Combined with appropriate design and construction, target amounts of water can be applied to each field with a major improvement in water management.

Irrigation Systems: Subsurface Drip

Carl R. Camp Jr.

Research and Extension Center, Kansas State University, Colby, Kansas, U.S.A.

INTRODUCTION

Subsurface drip irrigation (SDI) is generally defined as the application of water below the soil surface through emitters, with discharge rates in the same range as drip irrigation.[1] While this definition is not specific regarding depth below the soil surface, most SDI laterals are installed at a depth sufficient to prevent interference with surface traffic or tillage implements, and to provide a useful life of several years as opposed to annual replacement of surface or near-surface drip laterals.

Development of drip irrigation accelerated with the availability of plastics following World War II, primarily in Great Britain, Israel, and United States. SDI was part of drip irrigation development in the United States beginning about 1959, especially in Hawaii and California. While early drip irrigation products were relatively crude by modern standards, SDI devices were being installed in both experimental and commercial farms by the 1970s. As drip irrigation products improved during the 1970s and early 1980s, surface drip irrigation grew at a faster rate than SDI, probably because of emitter plugging problems and root intrusion. However, interest in SDI increased during the early 1980s, increased rapidly during the last half of the 1980s, and continues today, especially in areas with declining water supplies, with environmental issues related to irrigation, and where wastewater is used for irrigation. Initially, SDI was used primarily for sugarcane, vegetables, tree crops, and pineapple in Hawaii and California. Later, SDI use was expanded to other geographic areas and to agronomic and vines crops, including cotton, corn, and grapes.

SDI has the advantage of multiple-year life, reduced interference with cultural practices, dry plant foliage, and a dry soil surface. Multiple-year life allows amortization of the entire system cost over several years, often more than ten. If all system components are installed below tillage depth, surface cultural practices can be accomplished with minimal concern for system damage. Dry soil surfaces can reduce weed growth in arid climates and may reduce evaporation losses of applied water. Because the plant canopy is not irrigated, the foliage remains dry, which may reduce incidence of disease. SDI is also very adaptable to irregularly shaped fields and low-capacity water supplies that may provide design limitation with other irrigation systems.

The major disadvantages of SDI include system cost, difficulty in locating and repairing system leaks and plugged emitters, and poor soil surface. Most system components are installed below the soil surface and are neither easy to locate nor directly observable. In a properly designed and managed SDI system, the soil surface should seldom be wet. Consequently, seed germination, especially for small seeds, can be very difficult.

SDI systems offer considerable flexibility, both in design and operation. For example, SDI systems can apply small, frequent water applications, often multiple times each day, to very specific sites within the soil profile and plant root zone. Fertilizers, pesticides, and other chemical amendments can be applied via the irrigation system directly into the active root zone, often at a modest increase in equipment cost. In many cases, the operational cost may be less than that for applying these chemicals via conventional surface equipment.

SYSTEM DESIGN

Site, Water Supply, and Crop

Design of subsurface drip systems is similar to that of surface drip systems, especially with regard to hydraulic characteristics.[2] Specific crop and soil characteristics are used in the design process to select emitter spacing and flow rate, lateral depth and spacing, and the required system capacity. Emitter properties and lateral location are influenced by soil properties such as texture, soil compaction, and soil layering because these affect the rate of water movement through the soil profile and the subsequent wetting pattern for each emitter.

The water supply capacity directly affects the design of a SDI system. The size of the irrigated field or zone is often determined by the water supply capacity. For example, in some humid areas, high-capacity wells are not available but multiple low-capacity wells can be distributed throughout a farm. Fortunately, the design of SDI systems can be economically adjusted to correspond to the field size and shape, to the available water supply capacity, and to other factors. Water supply quality should be tested by an approved laboratory before proceeding with system design. This information is needed for the proper design and management of the water filtration and treatment system. Some water supplies require frequent or intermittent injection of acids and/or chlorine. Other saline and/or sodic water supplies may require treatment or special management. As water supplies become more limited, treated wastewater is becoming an increasingly important alternative water supply that can be applied through SDI systems. Camp[3] listed several reports that emphasized water supplies (saline, deficit, and wastewater) for SDI systems.

The SDI system is usually designed to satisfy peak crop water requirements, which vary with specific site, soil, and crop conditions. When properly designed and managed, SDI is one of the most efficient irrigation methods, providing typical application efficiencies exceeding 90%. In comparison with other methods of irrigation, reported yields with SDI were equal to or greater than those with other irrigation methods. Generally, water requirements with SDI are similar or slightly lower than those with other irrigation methods. In some cases, water savings of up to 40% have been reported.[3] However, unless more specific information is available, it is usually best to use standard net water requirements for the location when designing SDI systems.

Lateral Type, Spacing, and Depth

SDI lateral depth for various cropping systems is normally optimized for prevailing site conditions and soil characteristics.[3] Where systems are used for multiple years and tillage is a consideration, lateral depths vary from 0.20 m to 0.70 m. Where tillage is not a consideration (e.g., turfgrass, alfalfa) depth is sometimes less (0.10–0.40 m). Lateral spacing also varies considerably (0.25–5.0 m), with narrow spacing used primarily for turfgrass and wide spacing used for vegetable, tree, or vine crops. In uniformly spaced row crops, the lateral is usually located under either alternate or every third midrow area (furrow). For crops with alternating row spacing patterns, the lateral is located about 0.8 m from each row, usually in the narrow spacing of the pattern.

The lateral should be installed deep enough to prevent damage by tillage or injection equipment but shallow enough to supply water to the crop root zone without wetting the soil surface. Generally, laterals in SDI systems are placed at depths of 0.1–0.5 m, at shallower depths in coarse-textured soils and at slightly deeper depths on finer-textured soils. The selection of emitter spacing and flow rate are influenced by crop rooting patterns, lateral depth, and soil characteristics. It is also desirable to select an emitter spacing that provides overlapping subsurface wetted zones along the lateral for most row crops. For wider spaced crops such as trees and vines, emitters are normally located near each plant and may have wider spacings that do not provide overlapping patterns. Lateral spacing is determined primarily by the soil, crop, and cultural practice, and should be narrow enough to provide a uniform supply of water to all plants.

Special Requirements

Site topography must be considered in system design and selection of components as with any irrigation system, but SDI is suitable for most sites, ranging from flat to hilly. For sites with considerable elevation change, especially along the lateral, pressure-compensating emitters should be used.

Two special design requirements for SDI systems, which are significantly different from those for surface drip systems, are the needs for flushing manifolds and air entry valves. Flushing manifolds are needed to allow frequent flushing of particulate matter that may accumulate in laterals. Air relief valves are needed to prevent aspiration of soil particles into emitter openings when the system is depressurized. These valves must be located in sufficient number and at the higher elevations for each lateral or zone to prevent negative pressures within the laterals.

Emitter plugging caused by root intrusion is a major problem with some SDI systems, but can be minimized by chemicals, emitter design, and irrigation management. Chemical controls include the use of herbicides, either slow-release compounds embedded into emitters and filters or periodic injection of other chemical solutions (concentrated and/or diluted) into the irrigation supply. Periodic injection of acid and chlorine for general system maintenance can also modify the soil solution immediately adjacent to emitters and reduce root intrusion. In some cases, emitters plugged by roots may be cleared via injection of higher concentrations of chemicals, such as acids and chlorine.

Emitter design may also affect root intrusion. Smaller orifices tend to have less root intrusion but are more susceptible to plugging by particulate matter. Some emitters are constructed with physical barriers to root intrusion. Root intrusion appears to be more severe when emitters are located along dripline seams, which can be an area of preferential root growth. However, root intrusion problems appear to be greater for emitters, driplines, and porous tubes that are not chemically treated.

Irrigation management can also be used to influence root intrusion by controlling the environment immediately adjacent to the emitter. High frequency pulsing that frequently saturates the soil immediately surrounding the emitter can discourage root growth in that area for some crops but not others. Conversely, deficit irrigation sometimes practiced to increase quality or maturity, or to control vegetative growth, can increase root intrusion in lower rainfall areas because of high root concentrations in the soil zone near emitters.

SYSTEM COMPONENTS

Pumps, Filtration, and Pressure Regulation

Pump requirements for SDI are similar to those for other drip irrigation systems, meaning water must be supplied at a relatively low pressure (170–275 kPa) and flow rate in comparison to other irrigation methods. Because of the flushing requirement for SDI systems, a flow velocity of about $0.3\,\mathrm{m\,sec^{-1}}$ must be achievable, either by reducing the zone size while using the same pumping rate or by increasing the pumping rate without changing the zone size.

Water filtration is more critical for SDI systems than for surface drip systems because the consequences of emitter plugging are more severe and more costly. Generally, the better the water quality, the less complex the filtration system required. Surface and recycled or wastewater supplies require the most elaborate filtration systems. However, good filtration is the key to good system performance and long life, and should be a major emphasis in system design. Filtration systems range from simple screen filters for relatively clean water to more elaborate and complex disc and sand media filters for poorer quality water.

The pressure regulation requirement in SDI systems is similar to that in surface drip systems. When non-pressure-compensating emitters are used on relatively flat areas, pressure is typically regulated within the system supply lines (main and/or submain) using pressure-regulating valves. When pressure-compensating emitters are used, typically on more hilly terrain, the pressure within the system supply lines is controlled at a higher, but more variable, pressure that is within the recommended input pressure range for the emitters used. Water pressure should be monitored on a regular basis at the pump or supply port and at various locations throughout the SDI system, especially at the both ends of laterals.

Laterals and Emitters

Many types of driplines have been used successfully for SDI and most have emitters installed as an integral part of the dripline. This is accomplished by one of three methods: 1) molded indentions created during the fusing of dripline seams; 2) prefabricated emitters welded inside the dripline; or 3) circular prefabricated in-line emitters installed during extrusion. Regardless of the emitter used, dripline wall thickness and expected longevity must be considered along with other design factors in selecting the lateral depth. Flexible, thin-walled driplines typically are installed at shallow depths and normally have a shorter expected life. Thicker-walled, flexible driplines have been used successfully for several years provided they are installed deep enough to avoid tillage, cultivating, and harvesting machinery, but shallow enough to prevent excessive deformation or permanent collapse of the dripline by machinery or soil weight. Rigid tubing with thicker walls can be installed at deeper depths without deformation, and is often used on perennial crops or on annual crops for longer time periods (>10 yr). Some driplines are impregnated with bactericides or other chemicals to reduce the formation of sludge or other material that could plug emitters.

Chemical Injection

Subsurface drip systems offer the potential for precise management of water, nutrients, and pesticides if the system is properly designed and managed. The marginal cost to add chemical injection equipment is generally competitive with other, more conventional application methods. Water and fertilizers can be applied in a variety of modes, varying from multiple continuous or pulsed applications each day to one application in several days. Choice of application frequency depends upon several factors, including soil characteristics, crop requirements, water supply, system design, and management strategies. If labeled for the purpose, some systemic pesticides and soil fumigants can be safely injected via SDI systems. Use of the SDI system for chemical applications has the potential to minimize exposure to workers and the environment, to reduce the cost of pesticide rinse water disposal, and improve precision of application to the desired target (root pests). Injection of other chemicals, such as acids and chlorine, is often required to clean and maintain emitters in optimum condition. However, a high level of management with system automation and feedback control is required to minimize chemical movement to the ground water when chemicals are used.

Air Entry and Flushing

Air entry valves must be installed at higher elevations in SDI systems to prevent the emitter from ingesting soil particles that could plug emitters when the system is depressurized. Typically, air entry valves are located in water supply lines near the head works or control station, and in both the supply and flushing manifolds. In some cases, such as turf or pasture, air entry valves may be installed below the soil surface and enclosed within a protective box. Flushing valves installed on the flushing manifold are required to control periodic system flushing.

OPERATION AND MAINTENANCE

Operation

SDI systems can be operated in several modes, varying from manual to fully automated. Overall, SDI systems are probably more easily automated than many other types of irrigation. One reason is that most are controlled from a central point using electrical or pneumatic valves and controllers that vary from a simple clock system to microprocessor systems, which are capable of receiving external inputs to initiate and/or terminate irrigation events.

Irrigation scheduling is as important for SDI systems as for any other type of irrigation. Choosing to initiate an irrigation event and how much water to apply during each event depends on crop, soil, and irrigation system type and design. Factors that affect those decisions include soil water storage volume, sensitivity of the crop to water stress, irrigation application rate, weather conditions, and water supply capacity. Camp[3] discussed several irrigation scheduling methods that have been used successfully with SDI. However, the important point is that a science-based scheduling method can conserve the water supply and increase profit.

If seed germination and seedling establishment and growth are critical, especially in arid climates when initial soil water content is not adequate, either sprinkler or surface irrigation is often used for germination. However, the need for two systems increases cost and decreases economic return. If subsurface drip is used for germination, an excessive amount of irrigation is often required to wet the seed zone for germination, which could result in excessive leaching and off-site environmental effects as well as increased cost. Surface wetting can also occur when the emitter flow rate exceeds the hydraulic conductivity of the soil surrounding the emitter, but wetted areas are often not uniform.

Because salts tend to accumulate above the lateral, high salt concentrations may occur between the lateral and soil surface in arid areas where rainfall is not available to leach the salts downward. Salts may also be moved under the row when laterals are placed under the furrow.[4] Supplemental sprinkler irrigation may be required in some areas to control salinity if precipitation is inadequate for leaching during several consecutive years.

Maintenance

Often, SDI systems must have a long life (>10 yr) to be economical for lower value crops. Thus, appropriate management strategies are required to prevent emitter plugging and protect other system components to ensure proper system operation. Locating and repairing/replacing failed components is much more difficult and more expensive with SDI systems than with surface systems because most system components are buried, difficult to locate, and cannot be directly observed by managers. Consequently, operational parameters such as flow rate and pressure must be measured frequently and used as indicators of system performance. Good system performance requires constant attention to maintain good water quality, proper filtration, and periodic system flushing to remove particulate matter that could plug emitters. Periodic evaluation of SDI system performance in relation to design performance can identify problems before they become serious and significantly affect crop yield and quality.

CONCLUSION

Although there is general consensus that use of SDI is increasing, this growth is difficult to document. A recent survey of irrigation in the United States reported 156,070 ha of SDI, which is about 0.6% of the total irrigated area of 25,501,831 ha.[5] Use of SDI should increase in the future, depending primarily upon the economic and water conservation benefits in comparison to other irrigation methods. As water supplies become more limited, the high application efficiency and water conserving features of SDI should increase its application. Also, SDI offers potential advantages such as reduced odors and exposure to pathogens when using recycled domestic and animal wastewater. The SDI technology offers the capability to precisely place water, nutrients, and other chemicals in the plant root zone at the time and frequency needed for optimum crop production. With proper design, installation, and management, SDI systems can provide excellent irrigation efficiency and reliable performance with a system life of 10–20 yr.

Irrigation: Deficit

M.H. Behboudian
College of Sciences, Institute of Natural Resources, Massey University, Palmerston North, New Zealand

INTRODUCTION

Water is the most precious environmental resource and is increasingly in demand mainly because of population growth, increased industrialization, and deterioration of water quality. Because irrigation of agricultural lands uses at least 75% of the world's fresh water,[1] even a relatively minor reduction in irrigation water could substantially increase its availability for other purposes. Managing demand rather than trying to explore new supplies seems to be a realistic goal for irrigated agriculture. Deficit irrigation (DI) and partial rootzone drying (PRD), which is a variation of DI, are two water-saving irrigation strategies that could be employed for various crops with varying measures of success depending on the circumstances. In this presentation, I define both DI and PRD and briefly explore their potential for irrigated agriculture.

EXPLORING DI

Deficit irrigation is a system of managing soil water supply to impose periods of predetermined plant or soil water deficit that can result in some economic benefit. It involves giving less water to the plant than the prevailing evapotranspiration (ET) demand at selected times during the growing season. ET is a combination of evaporation (E) from the soil and transpiration (T) from the plant. Irrigation attempts to replace either all or part of ET. The term regulated DI (RDI) is normally used in the literature to denote DI of trees early in the season, before rapid fruit growth starts. Late-season RDI has also been used in some occasions to improve fruit quality.[2] The term DI is used by some authors to mean "no irrigation." Here we take DI to be synonymous with RDI because it implies partial replacement of ET for achieving a predetermined plant/soil water deficit. Irrigation water in DI is given to the entire rootzone.

The concept of RDI was first introduced in Australia and was used as a management strategy to control vigor in high-density plantings of "Golden Queen" peach[3] and "Bartlet" pear.[4] In these experiments, controlled water deficit was established in the plant during the period of rapid shoot and slow fruit growth. During RDI, trees were irrigated with less water than ET with sufficient water being made available to the plant just as the fruit started their rapid growth phase. The concept of RDI was subsequently explored in countries other than Australia including the United States.

Application of DI is more feasible in fruit trees, especially in deciduous fruit trees, than in herbaceous plants. The physiological basis of this application rests on three concepts: functional equilibrium between roots and shoots, the phenological separation of shoot and fruit growth, and the ability of fruit to restart rapid growth once irrigation is resumed. A functional equilibrium exists between growth of roots and shoots. For example, in peach trees in a given environment there is a constant relationship between the relative growth rates of the top and of the roots even though the allocation of dry matter toward the above- and below-ground portions of the tree changes markedly. This suggests that a particular ratio of roots to shoots is developed in a given environment. Restricting root development in fully grown trees by orchard management techniques, such as DI, can thus be used to reduce vegetative vigor, which has the secondary benefit of increasing flower production, bloom density, and allocation of dry matter to fruit. The phenological separation of shoot and fruit growth that occurs in certain cultivars of some deciduous fruit crops is another important factor allowing the application of DI. This separation allows the timely application of DI to check undesired vegetative growth through a reduction of plant water status. Fruit are assumed to be less affected by water deficit than are shoots because fruit are stronger sinks and accumulate large quantities of soluble solids over the season. This should therefore make feasible the use of DI in species whose shoot and fruit growth overlap. The third physiological concept forming the basis of DI is the ability of fruit to restart rapid growth once irrigation is resumed. Sometimes the previously irrigated fruit may briefly grow at a faster rate than well-watered fruit as shown for peach.[3] This compensatory growth has been attributed to active osmotic adjustment during DI.

Deficit irrigation will have the following advantages if applied judiciously. It will have a positive impact on environmental quality. Although well-drained soils are suitable for establishment of orchards, they also tend to facilitate the leaching into groundwater. Of special concern is leaching beyond rootzone of nitrates, biocides, and dissolved mineral salts. Deficit irrigation in conjunction with a reduced use of biocides and nutrients may help prevent groundwater contamination and it will adhere to the environmental protection legislation that exists in some countries. Deficit irrigation will also save water and decreases irrigation cost and total cost of crop production considering the lesser input of fertilizers that are often applied with irrigation water (fertigation). Early-season application of DI in deciduous orchards will decrease vegetative growth resulting in reduced costs of summer and winter pruning. Except for possible reduction of fruit size, research on deciduous trees and herbaceous plants has indicated an improvement in fruit quality that can be listed as another advantage of DI. The possible reduction of fruit size, and yield, has led to the exploration of another DI technique, PRD, which is discussed below.

PARTIAL ROOTZONE DRYING

Partial rootzone drying is an irrigation protocol where at each turn of irrigation only a part of the rootzone receives water and the other part would be allowed to dry to a predetermined level. This has proven effective in inducing regulated deficit in several horticultural crops including grapevine.[5] In theory, this system works because roots are only active in moist soil. Therefore by inducing ''dry spots'' within the rootzone the effective rooting volume is reduced. The theory behind PRD centers on the role that chemical signals, primarily abscisic acid, originating from roots in the drying soil play in the control of shoot growth and transpiration. Stimulation of these signals through PRD can result in reduced stomatal conductance and therefore less transpiration. Photosynthesis will be reduced less than transpiration does. Ideally, vegetative growth and total plant water use will be reduced while maintaining crop yield and improving fruit quality as shown in a number of studies.[6,7] However, the theoretical potential of PRD will still have to be realized with further experimentation in the field.

The PRD may be effective in limiting leaching and also reducing evaporation of irrigation water from the soil surface. It can also realize the other advantages mentioned for DI in the above. Partial rootzone drying can be achieved by the use of trickle irrigation or by careful placement of other water emitters. Dry and Loveys,[5] who introduced PRD for the first time on grapevine in Australia, showed its effectiveness in the control of vegetative growth and the enhancement of berry quality.

Research has generally shown that DI improves fruit quality in comparison to full irrigation. For apple, this has been in terms of higher fruit concentrations of soluble solids, sugars, some aroma volatiles; brighter color in red cultivars; higher firmness; better storability; and lower weight loss in storage. There has been less research on PRD and some results are available for apple, tomato, and hot pepper carried out in this laboratory. Apple under PRD has not shown significant improvement in fruit quality compared to fully irrigated fruits[8], while both DI and PRD have shown to improve some fruit quality attributes in processing tomato including higher concentration of soluble solids.[7] For PRD in hot pepper, water balance and fruit volume improved compared to DI, but the opposite was true for total soluble solid concentration and skin color.[6]

CONCLUSION

Reduced irrigation (RI) is a necessity now given the dwindling water supplies and increasing demand for water worldwide. Deficit irrigation is a better-known RI technology whose advantages have been realized for various crops especially for deciduous fruits. Partial rootzone drying is a more recently applied RI technology and has been tried on only a few crops so far. Future prospects call for more research on the application of DI, and especially of PRD, particularly in areas where water is either scarce or too expensive for crop production.

Irrigation: Efficiency

Terry A. Howell
Conservation and Production Research Laboratory, Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Bushland, Texas, U.S.A.

INTRODUCTION

Irrigation efficiency is a critical measure of irrigation performance in terms of the water required to irrigate a field, farm, basin, irrigation district, or an entire watershed. The value of irrigation efficiency and its definition are important to the societal views of irrigated agriculture and its benefit in supplying the high quality, abundant food supply required to meet our growing world's population. "Irrigation efficiency" is a basic engineering term used in irrigation science to characterize irrigation performance, evaluate irrigation water use, and to promote better or improved use of water resources, particularly those used in agriculture and turf/landscape management.[1–4] Irrigation efficiency is defined in terms of: 1) the irrigation system performance, 2) the uniformity of the water application, and 3) the response of the crop to irrigation. Each of these irrigation efficiency measures is interrelated and will vary with scale and time. Fig. 1 illustrates several of the water transport components involved in defining various irrigation performance measures. The spatial scale can vary from a single irrigation application device (a siphon tube, a gated pipe gate, a sprinkler, a microirrigation emitter) to an irrigation set (basin plot, a furrow set, a single sprinkler lateral, or a microirrigation lateral) to broader land scales (field, farm, an irrigation canal lateral, a whole irrigation district, a basin or watershed, a river system, or an aquifer). The timescale can vary from a single application (or irrigation set), a part of the crop season (preplanting, emergence to bloom or pollination, or reproduction to maturity), the irrigation season, to a crop season, or a year, partial year (premonsoon season, summer, etc.), or a water year (typically from the beginning of spring snow melt through the end of irrigation diversion, or a rainy or monsoon season), or a period of years (a drought or a "wet" cycle). Irrigation efficiency affects the economics of irrigation, the amount of water needed to irrigate a specific land area, the spatial uniformity of the crop and its yield, the amount of water that might percolate beneath the crop root zone, the amount of water that can return to surface sources for downstream uses or to groundwater aquifers that might supply other water uses, and the amount of water lost to unrecoverable sources (salt sink, saline aquifer, ocean, or unsaturated vadose zone).

The volumes of the water for the various irrigation components are typically given in units of depth (volume per unit area) or simply the volume for the area being evaluated. Irrigation water application volume is difficult to measure, so it is usually computed as the product of water flow rate and time. This places emphasis on accurately measuring the flow rate. It remains difficult to accurately measure water percolation volumes groundwater flow volumes, and water uptake from shallow groundwater.

IRRIGATION SYSTEM PERFORMANCE EFFICIENCY

Irrigation water can be diverted from a storage reservoir and transported to the field or farm through a system of canals or pipelines; it can be pumped from a reservoir on the farm and transported through a system of farm canals or pipelines; or it might be pumped from a single well or a series of wells through farm canals or pipelines. Irrigation districts often include small to moderate size reservoirs to regulate flow and to provide short-term storage to manage the diverted water with the on-farm demand. Some on-farm systems include reservoirs for storage or regulation of flows from multiple wells.

Water Conveyance Efficiency

The conveyance efficiency is typically defined as the ratio between the water that reaches a farm or field

This article previously published in the *Encyclopedia of Soil Science* 2002 Marcel Dekker, Inc.

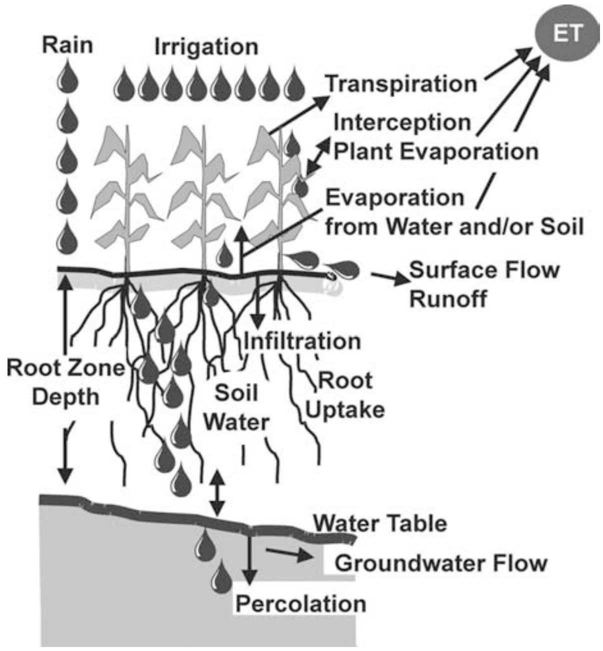

Fig. 1 Illustration of the various water transport components needed to characterize irrigation efficiency.

and that diverted from the irrigation water source.[1,3,4] It is defined as

$$E_c = 100\frac{V_F}{V_t} \tag{1}$$

where E_c is the conveyance efficiency (%), V_f is the volume of water that reaches the farm or field (m^3), and V_t is the volume of water diverted (m^3) from the source. E_c also applies to segments of canals or pipelines, where the water losses include canal seepage or leaks in pipelines. The global E_c can be computed as the product of the individual component efficiencies, E_{ci}, where i represents the segment number. Conveyance losses include any canal spills (operational or accidental) and reservoir seepage and evaporation that might result from management as well as losses resulting from the physical configuration or condition of the irrigation system. Typically, conveyance losses are much lower for closed conduits or pipelines[4] compared with unlined or lined canals. Even the conveyance efficiency of lined canals may decline over time due to material deterioration or poor maintenance.

Application Efficiency

Application efficiency relates to the actual storage of water in the root zone to meet the crop water needs in relation to the water applied to the field. It might be defined for individual irrigation or parts of irrigations (irrigation sets). Application efficiency includes any application losses to evaporation or seepage from surface water channels or furrows, any leaks from sprinkler or drip pipelines, percolation beneath the root zone, drift from sprinklers, evaporation of droplets in the air, or runoff from the field. Application efficiency is defined as

$$E_a = 100\frac{V_s}{V_F} \tag{2}$$

where E_a is the application efficiency (%), V_s is the irrigation needed by the crop (m^3), and V_f is the water delivered to the field or farm (m^3). The root zone may not need to be fully refilled, particularly if some root zone water-holding capacity is needed to store possible or likely rainfall. Often, V_s is characterized as the volume of water stored in the root zone from the irrigation application. Some irrigations may be applied for reasons other than meeting the crop water requirement (germination, frost control, crop cooling, chemigation, fertigation, or weed germination). The crop need is often based on the "beneficial water needs."[5] In some surface irrigation systems, the runoff water that is necessary to achieve good uniformity across the field can be recovered in a "tailwater pit" and recirculated with the current irrigation or used for later irrigations, and V_f should be adjusted to account for the "net" recovered tailwater. Efficiency values are typically site specific. Table 1 provides a range of typical farm and field irrigation application efficiencies[6–8] and potential or attainable efficiencies for different irrigation methods that assumes irrigations are applied to meet the crop need.

Storage Efficiency

Since the crop root zone may not need to be refilled with each irrigation, the storage efficiency has been defined.[4] The storage efficiency is given as

$$E_s = 100\frac{V_s}{V_{rz}} \tag{3}$$

where E_s is the storage efficiency (%) and V_{rz} is the root zone storage capacity (m^3). The root zone depth and the water-holding capacity of the root zone determine V_{rz}. The storage efficiency has little utility for sprinkler or microirrigation because these irrigation methods seldom refill the root zone, while it is more often applied to surface irrigation methods.[4]

Seasonal Irrigation Efficiency

The seasonal irrigation efficiency is defined as

$$E_i = 100\frac{V_b}{V_F} \tag{4}$$

Table 1 Example of farm and field irrigation application efficiency and attainable efficiencies

	Field efficiency (%)			Farm efficiency (%)

where E_i is the seasonal irrigation efficiency (%) and V_b is the water volume beneficially used by the crop (m^3). V_b is somewhat subjective,[4,5] but it basically includes the required crop evapotranspiration (ET_c) plus any required leaching water (V_l) for salinity management of the crop root zone.

Leaching requirement (or the leaching fraction)

The leaching requirement,[9] also called the leaching fraction, is defined as

$$L_r = \frac{V_d}{V_F} = \frac{EC_i}{EC_d} \tag{5}$$

where L_r is the leaching requirement, V_d is the volume of drainage water (m^3), V_f is the volume of irrigation (m^3) applied to the farm or field, EC_i is the electrical conductivity of the irrigation water (dS m^{-1}), and EC_d is the electrical conductivity of the drainage water (dS m^{-1}). The L_r is related to the irrigation application efficiency, particularly when drainage is the primary irrigation loss component. The L_r would be required "beneficial" irrigation use ($V_l \equiv L_r V_i$), so only V_d greater than the minimum required leaching should reduce irrigation efficiency. Then, the irrigation efficiency can be determined by combining Eqs. (4) and (5)

$$E_i = 100\left(\frac{V_b}{V_F} + L_r\right) \tag{6}$$

Burt et al.[5] defined the "beneficial" water use to include possible off-site needs to benefit society (riparian needs or wildlife or fishery needs). They also indicated that V_f should not include the change in the field or farm storage of water, principally soil water but it could include field (tailwater pits) or farm water storage (a reservoir) that wasn't used within the time frame that was used to define E_i.

IRRIGATION UNIFORMITY

The fraction of water used efficiently and beneficially is important for improved irrigation practice.

The uniformity of the applied water significantly affects irrigation efficiency. The uniformity is a statistical property of the applied water's distribution. This distribution depends on many factors that are related to the method of irrigation, soil topography, soil hydraulic or infiltration characteristics, and hydraulic characteristics (pressure, flow rate, etc.) of the irrigation system. Irrigation application distributions are usually based on depths of water (volume per unit area); however, for microirrigation systems they are usually based on emitter flow volumes because the entire land area is not typically wetted.

Christiansen's Uniformity Coefficient

Christiansen[10] proposed a coefficient intended mainly for sprinkler system based on the catch volumes given as

$$C_{\mathrm{U}} = 100\left[\frac{1 - (\sum |X - \bar{x}|)}{\sum X}\right] \tag{7}$$

where C_{U} is the Christiansen's uniformity coefficient in percent, X is the depth (or volume) of water in each of the equally spaced catch containers in mm or ml, and $\bar{x}$ is the mean depth (volume) of the catch (mm or ml). For C_{U} values >70%, Hart[11] and Keller and Bliesner[8] presented

$$C_{\mathrm{U}} = 100\left[1 - \left(\frac{\sigma}{x}\right)\left(\frac{2}{\pi}\right)^{0.5}\right] \tag{8}$$

where σ is the standard deviation of the catch depth (mm) or volume (ml). Eq. (8) approximates the normal distribution for the catch amounts.

The C_{U} should be weighted by the area represented by the container[12] when the sprinkler catch containers intentionally represent unequal land areas, as is the case for catch containers beneath a center pivot. Heermann and Hein[12] revised the C_{U} formula [Eq. (8)] to reflect the weighted area, particularly intended for a center pivot sprinkler, as follows:

$$C_{\mathrm{U(H\&H)}} = 100\left\{1 - \left[\frac{\left(\sum S_i\left|V_i - \left(\frac{\sum V_i S_i}{\sum S_i}\right)\right|\right)}{\sum(V_i S_i)}\right]\right\} \tag{9}$$

where S_i is the distance (m) from the pivot to the ith equally spaced catch container and V_i is the volume of the catch in the ith container (mm or ml).

Low-Quarter Distribution Uniformity

The distribution uniformity represents the spatial evenness of the applied water across a field or a farm as well as within a field or farm. The general form of the distribution uniformity can be given as

$$D_{U_p} = 100\left(\frac{\bar{V}_p}{\bar{V}_{\mathrm{f}}}\right) \tag{10}$$

where D_{U_p} is the distribution uniformity (%) for the lowest p fraction of the field or farm (lowest one-half $p = 1/2$, lowest one-quarter $p = 1/4$), $\bar{V}_p$ is the mean application volume (m^3), and $\bar{V}_f$ is the mean application volume (m^3) for the whole field or farm. When $p = 1/2$ and $C_{\mathrm{U}} > 70\%$, then the D_{U} and C_{U} are essentially equal.[13] The USDA-NRCS (formerly, the Soil Conservation Service) has widely used D_{Ulq} ($p = 1/4$) for surface irrigation to access the uniformity applied to a field, i.e., by the irrigation volume (amount) received by the lowest one-quarter of the field from applications for the whole field. Typically, D_{U_p} is based on the postirrigation measurement[5] of water volume that infiltrates the soil because it can more easily be measured and better represents the water available to the crop. However, the postirrigation infiltrated water ignores any water intercepted by the crop and evaporated and any soil water evaporation that occurs before the measurement. Any water that percolates beneath the root zone or the sampling depth will also be ignored.

The D_{U} and C_{U} coefficients are mathematically interrelated through the statistical variation (coefficient of variation, $\sigma/\bar{x}$, C_{v}) and the type of distribution. Warrick[13] presented relationships between D_{U} and C_{U} for normal, log-normal, uniform, specialized power, beta- and gamma-distributions of applied irrigations.

Emission Uniformity

For microirrigation systems, both the C_{U} and D_{U} concepts are impractical because the entire soil surface is not wetted. Keller and Karmeli[14] developed an equation for microirrigation design as follows

$$E_{\mathrm{U}} = 100[1 - 1.27(C_{\mathrm{vm}})n^{-1/2}]\left(\frac{q_{\mathrm{m}}}{\bar{q}}\right) \tag{11}$$

where E_{U} is the design emission uniformity (%), C_{vm} is the manufacturer's coefficient of variability in emission device flow rate (1/h), n is the number of emitters per plant, q_{m} is the minimum emission device flow rate (1/h) at the minimum system pressure, and $\bar{q}$ is the mean emission device flow rate (1/h). This equation is based on the D_{Ulq} concept,[4] and includes the influence of multiple emitters per plant that each may have a flow rate from a population of random flow rates based on the emission device manufacturing variation. Nakayama, Bucks, and Clemmens[15] developed a design coefficient based more closely on the C_{U} concept for emission device flow rates from a normal distribution given as

$$C_{\mathrm{Ud}} = 100(1 - 0.798(C_{\mathrm{vm}})n^{-1/2}) \qquad (12)$$

where C_{Ud} is the coefficient of design uniformity in percent and the numerical value, 0.798, is

$$\left(\frac{2}{\pi}\right)^{0.5}$$

from Eq. (8).

Many additional factors affect microirrigation uniformity including hydraulic factors, topographic factors, and emitter plugging or clogging.

WATER USE EFFICIENCY

The previous sections discussed the engineering aspects of irrigation efficiency. Irrigation efficiency is clearly influenced by the amount of water used in relation to the irrigation water applied to the crop and the uniformity of the applied water. These efficiency factors impact irrigation costs, irrigation design, and more important, in some cases, the crop productivity. Water use efficiency (WUE) has been the most widely used parameter to describe irrigation effectiveness in terms of crop yield. Viets[16] defined WUE as

$$\mathrm{WUE} = \frac{Y_{\mathrm{g}}}{\mathrm{ET}} \qquad (13)$$

where WUE is water use efficiency ($\mathrm{kg\,m^{-3}}$), Y_{g} is the economic yield ($\mathrm{g\,m^{-2}}$), and ET is the crop water use (mm). Water use efficiency is usually expressed by the economic yield, but it has been historically expressed as well in terms of the crop dry matter yield (either total biomass or aboveground dry matter). These two WUE bases (economic yield or dry matter yield) have led to some inconsistencies in the use of the WUE concept. The transpiration ratio (transpiration per unit dry matter) is a more consistent value that depends primarily on crop species and the environmental evaporative demand,[17] and it is simply the inverse of WUE expressed on a dry matter basis.

Irrigation Water Use Efficiency

The previous discussion of WUE does not explicitly explain the crop yield response to irrigation. Water use efficiency is influenced by the crop water use (ET). Bos[3] defined a term for WUE to characterize the influence of irrigation on WUE as

$$\mathrm{WUE} = \frac{(Y_{gi} - Y_{\mathrm{gd}})}{(\mathrm{ET}_i - \mathrm{ET}_d)} \qquad (14)$$

where WUE is irrigation water use efficiency ($\mathrm{kg\,m^{-3}}$), Y_{gi} is the economic yield ($\mathrm{g\,m^{-2}}$) for irrigation level i, Y_{gd} is the dryland yield ($\mathrm{g\,m^{-2}}$; actually, the crop yield without irrigation), ET_i is the evapotranspiration (mm) for irrigation level i, and $\mathrm{ET_d}$ is the evapotranspiration of the dryland crops (or of the ET without irrigation). Although Eq. (14) seems easy to use, both Y_{gd} and $\mathrm{ET_d}$ are difficult to evaluate. If the purpose is to compare irrigation and dryland production systems, then dryland rather than non-irrigated conditions should be used. If the purpose is to compare irrigated regimes with an unirrigated regime, then appropriate values for Y_{gd} and $\mathrm{ET_d}$ should be used. Often, in most semiarid to arid locations, Y_{gd} may be zero. Bos[3] defined irrigation WUE as

$$\mathrm{IWUE} = \frac{(Y_{gi} - Y_{\mathrm{gd}})}{\mathrm{IRR}_i} \qquad (15)$$

where IWUE is the irrigation efficiency ($\mathrm{kg\,m^{-3}}$) and IRR_i is the irrigation water applied (mm) for irrigation level i. In Eq. (15), Y_{gd} may be often zero in many arid situations.

CONCLUSION

Irrigation efficiency is an important engineering term that involves understanding soil and agronomic sciences to achieve the greatest benefit from irrigation. The enhanced understanding of irrigation efficiency can improve the beneficial use of limited and declining water resources needed to enhance crop and food production from irrigated lands.

Irrigation: Frost Protection and Bloom Delay

INTRODUCTION

Warm weather in the early spring initiates fruit tree bud development and blossoming. In many fruit-producing areas of the world, subsequent cold, frosty nights may kill the buds or blossoms because of ice crystals forming in the plant tissues. This leads to reduction in harvestable fruit or even total loss of the crop. Irrigation can be used to offset the detrimental effects of freezing fruit through freeze protection or sprinkling for bloom delay.

Winter Rest

In the fall, a deciduous tree loses its leaves and enters a condition known as winter rest. The tree is incapable of growth during this period and fruit buds cannot grow until the rest period has been completed. After rest is completed, which occurs sometime between mid-winter and early spring, depending upon the climate, changes begin occurring in the buds that will eventually cause blossoming and leafing of the tree.

When the required accumulation of chill units has been achieved for a particular fruit variety, trees are ready to begin their normal spring growth. (Chill units accumulate when the temperature is below a set threshold temperature measured in °C-days.) From this time on, the growth of the tree and development of the fruit is a function of temperature (measured in growing degree hours). The most critical time from a standpoint of freeze damage is from end of rest to full bloom.

The rate of bud development depends upon the temperature environment of the buds after the completion of rest. If the early spring temperatures are consistently cool, blossoming is delayed. However, when spring temperatures are considerably above normal, bud development accelerates and the trees blossom early. An average temperature of 1.7°C (3°F) above normal for 1 week will decrease the time to bloom by about 1 day.

If early bud development is followed by a sudden cold period, the freeze damage to fruit can be very serious. The extent of damage depends on how cold the temperature gets and how long it stays cold. The critical or lethal temperature is also a function of the development state of the fruit buds. Fruit growers have attempted to heat their orchards as a means of combating the cold, damaging temperatures. Heating is costly, may pollute the air, and is not always effective.

TYPES OF FROST EVENTS (FROM REF.[1])

Advection Frost

An advection frost occurs when cold air blows into an area to replace warmer air that was present before the weather change. It is associated with moderate to strong winds, no temperature inversion, and low humidity. Often, temperatures will drop below 32°F (0°C) and stay there all day. Advection frosts are difficult to protect against.

Radiation Frost

Radiation frosts are characterized by clear skies, calm winds, and temperature inversions. Radiation frosts occur because of heat losses in the form of radiant energy. Under clear, nighttime skies, more heat is radiated away from an orchard than it receives, so the temperature drops. The temperature falls faster near the radiating surface causing a temperature inversion to form (temperature increases with height above the ground).

If you measure high enough, the temperature will reach the point where it begins to decrease with height (a lapse condition). The level where the temperature profile changes from an inversion to a lapse condition is called the ceiling. A weak inversion (high ceiling) occurs when the temperatures aloft are only slightly higher than near the surface. When there is a strong inversion (low ceiling), temperature increases rapidly with height. Most frost protection methods are more effective during low-ceiling, strong-inversion conditions.

Energy Transfer

Energy or heat transfer determines how cold it will get and the effectiveness of protection. The four methods of energy transfer are radiation, conduction, convection, and latent heat. Understanding these heat transfer mechanisms is extremely important for good frost protection management.

Radiation

Radiation is electromagnetic energy transfer. A good example of radiation is sunlight. Because it is very hot, considerable energy is radiated from the sun to Earth. Although much cooler object on Earth also radiates energy to its surroundings. Normally, if an object radiates more energy than it receives from other sources, it will cool.

Conduction

Conduction is heat transfer through matter where the objects do not move. A good example is the transfer of heat through a metal rod of one end placed in a fire. The heat is transferred by conduction to the other end of the rod. Conduction is important in soil heat transfer and hence frost protection.

Convection

Convection is the process where heated matter physically moves from one place to another and takes heat with it. Air heated by smudge pots is an example of convection because the air, warmed by the heaters, rises and mixes with colder air in the orchard to raise the temperature. Smudge pots also radiate heat to nearby trees but the main protection comes from convection.

Latent Heat

When water condenses, cools, or freezes, the temperature of the environment around the water rises because latent heat is changed to sensible heat. Latent heat is chemical energy stored in the bonds that join water molecules together and sensible heat is heat you measure with a thermometer. When latent heat is changed to sensible heat, the air temperature rises.[2] When ice melts, water warms, or water evaporates, sensible heat is changed to latent heat and the air temperature falls.

IRRIGATIONS FOR FRUIT BUD PROTECTION FROM COLD TEMPERATURES

Irrigation water can be used for warming the fruit bud environment to mitigate the potential damaging effects of cold temperatures.[3] Strawberries have also been protected from frost by irrigation.[4] Flooding involves the distribution of large amounts of relative warm water throughout the orchard. This warms the air through radiant energy from water. The costs of flooding may be similar to sprinkling.

"The major drawbacks to this method (flooding) is the large amount of water needed, the reduction of the quality of this water during use and the lack of tolerance by the crop to being inundated by water for long periods of time. The volume of water needed is large because the field must be covered as much as possible to achieve maximum radiation. In averaging this over the ditches, furrows, and growing surfaces, the minimum would be about 0.3 ha-m (one acre foot per acre). Plants usually can tolerate standing water for short periods of time, but the periods of time required for protection during freezes usually far exceeds this tolerance. The time of inundation is much longer than the actual period of freezing temperatures due to the time it takes to totally inundate the field prior to freezing temperatures and remove the water after the freeze. The reduction in water quality can be high depending on the recent applications of herbicides, fertilizers, fungicides, etc. These three factors have led to the reduced use of flooding for freeze protection in most crops."

Sprinkler for Blossom Delay

Sprinkling for blossom delay, developed at Utah State University, retards the time of fruit bud development until the major danger of spring freeze is past. This is accomplished with overhead sprinklers that utilize evaporative cooling to delay bud development and growth. The system requires an overhead sprinkling system with automatic controls to turn the system on and off at the desired temperature.

If springtime comes early, after the tree has completed its winter rest, the system is activated on warm afternoons whenever the air temperature rises above 7.3°C (45°F). The water strikes the buds and then evaporates and this evaporation process keeps the buds cool and delays their development.

Along the Wasatch Front of Northern Utah, where the tests were first conducted,[5] it was found that apple tree bloom could be delayed 2 to 3 weeks, and prevent over 80% of the major freeze damage that has occurred in the past. If the bud delay is combined with ice-encasement freeze protection the chances for crop failure due to late spring freezes is even less. Sprinkling as a method of bloom delay for freeze protection has other advantages: it reduces fuel consumption and pollution of the environment. The same sprinkling system can be used to protect the trees against the late spring freezes and can also be used for irrigation during the summer growing season.

The amount of evaporative cooling that takes place on bare limbs depends upon 1) the temperature of the tree buds; 2) the difference in vapor pressure between the bud surface and the air; and 3) the rate at which evaporated water is removed from the boundary layer by diffusion or wind currents. Therefore, for maximum cooling, with the least amount of water application, it is necessary to completely wet the buds periodically and allow most of the water to evaporate before rewetting.

Sprinkling for Freeze Protection (Ice-Encasement)

Sprinkling for freeze protection differs from sprinkling for bud delay in that the sprinkling takes place during cold temperatures.[6–8] A combination of the two methods can considerably decrease the chances for late spring freeze damage.

Freeze protection is provided by overhead sprinkling when water turns to ice. This change in its phase is accompanied by the release of heat from the freezing ice-water film. As long as there is a mixture of ice and water on the buds, its temperature will remain near 0°C and it will not freeze.

There are several decisions that must be made when considering whether sprinkling can be used as a method of freeze protection. They are:

1. Can the trees withstand the potential ice load?
2. If yes, when should I begin sprinkling to insure protection?
3. When can I safely discontinue?

The determination of whether the trees can withstand the ice load or not depends on:

1. How the trees have been pruned.
2. The duration of the time trees must be sprinkled.
3. The amount of water that must be applied to maintain a mixture of ice and water on the buds.
4. The amount of wind and the depression of the wet bulb below the expected minimum temperature.

Sprinkling must begin at least by the time the wet bulb temperature drops to within 2°C (4°F) above the lethal temperature of the buds. The wet bulb temperature is the controlling temperature in sprinkling for freeze protection. Sprinkling must continue until the wet bulb temperature is back above the lethal temperature by the same amount. This 2°C (4°F) limit is required at the time of beginning sprinkling to allow the buds time to get thoroughly wet before the critical temperature is reached. On the discontinuing phase, the threshold is a safety factor because changing winds may bring in drier air and drop the wet bulb a few degrees after sprinkling has been discontinued and cause damage to the buds. This plus safety factor is a must on both ends of the sprinkling program. Even a higher margin may be advisable if the predicted minimum temperature is below −7°C (20°F).

If the required amount of water cannot be made available, then it is better not to begin sprinkling at all. Insufficient water will allow bud temperatures to drop to the wet bulb, which will be below the expected minimum and cause additional damage to the buds.

There are several considerations in the design of sprinkler systems for freeze protection which are different from installations used for bloom delay, irrigation, or both. The requirements for freeze protection are:

1. Capability of varying the sprinkler output over a wider range than is required for either of the other applications.
2. Capability of supplying different amounts of water in various parts of the orchard at the same time.
3. Capability of operating the sprinklers at below freezing temperatures without the sprinklers icing up. (Once sprinkling is begun it must be continued at an adequate rate until the wet bulb temperature is at least 1°C (2°F) above the lethal temperature of the buds.)

Variable Water Requirements for Protection in a Windy Orchard

Water requirements for freeze protection in a windy orchard are quite different than protection under relatively calm conditions. In the latter case, the water requirements are relatively uniform over the entire orchard, but under windy conditions, the wind is continually bringing air with a low wet bulb temperature into the upwind portion of the orchard. This dry air requires more water to maintain the mixture of ice and water on the buds of the trees than the air further downwind where the evaporated moisture has been added to the air to increase the wet bulb temperature and thus decrease the moisture requirements for protection.

Sprinkler Application Rates

When sprinklers are used for freeze protection, the two main factors to consider are 1) the application rate required for protection and 2) the proper time to start and stop the sprinklers.

Considerably more energy is removed by evaporation than is supplied by cooling and freezing of an

Table 1 Application rates for overhead sprinklers for frost protection of grapevines

Temperature (°C)	Wind speed (m/sec)	30-sec rotation (mm/hr)	60-sec rotation (mm/hr)	30-sec rotation ($l\ m^{-1}\ ha^{-1}$)	60-sec rotation ($l\ m^{-1}\ ha^{-1}$)
−1.7	0.0–0.5	2.0	2.5	334	418

−5.0	0.9–1.4	4.6	5.1	768	852

Source: From Ref.[1].

equal quantity of water. Actually, in order to break even, about six times as much water must be cooled and frozen than evaporated. Fortunately, evaporation rates are relatively low during freeze nights, and sufficient water can usually be frozen to supply more heat from cooling and freezing than is lost to evaporation. However, a higher application rate is needed to compensate for greater evaporation on nights with stronger wind speeds and lower humidity.

Application Rate Requirements

The application rate required for overplant sprinkling depends on the sprinkler rotation rate, wind speed, and the dew point temperature.[1] The wind speed and dew point temperatures are important because the evaporation rate increases with the wind speed and with decreasing dew point temperatures (a measure of water vapor content of the air). Sprinkler rotation rates are important because the temperature of wet plant parts initially rises as the water freezes and releases heat, but then it falls to near the wet-bulb temperature due to evaporation before the plant is hit again with another pulse of water. Often the wet-bulb temperature is below the critical damage temperate, so damage can result if there is too much time between hitting the plants with a pulse of water. The idea is to rewet the plants frequently so that the interval of time when the plant temperature is below the critical damage temperature is short. Generally, the rotation rate should not be longer than 60 sec; and 30 seconds is better. Sprinkler application rate recommendations for grapevines are given in Table 1. Application rates for other tall crops are similar. Distribution uniformity and good coverage of the plants with water are important. Application rates are somewhat lower for low-growing crops because it is easier to obtain good wetting of the vegetation when it is shorter.

Irrigation: Impact on River Flows

Robert W. Hill
Biological and Irrigation Engineering Department, Utah State University, Logan, Utah, U.S.A.

Ivan A. Walter
Ivan's Engineering, Inc., W.W. Wheeler, Denver, Colorado, U.S.A.

INTRODUCTION

The practice of irrigation necessitates developing a water source, conveying the water to the field, application of the water to the soil and collection and reuse or disposal of tailwater and subsurface drainage. These processes alter river basin hydrology and water quality in space and time. To sum up the effect of irrigation on a watershed in a word, it would be: *DEPLETION*.

In hydrologic studies it is common engineering practice to quantify the impact upon the stream(s) from which the irrigation water is diverted. The impact upon the stream is actually of two kinds: 1) diversions that decrease the streamflow and 2) return flows that increase the streamflow. The engineering term used to describe the overall impact is "streamflow depletion" which means the net reduction in streamflow resulting from diversion to irrigation uses. Actual stream depletions are a function of many factors including the amount and timing of diversions, the type of diversion structure (well vs. ditch), crops grown, soil type, depth to groundwater, irrigation method, irrigation efficiency, properties of the alluvial aquifer, area irrigated, and evapotranspiration of precipitation, groundwater, and irrigation water.

Depletion

Depletion, in this context, is the consumptive abstraction of water from the hydrologic system as a result of irrigation. It is in addition to consumptive water use that would have occurred in the unmodified natural situation. As an example, waters of the Bear River Basin of Southern Idaho, Northern Utah, and Western Wyoming, because it is an interstate system, are administered by a federally established commission under the authority of the Bear River Compact.[1] Depletion is the basis, in the compact, for allocating Bear River water use among the three states. It is defined by a "Commission Approved Procedure" which includes consideration of land use and incorporates an equation for estimating depletion based on evapotranspiration. In a study for the commission, Hill[5] defined crop depletion as:

$$\text{Dpl} = \text{Et} - \text{SMco} - \text{Pef} \tag{1}$$

where Dpl is estimated depletion for a given site or sub-basin; Et is calculated crop water use; SMco is moisture which is "carried over" from the previous non-growing season (October 1–April 30) as stored soil water in the root zone available for crop water use subsequent to May 1; and Pef is an estimate of that portion of precipitation measured at an NWS station during May–September, which could be used by crops.

The carry-over soil moisture (SMco) was estimated by assuming that 67% of adjusted precipitation from October through April could be stored in the root zone. If this exceeded 75% of the available soil water-holding capacity of the average root zone in the sub-basin, the excess was considered as lost to drainage or runoff and not available for crop use. Growing season precipitation was considered to be 80% effective in contributing to crop water use. The effectiveness factor of 80% allowed for precipitation depths throughout a sub-basin that might differ from NWS rain–gage amounts. It also included a reduction for mismatches in timing between rainfall events and irrigation scheduling.

HYDROGRAPH MODIFICATION

Diversion of significant amounts of water from rivers and streams for irrigation and subsequent return flows alters the shape and timing of downstream hydrographs. In watersheds where mountain snowmelt provides the irrigation supply, such as in the Western United States, diversion during the spring runoff attenuates the peak flow rate while later return flows extend the flow duration into late summer and early fall.

Reservoir Storage

Storage of water in reservoirs can significantly modify the natural stream hydrograph depending on the timing and quantity of the storage right. Irrigators with junior rights may only be able to store during time periods with low irrigation demand, such as during the winter, or during peak flow periods. Reductions of stream flow during the winter time may have considerable impact on downstream in-stream flows. Whereas, storage during periods of peak runoff may not affect minimum in-stream flow needs, but could deposit considerable amounts of sediment in the reservoir.

Irrigation Return Flows

Irrigation return flows are comprised of surface runoff and/or subsurface drainage that becomes available for subsequent rediversion from either a surface stream or a groundwater aquifer downstream (hydrologically) of the initial use. Reusable return flow can be estimated as irrigation diversion minus crop related depletions minus additional abstractions. Additional abstractions include incidental consumptive use from water surfaces as in open drains, along with non-crop vegetation. The timing of return flow varies from nearly instantaneous (recaptured tailwater) to delays of weeks and months or perhaps longer with deep percolation subsurface drainage. In a hydrologic model study of the Bear River Basin[4] delay times between diversion and subsequent appearance of the return flow at the next downstream river gage varied from 1.5 months to as long as 6 months. The delay appeared to be related to sub-basin shape and size.

Irrigation Methods

Four general irrigation methods are used: surface, subsurface, sprinkler, and trickle (also known as low flow or drip). Surface methods include wild or controlled

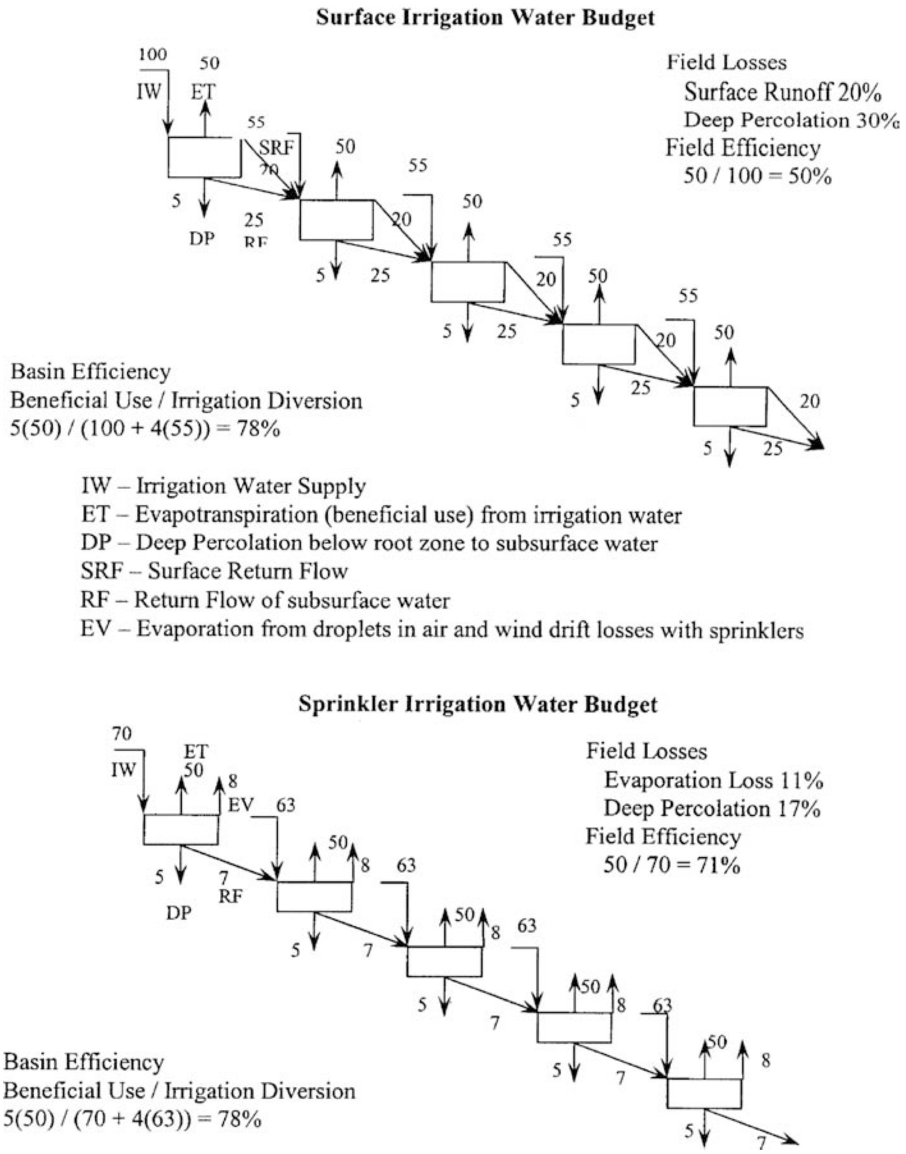

Fig. 1 Comparison of basin efficiencies between surface and sprinkler irrigation methods with four return flow reuse cycles.

flooding, furrow, border-strip, and ponded water (basin, paddy, or low-head bubbler). Hand move, wheel move, and center pivot are examples of sprinkler irrigation. Trickle irrigation includes point source emitters, microspray, bubbler, and linesource drip tape (above or below ground). Whereas the efficiency of surface irrigation is dependent upon the skills and experience of the irrigator, the performance of trickle and sprinkler systems is more dependent on the design. Generally, the more control that the system design (hardware) has on the irrigation system performance, the higher the application efficiency (E_a) can be. Thus, typical wheel move sprinklers have higher E_a values than surface irrigation, but lower values than for center pivots or trickle, assuming better than average management practices for each method.

The impact on river flows can be quite different among the various irrigation methods. The nature of furrow and border surface irrigation generally produces tail water runoff, which can be immediately recaptured and reused, as well as deep percolation, which may not be available for reuse until after a period of time. Tailwater is essentially eliminated and deep percolation reduced with sprinklers (Fig. 1) compared to conventional surface irrigation. Whereas, with drip methods, deep percolation can be further reduced. The reduction of deep percolation implies increased salt concentration in the root zone leachate, but, perhaps significant reduction in salt pick-up potential from geologic conditions.

Irrigation Efficiencies

Although a full discussion of the several variations of irrigation efficiency is beyond the scope herein, two terms will be defined and discussed. More complete discussions relating to irrigation efficiencies and water requirements are given elsewhere.[6–9,13] Keller and Bliesner[9] give a particularly thorough presentation of distribution uniformity and efficiencies.

Application efficiency (E_a):

$$E_a = 100 \times \frac{\text{Volume of water stored in the root zone}(V_s)}{\text{Volume of water delivered to farm or field}(V_f)}$$

Distribution uniformity:

The distribution uniformity is a measure of how evenly the on-farm irrigation system distributes the water across the field. The definition of DU is:

$$\mathrm{DU} = 100 \times \frac{\text{Average of the lowest 25\% of infiltrated water depth}}{\text{Average of all infiltrated water depths across the field}}$$

On-farm or field application efficiencies can be affected by the distribution uniformity and vary widely for both surface and sprinkle irrigation methods. This is largely due to difference in management practices, appropriateness of design in matching the site conditions (slope, soils, and wind), and the degree of maintenance. In addition, for a given system uniformity, the higher the proportion of the field that is adequately irrigated (i.e., infiltrated water refills the soil water deficit) the lower will be the application efficiency. This is due to greater deep percolation losses in the overirrigated portions of the distribution pattern. Some values determined in recent Utah field evaluations are:

	Observed		
Method	**High (%)**	**Low (%)**	**Typical (%)**
Surface irrigation			
E_a	72	24	50
Tailwater	55	5	20
Deep percolation	65	20	30
Sprinkler irrigation			
E_a	84	52	70
Evaporation	45	8	12
Deep percolation	37	8	18

The E_a for a particular field may vary greatly during the season. Cultivation practices, microconsolidation of the soil surface and vegetation will alter surface irrigation efficiency both up and down from the seasonal average. Seasonal and diurnal variations in wind, humidity, and temperature will also affect sprinkle application efficiencies.

BASIN IRRIGATION EFFICIENCY

The actual irrigation efficiency realized for several successive downstream fields where capture and reuse of return flows is experienced is higher than the E_a of an individual field. This notion of "Basin Irrigation Efficiency"[12,13] is illustrated in Fig. 1. This simple example comparison of surface and sprinkle methods assumes four reuse cycles. In each of the five "fields" Et is assumed to be 50 units. The surface runoff is captured for reuse on the next field. All of the irrigation-related evaporation is assumed "lost" as well as 5 units of deep percolation. After the fifth field, all surface and subsurface flows are lost. The basin efficiency for surface is 78%, which is the same as for sprinkle. The surface irrigation basin efficiency increase is dependent upon the surface return flow reuse, which is 20 units in this example. However, the depletion is greater for sprinkler due to the extra evaporation. In a Colorado

Irrigation–Journals

field study, Walter and Altenhofen[11] found a progressive increase in irrigation efficiencies from field (average E_a of 45%), to farm, to efficiency of ditch or sectors (average of 83%). This was due to the reuse of tailwater (10–20% of delivery) and deep percolation (46% of delivery).

ENVIRONMENTAL CONCERNS

The process of evapotranspiration, or crop water use, extracts pure water from the soil water reservoir, which leaves behind the dissolved solids (salts) contained in the applied irrigation water. The ''evapoconcentration'' of salts is an inevitable result of irrigation for crop production. As stated by Bishop and Peterson:[2]

> ''...Other uses add something to the water, but irrigation basically takes some of the water away, concentrating the residual salts. Irrigation may also add substances by leaching natural salts or other materials from the soil or washing them from the surface. Irrigation return flow is a process by which the concentrated salts and other substances are conveyed from agricultural lands to the common stream or the underground water supply...''

Water Quality Implications for Agriculture

Irrigated agriculture is dependent upon adequate, reasonably good quality water supplies. As the level of salt increases in an irrigation source, the quality of water for plant growth decreases. Since all irrigation waters contain a mixture of natural salt, irrigated soils will contain a similar mix to that in the applied water, but generally at a higher concentration. This necessitates applying extra irrigation water, or taking advantage of non-growing season precipitation, to leach the salts below the root zone.

Salt Loading Pick-Up

Water percolating below the root zone or leaking from canals and ditches may ''pick-up'' additional salts from mineral weathering or from salt–bearing geologic formations (such as the Mancos shale of Western Colorado and Eastern Utah). This salt pick-up will increase the salt load of return flows and consequently increase the salinity of receiving waters.

In the Colorado River Basin in the United States and Mexico salinity is a concern because of its adverse effects on agricultural, municipal, and industrial users.[10] The Salinity Control Act of 1974 (Public Law 93-320) created the Colorado River Basin Salinity Control Program to develop projects to reduce salt loading to the Colorado River. Salinity control projects include lining open canals and laterals (or replacing with pipe) and installing sprinklers in place of surface irrigation for the purpose of decreasing salt loading caused by canal leakage and irrigated crop deep percolation. Recently selenium in irrigation return flow has become a concern[3] and may also be reduced by salinity reduction projects.

In-Stream Flow Requirements

Diversions in some reaches in some Western United States streams are ''dried up'' immediately downstream of diversion structures during times of peak irrigation demand. This condition eliminates any use of the reach for fisheries and other uses which depend on in-stream flow. In some instances, negotiated agreements with senior water rights users have allowed for bypass of minimal amounts of water to sustain the fishery or habitat, and for control of tailwater runoff to reduce agricultural related chemicals in the receiving water.

Irrigation: Metering

John A. Replogle
Albert J. Clemmens
U.S. Water Conservation Laboratory, Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Phoenix, Arizona, U.S.A.

INTRODUCTION

The measurement of applied irrigation water is one of the major links in efforts to achieve effective water management worldwide. Measurement of flow for irrigation differs from most municipal and industrial water metering requirements because the water is spread over very large areas. This usually results in the need to measure both very large flows in canals near water supply sources and small flows spread over very large areas, perhaps in small trickle irrigation lines near the points of use. Irrigation was often done with waters that were not needed by other uses, although competition by these other uses is increasing, causing much controversy in water-use planning, policy, and development; therefore enhancing the need for accurate flow metering. Traditionally, flow meters have been classified according to the physical principle or property exploited, such as those related to sound; magnetism; electricity; chemical reactions; mixing; and volume, mass, and energy relations.[1] The device that exploits these properties to interact with the water is called the *primary element*, and produces an indication that can be detected with a *secondary element* for the user to observe, or otherwise use. This classification of meters according to exploited properties can be broadly grouped into *flow-rate meters* or *quantity meters*, according to the effect that is first observable. For example, a weir is a flow-rate meter, and a bucket is a simple quantity meter. Not all meters are currently practical for use in irrigated agriculture. Major restrictions to irrigation applications are often the lack of electric power at the metering site, capital cost, and poor maintenance support. Thus, practical irrigation metering emphasizes low cost, reasonable accuracy, and simplicity and the ability to meter waters with high sediment and/or trash loads. Meters that meet these criteria for the irrigation setting are discussed later. A wide variety of meters are discussed in more detail in Refs.[2,3].

OPEN-CHANNEL FLOW METERING

The most common measurement methods for open channels are: current metering, weirs, and flumes. A few additional metering methods will be discussed, but they represent a small portion of irrigation meters.

Current Metering

Current metering is a common method for the measurement of flow in rivers, streams, and large irrigation canals. In this method, a series of velocity measurements are made at many selected points across the channel, usually with a small propeller meter or a cup-type meter similar in concept to the cup-anemometer used for wind velocity. Other types of velocity meters are entering the market that are based on electromagnetic and ultrasonic concepts. The large number of velocity measurements, and their statistical averaging, helps to compensate for odd-shaped channels and the various flow velocities that may exist across the channel.

Details of current metering methods are given in Ref.[4]. Current meter measurements are labor intensive and represent only a sample of flow at a particular time. Thus, to be useful for continuous monitoring of flow, a relationship between water depth and flow is used to estimate flow during times between current meter measurements. This adds additional error to the measurement of flow volume over time.[4] For these large flows, measurements with flumes and weirs, discussed later, can be difficult due to the large size of the channel and the need for a drop in water surface as the water passes over the weir or flume.

More recently, ultrasonic meters have been used for stream gauging. Transit-time ultrasonic stream gauging is based on detecting stream flow velocity by using the difference in time for sound transmissions sent obliquely across the stream in opposite directions. This difference is translated into average velocity in the sound path that was sampled. Setting these meters so that the average velocity sampled is related to the average flow velocity is a limitation. Improved Doppler ultrasonic meters depend on reflected sound waves from flowing particles in the flow, rather similar to the action of the familiar Police-Radar units, and they are able to sample a series of locations within the flow profile. These meters are becoming more accurate and

Fig. 1 Flume in large canal. Note stilling well and the region of wavy water surface. Sill crest is located about midway between these two features. Canal flow depth is about 2.4 m (8 ft) and sill crest is about 1.4 m (4.5 ft) high.

less expensive. Both types of ultrasonic meters are also applicable to pipelines.

Weirs and Flumes

Flumes and weirs work on the principal of critical flow, which means that the flow rate is a maximum for a given energy (combination of depth and velocity functions). However, in order to cause critical flow, there must be a drop in water level through the flume or weir. A wide variety of flumes and weirs have been developed since the late 1800s. Most of these are gradually being replaced by a family of flumes and weirs that can be calibrated using computer techniques rather than relying on laboratory calibration. They are called long-throated flumes and broad-crested weirs. For these flumes and weirs, the channel size is reduced by contracting the sides or raising the floor to form what is called a throat section that is long relative to the flow depth, producing nearly parallel flow that can be treated mathematically; hence, these flumes are also called the "computable flumes." Additionally, the amount of water surface drop across the flume or weir needed to provide a measurement is not large, typically about 15% of the depth in the throat. Because they can be calibrated by computer, they can be made of essentially any prismatic shape and can be calibrated to as-built dimensions (Fig. 1). A number of portable and adjustable flumes have been developed for flow survey work, as opposed to permanent installation, and are available commercially (Fig. 2). Further details on these flumes and weirs can be found in Ref.[5]. Software for design and calibration is also available free-of-charge on the web: http://www.usbr.gov/wrrl/winflume/

Long-throated flumes and broad-crested weirs are often the simplest and most cost-effective method for measuring flow rates in open channels. They are used worldwide. However, in order to obtain flow volume, the instantaneous flow-rate measurements must be totaled over time. This requires either periodic observation or continuous recording. Devices for accomplishing this often cost more than the flume or weir itself. Also, there are locations where the opportunity for sufficient water surface drop is not available to produce flow measurements over the full range of desired discharges.

Fig. 2 Adjustable flume being installed while channel continues to flow. Capacity 56 L/sec (2 cfs).

PIPELINE FLOW METERING

While advances in canal flow measurements have significantly aided irrigation water management worldwide, developments in pipe flow measurements have also impacted irrigation flow measurements. A common method for irrigation flow measurement in pipelines, and often the least expensive, has been the propeller meter. Similar to the current meter, the velocity of the turning propeller is related to the average velocity of flow in the pipe. Early meters used mechanical gears to turn a cumulative volume meter, while magnetic indicators of propeller rotation and digital electronics are now common. The biggest problem with

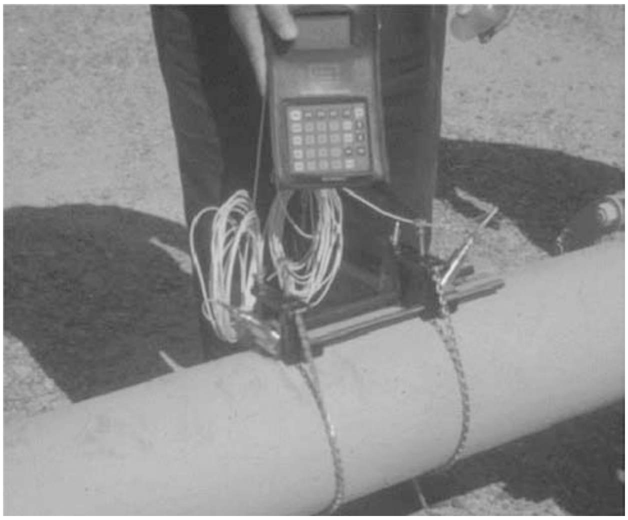

Fig. 3 Portable ultrasonic flow meter on outlet pipe of an irrigation well. Sensors are usually mounted on the side of pipe to avoid air bubbles that may be in the pipe.

these meters continues to be bearing wear from sand that is often in pumped wells, as well as errors in flow caused by poor approaching flow conditions. Pipe bends, elbows, valves, etc., can cause most pipeline flow meters to be inaccurate if they are closer than about 10 pipe diameters upstream and 2 pipe diameters downstream.[1,6]

Modern electronics have greatly improved the ability of secondary devices to monitor primary devices based on well-known primary elements, for example, the differential pressure across a Venturi meter or orifice meter, or the speed of sonic waves across a pipe. These electronic advances have resulted in lower-cost metering systems, often with improved accuracy. Many metering techniques depend heavily on these advances in electronics, such as vortex-shedding meters, ultrasonic Doppler flow meters, and the ultrasonic transit-time flow meters. Many of the older, popular meters are described in a number of references.[6] Vortex-shedding meters are becoming more common because of their relatively low cost. However, like propeller meters, they obstruct the flow and are not suitable where debris can enter the pipeline. Multipath ultrasonic meters are being used for large irrigation flows, and single path ultrasonic meters are used for smaller flows in a few locations. These meters are relatively immune to debris in the pipeline and so can be used in culverts or short pipe sections that are supplied by trash-filled open canals. However, they tend to have high cost and/or high maintenance. Doppler ultrasonic meters that measure point velocities are advancing and may prove more accurate and cost effective in the near future. Irrigation applications often require one-time flow surveys rather than permanent installations, and portable Doppler ultrasonic meters, portable transonic meters, and pitot-tube systems are useful for such surveys[7] (Fig. 3).

Sometimes the suggested 10 pipe diameters upstream from a meter are not available to assure proper meter functioning. It is sometimes more practical to attempt to modify the flow profile approaching the meter than to increase pipe length. Flow-conditioning devices, such as vanes to keep the flow from swirling and wall obstruction in the form of large-opening orifice to break up wall jetting have proven effective.

Irrigation: Preplant

James E. Ayars
U.S. Department of Agriculture (USDA), Parlier, California, U.S.A.

INTRODUCTION

Irrigation is the process of supplying supplemental water necessary for plant growth and development by several application techniques, e.g., microirrigation, surface irrigation, sprinkler irrigation, subirrigation (by raising a shallow water table), and subsurface irrigation. It is used not only in arid and semiarid areas of the world, but also in humid areas to supplement rainfall during periods of drought. In this context, water is applied after the crop has been planted and growth has begun. The depth and timing of the application are based on the crop water requirement, the irrigation water quality, the crop salt tolerance, and the available soil water storage capacity. These topics are discussed fully in other parts of the encyclopedia.

Preplant irrigation is the application of water to a field during a fallow period between crops to accomplish a goal to replenish soil water that is anticipated for future requirements for plant growth and development. Identified uses of preplant irrigation include germination, salinity management, soil water management, fumigation, weed control, and fertilizer placement. Preplant irrigation is used in arid, semiarid, and humid areas throughout the world with the largest applications being in arid and semiarid areas. The depth and timing of the application will depend on the following: the irrigation purpose, the irrigation water quality, the existing stored soil water, the soil salinity, the crop rotation, the crop salt tolerance, and the depth to shallow groundwater.

USES

Germination

Plant establishment and development are critical to achieving yield and production goals in annual cropping systems. Germination of the seed is the first step in this process followed by plant and root development and extension. An adequate supply of soil water is required in the zone of seed placement to assure that these processes occur and are sustained. In humid areas, rainfall is generally adequate for these purposes, but in arid and semiarid areas rainfall is insufficient to supply the necessary water either due lack of water or poor timing.

The San Joaquin Valley of California is typical of this situation. Rainfall occurs primarily during the winter months with the total varying from 150 mm to over 600 mm during this period. The effectiveness of the rainfall as a future water supply is a function of the depth and timing of the occurrences. Most of the rainfall can be lost to evaporation when only small 2–3 mm amounts occur. If the rainfall is in excess of about 12 mm, some of this water will be stored and be available later to meet plant water requirements. If a crop is being planted in the fall after either a period of summer fallow or the harvest of a summer crop, there will be little or no soil water stored and available for germination. As a result, it is necessary to irrigate the field to provide the water necessary for germination and early plant growth.

When a crop is planted in the fall immediately following a summer crop, irrigation will probably be withheld until after the crop has been planted. If the crop is planted in the fall following a summer fallow, the field will be irrigated prior to planting, and the crop planted into soil water allowing the producer to schedule operations in a timely fashion.

Spring planted crops generally follow a winter fallow period that is used to prepare fields for planting by creating seed beds and preplant irrigating to restore soil water. After irrigation, the seedbed is tilled to provide a mulched surface and prevent further evaporation. At planting, the seed is placed in the soil and allowed to germinate. After germination has been completed, the soil over the seed is removed mechanically, and the seed can sprout and continue to grow. This process is called planting to soil water and is used extensively in cotton production in California. Organic producers often use this method to germinate and sprout direct seeded crops. Usually, care is required in the dry soil layer mechanical removal process and must be applied soon after germination before seedling elongation begins.

Weed Control

Preplant irrigation plays an important role in weed management in both conventional and organic farming practices. In sugar beet production, preplant irrigation is used to germinate weed seed and carryover crop seeds (barley, wheat, and oats) prior to planting the sugar beet seeds. Sugar beet is not a very competitive crop and significant production can be lost to excessive growth of other plants. Once the weed or volunteer seed has germinated, it can be destroyed by using either chemicals (paraquat or glyphosate) or cultivation. When pre-emergence herbicides are used, preplant irrigation with sprinklers has improved the selectivity and activity of the chemicals because less water is used and less chemical is lost to leaching.

Organic producers use preplant irrigation to germinate weed seeds and then eliminate them either through cultivation or by burning. Another technique for weed control uses large amounts of compost applied prior to bed preparation. The compost is preplant irrigated to speed the composting process, which generates large amounts of heat that kills the existing weed seed. This process has to be completed prior to planting to prevent damage to the crop.

Salinity Management

Managing soil salinity is critical to successful agriculture in arid and semiarid areas of the world. Salts naturally occur in the soil, in the water used for irrigation, and in the fertilizers used for production. Crop growth and production will be reduced and eventually eliminated unless salinity in the root zone is controlled. Plants have a wide range of salt tolerance,[1] ranging from sensitive to salt tolerant. In addition to the basic tolerance, plant tolerance varies depending on growth stage with germination being the most sensitive time and maturity being the least sensitive.

Salt accumulates in the root zone as crops extract essentially pure water from the stored soil water; thus, leaving salt in the soil. In addition to salt applied by the irrigation water, salt can be transported up to the root zone from a shallow saline water table as the crop uses this water for plant growth. Evaporation from the soil surface also moves salt up into the soil profile and often to the soil surface. This accumulation of salt can have a significant negative impact on germination unless it is removed prior to planting. Leaching is the term used for removal of salt from the soil profile, and it is accomplished by irrigating in excess of the total water needed simply to meet the water requirements of the crop. The leaching requirement is the term used to describe the excess water needed to control the accumulation of salt in the soil profile. This requirement can be met incrementally with each irrigation or once a season.

Preplant irrigation is an effective method of managing salt in the profile. Generally, the large application made to replenish the stored soil water in the profile is adequate to transport the salt beneath the upper part of the soil profile, critical for germination and early crop development. Data in Fig. 1 show the salt mass in sprinkler irrigated and furrow irrigated plots to a depth of 120 cm for December 1997 and June 1998. In both cases, the salinity was higher at each depth increment in December than in June. The reductions in salinity through the profile was a result of deep percolation and salinity leaching from the preplant irrigation and rainfall.

In arid areas, there is generally inadequate rainfall to accomplish the necessary leaching, and preplant irrigation is required.

Soil Water Management

Crop yield and biomass are directly related to total crop water use. Soil is the reservoir that stores water for plant use, and rainfall and irrigation are the sources of supply of the stored soil water. Soil water holding capacity is a function of soil type with sandy soils being able to store small amounts of water and loams, silty clay loams, and clays storing larger amounts.

During the growing season, plants remove water from the stored soil water and irrigation replenishes the depleted water supply. Irrigation scheduling is used to determine when to irrigate and how much to irrigate. It is not a precise science because of the variability in climate, soils, and crop stand and development. The stored soil water acts as a buffer and

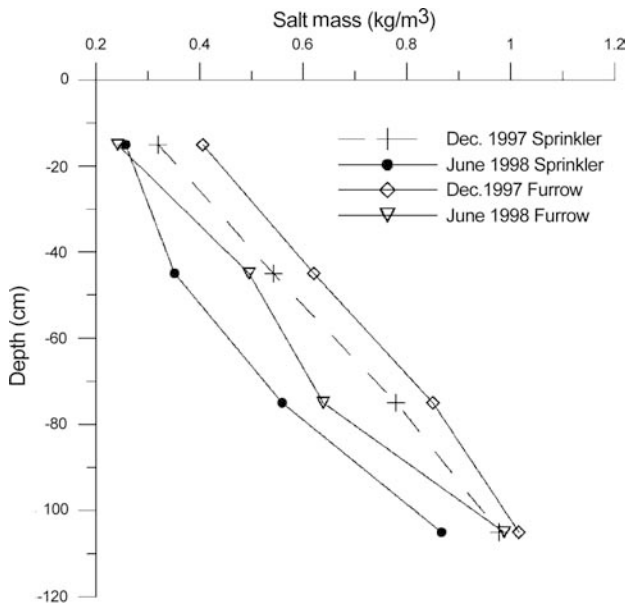

Fig. 1 Salt mass as a function of depth in sprinkler and furrow irrigated field.

Irrigation–Journals

reduces the impacts on plant growth due to water stress from errors in the scheduling process.

The total water available increases over the growing season as the root system extends and explores deeper into the soil profile. If water extracted by deep-rooted crops is not replaced by irrigation or rainfall prior to planting the next crop, the following crop might suffer water stress late in the growing season. Preplant irrigation is an effective means to refill the soil profile and to store water for late season plant use in soils with large storage capacity.

Fertilizer Placement

Microirrigation systems are sometimes used to apply fertilizers in the seedbed prior to planting. This is accomplished by injecting fertilizers into the water and only applying a small amount of water. This is possible with microirrigation and not with other systems. Applying fertilizers with surface irrigation can result in excessive losses due to the operational characteristics of these systems.

Fumigation

When fumigants are applied with preplant irrigation it has to be done well in advance of planting to ensure no damage is done to the crop. Fumigants are applied by sprinkler and microirrigation systems during preplant irrigation to minimize the losses due to deep percolation. Subsurface drip irrigation is being used to apply fumigants prior to planting strawberries.

MANAGEMENT

Depth of Application

The depth of application will be determined by the intended use. If weed control was the intent, the irrigation has to be small enough to provide water to germinate the weed seed and still permit timely cultivation or create a situation where the weeds subsequently die from lack of water. This might require only 5–10 mm of water. The same would be true with fumigation and fertilization applications. Only enough water would be applied to transport the chemical into the soil and position it in the correct portion of the crop root zone but not enough to transport it out of the root zone. The amount will be determined based on the existing soil water status, the irrigation system, and the size of the plot being irrigated.

Leaching and soil water management are often accomplished with a single application of water based on the existing soil water content. In arid areas with deep-rooted crops, the root zone often extends to a depth of 1m–2 m below the soil surface. The soil water depletion can be in excess of 200 mm in loams to clay soils, and replenishing the water is adequate to transport the salt from the soil surface well into the profile. This occurs in part because of the inefficiency of the irrigation systems. Surface irrigation systems and sprinkler systems have efficiencies of application in the range of 75–85%. This means that for the field to receive at least 200 mm of water, an additional 15–25% more water has to be applied. This inefficiency is generally adequate to provide the necessary leaching fraction when the water quality being used is considered. The depth of application can be determined by measuring the soil water content by soil sampling and a gravimetric determination, by neutron attenuation, by time domain reflectrometry, and by capacitance methods. The method selected will be a function of the crop, soils, and manager preference and experience. The closer the application is made to the time of planting, the more opportunity there is for rainfall to provide part of the water needed to replenish the root zone.

Timing of Application

Timing for the preplant irrigation will be determined by the intended use. For weed control, water has to be applied such that the weed will be dead prior to emergence of the crop and any irrigation associated with emergence. Fumigation has to occur early enough that the residual effect of the fumigants has dissipated prior to planting. This will be a function of the fumigant, the climate at the time of fumigation, the soil type, and the crop being grown following fumigation, whether it will be direct seeded or transplanted. Some crops, i.e., cotton, require a minimum soil temperature prior to planting to ensure good germination and stand establishment. In this instance, preplant irrigation needs to be done early to allow time for soil heating prior to the optimum planting date for the crop.

Managing soil water and leaching has to be done early enough that the soil has time to drain and return to a soil water content that is acceptable for cultivation. In large irrigated areas, this application of preplant irrigation occurs for several months prior to planting. This is possible because of the some of the planting techniques described in a previous section.

Water Quality Impacts

Improper management of preplant irrigation can have a significant negative impact on shallow groundwater quality and ultimately drainage water quality. This occurs primarily when preplant irrigation is used for soil water management, germination, and salinity control. Large amounts of water are applied in a single application during these operations and if the amount applied is significantly greater than what is required, deep percolation occurs. Deep percolation is the movement of water below the root zone and it is lost to crop production. This water carries along salt, fertilizers, and fumigants that are in the soil profile and mixes with the existing ground water. Depending on the chemical, this can create problems many years into the future.

Method of Application

Preplant irrigation can be done with any available irrigation system. The system normally used for irrigation during the season is the one that is most often used for preplant. Surface irrigation methods (furrow, flood, and basin) and sprinkler irrigation are the most common application methods when soil water management and salinity control are the goals. While surface systems are effective, they often have poor irrigation efficiency because the high infiltration rate as result of tillage following the crop. This inefficiency is manifested by excessive deep percolation losses and poor distribution uniformity. Surface systems and sprinklers cover the entire surface area and are thus very effective on large areas. Microirrigation systems are used when fumigation and fertilization are important because of the ability to apply small depths of water and to precisely place the water and chemical.

Irrigation: Saline Water

B. A. Stewart
Dryland Agriculture Institute, West Texas A&M University, Canyon, Texas, U.S.A.

INTRODUCTION

As water becomes more limited, there is increasing use of saline waters for irrigation that were previously considered unsuitable. Rhoades, Kandiah, and Marshali[1] classified saline waters as shown in Table 1. Electrical conductivity is a convenient and practical method for classifying saline waters because there is a direct relationship between the salt content of the water and the conductance of an electrical current through water containing salts. Electrical conductivity values are expressed in siemens (S) at a standard temperature of 25°C.

Most waters used for irrigation have electrical conductivities less than $2\,\mathrm{dS\,m^{-1}}$.[1] When water higher than this level is used, there can be serious negative effects on both plants and soils. As salinity in the root zone increases, the osmotic potential of the soil solution decreases and therefore reduces the availability of water to plants. At some point, the concentration of salts in the root zone can become so great that water will actually move from the plant cells to the root zone because of the osmotic effect. Salts containing ions such as boron, chloride, and sodium can also be toxic to plants when accumulated in large quantities in the leaves. The extent that plant growth is affected by saline water is dependent on the crop species. Some plants, such as barley and cotton, are much more resistant to salt than crops like beans. Rhoades, Kandiah, and Marshali[1] list the tolerance levels of a wide range of fiber, grain, and special crops; grasses and forage crops; vegetable and fruit crops; woody crops; and ornamental shrubs, trees, and ground cover. Soils are also negatively impacted by salt, particularly sodium salts. Sodium ions tend to disperse clay particles and this has deleterious effects on infiltration rate, structure, and other soil physical properties.

IRRIGATING WITH SALINE WATERS

Water limitations and the need to increase food and fiber production in many parts of the world have resulted in the use of water for irrigation containing increasing levels of salts. The United States, Israel, Tunisia, India, and Egypt have been particularly active in irrigating with saline waters.[1] Rhoades, Kandiah, and Marshali[1] published an extensive paper on the use of saline waters for crop production and it is a valuable guide for anyone interested in the subject. They reported that many drainage waters, including shallow ground waters underlying irrigated lands, fall in the range of $2\,\mathrm{dS\,m^{-1}}$ to $10\,\mathrm{dS\,m^{-1}}$ in electrical conductivity. Such waters are in ample supply in many developed irrigated lands and have good potential even though they are often discharged to better quality surface waters or to waste outlets. These waters can be successfully used in many cases with proper management. Reuse of second-generation drainage waters with electrical conductivity values of $10\,\mathrm{dS\,m^{-1}}$ to $25\,\mathrm{dS\,m^{-1}}$ is also sometimes possible but to a much lesser degree because the crops that can be grown with these waters are atypical and much less experience exists upon which to base management recommendations.

Miller and Gardiner[2] suggest that successful irrigation with saline water requires three principles. First, the soil should be maintained near field capacity to keep the salt concentration as low as possible. Second, application techniques should avoid any wetting of the foliage. Third, salts accumulating in the soil should be periodically leached. To accomplish these objectives, Miller and Gardiner[2] recommend the following general rules:

- Apply water at or below soil surface. Sprinklers should be used only if they avoid wilting the foliage (such as sprinkling before plant emergence or below-canopy to avoid salt-burn damage).
- Keep water additions almost continuous, but at or below field capacity so that most flow is unsaturated. This maintains adequate aeration.
- Enough water should be added to keep salts moving downward, thus avoiding salt buildup in the root zone.

Miller and Gardiner[2] stress that these rules are difficult to meet and are best satisfied by some form of drip irrigation. They also state that due to the need for high water levels and because of high sodium ratios that sandy soils are more adaptable to the use of saline waters than soils containing high percentages of silt and clay particles.

Table 1 Classification of saline waters

Water class	Electrical conductivity ($dS\,m^{-1}$)	Salt concentration ($mg\,L^{-1}$)	Type of water
Non-saline	<0.7	<500	Drinking and irrigation
Slightly saline	0.7–2	500–1500	Irrigation
Moderately saline	2–10	1500–7000	Primary drainage and groundwater
Highly saline	10–25	7000–15,000	Secondary drainage and groundwater
Very highly saline	25–45	15,000–35,000	Very saline groundwater
Brine	>45	>45,000	Seawater

Source: From Ref.[1].

Rhoades, Kandiah, and Marshali[1] also list specific management practices for producing crops with salty waters. Their list includes the following guidelines:

- Selection of crops or crop varieties that will produce satisfactory yields under the existing or predicted conditions of salinity or sodicity.
- Special planting procedures that minimize or compensate for salt accumulation in the vicinity of the seed.
- Irrigation to maintain a relatively high level of soil moisture and to achieve periodic leaching of the soil.
- Use of land preparation to increase the uniformity of water distribution and infiltration, leaching and removal of salinity.
- Special treatments (such as tillage and additions of chemical amendments, organic matter and growing green manure crops) to maintain soil permeability and tilth. The crop grown, the quality of water used for irrigation, the rainfall pattern and climate, and the soil properties determine to a large degree the kind and extent of management practices needed.

BLENDING LOW-SALT AND SALTY WATERS

Miller and Gardiner[2] reported that countries such as Israel have developed extensive canal and reservoir systems where both low-salt and salty waters are mixed to obtain usable water. Rhoades, Kandiah, and Marshali,[1] however, state that blending or diluting excessively saline waters with good quality water supplies should only be undertaken after consideration is given to how this affects the volumes of consumable water in the combined and separate supplies. They suggest that blending or diluting drainage waters with good quality waters in order to increase water supplies or to meet discharge standards may be inappropriate under certain situations. More crop production can usually be achieved from the total water supply by keeping the water components separated. Serious consideration should be given for keeping saline drainage waters separate from the good quality water, especially when the good quality waters are used for irrigation of salt-sensitive crops. The saline waters can be used more effectively by substituting them for good quality water to irrigate certain crops grown in the rotation after seeding establishment.

CONCLUSION

There is ample evidence that saline waters once considered unacceptable for irrigation can be used successfully provided that they are properly managed. There is also ample evidence, however, to show that these waters can be highly damaging to the environment and to the soil resource base when improperly managed. Therefore, saline waters should be only used for irrigation after careful study and considering as many factors as possible. Then, when the waters are used for irrigation, a careful monitoring program should be implemented of both the crops produced and of the resulting soil and environmental changes.

INTRODUCTION

One of the primary functions of soil is to buffer environmental change. This is the result of the biological, chemical, and physical processes that occur in soils. The soil matrix serves as an incubation chamber for decomposing organic wastes including pesticides, sewage, solid wastes, and many other wastes. Soils store, decompose, or immobilize nitrates, phosphorus, pesticides, and other substances that can become pollutants in air or water. Consequently, soil has, for centuries, been used for the application of sewage effluents. Sewage effluent provides farmers with a nutrient-enriched water supply and society with a reliable and inexpensive means of wastewater treatment and disposal. It should not, however, be assumed that irrigation is always the best solution for wastewater disposal. Disposal by irrigation should always be compared with alternative options based on environmental, social, and economic costs and benefits.

While disposal is the primary objective in many cases, the need of water for irrigation is becoming more often the driver for using sewage effluent on land. This is particularly true in areas like the Middle East where population growth is resulting in severe water shortages. The guidelines for using effluent for irrigation vary considerably among countries and other governing bodies. Cameron[1] conducted a literature review and found wide differences of guidelines for effluent irrigation projects being used throughout the world. In general, however, sustainable and environmentally sound systems can be developed in most situations provided proper management practices are followed.

CONCERNS OF IRRIGATING WITH SEWAGE EFFLUENT

In spite of the documented benefits associated with the use of sewage effluent for irrigation, there are numerous concerns. Many industrial wastewaters have been routinely dumped into municipal sewage lines. While this issue has been addressed in some jurisdictions, it has not in many others. In the United States, the Environmental Protection Agency requires that wastewaters be treated prior to disposal into municipal treatment plants or back into groundwater. Irrigating with wastewaters partially cleans water by percolation through the soil, but soluble salts and some inorganic and organic chemicals may continue to flow with the water to groundwater or surface supplies. In general, the Environmental Protection Agency allows sewage effluents to be used for irrigation only if it does not cause: 1) extensive groundwater pollution; 2) a direct public health hazard; 3) an accumulation in the soil or water of hazardous substances that can get into the food chain; 4) an accumulation of pollutants such as odors into the atmosphere; and 5) other aesthetic losses, within the limits.[2]

Bouwer[3] has also expressed concerns about the use of sewage effluent for irrigation. He is particularly concerned with pathogens and warns that complete removal of viruses, bacteria, and protozoa and other parasites should be required before the effluent can be used to irrigate fruits/vegetables consumed raw or brought into the kitchen, or parks, playgrounds and other areas with free public access. Bouwer also stresses that long-term effects of sewage effluent irrigation on underlying groundwater should be considered in addition to the changes in nitrate and salinity. Ground water in low rainfall regions can be highly affected by percolating sewage effluent because much of the water is used by the growing crops and this greatly concentrates the chemicals in the small amounts of water that actually percolate to the groundwater. These chemicals can include disinfection byproducts, pharmaceutically active chemicals, and compounds derived from humic and fulvic acids formed by the decomposition of plant material. Bouwer claims that many of these chemicals are suspected carcinogens or toxic. Therefore, Bouwer concludes that while sewage irrigation looks good on the surface, a more extensive look reveals a potential for serious contamination of groundwater. He states that municipalities and other entities responsible for irrigation with sewage effluent should do a groundwater impact analysis to develop management protocols and be prepared for liability actions. Those who benefit are local and state institutions in water resources, environmental quality protection, public health, consultants, and operators of effluent irrigation projects.

REUSE STANDARDS

The standards for using sewage effluent for irrigation of agricultural crops vary widely among different countries of the world. Mexico and many South American countries, e.g., use untreated wastewater for irrigation.[4] Most of these countries do not have the resources or capital to treat sewage effluents. Wastewater is utilized after little or no treatment, and health risks are minimized by crop selection. Mexico does not allow wastewater to be used to irrigate lettuce, cabbage, beets, coriander, radishes, carrots, spinach, and parsley. Acceptable crops include alfalfa, cereals, beans, chili, and green tomatoes. In contrast, Israel has very stringent water reuse requirements. Effluent water requires a high level of treatment (large soil-aquifer recharge systems with dewatering) before the water can be reused for irrigation of vegetables to be consumed raw.[5] Health guidelines for irrigation with treated wastewater developed in California indicate that effluent waters used on food crops must be disinfected, oxidized, coagulated, clarified, and filtered.[6] Total coliform counts cannot exceed a median value of 2.2/100 ml or a single sample value of 25/100 ml. Total coliforms must be monitored daily and turbidity cannot exceed 2 nephelometric turbidity units and must be monitored continuously. Less restrictive guidelines developed by Shuval et al.,[7] and adopted by most of the international agencies, suggested that effluent water reuse was relatively safe to use if it contained less than 1 helminth egg L^{-1}, and less than 1000 fecal coliforms/100 ml.

MONITORING GUIDELINES

Site selection is a critical and necessary step in initiating a sewage effluent irrigation system. The U.S. Environmental Protection Agency[8] published detailed information on site characterization and evaluation. Information was provided on the design of systems, site characteristics, expected quality of the effluent water after land treatment, and typical permeabilities and textural classes suitable for each land treatment process. Information was provided for designing and monitoring site characteristics for slow rate processes (sprinkler and other typical farm irrigation systems), rapid infiltration basins, and overland flow systems. Monitoring requirements will vary considerably among projects depending on the cropping patterns, soil characteristics, and specific environmental concerns. In most cases, monitoring procedures and criteria will be site specific. In all cases, however, the objectives should be to use the resources effectively, protect the land, protect the groundwater, protect the surface water, and protect the community amenity.

INTRODUCTION

Irrigation systems have evolved from flood systems to pressurized sprinkler and trickle systems. In flood irrigation, water is applied to a field in a controlled stream and allowed to flow over the soil surface by gravity, the final distribution being affected by variations in surface slope and water infiltration rates. Well-designed pressurized irrigation systems apply water at sufficiently low rates that it infiltrates with little or no surface movement, thus providing a greater degree of control and improved uniformity of application.

The primary objective of irrigation system design is to apply water (and dissolved chemicals) uniformly over a field planted with a uniform crop, the water requirement being determined primarily by the crop and climate. In recent years, sophisticated control systems have been developed that enable water and chemical application to be tailored to smaller areas if and when it is desirable to do so. The term site-specific irrigation (also known as precision-variable irrigation) refers to the practice of intentionally applying different amounts of water to different areas of a field to optimize crop production, minimize chemical and water use, or reduce environmental concerns. Although site-specific irrigation can be applied with any type of pressurized irrigation system, most of the potential application is with continuous-move sprinkler laterals, primarily center pivots.[1–5]

DESIGN AND MANAGEMENT OBJECTIVES

Some of the main reasons for site-specific irrigation are the following:

- Avoid watering non-productive areas such as roads, rock outcrops, canals, ditches, and ponds. Center pivots often traverse these areas that lie within a generally circular area.
- Apply different amounts of water and nutrients to different zones according to crop production capability. Soil depth, salinity, or other soil-related factors may limit the potential yield and the total water requirement on some soil types.
- Apply reduced amounts of water to steep slopes or zones of low infiltration where runoff is difficult to control. A permanent cover crop may be planted in these areas.
- Variable soil types within a field may benefit from different amounts of water during certain time periods. Under water-short scenarios, crops on coarse-textured soils having low water holding capacity need small, frequent water applications to avoid water stress, while the crop on finer-textured soils may be able to withdraw stored soil water.

SCALE CONSIDERATIONS

One of the main considerations is determining the minimum size area that must be treated individually.[6] The cost and complexity of the system escalate rapidly as the treatment area decreases. The wetted radius of the individual sprinkler patterns, the start–stop movement of the lateral, and the accuracy with which the lateral position can be determined all affect the minimum practical differential area. Typically, a 300-m^2 area is about the smallest desirable unit.

Maps defining soil types, unproductive areas, cropping and fertility patterns are used to define management zones (Fig. 1) requiring different water amounts. These zones should be created from the intersecting areas of only the map parameters that affect the water or chemical requirements.

EQUIPMENT FOR SITE-SPECIFIC IRRIGATION

Sprinkler Laterals

Continuous-move laterals that move in a straight line are called ‘‘linears’’ and those that rotate about a fixed

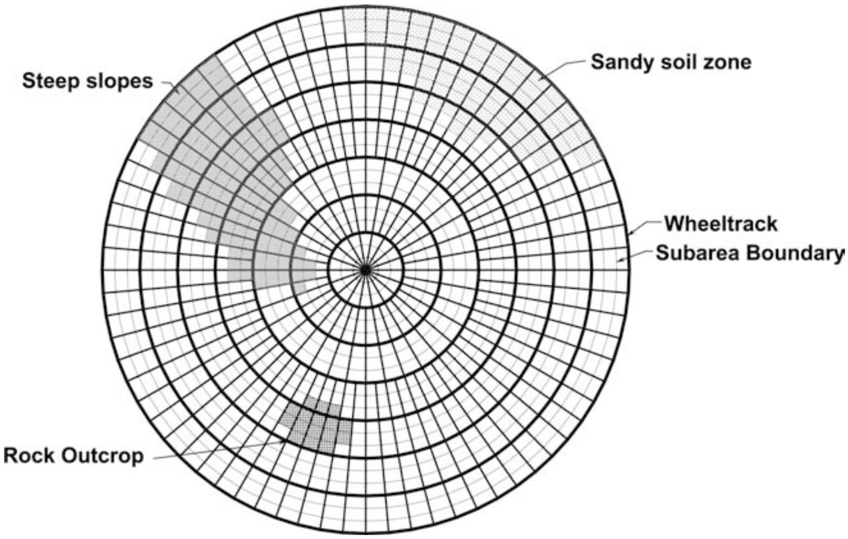

Fig. 1 Schematic of a field irrigated by a 7-span center pivot, with each span subdivided into three segments. Crosshatched areas are special water management zones (photo by Dennis C. Kincaid).

pivot at one end are called "center pivots." These laterals consist of several rigid spans, typically 40–50 m in length with a total length of about 400 m, although longer laterals are used. The outermost tower controls the rotation speed. The entire lateral is maintained in a nearly straight line by switches at intermediate towers that start and stop the drive motors according to the flex angle between adjacent spans. Center pivots use a transducer (pivot resolver) to determine the position of the first span with an accuracy of about 1° of rotation and a radial coordinate system to determine the position of any point on the lateral relative to the field map at any time. Recently, differential global positioning system (DGPS) units placed on the outer end of the lateral have been used to improve the positioning accuracy of center pivots.

Linear laterals use a guidance system to travel on a predetermined (normally straight) path. A calibrated ground wheel, fixed ground stakes with a trip switch on the lateral, or with a DGPS unit, can determine the lateral position along the travel path. Both end towers control the travel speed and guidance. Additional error is introduced by the guidance system that "steers" the lateral by adjusting the relative speed of the end towers, thus changing the angle of the lateral relative to the travel path. Therefore the positioning accuracy of linears is usually less than that of pivots.

Sprinkler Equipment and Controls

Traveling laterals use sprinkler equipment designed to discharge a desired amount of water per unit length of lateral. For pivots, the discharge rate increases with distance from the pivot. Sprinklers or spray heads are placed at fixed or variable spacing such that their water application patterns overlap, resulting in nearly uniform water distribution along the lateral. The pattern radii of the most popular spray heads are about 5–8 m. The travel speed of the lateral can be varied to change the water application depth in pie-shaped differential areas under a pivot or in rectangular differential areas under a linear. However, for all other differential areas, sprinkler flows must be varied along the lateral. There are three main methods of accomplishing this:

1. A variable flow rate sprinkler head uses a fixed nozzle with an insertable pin to produce either a high or low flow rate.[7] The pin can be cycled in or out to produce an effective flow rate anywhere between the high and low flow.
2. Automatic valves can be placed on individual sprinklers or groups of sprinklers on manifolds (Fig. 2). Manifold length is usually a fourth to half the span length. One-directional check

Fig. 2 An on–off spray manifold on a span of a traveling lateral. Note black automatic valve above manifold (photo by Kincaid).

Irrigation–Journals

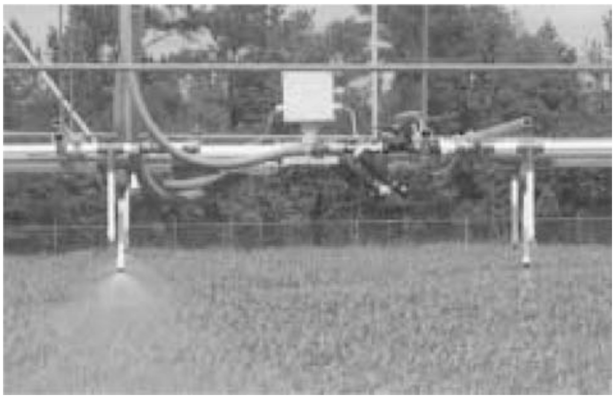

Fig. 3 Close-up of multiple-manifold spray system (photo by Sadler).

valves are used on the individual heads to prevent the manifold from draining when the manifold valve is off. The manifold valve can be cycled on and off at different time intervals to produce effective application rates between 0% and 100% of the maximum rate. The cycle interval must be much less than the time it takes the full sprinkler pattern to traverse a point on the ground.

3. Two or three complete sets of sprinklers designed with different unit flow rates are mounted on the lateral (Figs. 3 and 4). Any combination of the sprinkler sets can be turned on one at a time, resulting in several distinct rates. Two sets provide four possible rates (e.g., 0, 1/3, 2/3, and 1), and three sets provide eight possible rates.

The variable flow sprinkler (method 1) has not yet been commercially developed. At the present time, the on–off manifold (Fig. 2) is likely the most cost-effective configuration, as this involves the least additional equipment.

The computerized control system is normally located at the pivot or inlet end of the lateral.[8] The computer determines the location of the lateral, adjusts the travel speed, and turns sprinkler control valves on or off according to a predetermined program as the lateral passes over each subarea of the field. Valves are usually electric-solenoid-operated and each requires a separate control wire. Optionally, a code-based control system can send signals to individual valves through a single wire.[9]

Fig. 4 A site-specific center-pivot system with selected spray manifolds off (photo by Sadler).

CONCLUSION

New technologies have made precision variable water application technically feasible. Many different scenarios of variable soils, different crops, limited water supplies, and environmental concerns may make site-specific irrigation desirable. Because of the cost and complexity of these systems, economic feasibility will be highly case-dependent.

Irrigation: Sprinklers (Mechanical)

Dennis C. Kincaid
Northwest Irrigation and Soils Research Laboratory, Pacific West Area, Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Kimberly, Idaho, U.S.A.

INTRODUCTION

Sprinkler irrigation can be defined as the controlled distribution of water as discrete droplets through air. Sprinkler devices were first invented during the late 19th and early 20th centuries, primarily for lawns and gardens.[1] Their widespread use for agricultural crops did not come about until the availability of lightweight aluminum pipe and low cost electricity following World War II. Sprinkler irrigation is particularly well suited to rolling topography, shallow soils, and sandy soils, which are difficult to irrigate efficiently with gravity flow surface irrigation systems. Sprinkler systems are now used on one-half of the 50 million irrigated acres in the United States.[2]

Early sprinkler systems used manually moved pipe and fixed or portable pumps and mainlines. Hand-move lines are relatively low cost in terms of equipment investment, but are labor intensive. Labor costs provided the primary incentive to develop mechanically moved sprinkler systems. Another factor has been the increase in farm size and the desire to create automated irrigation systems so that one person can irrigate more land. This article describes the mechanics of the various systems. Special sprinklers, mounting devices, and pressure regulators have been developed for these systems. Information on the sprinklers, system design and management, etc. can be found in the listed references.[3–6]

STATIONARY OR PERIODIC-MOVE LATERALS

A sprinkler lateral is a continuous length of pipe upon which sprinklers are mounted, usually equally spaced. Mechanically moved or hand-moved stationary laterals remain in a fixed position while irrigating, which are then drained and moved to a new predetermined position. They normally irrigate rectangular fields and require several sets to completely irrigate the field.

Sideroll Wheeline

The sideroll wheeline lateral consists of an aluminum pipe that serves as an axle for a series of rigidly attached wheels, the whole of which is rolled sideways to move the entire lateral simultaneously when drained (Fig. 1). The pipe is a special high-strength alloy tubing, 100–125 mm in diameter, capable of withstanding considerable torque. The wheel spacing is usually about 12 m, with sprinklers located midway between the wheels. These laterals are typically 400 m in length, but may be as long as 800 m. The wheel radius must be at least as large as the height of the crops to be grown, typically about 0.75–1.0 m. Sideroll laterals are not used to irrigate tall crops such as corn. A powered mover unit located near the center of the lateral provides torque to roll the lateral. Some longer laterals use two movers located approximately one-fourth of the distance from each end and connected by a small rotating shaft to coordinate the movement. The movers are powered by a small gas engine, electric motors, or hydraulic motors. The lateral is moved 2–4 complete revolutions between sets (12–15 m). For convenience, some sideroll laterals can be moved by an operator standing at the inlet end of the lateral. A short flexible hose is used to connect the lateral to a water supply outlet. Water is supplied from a fixed mainline with outlets spaced at some unit multiple of the wheel circumference.

Trail-Line Lateral

The trail-line system, also called a movable solid-set, consists of a lateral mounted on two-wheel support towers (see section "Continuous-Move Laterals"), which serves as a movable mainline for a set of trailing sublaterals. The trail-lines are lightweight aluminum sprinkler sublaterals typically spaced about 12–16 m apart and up to 120 m in length. The powered lateral drags the trail-lines between sets. When one irrigation event is complete, the trail-lines are disconnected, and the lateral is moved to the opposite end of the trail-lines, which are then reconnected to the lateral. The whole system is then moved back across the field dry to the first position, or can irrigate each set in turn as it is moved back to the initial position.

CONTINUOUS-MOVE LATERALS

Continuous-move laterals are those which travel while irrigating, either smoothly or intermittently in small

Fig. 1 Sideroll lateral with mover unit in foreground. Note the small driveshaft parallel to the lateral pipe on the right, which transfers power to the mover mechanism.

increments. There are two main types: those called linears that travel in a nearly straight line path, irrigating rectangular areas; and pivoting laterals that rotate about one fixed end, and thus irrigate circular areas. Both types use the same hardware and differ mainly in the way they are controlled and supplied with water. Continuous-move laterals have been built in many variations and styles over the years, but the most common type in use today is shown in Figs. 2 and 3. The lateral pipe is steel or aluminum (100–250 mm diameter) and is usually supported 3–4 m above ground to provide sufficient clearance for most crops. The lateral is made up of several 30–55 m long spans, where each span pipe is integrated into a rigid truss. The pipe joints between spans are flexible, and one end of each span is supported by a two-wheeled tower, both wheels being powered. The wheels are typically powered by electric motors, but fluid motors (oil or water) are also used. The movement of the wheels on intermediate towers is controlled by switches or valves,

Fig. 2 Center-pivot lateral with swingspan corner system partly extended. Sprinklers are mounted on drop tubes below the lateral.

Fig. 3 Linear-traveling lateral, hose-drag type, with on-board engine. This lateral can also pivot about the inlet structure. Sprinklers are mounted on drop tubes.

which automatically function to keep the entire lateral in a nearly straight line. Travel speed determines the water application depth.

Linear-Move Laterals

Linear-move laterals are usually supplied with water through a flexible drag hose (Fig. 3), or alternatively through a suction pipe moving in an open canal. In addition, automatic coupling systems have been built. The hose-drag system can travel twice the length of hose in one set. An on-board diesel powered generator or drag cable provides electricity. The wheels normally follow the same track each pass to minimize crop damage. The outermost towers determine travel speed and travel direction. Special guidance systems must be used to keep the wheels traveling in the same path each pass. One method uses radio antennas to follow a buried cable, while another type follows an aboveground cable or small guide trench. Recently, Global Positioning System receivers have been employed to guide traveling laterals and swingspan pivots (Fig. 2). Traveling laterals up to 800 m in length have been built.

Center-Pivot Laterals

The pivoting lateral or center-pivot system is supplied with water and electrical power through simple swivel couplings at the fixed end. The lateral can rotate continuously about the pivot, so that when the first irrigation is completed the lateral is in position to begin the next irrigation. They require no coupling or uncoupling of hoses or pipes and a pivot without a swingspan requires no guidance system. The low labor requirement of this system has made it very popular, and they are used on about 50% of the sprinkler irrigated land.

The major disadvantage of the center-pivot is the circular irrigated area, which leaves the corners of a square field unirrigated. In large developments, the circles can be nested to minimize the unirrigated area. Where the economics of the situation dictate that the corners must be irrigated, several options exist. A large sprinkler mounted on the outer end of the lateral and controlled to turn only in the corner areas can irrigate a portion of the corners.

Another option is the swingspan corner system (Fig. 2) consisting of an additional span up to 70 m in length that pivots about the outer end of the lateral. As the lateral moves into a corner area, the swingspan pivots outward, effectively extending the length of the lateral. The swingspan wheels are steerable, and a buried cable or GPS guidance system similar to the linear-move controls its movement. Sprinklers on the swingspan are automatically sequenced on or off as the swingspan moves outward or retracts, thus maintaining a nearly equal water application per unit area. A center-pivot equipped with a swingspan can irrigate up to 97% of a square field.

Recently, manufacturers have developed traveling laterals that can operate both as linears or pivoting laterals, making it possible to irrigate odd-shaped fields and cover more area with a given length of lateral (Fig. 3). Pivot laterals can also be made towable so that they can irrigate more than one field.

TRAVELING SPRINKLERS

Large traveling sprinklers, called big guns, can throw water up to 70 m, and can irrigate large areas. They require relatively high-pressure (up to 1000 kPa) water supplies, so operating costs can be quite high.

Fig. 4 Hard-hose traveler completing a pass. Note inlet supply hose lower right.

Hard-Hose Travelers

The most popular traveler, called a hard-hose traveler, consists of a big-gun sprinkler mounted on a cart and supplied by a semirigid hose, which retains its round shape when wound upon a reel (Fig. 4). Water is supplied through the center of the reel from a mainline outlet. Initially, the hose is pulled out along the travel path by a tractor. The reel remains in a fixed position while irrigating and slowly rotates, dragging the hose and sprinkler across the field as the hose is reeled in. A water turbine, reciprocating cylinder, or small gas engine provides power to turn the reel. Reel speed is automatically adjusted to account for the change in diameter due to hose wrap. The hose can be up to 400 m in length and 115 mm diameter. The hose reel is mounted on a trailer for transport by a small tractor.

Soft-Hose Travelers

A similar traveling sprinkler uses a soft, collapsible hose (Fig. 5). The sprinkler cart is pulled by a cable and winch, usually mounted on the cart itself, and powered by a water turbine or reciprocating cylinder. Initially, the hose is laid out alongside the travel path and the cable is reeled out and attached to a fixed anchor. The sprinkler can travel twice the hose length

Fig. 5 Soft-hose traveler beginning a pass. The sprinkler cart is towed by a cable (not visible).

in one set. The hose must be drained and reeled up between sets.

Boom Travelers

Boom travelers are similar to big-gun travelers except that the gun sprinkler is replaced by a horizontal boom structure extending perpendicular to the travel path, and high enough to clear the crop. This in effect creates a traveling lateral upon which sprinklers or spray heads are mounted. The advantage of this system is that it requires much less water pressure than the large gun sprinklers, and water application uniformity is improved.

CONCLUSION

Mechanically moved sprinkler systems will increase in sophistication as computerized controls are developed, particularly for precision variable water and chemical application. Center-pivot systems will likely predominate because of their inherent advantages, including ease of automation and continuous rotation capability.

Irrigation: Supplemental

Phillipe Debaeke
Unite d'Agronomie, Institut National de la Recherche Agronomique (INRA), Castanet-Tolosan, France

INTRODUCTION

The main objective of irrigation consists of supplying water to crops when soil-stored water at planting and seasonal rainfall are too erratic or limited to satisfy the plant transpiration demand with enough regularity, at a level defined by the farmer.

Supplemental (or supplementary) irrigation (SI) was defined as follows: "In an area where a crop can be grown by natural rainfall alone but additional water by irrigation stabilizes and improves yield, this irrigation is termed supplemental, the additional water alone being insufficient to produce a crop."[1] SI is applied to complete a deficient or uneven precipitation regime, enhancing and securing crop production, both in quantity and quality, in such pedoclimatic conditions where rainfed production is still feasible although less profitable.

AREAS AND CROPPING SYSTEMS CONCERNED

When natural contributions by rainfall or groundwater are too scarce to satisfy full crop water requirements only occasionally (amount and distribution within the season), the continuous optimal water regime can be obtained through SI, i.e., by a temporary and discontinuous irrigation regime.[2] Such situations are frequently observed in humid and subhumid regions, generally for spring-sown crops such as soyabean, maize, sugarbeet, potatoes, and for some tree crops. For instance, in southwestern France, most of the maize is grown under SI (up to 250–300 mm).

In the regions where both natural and irrigation resources are too limited for ensuring a permanent optimal water regime to crops, SI is mainly supplied at the critical periods of the crop-growth cycle, in order to maintain or improve crop production.[2] This is the case in arid and semiarid regions of the Mediterranean basin where SI is practiced for species generally grown profitably without irrigation but their yields are subjected to great variations over the years because of rainfall variability. These species are: winter cereals (mostly durum and bread wheat), autumn-sown legumes (faba bean, peas), spring-sown crops having a dense and deep rooting system (sorghum, sunflower, cotton, etc.), and tree crops (olive, almond, peach, vine, etc.). In those regions, spring-sown crops (such as maize or sugarbeet) with high water requirements but restricted rooting system are only grown under intensively-irrigated systems, irrigation amounts (until 800–1000 mm) exceed the contribution of natural resources (rain and stored soil water).

Surprisingly, SI is also widely practiced in Northern Europe, such as United Kingdom and Scandinavia.[3] In most years, spring-sown crops (potatoes, sugarbeet, horticultural crops) have their growth restricted and yields reduced by water shortage, the extent of this depending very much on soil type (e.g., shallow soils, low water holding capacity), weather conditions, and the timing and duration of stress periods. Although rainfall is fairly evenly distributed throughout the year, potential evaporation rates exceed rainfall throughout most of the summer months. In Scandinavia, the growing season is much shorter and so early sowing cannot be practiced to moderate the effects of summer drought periods. In Denmark, SI is needed nearly every year on sandy soils to maintain a stable production and 15% of the agricultural land is grown under irrigation.[4]

In temperate humid and subhumid environments, where water deficit is occasional, generally terminal and/or of short duration, SI is used by farmers to stabilize yield and quality at higher levels (to improve profits), and to maintain crop uniformity. In drier environments, SI can be considered to be more a dry farming technique since it contributes to optimize the use of limited water resources:[2] its purpose is to prevent complete yield loss (through irrigation at sowing, in exceptionally dry years) or to improve yield in years not excessively dry (by irrigation during shooting). In every case, SI is a means of insuring farmers against climatic risks.

SI SCHEDULING

The strategy of applying restricted amounts of water based on the amount and distribution of rainfall in addition to the incremental effect of water on crop yield is the essence of the SI concept.[5]

Either because irrigation volume (or discharge) is limited (dry winter season, low storage capacity of reservoirs, equipment not available, etc.) or because soil-water deficit is moderate, SI generally results in a limited number of water applications. The goal of these applications is either to save crop life but more generally to improve the efficiency of the other inputs.[5] Positive impacts are expected such as: sowing in due time, assurance of an uneven and minimum plant emergence, more efficient placement and use of fertilizers, thus limiting soil N leaching and residue at harvest, use of high-yielding cultivars and avoidance of moisture stress for plant, particularly during the initial stages of its development in semiarid regions, later (around flowering) in wetter regions.

For instance, in the West Asia–North Africa (WANA) region, with a Mediterranean-type climate, wheat production is increasingly declining. Cereal yields are low and variable in response to inadequate and erratic seasonal rainfall (350 mm rainfall and above) and related management factors, such as lack of nitrogen and late sowing. It is clear that small amounts of SI water can make up for the deficits in seasonal rain and produce satisfactory yields.[6] A minimum yield of more than 3.5 Mg/ha is guaranteed for wheat with an amount of irrigation varying from 50 mm to 200 mm depending on the root zone soil water and the amount and distribution of the seasonal rainfall, whereas the average yield is below 1.5 Mg/ha under rainfed management.[1] An addition of only limited irrigation (1/3 full irrigation) may achieve over 60% of the potential increase in yield with full SI. In addition, use efficiency for both soil water and nitrogen is greatly increased by SI. Oweis, Pala, and Ryan[6] observed a wheat yield increase up to a fertilizer input of 100 kg N/ha under SI management in Syria, while optimum response for rainfed conditions was with 50 kg N/ha.

In southwestern France, under a temperate subhumid climate, grain yield was increased by 17%, 27%, 37%, and 70% for sunflower, sorghum, soybean, and maize respectively, with an irrigation amount of 120 mm (supplied around flowering) when compared to rainfed management during nine years on a deep silty-clay soil.[7] This shows the differential sensitivity of spring-sown crops to SI as related to ecophysiological traits such as depth and extraction efficacy of rooting system, drought tolerance mechanisms (sunflower and sorghum), indeterminate reproductive period (for soybean) acting as an escaping strategy.

With limited available water, the challenge is to satisfy crop water demand at the critical (and most responsive) stages. An extensive review of specific periods for optimizing irrigation was made by FAO.[8] For instance, the most sensitive stages of wheat to water stress are the booting and the early earing stage from some research, and the preflowering and ear formation stages according to other research, whereas seed germination and crop emergence periods are only exceptionally considered to be sensitive to water stress.[2] The decision of irrigation at a given growth stage depends on the crop sensitivity to water stress, on the climatic pattern and on the need to exploit natural water resources. Irrigation on cereals in autumn during dry sequences aims at ensuring an optimal plant density and a satisfactory root establishment in order to fully use soil water reserves later but also to cover rapidly the soil surface for controlling soil evaporation and maximizing early radiation interception and biomass accumulation.

In semiarid regions, when a single application is available for sunflower, it should be placed either at presowing (soil refillment, crop establishment) or between flower bud appearance and flowering (to increase leaf area index) while in wetter areas, one irrigation is generally recommended after anthesis to enhance the leaf area duration and favor oil production.

SI METHODS

The irrigation methods usable for SI must satisfy the following specifications:[2] low equipment cost per ha of irrigated land, high degree of transferability from one field to another, limited labor to set up the irrigation system, high water distribution efficiency, possibility to bring limited water amounts (20–50 mm) timely and accurately at specific growth stages.

For these reasons, in rainfed systems, sprinkler irrigation (travelling rainguns, for instance) seem to be the most flexible for field crops while, for vegetables and fruit trees, drip irrigation may be more suitable. The source of water is generally small reservoirs (run-off and rainwater harvesting) but deep groundwater is also used.

NEED FOR MODELS

In the last 15 years, on the basis of ecophysiological studies, numerous soil-plant models (either crop-specific or generic) have been developed to simulate the response of major crops to water use. By running on long-term weather records, these mechanistic models, more or less complex, are useful to determine a probabilistic response of grain yield to SI, in interaction with crop management (sowing date, cultivar, crop density, N-fertilization), and to define at field or farm level the optimal irrigation schedules under limited water management (e.g., Refs.[4,9–11]).

At farm level, linear programming models have been developed to optimize the crop planning and to allocate scarce water between competing fields, according to the response of yield relatively to crop water requirements (resulting from mechanistic models or from simple production functions), to stochastic distribution of rainfall, to input availability (labor, equipment, water), to cost of production (water, other inputs), and to crop value.[12,13] Such models can be used to test if limited amounts of irrigation water can be used more efficiently by applying small amounts to more land than by fully irrigating less land, or to predict the optimal cropping pattern under SI.

To conclude, SI cannot be restricted to a simple problem of tactical decision at field level (''when and how much water to apply on this field?'') but has to be considered also as a major strategical decision at farm level (''which fields and which crops to irrigate using what type of equipment?'').

Irrigation: Surface

Wynn R. Walker
Biological and Irrigation Engineering Department, Utah State University, Logan, Utah, U.S.A.

INTRODUCTION

Surface irrigation, also referred to as ''flood irrigation,'' is the oldest and most common method of applying water to croplands. There are three broad classifications: 1) basin irrigation; 2) border irrigation; and 3) furrow irrigation. Each classification can be distinguished on the basis of shape, slope, and field boundaries. It is important to understand that references to the ''surface irrigation system'' may include more than the individually irrigated field. Specifically, the irrigation system may consist of four subsystems, as illustrated in Fig. 1. These are: 1) the water supply subsystem; 2) the water delivery subsystem; 3) the water use subsystem (field); and 4) the water removal (drainage) subsystem.[1] Thus, the terms basin, border, and furrow irrigation are specific configurations of the water use subsystem. Optimizing basin, border, or furrow irrigation practices requires that each component of the irrigation system be designed, constructed, maintained, and operated effectively.

TYPES OF SURFACE IRRIGATION SYSTEMS

The advantages and disadvantages of a specific surface irrigation configuration depend on a number of factors. For example, the need and extent of land leveling for furrow irrigation are much less than for basin irrigation. Very small or irregularly shaped fields are more easily irrigated with basins than furrows. The infiltration characteristics of the soil combined with the nature and availability of the water supply in terms of flow rate and duration may favor one method over another. The density and arrangement of the crop as well as the season-to-season cropping pattern will impact the method of applying water; and, the historical traditions of the irrigators may suggest one method over another.

Basin Irrigation

Two typical examples of basin irrigation are shown in Fig. 2. Basins are level fields with perimeter dikes to prevent runoff. To distinguish them from level borders (discussed in ''Border Irrigation''), basins tend to be squarer in shape while level borders are more rectangular.

The most important design parameter for basins is the inflow rate per unit width of the basin (unit discharge). Basins require a high unit discharge. Most soils can be irrigated by basin systems although soils with a moderate to low infiltration rate result in the best efficiency and uniformity. Basin systems typically apply a relatively large depth of water during irrigation and thus deep-rooted, closely spaced crops are best suited for this type of irrigation. Crops, which cannot be inundated for extended periods, should be planted on raised beds or furrows.

There are three important advantages of basins: 1) they are effective and efficient methods of leaching salts from the soil profile; 2) they are easily automated with relatively simple flow controls at the basin inlet; and 3) they can achieve efficiencies and uniformities which equal or exceed those of sprinkle systems without the corresponding investment in energy.

Border Irrigation

Borders are somewhat like basins though they are rectangular or contoured fields. They typically have a longitudinal but cannot have a lateral slope. They may be free draining or blocked at the lower end. Fig. 3 illustrates three typical border irrigation systems.

Borders are suited for most crops and perform well on soils with moderately low to moderately high infiltration characteristics. If the soil crusts easily, borders can be furrowed, so, plants are grown on raised beds. If the border is not diked at the lower end, substantial tailwater losses may occur as illustrated in Fig. 4. Free-draining borders exhibit high application uniformities but generally are less efficient than sprinkle systems. Blocked-end borders enjoy the same high uniformities and efficiencies as basins and have further advantage of better field drainage in cases of excess rainfall or errors in irrigation duration.

Furrow Irrigation

By ''furrowing,'' ''creasing,'' or ''corrugating'' a field surface and then regulating a flow to each furrow,

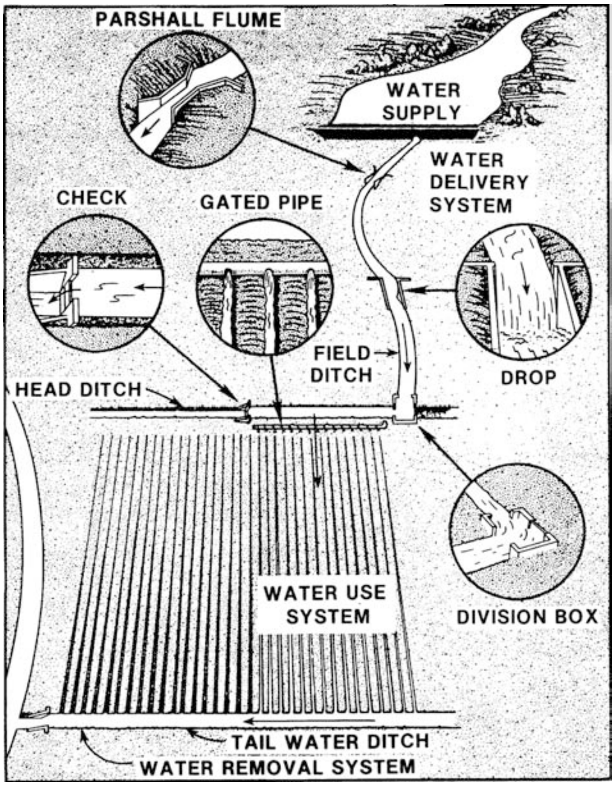

Fig. 1 Typical elements of a surface irrigation system. *Source*: From Ref.[1].

Fig. 2 Two illustrations of common basin irrigation systems: (A) a basin in Southeast Asia; and (B) A basin in central Utah. (Utah State University Irrigation Photo Archives.)

a field can be watered with substantially less flow and can have slopes in both the longitudinal and transverse directions. Water flowing in the furrow infiltrates through the wetted perimeter and moves vertically and laterally thereafter to refill the soil reservoir. As noted above, furrows can be used in conjunction with basins and borders, which should be referred to as "furrowed" borders or basins. A typical furrow irrigation system is shown in Fig. 5.

Furrows provide somewhat better flexibility in on-farm water management, achieve the same high uniformities as basins and borders, and require less land leveling to implement. Furrow systems require more farm labor and thus tend to be less efficient than basins and borders. Flow rates per unit width can be substantially reduced and topographical conditions can be more severe and variable. Furrows provide operational flexibility important for achieving high efficiencies for each irrigation throughout a season by regulating the flow into each furrow. It is a simple (although labor intensive) matter to adjust the furrow stream size to changing intake characteristics by simply changing the number of simultaneously supplied furrows. Two of the more common ways in which water is introduced to furrows are shown in Fig. 6.

In a general situation, furrows are less efficient that either basins or borders, primarily because of the difficulty in setting the proper flow rate into each furrow and thus causing either too much deep percolation or too much tailwater. Salts can accumulate between furrows, which are used for a long period of time. The additional tillage associated with construction of the furrows adds costs to the farm operation. Finally, the danger of erosion from furrow irrigation is higher than with either basins or borders.

IMPROVING THE OPERATION AND MANAGEMENT OF SURFACE SYSTEMS

Walker and Skogerboe[2] describe the surface irrigation water management in the following terms.

> Even though it is the oldest and most common method of irrigation, surface irrigation is the least amenable to consistently high levels of performance. Of all the reasons why this is so, probably none have the significance that is associated with the uncertainty of soil infiltration rates. The rate at which water will be absorbed through the soil surface is a non-linear process which

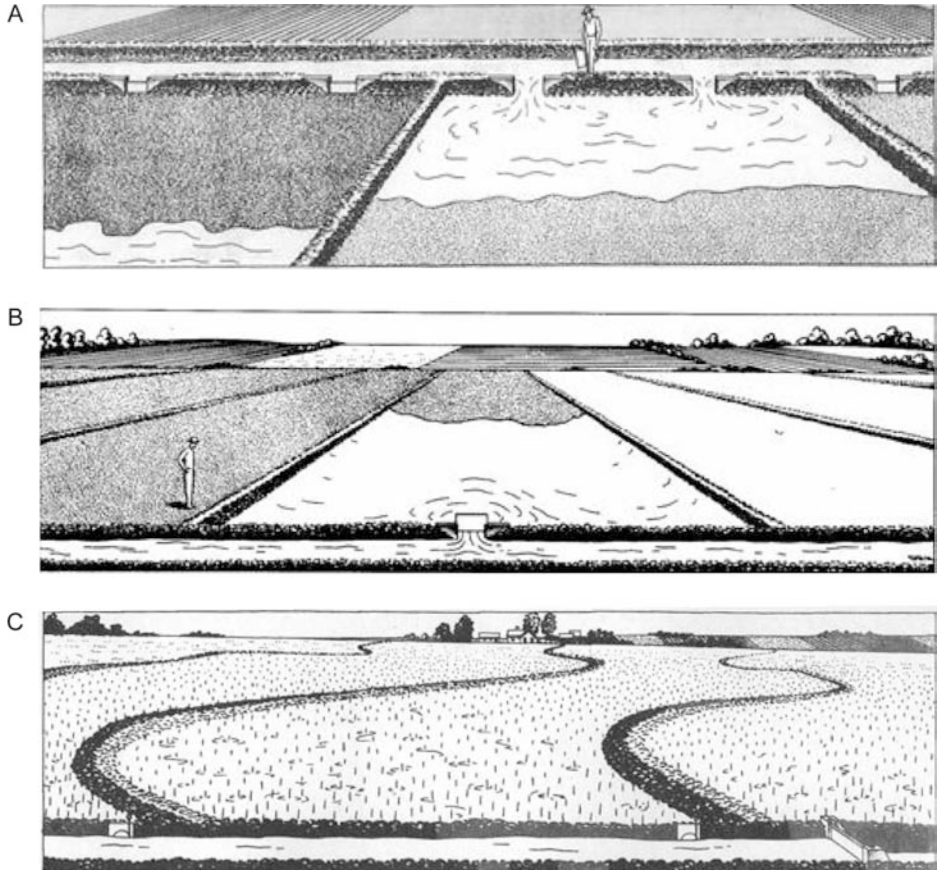

Fig. 3 Examples of border irrigation systems: (A) Typical graded border irrigation system; (B) typical level border irrigation system; and (C) typical contour levee or border irrigation system. *Source*: From Ref.[1].

varies both temporally and spatially. It is affected by year-to-year changes in cropping patterns, cultivation, the weathering due to climate, and many other unknown influences. As a result, neither the irrigator nor the engineer can accurately predict the uniformity and efficiency of an irrigation before it occurs, particularly the first water application following planting. There are other factors limiting surface irrigation system performance, such as a relative lack of standardized equipment for regulation and automation. These and the intake variability noted above place particular emphasis on the management practices applied to surface irrigation, and the art of surface irrigation management is very important.

Fig. 4 Tailwater runoff under border irrigation. (Bureau of Reclamation Photo: www.yao.lc.usbr.gov/WaterConser/ConservationDefined.htm.)

Fig. 5 A typical furrow irrigation system. (Utah State University Irrigation Photo Archives.)

There are four ways in which the operation and management of basins, borders, and furrows can be improved: 1) improving the management of flow and time of cutoff; 2) precision leveling of the field surface; 3) blocking the end of the field; and 4) water recovery and reuse.

Regulating Inflow and Time of Cutoff

The irrigator of a free-draining surface irrigation system must balance the need for a high inflow to achieve uniform water application against a low inflow to minimize tailwater losses. The intake opportunity time at the end of the field plus the time required for the inflow to reach the end of the field dictate a unique time of cutoff. If the inflow can be reduced (cutback) when the water has advanced to the end of the field, then the advantages of both a high flow during advance and a low flow to reduce tailwater can be met. One of the most promising ''cutback'' practices is surge flow in which the inflow is rapidly cycled on and off to create a ''time-averaged'' reduction in inflow.

Precision Land Leveling

There are few practices as important to surface irrigation performance as precision land leveling, grading, or smoothing. The advent of laser guided equipment as shown in Fig. 7 has improved land surface preparation by at least an order of magnitude over historical

Fig. 6 A common method of supplying water to furrows using siphon tubes. (Utah State University Irrigation Photo Archives.)

Fig. 7 Laser guided land leveling equipment. (Utah State University Irrigation Photo Archives.)

practices. The impact on surface irrigation uniformity and efficiency has been very high. It is not unusual to hear an irrigator state that the most important part of surface irrigation is ‘‘lasering.’’

Blocked-End Systems

An alternative to reducing the inflow at the end of the advance period as a way to reduce tailwater losses is simply to block the end of the field and prevent the runoff from occurring. This is a common feature of basins and the reason for their high performance. It is less common in borders and furrows because of the risk of crop damage at the lower end of the field due to lengthy ponding. With proper regulation of inflow and time of cutoff, excessive ponding can be prevented or an emergency drain may be necessary to remove excessive ponding. In any event, the application efficiency of blocked-end systems is usually 15–20% higher than free-draining systems. Blocked-end systems should have fairly low field slopes if ponding is a problem.

Wastewater Recovery and Reuse

In some areas, the tailwater problem can be resolved by constructing a small reservoir at the end of the field, capturing the runoff, and then reusing it elsewhere on the farm. This is a particularly useful practice where irrigators must control sediments, pesticides, and fertilizer runoff as well. Fig. 8 shows a typical tailwater pond.

Fig. 8 A typical tailwater recovery and reuse facility. (Utah State University Irrigation Photo Archives.)

CONCLUSION

Surface irrigation is critically important to the production of the world's food and fiber. Advances in design, management, and field preparation have made surface irrigation systems as efficient as alternatives such as sprinkle irrigation. Surface irrigation is labor intensive, but requires low energy inputs making this method of watering crops more advantageous in developing countries than in countries like the United States. As the world population increases over the next two or three decades, improving the efficiency of surface irrigation systems to their potential will be one of the most important water management tasks that arid and semiarid regions will face.

Isotopes

Michael A. Anderson
Department of Environmental Sciences, University of California–Riverside, Riverside, California, U.S.A.

INTRODUCTION

The substance we know as water (H_2O) is actually comprised of a number of isotopes of O and H. Isotopes are atoms that have the same number of protons and electrons, and therefore the same basic chemical properties, but differ in their mass. Their differences in mass arise due to different numbers of neutrons within their nucleus. Isotopes can be stable or radioactive, and can be both naturally occurring and man-made. Six different isotopes of hydrogen and oxygen are found in nature (Table 1).

BACKGROUND

The heavy isotopes of oxygen (^{17}O and ^{18}O) were discovered by Giaugue and Johnston.[2] Shortly thereafter, an isotope of hydrogen (^{2}H) was discovered by Urey, Brickwedde, and Murphy[3] for which Urey received the Nobel prize. The isotope was called deuterium and is often written as D. A third isotope of hydrogen (^{3}H, tritium), postulated to exist in 1931, was detected in natural waters in 1950.[4,5]

All of the above isotopes are stable, except for tritium (^{3}H), which is radioactive and decays yielding a β^- particle to form ^{3}He. The half-life of tritium is 12.43 yr. Tritium is produced naturally in the upper atmosphere by reaction with cosmic radiation to produce $\sim$0.25 atoms cm^{-2} sec^{-1}.[6] Substantially higher amounts of ^{3}H were released to the atmosphere with the above-ground nuclear weapons testing of 1953–1962 that ended with the nuclear test ban treaty ratified in 1963. The peak concentration of ^{3}H in precipitation reached levels shortly before the treaty as high as 10^{-12}% or 1000 $\times$ higher than concentrations from natural cosmogenically produced ^{3}H.[7]

The above isotopes can form a total of 18 different species of water, with the natural abundance of the 4 major species given in Table 2.

While the above isotopes of water are chemically essentially the same, there are nevertheless subtle differences in their physical and chemical properties. For example, the density of water is influenced by its isotopic composition. ‘‘Light’’ or normal water ($^{1}H_2^{16}O$) has a lower atomic weight, and therefore also a lower liquid density than ‘‘heavy water’’ ($^{2}H_2^{16}O$ or, more simply, D_2O) (Table 3). The temperature at maximum density, boiling point, vapor pressure, and freezing point are also dependent upon the isotopic composition and mass of water (Table 3).

Viscosity is also higher for the heavier isotopes of water (e.g., the viscosity of D_2O at 25°C is 1.095 cP, while that for $^{1}H_2^{16}O$ is 0.890 cP). Moreover, intramolecular vibrational frequencies, which are influenced by mass of the atoms forming a chemical bond, are also sensitive to the isotopic composition of water. Thus, ‘‘heavy water’’ ($^{2}H_2^{16}O$ or, more simply, D_2O) exhibits lower frequencies of vibration than ‘‘light water’’ ($^{1}H_2^{16}O$).

The above noted differences in vapor pressure between different isotopes of water have implications for the partitioning of isotopes between the gas and liquid phases. That is, since ‘‘light’’ molecules of water ($^{1}H_2^{16}O$) are more volatile than those containing a heavy isotope, molecules evaporating from water are enriched in ‘‘light’’ isotopes and depleted in the heavier isotopes. The relative enrichment or depletion in heavy isotopes is commonly expressed as a δ-value (in ‰ or parts per thousand/per mil), defined as:

$$\delta(‰) = \left(\frac{R_x}{R_{ref}} - 1\right) \times 1000$$

where R denotes the abundance ratio of the heavy to light isotope (e.g., $^{2}H/^{1}H$), and R_x and R_{ref} are the ratios in the sample and the reference standard. The reference for oxygen and hydrogen isotopes in water is taken to be the so-called VSMOW or Vienna Standard Mean Ocean Water. As a result, water evaporated from the ocean is depleted by $\sim$12‰–15‰ in ^{18}O (denoted $\delta^{18}O$) and by $\sim$80‰–120‰ in ^{2}H relative to the source ocean water.

Subsequent cooling and condensation of water vapor evaporated from the ocean preferentially removes the less volatile, heavy isotopes of water. Thus, clouds and precipitation are enriched in the heavy isotopes of water, while the remaining vapor is depleted in ^{2}H and ^{18}O. Moreover, the temperature of formation of droplets and precipitation also influences the isotopic composition of rain.[8] Thus, winter precipitation is depleted in heavy isotopes relative to

Table 1 Isotopes of hydrogen and oxygen

Isotope	Weight (amu)	Natural abundance (wt %)
^{1}H	1.0078	99.970
^{2}H	2.0141	0.030
^{3}H	3.0160	10^{-15}
^{16}O	15.9949	99.732
^{17}O	16.9991	0.039
^{18}O	17.9992	0.229

summer, high latitude precipitation is depleted relative to that formed at lower latitudes, and high altitude precipitation is depleted in heavy water relative to that formed at lower altitudes. These differences have been exploited in a wide range of hydrological, geological, and environmental studies.

ENVIRONMENTAL APPLICATIONS OF ISOTOPE ANALYSES

Hydrological Studies

The history, age, and pathway of water within the hydrologic cycle can be inferred from the relative abundance of ^{2}H, ^{3}H, and ^{18}O in water. The isotopic composition of groundwater can be used to determine recharge to an aquifer, including the source area and rate of recharge. The source area can be identified by the ^{2}H and ^{18}O concentrations in the groundwater and correlating them with the altitude at which precipitation infiltrated the soil. For example, Friedman and Smith[9] reported an ~40‰ decrease in ^{2}H for every 1000 m increase in altitude on the west slope of the Sierra Nevada range in California. This trend, along with the so-called "Continental Effect" is shown for the western United States in Fig. 1.[10]

The mechanism for the "Continental Effect" is the same as that for altitudinal effects, that is, the raining out of heavier isotopes, leaving vapor and subsequent precipitation isotopically lighter as one moves inland.

In a somewhat different way, the rate of recharge can be estimated by quantifying the tritium concentrations in the subsurface. Specifically, a peak ^{3}H concentration associated with nuclear weapons testing would correspond to ~1962, and thus its location beneath the land surface would yield a travel distance over approximately 40 yr. For example, Cook et al.[11] have used observed ^{3}H transport to estimate effective unsaturated hydraulic conductivities and recharge rates within arid zone soils in Australia.

The rate of movement of nutrients, pesticides, and other chemicals within the subsurface has also been quantified in laboratory and field experiments through co-application of $^{3}H_2O$. The breakthrough or transport of the chemical relative to that of tritiated water provides a direct measure of chemical transport and the extent of reaction and retardation within the soil. For example, Gupta, Destouni, and Jensen[12] recently compared phosphorus and tritium transport in structured soil and found that 60%–100% of the water flow was associated with 25%–40% available flow paths. Moreover, preferential flow increased phosphorus mass transport by 2–3 × than without preferential flow. It should be noted, however, that such studies require careful consideration of safety and other issues.

Paleoclimate and Climate Change Studies

The relative differences in vapor pressure of heavy and light water and the temperature induced differences in isotopic composition of water referred to above make it possible to infer past climatic conditions. For example, Johnsen et al.[13] used ^{18}O composition of ice cores from Antarctica and Greenland to estimate climatic conditions over the past ~100,000 yr. Their study clearly shows colder temperatures from about 70,000 yr to 12,000 yr before present (B.P.), corresponding with the Wisconsin glaciation (Fig. 2).

Table 3 Some properties of different isotopes of water

Species	Density$_{max}$ (kg m^{-3})	Temperature at density$_{max}$ (°C)	Boiling point (°C)	Freezing point (°C)
$^{1}H_2^{16}O$	999.97	3.984	100.0	0.0
$^{2}H_2^{16}O$	1106.00	11.185	101.4	3.8
$^{1}H_2^{18}O$	1112.49	4.211	NA	NA
$^{3}H_2^{16}O$	1215.01	13.403	NA	NA

Source: From Ref.[1].

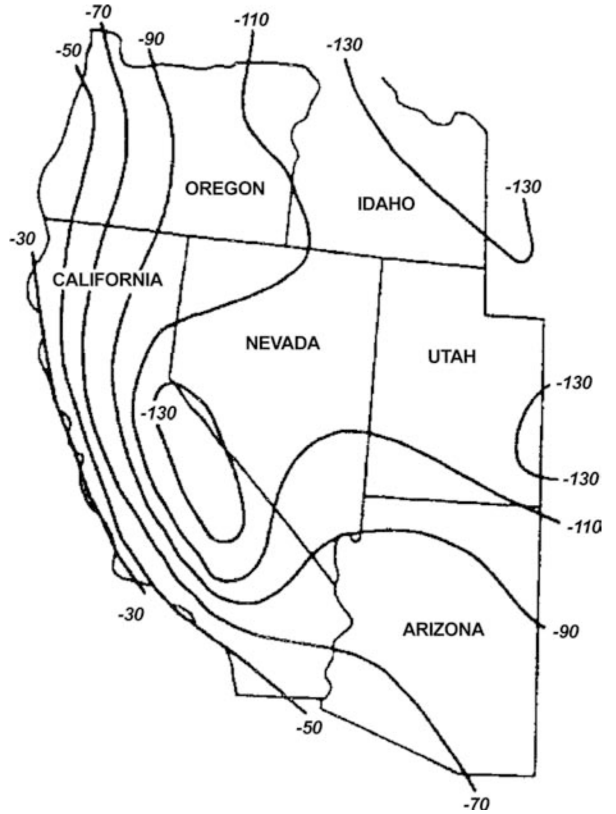

Fig. 1 Isotopic composition of ^2H in precipitation in the western United States.[10] (From Elsevier Science.)

The paleotemperatures of the ancient oceans have been estimated from the oxygen isotope distribution between $CaCO_3$ and water.[14] That is, $CaCO_3$ is enriched in ^{18}O relative to ocean water. Moreover, the relative enrichment, as with other isotopic fractionation reactions, is dependent upon the temperature at which it formed. Thus, the ^{18}O content of $CaCO_3$ provides a record of the ocean temperature at the time it was laid down. Such analyses have demonstrated significant variations in the ocean temperature over the past 700,000 yr.[15] Analyses by Woodruff, Savin, and Douglas[16] show greater variations over the past ~20 million yr.

Paleoclimatic information on the continents is available from the ^{18}O signature of biogenic apatite[17] and $CaCO_3$ deposits in caves.[18] The $\delta^{18}O$ values of snail shells have also been used.[19]

The isotopic composition of rocks and minerals also provides important information about the conditions at the time of their formation or alteration. For example, the clay minerals in soils over large regions of the United States formed during the Tertiary period under warmer conditions than those of the present.[20] Furthermore, limestone deposited in freshwater environments is depleted in ^{18}O relative to those formed in marine settings, reflecting differences in the ^{18}O status of the two types of waters.

INTRODUCTION

To understand a field of study, you must read its literature, including the bulwark of any discipline, its scholarly journals. Capturing the breadth of hydrologic sciences literature that addresses agricultural issues requires exploring a variety of journals. While there may be overlap in topical coverage, each journal fills a particular subject matter and readership niche. This article focuses on key journals in the hydrologic sciences, especially those covering agricultural issues.

OVERVIEW OF JOURNALS

Scholarly journals are a means of sharing information in a given field. Journals serve to expand the knowledge base of a subject. Journal articles in hydrologic science—a multidisciplinary field that focuses upon the occurrence, movement, and properties of water—describe experimental studies and their implications, discuss theoretical approaches or analyze the ramifications of public policy. A special type of journal article—the literature review—synthesizes the findings of seminal publications on a given topic. A literature review, like other journal articles, includes a list of publications referenced in the article. Journals may also publish commentaries or letters to the editor on issues relevant to the field or on previously published articles.

Journal articles are written by researchers from academia, government, and the private sector. Published articles are often viewed as a measure of professional productivity. Institutions gain prestige when their employees' articles are published in respected scholarly journals.

People who need to stay abreast of developments in their fields read or review scholarly journals and articles of interest. Researchers learn about advancements in experimental techniques or theories. Reported findings and methodologies influence how researchers approach their own scientific inquiries. Educators acquire information to keep their courses current. Decision makers obtain unbiased scientific bases for recommending or implementing actions. Undergraduate and graduate students gain knowledge in their fields by reading and studying scholarly articles.

Most journals in the hydrologic sciences are published by either commercial scientific publishers or professional societies. Publication schedules vary, as do subscription prices. Online versions of journals are increasingly available. Publishers often allow nonsubscribers online access to tables of contents, abstracts, or sample issues. Libraries at institutions with departments involved with hydrologic sciences have print and/or online subscriptions to relevant journals.

SPECIFIC HYDROLOGIC SCIENCE JOURNALS

Table 1 lists hydrologic science journals that are important for the agricultural sector. These journals cover hydrologic science issues beyond agriculture, but they publish many agriculturally related articles. There are journals for hydrologic sciences in addition to those listed in Table 1, but they have less relevance to agriculture.

Relevant articles concerning water resources and agriculture can also be found in broader environmental publications and in the agricultural literature. See Tables 2 and 3 for a sampling of germane journals in these fields. In addition, journals in fields such as meteorology, climatology, limnology, aquatic biology, and forestry are sources of related information.

Tables 1–3 also provide the World-Wide-Web address of each journal's publisher. Visit the Web sites of the respective journals to obtain detailed information about each journal, including frequency of publication, subscription cost, and scope of coverage. Most journals also provide this information in each issue. Indexes to journal articles are usually published in the last issue of a volume. Articles can also be located by using abstracting and indexing services such as the Water Resources Abstracts and AGRICOLA

databases. There is a trend for online indexes to hyperlink directly to journal articles when those articles are available electronically.

Reference directories, such as *Ulrich's International Periodicals Directory* and the *Serials Directory: An International Reference Book*, available in paper or online at many libraries, are other good sources of information on particular journals. These directories are also useful for finding information about journal name or publisher changes.

Additional information about several journals representative of the literature is provided below. These journals were recommended by knowledgeable professionals working in various areas of water resources and agriculture. The brief descriptions are based on reviews of recent issues and information published in the journals and their respective Web sites. See these sources for additional information.

Examples of Journals for Hydrologic Sciences Covering Agricultural Issues

Agricultural Water Management: an international journal. 1977–present. 15/yr. Elsevier Science BV, P.O. Box 211, 1000 AE Amsterdam, Netherlands. http://www.elsevier.com/. ISSN: 0378-3774.

Readers of this international journal include agricultural engineers, agricultural hydrologists, and agronomists. Research articles on various aspects of irrigation are a major theme of the journal. Other areas covered include drainage, erosion, and water quality. Theme issues, such as "The Use of Water in Sustainable Agriculture," are occasionally published.

Journal of the American Water Resources Association. 1965–present. Bi-monthly. American Water Resources Association, P. O. Box 1626, Middleburg, VA 20118-1626. http://www.awra.org/. ISSN: 0043-1370.

Formerly known as the *Water Resources Bulletin*, the main focus of this journal is on water resources management issues of broad interest. The journal organizes articles under one of three categories: "Dialogue on Water Issues," "Technical Papers," and "Discussion Papers" (and replies). Articles in the "Dialogue" section cover policy and critical management issues. The "Technical" section contains articles on subjects such as phosphorus and wetlands, stream channel instability, and artificial neural networks for subirrigation systems. Comments on earlier articles are published in the "Discussion" section, along with replies from the original author(s). Special issues, such as "Water Resources and Climate Change," are sometimes published. *Impact* is a sister publication of the journal that focuses on a single theme for each issue. Articles address timely issues for water resource professionals.

Journal of Hydrology. 1963–present. 56/yr. Elsevier Science BV, P.O. Box 211, 1000 AE Amsterdam, Netherlands. http://www.elsevier.com/. ISSN: 0022-1694.

Water, Air and Soil Pollution	www.wkap.nl/

This journal, with U.S. and international editors, publishes highly technical research papers, and comprehensive reviews in the hydrologic sciences. Topics include the "physical, chemical, biogeochemical, stochastic and system aspects of surface and groundwater hydrology, hydrometeorology, and hydrogeology." Articles may be of an empirical, theoretical, or applied focus. Theme issues are sometimes published.

Journal of Soil and Water Conservation. 1946–present. Quarterly. Soil and Water Conservation Society, 7515 N. E. Ankeny Rd., Ankeny, IA 50021. http://www.swcs.org/. ISSN: 0022-4561.

Published by a professional society whose members include soil and water conservation professionals, researchers, planners, educators, administrators, and others, this journal focuses on the conservation, improvement and sustainable use of soil, water and related natural resources worldwide.

Journal issues contain primarily "Features" and "Research" articles. The former are overview and synthesis articles, including literature reviews, while the latter report on specific research studies. Articles in both sections address a broad range of soil and water conservation topics and include articles focussing on social sciences and economics. The general emphasis of the journal is on agricultural and other rural lands. The journal also publishes commentaries from readers, a listing of future conferences and some advertisements, including employment opportunities. A less technical, magazine-style sister publication, *Conservation Voices*, also covers soil and water conservation topics. In January 2002, *Conservation Voices* and the *Journal of Soil and Water Conservation* will be merged into a single journal published six times a year.

Water Resources Research. 1965–present. Monthly. American Geophysical Union, 2000 Florida Ave. N. W., Washington, DC 20009. http://www.agu.org/. ISSN: 0043-1397.

This is an interdisciplinary journal that covers research in the social and natural sciences related to

water. The journal publishes articles in scientific hydrology covering the biological, chemical, and physical sciences as well as economics, sociology, and law.

There are deputy editors for erosion, sedimentation, and geomorphology; geochemistry and geobiology; groundwater; surface water; vadose zone; and water policy, economics and systems analysis. Many articles are theoretical.

Examples of Environmental Journals that Cover Water and Agriculture

Agriculture, Ecosystems and Environment. 1974–present. 15/yr. Elsevier Science BV, P.O. Box 211, 1000 AE Amsterdam, Netherlands. http://www.elsevier.com/. ISSN: 0167-8809.

Covering the interface between agriculture and the environment, *Agriculture, Ecosystems and Environment* promotes interdisciplinary approaches to research. The journal is aimed at scientists studying many aspects of agricultural ecosystems. Papers in this journal have covered topics such as water availability and use, non-point-source pollution, and seasonal flooding. Special issues are occasionally published, including an issue on sustainable land management.

Agriculture, Ecosystems and Environment is an amalgamation of two earlier journals, *Agro-Ecosystems and Agriculture* and *Environment*. A section of *Agriculture, Ecosystems and Environment* is currently published as *Applied Soil Ecology*. Both journals are included in the same subscription.

Journal of Environmental Quality. 1972–present. Bi-monthly. American Society of Agronomy, 677 S. Segoe Rd., Madison, WI 53711. http://www.agronomy.org/. ISSN: 0047-2425.

The professional societies, American Society of Agronomy, Crop Science Society of America and Soil Science Society of America, cooperatively publish the *Journal of Environmental Quality*. The journal contains research and review articles on topics covering agricultural and natural ecosystems. A section of the journal, headed "Environmental Issues," contains articles from "a combination of scientific, political, legislative, and regulatory perspectives."

Water, Air, and Soil Pollution: An International Journal of Environmental Pollution. 1971–present. 32/yr. Kluwer Academic Publishers, P.O. Box 17, Dordrecht, 3300 AA, Netherlands. http://www.wkap.nl/. ISSN: 0049-6979.

All aspects of the biological, chemical, and physical processes of environmental pollution are covered by this interdisciplinary journal. *Water, Air, and Soil Pollution* includes articles on wastewater irrigation, forest management, and nitrate depletion. Other papers published in the journal include those describing methods used to study and measure environmental pollutants.

Examples of Agricultural Journals that Cover Hydrologic Sciences

Journal of Irrigation and Drainage Engineering. 1956–present. Bi-monthly. American Society of Civil

Engineers, 1801 Alexander Graham Bell Dr., Reston, VA 20191. http://www.pubs.asce.org/. ISSN: 0733-9437.

This journal covers research on "engineering hydrology, irrigation, drainage, and related water management subjects, such as watershed management, weather modification, water quality, groundwater, and surface water." Articles appear in three categories: "Technical Papers" discuss experimental results and conclusions or analytical approaches to water management problems. Shorter articles, or reports of preliminary research results, are published in "Technical Notes." The "Discussion" section contains short pieces that offer substantive comments on previously published papers and includes a closure response from the original author(s). The journal was formerly known as the *Journal of the Irrigation and Drainage Division, Proceedings of the American Society of Civil Engineers*.

Soil Science Society of America Journal. 1936–present. Bi-monthly. Soil Science Society of America, 677 S. Segoe Rd., Madison, WI 53711. http://www.soils.org/. ISSN: 0361-5995.

The table of contents for this journal, formerly *Soil Science Society of America Proceedings*, divides the articles into several different subject categories. While the section on "Soil and Water Management and Conservation" contains articles most relevant to hydrologic science, other sections may also contain water-related articles.

Articles primarily describe and discuss different aspects of soil science research. Comments on specific articles or other soil science topics are also published, as are the occasional invited essay or review. A list of new soil science books is sometimes published.

Transactions of the ASAE. 1958. Bi-monthly. American Society of Agricultural Engineers, 2950 Niles Rd., St. Joseph, MI 49085-9659. http://www.asae.org/. ISSN: 0001-2351.

Each issue in this journal, from ASAE—the professional society for engineering in agricultural, food, and biological systems—contains a soil and water section. Articles cover a range of water-related topics such as water flow in riparian areas, irrigation efficiency, and nitrate leaching. Topics are approached from various perspectives including computer modeling, engineering design, and scientific investigation. *Resource* is a magazine by ASAE that occasionally publishes articles or short news pieces covering water and agriculture issues.

Karst Aquifers

John Van Brahana
Division of Geology, Department of Geosciences, University of Arkansas, Fayetteville, Arkansas, U.S.A.

INTRODUCTION

Karst aquifers are water-bearing, soluble rock layers at or near the earth's surface in which groundwater flow is concentrated along secondarily enlarged fractures, fissures, conduits, and other interconnected openings. They are formed by the chemical dissolving action of slightly acidic water on highly soluble rocks, most notably limestone and dolomite, and to a lesser degree, gypsum, anhydrite, and halite. For the processes of karst to be active, water must dynamically circulate through these soluble rocks—exposing the rock to interaction with water and enabling transport of solutes, and the water must be undersaturated with respect to the chemical constituents of the rock—enabling dissolution to occur. This interplay of flow (hydrology) and dissolution (geochemistry) removes rock, creating increasingly larger voids along the pathways the water follows through time. Karst aquifer development commonly results in distinctive landforms, but visible surface features are not an essential attribute of karst, because in many instances, the surface features may be covered by soil or regolith. Although karst and karst aquifers most commonly are recognized as having distinctive landforms and topography (e.g., closed depressions, sinkholes, sinking streams, dry valleys, caves, dissolutionally enlarged joints or bedding planes, grikes, karren, and springs), these are indicators of karst rather than definitive elements. Whereas most karst areas express part or all of these features, the key essential element of the karst definition must include "distinctive subsurface hydrology,"[1] characterized by secondarily enlarged flow pathways. Other distinctive hydrology components include a high degree of interconnectivity between surface and groundwater, relatively rapid groundwater flow, great areal and temporal variability of aquifer properties, numerous springs, great susceptibility for contamination from human and natural activities at the land surface, and lack of filtration and attenuation of contamination. Water-bearing rocks with these attributes are likely karst aquifers if they are highly soluble, even if no karst landforms are present.[1]

Karst aquifers are widespread and intensively utilized. Their worldwide occurrence ranges from 12% to 25% of the earth's surface.[1–4] About 25% of the world's population is estimated to rely on freshwater supplies from these aquifers.[3] Fig. 1 shows the dominant regional karst aquifers in the United States in terms of water use, well yields, and spring discharge.[4] Globally, karst aquifers comprise important water resources in, e.g., southern China, southeast Asia, western Europe and the Mediterranean basin, and the Caribbean islands.

MAJOR SOURCES OF KARST INFORMATION

Karst-forming processes can be some of the most dynamic, erosive forces that counterbalance the uplifting forces of tectonics.[5] Karst can be responsible for the most active surface water/groundwater interactions of all aquifer types.[6] Coupled with more than 60 controlling influences (e.g., lithologic, structural, hydrologic, geochemical, and geomorphic), these processes result in the most variable hydrogeology within a single aquifer type of all the earth's rocks.[7] These facts notwithstanding, the hydrology of these aquifers is not unpredictable. Refs.[2,3,8–20] synthesize the current state of understanding of the hydrology of karst aquifers as well as numerical simulation as a hydrogeologic tool. Websites include the National Speleological Society,[21] the Karst Waters Institute,[22] and the Karst Commission of the International Association of Hydrogeologists.[23,24]

UNIQUE ATTRIBUTES OF KARST AQUIFERS

Notable differences between karst and porous media aquifers are: groundwater flow is commonly turbulent in karst, and Darcy's law is not appropriate for quantification in a karst aquifer, except at large scales exceeding several kilometers; groundwater in karst aquifers contains multiple components of flow types, a mix of fastflow and slowflow conditions from the epikarst, the vadose zone, and the phreatic zone; fastflow in karst aquifers dominates advective transport; fastflow paths in karst aquifers are difficult to predict without tracing studies; the interaction between surface water and groundwater in karst lands is more pronounced

Fig. 1 Distribution of karst aquifers in the U.S. *Source*: From Ref.[4].

than in non-karst terrane; allogenic recharge to karst aquifers by subsurface capture of streamflow derived outside of the groundwater basin is common in karst; spring recharge boundaries in karst commonly do not coincide with surface water boundaries; karst aquifers generally exhibit a much wider range of variability of hydraulic characteristics than porous media aquifers (Table 1); hydraulic characteristics can vary areally, in orientation, and temporally, increasing as dissolution progresses, and decreasing as deposition of insoluble sediments occur or chemical precipitation occludes zones of enhanced permeability; karst aquifers commonly have greater hydraulic conductivity but lower storativity than comparably sized non-karst aquifers; water quality in karst aquifers varies temporally, a result of mixing from the different flow components; karst aquifers typically have more permeable, open flow systems, and less chance for filtration and solute retardation; karst aquifers are generally more prone to contamination; karst aquifers tend to concentrate and accumulate flow, whereas porous-media aquifers tend to retain diffusive conditions; springs integrate flow from all parts of a karst aquifer; springs and cave streams are excellent locations to sample characteristic water quality from a karst aquifer; and wells are not a representative way to sample karst aquifers, unless it has been documented that the wells intersect the zones of fastflow.

FACTORS CONTROLLING THE FLOW OF GROUNDWATER IN KARST AQUIFERS

The laws of physics that govern the flow of groundwater in other aquifers apply equally to karst (water flows from areas of high energy to areas of low energy). Groundwater obeys the laws of thermodynamics, always following the path of least resistance.

While all factors responsible for the creation of a karst aquifer are important (Table 2), there is a general hierarchy of relative importance of geologic factors as they affect karst aquifer formation. From most important to less important, one version of this ranking follows.[7] Lithology of the hydrogeologic framework of aquifers and confining beds, including bulk chemical purity, grain size, original porosity and permeability inherited from early diagenesis, layer thickness, sequence thickness, caprock integrity and strength, and vertical variability in permeability, plays an essential role in karst aquifer formation. Simply stated, if no soluble rocks exist, there is no karst. As well as defining the aquifer potential of the rock matrix to be dissolved,

Table 1 Comparison of typical flow and hydraulic characteristics of karst aquifers

Rock type	Primary porosity and permeability	Secondary porosity and permeability	Flow regime	Discharge from large springs
Cavernous limestone	Low porosity low average but highly variable permeability	Low porosity anisotropic; huge permeability in conduits, very low permeability in rock mass	Laminar to turbulent, if deeply buried, may be stagnant	Regional aquifers > 10^3 L sec^{-1} at major springs
Chalk	High porosity, low permeability, intergranular	Usually not significant, usually undeveloped regionally, jointing can be important	Usually stagnant, very sluggish, commonly only local if at all	Commonly confining layers—>10^3 L sec^{-1} or less; 0 L sec^{-1} is common, may be local aquifer if fractured
Dolomite	Low porosity, low to moderate permeability	Variable from diagenetic pin-point porosity to conduit flow. Joints and faults can be important	Variable usually laminar, can be turbulent to sluggish	Vary from confining layers to regional aquifers: 10^1 to 10^2 L sec^{-1}
Marble	Very low, essentially none	Significant if jointed or fractured, solution conduits can develop if flow system complete	Usually laminar where secondary permeability developed—can be variable, turbulent to sluggish	Typically local aquifers yield 10^2 to 10^1 L sec^{-1}, 0 is common

Source: Adapted from Ref.[7].

Table 2 Geologic factors, processes and controls that affect porosity and permeability of karst aquifers

Factor	Processes	Controls	General influence
Diagenetic	Compaction Cementation Pressure solution Solution (includes recrystallization, inversion, micritization)	Original porosity and permeability; original mineralogy; grain size/ surface area; proximity to sea level (uplift or burial); volume and rate of water movement; fluid chemistry: pH, pCO_2 salts in solution; temperature, pressure	Influences initial distribution of porosity and permeability of indurated rock mass. Many of these are geochemical in nature; they occur very early in the history of the rock
Geochemical	Solution (dissolution) Dolomitization Dedolomitization Precipitation Sulfate reduction Redox	Groundwater flux; original porosity and permeability; mineralogy; fluid chemistry: pH, pCO_2, salts in solution, temperature, pressure, mineral-water saturation	Influences later development of porosity and permeability; influences water chemistry
Lithologic-stratigraphic		Layer thickness; sequence thickness; variability in texture (vertical); variability in permeability (vertical); original porosity and permeability inherited from diagensis; bulk chemical purity; grain size	Influences anisotropy of rock mass, thereby resulting in zones potentially more permeable if other geologic factors are favorable
Structural-tectonic	Uplift Tilting Folding Jointing Faulting Metamorphism	Fracture density; openness of fractures; layer (permeability) orientation	Influences orientation of permeability zones. Influences integrity of confining layers. In extreme instances (metamorphism), influences existence of permeability zones
Hydrologic	Dynamic groundwater	Climatic—temperature; climatic—precipitation; depth of circulation; location of boundaries; existence of complete flow systems; flux; initial anisotropy–vertical variation; springs; surface water/groundwater relation; recharge; hydraulic gradient; size of groundwater basin	Influences existence of flow systems. Influences rate of flow system evolution
Weathering geomorphic	Infilling (fluvial and glacial) Unloading	Topography; relief; soil development by sedimentation; cap rock; degree of karstification; base level; surface slope	Influences development of flow systems. Influences destruction of permeability. Influences shallow porosity–permeability development
Historical geologic–chronologic		Sequence of events; duration of events	Influences stage of development of specific permeability zones

Source: From Ref.[7].

lithologic factors influence the anisotropy and heterogeneity of the rock mass, and define zones potentially more permeable and therefore more favorable for flow. For given groundwater conditions, there is a preferential pathway of flow, one that successfully captures increasingly large volumes of flow in the karst system at the expense of other competing pathways. Structural and tectonic factors, including brittle fracture and folding processes, uplift, tilting, and metamorphism, can be very important in karst aquifer development.[2,3,7,9] Structural processes not only influence the orientation of preexisting permeability zones through folding, tilting, and uplift, they also create new pathways in the form of secondary rock fractures (such as joints and faults), both in confining beds and aquifers. Under the extreme conditions of metamorphism, structural processes can obliterate previous permeability by recrystallizing carbonate aquifers into marble. The role of structure in creating vertical short circuits along subsurface flowpaths is almost as important as lithology, but the dimensions are typically smaller by several orders of magnitude, and structure is ranked lower only for this reason. Other factors (Table 2), including hydrologic, geochemical, diagenetic, weathering-geomorphic, and historical geologic–chronologic influences,[7] can be important at a local scale, but owing to the extensive variability of karst aquifers, their role and influence is not ubiquitous regionally.

SINKHOLE FLOODING

Sinkhole flooding is a common problem around karst aquifers, especially in areas where there is rapid development by humans. Construction in a watershed locally modifies the hydrologic budget, inhibiting infiltration in some areas, diverting infiltration to overland flow which is in turn pirated underground at focused recharge points elsewhere. When storms generate more discharge than the karst aquifer can transmit, water levels in the aquifer rise rapidly. Unlike surface streams that have wide flood plains, karst aquifers have relatively narrow, confined boundaries within the rock. The water level of these aquifers reflects the least-constrained dimension, and when more flow is introduced than can pass, water levels rise precipitously (>100 ft), and flood low-lying areas of the karst flow system. Some flood-prone sinkholes are miles from the nearest surface stream or flood plain, and property owners may not realize they are at risk until a flood occurs.[20]

CAVITY COLLAPSE, SUBSIDENCE, AND OTHER ENGINEERING AND CONSTRUCTION PROBLEMS

Collapse of cave passages, underground voids, and more commonly, collapse of the soils and sediments overlying karst bedrock is a natural process that occurs in response to the continual evolution of the enlarging karst ground water-flow system. This process is exacerbated by human activity, including rapid lowering or raising of the water level, changes in runoff chemistry (pH), increased vibrations, and loading the land above the aquifer with buildings and other massive structures. Highways, bridges, dams, buildings, cars, and homes have been lost as karst rocks equilibrate to the loads they support. Millions of dollars in construction have been spent repairing cracks, filling openings, grouting leaks, and otherwise restoring the structures. The most catastrophic sinkhole event in recorded history occurred in December 1962 in West Driefontein, South Africa. Twenty-nine lives were lost by the sudden disappearance of a building into a huge sinkhole that measured more than 180 ft across.[4] Loss of life is not common, but this incident reflects the dynamic, rapid changes that are associated with water resources and hydrogeologic framework in areas underlain by soluble rocks.

CONCLUSION

Karst aquifers occur beneath a significant portion of the earth's surface (from 12% to 25%, depending on one's definition of karst). Karst aquifers are more highly soluble than other rock types, and most commonly include limestones, dolomites, marbles, and evaporites. In fact, given enough time, karst-like dissolution features have been observed in most lithologies. Karst aquifers are unique compared to porous media aquifers in that they are highly variable in water transmission properties, and if flow is concentrated along focused pathways, and the water in the aquifer is aggressive, these aquifers evolve, flowpaths become enlarged, and rapid movement of groundwater becomes the norm. Karst aquifers are more easily contaminated than porous media aquifers; attenuation of contamination in these aquifers typically is minimal, owing to significantly reduced surface area of solid aquifer/water contact Collapse of the cave passages, underground voids, and more commonly, collapse of the soils and sediments overlying the soluble bedrock is a natural process, and the resulting topography that overlies these aquifers typically is characterized by internally drained depressions called sinkholes (dolines).

Karst Aquifers: Water Quality and Water Resource Problems

John Van Brahana
Division of Geology, Department of Geosciences, University of Arkansas, Fayetteville, Arkansas, U.S.A.

INTRODUCTION

Owing to the rapid flow, the open nature of the flow paths, and the general lack of aquifer surface area for water/rock interaction, karst aquifers are more at risk to contamination than porous-media aquifers. Problems typically include lack of attenuation, little or no response time, and unexpected flow directions and plume transport. In addition to water quality problems, catastrophic subsidence and flooding are common problems where soluble rocks occur near land surface.

FACTORS CONTROLLING GROUNDWATER QUALITY IN KARST AQUIFERS

Dissolution is the dominant chemical process in karst aquifers, and water type is controlled by the inorganic reactions of the recharge water and the aquifer matrix.[1–5] In carbonate aquifers, bicarbonate (HCO_3^-) is the dominant anion. Where limestone is the dominant lithology, calcium (Ca^{+2}) is the prevailing cation. Where dolomite aquifers predominate, magnesium (Mg^{+2}) and Ca^{+2} are the dominant cations, typically in a ratio of about 1 : 3, respectively. Carbonate aquifers yield hard water, hardness being a measure of the soap-consuming properties of water, a function of the concentration of Mg^{+2} and Ca^{+2} ions in solution. The chemistry of meteoric recharge water to the aquifer is predominantly a weak (pH 5–7) carbonic acid (H_2CO_3), formed from H_2O mixing with carbon dioxide (CO_2) in the atmosphere and from soil gas picked up in solution during recharge through organic-rich soil and regolith. At some locations, however, such as the area of the Pecos River in west Texas and eastern New Mexico (see Fig. 1) in the vicinity of Carlsbad Caverns, meteoric H_2O has mixed with hydrogen sulfide gas (H_2S) generated by organic matter degradation and oil formation from basins to the east. This reaction formed sulfuric acid (H_2SO_4), resulting in groundwater of a mixed sulfate/bicarbonate type.

Karst aquifers formed in evaporite rocks are much less common than karst aquifers in carbonate rocks, primarily because their solubility is much greater than carbonates, and in humid climates the chemical rates of erosion are extremely rapid. Evaporite karst is preserved in arid and semiarid climates of the western United States (see Fig. 1) and other areas of the world, but these aquifers typically yield highly-mineralized, non-potable water and are seldom used for water supply. Gypsum and anhydrite yield calcium sulfate type waters (Ca^{+2}, SO_4^{-2}), and halite produces brines of sodium chloride (Na^+, Cl^-) character.[1]

The overall water quality of karst aquifers is a reflection of the geochemistry of all the sources of recharge, weighted by the proportion of the percentage contribution of that source to the total hydrologic budget, coupled with water/rock reactions within soils and rocks upgradient from the aquifer.[1–5] Mixing of karst waters is a major chemistry-controlling process. If land use in the recharge area of the aquifer allows undesirable constituents, water quality in the aquifer will be degraded, as elaborated under the pollution section that follows.[6–11]

Sediment is an important part of water quality of karst aquifers. Turbulent flow, coupled with open flow systems allows clay-sized particles of soil to be transported through these groundwater systems.[12] The importance of sediment to water quality is that these particles have huge surface areas, and they typically have electrical charges that attract and hold potentially hazardous substances, such as trace metals and organic chemicals. Sediments also provide a substrate for the preservation and transport of bacteria, virus, and other pathogens. Therefore, contaminants that otherwise would not be present within the aquifer may be mobilized and attached to sediment particles. Contaminants here are sorbed to particles in suspension, and are not in solution; they are in transit through the aquifer just the same, and are available for reaction. If these are ingested in any form by organisms (such as mercury attached to clay may be ingested by bottom-feeding fish) the contaminant may become biologically active (methylated) and bioaccumulated.

WATER-RESOURCE PROBLEMS IN KARST AQUIFERS

The most recurring problems humans experience when dealing with karst aquifers are those related to

Fig. 1 Distribution of Karst aquifers in the U.S. *Source*: Modified from Ref.[6].

pollution,[6–11] flooding,[3,4,6] and subsidence.[3,4,6] This is because human activity creates disequilibrium. Changes within the aquifer occur rapidly in response to changes at the surface, flow velocities can typically transport sediment and other potentially large conduit-plugging debris into the aquifer, and there is less chance for filtration or sorption of unwanted solutes and constituents in karst. Thus, land use in the area contributing recharge to a karst aquifer needs to be closely monitored to minimize negative impacts.

Pollution

Pollution is common in karst aquifers near areas with high human or animal population densities. Unwanted constituents can move into an aquifer and mix with the native ground water, polluting the aquifer, rendering it unsuitable for further use. Many pollutants move through fast-flow karst aquifers rapidly, and the duration of the impact is short, a matter of days, weeks, or months. Some contaminants, however, such as dense, non-aqueous phase liquids (DNAPLs), sink to the bottom of flow zones in karst aquifers and remain until decomposed by natural processes; the duration of pollution of this sort may be hundreds of years or more. Manufacturing spills, illegal dumping in sinkholes, spills from transporting hazardous wastes, leakage from underground storage tanks, leachate plumes from landfills, excess nutrients from animal manure and inorganic fertilizers, pharmaceuticals and endocrine disruptors from water-treatment facilities, and microbial pathogens from leaky sewers, improperly functioning septic systems, and confined animal feeding operations (CAFOs) are but a few of the well-documented pollution problems found in karst aquifers.[4,6–11] Wherever concentrations of constituents exist at the surface in karst terrane, the chance for movement into the subsurface is great.[13] These risks, combined with the susceptibility of this type of aquifer to contamination, call for vigilance in conducting most human activities in all karst areas, and long-term planning and zoning for those areas that are particularly susceptible. Websites include the the Karst Waters Institute,[14] and the Karst Commisssion of the International Association of Hydrogeologists.[15]

La Niña

David E. Stooksbury
Biological and Agricultural Engineering Department, University of Georgia, Athens, Georgia, U.S.A.

INTRODUCTION

La Niña is a change in global weather patterns associated with colder than normal sea surface water temperatures in the equatorial Pacific Ocean (see Fig. 1). La Niña is the cool phase of the best known example of interannual variation in the earth's weather and climate patterns, El Niño-Southern Oscillation (ENSO). Since El Niño, which means boy in Spanish, is the warm phase of ENSO, the cool phase of ENSO is called La Niña, which means girl in Spanish. Another term for La Niña is El Viejo, which means old man in Spanish.

The La Niña pattern leads to changes in positions of jet streams, the steering currents for weather systems. Changes in the polar jet streams cause changes in weather patterns across North America during the winter. While the change in weather patterns associated with La Niña can be dramatic, most regions experience minimal to no direct impact from La Niña. La Niña events occur every three to seven years lasting a few months to a year or more.

IMPACTS

In the United States, La Niña weather patterns usually mean a dry to very dry winter for the coastal plain of Georgia and the Carolinas as well as Florida (see Fig. 2). While the Southeast is experiencing a dry winter, the lower Mississippi River and the Ohio River Valleys normally experience a wet winter. Much of the remainder of the United States experience very little winter time precipitation impacts associated with La Niña. During La Niña winters, the polar jet stream is positioned such that most storms move from the lower Mississippi River to the Ohio River Valleys exiting the Northeast coast. Compared to a normal winter, the southeastern United States experiences fewer storms during a La Niña winter.

During the summer and fall, La Niña events are associated with increased tropical weather activity in the Gulf of Mexico and Atlantic Ocean. This increase in tropical weather makes the east coast more vulnerable to tropical storms and hurricanes during La Niña years. The increase in tropical weather activity associated with La Niña events, usually causes the Southeast to experience wetter than normal falls during La Niña years.

Not all regions impacted by La Niña have decrease in precipitation. The La Niña weather pattern usually brings wetter than normal conditions to northern Australia, Indonesia, and the Philippines.

The impacts of La Niña weather patterns vary from one event to another. The impacts depend on the coolness of the surface water, the exact location of the cool surface water, the areal extent of the cool surface water, and other regional and global weather patterns.

Mechanism

The oceans and the atmosphere are linked. The discovery of the ocean–atmosphere linkage is one of the most important breakthroughs in modern environmental research. The linkage between the equatorial Pacific Ocean and the atmosphere helps to determine weather patterns across much of the earth. The variation in atmospheric pressure patterns over the Pacific Ocean that are linked to the equatorial Pacific Ocean temperature patterns is called the Southern Oscillation, SO.

The strength of SO is calculated by the surface atmospheric pressure anomaly differences between Tahiti and Darwin, Australia (Tahiti anomaly minus Darwin anomaly). This measure of SO strength is called the Southern Oscillation Index, SOI. A surface atmospheric pressure anomaly is calculated by subtracting the mean atmospheric surface pressure from the observed atmospheric surface pressure. Thus, if the observed atmospheric surface pressure is more than the mean, the anomaly has a positive value. When the SOI has a positive value, it means that the surface atmospheric pressure difference between Tahiti and Darwin is greater than normal. A positive SOI is correlated with a cooler than normal surface water in the eastern and central equatorial Pacific Ocean.

The linkage between the SO and La Niña is complex. At the most basic level, sea surface temperature patterns influence atmospheric pressure patterns, and

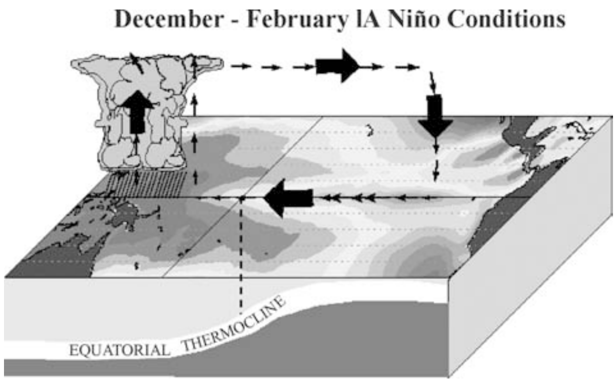

Fig. 1 Atmospheric and oceanic patterns during a La Niña. (From the National Weather Service Climate Prediction Center, Camp Springs, MD.)

atmospheric pressure patterns influence wind speed and direction and thus the sea surface temperature patterns.

Under neutral conditions (climatologists prefer the term ''neutral'' instead of ''normal'') the normal cold surface water of the eastern Pacific Ocean is associated with relatively high surface atmospheric pressure over the region. Air moves (wind) from areas of high atmospheric pressure to areas of low atmospheric pressure. The greater the pressure gradient (pressure difference between two locations divided by the distance between the two locations), the greater the wind speed. The moving air in contact with the ocean surface causes ocean surface currents, which redistribute the ocean surface temperature pattern. The stronger the wind, the more the redistribution of surface water temperatures.

With ENSO (either the cool phase, La Niña or the warm phase El Niño), the linkage between the ocean and the atmosphere results in decreasing or increasing easterly trade-wind (wind from the east to the west) speeds over the equatorial Pacific Ocean. When the SOI is positive (La Niña phase), the pressure gradient across the eastern and western Pacific Ocean is increased. With an increased pressure gradient, the speed of the easterly trade-winds increases, and allows cold upwelled water from the eastern equatorial Pacific Ocean to cool the central equatorial Pacific Ocean thus producing a La Niña event.

Since La Niña and neutral phases of ENSO have the same atmospheric pressure and wind patterns, many climatologists consider a La Niña event ''an extreme case of normal.'' While the atmospheric pressure and wind patterns are the same for La Niña and neutral phases, the pressure gradient and thus the easterly winds are much more pronounced during La Niña events. The stronger easterly winds cause a major expansion of cold sea surface temperatures across the central equatorial Pacific Ocean and the associated changes in global weather patterns.

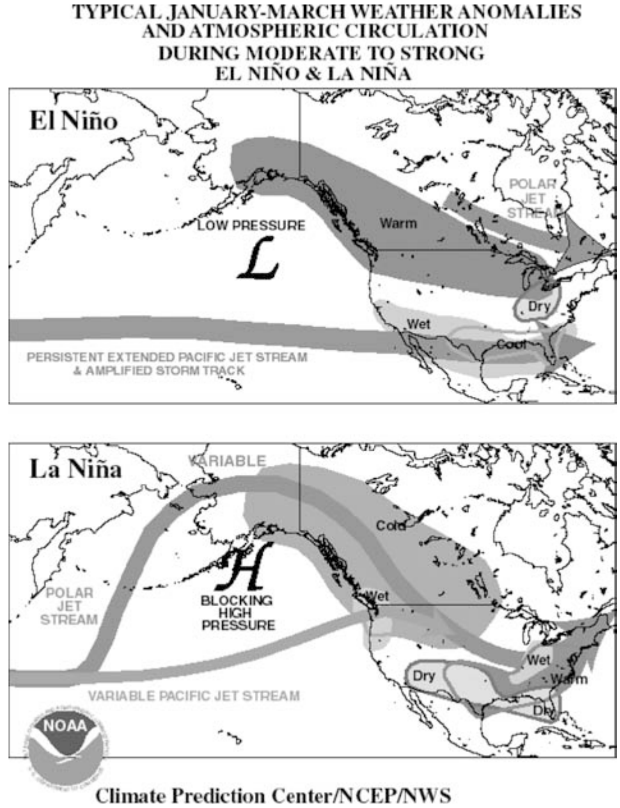

Fig. 2 Typical jet stream and climate patterns during an El Niño (top) and a La Niña (bottom). (From the National Weather Service Climate Prediction Center, Camp Springs, MD.)

Since the 1990s scientists have used Pacific Ocean surface temperature data and computer models to predict the occurrence of a La Niña event months in advance. While these predictions are not perfect, they allow for planning to mitigate or take advantage of a shift in weather patterns. Thus, regions that normally experience drought during a La Niña event can plan to mitigate the impacts. For regions like the southeastern United States, drought mitigation plans can be activated months in advance.

For more detailed information about La Niña, see Ref.[1].

Land Drainage: Subsurface

Stephen R. Workman
University of Kentucky, Lexington, Kentucky, U.S.A.

INTRODUCTION

Subsurface land drainage is the removal of excess soil water through the use of ditches or buried perforated pipe. Ideally, the excess water is removed quickly enough to allow timely field operations to occur or to limit crop damage if a crop is present. This chapter presents the design of subsurface drainage systems using knowledge of soil physical properties, crop susceptibility to excess water, and the flow of water in pipe systems.

The water table (saturated soil conditions) is present near the soil surface in many places. Soils located near streams, lakes, and oceans are familiar examples. Other cases might include areas where an impermeable or slowly permeable layer exists in the soil profile that causes a perched water table to exist. The primary limitation for effectively using these soils for recreation, construction, or agriculture is the high water table.

SYSTEM LAYOUT

The drains in a subsurface land drainage system can either be placed in a systematic pattern if a large area is to be drained or randomly placed near hard-to-drain areas. A random layout of drains is used to remove excess water from localized depressions in a field. The primary design considerations are to maintain adequate slope to the outlet and to ensure that adequate cover over the drain is maintained. A random layout is typically used as the drainage system under rolling topography, constructed grass waterways, and the greens of golf courses.

For most cases where the entire field is poorly drained, a system of parallel drains or laterals is installed throughout the entire field. The laterals are connected to a series of sub-mains and mains that transport the water to the outlet. The spacing between the parallel drains is important to the cost of the system and can result in considerable savings if an optimal design is chosen.

Besides random or parallel layouts, an interceptor drain may be used near seepage or overland flow areas. These drains are typically installed at locations of water seeps and excess runoff such as at the bottom of a hill.[1]

SUBSURFACE LAND DRAINAGE DESIGN

A combination of factors influences the depth and spacing of laterals within a drainage system. These factors include hydraulic conductivity, drainable porosity, thickness of soil layers, depth to a restrictive layer, and quality of surface drainage. The single most important soil property affecting the design of drainage systems is hydraulic conductivity.[2] Hydraulic conductivity (K) is spatially variable and should be determined at numerous positions across the site. In the design of large systems where large differences in conductivity may occur, the spacing may be wider or narrower in some regions of the field. From a construction standpoint, however, it is best to maintain uniform drain spacing for as large an area as possible.

Whereas the hydraulic conductivity indicates the rate that water can move through the soil, another parameter called the drainage coefficient (DC) has been defined to represent the rate of water to be removed by the drainage system. The DC is the depth of water to be removed in 24 hr by the drainage system and has the same units as hydraulic conductivity (L/t). In humid areas where uniform, low-intensity rainfall events are common, the DC depends largely on a design rainfall event. The DC should be selected to remove excess water rapidly enough to prevent serious damage to the crop. Loss of crop will generally occur if the soil profile is allowed to remain saturated for more than 24 hr.[3,4] Typical values of DC are 10–20 mm/day.[5] The DC should be increased for high value crops or special soil conditions.[5]

Steady-State Design

One method of designing a subsurface drainage system is to assume that a uniform rainfall occurs on the soil surface over a long period of time. At steady state, all inflows (rate of groundwater recharge) must equal outflows (discharges through the drainage system). These steady-state conditions can be computed by the Hooghoudt equation where S is drain spacing (L), R is the drainage coefficient or rainfall rate per unit area (L/t), K is the hydraulic conductivity (L/t), d is the depth of the drain to the restrictive layer (L), and b is the vertical distance from the drain to the water table position at the midpoint between drains (L).[3]

$$S = \left[\frac{8Kdb + 4Kb^2}{R}\right]^{1/2} \quad (1)$$

The primary limitation of the earlier equation is that flow is assumed to move horizontally towards a ditch.[4] For the case of flow to drain pipes, convergence losses near the drain must be included. The effect of the convergence is to reduce the amount of flow because there are vertical and horizontal components of flow, conceptually similar to reducing the thickness of the soil profile. An effective depth (d_e) can be computed by the equation,

$$d_e = \frac{\pi S}{8\left(\ln\left(\frac{S}{\pi r_e}\right) + F(x)\right)} \quad \text{for} \quad x = \frac{2\pi d}{S} \quad (2)$$

$$F(x) = \sum_{n=1}^{\infty} 2 \ln \coth(nx) = \sum_{i=1}^{\infty} \frac{4e^{-2ix}}{i(1 - e^{-2ix})}, \quad (n = 1,2,3,\ldots),(i = 1,3,5,\ldots) \quad (3)$$

for $x < 0.5$, $F(x)$ may be closely approximated by,

$$F(x) = \frac{\pi^2}{4x} + \ln\left(\frac{x}{2\pi}\right) \quad (4)$$

where r_e is the effective radius for the drain that accounts for the fact the drain has a limited amount of openings for water entry. In the design process for steady-state analysis, the drainage coefficient is considered to be the design rainfall amount.

Transient Methods

In areas where frequent, high-intensity storms occur during the growing season, a transient analysis should be conducted to assure that the water table falls quickly enough to maintain a well-aerated root zone. Mathematical analysis of the falling water table case is far more difficult than for the steady-state case. If the assumptions of horizontal flow, vertical equipotentials in the saturated zone, and instantaneous release/addition of water at the water table can be imposed, then the unsaturated zone can be neglected. In the transient case, the drainage coefficient is related to the water table drop over a period of a day. The drainage rate is then the amount of water released as the water table drops

$$DC = (b_0 - b)_{24\,\text{hr}} \times f \quad (5)$$

where $(b_0 - b)_{24\,\text{hr}}$ is the prescribed drop in the water table in 24 hr and f is the drainable porosity (L^3/L^3). Note that the drainable porosity is much smaller than the porosity of the soil because only the pores that drain as the water table falls from b_0 to b are included.

For the falling water table case the drain spacing can be computed as,[2]

$$S = \left[\frac{9Ktd_e}{f \ln\left(\frac{b_o(2d_e + b)}{b(2d_e + b_o)}\right)}\right]^{1/2} \quad (6)$$

where the effective depth to the impermeable layer (d_e) has been included to account for convergence losses to the drain, t is the time period for the water table to drop from b_0 to b, and all other parameters are as defined earlier. Both the steady state and the transient methods involve the determination of S and d_e through the process of iteration.

SYSTEM DESIGN

Layout

The subsurface drainage system is designed to transport excess water to the outlet. The outlet has to have the capacity of carrying the excess water away from the site. The outlet may be a drainage channel, an existing main, or a stream channel. After the outlet location is chosen and checked for capacity, the layout of the system in the field is determined. Some key characteristics of an efficiently designed system include making the laterals as long as possible, placing the laterals parallel to the topographic contour of the field, and minimizing lengths of sub-mains, mains, connections, and fittings.[6]

Design Flow

The design flow for the system is related to the drainage coefficient used to compute the drain spacing and can be computed from the equation,

$$Q = DC \times A_d \quad (7)$$

where Q is the flow rate (L^3/t), DC is the drainage coefficient (L/t), and A_d is the area-drained (L^2).

Grades

Maximum grades are limiting only where pipes are designed for near-maximum capacity or where pipes are placed in unstable soil. For nearly level areas, the drain should be as steep as possible while maintaining adequate depth at all locations to reduce the size of the mains and sub-mains. Drains should not be placed at a grade less than 0.2% under most conditions. If fine sand or silt is present, then larger grades may be necessary to keep the pipe clean.

Pipe Size

The following equation can be used to size the pipe needed to carry the drainage water.

$$d = 51.7(DC \times A \times n)^{3/8} s^{-3/16} \tag{8}$$

where A is the drainage area entering the drain (ha), d is the pipe diameter for a pipe flowing full (mm), n is Manning's roughness coefficient, s is the drain slope (m/m), and DC is the drainage coefficient (mm/day). Typical Manning's roughness values for corrugated plastic pipe are 0.015 for 75–200 mm diameter pipe, 0.017 for 250–300 mm diameter pipe, and 0.2 for pipes greater than 300 mm.

ACCESSORIES

Accessories for subsurface drainage systems include surface inlets, blind inlets, sedimentation basins, and control structures.[2] A surface inlet, sometimes called an open inlet structure, is used to remove surface water from potholes, road ditches, or other depressions. Blind inlets may be used where the amount of surface water to remove is small or the amount of sediment is too great to permit surface inlets. Sedimentation basins are any type of structure that provides for sediment accumulation, reducing deposition in the drain. Finally, control structures are placed in the drainage system to maintain the water table at a specified level.

INSTALLATION CONSIDERATIONS

During installation, several factors such as machinery, grade control, corrections, and documentation must be considered. Examples of machinery used in the installation process include a trencher or backhoe to install the mains, a backhoe to clear enough soil away at junctions to make a connection and insert a plow or trencher boot, a drain plow or trencher to install the laterals, and pipe feeders to reduce stretch in pipe. For grade control, the bottom of the trench should be shaped with a supporting groove to provide good alignment and bottom support. Laser or manual methods may be used to establish grade.[6,7] Connections, an essential part of the drain system, should be made with a T- or a Y-manufactured junction. Manufactured connections should be used when changing pipe size, and end caps or plugs are required for preventing soil from entering the end of the lateral. Finally, the necessary documentation includes a map of the drainage system filed with the deed to the property. The use of GPS and GIS technologies is encouraged for correct identification of the drainage system.[8]

CONDUIT LOADS

Loads on underground conduits include those caused by the weight of the soil and by concentrated loads resulting from the passage of equipment or vehicles. At shallow depths, concentrated loads from field machinery largely determine the strength requirements of conduits; at greater depths, the load from the soil is the most significant factor.[6,9]

Land Drainage: Wells

Rameshwar Kanwar

INTRODUCTION

Land drainage is the removal of excess surface and subsurface water from the land to enhance crop growth, including the removal of soluble salts from the soil.[1] In a more scientific sense, drainage can also be defined as the techniques or methods employed to lower and control the elevation of shallow water table depths at such a depth within the root zone where maximum crop productivity can be achieved.[2] Drainage increases the depth of soil free of water for plants to develop their rooting system, absorb more nutrients and, therefore, sustain yields over a longer period of time.[3] Drainage can be either natural or artificial. Artificial drainage usually supplements and enhances the natural drainage capability of the soils to keep a favorable balance of water, salts, and air in the root zone for optimum plant growth. The man-made landscape changes, however, not only increase crop production by bringing more area under cultivation but also alter the natural drainage ways. Moreover, the construction of roads, highways, and installation of irrigation sources/practices and land-forming operations also affect the natural drainage capability of the soils. Under these conditions, the long-term benefits and productivity of the poorly drained soils and mitigation of the irrigation effects can only be sustained by providing and maintaining the adequate surface and subsurface drainage systems for poorly drained soils.

Benefits

The main objective of land drainage is to provide and maintain a healthy root zone environment that is suitable for maximum crop productivity with the following benefits:

1. Drainage helps maintain a balance of air, water, and salts in the root zone and also increases root growth and crop yields by increasing uptake of plant nutrients.
2. Drainage increases biological activities in the root zone and, therefore, improves the nitrogen availability to plants.
3. Drainage removes excess water from the soil profile and improves the soil structure, workability, and other related field operations such as cultivation, planting, and harvesting practices.
4. Drainage improves soil temperature that is important for seed germination and plant growth processes.
5. Drainage helps reclaim the salt-affected soils.
6. The other associated benefits include mosquito control, improvement, and maintenance of roads, easy movement of farm machinery, wider selection of crops, longer growing season, better crop yields, and overall lower operational costs.

Primarily, there are two types of drainage systems. One is horizontal drainage by means of surface ditches or subsurface buried field drains and the other is vertical drainage that is performed using wells. This article is mainly concerned with the vertical drainage and the subsequent discussion is limited to drainage with wells.

OPEN WELLS

The open wells consist of a pit, dug to the groundwater level so that enough water can be collected. The depth of the well also depends on the soil formation and aquifer yield. The dug wells are mostly shallow because of the difficulty in their digging deeper through high water table soils and, therefore, have relatively lesser water yields. The dug wells are sometimes lined with masonry, gravel, rocks, or stone to avoid caving problems. After construction of these wells, water is lifted from wells at a faster rate to remove the fine soil particles in the adjacent area of the wells. This practice is called "well development," which opens the pores of the soil formation and increases flow of water to the wells. Larger diameter open wells are also constructed to increase the flow area to the wells and also to increase the storage volume of water in the wells. At some places, tile drains discharge into shallow wells called ‘‘sumps’’ and water is lifted from these wells into nearby canals, reservoirs, or natural streams for its use in irrigation or disposal purposes. This method is well illustrated in a number of places in California, e.g., Sutter Basin.[4] These conditions, however, may vary from site to site. Higher well yields are not possible as sand can start slipping into the well when water depth is lowered to a certain level in the well. Adding stones or gravel at the bed of the well can help stop slipping of sand and increase water yield at some places. Water yields of open wells, however, can be increased by installing strainers at the bottom of the wells to tap groundwater from the deep layers, depending on the local hydrogeological conditions. Persian wheels are also used to lift water from such wells.

PERSIAN WHEELS

Persian wheels lift water from open wells by means of small buckets tied with flexible rope or chains on a rotating drum or wheel. Power to this rotating wheel is provided through the shaft coming from another rotating drum driven by a pair of bullocks. The rotation of rope or chain brings the buckets up, full of water, from the well and empties them automatically as the buckets descend over the rotating drum. This mechanism provides continuous lifting of water from the well. Water lifted from open wells was mostly used for irrigation purposes, but at the same time it was providing drainage to the surrounding area because of its wide diameter and sizable capacity to store the groundwater seeping from the water bearing formations. A Persian wheel can yield water between 0.1 and $0.2\,ft^3/s$, and can command an area of about 5–15 acres.[5] The use of the Persian wheel is feasible where groundwater is shallow and of good quality for usable purposes. These wells, in addition to their use for supplying water, have also been used as a source to drain the excess water from the soil surface as well as from the root zone called ‘‘drainage wells.’’

DRAINAGE WELLS

The drainage of low lands or field pockets, which have no gravity outlet, was usually made possible by drilling sinkholes or wells into the water absorbing formations at a certain depth below the ground surface. The excess water was used to drain into these wells where it can flow into the coarse formations below the ground surface. Such vertical drainage through holes or wells can fall in two categories, depending on the depth of the wells, i.e., shallow and deep. Both these conditions are site-specific and depend on the local hydrogeology of the area and the amount of drainage water to be disposed of. When the water bearing formation of sufficient thickness is available at a shallow depth of about 6–10 m below the ground surface, it is termed as the shallow vertical drainage. When a deep well is drilled, it transports the surface or subsurface drainage water into the deep layers called deep vertical drains. The functions of such drainage wells, however, depend on the transmissivity characteristics of the geologic formations. Both shallow and deep wells serve the same purpose of removing excess water from the root zone by flowing it into the main groundwater body of the area. These wells have also been called ‘‘agricultural drainage wells.’’

AGRICULTURAL DRAINAGE WELLS (ADWs)

When the state of Iowa in the United States was first inhabited by Europeans, the North Central part of the state was covered with wetlands and depressions were scattered. The lands were waterlogged with standing water, especially in the low-lying areas. Subsurface tile lines were laid and a drainage network was established to drain the excessive water from the surface as well as from the root zone. Meanwhile, agricultural drainage wells were also constructed to drain the surface as well as subsurface water from those depressions that otherwise were not drained. The collected water was guided downward to the bedrock aquifer through ADWs. Of the estimated 400–500 ADWs in Iowa, 359 were registered in four counties.[6]

These ADWs have been used to provide outlets for removal of excessive soil moisture from the areas where other drainage systems were not feasible. These wells allow injection of surface or subsurface water using surface outlets down to the aquifer. Agricultural drainage wells help manage soil moisture so that crops can grow better. Depending on the local conditions, these wells are also used to recharge the aquifers. These wells include buried collection basins, one or more tile drainage lines to collect water, and a drilled or dug well in the low-lying areas of the fields (Fig. 1). The design of this system should consider the aquifer capabilities to handle such large quantities of water generated through thunderstorms.

The United States Environmental Protection Agency has reported that there are more than 2842 agricultural drainage wells in the nation, including 359 in Iowa.[6] These ADWs, however, have been reported to be a concern of aquifer pollution with

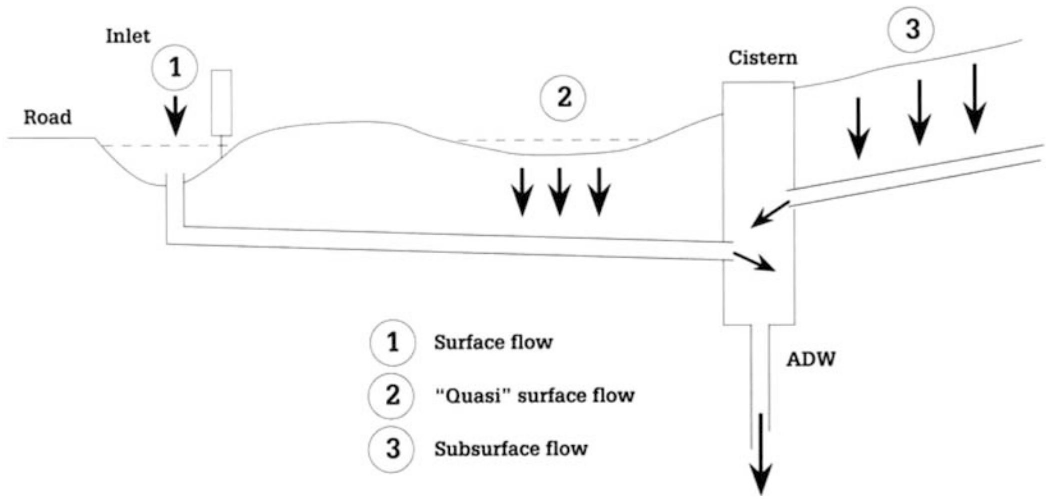

Fig. 1 A schematic diagram of ADW installation. *Source*: From Ref.[6].

agricultural chemicals such as fertilizers, pesticides, or bacteria and other microorganisms. These wells short-circuit the drainage water from the surface or root zone directly into the aquifer without passing through the soil matrix. The quality of drainage water improves when it goes through the soil filtering process and chemical degradation before joining the main groundwater body.

TUBEWELL DRAINAGE

This method of drainage uses wells to control the water table levels in the root zone. These wells can be shallow or deep depending on the hydrogeologic conditions of the area. The suitability of this system, however, is governed by the hydraulic properties of the soil horizons or aquifer. The shallow wells will directly lower the water table in the root zone whereas deep wells may tap the confined aquifers. Proper design and installation of wells can quickly lower the water levels depending on the local conditions. Vertical drainage or tubewell drainage can be performed using different types and methods related to pumping groundwater from the aquifer under different hydrogeological conditions, such as confined and unconfined aquifers.

Tubewell drainage is a technique of removing excess water from the root zone by lowering the groundwater level of the waterlogged area using a single well or a series of wells.[7] To maintain the water table at a certain depth below the ground surface, tubewell discharge is usually equal to the drainable surplus of the area being drained. The success of tubewell drainage lies in pumping enough water from the aquifer so that the root zone can provide a favorable environment for crop productivity on a sustainable basis. The rate of lowering the water table depends on many factors such as hydrogeological conditions of the area, physical properties of the aquifer, and the physical properties of the overlying soil layers of the earth profile.

The earth profile can basically be divided into two zones: fractured rock zone and the rock flowage zone. From a groundwater point of view, the fractured rock zone is of interest and is further composed of the saturated and unsaturated zones. The unsaturated zone has no free drainage of water but may contain perched water table depending on the soil horizon properties of the area. The saturated zone, however, contains the main groundwater body in the unconfined or confined soil layers depending on the geologic formation of the area and the sources of recharge of the aquifers. The wells, based on the availability of water from these soil layers, can be divided into gravity, artesian, or both types, depending on the soil conditions and the aquifer characteristics. Tubes or pipes in combination with the pumping set equipment can be used to pump groundwater for irrigation or drainage purposes. The pumping set increases the flow energy of groundwater by creating an artificial sink within the saturated zone called "drawdown." This drawdown extends to the crop root zone and controls the water table at the desired depth within a desired area, depending on the well spacing and aquifer conditions.

The tubewell or pumped well drainage system is also characterized by its higher initial and operating costs. This high cost, however, is balanced with the benefits obtained from tubewell drainage in comparison with other drainage systems that are described as follows:

1. Tubewell drainage is a quick and effective method to lower the water table at a faster rate than any other method.

2. Water table can be lowered to a greater depth and can also be maintained at a desired level within the root zone because of the flexible control of its operational schedule.
3. The deeper installation of tubewell perforated pipes also offers an option to select the more permeable sandy layers from the soil horizon data "well log."
4. The productive land is saved from construction of open ditches and farm machinery movements become easy.
5. Depending on the undulating topography and landscape features, sometimes tubewell drainage is the only option left to avoid digging long channels through hilly ridges.
6. The maintenance cost is less when compared with other drainage systems and its easy operation offers advantages over the others. The water-borne diseases are also preventable.
7. The pumped drainage water can also be used to supplement the irrigation water depending on its quality and would be available at the time when crops need it.

The feasibility of the well drainage method, however, depends on the hydrogeological characteristics of the area, sources of excess water, aquifer properties, well spacing, energy charges, groundwater quality, and also the feasibility to dispose the drainage effluents.

DRAINAGE EFFLUENTS' DISPOSAL PROBLEMS

The cost-effective and environmentally safe disposal of drainage effluents is a real problem both in the humid and arid regions, although characteristics of the drainage effluents can vary for both the regions. In humid areas, soil salinity is not the problem because of the availability of fresh water from rainfall, but at the same time, studies have shown that drainage effluents are a potential carrier of nutrients, pesticides, and herbicides from the agricultural fields to surface and groundwater bodies. Although application rates of agrochemicals are high in some humid zones of the world because of high cropping intensity to obtain higher crop yields, drainage of these agricultural lands has played a significant role in transporting these chemicals to lakes, streams, reservoirs, and oceans. Therefore, disposal of drainage effluents from humid areas needs treatments to reduce nutrient loads to minimize eutrophication problems causing low oxygen levels that are preventable. Similarly, the drainage water from an arid zone carries significant amounts of salts and can neither be used for irrigation nor be found suitable for wild habitat and aquatic life. The disposal of salty drainage water is a serious issue, particularly in the arid zones where enough water is not available for its dilution.

CONCLUSIONS

In arid regions, irrigated agriculture has increased agricultural production, but at the same time, it has disturbed the ecosystem from the construction of different size reservoirs, canals, and irrigation and drainage ditches. The irrigation network usually increases seepage, percolation, and ultimately contributes to the rise of groundwater levels as well as salt accumulation in the root zone. To mitigate the effects of irrigation and sustain the productivity of irrigated fields, drainage of irrigated lands becomes essential to keep a favorable balance of salts, air, and water in the root zone. Besides overcoming the irrigation effects, drainage also helps in bringing more areas under cultivation, which were earlier waterlogged, under depressions and potholes, or in swamps. Drainage of agricultural land not only maintains productivity of the poorly drained soils but also induces transport of nutrients and chemicals from the agricultural fields to as near as lakes and as far as oceans.[8]

According to Newton's third law of motion, every action has a reaction. The same is true in the sense of our ecosystem. The man-made structures and human activities exploited the natural resources to grow more and more food by increasing the crop yields, from increased use of chemical inputs, and by bringing more area under cultivation at the cost of losing forest lands, wetlands, or other places of wildlife habitat, which had devastating effects on the environment. The development of society in the early 1900s did not recognize the long-term effects of development but now conditions are reaching to such a level where global warming, glacier melting, sea level rising, more floods, hurricanes, and El-Nino effects could be the reaction of disturbing the nature in response to the human actions. Depending on the climate, hydrogeology, soil characteristics, topography, and farming practices, drainage effluents and their chemical characteristics and their effects on agroecology during transport of drainage effluents need to be managed. In humid regions, reducing drainage effluents by using wetlands as ecological filters can help in reducing the adverse effects of the drainage waters on the soil and water quality. Similarly in arid regions, improving irrigation efficiency, identifying, and checking the sources of excess water and salts need to be identified and managed accordingly. The disposal and management of drainage effluents require effective practices to minimize their offsite effects on the environment.

Leaf Water Potential

Andreas J. Karamanos
Laboratory of Crop Production, Agricultural University of Athens, Athens, Greece

INTRODUCTION

Leaf water potential is the thermodynamic expression of the water status of leaves, which is widely used in plant science research in the last 40 years. In this article, a description of the physical principles leading to the definition of the leaf water potential and its component potentials is initially given. Then, the way of development of water deficits in leaves and the compartmentation of the water and its component potentials in leaf cells and tissues subjected to different degrees of water shortage are presented. Some useful implications for the development of adaptive mechanisms to drought result from this analysis. Finally, the existing methods for the determination of leaf water potential are presented and classified in groups according to their basic principles.

DEFINITIONS

According to Slatyer and Taylor,[1] the state of water in any system is expressed thermodynamically in terms of its chemical potential (μ_w) or the partial molal Gibbs free energy ($\bar{G}_w$) as follows:

$$\mu_w = \bar{G}_w = \left(\frac{\partial G}{\partial n_w}\right)_{T,P,n_s} \qquad (1)$$

where G is the Gibbs free energy of the system (a function of its internal energy) and n_w the number of water moles. Thus, μ_w or ($\bar{G}_w$) are defined more simply as the change that occurs in the energy content of a system for a given change in the number of moles of water in the system at constant temperature (T), pressure (P), and solute content (n_s).

The water potential of a system ($\boldsymbol{\Psi}$) is defined as:

$$\boldsymbol{\Psi} = \frac{\mu_w - \mu_w^0}{\bar{V}_w} \qquad (2)$$

where μ_w^0 is the chemical potential of pure free water and $\bar{V}_w$ the partial molal volume of water (18 cm^3 mole^{-1}). $\boldsymbol{\Psi}$ is expressed as energy per unit volume, which is dimensionally equivalent to pressure. Thus, traditional pressure units (e.g., bar, MPa, etc.) are used for the expression of $\boldsymbol{\Psi}$. The concept of water potential can be realized as a measure of the capacity of water at a point in the system to do work in comparison with the work capacity of pure free water (μ_w^0) which is taken arbitrarily as zero. Accordingly, $\boldsymbol{\Psi}$ provides a unified measure for the energy status of water at any place within the soil–plant–atmosphere continuum.

Since the energy status of water results from the interaction of forces of different origin exerted on water molecules, $\boldsymbol{\Psi}$ is thought to consist of several components each one representing a different kind of the forces involved. *The effect of solutes*, which are very common in any aqueous system, is expressed as the osmotic component of $\boldsymbol{\Psi}$, the osmotic or solute potential (Ψ_s). The solutes lower the vapor pressure, and, hence, the potential energy of water in the system. Thus, Ψ_s takes values below zero, which are proportional to the concentration of osmotic substances ($c_s = n/V$, where n = number of moles and V = volume):

$$\Psi_s = -RTc_s = -\pi \qquad (3)$$

where R is the gas constant, T the absolute temperature, and π the osmotic pressure.

External pressure, either above or below the value of the local atmosphere, increases or decreases, respectively, the water potential. Its effect is described in terms of the pressure potential (ψ_p), which usually takes values above zero.

Forces arising both *at the liquid–air and at the solid–liquid interfaces* are responsible for another component of $\boldsymbol{\Psi}$, the matric potential (ψ_m). They are considered to arise in systems rich in matrix, i.e., with large surface to volume ratios (e.g., soils, plant cell walls, gels, and colloids). Water is bound by matrix with forces related to its water content. Thus, the capacity of water to do work is reduced, and, hence, ψ_m takes negative values.

It follows that, at any time, $\boldsymbol{\Psi}$ is a function of ψ_s, ψ_p, and ψ_m:

$$\boldsymbol{\Psi} = f(\psi_s, \psi_p, \psi_m) \qquad (4)$$

However, Eq. (4) is usually described, in a simplified way, as an algebraic sum:

$$\Psi = \psi_p + \psi_s + \psi_m \qquad (5)$$

A further component due to gravity, called gravitational potential (ψ_g) might also be added to Eqs. (4) and (5) only in specific cases (e.g., in tall trees or when reverse water flow is considered).

WATER IN THE LEAVES

Water enters the leaves via the vascular system of the petiole and it flows through the veins of the lamina down to the vein endings which are embedded in the mesophyll. Lateral water movement towards neighboring mesophyll tissue along the xylem tissue of the veins also occurs to a substantial extent. The specific important characteristic of the vascular system of the leaf is its close spatial relation to the mesophyll.[2] According to Kramer,[3] the actual distribution of water in the mesophyll occurs chiefly from the smaller veins, which are so numerous that most cells of a leaf are only a few cells away from a vein or vein ending.

Fig. 1 shows diagrammatically the pathway of water from a xylem vessel to the evaporating surfaces in a substomatal cavity through a mesophyll cell. Water moves mainly through the apoplast (cell walls and intercellular spaces) where the resistance (r_w) is minimal. Water exchanges (f) from and to the vacuole (symplastic pathway) are more difficult because of the resistance of the two cell membranes (plasmalemma and tonoplast) to be crossed (r_v). The water flux can be represented by an electric analog [Fig. 1(B)] where the apoplast exhibits mainly conductive properties (appearing as the resistance r_w), whereas the symplast both conductive (r_v) and storage properties represented as the capacitance c_v.

At any time, leaf water balance results from the relative magnitudes of the water supply through the roots and stem and the water loss through transpiration. To understand the mode of development of leaf water deficits we can consider the simple physical model proposed by Dixon in 1938 as quoted by Weatherley[4] (Fig. 2). In this model, the plant is regarded as consisting of two porous pots filled with water and connected by a tube through a manometer. The lower pot representing the root is semipermeable and buried into the soil. The upper pot indicates the transpiring leaf surface; the manometer represents the vacuoles of the mesophyll cells, which are off the main pathway since water moves mainly through the apoplast. Once transpiration starts, water evaporates quickly from the upper pot and a negative tension is transmitted through the tube to the lower pot resulting in water absorption from the soil. The existence of a considerable root resistance induces a lag of absorption behind transpiration, and water absorption cannot meet instantaneously transpirational fluctuations. Thus,

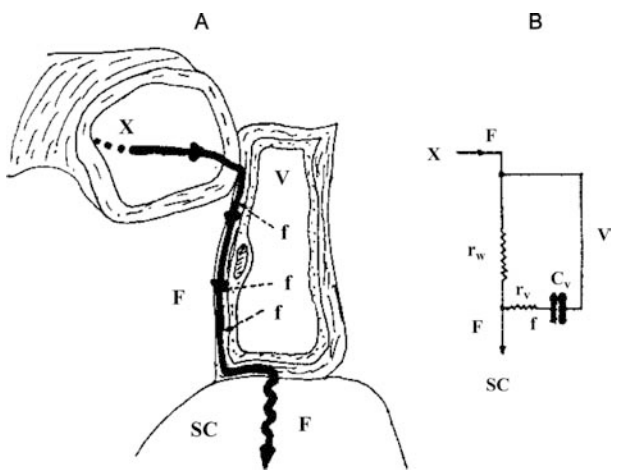

Fig. 1 (A) Schematic representation of the water pathway from a xylem vessel (X) to the evaporating surfaces at the substomatal cavity (SC) through a mesophyll cell. (B) A simplified electric analog of the water movement in (a). F: main flow through the cell wall (W), f: secondary flow from the vacuole (V), r_w: apoplast resistance, r_v: symplast resistance, c_v: symplast capacitance.

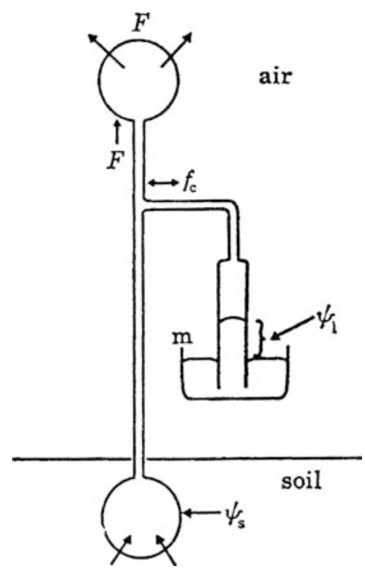

Fig. 2 Dixon's simplified model of a transpiring plant. The upper and lower porous pots represent the leaves and roots, respectively, while the manometer (m) represents the mesophyll cells. The negative pressure registered by the manometer is equivalent to the leaf water potential (Ψ_l) which fluctuates in response to lateral water movement (f_c) from and to the cells. F denotes the main transpiration stream. *Source*: From Ref.[4].

water will be drawn from the vacuoles of the mesophyll cells and the manometer will register the tension in the system. The leaf water potential ($\boldsymbol{\Psi}_l$) is equivalent to the tension registered by the manometer and proportional to the amount of water drawn from the cells. Accordingly, the fluctuations in $\boldsymbol{\Psi}_l$ arise from mesophyll-water exchanges with the main transpiration stream.

WATER POTENTIAL AND ITS COMPONENTS IN LEAVES

The Osmometer Concept

In order to study leaf water relations, it is necessary to consider a leaf as consisting of mature parenchyma cells. Mature cells consist of three distinct phases: an elastic cell wall, the parietal cytoplasm with the nucleus and the organelles, and a central vacuole containing a dilute aqueous solution of sugars, ions, organic acids etc. [Fig. 3(B)]. The vacuole occupies about 80–90% of the cell volume and is surrounded by a semipermeable membrane, the tonoplast. It is, therefore,

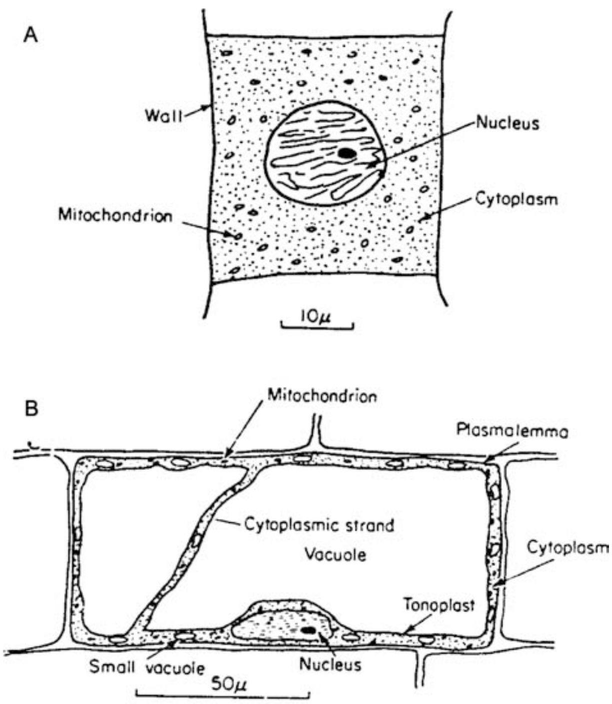

Fig. 3 Diagrammatic representation of (A) a meristematic, and (B) a mature parenchyma cell from higher plants. The large vacuole of the mature cell controls its water exchanges in a manner close to that of an ideal osmometer. The same may not apply to the meristematic cell where vacuolation is small. *Source*: From Ref.[5], p. 129.

reasonable to consider, as a first approximation, that cell water exchanges are controlled by the vacuole, which behaves as an osmometer. The adoption of the osmometer-concept for mature leaf parenchyma cells presupposes that the contribution of matrix to $\boldsymbol{\Psi}_l$ is negligible (i.e., $\psi_m = 0$). Thus, Eq. (5) becomes:

$$\boldsymbol{\Psi}_l = \psi_p + \psi_s \tag{6}$$

The solute potential (ψ_s) is determined by the concentration of the osmotically active substances in the vacuole. In leaf cells, ψ_s always takes negative values which vary with cell volume: they are least negative in fully hydrated cells (maximum volume) and more negative in dehydrated ones (smaller volume) and they are supposed to follow the Boyle–van't Hoff relationship:

$$\psi_s V = \text{constant} \tag{7}$$

It follows that a linear relationship is expected either between ψ_s and $1/V$ or between $1/\psi_s$ and V.

The changes in cell volume are also responsible for the development of the *pressure potential* (ψ_p). When water enters the cell, the vacuolar volume increases, and a pressure, called turgor pressure, is exerted on cell wall. At the same time, a pressure equal to turgor pressure is developed at the opposite direction, namely, from the wall to cell interior. This latter pressure, called wall pressure, acts like a hydrostatic pressure, increases the energy status of water in the cell by raising the pressure exerted on it above the local atmosphere, and represents the cell pressure potential (ψ_p). Obviously, ψ_p takes positive values as long as the vacuole exerts a pressure on the surrounding wall. When cells lose water, the vacuole shrinks progressively with a concomitant fall in cell turgor and ψ_p. The relationship between cell volume and ψ_p is curvilinear and depends on the elastic properties of the cell wall.

Fig. 4 shows the relationship between $\boldsymbol{\Psi}$ and its component potentials and the changes in cell volume (Hoefler diagram). When the cell achieves its maximum hydration (full turgor) $\boldsymbol{\Psi}$ bears its maximum value (zero) because $|\psi_p| = |\psi_s|$. As cell hydration falls, $\boldsymbol{\Psi}$ drops curvilinearly to more negative values, and at incipient plasmolysis $\psi_p = 0$ and $\boldsymbol{\Psi} = \psi_s$. From this point onwards $\boldsymbol{\Psi}$ is exclusively determined from the changes in ψ_s: it falls linearly with any further dehydration according to Eq. (7).

Fig. 5 shows the relations between $1/\boldsymbol{\Psi}_l$ against water deficit, known as pressure–volume curves[7] for leaves from different plant species. The curvilinear (turgor component) and the straight line (solute component) portions of the relationship are evident in all cases.

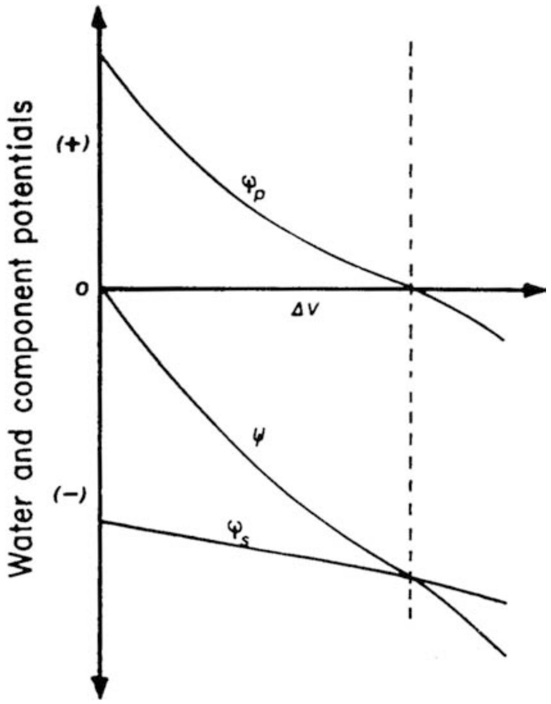

Fig. 4 The relationship between the volume of water lost (ΔV) and the water ($\boldsymbol{\Psi}$) and its component potentials, solute (ψ_s), and pressure potential (ψ_p) for a cell or tissue showing ideal osmotic behavior. The dashed line indicates the point of zero turgor (incipient plasmolysis). *Source*: From Ref.[6].

The diagram of Fig. 4 leads to two ecologically important conclusions. First, in view of the great significance of cell turgor to many physiological processes,[8] the maintenance of ψ_p above zero at relatively high levels of leaf dehydration should be beneficial for plants growing in arid regions. This can be achieved by means of a more elastic cell wall, which makes the fall of ψ_p with increasing dehydration less abrupt. Secondly, it is possible that an accumulation of osmotically active substances takes place in the vacuole. This leads to a drop of ψ_s to values more negative than those expected by a simple volume reduction caused by cell dehydration. This solute accumulation in cells subjected to water stress constitutes an adaptive mechanism known as *osmotic adjustment* or *osmoregulation*. Osmotic adjustment has been detected in many plant species[9] and acts in two ways: 1) it enables cells to lose more water before their turgor drops to zero; 2) it increases the ability of cells to absorb water under dry conditions by lowering the cell water potential and thus maintaining a potential gradient between plant cells and their medium, necessary for water absorption.

The Effects of Cell Matrix

As stated before, matric effects arise in systems rich in substances with large surface to volume ratios. At the cellular level, matrix is present in the cell walls in the form of interwoven cellulose microfibrils, and in the cytoplasm as the various gels and colloids. The real nature of ψ_m has been the subject of many discussions among specialists. Initially, ψ_m was thought to be the result of forces retaining water molecules by capillarity, adsorption, and hydration.[5,10] Tyree and

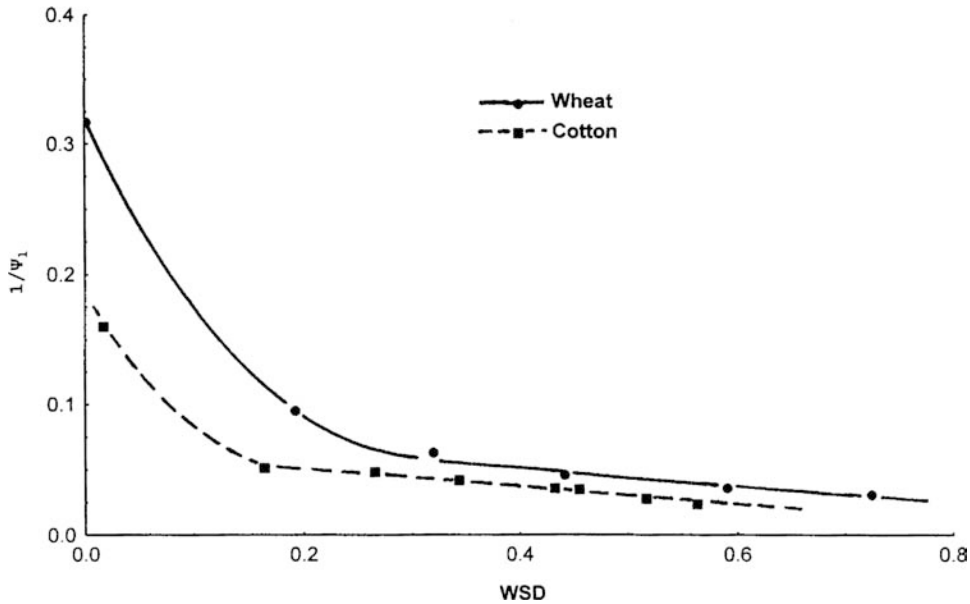

Fig. 5 The relationship between the inverse of the leaf water potential ($1/\boldsymbol{\Psi}_l$) and the leaf water saturation deficit (WSD) (pressure–volume curves) for leaves of wheat and cotton plants. No obvious deviations in the straight-line portions of the curves at high levels of dehydration are detectable.

Karamanos,[11] based on a physicochemical study of the forces arising near solid phases with substantial surface charge densities, identified ψ_m as the energy of interaction of the water dipoles with the electric field in the double layer,[12] and separated the effects of surface tension within the micropores as belonging to forces of a different nature (i.e., negative pressure). On this account, ψ_m exerts its major impact in cell walls within a very short distance from the charged surfaces and its contribution is minor in comparison to both ψ_p and ψ_s.

The osmometer approach assumes that the effects of cell matrix on tissue water exchanges are negligible and, thus, ψ_m equals zero. This assumption might be almost true in fully vacuolated parenchyma cells [Fig. 3(B)], because the vacuole contains no matrix. In meristematic cells, however, the situation could not be so clear because of the poor vacuolation and the large volume fraction of cytoplasm [Fig. 3(A)]. Within the cytoplasm ψ_m is important only in the matrix double layers which are expected to be less abundant in comparison with the cell wall. Since we have already concluded that ψ_m influences the state of only a small fraction of the total cell wall water, the overall effect in the cytoplasm is probably even smaller.[11] Nevertheless, no data on water exchanges of growing leaves are available to test this hypothesis.

A further complication to the osmometer approach is the question concerning the role of the apoplast as a water reservoir of cells and tissues. There is evidence that a high apoplastic water content is a common feature of xerophytes.[13,14] On this account, apoplastic water could compensate for any water loss from the symplasm. Such an assumption does not seem to be valid for several reasons. First, no systematic deviations along the pressure–volume curves were detected, even in drought adapted species[15] and at high levels of dehydration (Fig. 5), an indication that the osmometer model holds satisfactorily. Secondly, the values of leaf relative water content seldom fall below 50% in the most severe cases of natural dehydration. Accordingly, significant amounts of not easily extractable water are still retained in leaves suffering from intense water stress. Thirdly, the rate of net water loss from leaves accounts for less than 5% of the evapotranspiration rate of plants during daylight hours.[16] Thus, no part of the leaf water content could ever act as an effective reservoir for water, especially cell apoplast which functions as the pathway for free water movement from the xylem to the evaporating surfaces when leaf is transpiring (Fig. 1).

In conclusion, cell matrix does not seem to play a detectable role in leaf water relations. The osmometer concept holds satisfactorily, an indication that the cell vacuole is the key-site which regulates the water status of mature leaves.

METHODS OF MEASURING LEAF WATER POTENTIAL

A relatively large number of methods for determining leaf water potential have been used. The existing methods can be classified into three basic groups:

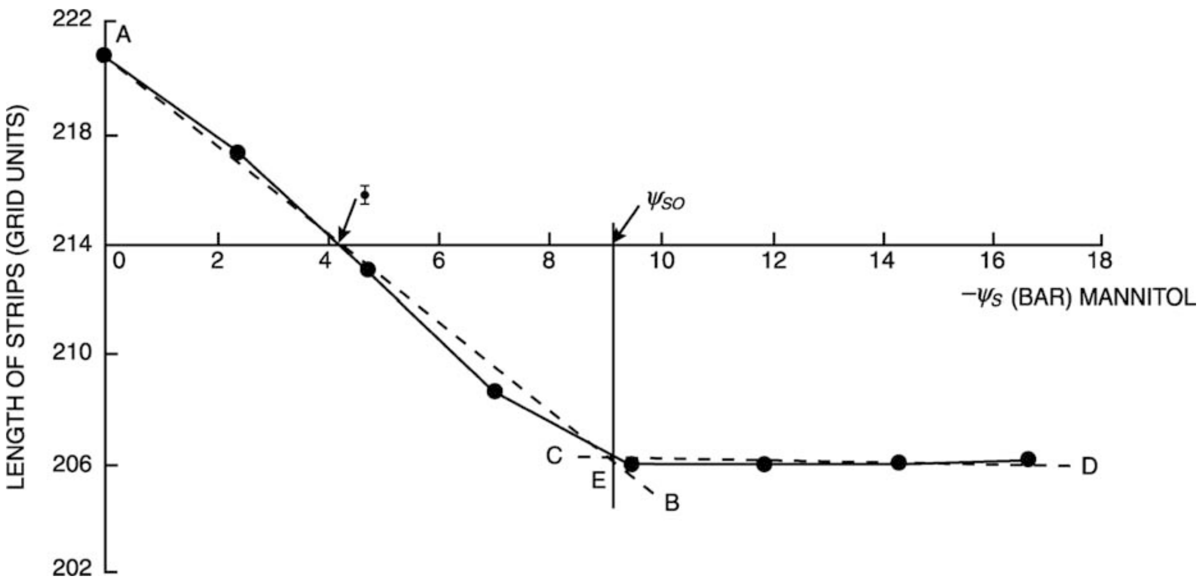

Fig. 6 Determination of the leaf water potential of fava bean leaves by the change in length of leaf strips floated on a series of mannitol solutions of different osmotic potentials (Ψ_s). The leaf water potential (**Ψ**) coincides with the Ψ_s of the solution where the initial length of the strip (214 grid units) remained unchanged. The osmotic potential at zero turgor (Ψ_{s0}) can also be traced on the axis of mannitol osmotic potentials from the point E of intersection of lines AB and CD. *Source*: From Ref.[20].

1) compensation methods; 2) psychrometric methods; and 3) pressure chamber method. A thorough description of these techniques is given in the works of Slavìk[17] and Wiebe et al.[18]

Compensation Methods

In the compensation methods, we search for the solution of a known osmotic potential which is isotonic to the leaf water potential of the sample. A set of uniform parallel leaf tissue samples (discs, strips, etc.) are floated in a series of graded test solutions of known osmotic potential and left for equilibration.[19] The net water transfer between the tissue and the solution depends on the relative magnitudes of $\boldsymbol{\Psi}_1$ and the ψ_s of the solution and is manifested as a change either in the weight or the size (length, thickness, or area) of the sample. The isotonic solution is usually detected by interpolation. Fig. 6 shows the determination of $\boldsymbol{\Psi}_1$ by the change in length of leaf strips. This technique can also give the ψ_s of the tissue at zero turgor.

The test solutions to be used must not: 1) be harmful to the tissues; 2) penetrate through cell membranes; and 3) be metabolized by plants. Mannitol, polyethylene glycol, and sucrose are the most common osmotica, but none of them completely fulfils all the requirements set above.

An alternative method is the equilibration of the leaf samples in the gaseous phase. A parallel set of samples is left to equilibrate in closed vessels over a series of graded test solutions.[21] The direction and relative rate of the water vapor transfer between the sample and the solution is then determined by measuring either the sample weight or the volume of the osmotic solution.

All compensation methods are time-consuming, temperature-dependent, laborious, and of relatively low accuracy (from 1 MPa to 0.3 MPa).

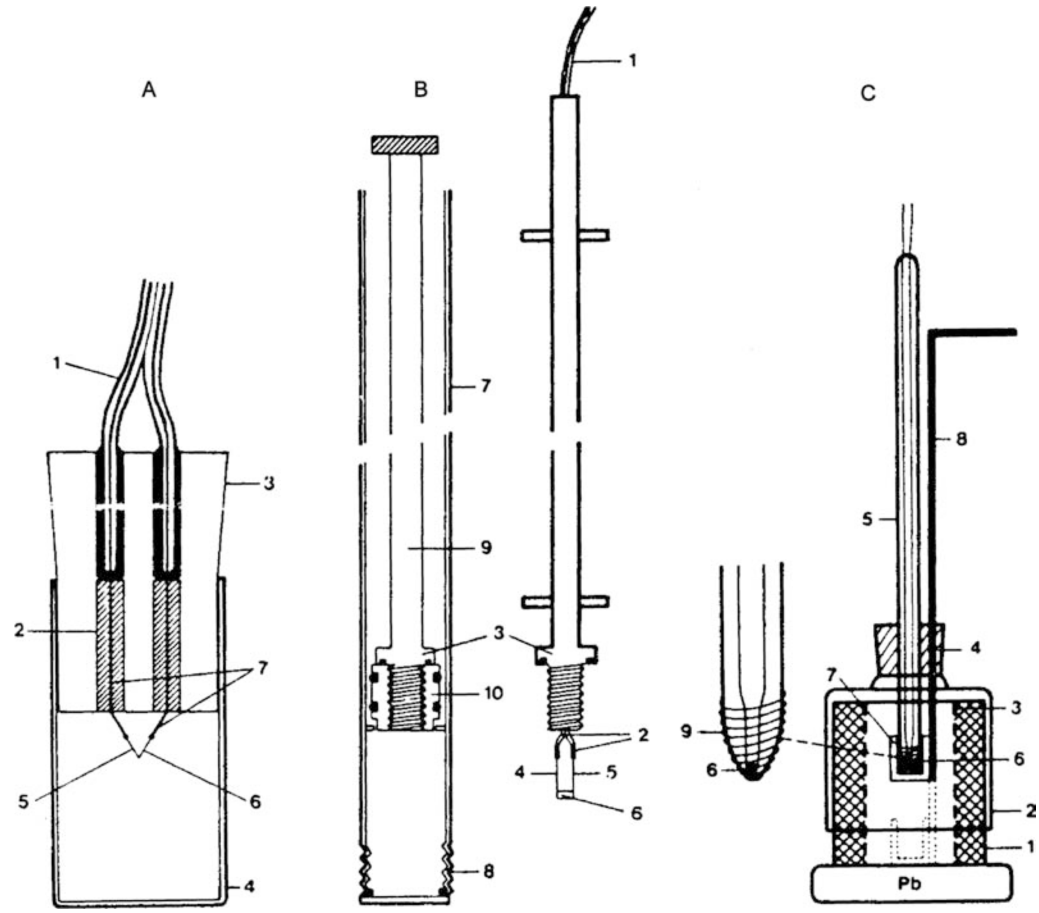

Fig. 7 Different types of thermocouple psychrometers. (A) A type. 1: wires, 2: copper rods, 3: rubber stopper, 4: measuring chamber, 5 and 6: chromel–constantan wires, 7: copper wires. (C) C type. 1: glass vessel, 2: rubber cap, 3: copper net cylinders with insulation, 4: rubber stopper, 5: glass tube, 6: thermistor, 7: plastic ‘‘spoon’’ filled with water, 8: holder of the plastic ‘‘spoon,’’ 9: wetting thread, Pb: copper plate Pb—lead weight. *Source*: From Ref.[17], Figs. 1.14, 1.18, and 1.21.

Psychrometric Methods

These methods measure water potential by determining the wet bulb depression in a closed gaseous system which is in equilibrium with the leaf sample. The wet bulb depression depends on the relative humidity of the air in the system, which in turn is related to **Ψ** as follows:

$$\boldsymbol{\Psi} = \left(\frac{RT}{\bar{V}_{\mathrm{w}}}\right) \ln \frac{e}{e_{\mathrm{o}}} \tag{8}$$

where e/e_o is the relative humidity.

There are three kinds of psychrometers for measuring the wet bulb depression. In the first (type A, [Fig. 7(A)], a thermocouple junction (chromel and constantan wires) is used alternatively as wet and dry: the output of the thermocouple is read first when the junction is dry, then condensation of a fine water droplet is achieved by Peltier cooling.[22] The thermocouple functions as a wet junction as long as water remains on its surface, and the difference between the two readings is equivalent to the wet bulb depression.

In the second type (type B, Fig. 7(B)), the output of a thermocouple with the thermojunction permanently wetted by a small drop of pure water is measured.[23] The droplet of water is held on a small silver ring supported by thin chromel and constantan wires. The diffusion flux of water from the junction to the leaf-tissue sample serving as a vapor sink is measured. In another version of this type, an additional similar dry thermocouple is included in the sample chamber and measured as reference.[24]

In the third type (type C, Fig. 7(C)), temperature sensitive resistance units (thermistors) are used instead of thermocouples.[25] The dry bulb temperature is measured with a thermistor to which a miniature chamber filled with water or wetted filter paper can be tightly attached. The wet bulb temperature is then measured by the same thermistor after temporarily lowering the wet chamber: water starts evaporating from the thermistor at a rate depending on the vapor pressure in the sample chamber, which is in equilibrium with the water potential of the plant material.

The readings from all types of psychrometers are calibrated against salt or sucrose solutions of known ψ_s. Leaf tissue segments (punched discs or strips) are used as samples. However, specially designed psychrometers or hygrometers are also used for the in situ measurement of the water potential of attached leaves (see Ref.[18] for a review).

Psychrometric techniques are extremely temperature-sensitive. Nevertheless, their mean accuracy is very high (up to $\pm$ 0.01 MPa).

The Pressure Chamber Method

The pressure chamber (or pressure bomb) was first used extensively by Schollander et al.[26] A cut leaf is inserted within a cylinder with its petiole protruding from the lid, so that it can be observed for sap exudation (Fig. 8). The chamber is then hermetically sealed and the pressure inside is gradually increased by compressed air or nitrogen until sap appears at the xylem vessels on the cut surface. According to the theoretical analysis of the technique,[7,27,28] the water potential in the xylem vessel ($\boldsymbol{\Psi}_x$) is dominated by the negative hydrostatic pressure (tension) $\psi_{p,x}$ caused by the transpiration stream. Both solute ($\psi_{s,x}$) and

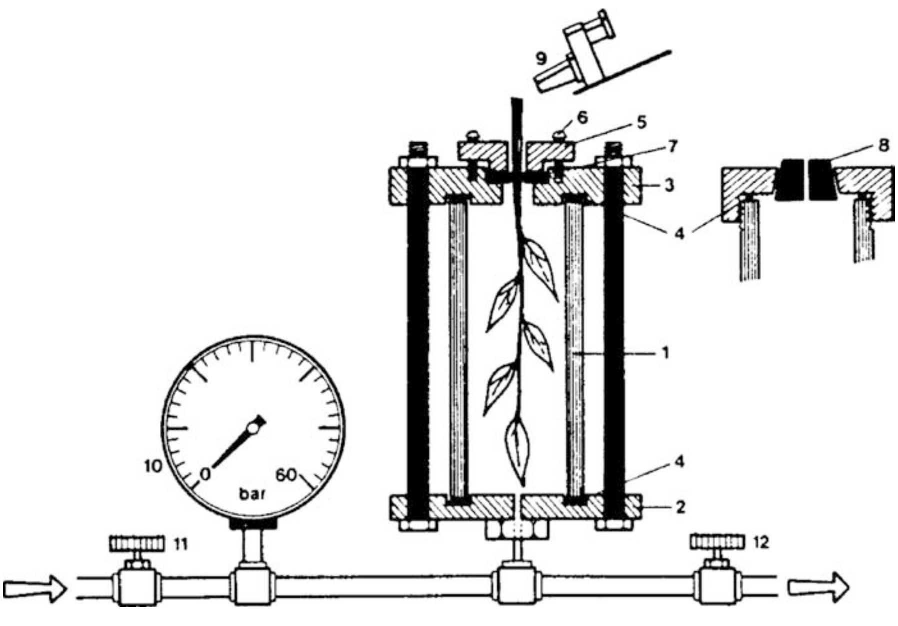

Fig. 8 Diagrammatic representation of a pressure chamber apparatus. 1: cylinder, 2: lower cover, 3: upper cover, 4: O-rings, 5: insertion held with four screws (6) used to seal the stem by means of an O-ring (7), 8: rubber stopper, 9: binocular microscope, 10: pressure gauge, 11: inlet valve, 12: outlet valve. *Source*: From Ref.[17], Fig. 1.33.

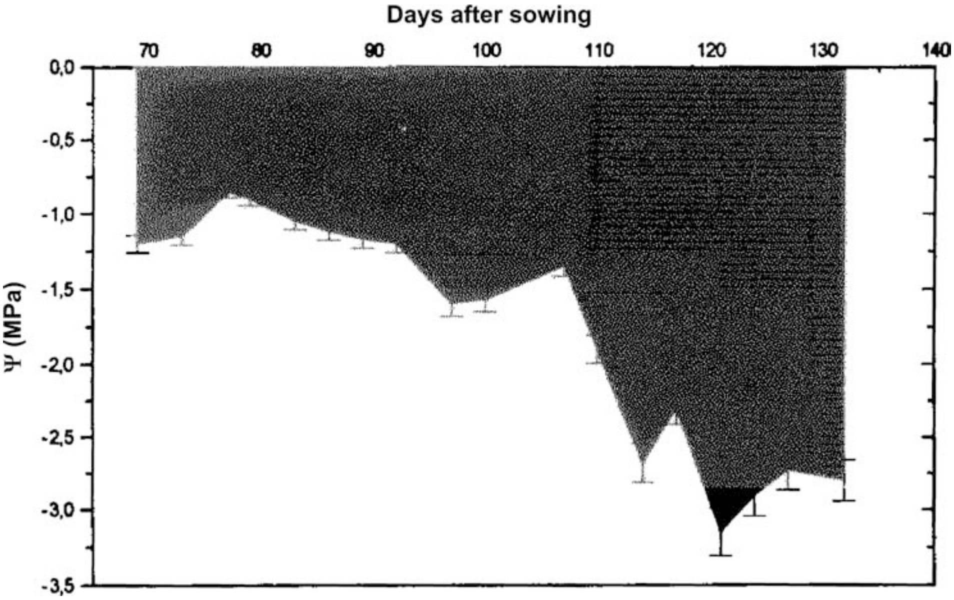

Fig. 9 The time course of the leaf water potential ($\mathbf{\Psi}_l$) for the wheat cultivar Yecora grown in Athens under rainfed conditions. The shaded area indicates the WPD and the vertical bars, the standard errors of the means. *Source*: From Ref.[29].

matric components ($\psi_{m,x}$) in the xylem are negligible.[26] It follows that:

$$\mathbf{\Psi}_x \cong \psi_{p,x} \tag{9}$$

The pressure required to force the sap to the cut petiole (P) compensates the original negative pressure in the intact xylem vessels ($\psi_{p,x}$), so that:

$$-P = \psi_{p,x} = \mathbf{\Psi}_x \tag{10}$$

$\mathbf{\Psi}_x$ then equals $\mathbf{\Psi}_l$ when single leaves are used.

The technique is quick, easy, and quite accurate (± 0.02 MPa) provided that some precautions are taken: 1) an appropriate rate of pressure increase is applied; 2) the water loss from the leaf during determination is minimal; 3) the pressure gauge is as accurate as possible.

In addition, this technique is very useful for producing pressure–volume curves[7] which offer useful and reliable information on the mechanisms involved in the regulation of leaf water status.

THE WATER POTENTIAL INDEX

At any time, leaf water potential is the combined result of interactions of soil water availability, evaporative demand, and plant responses. Accordingly, it can be considered as a reliable indicator of leaf water balance. Karamanos and Papatheohari[29] suggested a method to assess the water stress history experienced by a plant or crop by using serial values of $\mathbf{\Psi}_l$ over an observation period (Fig. 9).

The integral of the course of $\mathbf{\Psi}_l$ over time (i.e., the shaded area in Fig. 9) describes the "duration" of $\mathbf{\Psi}_l$ [water potential duration (WPD), in MPa days]:

$$\mathrm{WPD} = \int_{i=1}^{v} \mathbf{\Psi}_{l,i}\,\mathrm{d}t \tag{11}$$

where $\mathbf{\Psi}_{l,i}$ is the leaf water potential at day t within the observation period, i.e., from days 1 to v. In order to make the values of WPD comparable among observation periods of different duration, the Water Potential Index (WPI) is derived by dividing WPD by the length of the period of study:

$$\mathrm{WPI} = \mathrm{WPD}/n \tag{12}$$

where n is the length of a period in days.

The use of the WPI as an objective indicator of the total water stress experienced by plants in a given environment looks promising in genotype evaluation studies for drought stress resistance.[29]

Library Resources

Robert Teeter
Library, Santa Clara Valley Water District, San Jose, California, U.S.A.

INTRODUCTION

This article describes some representative water libraries in different kinds of institutions, both in the United States and internationally. It also describes the major databases available for finding journal articles and other literatures about water and related fields.

LIBRARIES: UNITED STATES

The U.S. Geological Survey's library system claims to be "the largest earth-science library in the world." Just as water is a major part of the Survey's mission, so too is it a major subject in its libraries. The USGS libraries collect materials in water resources, water quality, hydrology, surface water, groundwater, meteorology, glaciology, aquatic ecology, and aquaculture. The libraries hold more than 450,000 maps and 350,000 photographs, as well as more than 1.2 million scientific books and a comprehensive collection of the USGS's own publications. The USGS has its main library in Reston, Va., with regional libraries in Denver, Colorado; Flagstaff, Arizona; and Menlo Park, California. These libraries are open to the public as well as USGS staff. There are also smaller "science center libraries" around the country, such as the Water Resources Division library in New Cumberland, Pennsylvania, and the National Wetlands Research Center library in Lafayette, Louisiana.[1]

As part of the National Agricultural Library in Beltsville, Maryland, the Water Quality Information Center (WQIC) focuses on water management issues as they relate to farming and animal husbandry. In order to serve users nationwide, many of WQIC's products are provided through its Website. These include a database of electronic publications on water and agriculture and bibliographies on water-related subjects. Some of the bibliographies are automatically updated as the National Agricultural Library's catalog is updated.[2]

Agencies like the Illinois State Water Survey perform research and disseminate information on their state resources, just as the USGS does at the national level. The library of the ISWS, in Champaign, Ilinois, collects materials on groundwater, hydrology, water supply and treatment, water-use planning, and climate change. In addition to its own survey publications, the library has significant collections of reports from the University of Illinois Water Resources Center, U.S. Environmental Protection Agency, and other state and federal agencies.[3]

The University of Wisconsin Water Resources Library, in Madison, has a collection of about 30,000 volumes focusing on the water resources of Wisconsin and the other Great Lakes states. Unlike many academic libraries, this one lends materials to the general public (as long as they are Wisconsin residents) and even has services for children. Its Website features research guides, advice on finding a water-related job, a directory of water experts, and links to water Websites.[4] The library is affiliated with the university's Water Resources Institute, one of 54 such state institutes, many of which have libraries.[5]

Many other universities have extensive archives from local water agencies and officials. A product of 12 universities, the Western Waters Digital Library provides online access to records concerning the major watersheds of the Western United States.[6] The Everglades Digital Library, a service of Florida International University and other organizations, presents scientific reports, maps, data sets, photos, and other materials related to the wetlands of south Florida.[7] The Water Resources Center Archives at the University of California, Berkeley, has an important collection of documents and archives relevant to its state.[8]

The StreamNet Library, in Portland, Oregon, serves scientists and the general public interested in the fisheries (especially salmon) and ecosystems of the Columbia River Basin in the Pacific Northwest. The library has approximately 20,000 items—books, technical reports, journals, computer files, and other formats.[9]

The Rivers Institute at Hanover College in Hanover, Indiana, maintains a physical collection in the college's library and an online learning center on the Web. Among the online resources are an extensive directory of Web links, resources for K-12 teachers, a list of water dates and events, and lists of publications and presentations by institute staff.[10]

The Santa Clara Valley Water District manages the wholesale water supplies of Santa Clara County, California (Silicon Valley), while providing flood protection to its 1.7 million residents and serving as stewards of the county's more than 800 miles of streams. The district's library, in San Jose, consists of approximately 18,000 books, reports, government documents, electronic databases, and audio-visual materials. The collection includes the areas of engineering, environmental and earth sciences, and management. The library also serves the general public by making available district reports and by interlibrary lending.[11]

St. Johns River Water Management District, based in Palatka, Florida, provides regional water supply, surface water protection, and flood protection to the residents of 18 counties in northwestern Florida. The library covers water resources (surface and groundwater), civil engineering, environmental and life sciences, earth sciences, and Florida local and natural history. The library contains about 20,000 books, government documents, and technical reports. Check-out privileges are for staff only, but members of the public are welcome to visit.[12]

LIBRARIES: INTERNATIONAL

The Centre for Ecology and Hydrology, a research institute in the United Kingdom, maintains libraries at its eight locations. The libraries hold 50,000 books and reports on hydrology, aquatic ecology, climate change, and related subjects. Access is restricted to staff and approved external researchers.[13]

Natural Resources Canada's library covers all aspects of earth sciences, including water resources. Its main library is in Ottawa, but a branch in Quebec City specializes in groundwater; there are branches elsewhere in the country. The library serves Canadian government staff, scientists, and the general public.[14]

The Bundesanstalt für Gewässerkunde (German Federal Institute of Hydrology), a government agency in Koblenz, Germany, holds 85,000 publications in hydrology, water conservation, water resources management, aquatic biology, and related topics. It directly circulates materials to residents of the region and to others via interlibrary loan.[15]

The Water Reference Library, University of New South Wales, Australia, is part of the university's library, but also serves the Water Resource Laboratory. Its collection numbers 21,000 items in the fields of hydraulics, hydrology, coastal engineering, groundwater, irrigation, water quality, and oceanography.[16]

The library serving WaterCare Services, Ltd, in Auckland, New Zealand, has a collection in the areas of water supply, water resources planning, water quality, sewage treatment, engineering, and financial and asset management. Librarian Sarah Knight provides research and current awareness for staff in these subjects.[17]

Sydney Water, a utility serving Australia's largest city, has a library serving staff and the general public (by appointment). Its collection focuses on water, wastewater, environment, and engineering. Library staff provide books, reports, internal documents, audiovisual material, and online and CD-ROM databases. Library staff members also offer current awareness, journal alert, and interlibrary loan services.[18]

The Winnipeg (Manitoba) Water and Waste Department's library contains civil engineering references and standards, department reports, manufacturers' catalogs, and archival material. The library primarily serves department staff, but other city staff and engineering students also use it.[19]

DATABASES: SUBSCRIPTION

The following databases are available by subscription only. Many academic libraries, as well as special water libraries, have access to one or more of them. Except for the Water Library, all of these databases contain citations and abstracts rather than full text.

Water Resources Abstracts, published by Proquest CSA, indexes journals, conference proceedings, books, and reports in the areas of groundwater, surface water, water supply, water quality, watersheds, water engineering, and desalination. Coverage dates from 1967. A complementary database from Proquest CSA, Aquatic Sciences and Fisheries Abstracts (ASFA) focuses on aquatic biology.[20]

Aqualine covers a similar range of subjects as Water Resources Abstracts, but with a British emphasis. Its index goes back to 1960. It is jointly produced by Proquest CSA and the Water Research Centre (WRc).[21]

The American Water Works Association's database Waternet indexes journals, books, reports, and conference proceedings from the AWWA and other publishers. It covers water infrastructure, water treatment, water utility management, water conservation, water law, and water security from 1971 on. It is sold on CD-ROM from AWWA and is also available through the Dialog database service. The Water Library, an online service of AWWA, provides the full text of articles (for a fee) from the association's journal back to 1971.[22]

DATABASES: FREE

The American Society of Civil Engineers offers a database of its publications (many water related)—the CE Database. Citations and abstracts are free; full articles may be purchased for a fee.[23]

Similarly, the National Ground Water Association permits free searching of its Ground Water Online database. Abstracts and articles are free to NGWA members; nonmembers must pay a fee for articles.[24]

Researchers worldwide post abstracts of their current and recent work at the Water Research Network, based in Norway.[25]

The University of Florida Center for Aquatic and Invasive Plants makes available a database known as APIRS, which indexes the literature of aquatic, wetland, and invasive plants.[26]

CONCLUSION

Water libraries exist wherever scientists and engineers need the support a good library (and librarians) can provide to do their research. However, if there is not one near you, check to see what your nearest university or research institution can offer.

Livestock and Poultry Production: Water Consumption

David B. Parker
Michael S. Brown
Division of Agriculture, West Texas A&M University, Canyon, Texas, U.S.A.

INTRODUCTION

Competition for drinking water has increased in many locations across the world. Groundwater continues to decline in many areas. Water once used for agriculture is now being directed to municipal and industrial uses. There is a trend away from the family-sized farm or ranch to fewer large-sized animal production operations called concentrated animal feeding operations (CAFOs). Water consumption data are a necessary component in the design of a drinking water supply system for new livestock and poultry production operations.

Water is the primary constituent in the body of livestock and poultry, constituting 50–80% of the live weight of the animal. Water serves as an essential solvent and plays a vital role in regulation of body temperature, lactation, digestion, elimination of waste products of digestion and metabolism, regulation of osmotic pressure, reproduction, transportation of sound, and vision.[1,2] Livestock and poultry fulfill their water needs by drinking or eating snow and/or ice, ingesting water contained in feed, and in minor amounts through metabolism (water produced by the oxidation of carbohydrate, fat, and protein). The primary avenues of water loss are urinary excretion, fecal excretion, perspiration, and respiration.[1]

When evaluating water requirements of livestock and poultry, it is important to distinguish between free water intake (FWI), which is water consumed by the animal by drinking, and total water intake (TWI), which is the sum of FWI and any water ingested in the feed. The amount of water ingested in processed feed and grazed forage can be substantial. For example, many ''dry'' feedstuffs contain 10–14% water, while grazed forages and silages contain 60–80% water. Free water intake is usually measured as the amount of water disappearance from a water trough. Because of spillage by ''leisure'' activities, water disappearance does not always equal the amount of water ingested or actual water requirement. However, water disappearance and FWI are assumed to be equal in most production situations.

WATER CONSUMPTION FOR LIVESTOCK

Cattle

Cattle can be divided into three groups: feedlot cattle, range cattle, and dairy cattle. Within these groups, a variety of factors may affect water consumption, including species or breed, type of diet, feed intake, rate and composition of gain, pregnancy, lactation, activity, and environmental conditions. One of the first references for daily water intake by dairy and beef cattle was published by Winchester and Morris.[3] Although the water intake values presented in this publication are often referenced, there are many things that have changed to alter water intake in cattle today, most notably breed characteristics, feeding management, and dietary ingredients. In this chapter, we have attempted to provide a concise summary of the latest in water consumption data available for current feeding and management conditions.

Feedlot cattle

Most commercially fed cattle in the United States are housed in open, earthen-surfaced lots with 50–200 animals per pen. Until recently, few data were available from which to establish water requirements for feedlot cattle.[1] Parker et al.[4] monitored total water usage over a two-year period at a 50,000 animal beef cattle feedlot. Average daily water usage over the two year period was 40.9 L per animal, which included all water used for drinking, in the feedmill for steam flaking grain, and water used in overflow water troughs in the winter to prevent ice formation. In the winter, 66% of total usage was for drinking and in the summer 89% was used for drinking. A regression equation was developed to predict daily water usage for the entire feedlot:

$$\begin{aligned} \mathrm{DFWU} &= 39.2 - 0.648\,\mathrm{MaxT} + 0.0421\,\mathrm{MaxT}^2 \\ &\quad - 0.0717\,\mathrm{MinRH} \qquad (1) \\ R^2 &= 0.60 \end{aligned}$$

where DFWU is the daily feedlot water use (L per animal), MaxT, the maximum daily temperature (°C), and

MinRH, the minimum daily relative humidity (%). Jeter[5] measured FWI by feedlot steers and developed the following equation:

$$\mathrm{DFWI} = 40.61 + 0.46\,\mathrm{MinT} - 0.45\,\mathrm{MinRH} \quad R^2 = 0.93 \tag{2}$$

where DFWI is the daily free water intake (L/day), MinT, the minimum daily temperature (°C), and MinRH, the minimum daily relative humidity (%).

Range cattle

The livestock category of range cattle describes both diverse classes of cattle (non-lactating and lactating cows, growing steers and heifers, and mature bulls) and diverse types of grazing conditions (e.g., introduced forages and winter or spring cereal grains, native range) in which forage quality varies. The potential relationships between climatologic variables and the distance animals must travel to obtain forage and drinking water are poorly understood for grazing cattle. Although the majority of data available do not consider the water consumed in forage, it is well recognized that forage dry matter concentration is dynamic and dependent on environmental influences.

Winchester and Morris[3] summarized total water intake data from six studies generally involving various classes of cattle that were individually fed and housed in environmental chambers for periods of 7–14 day (Table 1). Although these data were primarily derived under ''laboratory'' conditions, few data from production studies are available. Kattnig et al.[6] reported that FWI by 234 kg Holstein steers fed hay in individual pens was 91 mL/kg of body weight; average daily maximum temperature was 20.7°C. Ojowi et al.[7] conducted an 84 day grazing study by using growing steers (308 kg) gaining 0.9 kg/day and indicated that FWI averaged 94 mL/kg of body weight. Ali, Goonewardene, and Basarab[8] monitored ambient temperature, relative humidity, and FWI of grazing cattle (cows with calves, heifers, and a mature bull) during an 84 day grazing period. The average daily maximum temperature was 22.2°C, and FWI averaged 108 mL/kg of body weight.

Dairy cattle

Water is the most important dietary component for dairy cattle, as insufficient water can limit milk production.[3] Lactating dairy cows require about 4 L of water for each kg of milk produced.[9] Many regression equations have been developed to predict the amount of water consumed by dairy cows.[10] Dahlborn, Akerlind, and Gustafson[11] developed the following equation:

$$\mathrm{DFWI} = 14.3 + 1.28\,\mathrm{MP} + 0.32\,\mathrm{DM} \tag{3}$$

where DFWI is the daily free water intake (drinking only), MP, the milk production (kg/day), and DM, the dry matter (% of diet). A summary of estimated water requirements for various classes of dairy cattle is presented in Table 2.

Table 1 Total water intake by beef cattle with an ambient temperature of 4.4–32.2°C

	Daily total water intake	
Class of cattle	**L/day**	**mL/kg of body weight**
Bulls		
544 kg	28–66	51–121
816 kg	33–78	40–96
Non-lactating, pregnant cows[a]		
408 kg	25–37	61–91
500 kg	23–33	46–66
Lactation adjustment [added for each 1 kg of milk produced (4% milk fat)][b]		
	2.1–2.7	
Growing heifers and steers (average daily body weight gain of 0.4–0.7 kg/day)		
180 kg	15–22	83–122
360 kg	24–35	67–97

Total water intake was determined to be constant below 4.4°C.
[a]Data were not determined above an ambient temperature of 21.1°C.
[b]Data were derived from lactating dairy cows with an ambient temperature of 4.4–32.2°C.
Source: From Ref.[3].

Swine

Weanling pigs age (3–6 weeks) will drink about 0.5 L/day in the first week after weaning and 1.5 L at age 6 weeks.[13,14] Growing swine will consume about 2.5–3.0 L of water for each kg of feed consumed.[14] Pigs drink about the same at temperatures of 7–22°C, but the amount of water consumed increases considerably at 30°C.[15] A summary of estimated water requirements for various classes of swine is presented in Table 3.

Horses

Horses consume about 8.4 L per 100 kg of body weight. Horses need 2–3 L of water per kg of dry matter intake.[18] Fonnesbeck[19] determined that horses fed an all-hay diet resulted in a water-to-feed ratio of 3.6:1, while horses fed a hay–grain diet had a

Table 2 Water requirements for various classes of dairy cattle

Class	Production (kg milk/day)	Estimated water consumption (L/day)
Holstein calves	—

water-to-feed ratio of 2.9 : 1. Working horses may drink 20–300% more water than horses at rest.[18] A summary of estimated water requirements for various classes of horses is presented in Table 4.

Sheep

The water required for sheep depends on the same factors as other livestock. In addition, the water requirements may vary with wool covering.[20] A summary of estimated water requirements for various classes of sheep is presented in Table 5.

Goats

A high proportion of the world's goat population lives in arid areas where water requirements are not easily met. Goats are one of the most efficient animals in the use of water, having one of the lowest rates of water turnover per unit of body weight.[21] Data for water consumption by dairy and meat goats is limited. Dairy goats require about 1.43–3.5 L of water per kg of milk, significantly less than dairy cattle.[21] Penned meat goats drink about 0.7 L of water per day.

Table 3 Water requirements for various classes of swine

Class	Estimated water consumption (L/day)
Weanling pig	0.5–1.5
11 kg pig	1.9
27 kg pig	5.7
45 kg pig	6.6
90 kg pig	9.5
Gestating sow	17.0
Pregnant gilt	20.8
Sow plus litter	22.7
Boar	10–15

WATER CONSUMPTION FOR POULTRY

Chickens

Xin[22] developed the following equation for broilers between 1 day and 56 day of age:

$$\begin{aligned} \mathrm{DFWI} &= 2.78 + 4.70D + 0.128D^2 - 0.00217D^3 \\ R^2 &= 0.999 \end{aligned} \tag{4}$$

where DFWI is the daily free water intake (L per 1000 birds) and D, the age in days. A summary of estimated water requirements for various classes of chickens is presented in Table 6.

Turkeys

Parker, Boone, and Knechtges[24] monitored water intake in tom turkeys at temperatures ranging from

Table 5 Water consumption of various classes of sheep

Class	Water requirement (L/day)
Rams	7.6
Dry ewes	7.6
Ewes with lambs	11.3
5–20 lb lambs	0.4–1.1
Feeder lambs	5.7

10.0 to 37.8°C, with water consumption of 0.3 L/day and 1.3 L/day, respectively. A summary of estimated water requirements for various classes of turkeys as reported at commercial turkey production companies is presented in Table 6.

Ducks

Veltman and Sharlin[25] evaluated water consumption in White Pekin ducks between 14 day and 42 day of age. Ducks that were allowed access to water 24 hr per day consumed 0.8 L/day, while ducks provided access to water only 4 hr/day consumed 0.6 L/day.

INTRODUCTION

A plentiful and consistent supply of high-quality water is essential for optimal production and health of feedlot cattle. Water of inadequate quality can result in decreased gains, poor feed conversion, and adverse affects on animal health. The greatest losses to livestock producers from low-water quality are often through undetected production inefficiencies and hidden but considerable influences on profitability.

WATER REQUIREMENTS

Water constitutes 60–70% of the body of livestock. Water consumption is critical for animal maintenance. Animals that do not drink sufficient water may suffer stress or even dehydration.

The amount consumed depends on the species, weather, and characteristics of feedstuffs consumed. For instance, dry beef cows need about 8–10 gal of water daily, whereas beef cows in their last 3 mo of pregnancy may drink up to 15 gal a day. Those in milk need about five times as much water as the volume of milk produced. Also, calves require much more water after weaning than before. Ignoring this fact may irreversibly retard growth of calves from which they may never fully recover.

WATER QUALITY

Safe supplies of water are absolutely essential for livestock. Livestock may suffer health problems or below-normal consumptions resulting from substandard quality water. Ingestion of mineral or organic contaminants can cause poor performance or non-specific disease conditions. Major livestock health problems associated with water quality are seldom reported except in site-specific instances. When evaluating the quality of water for livestock, one has to consider whether livestock performance will be affected; whether water could serve as a carrier to spread disease; and whether the acceptability or safety of animal products for human consumption will be affected.

The most common water quality problems affecting livestock production are the following.

- Excess salinity—high concentration of minerals, measured as total dissolved solids (TDS).
- High nitrates or nitrites.
- Bacterial contamination.
- Blue-green algae.
- Accidental spills of petroleum, pesticides, or fertilizers into water supply.

The importance of nitrate, nitrite, sulfate, and TDS as factors influencing water quality for livestock has been recognized. Concentrations generally considered safe for consumption by cattle have been established (Table 1). However, these values may vary slightly depending on type and formulation of rations fed to cattle.

In 1999, the USDA's National Animal Health Monitoring System[1] conducted a water sampling study on beef feedlots with 1000 head or more capacity in the 12 leading cattle feeding states. These feedlots accounted for 96.1% of U.S. cattle feedlot inventory (January 1, 2000) and 84.9% of feedlots with 1000 head or more capacity.[1]

One representative water sample per feedlot was analyzed for nitrate, nitrite, sulfate, and TDS. A total of 263 feedlots from 10 states (all west of the

Table 1 Concentrations of nitrate, nitrite, sulfate, and total dissolved solids in water typically considered safe for livestock usage

Measurement	Concentration considered safe[a] ($mg\,L^{-1}$)
Nitrate, NO_3	Less than 440
Nitrate, NO_3-N	Less than 100
Nitrite, NO_2	Less than 33
Nitrite, NO_2-N	Less than 10
Sulfate, SO_4	Less than 300
Total dissolved solids, TDS	Less than 3000

[a]mg/L is equivalent to parts per million (ppm).
Source: From Ref.[1] and National Research Council, National Academy of Sciences, Washington, DC.

Mississippi River) supplied a water sample for analysis. (No water samples were submitted from Arizona or Oklahoma.) The majority of samples (89.7%) were drawn from a well. Other sources included municipal/city (4.6% of samples), spring/river (2.3%), and pond/lake (2.3%).

Only 1.7% of samples came from shallow wells (less than 30 ft deep), while 45.3% of samples were from wells that were 101 ft–300 ft deep, and 22.5% were from wells deeper than 300 ft.

The mean nitrate concentration was $33.6\,mg\,L^{-1} \pm 3.5\,mg\,L^{-1}$ NO_3 (or $7.6\,mg\,L^{-1} \pm 0.8\,mg\,L^{-1}$ NO_3-N) while sulfate averaged $205\,mg\,L^{-1} \pm 24\,mg\,L^{-1}$ SO_4. Both these values are considered safe levels (See Table 1). Nitrite was detectable in only 0.4% of the samples. No water samples exceeded the recommended nitrate limit and only 23% exceeded the sulfate limit.

MINERALS AND SALINITY

Livestock tolerance of minerals in water depends on many factors: kind, age, diet, and physiological condition of the animal; season; climate; and kind of salt ions in the water. Livestock may drink less if the water tastes bad. Livestock restricted to waters with high salt content may suffer physiological upset or death.

Several mineral elements found in water seldom offer problems to livestock because they do not occur at high levels in soluble form, or because they are toxic only in excessive concentrations. Examples are iron, copper, cobalt, zinc, iodide, and manganese. These elements do not seem to accumulate in meat or milk to the extent that they would cause problems.

Common compounds found in waters with excess salinity include sodium, chloride, calcium, magnesium, sulfate, and bicarbonate. Bicarbonates and carbonates may contribute to alkalinity (pH) levels. When feed also is high in salt, lower water salinity would be desirable. Moreover, animals consuming high-moisture forage can tolerate more saline waters than those grazing dry grain rations, dry brush, or scrub. Hard water without high salinity does not harm animals.

NITRATE AND NITRITE

Sources of nitrates and nitrites include decaying animal or plant protein, animal metabolic waste, nitrogen fertilizers, silage leachate, and soil high in nitrogen-fixing bacteria. Nitrates and nitrites are water soluble and may be leached away to the water table or into ponded water.

Nitrate is important in livestock health. Although nitrate is not a particularly potent toxin, it is readily reduced to highly toxic nitrite within the rumen. Nitrite is about 10 times more toxic than nitrate. Nitrite is absorbed where it interacts with red blood cells by inhibiting their ability to effectively transport oxygen. Moderate nitrate intake may not cause any noticeable effect on animal health but may result in decreased animal gains and poorer feed conversion. Intake of large amounts of nitrate may result in death.

SULFATE

Sulfur is required by all animals. The recommended sulfur intake for beef cattle is 0.15% of the ration and the maximum tolerable limit is 0.4% of the ration on a dry matter basis. Water can contribute significant quantities of sulfur, as sulfate, towards total sulfur consumption. Sulfur and sulfate are relatively non-toxic in these forms, but sulfate/sulfur is readily reduced in the rumen to highly toxic sulfide products. Excessive total sulfur consumption through feed and water can result in decreased water consumption, feed intake, and reduced average daily gains feed conversion.[2]

Cattle on pasture can tolerate up to a maximum of $2000\,mg\,L^{-1}$ sulfate (SO_4). However, cattle on full feed with a heavy proportion of concentrate in the diet should have water containing $300\,mg\,L^{-1}$ sulfate or less.

If native cattle are moved onto water with a high sulfate level during a hot, dry period, there may be problems with adequate consumption. The same water may be well tolerated and consumption increased as needed in animals that were introduced to the water source in a cooler season, when demand was initially low (due to sufficient time for adaptation/acclimatization).

BIOLOGICAL ORGANISMS

All surface waters must be assumed to carry bacteria. Livestock should be kept away from contaminated water that has not been adequately aerated (oxygenated) because of the likelihood of excessive levels of bacterial pathogens that may be present. Surface water sources may have problems with algae growth as a result of high-nutrient loading in runoff water. Avoid using waters bearing heavy growths of blue-green algae, as several species can produce animal toxins (poisons). To control algae in storage tanks, reduce the introduced organic pollution and exclude light. Water storage tanks can be disinfected by adding 1 oz of chlorine bleach per 30 gal of water, holding for 12 hr before draining, and then refilling with clean water. Chlorination can also control certain bacteria.

WATER QUALITY CRITERIA

There are no regulations regarding livestock water quality. *Suggested* limits of concentrations of specific substances in water for livestock, where these have been established, are shown in Table 2, which shows that suggested upper limits for livestock are generally higher than for humans, with the exception of copper and fluoride. Generally, salinity is more restrictive for young animals, pregnant, or lactating animals. Also, monogastic animals (poultry and swine) are less tolerant to salinity than ruminant animals (cattle or sheep).

WATER QUALITY EVALUATION

To evaluate water quality in relation to livestock health problems, it is imperative to obtain a thorough history, make accurate observations, ask intelligent questions, and submit suspected water and properly prepared tissue specimens without delay to a qualified laboratory.[7] Obtain assistance from a local veterinarian, county Extension agent, or state veterinary medical diagnostic laboratories, usually affiliated with the land grant university in each state.

SOURCES OF WATER QUALITY CONTAMINATION

Contaminant levels may be affected by runoff from surrounding lands and by concentration caused by water evaporation from a pond or storage tank.[8] Salinity is of special concern in the western half of the United States where naturally occurring salinity in watersheds or geological formations can restrict livestock water uses (Table 3). Livestock grazing operations may influence stream water quality where cattle are watered in or along the streams or drainage features. Potential sources of localized groundwater contamination include: livestock manure accumulations around water wells, ponds and stock pens, and agricultural chemicals or containers at spray pens, dipping vats, and disposal sites. Other potential non-point pollution sources that require careful site selection

Table 2 Recommended limits of concentration of some potentially toxic substances in drinking water for livestock vs. comparable values for humans

MCL = Maximum contaminant level, highest level allowed in drinking water, an enforceable standard for public drinking water supply; MFL = million fibers per liter; N.A. = Not applicable; N.E. = Not established.
[a]Primary standards only, not including current human drinking water quality standards for micro-organisms; disinfectants or disinfection byproducts; organic chemicals; or radionuclides.[4]
[b]Available data are not sufficient to warrant definite recommendations.

Table 3 Guide to using saline waters for livestock

Total soluble salts content of waters (mg L^{-1})	Comments—livestock water use
Less than 1,000	Relatively low level of salinity, no serious problem expected
1,000–2,999	Considered satisfactory; may cause temporary mild diarrhea in livestock unaccustomed to them, but should not affect animal health or performance
3,000–4,999	Should be satisfactory; may cause temporary diarrhea or be refused at first by animal unaccustomed to them
5,000–6,999	Can be used with reasonable safety; avoid using those approaching the higher limits for pregnant or lactating animal
7,000–10,000	Use should be avoided; considerable risk for pregnant or lactating livestock, young animals, or for any animals subjected to heavy heat stress or water loss; older livestock may subsist under conditions of low stress
More than 10,000	Excessive risks; cannot be recommended for use under any conditions

Source: From Ref.[5].

and management include:[9] concentrated animal feeding operations; wastewater holding ponds; lagoons; manure stockpiles; silos; dead animal disposal sites; and onsite sewage treatment systems.

Fertilizers, including manure and wastewater, should be carefully selected and applied to land in accordance with soil and crop requirements or nutrient management plans. This will help prevent contaminating underlying aquifers and with nutrients or salts. Always handle and apply pesticides in strict accordance with the recommendations on the label. Do not apply pesticides around a water supply or other vulnerable sites.

Wellhead protection measures are specified in water well drillers' guidelines in most states. Locate wells at least 150–300 ft from livestock corrals, septic tanks, manure treatment lagoons, and runoff holding ponds.[8] To prevent infiltration, case, and grout wells down to a restrictive layer or to the water table, and seal around the wellhead with a concrete pad.

CONCLUSION

Livestock producers should provide sufficient safe water for animals by preventing contamination and providing adequate sources of year-round, high-quality drinking water supply. Livestock should be protected from unsafe drinking water by providing alternative sources of acceptable quality water.

Water-related health problems in livestock are usually caused by stress conditions that may include inadequate water supply or unpalatable water with a high level of dissolved substances.

Livestock: Water Harvesting Methods

Gary W. Frasier
U.S. Department of Agriculture (USDA), Fort Collins, Colorado, U.S.A.

INTRODUCTION

Approximately, 40% of the world's land area is classified as rangeland with over 80% in the arid and semiarid zones.[1] In these rangeland areas, there is usually sufficient water, primarily as precipitation, for plant growth in the form of grasses and small shrubs which are the primary foodstock for herbivores, both wildlife and domestic. While there is sufficient forage for the animals, many of these rangelands cannot be used for livestock production because of inadequate drinking water sources such as streams and springs. Traditionally, supplemental animal drinking water has been supplied by wells, ponds, and in some instances physical water transport. There are areas where even these supplemental water techniques are not available or otherwise unsuitable. One technique of water supply that can be used in most places in the world when other sources are unavailable is a process called water harvesting.

DEFINITION AND BACKGROUND

Water harvesting is defined as the collection of precipitation from a prepared area for some beneficial use. Water harvesting for livestock and human drinking water supplies is an ancient practice dating back to the first-half of the Bronze Age, about 4000 yr ago.[2] It is probable that the first water harvesting system for drinking water was nothing more than a simple depression that filled with water running off a rock surface. Even today, in many arid regions, we can find rain-filled depressions in rock outcroppings that provide drinking water for wildlife.

In the past 40 yr, there has been a renewed interest in water harvesting as a means of water supply for both livestock and domestic uses. There is no universally ''best'' method of water harvesting, since each site has its own unique characteristic features: soil type and topography; precipitation quantities and intensities; and water needs, timing, and quantities. The designer, installer, and ultimate user of a water harvesting facility should become as familiar as possible with the available techniques and adapt one that is best suited to the local environment, social, and economic conditions and site features. Many of the elements of a water harvesting facility are interrelated and must be considered simultaneously.

There is a considerable amount of technical literature, which describes or presents information concerning the various techniques of water harvesting. Unfortunately, much of this information is scattered in scientific or technical journals and proceedings of various meetings, and is written in a manner that is difficult to interpret for direct field application by farmers and technicians.[3]

WATER HARVESTING SYSTEM

All water harvesting facilities for livestock watering have the same basic components (Fig. 1). The collection area (catchment area) can be a natural hillside, a smoothed soil area, an area treated or covered to reduce water infiltration and increase surface runoff, or even the roofs of buildings. The collected water is stored in some container, pond, or tank until it is needed.

There are many ways the catchment area can be modified to reduce water loss by infiltration and increase the quantity of precipitation runoff. These can be separated into three general categories: 1) topography modification; 2) soil modifications; and 3) impermeable coverings or membranes. Table 1 presents a list of some of the more common catchment treatments with their estimated runoff efficiency and life expectancy. Generally, the lower runoff efficiency treatments require storms of higher intensities and total volume to produce significant quantities of runoff. For example, a sheet metal roof will have runoff from storms of lower rainfall intensities and quantities than a catchment of compacted earth. It is usually necessary to increase the size of catchments which have low runoff efficiency treatments compared with the size of a catchment with an impervious surface.

Storage techniques for animal drinking water usually involve some form of container, tank, or lined pond. Unlined earthen pits or ponds are not usually satisfactory methods for water harvesting unless seepage losses are low or can be controlled. There are many types, shapes, and sizes of wooden, metal, and reinforced plastic or concrete storage containers. Costs and availability are primary factors for determining

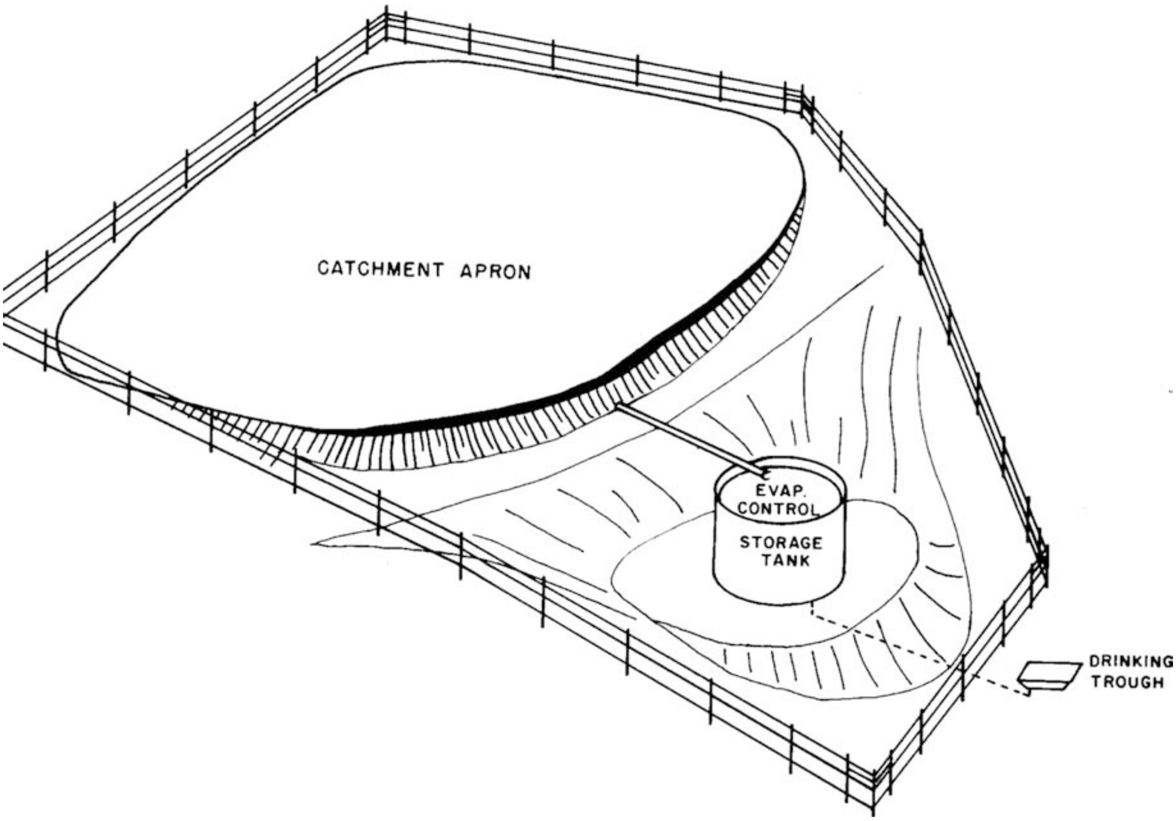

Fig. 1 Typical water harvesting system for livestock water. *Source*: From Ref.[4].

the suitability of these containers. Containers constructed from concrete wand plaster are relatively inexpensive, but their construction requires a significant amount of hand labor. One common type of storage is a steel rim tank with a concrete bottom.

Table 1 Potential water harvesting catchment treatments

Treatment	Runoff efficiency (%)	Estimated life (yr)
Topography modification		
Land smoothing and clearing	20–35	5–10
Soil modification		
Sodium salts	50–80	5–10
Water repellents and paraffin wax	60–95	5–8
Bitumen	50–80	2–5
Impermeable coverings		
Gravel-covered sheeting	75–95	10–20
Asphalt-fabric membrane	85–95	10–20
Concrete, sheet metal, and artificial rubber	60–95	10–20

Source: Adapted from Ref.[5].

Because water harvesting is a relatively expensive method of water supply, controlling evaporation losses is an important factor and should be an integral component of all water storage facilities. Although relatively expensive, roofs over the storage are commonly used. Evaporation control on sloping-sided pits or ponds is more difficult because the water-surface area varies with depth.

SOCIOECONOMIC CONSIDERATIONS

Water harvesting techniques are practical methods of water supply for most parts of the world, but they are also a relatively expensive method of water supply. During the past few decades, there have been numerous water harvesting systems constructed worldwide. While many of the systems have been outstanding successes, others have failed. Some systems failed despite extensive efforts because of material and/or design deficiencies. Others have failed because of personnel changes, communication failures, or because the water was not perceived as needed by the local user. Word-of-mouth publicity of one failure will often spread more widely than all the publicity of 10 successful systems.

Low-Impact Development

INTRODUCTION

Low-Impact Development (LID) is a strategy for storm-water management that uses on-site natural features integrated with engineered, small-scale hydrologic controls to manage runoff by maintaining or closely mimicking predevelopment watershed hydrologic functions.[1] Planning for LID is most effective at the scale of an entire subdivision or watershed; engineering and site design elements, however, are implemented at the scale of individual parcels, lots, or structures. In combination, these actions seek to store, infiltrate, evaporate, or otherwise slowly release storm-water runoff in a close approximation of the rates and processes of the predevelopment hydrologic regime.

TYPICAL CHACTERISTICS OF LOW-IMPACT DEVELOPMENT

Most applications of LID have several common components (Fig. 1):

- Preserving elements of the natural hydrologic system that are already achieving effective storm-water management, recognized by assessment of a site's watercourses and soils; channels and wetlands, particularly with areas of overbank inundation; highly infiltrative soils with undisturbed vegetative cover; and intact mature forest canopy.
- Minimizing the generation of overland flow by limiting areas of vegetation clearing and soil compaction; incorporating elements of urban design such as narrowed streets, structures with small footprints (and greater height, as needed), use of permeable pavements as a substitution for asphalt/concrete surfaces for vehicles or pedestrians;[3] and using soil amendments in disturbed areas to increase infiltration capacity.
- Storing runoff with slow or delayed release, such as in cisterns or distributed bioretention cells, across intentionally roughened landscaped areas or on vegetated roofing systems (''green roofs'').[4,5] Runoff storage in LID differs from traditional storm-water management, notably the latter's use of detention ponds, primarily by its scale—small and distributed in LID, large and centralized in traditional approaches.

Native soils play a critical role in storage and conveyance of runoff, particularly in humid regions. In such regions, one to several meters of soil, generally high in organic material and relatively permeable, overlay less permeable substrates of largely unweathered geologic materials. While water is held in this soil layer, solar radiation and air movement provide energy to evaporate surface soil moisture and contribute to the overall evapotranspiration component of the water balance. Water not evaporated, transpired, or held interstitially moves slowly downslope or down gradient as shallow subsurface flow (also called interflow) over many hours, days, or weeks before discharging to streams or other surface-water bodies. In arid regions with relatively lower organic content soils and vegetation cover, precipitation events can produce rapid overland flow response naturally; however, the principles of LID remain—retain native soils, vegetation, topography, and hydrologic regime to preserve aquatic ecosystem structure and function.

The transition from a native landscape to a built environment increases the coverage of impervious surface from roads, parking areas, sidewalk, rooftops, and landscaping. The upper soil layers that evaporate, store, or infiltrate storm water are compacted or covered altogether. As a result, the watershed area contributing direct overland flow to streams, lakes, and wetlands increases; hence, precipitation will reach receiving waters much more rapidly and in greater volumes.[6]

Typical storm-water management focuses on flood control and thus emphasizes the efficient collection and rapid conveyance of precipitation away from residential and commercial development, commonly to central control ponds. Several factors have led to this

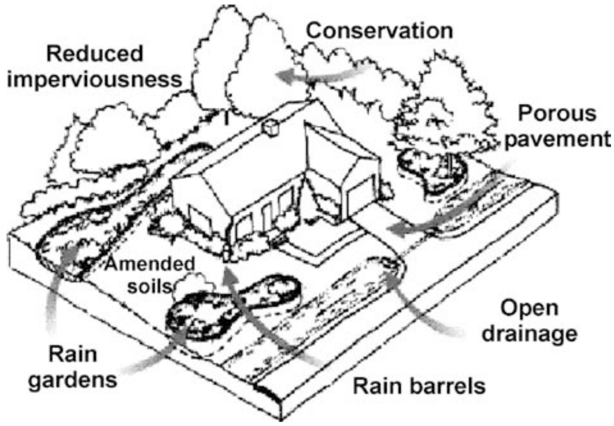

Fig. 1 Schematic of typical LID applications at the scale of a residential building lot. *Source*: Modified from Ref.[2].

approach: Storm water has been perceived as a liability and applications have evolved from wastewater technology, hard conveyance structures and central control ponds are considered reliable and relatively simple to maintain, and the conveyance and collection approach is relatively simple to model for regulatory requirements. Although newer conveyance and pond strategies, if properly designed and maintained, can manage predevelopment peak flows under some conditions, a number of problems (e.g., increased runoff volume and extended flow durations, conversion of dispersed flow to point discharges) will continue to challenge this traditional strategy of storm-water management.[7]

LIMITATIONS

Although the goal of LID to mimic the predevelopment hydrologic regime is laudable, it cannot feasibly be achieved everywhere or at all times. The hydrologic system evolved from, and is dependent on, the characteristics of undisturbed watersheds—mature vegetative cover, uncompacted soils, ungullied hillslopes—whose function cannot be expected to remain unchanged where half or more of the landscape has been appropriated for human uses. Thus the objectives of any given LID must be strategically chosen, recognizing both the opportunities and the limitations of any given site. The limitations are not simply those of subdivision design and development density; they are also limitations of site topography, soil permeability and depth, and groundwater movement. They are likely to be most prominent during periods of extended rainfall, where the distributed on-site infiltration reservoirs common to most LID designs will experience their highest water levels and soil layers approach or reach full saturation. Under such conditions, the downstream impacts of uncontrolled runoff—be it flooding, channel erosion, or aquatic habitat disruption—could be as severe as with conventional storm-water control. Regulatory requirements, typical zoning and housing type, and costs of sophisticated control technology required on sites with higher development density and soils with low infiltration rates also create significant challenges for reducing or eliminating hydrologic impacts from development sites.

The potential failure of LID to control all flows from all storms, no matter how severe, is not an indictment of the approach as a whole. Indeed, LID probably represents the best opportunity to maintain a "natural," or at least minimally disrupted, flow regime in an urban watershed. Where downstream flooding or channel erosion are concerns, however, a comprehensive drainage design will need to consider more traditional storm-water management approaches (such as detention ponds or bypass pipelines) in addition to LID applications. Although such ponds would be smaller, they may still be required to achieve human or ecosystem protection at storm recurrence intervals that may be relatively long but still fall within regulatory thresholds.

SITE DESIGN AND MANAGEMENT OBJECTIVES FOR LOW-IMPACT DEVELOPMENT

The goals for LID are achieved through the following site objectives:

- Maximize retention of mature vegetation cover and restore disturbed vegetation to intercept, evaporate, and transpire precipitation.
- Preserve permeable, native soil and enhance disturbed soils to store and infiltrate storm flows.
- Retain and incorporate topographic site features that slow, store, and infiltrate storm water.
- Retain and incorporate natural drainage features and patterns.
- Locate buildings and roads away from critical areas and soils that provide effective infiltration.
- Minimize total impervious area and eliminate effective impervious surfaces ("effective" impervious surfaces are the subset of the total imperviousness that has a direct hydraulic connection to the stream or wetland).
- Manage storm water as close to its origin as possible by utilizing small-scale, distributed hydrologic controls.
- Create a hydrologically rough landscape that slows storm flows and increases the time of concentration.
- Increase reliability of the storm-water management system by providing multiple or redundant points of control.

- Integrate storm-water controls into the development design and utilize the controls as amenities, creating a multifunctional landscape.
- Utilize an interdisciplinary approach that incorporates planners, engineers, landscape architects, and architects working together from the initial phases of the project.
- Reduce the reliance on traditional conveyance and pond technologies.
- Provide community education and promote community participation in the protection of LID systems and receiving waters.

These objectives can be grouped into five basic elements that constitute a ''complete'' LID design:[8]

1. Conservation measures.
2. Minimization techniques.
3. Flow attenuation.
4. Distributed integrated management practices.
5. Pollution prevention measures.

Although these five elements can be applied to any development, the manner in which they are used must be determined by the local climate and soils.

Conservation Measures

Conservation measures maintain as much of the natural landscape as possible. This includes retaining forests and other native vegetation, not filling wetlands, and providing buffers around wetlands and streams. These natural areas can then provide passive storm-water management opportunities, and they also double as open space.

Minimization Techniques

Minimization techniques reduce impacts of development on the hydrologic regime by reducing the amount of disturbance when preparing a site for development. Instead of grading an entire development site, only the lots and roads are graded while the rest of the ground is left undisturbed. Impervious surfaces are limited to areas where they are absolutely required. Cluster design is used to decrease the amount of the site developed and increase the amount of open space. Graded soils with high infiltration-capacity soils are stockpiled and reused.

Flow Attenuation

By slowing runoff velocity, the opportunity for storm-water infiltration increases and the magnitude of peak discharges decline. Whereas traditional storm-water management directs water from a site as quickly as possible, LID holds runoff on-site as long as possible without causing flooding or other potential problems.

Distributed Integrated Management Practices

LID incorporates a range of integrated best management practices throughout a site, commonly in sequence. An example of this is connecting a bioretention area to a natural area by conveyance through a grass swale. During high flow events, excess storm water is given the opportunity to continue to infiltrate while flowing from the site.

Fig. 2 Retrofitted residential block in north Seattle, displaying a variety of LID techniques: limited impervious area, amended soils, rain gardens, and bioswales. (Photo courtesy of Seattle Public Utilities.) *Source*: From Ref.[9].

Pollution Prevention Measures

Pollution prevention measures are accomplished through a variety of source control, rather than treatment, approaches. For example, community outreach activities, such as the publication of educational materials, can control pollution by not allowing contaminants to enter the watershed or to be released in the first place. This strategy complements other elements of LID design that also reduce the downstream delivery of pollutants by minimizing stormwater runoff volumes and by promoting filtration through soil.

CONCLUSION

Low-Impact Development uses on-site natural features and small-scale hydrologic controls to manage runoff, closely mimicking predevelopment watershed hydrologic functions. Challenges for more widespread use of this approach include uncertainty in its application on relatively non-infiltrative soils, its role in mitigating high-intensity and (or) large-volume storms, and its construction in new or previously developed areas where high urban densities are desired or already present (Fig. 2). Although additional research will be needed to characterize fully the performance of LID practices across different physical settings and development scenarios, available information indicates that LID can fully control flows associated with low-intensity storms, improve water-quality treatment by increasing storm-water contact with soils and vegetation, and significantly reduce flows from larger-volume storms on sites with relatively permeable soils. LID is a significant conceptual shift from conventional storm-water management; its broader application should encourage designers to incorporate native hydrologic processes as important organizing principles in the development of the urban and suburban landscape.

Manure Management: Beef Cattle Industry Requirements

Brent W. Auvermann
Texas A&M System Agriculture Research and Extension Center, Amarillo, Texas, U.S.A.

John M. Sweeten
Agricultural Research and Extension Center, Texas Agricultural Experiment Station (TAES), Amarillo, Texas, U.S.A.

INTRODUCTION

Although cattle drinking water requirements are significant, averaging 10.8 gal $hd^{-1}day^{-1}$,[1] the beef cattle sector of America's \$100 billion yr^{-1} animal agriculture industry uses relatively little water for manure management. The vast majority (perhaps 98%) of the nation's average of 10.3 million head of cattle on feed for slaughter and beef processing are fed in open, soil-surfaced feedyards. As a result, nearly all feedyard manure is collected in solid form. With an average turnover rate of 2–2.3 times per year, over 20 million head of cattle are fed in this manner, generating roughly a ton of as-collected manure per head fed and harvested. In the typical beef cattle feedyard, all manure deposited on the feedlot surface undergoes concurrent processes of: a) partial evaporative drying (from 75 + % wet basis as-excreted down to 20–50% wet basis as-collected); b) partial decomposition of volatile organic solids; and c) atmospheric release of gaseous compounds that include carbon dioxide, volatile organic compounds, and ammonia.

MANURE COLLECTION AND HANDLING

Manure collection practices from open feedyards include use of wheel loaders, box scrapers, dozers, or elevating scrapers.[2] Transportation of collected manure is provided in open top manure spreader trucks to farmland. Intermediate storage may be needed in temporary stacks within feedpens or in stockpiles adjacent to the cattle feedpens. This intermediate storage should be located within the envelope of containment of storm water runoff in accordance with state and federal requirements. The manure mechanically collected in air-dry form is in its least voluminous state and usually has good cash market demand from nearby farmers for use as bulk fertilizer.

Collection, marketing, and/or distribution to farmers are handled by contractors in most cases. Most manure is sold and applied within 10–20 mi of the feedyard. Consequently, there is no incentive to add water to liquefy manure from beef cattle feedlots during collection, storage, treatment, and/or distribution. Because the limiting factor for marketing manure is usually the hauling cost, added water lowers the manure's net fertilizer value.

WATER USE IN MANURE HANDLING

Exceptions to the normal practice of handling of cattle feedlot manure in solid form may include these situations or considerations:

1. Intermittent water additions to compost windrows to raise moisture content to approximately 50% wet basis to initiate or restore active composting.
2. Spillage or leakage of water trough overflow onto a feedyard surface (e.g., water line leaks or trough overflow), which can carry very small quantities of manure solids (e.g., <1%) into runoff collection channels or basins.
3. Rainfall runoff, which can carry a small percentage (<5–10%) of the manure solids from the pen surfaces into runoff settling basins, holding ponds, or evaporation basins, as required by federal (EPA) and state water pollution abatement regulations.[3,4]
4. Water application onto a feedyard surface for dust control in dry weather, with requirements as high as 2–5 times the normal daily drinking water requirement of 10–12 gal day^{-1} for feedlot cattle, with amount for sprinkling depending on cattle spacing, animal liveweight, depth of manure pack, frequency of manure harvesting, evaporation rate, and precipitation.[5]
5. Instances where beef cattle are fed in confinement barns or concrete floors with manure collection by flushing using fresh or recycled effluent.[6] In these instances, water requirements for flushing generally follow a "rule of thumb" of approximately 12 gal of water (100 lbs) required for gravity-flushing of one

pound of manure total solids. These water requirements can be met by fresh water usage (surface or groundwater) or recycled wastewater from treatment lagoons or runoff holding ponds.

6. Anaerobic digestion under mesophilic, thermophilic, or ambient temperature conditions, in which a manure slurry of 8–12% total solids serves as an energy feedstock. The digested slurry, containing all the original nutrients following carbohydrate conversion to methane and carbon dioxide, must be handled and land-applied as a wastewater including storage, conveyance, and irrigation.

CONCLUSION

Of the above scenarios, dust control is undoubtedly the greatest use of fresh water where needed by climatic circumstances, including prolonged seasonal dry weather and/or proximity to neighbors. Feedyard dust consists of relatively coarse particulate matter (PM) generated from the manure surface by cattle hoof action, which intensifies during early evening hours, especially in warm weather. Many factors, as yet not fully defined, can interact to generate feedlot dust. In terms of water use, evaporative demand with continual hoof shear and churning action can be 0.25–0.50 in. day^{-1} in hot, dry weather.[5] This evaporative demand can be met by a) increasing stocking density to focus excreted moisture in feces and urine onto a smaller area; b) frequent removal of accumulated dry manure; c) intermittent rainfall; or d) water application with water tankers with spray nozzles or sprinkler irrigation.[7] Water additions by the latter method can be expected to be on the order of 25–50 gal hd^{-1} day^{-1} as fresh water or recycled water during a typical 6-month dust season.

Manure Management: Dairy

D. R. Bray
H. H. Van Horn
Department of Animal Sciences, University of Florida, Gainesville, Florida, U.S.A.

INTRODUCTION

Water use is essential for all dairies. Drinking water is indispensable for cattlelife; some amount of water is necessary for cleaning and sanitation procedures; moderate amounts are important during periods of heat stress for evaporative cooling of cows to improve animal production and health; additional amounts can be used in labor-saving methods to move manure and clean barns by flushing in properly designed facilities; and the recovered wastewater can be recycled to supplement water requirements of forage crops grown to meet roughage requirements of the dairy herd. Extensive water use, however, increases the potential of surface runoff and its penetration into the ground with possible environmental impacts offsite. Heightened environmental concerns and the need for resource conservation, in many cases, have caused implementation of water-use permits. Thus, it is important to determine various essential uses of water, other uses that are important to management, and also consider whether reuse of some water is possible and if it is necessary to do so.

Some of the useful unit conversions are listed as follows:

1 gal of water = 8.346 lb.
1 ft^3 of water = 7.48 gal.
1 acre = 43,560 ft^2.
1 acre in. of water = 27,152 gal.

Calibration methods to estimate use: Water flow meters should be installed on major water supply lines. If water meters are not in place to measure gallons pumped, it becomes necessary to estimate the usage. This can be achieved by capturing flow through various water lines for specified times and multiplying by the time the water flows through these lines every day.

DRINKING

Table 1 provides estimates of drinking water requirements in gallons per cow per day. Consumption of 25–30 gal of water per day by lactating cows is common, which varies depending on milk yield, dry matter intake (DMI), temperature, and other environmental conditions.[1]

COW WASHING

Presently most dairies, in warm climates, bring cows to be milked into a holding area equipped with floor-level sprinklers, which spray water upward to wash cows. Each cow usually has a holding area of about 15 ft^2 and are typically washed for 3 min. Amount of water used per cow should be calculated for each dairy. An estimate for conservative use is that a holding area for 300 cows is 30 × 150 ft^2 (15 ft^2 per cow) and is equipped with sprinklers with 5-ft spacing (say 7 across and 30 rows) having 210 sprinklers. If each sprinkler applies 5 gal min^{-1}, total usage is 1050 gal min^{-1} or 3150 gal for 3 min, the average consumption per cow would be $3150/300 = 10.5$ gal per cow per wash cycle. If cows are milked three times this would require 31.5 gal per cow per day.

The washing system previously described also helps in cooling of cows while they are crowded together waiting to be milked. However, the cooling effect could be achieved by sprinkling a little amount of water from above, alternatively with fans to give evaporative cooling, if cows were clean enough so that extensive washing was not required and water conservation was necessary.

WASHING MILKING EQUIPMENT AND MILKING PARLOR

Use of water for these purposes is not as directly related to the number of cows as for other uses. For washing milking equipment, a common wash vat volume is 75 gal. If this is filled for rinse, wash, acid rinse, and sanitizing at each of three milkings, this amounts to 900 gal for the herd, e.g., with 300 cows, only 3 gal per cow per day. This is an extremely small component of the total water budget. The amount used to wash out the milking parlor varies largely. If only hoses are used, the amount may be as little as 2 gal per cow per milking or 6 gal per cow per day if cows are

Table 1 Predicted daily water intake of dairy cattle as influenced by milk yield, DMI, and season[a,b]

	Cool season (e.g., February)		Warm season (e.g., August)	
Milk yield (lb)	**DMI (lb)**	**Water intake (gal)**	**DMI (lb)**	**Water intake (gal)**
0	25	11.5	25	16.3
60	45	22.2	44	26.8
100	55	28.6	48	31.9

[a]Drinking water intake predicted from equation of Murphy et al., J. Dairy Sci., **1983**, 66, 35: Water intake (lb day^{-1}) = 35.2 × DMI (lb day^{-1}) + 0.90 × milk produced (lb day^{-1}) + 0.11 × *sodium* intake (g day^{-1}) + 2.64 × weekly mean minimum temperature [°C = (°F − 32) × 5/9]. For examples above, diet dry matter was assumed to contain 0.35% Na. Predicted water intakes (lb) from formula calculations were divided by 8.346 lb water per gal to convert to gallons.
[b]Average minimum monthly temperatures for February (43.5°F) and August (71°F) used with prediction equation were 70-yr averages for specified months at Gainesville, FL (Whitty et al., Agronomy Dept, Univ. FL, 1991).

milked three times daily. If flush tanks are used, the amount may be more, i.e., nearly 3000 gal per milking or 9000 gal day^{-1} for three times, equivalent to 30 gal per cow per day for a 300-cow system.

SPRINKLING AND COOLING

Sprinklers along with fans are used for evaporative cooling to relieve heat stress in dairy cows during hot periods of the year. Their use has shown increased cow comfort (lowered body temperature and respiration rates) and economic increases in milk production and reproductive performance.[2,3] Application rates used by dairymen vary. Florida experiments compared application rates of 51 gal per cow per day, 88 gal per cow per day, and 108 gal per cow per day at 10 psi in one experiment and 13 gal per cow per day, 25 gal per cow per day, and 40 gal per cow per day in another experiment. The application rate, 13 gal per cow per day, is close to the estimated evaporation rate from the cow and surrounding floors. This component should be considered in water use but not in runoff water that must be managed in the manure management system. We estimate 25 gal per cow per day as the minimum practical application rate in order to get adequate coverage of cows to cool them because often they are not in the sprinkled area. Total application days per year vary from 120 days to 240 days. A separate water well, or reserve tank and booster pump, may be needed to supply short-term high demand required by the sprinkler system.

FLUSHING MANURE

Flushing manure can be made a clean and labor-saving process, if facilities include concrete floors with enough slope so that water flow propelled by gravity could be used to move manure. Amounts of water used per cow vary widely depending on size and design of facilities and frequency of flushing. However, usually a flush of about 3000 gal is required to clean an alley width of 10–16 ft. If 4 alleys are common for every 400 cows and alleys are flushed twice daily, this would amount to an average use of 60 gal per cow per day. Many dairies use more flushings per day.

RECYCLING DAIRY WASTEWATER THROUGH IRRIGATION OF FORAGE CROPS

Most often nitrogen is the nutrient on which manure application rates are budgeted. To maximize nutrient uptake, crop growth should be as vigorous as possible. This requires irrigation during most of the year in many dairy regions for the disposal of flushed wastewater. In southern regions, multiple cropping systems are possible, which will recycle effectively nitrogen excretions from 100 cows on a sprayfield or manure application field of about 30 acre.[4]

Tentative estimates of total water needs of the growing crops in warm climates average about 1.75 in. of water per week (0.25 in. per day) from irrigation plus rainfall with a minimum of 0.5 in. per week tolerated even in rainy season on sandy soils.[5,6] Table 2 provides estimates of water requirements for two triple cropping forage systems that are common in southern climates. In sandy soils that hold only about 1.0 in. of water per foot of soil depth, some amount of rainfall cannot be stored. Therefore, even in heavy rainfall seasons, judicious irrigation is often needed during lower rainfall weeks. Limited data are available on the maximum amount of water that could be applied and not reduce yield or quality of forage and not result in pollution of groundwater with nitrates and other minerals. However, the maximum probably is at least 35–45 in. per year above the acre in. totals in Table 2.

RAINWATER FROM ROOFS AND CONCRETE AREAS

Rainwater entering wastewater holding areas can be significant. For example in the dairy representing typical minimum water usage with a flush system in southeast United States (Table 3), the net accumulation during the hot season was calculated as follows: assumed wastewater holding area is 1 acre surface area

Table 2 Crop yield and water requirement estimates for two triple cropping forage systems[a]

		Silage yield			Water required			
Crop No.	Name	Ton/A 35% DM	Ton/A DM	lb/A DM	lb/lb DM	lb/A Total	gal/A Total	A-in. Total
1	Wheat	10	3.5	7,000	500	3,500,000	419,362	15.4
2	Corn	24	8.4	16,800	368	6,182,400	740,762	27.3
3	Corn	14	4.9	9,800	368	3,606,400	432,111	15.9
	Total	48	16.8	33,600		13,288,800	1,592,235	58.6
1	Rye	10	3.5	7,000	500	3,500,000	419,362	15.4
2	Corn	24	8.4	16,800	368	6,182,400	740,762	27.3
3	F. Sorghum	18	6.3	12,600	271	3,414,600	409,130	15.1
	Total	52	18.2	36,400		13,097,000	1,569,254	57.8

[a]A = acre; No. = number; DM = dry matter.

per 100 cows, net rainfall accumulation in holding area is 3 in. more than evaporation per month, concrete areas and/or undiverted roof areas that capture rainfall are 15,000 ft^2 per 100 cows that divert 15,000/43,560 ft^2 per acre of the 3 in. to the wastewater holding facility. Thus, 3 in. + 0.344 × 3 = 4.03 acre in. mo^{-1} or essentially 1.0 acre in. per week per 100 cows (approximately 27,000 gal per 100 cows).

DEVELOPING A WATER BUDGET

A wide range exists in water usage on dairy farms. For most dairy waste management systems designed to utilize flushed manure nutrients through cropping systems grown under irrigation, water amounts are small in relation to irrigation needs for crop production. Costs for construction of storage structures for holding

Table 3 Estimated water budgets for three example dairies

	Flush systems			
Water use in the dairy	Typical need during hot season	Common usage on some dairies	Non-flush Theoretical minimum	Worksheet for your dairy
Drinking (cows)	25	25	25	
Cleaning cows	32	150	0	
Cleaning milking equipment	3	5	3	
Cleaning milking parlor	30	30	6	
Sprinklers for cooling	25	130	12	
Flushing manure	60	80	0	
Total use per cow per day	175	400	46	
Total use per 100 cows per day	17,500	40,000	4,600	
Use per 100 cows per week	122,500	280,000	32,200	
Water in milk per 100 cows per week	4,500	4,500	4,500	
Estimated evaporation (at 20% of use)	24,500	56,000	6,440	
Average rainfall and watershed drainage into storage facility per 100 cows per week	27,000	27,000	13,000	
Wastewater produced from 100 cows/week	120,500	246,500	38,760	
Acre in. per 100 cows per week	4.44	9.08	1.43	
in. per week if 30 acre in sprayfield	0.15	0.30	0.05	

All values are in gal unless otherwise noted.

Example calculations (column 1): Total use per cow per day = 175 gal; total use per 100 cows per week = 122,500 gal less 4500 in milk and 24,500 gal evaporation = 93,500 gal $week^{-1}$; net rainfall and watershed drainage to storage per 100 per cows per week = 27,000; acre in. per 100 cows per week = (93,500 + 27,000)/27,152 gal per acre in. = 4.44.

If 30 acre were in sprayfield, 4.44/30 = 0.15 in. $week^{-1}$.

If crop needed 1.75 acre in. $week^{-1}$ (a common average), a total of 1.75 in. × 30 acre × 27,152 gal per acre in. = 1,425,480 gal is needed of which only 120,500 gal (8.5%) would come from dairy wastewater. The remaining (91.5% of total) would have to come from rainfall or fresh irrigation water.

wastewater until used for irrigation warrant consideration. For example, water-use budgets given in Table 3 show that water usage is small in comparison to irrigation needs when there are 30 acre of sprayfield crop production per 100 cows. Conversely, the amounts used in most dairy systems would be large and unmanageable if application through irrigation is not an option or if less acreage for irrigation is available than needed for application of all manure nutrients.

If a dairy does not have acreage available close by to utilize manure nutrients and water through an environmentally accountable sprayfield application system, it would be necessary to export nutrients off the farm, preferably as solid wastes to avoid excessive hauling or pumping costs. If the water and manure nutrients cannot be used through irrigation, a non-flush system should be utilized. However, usually some irrigation is possible, permitting dairymen to use cow washers and limited flushing if they scrape and haul manure from some areas.

Strategies to minimize water usage: Table 3 presents one column indicating a theoretical minimum amount of water use in a dairy. This system implies that cows are clean and cool enough so that sprinkler washers are not required to clean and cool cows while being held for milking. In addition, it is assumed that all of the manure is scraped and hauled to manure disposal fields or transported off the dairy in some other fashion. Intermediate steps that might be taken include the following:

1. Scraping and hauling manure from high use areas such as the feeding barn so that this manure can be managed off the dairy.
2. Using wastewater rather than fresh water to flush manure from feeding areas and freestall barns.
3. Using a housing system that will keep cows clean enough so that cow washers are not required to clean cows before milking. This system, however, may require use of alternating sprinklers and fans to keep crowded cows cool during hot weather conditions.

If flushing is desired in conjunction with scraping and hauling from heavy use areas, perhaps the feeding area could be flushed with recycled water after scraping to clean the area. These procedures would reduce total nutrient loads retained in wastewater and would significantly reduce the size of the sprayfield needed for water and manure nutrient recycling.

Manure Management: Poultry

Patricia K. Haan
Saqib Mukhtar
Biological and Agricultural Engineering Department, Texas A&M University, College Station, Texas, U.S.A.

INTRODUCTION

Poultry production in the United States has increased steadily and accounts for about 5.5% of the total manure produced annually. Water requirements for poultry manure management and utilization vary according to how manure is handled and stored. Wastes from broiler chickens and turkeys are in a solid (litter) form while layer chicken waste may be either solid or liquid. Litter is most often land applied as a fertilizer source for plants. Liquid manure from laying operations is flushed into anaerobic lagoons for dilution and treatment. Large quantities of water are required to flush and treat liquid manure. The treated effluent is then land applied to crops and pastures. Poultry manure is an excellent source of nutrients for plant growth, including nitrogen, phosphorus, and potassium, and can improve soil physical properties by addition of organic matter. Poultry manure can also be a low cost alternative to mineral fertilizers. Application of poultry manure and wastewater requires proper management to reduce adverse effects to human health and water quality due to loss of nutrients and pathogens from fields to adjacent surface and groundwater bodies.

BACKGROUND

Poultry production involves raising chickens, turkeys, and ducks for the consumption of meat and eggs. While ducks are included in this category, chicken and turkey operations are the focus of this article. Turkeys are raised for meat production, but chicken are raised either as broilers for meat or as layers for the production of eggs. Since the early 1990s, turkey production has remained steady but consumer demand for broilers and eggs has resulted in a steady increase in the total production of chicken in the United States. For example, from 1991 to 1999, the total number of layers and broilers increased by 18% and 33%, respectively.[1] Table 1 shows the total number of broilers, layers, and turkeys produced in 1999 along with estimates of manure excreted by the birds in each category. A total of 55.7 million tons of manure was produced in 1999, suggesting that poultry operations produced nearly 5.5% of the estimated 1 billion tons of manure produced annually[2] in the United States.

POULTRY MANURE MANAGEMENT SYSTEM

Poultry manure may be comprised of excreta, feathers, spilled water and feed, process generated wastewater (water for flushing gutters etc.), litter for bedding (sawdust, wood shavings, peanut hulls, etc.), and mortality. Poultry manure management water requirements may best be explained by first understanding the manure management system for poultry operations. A common theme with any livestock or poultry manure management system is the functional parameters that dictate the type and nature of manure management components of a system. These parameters include manure production, collection, storage, transfer, treatment, and utilization. Production refers to the total volume and nature of animal waste. For example, Table 1 shows that the amount of excreta produced by the type of bird will differ based upon the size and period of confinement. Additionally, moisture content and other physicochemical constituents of excreta vary from one species to another due to differences in feed, digestive system, and climate. Collection of manure refers to gathering of excreta and other waste from initial deposition to short or long-term storage.

In broiler and turkey houses, manure is mixed with litter and handled as ‘‘solid’’ waste. Manure around drinkers, also known as ‘‘cake’’ is relatively high in moisture and more composted, therefore, removed between each flock (approximately 3 and 6 flocks per year for turkeys and broilers, respectively) while the remaining low density manure pack known as ‘‘clean out’’ is generally removed once every year. Both the cake and clean out litter are either transported directly to land for fertilizing crops and pastures or transferred to a stacking facility for a later land application. A part of this solid waste may be sold as a fertilizer source for gardens and nurseries. For this type of broiler or turkey manure management, no water is required except to initiate and maintain composting, if practiced.

Table 1 Poultry manure production estimates, as excreted in 1999

Bird type[a]	Manure per 1000 birds per day[b] (kg)	Total number of birds[c] (1,000s)	Total manure[d] (ton/yr)
Broilers	80	8,146,010	32,584,000
Layers	118	329,320	14,183,900
Turkeys	267	272,994	8,892,458
		Total manure production	55,660,358

[a]Manure production based on 2 kg, 1.8 kg, and 10 kg live weight for broilers, layers and turkeys, respectively.
[b]Data from Natural Resource and Engineering Service (NRAES) publication, NRAES-132 (1999).
[c]1999 data from Agricultural Statistics, USDA–National Agricultural Statistics Service (2001).
[d]Manure totals based upon 50 day, 122 day, and 365 day of occupancy by broilers, turkeys, and layers, respectively.

Some of the litter may be used after deep stacking or composting as bulk feedstuffs for cattle herds (breeding or stocker phases). A small portion of the litter may be used together with straw, hay, or crop residue as a carbon source for mortality (dead bird) composting, with the resulting compost used on pastures for fertilizing.

Poultry layer production houses are designed to handle manure as a solid or a liquid (slurry). Manure from high-rise (elevated cages allowing manure removal with a tractor scraper) and belt scrape (manure removed by a belt system running under cages) houses may be handled as solid waste or slurry. Layer manure from a shallow-pit house is handled as slurry only. It is removed with a scraper or by flushing. The slurry may be stored in a tank or flushed to a waste treatment anaerobic lagoon or storage pond before it is land applied as fertilizer.

WATER REQUIREMENTS AND UTILIZATION OF WASTEWATER

The amount of water withdrawn for all livestock and poultry operations and for processing in the United States in 1995, was estimated to be 20.8 million m^3 per day, or nearly 2% of freshwater use for all off-stream categories.[3] The vast majority of this consumption was attributed to fish farming.

Fresh, recycled, or a combination of fresh and recycled flush water is used to remove manure from layer houses handling slurry manure. Manure removal by flushing requires minimum labor, reduces fly problems in the layer house, and reduces odors. Researchers[4] found that a flush water volume of $0.53\,L\,kg^{-1}$ live layer weight/day compared well with the volume of flush systems designed for other species. The manure removal interval may vary from daily to once a week flushing, but most layer houses may be flushed once a day, for 20 min, using between $38\,m^3$ and $76\,m^3$ of flush water.[5] Poultry manure stored and treated in an anaerobic lagoon requires large quantities of water for dilution and decomposition of organic matter by micro-organisms. Poultry anaerobic lagoon design includes this water storage volume known as the ''treatment volume.'' The estimated water requirements for manure dilution and treatment are temperature dependent, and excessive dilution of organic waste is required in colder climates since the microbial activity is slower in such climates. Therefore, the treatment volume may vary from $370\,L\,kg^{-1}$ live weight of poultry contributing manure to a lagoon in the cold climate, to nearly one half or $200\,L\,kg^{-1}$ in the warm climate of the United States.[6]

Water in the form of treated effluent from anaerobic lagoons or slurry storage structures is typically land applied to irrigate crop and forage lands either by irrigation, surface spreading or subsurface injection. Land application is an efficient utilization alternative because of lower costs as compared to wastewater treatment and the benefits to cropped lands derived from nutrients in the wastewater. Manure can also be a low cost alternative to mineral fertilizers.[7] Land application of wastewater utilizes water to recycle nutrients, enhance soil fertility, and improve soil physical properties. However, a balance must be maintained when land applying animal manure to ensure maximum utilization of nutrients by crops while minimizing the risk of health and environmental effects.

Poultry wastewater from anaerobic lagoons has nutrients essential to plant growth including nitrogen (N), phosphorus (P), and potassium (K). The nutrient composition of waste is affected by housing and waste-handling system. Bedding and additional water can dilute manure, resulting in less nutrient value per kilogram. Nutrient losses from storage and handling reduce the amount of nutrient available for land application. Phosphorus and potassium losses are usually negligible but nitrogen losses can be significant. Table 2 shows a typical nutrient composition of raw poultry manure compared to the nutrient composition of the effluent from an anaerobic lagoon.

Fields receiving manure should be tested for available nutrients before application. Application rates have typically been based on crop N requirements. However, inherent variability of waste and the uncertainty associated with nutrient release rates make it difficult to determine the amount of each nutrient being applied in any one application to meet plant demands. To agronomically apply manure, application should be made based on soil levels of phosphorus.

Addition of poultry manure and wastewater to soils improves soil physical properties by adding organic

Table 2 Nutrient composition of poultry manures, as excreted and in lagoon effluent

	Animal type	Nutrient content[a] N ($kg\,t^{-1}$)	P_2O_5 ($kg\,t^{-1}$)	K_2O ($kg\,t^{-1}$)
Raw manure	Broilers	12.7	7.8	5.9
	Layers	13.2	10.3	5.9
	Turkey	13.7	11.8	5.9
Liquid handling system				
Anaerobic lagoon	Poultry	3.2	0.8	5.0

[a]Data from Natural Resource and Engineering Service (NRAES) publication, NRAES-132 (1999).

matter. Organic matter in turn helps to build soil structure and increase the soil water holding capacity. This can also improve soil tilth, lessen wind and water erosion, improve aeration, and promote beneficial organisms.

Careful management of waste application is needed to reduce adverse health and environmental effects due to losses of nutrients and pathogens from fields to adjacent surface and groundwater bodies. Applying waste in a way that exceeds a crop's ability to take up N can be a threat to drinking water. Nitrogen in the nitrate form is a highly mobile compound that can cause health problems in humans and animals in concentrations greater than $10\,mg\,L^{-1}$. Alternatively, applying manure based on nitrogen concentrations can lead to excessive phosphorus concentrations. Phosphorus accumulation can take place in some soils as a result of over-fertilization. Accumulation occurs when the amount applied exceeds the amount removed by crops. Phosphorus applied to fields as inorganic fertilizer or manure can move into bodies of water through erosion and runoff events. Phosphorus enrichment of water bodies can accelerate eutrophication (the natural aging process of lakes and streams) leading to excessive algal growth, oxygen deficiency, and fish mortality. Therefore application should be based on existing soil-fertility levels, manure nutrient content, crop nutrient needs, site limitations, slope, runoff potential, and leaching potential.

Manure Management: Swine

Frank J. Humenik
National Center for Manure and Animal Waste Management, North Carolina State University, Raleigh, North Carolina, U.S.A.

INTRODUCTION

Water conservation is a major goal in swine production, so national recommendations are not to use any fresh water for waste management in swine facilities. One exception is when there is no pond or lagoon liquid to recycle for manure collection pits or hosing solid concrete floors. Fresh water is used for drinking and fogging for animal cooling but this water is for animal production and not waste management.

On a total farm basis, swine drink about 5 gal per day and produce about 1.6 gal of waste.[1,2] Water often enters the waste stream from fogging, cleaning water, and waterer overflow. Prompt waterer valve maintenance keeps water overflow at a minimum.

Waste can be stored in an underfloor pit for long periods or shorter periods with pull–plug systems. Waste can be removed frequently with waterwash or flushing systems. Solid concrete floors may be scraped or hosed to a collection gutter for cleaning as often as daily.

FLUSHING SYSTEMS

In a flush system, large volume of water flows down a sloped, shallow gutter or alley. The water carries waste to a lagoon. There are underslat gutters, which collect waste from swine houses with either totally slotted or partially slotted floors. Narrow open gutters, which are used primarily in hog finishing buildings, attract hogs to the channel and induces dunging, helping to ‘‘toilet train’’ the animals.[3]

Water should be recycled from a lagoon, earth basin, or a holding pond for flushing. In a recycling flush system, a pump transports the water to a flush tank at the high end of the gutter in the building. The flush tank periodically discharges water into the gutter. Flush frequency is determined by the rate at which water is pumped into the tank or timer to open the tank valve. The minimum total flush volume to clean wastes varies from 4 gal per day for nursery pigs to 15 gal per day for finishing pigs to 25 gal per day for gestating sows.[3]

Recommended maximum gutter length is 125 ft. For gutters, 125–250 ft long, both ends of the gutter are sloped so they flush towards the middle of the building length.

RECIRCULATION FLUSH PITS

Recirculation flush pits are a modification of the gutter flushing concept. Their design evolved to help alleviate pit odor problems in remodeled buildings, but they are also being installed in new swine, beef, and dairy buildings. They also solve some of the problems associated with flushing systems, such as mechanical failure of flush tanks, failure of small continuously running pumps, and salt precipitate forming in continuously used small diameter lagoon recycling pipes. The pit is usually under a partly slotted floor and is relatively shallow—2–4 in. deep on the high end and sloped from 1 ft/20 in. (for swine buildings) to 1.5% toward the outlet end. The pit is flushed twice a week to a lagoon and refilled with cleaner lagoon water. Initial cost is somewhat greater than for flush systems because of the large recycling pump and pipe (often 3–6 ft diameter). However, the system can be shut down and drained after each use, which reduces contact with corrosive lagoon water.[3]

PIT STORAGE SYSTEMS

The frequency of pit emptying is dependent on the waste utilization plan for each farm. Long storage periods are used when waste is applied to land as fertilizer several times a year. Pull–plug systems are emptied on a more frequent basis, sometimes 2–3 times a week.

Recycled lagoon or pond water should be used as precharge bottom water to facilitate solids removal when emptying and can vary from 6 in. to about 2 ft. For pull–plug systems, the plug is pulled several times a week thus allowing the total waste contents to empty to a lagoon. This more frequent emptying reduces odor and ammonia volatilization. There is also less moisture in the house than with open-gutter flushing systems, which remain wet after a flushing event. Emptying frequency depends upon facility management, which generally directs only emptying several houses per day but frequently enough to minimize odor and ammonia volatilization.

WATER CONSERVATION GOALS

Water conservation goals to minimize the use of fresh water for the waste management system minimizes the volume of water that must be handled and thus the required size of system components. Pressure washers, which reduce the amount of fresh water used, are recommended for building cleaning between herds which is about 2.4 times per year. Pressure washers reduce fresh water use by about 50%. Fresh water use can also be reduced, by employing dripless nipple waterers in controlling temperature by ventilation in totally enclosed housing units.

CONCLUSION

Recommendations for minimal fresh water use in swine production facilities and water conservation for waste management result in reduced equipment operation, reduced treatment and storage unit sizes, reduced cost, and improved environmental quality.

INTRODUCTION

Water is necessary for all life on Earth. It is a finite natural resource, which means that the total amount of water available is limited. According to the Environmental Protection Agency,[1] 97% of the earth's water is salt water stored in the oceans and the remaining 3% of the earth's water is fresh water. Only 1% of the earth's fresh water is of the quality and in the location to be acceptable for human consumption.

The population of the world has increased dramatically during the past 50 yr, but the water resources are finite, and irrigated agriculture uses approximately 70% of world's supplies of developed water.[2] With increasing urban populations come industrial users and power plants, both of which need water. In-stream water for recreation, wildlife, or other environmental purposes is in addition to the increased urban demands. Increasing demand because of increasing population makes available water supply inadequate. Augmentation of fresh water supplies from sea water is currently prohibitively expensive; therefore, new demands for water must be met by reallocation of existing supplies.[3] Allocation of scarce supply among unlimited demands requires allocation systems. Scarcity of water has enticed people to develop and implement procedures to facilitate water marketing that can serve as a tool for efficient allocation of water among different users.

SOCIAL VS. ECONOMIC ALLOCATION

Optimizing water allocation requires that net marginal value of a unit of water diverted and not returned to the source, i.e., consumptive use, equals the sum of the net marginal values of non-rival, non-consumptive use. Water resource development, transfer, and use are subject to social and legal factors that contribute to uncertainties and externalities that may preclude attaining an optimal economic condition. Among these factors is the community value of water. Many argue that water is not just a commodity but also a necessity to the economy and social structure of a society, and that a threat to the system for allocating water is a threat to the communal enterprise. The community value of water leads to a divergence between social and private benefits of water use and failure of the market to achieve a Pareto efficient allocation. This failure provides a strong argument for central management of water allocation.[4]

A competitive market may be an efficient allocative process for achieving maximum profit/wealth; it is not an efficient allocative institution for achieving social goals because of infrastructure dislocation.[5] It is not particularly efficient in achieving community goals such as ecological preservation, species protection, and welfare promotion for future generations. Therefore, for efficient water allocation both the social and the economic benefits should be considered.

The incentive for water reallocation is based on the presumption that economic gains will be captured by reallocating water from lower valued to higher valued uses.[6] As demand increases and the cost to obtain additional water increases beyond lower valued current uses, economic pressure is applied to reallocate water to higher valued uses. Typically, the market mechanism plays a role in reallocating resources from lower valued to higher valued uses.

WATER RIGHTS

Historically, water has been used to promote development. Water rights (ownership or right to use) were established to reduce uncertainty especially in agricultural production. Since agriculture was one of the earliest fields to use water and, in accordance with the prior appropriation doctrine of first in time and first in rights, farmers hold a large share and many of the most senior or reliable water rights. Despite rapid urbanization, most of the water is still being used for agriculture. Howe, Lazo, and Weber[7] stated that, according to the U.S. Geological Survey data, "80% of all water diversions and nearly 90% of all water consumption in the western United States occur in irrigated agriculture." However, the value of water used in agriculture is often lower than the value of water for other uses.[8] Therefore, it should not be surprising that irrigated agriculture is the source of water for many water right transfers.

A water right is the right to use a specific amount of water for a specific purpose at a specific place and time. A water right can be bought, sold, bequeathed, or inherited like any other property right.[9] The conveyance, however, is subject to the limitation that other users of the same watercourse cannot be harmed. Although water rights are property rights, they lack at least three of the four elements necessary for the efficient functioning of a market, i.e., universality, exclusivity, transferability, and enforceability.[10]

Economic growth and prosperity are dependent upon the availability of water and water rights. Five types of water right systems include riparian, appropriative, use permits, entitlements, and mutual stock. The water right system must provide security for the right holder and flexibility to accommodate new uses. The need for flexibility is reflected in the diversity of emerging marketing systems.[11] Sales, leases, options, and negotiated adjustments occur within each of these kinds of systems.

WATER MARKETING

For every price there is a quantity supplied and quantity demanded for each use. The difference between quantity supplied and quantity demanded equals the excess supply or excess demand for water for that use. Water marketing may be defined as the selling of excess water supply from one use to individuals or institutions for uses where there is excess demand. In other words a water market is an arrangement in which holders of water rights, trade them with each other or to outside parties. The trade transactions relevant to water marketing can occur either through the sale of a water right permit or through the sale of water by means of a water supply contract.

Most resource economists agree that opportunities to develop traditional large-scale water reservoirs to increase surface water supplies are limited because of rising economic, environmental, and political difficulties. The cost of developing new groundwater supplies has also increased many folds as a result of ever increasing depletion of aquifers. This has led to difficulties in mining of groundwater aquifers. The only feasible option to cope with ever increasing demand for water in deficit areas is the reallocation of water through water marketing.

Water marketing could be an inexpensive way to reallocate water in areas where water shortage exists. Water marketing provides reallocation of water, particularly to large metropolitan areas and during water shortage periods due to severe drought. Water marketing can also help in providing and ensuring water supplies for environmental as well as recreational needs. Water marketing acts as an incentive for water conservation and efficient use by those who control this natural resource. Therefore, the reallocation of water through water marketing promotes political and social harmony among the groups with excess supply and excess demand of water.

Water scarcity and defined property rights in water are two requirements for water marketing to occur. Water markets develop when buyers of this commodity have no other option to secure a certain and consistent water supply, and sellers would be able to accrue more net benefits by marketing the water than using it in its existing form. However, success of water marketing will depend on a combination of economic, legal, institutional, environmental, and technical factors. The potential economic gains from water trade will motivate water transfers from lower value to higher value uses.[12]

Water transfers usually involve a dispute over the issue of compensation between those in the basin-of-origin and the receiving area. Four mechanisms for resolving water disputes include legislation, litigation, water markets, and negotiation/mediation. Legislation and litigation are more common and negotiation/mediation is considered to be a localized procedure. Water markets can resolve conflicts by establishing a price acceptable to all parties. They can also provide efficiency by determining the highest and best resource use by incorporating all costs in the transfer of water. Two conditions are necessary for optimal transfer of water. These conditions are that the transfer is the least cost alternative and that the benefits exceed the losses to the area of origin including downstream basins. Transfer related costs as well as operation and maintenance costs of the movement of water are considered. Jordan[13] identified the following five prerequisites for an effective system of marketing water:

1. Water rights must be clearly defined, meaning that there must be clear title to the water to be transferred or marketed.
2. The water right to be transferred must be quantifiable.
3. Institutional support must be available to administer water rights.
4. The infrastructure must be available or be feasible to move water between buyer and seller.
5. Externality issues are included in the marketing system to provide an efficient transfer of water.

FUTURE OF WATER MARKETING

Water right markets emerging all over the world are still in their infancy and are subject to several challenges. One common problem of all water markets is lack of information. Buyers and sellers face difficulties in finding trading partners. Limited market information forces affects prices and terms of trade. Another problem challenging the future of water marketing is the effectiveness of various governmental agencies responsible for approval of each transaction. Buyers and sellers complain that the approval process is slow, costly, and limits water market growth. However, the approval process must ensure that resulting transfers do not impair other water right claims.

Despite increasing recognition of the benefits of and need for market exchanges of water, barriers to functioning water markets include equity protection, state protection of authority over in-state water, uncertainty of the status of federal agencies involved, and state and regional water agency inconsistencies in policies for defining and approving transfers, quantities, prices, and lease costs. Other problems with water transfer include utilization of salvaged or conserved water, temporary transfers, and introduction of public interest and public trust doctrines in administrative and judicial decision-making.

CONCLUSION

Water rights and municipal water supply systems are two of the fastest-growing market areas in the water marketing industry. Many federal, state, and local agencies involved with the marketing of water rights in the United States have started streamlining the approval process. Water marketing is not confined to the United States. For example, water marketing also occurs in Australia, Chile, and Mexico, where water markets have encouraged conservation and stimulated economic opportunities. The potential for water markets is also expanding in Africa, Asia, and the Middle East. In Pakistan, young farmers lease water from established farmers who can afford to develop wells. Development of markets for water rights and water supply systems is a global phenomenon. Water marketing systems are providing potential buyers and sellers with the incentive to conserve water and are helping globally to achieve equitable and efficient water reallocation.

Matric Potential

Melvin T. Tyree
Aiken Forestry Sciences Laboratory, Forest Service, U.S. Department of Agriculture (USDA), Burlington, Vermont, U.S.A.

INTRODUCTION

Matric potential, τ, is a component of water potential, Ψ, but has different meanings in plant physiology vs. soil science. A rigorous definition of τ requires a reference to principles of thermodynamics (both classical and irreversible thermodynamics). A rigorous treatment is beyond the scope of this brief overview. Readers interested in a detailed definition are advised to read the article of Ref.[1], but should be prepared to wade through 227 equations in a terse, 25-page article requiring a firm grasp of thermodynamics. Less detailed treatments can be found in Ref.[2] for soils and Ref.[3] for plant tissue.

MATRIC POTENTIAL IN PLANT PHYSIOLOGY

Water potential, Ψ, is the chemical potential of water expressed in pressure units. In plant tissues, Ψ is traditionally written as the sum of three components:[4]

$$\Psi = P + \pi + \tau$$

where P, π, and τ are the pressure, osmotic, and matric potentials, respectively. Ψ and its components are intensive variables that vary from point to point in a cell and tissue.[5] Some people have attempted to define τ in terms of a measuring procedure without regard to thermodynamic principles (e.g., Refs.[6,7,8]), but such attempts have been unsatisfactory because the approaches were derived from tissue properties obtained by volume or weight averaging over the heterogeneous phases of vacuole, cytoplasm, and cell wall. A satisfactory definition of τ must be based upon the consideration of it as an intensive property acting at a point. A more correct approach has been taken in Ref.[9] for plant tissues, and in Ref.[10] for soils.

The forces contributing to τ are short range, and influence only a small fraction of the total water in plants when the water is near a solid surface. At uncharged surfaces, the force interactions are largely London–van der Waals forces or hydrogen bonds and extend for only one or two water molecules, 0.3–0.6 nm. At charged surfaces, e.g., cell walls, there is a concentration of negative charges that tends to cause an aggregation of cations in the surrounding electrolyte solution and contributes to low localized values of π, which equals $-RTC$, where R is the gas constant, T, the Kelvin temperature, and C, the localized concentration of all solutes including electrolytes in osmol kg^{-1}. The impact of the charged surfaces on π has been calculated by using the Gouy–Chapman theory, which predicts the influence of fixed charges on ion accumulation near the charges. Tyree and Karamanos[9] have shown that the localized concentrations can exceed 2 M resulting in π below -5 MPa. Soil scientists tend to include most of π and some other effects in τ (discussed below) but this is not done by plant physiologists. The argument is that if pressure and concentration are already accounted for in P and π, then τ ought to be something independent.

Within the electric fields of the surface charge, there is another effect that reduces the energy of water molecules, i.e., the interaction of the water dipole with the electric field. As both plant cell wall surfaces and clay surfaces have a net negative charge, the water dipole tends to be oriented with the positive (hydrogen) end aligned nearer the charged surface than the negative (oxygen) end of the dipole. The net effect is a lowering of the free energy of the water molecules within the electric field. In terms of water potential, the magnitude of the effect is given by

$$\tau = -\left(\frac{N_0^2 P_0^2}{3V_{\mathrm{w}}RT}\right)F^2$$

where N_0 is the Avogadro number, V_{w}, the volume of a mole of water, P_0, the dipole moment of water, and F, the electric field at the point where τ is evaluated.

Fig. 1 shows the magnitudes of the components of Ψ near a charged surface computed from the Gouy–Chapman theory for a charged surface with a net charge of $-0.4\,\mathrm{C\,m^{-2}}$ in equilibrium with 10 mM NaCl solution at $\Psi = -1.5$ MPa. A large positive pressure develops near the charged surface because of the force with which water molecules are drawn towards the charged surface. Given that both π and τ are very negative near charged surfaces, large positive values of P are necessary to make $\Psi = -1.5$ MPa everywhere. Tyree and Karamanos[9] go on to argue that even in cell walls, where the ratio of charged solids to

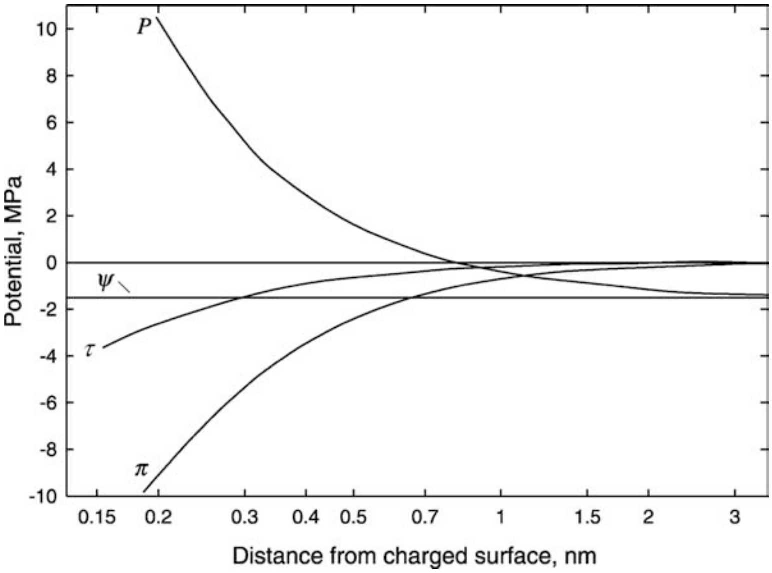

Fig. 1 The components of water potential near a charged surface according to the Gouy–Chapman double layer theory with a surface charge of $-0.4\,\mathrm{C\,m^{-2}}$. The univalent ion concentration outside the double layer is taken as $10\,\mathrm{m}M$. π and τ are calculated at distances from the charged surface from the calculated electrical potential and electric field, respectively. $P = \Psi + \pi + \tau$ with $\Psi = -1.5$ MPa. **Source**: From Ref.[9].

water is about 1:1 that the influence of τ extends only to a small fraction of the water volume, and will begin to influence measures of Ψ only when water potentials approach -14 MPa, at which point most plants are dead anyway. So, as defined by plant physiologists, τ can usually be ignored.

MATRIC POTENTIAL IN SOIL SCIENCE

Matric potential in soil science, τ_s, was originally defined in terms of the instrument(s) used to measure τ_s. Note that the subscript, s, is used in τ_s in soil science to distinguish it from the τ in plant physiology. In situ measurement of τ_s in soils is made with a tensiometer, which consists of a water-filled tube with an attached pressure sensor. The fluid in the tube makes contact with the soil water through a porous plate (often ceramic). When the soil is wet, the fluid in the tensiometer is in good contact with the soil water and is at a pressure of 0 MPa relative to atmospheric pressure. As the soil dries, the fluid pressure drops below atmospheric. When the pressure drops below that of a perfect vacuum (-0.1013 MPa), the water column usually cavitates, i.e., an air bubble forms because of a breakdown in the adhesion of water to the solid surfaces of the tensiometer. Cavitations limit the range of useful measurement of τ_s using tensiometers, as most plants can function well to $\tau_s < -1.5$ MPa. It is possible to make fluid-filled pressure-measuring devices (called cell pressure probes) that can measure fluid pressures down to -1 MPa in plant cells, but these have never been used in soils and probably would not work reliably.

In order to measure τ_s below -0.1 MPa, the soil samples have to be removed and placed in another apparatus. One such system is a pressure plate apparatus. The soil is placed at the bottom of a pressure chamber. The bottom of the chamber is porous so that water can pass through the porous plate when air pressure above the soil is increased high enough to extract water from the soil. The value of τ_s is equated to $-$(the applied pressure) at an incipient water extraction. Water can also be extracted from the soil in a centrifuge. The soil is spun in the centrifuge tube with a porous bottom until the centrifugal force (expressed in pressure units) is sufficient to extract water and τ_s is equated to $-$(the centrifugal force).

A number of papers have been written to discuss what, based on thermodynamic theory, is measured by the instruments described earlier. Passioura[2] equates τ_s approximately with Ψ. To be precise, $\tau_s = \Psi - \pi_D$, where π_D is the osmotic potential of the ''equilibrium dialysate,'' i.e., the osmotic potential of the soil solutes that can pass through the porous plate of the tensiometer or pressure plate apparatus or centrifuge tube. The ions in solution in the ion ''cloud'' near the charged surface of soil particles would not be included in π_D, because these ions are not extractable. In most soils, π_D is usually ≥ -0.02 MPa; hence in drying soils, $\tau_s \cong \Psi$ within good tolerance. In a more recent exhaustive treatment of the theory behind τ_s, it appears that τ_s is identified exactly with Ψ in the equilibrium vapor phase of soils, i.e., see Eq. (202) in Ref.[1]. Hence, this meaning of τ_s is identical to the meaning of Ψ, which is often also measured on plant tissue by using the equilibrium vapor phase.

CONCLUSIONS

Matric potential as used by soil scientists is nearly identical with water potential as used by plant physiologists.

The main difference is that plant physiologists divide water potential into two quantities that frequently can be measured independently, i.e., pressure potential, P, and osmotic potential, π. Soil physicists like to equate matric potential in plants with "capillary or adsorption forces which in a plant are forces such as those at the cell walls."[11] However, this definition is equivalent to water potential, Ψ, and does nothing to help elucidate the osmotic relations of living cells that can be quantified only by independent measures of P and π. In the older plant physiology literature, some people attempted to come up with a different meaning of matric potential, but this approach has been discredited.[3,9] It is unfortunate that these two closely allied sciences should use different words to describe the same quantity (matric potential vs. water potential), but the attentive reader can usually distinguish the meaning of matric potential from the context of scientific reports.

INTRODUCTION

One of the critical requirements in designing a water sampling plan for microbial analysis is a clear understanding as to the overall objectives behind the sampling, what sampling equipment is available, and what type of analyses are going to be conducted on the samples.

The focus of this article is to provide an overview of the methods to sample water bodies to detect fecal contamination. There are distinct differences in the type of sampling methods that one would have to use depending on whether groundwater, surface water, or distribution system (finished drinking water) is being sampled. The differences arise from the need to retrieve the samples using specialized sampling equipment and sample concentration methods.

OVERVIEW

Groundwater Sampling

A key prerequisite in obtaining a representative groundwater sample is to have a properly installed "monitoring" or "sampling" well. The design is of obvious importance since a simple hole in the ground will not be representative of the aquifer. Attention has to be paid to the proper "setting" of the well, the selection of the appropriate filter pack, and proper "well development." Well development, refers to the process by which the aquifer's natural hydrodynamics are restored in the aquifer around the well after the installation of the well. The USEPA generalizes that three well volumes be removed from a well before sampling. Thus, when obtaining groundwater from a well, information about the well depth, pump setting (height at which the pump draws in water), well diameter, standing water level, volume of all holding tanks, pressure tanks, and connecting pipelines should be obtained so that an adequate amount of purging can be performed before an authentic "groundwater" sample is obtained. Information on drainage features, proximity to septic systems, and other features that could influence water quality should also be documented. Typically, sample bottles are obtained presterilized from the laboratory. It is essential that the sampler coordinate sample delivery with the laboratory so that the short holding times can be achieved.

Some of the equipment for sampling are bailers, grab samplers, and submersible pumps.[1] Bailers are one of the least expensive methods of sampling and are best suited for wells that are shallow or slow to recharge and for the collection of small volume samples. One-time use bailers or multiple-use bailers can be used. The sampling materials must be cleaned and disinfected between samples. The disinfection could be achieved by soaking the bailers in large containers containing a 1–2% chlorine (bleach) solution. However, care must be taken to remove all residual chlorine from the bailers by thoroughly washing in clean water. Grab samplers are different from bailers in that samples can be obtained from discrete depths. Submersible pumps are one of the better ways of collecting groundwater samples. However, they can be relatively expensive and require the need for electrical power at the field site. Pumps are ideally suited for use in larger wells or when large volumes of water need to be collected and passed through sample concentrators for virus and protozoan sampling. Some groundwater wells may have chlorinators installed in them. It is important that these chlorinators are disconnected before samples are collected or the samples are obtained at a spot prior to the chlorinator input into the line. All public water supply wells are required by law to have a sampling spigot prior to the chlorinator.

Surface Water Sampling

Unlike groundwater sampling, sampling from surface waters is relatively straightforward. Grab samples (for bacteriological analysis) or portable pumps (for viral and protozoan analysis) can be employed. However, attention should be paid that the sample being collected is as representative of the surface water source as possible. When sampling rivers and canals, effort should be made to collect the sample as far as away from the bank as possible. When sampling lakes, the use of a boat is desirable. If wading, the sampler should slowly wade upstream taking the sample upstream and ahead of any wading-induced agitated sediments. Since no guidelines have been developed for specific sampling locations, the sampler must predetermine the locations that provide a representative water sample. For example, the sample can be taken ahead of a water intake, if the objective is to understand the source water quality. Microbial populations can be highly variable with a stream and typically, samples are taken from a midpoint in a stream rather than in shallow pools or riffle areas. Multiple samples taken from riffles, runs, and pools provide a better representation of the microbial populations, however, the sampling and subsequent analysis may be cost prohibitive.

Distribution System Sampling

This is probably one of the easiest to sample in that spigots and faucets on the distribution lines can be used to collect the samples. However, drinking water distribution lines have residual chlorine present within the system. It is important that this disinfectant residual be removed especially when virus sampling is conducted. Sodium thiosulfate is often used to remove residual chlorine. Faucets and spigots within the distribution system (as well as in groundwater wells) may harbor microbial populations within them as biofilms. Even though it is impossible to remove the biofilm within distribution lines, attention must be paid to remove as many indigenous microbial populations from the sampling spigot (faucet) as possible. Heat surface sterilization (using flame or torch) or chemical disinfections can be used. It is critical that the water is allowed to run for at least 10–15 min after these treatments.

Sampling for Bacteriological Analysis

Since the sample volume for bacteriological analysis is always around 100–1000 ml, grab samples are often the method of choice. However, the sample container should be sterile, clean latex gloves should be worn (to prevent the sampler from contaminating the sampling port or sample), and in the case of groundwater or distribution system samples, the water should be allowed to run for at least 3 well volumes or 10 min, respectively. (There are, however, times when one may want to collect a sample directly from the tap/spigot to determine the quality of the distribution system). The sample bottle should be filled up to the desired volume and the bottle should be removed sideways from the flow of water. The cap has to be replaced and after appropriate labeling the sample bottle has to be placed in a clean cooler containing blue-ice or wet-ice and maintained at or below 4°C. The specific volume that is collected will depend on the number of bacteria that are being screened. There are recommended volumes for the different bacteriological detection methods.[2] There are different maximum holding time recommendations depending on the organism. For *Escherichia coli* the samples should be analyzed within 8 hr.

Sampling for Viral Analysis

Enteric viruses are of particular concern to human health since they have low infectious doses. These viruses are very often found in much lower concentrations than bacteria in environmental waters. The current USEPA recommended method for sampling and concentrating viruses require sampling large volumes of water and concentrating the viruses on positively charged filters. The filter used for concentrating the enteric viruses from water samples is the 1MDS filter ZetaPor, virosorb (Cuno, Inc., Meridian, CT). (The retention of viruses on to these filters is thought to occur through electrostatic attraction between the negatively charged virus particles and the positively charged filter.) These filters have to be contained within a filter housing. The filter and filter housing is connected in series to a backflow control valve, backflow regulator, and a flow meter (Fig. 1). Typically, when sampling groundwater for viruses, 500 gal are passed through the filter before the filter is removed and shipped to the laboratory for analysis. For distribution system samples, as much as 1500 gal need to be passed through the positively charged filters to screen for viruses. A major drawback of using cartridge flow-through filters is that, depending on the amount of debris in the sample the filters could get clogged. Using a prefilter to avoid clogging is counter-productive in that very often viruses get trapped and adsorbed in these prefilters rather than being adsorbed in the 1MDS filter. In addition to the 1MDS cartridge filters, tangential flow and hollow fiber filtration have also shown promise as virus concentration methods. Thus, in the case of virus sampling, sampling involves sample concentration as well. Samples should be analyzed for enteric viruses within 72 hr of collection.

Male-specific coliphages are viruses that infect specific coliforms bacteria. Such viruses are termed bacteriophages. Male-specific coliphages have been shown to serve as efficient fecal contamination indicators.

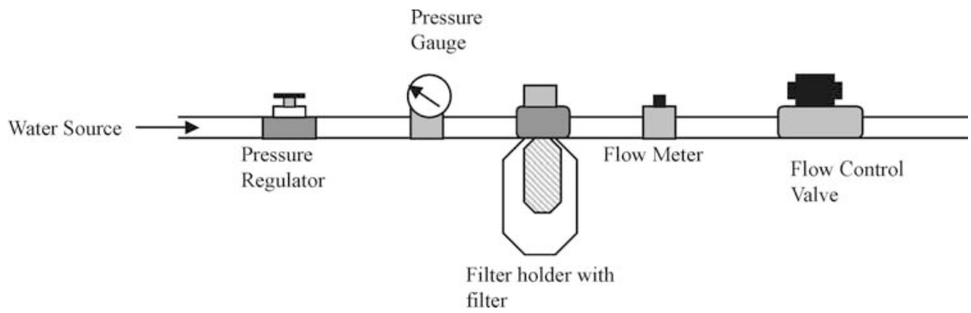

Fig. 1 Filtration setup for viruses and protozoa.

The USEPA methods 1601 and 1602 describe the methods that can be used to sample and detect coliphages.[3,4] Unlike enteric viruses, grab samples ranging from 100 ml to 1000 ml can be used for coliphage analysis. Since coliphages are viruses, the holding times should not exceed 72 hr.

Sampling for Protozoan Analysis

The selection of an appropriate water sampling and concentration method for *Cryptosporidium* and *Giardia* greatly depends upon the water sample matrix (e.g., surface water, finished drinking water, or wastewater), the volume to be concentrated, and the anticipated density of organisms. Concentration is typically achieved through various filtration and centrifugation steps. Unfortunately, these concentration methods also concentrate inorganic and organic debris and non-target organisms. In addition, downstream sample purification and detection methods should also be considered. In wastewaters where the numbers of *Cryptosporidium* and *Giardia* are expected to be high, a 100–1000 ml grab sample, directly concentrated by centrifugation may be sufficient. In contrast, for finished drinking water in which the number of organisms is expected to be low, filtration of 100–1000 L or greater may be required. The concentration of raw surface water requires the most consideration since characteristics such as turbidity or presence of algae will vary significantly and can greatly affect the concentration procedure. If clogging occurs, then the actual volume that was concentrated should be noted.

There are several methods for the sampling and concentration of *Cryptosporidium* and *Giardia* in surface water and finished drinking water. The USEPA Information Collection Rule (ICR) method uses a polypropylene yarn wound filter for the concentration of raw surface water samples.[5] In contrast to the electrostatic attachment of viruses to the positively charged filter in the virus sampling/concentration procedure, the yarn wound filter physically traps the oocysts and cysts. The yarn wound filter is placed in a suitable filter housing and placed in series along with the pressure regulator, pressure gauge, flow meter, and flow control valve (Fig. 1). Although the yarn wound filter method

Table 1 Guidance for selection of water sample collection and concentration methods for *Giardia* and *Cryptosporidium* analyses

	Application			
Procedure	**Typical sample volume**	**Water turbidity**	**Advantages**	**Disadvantages**
Grab sample (concentration using centrifugation)	1–20 L (wastewater and raw surface water)	Low to high	Easy to collect, no filter costs	Samples greater than 1 L are time consuming to handle and concentrate
USEPA ICR (yarn wound filters)	$\leq$100 L (surface water); $\geq$1000 L (finished water)	Low to high	High filtration rate, low cost and ease of use	Variable efficiency of concentration, time consuming processing
USEPA 1622/1623 (pleated membrane capsule filters)	$\leq$100 L (surface water); $\geq$1000 L (finished water)	Low to moderate	Good retention and oocyst recovery, ease of use	Expensive, slow filtration rate
USEPA 1622/1623 (compressed foam filters)	$\leq$50 L (surface water); $\geq$1000 L (finished water)	Low to high	Excellent retention and oocyst recovery	Awkward handling, decontamination required

is relatively inexpensive, studies have shown that the efficiencies can be relatively low and the filter processing methods can be extremely labor-intensive. The recent USEPA Methods 1622 and 1623 include several different options for filtration including capsule membrane filters and compressed foam filters.[6,7] Methods 1622 and 1623 use immunomagnetic separation for purification of protozoa. Recent studies have also shown that hollow fiber filters have the ability to concentrate protozoa. The samples should be eluted and concentrated from the filters within 96 hr of sample collection. Guidance for the selection of concentration methods is provided in Table 1.

CONCLUSION

Microbial sampling is a critical component of any environmental assessment. Given the complexities associated with sampling for different microorganisms, it is critical that careful attention be paid to the sampling objectives. While guidelines and sampling protocols have been established the responsibility of obtaining the most appropriate sample still lies with the sampler who must determine the data quality objectives and develop a sampling plan to meet those objectives. Many states are developing specific water-use standards for surface water based on use as recreational water bodies and drinking water supplies. These regulations can have profound implications for concentrated animal operators. Meeting these water-use standards and still maintaining profitable animal production levels will pose a challenge to the regulatory agencies as well as the agricultural community.

Mining Impact: Metals

Mark Patrick Taylor
Department of Physical Geography, Macquarie University, Sydney, New South Wales, Australia

INTRODUCTION

Mining is defined as the excavation of a resource from the earth. This may include metals (e.g., copper, lead, and zinc), metalloids (e.g., arsenic), minerals (e.g., halite, phosphorous, and gypsum), organic fuels (e.g., oil, gas, coal, and peat), and aggregate materials (e.g., sands and gravels). The extraction of such resources frequently causes numerous offsite impacts. These impacts are dependent on a variety of environmental factors, which may include climate, landscape stability, topography, bedrock type, and groundwater movement, amongst many others. This entry will focus on how metal mines, their associated waste (tailings and gangue materials) and associated ore deposits can affect rivers and their associated sediment sources and sinks if they enter the drainage network.

OVERVIEW OF METAL IN RIVER AND FLOODPLAIN SYSTEMS

The extraction of heavy metals and metalloids such as arsenic, cadmium, chromium, cobalt, copper, lead, zinc, and gold has affected the environment since process metallurgy was initiated by early civilizations at least 6000 years ago. In particular, the effect of metal extraction on river environments has been studied extensively, with the focus of research being in temperate climatic zones. Since the Industrial Revolution some 200 years ago, the global footprint of mining and its impacts has increased due to technological improvements in extraction efficiency. Until the most recent decades, when offsite effects of metals on the environment and biota became more apparent (e.g., Minamata disease, which was caused by methyl mercury ingestion via the consumption of fish in southern Japan in the 1950s), environmental legislation and its application have frequently lagged behind the rush to exploit the earth's resources. Frequently, this has led to mine waste being directly or indirectly incorporated into river systems through mine discharge or during erosive storm flow events. A study of river and floodplain environments, which are the primary pathways for energy and matter (e.g., sediment and water) movement through the landscape, can reveal the insidious and more conspicuous impacts of heavy metal pollution.

Mine tailings invariably contain large quantities of fine sediment enriched in heavy metals. Unprotected from the elements by vegetation or artificial coverings such as concrete or geotex matting, these tailings deposits may be subject to wind, water erosion, or oxidation processes. The release of metals into the adjacent environment can occur over a range of timescales. In some cases, this may be a relatively slow process that is controlled by chemical dissolution, wind, or water erosion rates or it may be extremely rapid, such as that associated with the catastrophic collapse of tailings dams. In arid and semi-arid areas where vegetation growth is limited by climatic factors, wind erosion of tailings has contributed to human health problems due to the absorption of heavy metals associated with household dust.[1] However, water erosion and transport of tailings is usually the primary source of river and floodplain contaminated-sediment pollution. This can be particularly severe when tailings retention dams catastrophically fail, such as that which occurred in 1979 when a heavily contaminated uranium tailings dam collapsed on the Puerco River, New Mexico, resulting in serious contamination of the river with thorium-230.[2]

Acid mine drainage from both active mines and abandoned sulfide tailings dumps is also known to cause major environmental problems for river and floodplain water and sediment quality. Acid mine drainage results from the oxidization of sulfide minerals (such as pyrite), which when discharged release metal ions into the aqueous environment, e.g., lakes, rivers, and groundwater bodies. These metals are then transferred in solution through the system and may be precipitated with alluvial sediments where they can be stored for extended periods of time (10^{-1}–10^{4} yr) causing potential long-term environmental problems.[3]

THE TRANSPORT, STORAGE, AND AVAILABILITY OF METALS IN THE ALLUVIAL ENVIRONMENT

Contamination of river and floodplain environments is complex in time and space. Heavy metals are not readily dissipated in the natural environment and can have extremely long residence times in sediment, depending on their physical and chemical mobility within an affected sediment system. Heavy metals are transferred through a river system by four principal mechanisms: hydraulic sorting according to particle size and density; chemical dispersal—solution, adsorption, Fe and Mn complexes, and biological uptake; dilution with clean uncontaminated sediments; and loss and exchange with floodplain sediments.[3] These processes may occur in differing amounts depending on the prevailing physicochemical conditions and the hydroclimatic regime. For example, the dispersal of mining related metal contamination may, under some circumstances, be controlled by physical processes rather than chemical mobility. Metals such as cadmium, copper, lead, and zinc are often absorbed on grain surfaces or on oxides, hydroxides, and oxyhydroxides particularly in iron and manganese forms, which are then transported by physical processes. In particular, manganese oxides have been shown to be one of the most significant groups of substances that control heavy metal concentrations in alluvial sediment.[4] Where a catchment is rich in calcareous materials, the release of metals into the aqueous system may be buffered by an increase in sediment and water alkalinity. The chemical mobility of metals and their availability and dispersal in the environment may also be related to fluctuations in the water table and/or changes in pH. For example, a rising water table or decreasing pH may cause the dissolution of oxide substances resulting in the release of metals previously bound up. In contrast, under ambient conditions, oxide substances such as iron and manganese may act as long-term stores for heavy metals in alluvial sediment.[5]

One of the main issues surrounding systems affected by historical metal mining is the storage and dispersal of contaminants in floodplain and in-channel sediment sinks because they may pose an ongoing and a long-term risk to the environment.[6,7] Alluvial systems are notoriously complex in terms of their morphology and sediment dynamics and the spatial distribution and concentration of metals will often reflect the channel and floodplain depositional environments in which they are stored. The dispersal of metals within a river system may occur both laterally across the floodplain and longitudinally throughout the system. Generally, metal concentrations will diminish away from the channel towards the margins of a floodplain and also in a downstream direction. This general distance-decay pattern of metal concentrations away from the polluting source may vary according to channel and floodplain geomorphology. For example, sediment-metal concentrations may become elevated in slack water environments (e.g., paleochannels) on the floodplain. This is because metals in the fine sediment fractions have a greater surface area to volume ratio. When metals become adsorbed (fixed) onto particle surfaces, this produces a strong relationship between trace metal concentration in the solid phase and decreasing particle size. This is not the case, however, in environments where the fine fraction may either be absent or have been transported downstream. Under these circumstances, a lag of larger, denser particles will give rise to the contaminant signal found in alluvium.[8] Within channels, metal concentrations may be considerably lower in reaches that are characterized by high stream power values, due to the dominance of erosion processes. In contrast, elevated metal concentrations will tend to occur where alluvial deposition processes are dominant.

The dispersal of toxic metal mining waste into catchment systems can have deleterious effects on the ecological functioning of channel, floodplain, and associated urban and agricultural environments. Elements such as zinc and selenium are typically only necessary in trace concentrations for normal plant and animal growth. However, heavy metals such as cadmium, copper, lead, mercury, and zinc in toxic quantities can reduce the extent and effectiveness of stabilizing channel bank riparian vegetation and cause changes in river morphology. In addition, and of perhaps greater concern to the population at large, are the effects of elevated sediment- and soil-metal concentrations on food quality and safety, crop production, and environmental health. Metals move through the food chain via uptake and bioaccumulation and biomagnification in plants, animals, and, ultimately, humans. The physical impacts of mining activity on channel systems can also be quite significant through the removal of metal rich river deposits (placer mining) or via the direct dispersal of tailings into a river. Such changes can have rapid and significant impact on the sediment supply rates of a system. For example, 19th-century gold mining of alluvial gravels within the catchment of the Sacramento River, Sierra Nevada, central California, resulted in massive increases in channel sediment load causing the channel bed to aggrade by up to 100 m.

AN EXAMPLE OF MINING IMPACT: RUM JUNGLE MINE, NORTHERN AUSTRALIA

Contamination due to metal extraction has seriously affected the channel of the East Branch of the Finniss River downstream of Rum Jungle mine in tropical northern Australia [inset (a), Fig. 1]. The environmental impacts experienced at Rum Jungle are typical of those associated with metal mining and acid mine drainage. Rum Jungle was principally a uranium–copper mine that was active from 1953 through to 1971, after which it underwent remediation. The Rum Jungle tailings dumps were covered to reduce the infusion of oxygen that controls oxidation rates and ultimately the generation of pollution from the

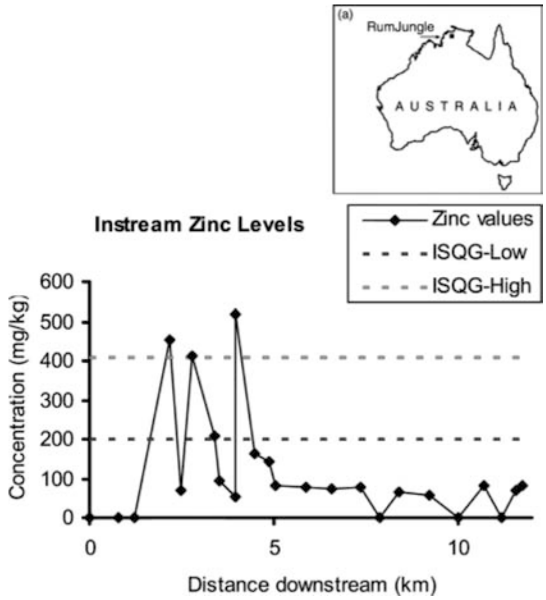

Fig. 1 Stream sediment-associated zinc concentrations down the East Branch of the Finniss River. Inset (a)—location of Rum Jungle mine, northern Australia. The Rum Jungle mine site occurs 2–4 km downstream from the most upstream sample site (0 km). Sediment-metal concentrations in the area adjacent to and immediately downstream of the mine are the most contaminated with some values significantly above the Australian guidelines for highly contaminated sediment. Sediment samples were analyzed using Instrumental Neutron Activation Analysis. The sediments analyzed were not partitioned for grain size but were bulk samples of the channel sediments. These data provide an indication of the gross pollution values of the system rather than the specific concentration values per grain size fraction. ISQG—Interim Sediment Quality Guideline. The ''Low'' value is the trigger value for contaminated sediment and is used to initiate remedial management/investigations while the 'High' value corresponds to situations where greater environmental impacts are expected. *Source*: From Ref.[2].

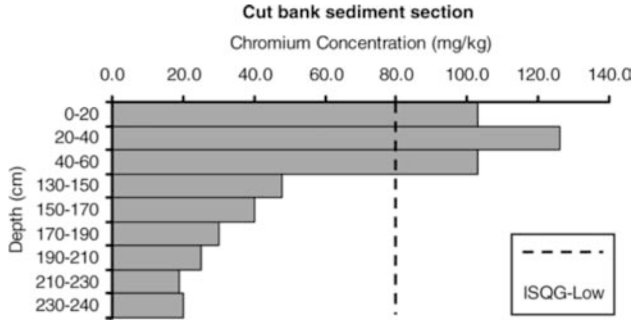

Fig. 2 Chromium concentrations in overbank sediment from the East Branch of the Finniss River, some 1.5 km downstream of the Rum Jungle mine. The floodplain surface is at 0 cm. Elevated levels of chromium in the upper part of the sequence are below the high concentration Australian guideline value for chromium (ISQG—High, 370 mg/kg) but above the low trigger value (ISQG—Low, 80 mg/kg). Towards the base of the section, the cut bank is well below guideline values. Sediment samples were analyzed using Instrumental Neutron Activation Analysis. The sediments analyzed were not partitioned for grain size but were a bulk sample of the overbank sediments. These data provide an indication of the gross pollution values of the system rather than the concentration values per grain size fraction.

site. Other remediation methods included the building of runoff channels and erosion banks around tailings dumps, along with the application of lime to neutralize acidified water. Prior to remediation, short-term elevations in water contaminant concentrations caused fish kills downstream of Rum Jungle and were also shown to immediately reduce fish diversity and abundance. Post remediation treatments were effective in reducing annual metal loads, e.g., copper, zinc, and manganese decreased by up to a factor of 7, 5, and 4, respectively, and consequently fish diversity started to recover.[9]

Although the leakage of water-borne contaminants is now much reduced, elevated concentrations of a range sediment-associated metals, for example, chromium and zinc (Figs. 1 and 2), remain stored within the alluvial system. Recent studies of channel and floodplain sediment-metal from the East Branch of the Finniss River demonstrate the effect of metal storage within an alluvial system. At Rum Jungle, concentrations of numerous elements were found to be above Australian sediment guideline values[10] in both overbank and in-channel environments (Figs. 1 and 2 show zinc and chromium levels in channel and cut bank sediment, respectively).

Heavy metals stored within alluvium can cause a management problem if they are eroded, leached, and released into the environment where they can result in continued or renewed ecological dysfunction, even if the principal source of pollution, i.e., mine tailings has been effectively remediated. The downstream distribution of metals throughout a river system may also vary from a distance-decay type pattern from the source of contamination through to more complex patterns where the metal is transferred as a sediment slug or wave. In some cases, sediment-metal distribution patterns are determined by channel hydraulic parameters such as shear stress or stream power.[2,6] The distribution of alluvial metals in the East Branch of the Rum Jungle is neither linear nor possesses a distance-decay type relationship, but has a saw-tooth configuration (Fig. 1) that probably relates to changes in the storage and transfer of metals between different reaches. Similar to the study on the Puerco River, New Mexico,[2] this is probably related to channel dimensions and associated hydraulic parameters such as shear stress and stream power.

Akin to other contaminated fluvial systems, the storage of metals in floodplain and channel sediment sinks can present a long-term latent environmental problem. A catchment-wide assessment of the fate and storage of mining related contaminants in northern England[11] has shown that only a small fraction of the total metals released into the fluvial system are actually flushed out into the estuary and to the ultimate sink, the ocean bed. The vast majority of metals remain stored within river and floodplain sediments throughout the drainage network.

CONCLUSION

Depending on the extent and magnitude of pollution, the impact of metal mining on a river system may manifest itself in a variety of forms. These may encompass physical, chemical, and biological changes to the preimpact condition. The release of large volumes of toxic materials into watercourses may not only affect riparian and in-channel species diversity, but are often paralleled by changes in river planform morphology as the river laterally and vertically adjusts to a new sediment load. The storage of metals in sediment sinks can present a pollution ‘‘time-bomb’’ which may not be effective until the stored pollutants are released back into the environment through physical, chemical, or biological mobilization.

Natural Levees

Paul F. Hudson
Department of Geography and the Environment, University of Texas at Austin, Austin, Texas, U.S.A.

INTRODUCTION

Floodplains are comprised a variety of depositional environments formed by distinct fluvial processes (Fig. 1). Natural levees are formed from numerous flood deposits that create sinuous ridges of coarse sediments along river channels. Sediment sorting during overbank conditions results in lateral fining of flood deposits. This results in a landform that slopes toward lower lying floodplain bottoms, and is the highest component of floodplain topography.[1,2] Understanding natural levees is important to a variety of disciplines, including earth sciences, engineering, and archaeology. Because natural levees are aggregate flood deposits and represent the sediment and stream flow regime of a river over medium time scales (10^{2-3} yr), earth scientists study natural levees for insight into the pattern of flood sedimentation and how it has varied over time. Although natural levees do not represent a significant component of floodplain construction, they may become a "permanent" part of the floodplain in the event of a channel cutoff, and the recognition of buried natural levee deposits is essential to understanding valley-fill chronologies and floodplain evolution.[3] Geotechnical properties of natural levees are important to proper river engineering, particularly design of artificial flood control levees (dikes) and for bank stability structures. Because of their topographic and drainage characteristics natural levees are significant to floodplain hydrology. Indeed, natural levees were utilized by prehistoric civilizations for settlement and agriculture, and archaeologists are interested in active and abandoned natural levees because of their excellent archaeological potential.[4]

LOCATION

Although natural levees are most associated with lowland meandering river floodplains, natural levees form on any type of river floodplain that regularly floods and includes braided, straight, anastomosing, estuarine, crevasse, and deltaic distributary channels. Along active meandering rivers natural levees extend into floodplain bottoms where they overlay older channel deposits or backswamps. Natural levees tend to be large along cutbanks, but smaller natural levees often form on the inside of meander bends (burying point bar deposits) in rivers with low rates of lateral migration.[5] In non-meandering channels natural levees are approximately the same size on either side of the river.[1]

FORM AND PROCESS

Natural levees are formed by the process of overbank flood sedimentation, but an understanding of natural levee formation should also consider the overall floodplain style and mechanism of floodplain inundation. The thickness of individual flood deposits varies from several millimeters to tens of centimeters, and decreases laterally in thickness and particle size away from the channel bank.[6,7] Natural levee sedimentation involves several processes, which is in part dependent upon the amount of inundation within the floodplain bottoms. Upon exiting the channel and flowing onto the floodplain there is an abrupt reduction in flow velocity, which results in immediate deposition of coarser sand and silt, which is transported along the floodplain surface as bedload.[8] At upper flow regime (high velocity) this results in planar bedding, while at lower flow regime coarse sediment is transported along the surface by saltation (bouncing), forming ripples, and cross-strata. The distance that coarser sediments are transported across the floodplain surface as bedload is not far, perhaps one channel width, in part because floodplain vegetation results in flow resistance. Where overbank flood deposits are transported into floodplain bottoms previously inundated by sources such as crevasse, conduit, groundwater, or local precipitation, natural levee sedimentation is dominated by turbulent diffusive mechanisms (Fig. 1).[9] Essentially, this sedimentation process occurs in floodplains that have flood basins with high water levels adjacent to the channel. During a flood event this produces a steep lateral sediment concentration gradient between the channel and flood basin and sediment quickly falls out of suspension.[10] This mechanism results in steep (high gradient) natural levees.[9] Alternatively, during flood events in which floodplain bottoms are not significantly inundated (water level remains low), advective

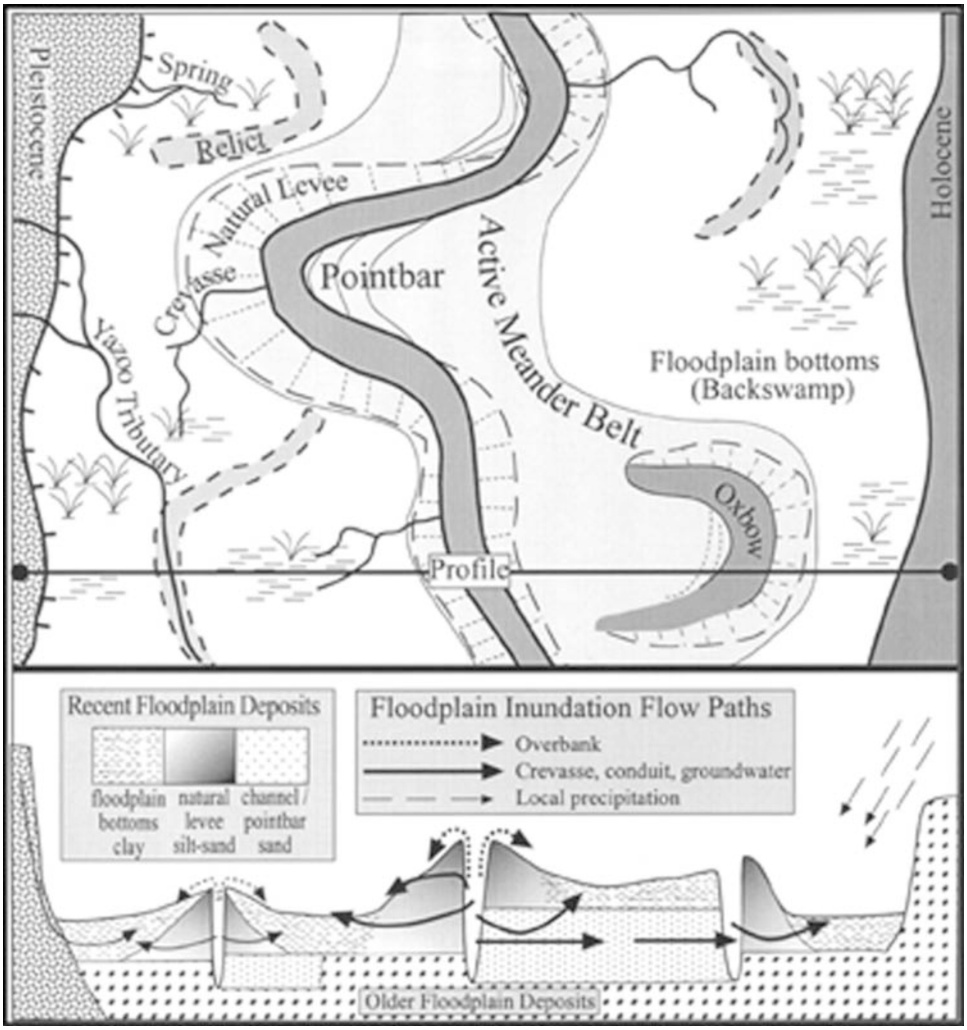

Fig. 1 Meandering river floodplain deposits and processes of inundation for a large lowland alluvial valley. Natural levees form the highest surfaces along the active floodplain. Relict natural levees remain part of the floodplain after a channel cutoff. Floodplain inundation flow paths are displayed by arrows.

sedimentation processes dominate. This process is characterized by flood waters flowing down the levee flank to a low lying bottomland not significantly inundated (water level is low relative to river stage). This process is associated with natural levees having a lower gradient and a curvilinear morphology. At the distant margins of natural levees, slack-water deposition of clay is the dominant mode of sedimentation. In large river valleys the distal portions of natural levees also experience slackwater sedimentation and very low rates of vertical accretion from other mechanisms of floodplain inundation. Crevasse and sloughs connected to the main-stem channel, or smaller tributaries draining adjacent terraces may inundate floodplain surfaces, including the backslope of levee surfaces (Fig. 1). These mechanisms result in very thin clay laminations. Sedimentation rates are influenced by sediment supply and sediment size, as well as flood characteristics such as frequency, seasonality, duration, and magnitude. The amount of time required for natural levees to form probably requires several hundred to several thousand years and can be investigated by analysis of soils and sediments exposed at channel cutbanks.

SEDIMENTOLOGY AND SOILS

In contrast to the overall vertical fining-up particle size trend of floodplains, individual natural levees have a distinctive coarsening-up trend in particle size. This is more pronounced in laterally active meandering river floodplains because of progradation (e.g., lateral extension of the deposit) of the levee unit over fine-grained floodplain bottoms (Fig. 2). Because natural levees are constructed by large discharge events, cutbank stratigraphy is similar to other upper channel-bar

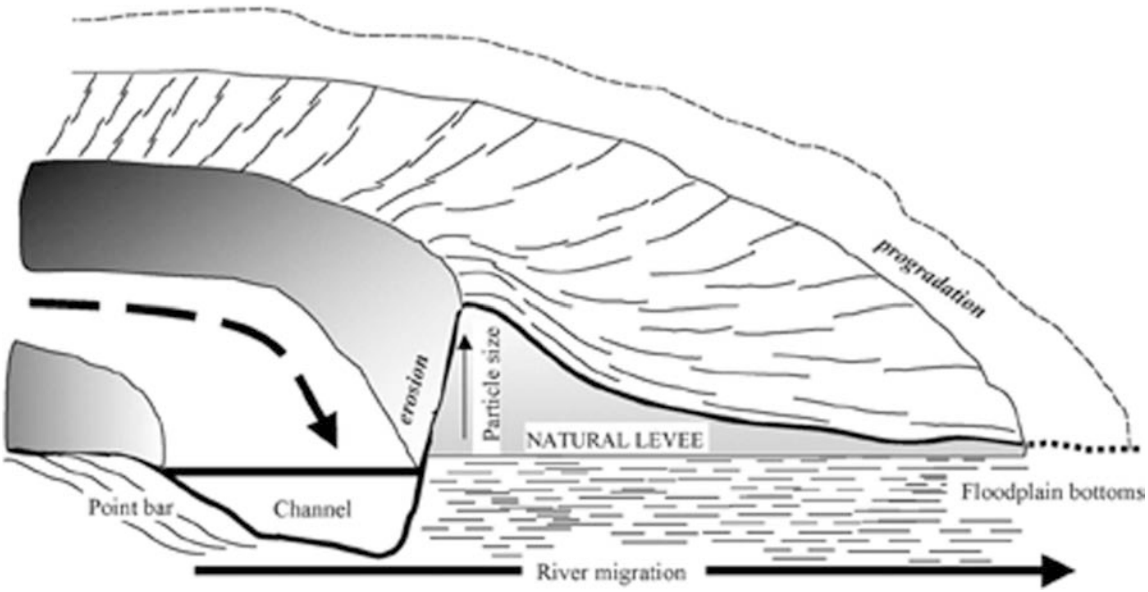

Fig. 2 Natural levee at a meander bend. Progradation of coarser natural levee deposits over fine-grained floodplain bottoms deposits results in a coarsening-up particle size trend.

facies.[6] Individual stratasets are centimeters to decimeters thick, and decreases in thickness away from the channel bank. Lateral decreases in sedimentation rates result in individual stratasets being wedge shaped. These deposits merge with floodplain soils in floodplain bottoms, resulting in a diffuse distal boundary to the natural levee. Each levee deposit consists of multiple stratasets and for larger rivers a natural levee may be several meters in thickness.[11,12] A typical sandy strataset may be characterized as having millimeter-thick bedding, consisting of planar laminae at the base associated with a high flow regime, overlain by small-scale cross-strata formed by migrating ripples. Medium-scale bedding from migrating dunes is less common, but would be associated with much larger flood events. Fine-grained (mud) laminations may overlay coarser ripples. The length of time for sedimentary structure to be preserved depends not only on primary sedimentology, particle size, and bedding, but also on pedogenic regime. Individual laminations may be destroyed after several years of bioturbation by plants and burrowing organisms, particularly in hot and humid regions. In general, sandy sediment structure will be preserved longer than fine-grained bedding.

Natural levees may be considered a single depositional environment, but pedogenic characteristics vary spatially, laterally, away from the channel.[8] Natural levees are considered to exhibit soil catenas, which means that there are rather predictable changes in soil characteristics along the levee from channel bank to floodplain bottoms.[13] Soils developing on thicker, sandier, and well-drained surfaces of natural levees (near the channel) have oxidized and leached horizons with abundant iron and manganese nodules, and are likely affected by bioturbation. These soils may have medium to stiff, mottled gray, tan, and brown silty clay, sandy clay, or silty sand and overlay darker fine-grained soils with considerable organic matter, developed in floodplain bottoms. In regions undergoing strong seasonality with a fluctuating water table, soils may develop a calcium carbonate horizon at the capillary fringe. Commonly, these soils will lack elluvial (E) or illuvial (B) horizons, and are frequently characterized by soil profiles with A/C horizons. High rates of overbank sedimentation result in ‘‘A’’ horizons having little organic matter. Soil maturity increases with distance from the channel because of a reduction in sedimentation rates. These soils are associated with higher rates of bioturbation, lack of stratification, a higher percentage of soil nodules, evidence of illuviation (Bt), and possibly slickensides. Soils on the backlopes of natural levees may also exhibit gleyed conditions in river floodplains with a high water table. The root zone (rhyozone) is confined to the surface in the case of a high water table, but may extend vertically in floodplains that undergo large seasonal fluctuations, which has implications to the preservation of sediment structure.[8] Any field study of natural levee deposits should consider the presence of paleosols, which are usually buried organically enriched soil ‘‘A’’ horizons (originally formed at the surface), as they represent an archive of flood deposits and thus provide insight into climate change.[13]

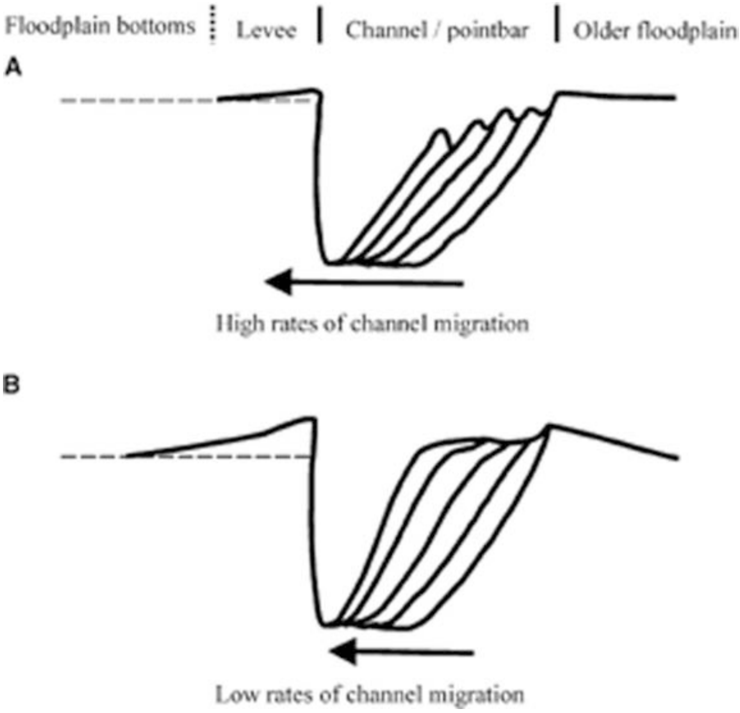

Fig. 3 Relationship between rates of channel migration and floodplain topography: (A) higher rates of lateral migration result in smaller natural levees because of the reduction in the time for sediment to accumulate; (B) lower rates of lateral migration results in a larger and more stable natural levee.

TEMPORAL AND SPATIAL VARIABILITIES

Because natural levees are formed from numerous individual flood events the shape of natural levees is time-transgressive, and evolves in size and form after avulsion.[3,7] Natural levee slopes are highest immediately after avulsion, and decreases with time as the levee widens. After the channel switches course (avulsion), sedimentation rates of coarse deposits are initially high adjacent to the channel bank, resulting in a steeply sloping levee surface. With time the increased bank height reduces coarse sediment deposition adjacent to the channel, resulting in greater amounts of fine-grained sediments deposited along levee backslopes, which reduces the levee slope gradient.

The height of natural levees adjusts to flood stage, suggesting the concept of dominant discharge is appropriate for this element of alluvial morphology. However, the evolution of natural levees may be significant to fluvial processes, and in particular should be considered as a control on channel avulsion,[3] which occurs when a river abruptly changes course. In laterally stable rivers the height of levee construction must reach some maximum, whereby continued buildup reduces the frequency of overbank flooding. In such cases larger floods are necessary to overtop natural levees, increasing the probability of channel avulsion.[3] However, in laterally active meandering rivers, rates of lateral migration represent a control on the size of natural levees.[1,5] Thus, if migration rates and sedimentation rates remain constant through time, the height and morphology of the levee should reach a steady-state or equilibrium form (Fig. 3).

Similar to other components of fluvial systems, natural levees are scale dependent and increase in size with drainage area due to increases in sediment and streamflow. Natural levees increase in size downstream of tributaries, and may abruptly increase in size if there are large increases in sediment load. Toward the lower reaches of large coastal plain river systems natural levees attain a maximum size and abruptly decline in size because of exhaustion of coarse suspended sediments.[12,14]

CONCLUSIONS

Natural levees represent significant floodplain topography within a flat landscape and have long been heavily utilized for human settlement and floodplain agriculture. The formation of natural levees occurs through several different flood sedimentation mechanisms, and is in part dependent on the process of flood inundation and floodplain style. Fluvial sedimentology and soil science provide useful approaches for examining natural levee sediments, and for relating natural levee deposits to the broader topic of floodplain construction. Moreover, because natural levees are formed from numerous individual flood deposits they are a climate-sensitive archive that represents great promise for furthering our understanding of watershed-scale hydrologic variation in response to climate change.

Neuse River

Curtis J. Varnell

John Van Brahana
Division of Geology, Department of Geosciences, University of Arkansas, Fayetteville, Arkansas, U.S.A.

INTRODUCTION

The Neuse River of North Carolina has been significantly impacted by the influx of nutrients from the concentrated animal feeding operations (CAFOs) located in the watershed area. Phosphorus and nitrogen rates have increased dramatically causing subsequent algae blooms, fish kills, and eutrophication in the lakes, rivers, and estuaries along the waterway. Unpredictable weather events can intensify the problem and could have dramatic environmental consequences.

BACKGROUND

The Neuse River is one of the major rivers on the East Coast of the United States. The entirety of its 300-mi length is located in North Carolina. The river drains land in 19 counties that contain about one-sixth of the states' population. The river originates in north central North Carolina and flows in a southeasterly direction past Raleigh, Kinston, and New Berm and into the tidal basin of the second largest estuarine systems in the United States, the Albemarle–Pamlico estuary. What was once considered a pristine stream has, in recent years, been rated by the renowned environmental group, American Rivers, as one of the 20 most threatened rivers in North America.[1]

The Neuse carries the highest concentrations of total nitrogen and total phosphorus of any of the four rivers draining into the Pamlico and Albemarle Sounds even though it drains only 20% of the contributing land area.[2] In 1983, the North Carolina Environmental Commission classified the Falls Lake portion of the stream as a Nutrient Sensitive Area. In 1998, the lower Neuse River basin was added to that classification. Despite efforts by the various state organizations, phosphorus and nitrogen concentrations in the water of the river have not decreased.

FACTORS CONTRIBUTING TO ENVIRONMENTAL PROBLEMS

Many factors contribute to the environmental problems faced by the Neuse River. Roughly, 15% of the states' population live within the basin and the population is increasing rapidly. Wastewater effluent, storm water discharge, and urban run-off contribute a large percentile of the nutrient contamination in the basin. Currently, more than 400 point source discharge permits are active in the watershed and legislation is being enacted to lessen the amount of contaminants entering the river.

Non-point source run-off and shallow groundwater migration are now the most significant pollution source for North Carolina. The state is a large farming state and contains some of the largest CAFOs in the world. The state ranks number one in the nation in turkey production, number four in broiler production, and number two in the production of swine. All these produce excessive amounts of organic waste containing large amounts of nitrogen and phosphorus. Hog production is of extreme importance to the Neuse River because of the intense concentration in farm numbers found in the lower river basin and flood plain area.

Most of these farms are CAFO type productions containing hundreds or even thousands of swine at each farm location. These farms are part of integrated systems owned by huge corporations that have moved their business into North Carolina because of the relatively lax regulations that the state enforces. Hog production has increased over 270% since 1990, and will top out over 12 million hogs in the next few years.

The 10 million hogs (Fig. 1) now populating North Carolina's coastal region produce 19 million tons of waste each year.[3] Ammonia is also released as a

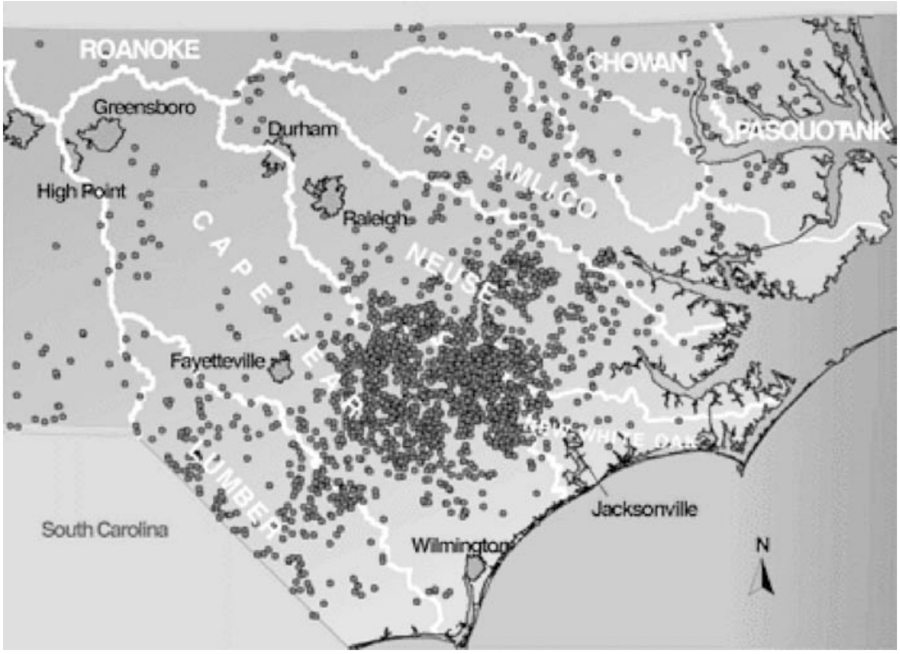

Fig. 1 Hog farms of Coastal Carolina. *Source*: From Linda Huff, *American Scientist*.

by-product of swine production (Fig. 2). Two million pounds of ammonia per year are deposited by rainfall in the Neuse River basin from hog operations.[4] To put this into perspective, the wastewater plants of the entire state contributed only 2.1 million pounds of nitrogen in 1995.

The hogs are raised in confined barns containing hundreds of animals in close proximity. A lagoon is constructed to deposit waste materials from the large farms. In order to utilize the nutrients in the waste materials, water is withdrawn from the lagoons and sprayed onto adjacent pastures that use the nutrients to grow crops, usually various types of grasses required for cattle production. In an ideal system, the grasses would use up most of the nutrients; the cattle would consume the grass, and the run-off would be negligible. In actuality, even with clay liners in the lagoons, waste leaches into the local groundwater system. Even when the rate of flow is slow, over a period of days or weeks a 2-acre lagoon would leak thousands of gallons into the local watershed. There are nearly 4000 such lagoons in the state, leaching water into the ground and ammonia into the atmosphere.[3] The spraying is also inefficient. Most of the spraying is done during the spring and fall during the peak periods of precipitation, and the nutrients

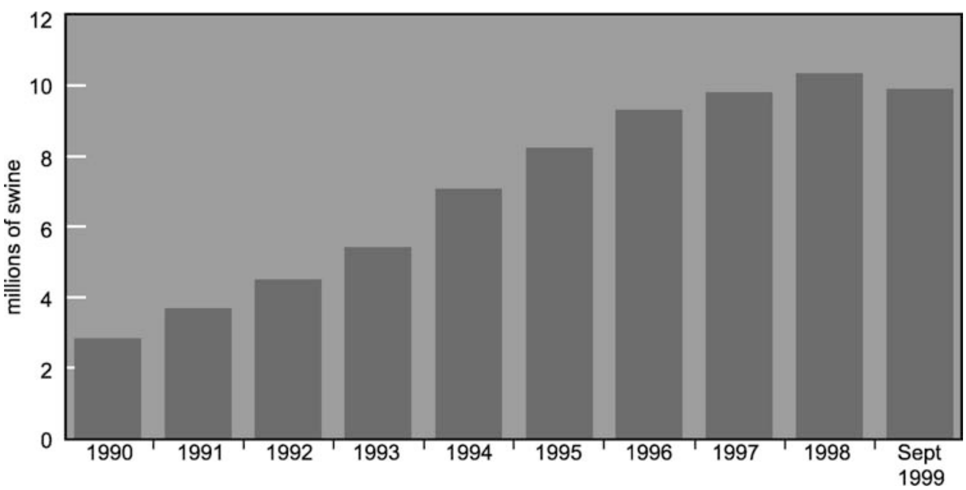

Fig. 2 Swine production in North Carolina.

are quickly washed into the streams of the watershed area. North Carolina farmers have found that it is more profitable to raise cattle on the pastures than to bale the grass into hay and remove it from the site. As a result, the animals consume the grass and then redeposit the nutrients as urine or feces back onto the pasture where some of them later wash into the local streams.

North Carolina's best management practices (BMP) suggest but do not require a buffer zone along the streams and rivers. Without an effective riparian zone, nutrients are easily deposited into the watershed area. Nearly 60% of the pollution load in the Neuse River comes from agriculture and a large portion of this is from the by-products of swine production.[4] Transported by surface and underground water, nitrates move through the soils and into the local streams. Phosphorus is less soluble and is transported primarily by surface run-off. Enriched levels of nitrogen and phosphorus have accumulated in lakes, streams, and estuaries of the Neuse watershed area. The most immediate effect of this concentration of nutrients is the depletion of dissolved oxygen and eutrophication of the water. Studies in the coastal plains of North Carolina have shown that nitrate levels in stream and ground water are the highest in areas with the greatest numbers of CAFOs.[5]

Algae blooms, including *Pfiesteria*, and fish kills result from surpassing the limiting amounts of nitrogen and phosphorus that are needed in the streams. Excess phosphorus appears to have dramatic effects on the production of huge amounts of nuisance algae in the standing waters of lakes and estuaries as well as at the mouth of the Neuse River. It is extensive enough at times to cause a visible discoloration of the water and to form mats on the surface. This results in further reduction of oxygen in the water and greater fish kills. The Neuse River modeling and monitoring project (MODMON) provides data that can be accessed on a regular basis to determine the water quality at several points along the Neuse River.[6]

The dinoflagellate *Pfiesteria* increases in concentration as a result of excessive nutrient enrichment in the poorly flushed estuaries and waterways of the Neuse. Fish kills and disease events have been linked to the organism. Thirteen researchers who worked with dilute toxic cultures of *Pfiesteria* sustained mild to adverse health impacts through water contact or by inhaling toxic aerosols from the lab cultures. These included severe headaches, blurred vision, short- and long-term memory loss, and other health problems. Some of the effects have reoccurred for a period of up to eight years.[7]

North Carolina is often impacted by unforeseen precipitation events that can greatly impact the quality of the local watersheds. CAFOs are often constructed on the flood plain with little thought to these unusual weather conditions and with little preparation for their occurrence. A case in point occurred on September 16, 1999 when Hurricane Floyd struck the East Coast of the United States. Fifty-seven lives and thousands of homes were destroyed as record amounts of rainfall from 15 in. to 20 in. battered the coast and storm surges from the ocean rose as much as 10 ft. Hurricane Floyd inundated more than 250 animal operations, mostly hog farms, in the eastern part of the state. Estimated animal deaths exceeded 500,000 hogs, 2.1 million chickens, and 737,000 turkeys. Three lagoons burst, others overflowed, adding to the millions of gallons of waste from 24 flooded sewage plants.[8] Flood run-off in the aftermath of Hurricane Floyd carried huge plumes of sediment and decomposing animals down the Neuse and other rivers and into the estuaries along the coast. Salinity and dissolved oxygen dropped to zero, excessive blooms of algae occurred for months resulting in greater and greater fish kills. The public was exposed to coliform bacteria and other pathogens too numerous to mention. The public addressed the problem after the event with some subsequent changes in policy, but there would yet be tremendous problems for the people of the Neuse watershed basin if they were again struck by a storm of similar magnitude.

CONCLUSION

The quality of water in the Neuse River basin is greatly impacted by anthropogenic activities. With the population of the region increasing at a very rapid rate, greater water resources will be required even as greater stresses will be placed on those water sources because of human activities. Several steps are required to prevent contamination and to improve the quality of the water of the Neuse for the benefit of both mankind and other organisms.

The EPA's revised Clean Water Act of 2002 will implement new and more stringent regulations on CAFOs.[9] States containing large numbers of CAFOs must require more stringent regulations if they are to prevent further problems from water contamination. These include requiring water treatment of effluent from lagoons, establishment of riparian zones along streams, required implementation of BMP, and preventing the expansion of existing CAFOs. Continuous monitoring of water resources in the Neuse River should allow for the construction of a water-use model that will be more effective in regulating the quality of water in the watershed area.

Nitrogen Measurement

Jacek A. Koziel
Texas A&M System Agriculture Research and Extension Center, Amarillo, Texas, U.S.A.

INTRODUCTION

Nitrogen (N) (MW = 14.0067) is an integral part of the hydrosphere (2.3×10^{13} tn), atmosphere (3.5×10^{15} tn), and lithosphere (5×10^{16} tn).[1,2] Nitrogen serves as an essential component of cells and participates in almost every biological phenomenon in the biosphere.[2] Nitrogen cycles in the biosphere along with carbon, water, oxygen, sulfur, phosphorus, and other elements. Nitrogen in the form of nitrate (NO_3^--N), nitrite (NO_2^--N), ammonium (NH_3-N), and organic N are of great importance in waters and wastewaters.[3] Approximately 95% of the hydrosphere's N is stored as molecular N with the remaining 5% distributed in a 60:40 ratio between inorganic nitrates and organic N. Although N is very abundant—a significant disturbance on a local level, such as wastewater or fertilizer introduction, can result in abnormal N redistributions on regional, continental, and even global levels.[2] Thus, it is very important to recognize and quantify N sources and cycle pathways. This entry discusses typical concentrations of N in waters and wastewaters, and methods suitable for measuring N concentrations in water and wastewater.

The sum of nitrate- and nitrite-N is referred to as total oxidized nitrogen. Plants use nitrate as their primary source of N. Nitrate typically occurs in trace levels in surface waters, but it can be significantly higher in contaminated groundwater. Excessive fertilizer run-off and/or leaching are concerns for the contamination of surface water and groundwater. Fresh domestic wastewater can contain as much as $30\,mg\,L^{-1}$ NO_3^--N. The U.S. EPA (Environmental Protection Agency) drinking water standard for concentrations of NO_3^--N is $10\,mg\,L^{-1}$.[3] At high concentrations, nitrous acid that is formed from nitrite in acidic conditions, can react with secondary amines to form nitrosamines, some of which are known or suspected carcinogens. Nitrate can also react with hemoglobin in red blood cells causing methemoglobinemia or "blue baby" syndrome. Nitrite is formed via oxidation of ammonium and via reduction of nitrate in wastewater treatment plants, and municipal and natural waters.[3] Ammonium is present in surface water at levels typically less than $10\,\mu g\,L^{-1}$ to more than $30\,mg\,L^{-1}$ of NH_3-N in some wastewaters.[3] Ammonium is produced by deamination of N-containing compounds involving enzymes and microorganisms and by hydrolysis of urea. Organic N is defined as "organically bound" N in 3^- oxidation state, e.g., proteins, peptides, nucleic acids, urea, and many synthetic organic materials.[3] Typical organic nitrogen concentrations range from a few hundred $\mu g\,L^{-1}$ in lake water to more than $20\,mg\,L^{-1}$ in raw sewage.[3] The main factors influencing the selection of a method for analysis of N is the range of concentrations, interferences, solution matrix, and the availability of analytical instrumentation. The full description of standard methods for determination of N in water and wastewater is presented in *Standard Methods*,[3] its updated versions,[4] and in U.S. EPA manuals.[5,6]

NITROGEN MEASUREMENT

Total Nitrogen

Total nitrogen content of all digestible nitrogen forms (limited organic, NH_3^-, NO_2^-, and NO_3^--N) can be determined by persulfate/UV digestion and persulfate digestion. This is accomplished by oxidative digestion to nitrate and subsequent quantification of nitrate. For concentrated samples (N$>$0.05%) total N analysis can be completed using automated combustion methods. Table 1 summarizes the characteristics of the persulfate/UV digestion and persulfate digestion that are specifically proposed for waters and wastewaters.[4] The U.S. EPA lists several variations of the total Kjeldahl N method as 0351.1–0351.4 for the automated colorimetric, colorimetric, colorimetric/titration, and potentiometric methods, respectively.

Ammonium Nitrogen

A summary of methods for the determination of ammonium nitrogen in waters and wastewaters is presented in Table 2. These include titration, phenate, ammonium-selective electrode, and gas segmented continuous flow colorimetric analysis methods.[3,4] The ammonium selective electrode method is highly matrix-dependent with an applicable range from $0.03\,\mu g$ to $14\,mg$ of NH_3-N L^{-1} and can be affected by signal drift and interferences. Lower concentrations

Table 1 Methods for measurement of total nitrogen in waters and wastewaters

Method	Applicability	Equipment	Interferences	Sample preservation
In-line UV/persulfate digestion and oxidation with flow injection analysis. Also available is the segmented flow analyzer	All forms of nitrogen except molecular N, amines, nitro-compounds, hydrazones, oximes, semicarbazones, and some refractory tertiary amines	Flow injection analysis equipment with injection valve and sample loop; multichannel proportioning pump; manifold, absorbance detector (540 nm, 10-nm bandpath)	Large particulates need to be filtered out. Chloride ions decrease the rate of reduction to nitrate	Acid can be used for sample preservation
Persulfate	All forms of nitrogen. Not applicable to molecular N and high organic N loads	Autoclave, or hotplate and pressure cooker; glass culture tubes; apparatus for nitrate determination; automated analytical equipment	Large particulates need to be filtered out. Chloride ions decrease the rate of reduction to nitrate	Samples preserved with acid cannot be analyzed with this method

Source: From Ref.[4].

can be detected using the manual phenate method. Preliminary distillation and subsequent titration should be used for samples with NH_3-N concentrations greater than $5\,mg\,L^{-1}$. Distillation is also recommended before the phenate method when interferences are present. The phenate method can be automated. The indophenol blue method, based on semiautomated colorimetry, can be used to determine ammonium-nitrogen (as part of the total Kjeldahl nitrogen determination). Nesslerization, which was the traditional ammonium determination method, is no longer recommended due to the use of mercury and potential hazardous waste disposal problems.[4] The U.S. EPA assigned several variations of the ammonium N method as 0350.1 to 0350.3 for the colorimetric and semiautomated colorimetric, colorimetric/titration, and potentiometric methods, respectively.

Nitrite Nitrogen

Nitrite (NO_2^-) N in water/wastewater samples can be determined using the manual and automated cadmium reduction colorimetric methods. This method is applicable for concentrations ranging from 5 μg to 1000 μg of NO_2^--N L^{-1}. Nitrate N can also be estimated with ion chromatography and other flow injection methods discussed in the next paragraph and Table 3.[3] The colorimetric method uses either a spectrophotometer (543 nm and a light path of at least 1 cm) or filter photometer (green filter with maximum transmittance near 540 nm and a light path of 5 cm or more). Solids need to be filtered out and some ions, including Sb^{3+}, Au^{3+}, Bi^{3+}, Fe^{3+}, Pb^{2+}, Hg^{2+}, Ag^+, $PtCl_6^{2-}$, and VO_3^{2-} should be absent. Samples are typically collected in 50-mL polypropylene bottles and can be preserved for up to 48 hr at 4°C or frozen at −20°C. Acids should never be used for sample preservation. The U.S. EPA lists several methods for determination of nitrite N. These include 0300.0 (ion chromatography), 0354.1 (spectrophotometry), 0353 (1, 2, 3, and 6 variations of these methods use manual and automated colorimetry), and 0353.4 (gas segmented continuous flow colorimetric analysis).

Nitrate Nitrogen

A summary of methods for the determination of nitrate (NO_3^-) nitrogen in waters and wastewaters is presented in Table 3. These include ion chromatography, ultraviolet spectrophotometry, nitrate electrode, cadmium reduction (also using gas segmented continuous flow colorimetric analysis), titanous chloride reduction, and hydrazine reduction methods.[3,4] The ultraviolet spectrophotometry is used as a screening method to estimate concentration range and interferences in samples. This is followed by selection of a suitable method. Samples are typically collected in 100-mL polypropylene bottles and storage time should be limited to the absolute minimum. Samples are maintained at 4°C and can be held for up to 48 hr. For longer storage, addition of H_2SO_4 to a pH of <2 (typically about $2\,mL\,L^{-1}$) and refrigeration at 4°C can be used. When acid is used for preservation, NO_3^- and NO_2^- cannot be determined as individual species,[3] however, the sample can be held up to 28 days. The results are reported as nitrate–nitrite N. Samples are typically collected in 100-mL polypropylene containers. The U.S. EPA lists methods 0300.0 (ion chromatography), 0353 (1, 2, 3, and 6 variations of these methods use manual and automated colorimetry for nitrate–nitrite), 0352.1 (colorimetric), and 0353.4 (for

Table 2 Methods for measurement of ammonium-nitrogen in waters and wastewaters

Method	Applicability	Range of applicability	Equipment	Interferences	Sample preservation	Comments
Phenate	Drinking, surface, saline waters, domestic and industrial wastewaters	10–600 μg NH_3-N L^{-1}	Magnetic stirrer and spectrophotometer (630 nm and a light path of at least 1 cm)	Turbidity, color, alkalinity >500 mg as $CaCO_3$ L^{-1}, acidity >100 mg as $CaCO_3$ L^{-1} should be removed by preliminary distillation	Acid (needs to be removed by preliminary distillation)	Automated phenate method applicable from 20 μg up to 2 mg NH_3-N L^{-1} without dilution
Titration	Used only after preliminary distillation	For samples >5 mg NH_3-N L^{-1}	Distillation apparatus			
Selective electrode	Drinking and surface waters, domestic and industrial wastewaters	0.03–1400 mg NH_3-N L^{-1}. Longer response times needed for concentrations <1 mg NH_3-N L^{-1}	Ammonium selective electrode, electrometer, and magnetic stirrer	High concentrations of dissolved ions; amines. Effects of Hg and Ag are minimized with the NaOH/EDTA. Turbidity and color cannot affect the measurement	Refrigeration at 4°C if analyzed within 24 hr; Refrigeration at pH = 2 (by H_2SO_4) or freezing at −20°C for upto 28 days	Does not require preliminary distillation. Known addition can be used when no calibration is needed
Flow injection analysis	All waters and wastewaters		Flow injection analysis equipment with injection valve and sample loop; multichannel proportioning pump; manifold, absorbance detector (660 nm, 10-nm bandpath)	Large and fibrous particles should be filtered out		
Gas segmented continuous flow colorimetric analysis	Estuarine and coastal waters	0.3 μ L^{-1} to 4.0 mg L^{-1}	Automatic sampler, analytical cartridge, proportioning pump, spectrophotometer, or photometer with a 640 interference filter, nitrogen gas	Hydrogen sulfide >2 mg S L^{-1}; turbidity needs to be eliminated	Refrigeration in tightly sealed glass or HDPE container in the dark works for up to 3 hr. Concentrated samples >20μ L^{-1} can be preserved for 2 wk	Based on the indophenol reaction

(Continued)

Table 2 Methods for measurement of ammonium-nitrogen in waters and wastewaters *(Continued)*

Method	Applicability	Range of applicability	Equipment	Interferences	Sample preservation	Comments
Nesslerization (not recommended as standard method)	Purified drinking water, natural waters, and highly purified wastewater effluents	20 μg to 5 mg NH_3-N L^{-1}	pH meter and spectrophotometer (400–500 nm, light path of at least 1 cm), or filter photometer (light path of at least 1 cm; violet filter with max transmittance at 400–425 nm), or Nessler tubes	Turbidity, color, Mg, and Ca can be removed via preliminary distillation or by precipitation by zinc sulfate and alkali	Dechlorination, 0.8 mL H_2SO_4 L^{-1} sample, and storage at 4° C. The pH should be between 1.5 and 2 when acid is used and samples need to be neutralized immediately before analysis	This traditional method is not recommended because of potential problems with mercury disposal

Source: From Ref.[3].

Table 3 Methods for measurement of nitrate-nitrogen in waters and wastewaters

Method	Applicability	Range of applicability	Equipment	Interferences	Comments
Ultraviolet spectrophotometric screening	Used for screening only of uncontaminated natural and drinking waters, i.e., waters with low organic N content		Spectrophotometer (220 and 270 nm, light path of at least 1 cm)	Dissolved organic matter, surfactants, NO_2^-, Cr^{6+}, chlorite, chlorate	Measurement at 270 nm is used to correct for dissolved organic matter that may interfere at 220 nm. U.S. EPA method 0354.1
Ion chromatography		From 0.1 mg L^{-1}	Ion chromatograph, anion separator column, guard column, fiber or membrane suppressor, conductivity detector	Bromide can coelute	U.S. EPA method 0300.0
Nitrate electrode	Drinking water	2 mg L^{-1} to 1000 NO_3^--N L^{-1}	Double-junction reference electrode, nitrate ion electrode, pH meter, magnetic stirrer	Chloride and bicarbonate when their weight ratios to NO_3^--N are >10 and >5, respectively; NO_2^-, CN^-, S^{2-}, Br^-, I^-, ClO^{3-}, ClO^{4-}	Ionic strength adjustments can remove interferences
Cadmium reduction	All waters	0.01–1 mg NO_3^--N L^{-1}; For automated method 0.5–10 mg NO_3^--N L^{-1}	Reduction column and spectrophotometer (543 nm, light path of at least 1 cm) or filter photometer (a filter with maximum transmittance near 540 nm and light path of at least 1 cm)	Suspended matter can restrict column flow; concentrations of metals >1 mg L^{-1}, oil, grease, residual chlorine can decrease reduction efficiency	This method is also applicable for determination of NO_2^- when the reduction step is omitted. This method can also be automated and also combined with flow injection method. U.S. EPA method 0353.3
Gas segmented continuous flow colorimetric analysis	Estuarine and coastal waters, applicable also for nitrite determination	0.075 μ L^{-1} to 5.0 mg L^{-1}	Automatic sampler, analytical cartridge, open tubular cadmium reactor or cadmium reduction column proportioning pump, spectrophotometer or photometer with a 540 interference filter, nitrogen gas	Hydrogen sulfide >2 mg S L^{-1}; turbidity needs to be eliminated	Samples should be analyzed within 3 hr. U.S. EPA method 0353.4
Titanous chlorine reduction	All waters	0.01 to 20 mg NO_3^--N L^{-1}	pH meter, ammonium gas sensing electrode, magnetic stirrer	NH_3, NO_2^-	Proposed method
Automated hydrazine reduction	All waters	0.01 to 10 mg NO_3^--N L^{-1}	Automated analytical equipment	Sample color that absorbs in the photometric range used	Proposed method

nitrate–nitrite using gas segmented continuous flow colorimetric analysis).

Organic Nitrogen

A summary of methods for determination of organic nitrogen in waters and wastewaters is presented in Table 4. These include macro or semimicro-Kjeldahl method, and block digestion combined with flow injection analysis. Kjeldahl methods do not account for N in the form of azide, azine, azo, hydrazone, nitrate, nitrite, nitrile, nitro, nitroso, oxime, and semicarbazone.[3] If ammonium is not removed in the initial digestion, the result is the ‘‘Kjeldahl nitrogen’’ often called ‘‘total Kjeldahl nitrogen’’ that is defined as organic plus ammonium N.

CONCLUSION

Measurements of N content in waters and wastewaters are of great interest because they relate to many natural and anthropogenic processes and their effects including human, animal, and plant health and well-being. Standard analytical methods available for the determination of various forms of N, including total N, ammonium, nitrite, nitrate, and organic N, are briefly discussed in this article. Nitrogen detection limits and applicable concentration ranges for these methods cover the typical levels encountered in water and wastewater. The reader is encouraged to use the full standard method description for all described methods in this article.[4–6]

ACKNOWLEDGMENT

The author would like to thank Drs. Robert Schwartz and N. Andy Cole (USDA-ARS-Bushland) and Drs. David Parker and Jim Rogers (West Texas A&M University) for useful discussions of N measurement methods.

INTRODUCTION

Non-point source pollution (NPSP) has no obvious single point source discharge and is of diffuse nature (Table 1). An example of NPSP includes aerial transport and deposition of contaminants such as SO_2 from industrial emissions leading to acidification of soil and water bodies. Rain water in urban areas could also be a source of NPSP as it may concentrate organic and inorganic contaminants. Examples of such contaminants include polycyclic aromatic hydrocarbons, pesticides, polychlorinated biphenyls that could be present in urban air due to road traffic, domestic heating, industrial emissions, agricultural treatments, etc.[1–3] Other examples of NPSP include fertilizer (especially Cd, N, and P) and pesticide applications to improve crop yield. Use of industrial waste materials as soil amendments have been estimated to contaminate thousands of hectares of productive agricultural land in countries throughout the world.

CONTAMINANT INTERACTIONS

Non-point pollution is generally associated with low-level contamination spread at broad acre level. Under these circumstances, the major reaction controlling contaminant interactions are sorption–desorption processes, plant uptake, surface runoff, and leaching. However, certain contaminants, in particular, organic compounds are also subjected to voltalization, chemical, and biological degradation. Sorption–desorption and degradation (both biotic and abiotic) are the two most important processes controlling organic contaminant behavior in soils. These processes are influenced by both soil and solution properties of the environment. Such interactions also determine the bioavailability and/or transport of contaminants in soils. Where the contaminants are bioavailable, risk to surface and groundwater and soil, crop, and human health are enhanced.

IMPLICATIONS TO SOIL AND ENVIRONMENTAL QUALITY

Environmental contaminants can have a deleterious effect on non-target organisms and their beneficial activities. These effects could include a decline in primary production, decreased rate of organic matter break-down, and nutrient cycling as well as mineralization of harmful substances that in turn cause a loss of productivity of the ecosystems. Certain pollutants, even though present in very small concentrations in the soil and surrounding water, have potential to be taken up by various micro-organisms, plants, animals, and ultimately human beings. These pollutants may accumulate and concentrate in the food chain by several thousand times through a process referred to as biomagnification.

Urban sewage, because of its nutrient values and source of organic carbon in soils, is now increasingly being disposed to land. The contaminants present in sewage sludge (nutrients, heavy metals, organic compounds, and pathogens), if not managed properly, could potentially affect the environment adversely. Dumping of radioactive waste (e.g., radium, uranium, plutonium) onto soil is more complicated because these materials remain active for thousands of years in the soil and thus pose a continued threat to the future health of the ecosystem.

Industrial wastes, improper agricultural techniques, municipal wastes, and use of saline water for irrigation under high evaporative conditions result in the presence of excess soluble salts (predominantly Na and Cl ions) and metalloids such as Se and As in soils.

Table 1 Industries, land uses, and associated chemicals contributing to non-point source pollution

Industry	Type of chemical	Associated chemicals
Agricultural activities	Metals/metalloid	Cadmium, mercury, arsenic, selenium
	Non-metals	Nitrate, phosphate, borate
	Salinity/sodicity	Sodium, chloride, sulfate, magnesium, alkalinity
	Pesticides	Range of organic and inorganic pesticides including arsenic, copper, zinc, lead, sulfonylureas, organochlorine, organophosphates, etc., salt, geogenic contaminants (e.g., arsenic, selenium, etc.)
	Irrigation	Sodium, chloride, arsenic, selenium
Automobile and industrial emissions	Dust	Lead, arsenic, copper, cadmium, zinc, etc.
	Gas	Sulfur oxides, carbon oxides
	Metals	Lead and lead organic compounds
Rainwater	Organics	Polyaromatic hydrocarbons, polychlorbiphenyls, etc.
	Inorganic	Sulfur oxides, carbon oxides acidity, metals and metalloids

Salinity and sodicity affect the vegetation by inhibiting seed germination, decreasing permeability of roots to water, and disrupting their functions such as photosynthesis, respiration, and synthesis of proteins and enzymes.

Some of the impacts of soil pollution migrate a long way from the source and can persist for some time. For example, suspended solids can increase water turbidity in streams, affecting benthic and pelagic aquatic ecosystems, filling reservoirs with unwanted silt, and requiring water treatment systems for potable water supplies. Phosphorus attached to soil particles, which are washed from a paddock into a stream, can dominate nutrient loads in streams and down-stream water bodies. Consequences include increases in algal biomass, reduced oxygen concentrations, impaired habitat for aquatic species, and even possible production of cyanobacterial toxins, with series impacts for humans and livestock consuming the water. Where waters discharge into estuaries, N can be the limiting factor for eutrophication; estuaries of some catchments where fertilizer use is extensive have suffered from excessive sea grass and algal growth.

More insidious is the leaching of nutrients, agricultural chemicals, and hydrocarbons to groundwater. Incremental increases in concentrations in groundwater may be observed over long periods of time resulting in initially potable water becoming undrinkable and then some of the highest valued uses of the resource may be lost for decades. This problem is most severe on tropical islands with shallow relief and some deltaic arsenopyrite deposits, where wells cannot be deepened to avoid polluted groundwater because underlying groundwater is either saline or contains too much As.

SAMPLING FOR NON-POINT SOURCE POLLUTION

The sampling requirements of NPSP are quite different from those of the point source contamination. Typically, the sampling is required to give a good estimate of the mean level of pollution rather than to delineate areas of pollution. In such a situation, sampling is typically carried out on a regular square or a triangular grid. Furthermore, gains may be possible by using composite sampling.[4] However, if the pollution is patchy, other strategies may be used. One such strategy is to divide the area into remediation units, and to sample each of these. The possibility of movement of the pollutant from the soil to some receptor (or asset) is assessed, and the potential harm is quantified. This process requires an analysis of the bioavailability of the pollutant, pathway analysis, and the toxicological risk. The risk analysis is then assessed and decisions are then made as to how the risk should be managed.

MANAGEMENT AND/OR REMEDIATION OF NON-POINT SOURCE POLLUTION

The treatment strategies used for managing NPSP are generally those that modify the soil properties to decrease the bioavailable contaminant fraction.

This is particularly so in the rural agricultural environment where soil–plant transfer of contaminants is of greatest concern. Soil amendments commonly used include those that change the ion-exchange characteristics of the colloid particles and those that enhance the ability of soils to sorb contaminants. An example of NPSP management includes the application of lime to immobilize metals because the solubility of most heavy metals decreases with increasing soil pH. However, this approach is not applicable to all metals, especially those that form oxyanions—the bioavailability of such species increases with increasing pH. Therefore, one of the prerequisites for remediating contaminated sites is a detailed assessment of the nature of contaminants present in the soil. The application of a modified aluminosilicate to a highly contaminated soil around a zinc smelter in Belgium was shown to reduce the bioavailability of metals thereby reducing the Zn phytotoxicity.[5] The simple addition of rock phosphates to form Pb phosphate has also been demonstrated to reduce the bioavailability of Pb in aqueous solutions and contaminated soils due to immobilization in the metal.[6] Nevertheless, there is concern over the long-term stability of the processes. The immobilization process appears attractive currently given that there are very few cheap and effective in situ remediation techniques for metal-contaminated soils. A novel, innovative approach is using higher plants to stabilize, extract, degrade, or volatilize inorganic and organic contaminants for in situ treatment (cleanup or containment) of polluted topsoils.[7]

PREVENTING WATER POLLUTION

The key to preventing water pollution from the soil zone is to manage the source of pollution. For example, nitrate pollution of groundwater will always occur if there is excess nitrate in the soil at a time when there is excess water leaching through the soil. This suggests that we should aim to reduce the nitrogen in the soil during wet seasons and the drainage through the soil. Local research may be needed to demonstrate the success of best management techniques in reducing nutrient, sediment, metal, and chemical exports via surface runoff and infiltration to groundwater. Production figures from the same experiments may also convince local farmers of the benefits of maintaining nutrients and chemicals where needed by a crop rather than losing them off site, and facilitate uptake of best management practices.

GLOBAL CHALLENGES AND RESPONSIBILITY

The biosphere is a life-supporting system to the living organisms. Each species in this system has a role to play and thus every species is important and biological diversity is vital for ecosystem health and functioning. The detection of hazardous compounds in Antarctica, where these compounds were never used or no man has ever lived before, indicates how serious is the problem of long-range atmospheric transport and deposition of these pollutants. Clearly, pollution knows no boundaries. This ubiquitous pollution has had a global effect on our soils, which in turn has been affecting their biological health and productivity. Coupled with this, over 100,000 chemicals are being used in countries throughout the world. Recent focus has been on the endocrine disruptor chemicals that mimic natural hormones and do great harm to animal and human reproductive cycles.

These pollutants are only a few examples of contaminants that are found in the terrestrial environment.

Nutrients: Best Management Practices

Keith A. Kelling
Department of Soil Science, University of Wisconsin–Madison, Madison, Wisconsin, U.S.A.

Scott J. Sturgul
Nutrient and Pest Management, University of Wisconsin–Madison, Madison, Wisconsin, U.S.A.

INTRODUCTION

Soil nutrients need to be managed properly to meet the fertility requirements of crops without adversely affecting the quality of water resources. The nutrients of greatest concern relative to water quality are nitrogen (N) and phosphorus (P). Nitrogen not recovered by crops can add nitrate to groundwater through leaching. Nitrate is the most common groundwater contaminant found in the United States.[1,2] Nitrate levels that exceed the established U.S. drinking water standard of 10 ppm nitrate-N have the potential to adversely affect the health of infants and livestock.[3] Surface water quality is the concern with P, as runoff and erosion from cropland add nutrients to water bodies that stimulate the excessive growth of aquatic weeds and algae. Of all crop nutrients, it is critical to prevent P from reaching lakes and streams since the biological productivity of aquatic plants and algae in fresh water environments is usually limited by this nutrient.[4] Consequences of increased aquatic plant and algae growth include reduced aesthetic and recreational value of lakes and streams as well as the seasonal depletion of water dissolved oxygen content, which may result in fish kills as well as other ecosystem disruptions.

OVERVIEW

Nutrient best management practices vary widely from one area to another due to cropping, topographical, environmental, and economic conditions. With the variety of factors to consider, no single set of best management practice can be recommended for all farms. Nutrient management practices for optimizing crop production while protecting water quality must be tailored to the unique conditions of individual farms. Practices that need to be considered in any nutrient best management program include the following.

Establish Nutrient Application Rates

The most important management practice for environmentally and economically sound nutrient management is the application rate.[5] Optimum nutrient application rates are identified through fertilizer response/calibration research for specific soils and crops. Economically optimum nutrient application rates provide maximum financial return, but as application rates near the economic optimum, the efficiency of nutrient use by the crop decreases and the potential for loss to the environment increases. Any nutrient application above this rate reduces profit and increases the likelihood of detrimental impact to the environment. Because of the overall importance of nutrient application rates, accurate assessments of crop nutrient needs are essential for minimizing threats to water quality while maintaining economically sound production. Soil testing is the most widely used method to accurately estimate nutrient needs of crops.

Use Additional Tests for Fine-Tuning Nitrogen Applications

The development of tests for assessing soil N levels provides additional tools for improving the efficiency of N fertilizer applications.[6] These tests allow fertilizer recommendations to be adjusted to site-specific conditions that can influence N availability. Tests include the preplant soil profile nitrate test,[7] the presidedress soil nitrate test,[8] plant analysis,[9] chlorophyll meters,[10] the basal stalk nitrate test,[11] and the end of season soil nitrate test.[12]

Use Calibrated Soil Tests for Phosphorus and Potassium

In recent years, soil test recommendation programs for phosphorus (P), potassium (K), and other relatively immobile nutrients have tended to de-emphasize the soil build-up and maintenance philosophy in favor of a better balance between environmental and economic considerations by using a crop sufficiency approach.[13] These tests must be calibrated by field experiments to obtain predictable crop yield responses. Such an approach adds extra emphasis on regular soil testing. It is recommended that soil tests be taken at least every three to four years and more frequently on sands and other soils of low buffering capacity.[14]

Establish Realistic Yield Goals

For many soil fertility programs, the recommendation of appropriate nutrient application rates is dependent on the establishment of realistic yield goals. Yield goal estimates that are too low will underestimate nutrient needs and can limit crop yield. Yield goal estimates that are too high will overestimate crop needs and result in soil nutrient levels beyond that needed by the crop which, in turn, has the potential to increase nutrient contributions to water resources.[15,16] Estimates should be based on field records and some cautious optimism—perhaps 10% above the recent three- to five-year average crop yield from a particular field.

Credit Nutrients from All Sources

The best integration of economic return and environmental quality protection is provided by considering nutrients from all sources. In the determination of supplemental fertilizer application rates, it is critical that nutrient contributions from manure, previous legume crops grown in rotation, and land-applied organic wastes are credited. In many cases, commercial fertilizer application rates can be reduced when nutrient credits are accounted.

Time Nutrient Applications Appropriately

Timing of application is a major consideration for the management of mobile nutrients such as nitrogen. The period between application and crop uptake of N is an important factor affecting the efficient utilization of N by the crop with the loss of N minimized by supplying it just prior to the period of greatest crop uptake.[17] However, several considerations, such as soil, equipment, and labor, are involved in determining the most convenient, economical, and environmentally safe N fertilizer application time. Although fall applications of N are commonly discouraged, they continue to be made primarily to ensure adequate time for spring planting. If fall applications of N are to be made, it is recommended that ammonium–nitrogen sources be used and that the applications be delayed until soil temperatures are below thresholds of biological activity (i.e., 50°F). Fall applications of N fertilizers are not recommended on coarse textured soils or on shallow soils over fractured bedrock.

For less mobile nutrients, application timing is not a major factor affecting water quality protection. However, nutrient applications on frozen sloping soils or surface applications prior to periods likely to produce runoff events should be avoided to prevent P contributions to surface waters.

Use Nitrification Inhibitors When Appropriate

Nitrification inhibitors are used with ammonium or ammonium-forming N fertilizers to improve N efficiency by slowing the conversion of ammonium to nitrate, thereby reducing the potential for losses of N that occur in the nitrate form. The effectiveness of a nitrification inhibitor depends greatly on soil type, time of the year applied, N application rate, and soil moisture conditions that exist between the time of application and the time of N uptake by plants. Research has shown that the use of nitrification inhibitors on medium- and fine-textured soils with fall N applications, or on poorly drained soils with fall or spring N applications, or on coarse-textured, irrigated soils with spring preplant N applications has the potential to increase corn yield and total crop recovery of N.[18,19] Fall applications of N with an inhibitor on coarse textured soils are not recommended.

Manage Manure to Maximize Benefits

Manure applications to cropland provide nutrients essential for crop growth, add organic matter to soil, and improve soil physical conditions. The major concerns associated with manure applications are related to its potential for overloading soils with nutrients if manure applications exceed crop needs, or its application at times of the year when the risk of runoff losses are high. Recommended management practices include accounting for (or crediting) the nutrients supplied by manure, incorporating or injecting manure, distributing manure over numerous cropland fields, minimizing applications to frozen soils, avoiding fall applications to highly permeable soils, and avoiding applications to areas with direct access to surface water (i.e., floodplains, waterways, etc.), or groundwater (i.e., shallow or permeable soils over fractured bedrock, etc.).[20]

Manage Irrigation Water

Overirrigation or rainfall on recently irrigated soils can leach nitrate and other contaminants below the root zone and into groundwater. Accurate irrigation scheduling that considers soil water holding capacity, crop growth stage, evapotranspiration, rainfall, and previous irrigation to determine the timing and amount of irrigation water to be applied can reduce the risk of leaching losses.[21]

Use Soil Conservation Practices

Land-use activities associated with agriculture often increase the susceptibility for runoff and sediment transport from cropland to surface waters. The key to minimizing nutrient contributions to surface waters is to reduce the amount of runoff and eroded sediment reaching them. Runoff and erosion control practices range from changes in agricultural land management (cover crops, diversified crop rotations, conservation tillage, contour farming, and contour strip cropping) to the installation of structural devices (diversions, grade stabilization structures, grassed waterways, and terraces). Recently, substantial emphasis is being placed on the benefits and installation of buffer strips which are effective in reducing contaminant transport to surface waters.[22]

CONCLUSION

The previous text provides a brief summary of general nutrient management practices for crop production. This is not a complete inventory but rather an overview of soil fertility management options available to growers for improving farm profitability and protecting water quality. The selection of appropriate nutrient management practices for an individual farm needs to be tailored to the specific conditions existing at a given location.

Observation Wells

Phillip D. Hays
John Van Brahana
Department of Geosciences, University of Arkansas, Fayetteville, Arkansas, U.S.A.

INTRODUCTION

Observation wells are engineered openings constructed through the solid earth, usually circular in cross-section, that are drilled or otherwise excavated to allow human access to specific zones of underground water for the purpose of measuring attributes such as water levels or pressure changes that would otherwise not be observable at the Earth's surface. Wells constructed to sample groundwater quality have been called observation wells by some hydrogeologists, but common accepted practice restricts the term monitoring wells to wells from which water samples may be collected for chemical analysis.[1] Groundwater-level monitoring networks incorporate multiple observation wells, and maps constructed from these water levels allow hydrogeologists and engineers to determine the direction of the subsurface flow. Observation wells are occasionally called "piezometers," although most hydrogeologists consider piezometers to be a special type of observation well in which a simple tube emplaced in an aquifer, open at the top for access and measurement and open at the bottom to allow communication with the aquifer.[2] No matter what the name used for these features, observation wells are windows to the groundwater system, and they allow us to collect in situ information from which we can develop an understanding of the degree of interconnection of openings in the aquifer, calculate the amount of water that is stored in the subsurface openings, and determine the hydraulic head and pressure gradients present in the subsurface which control groundwater flow and rates of movement.

BASIC CONSTRUCTION

Observation wells differ from groundwater monitoring and water-supply wells primarily in their objectives, and thus usually are constructed to be only large enough to allow accurate and rapid water-level measurements.[3–5] Observation wells typically are of small diameter, 2–10 cm, open to a discrete interval in an aquifer and have a shorter section of screen or other openings than would be desirable for a pumping, monitoring, or production well. Otherwise, all wells are constructed in the same general manner, by boring a hole, inserting into the borehole a string of solid pipe (casing), on the bottom of which are openings (perforations, slots, or screen) that allow water from a specific subsurface zone into the well (Fig. 1). Porous-media filter pack, typically sand, is added to the annulus of the borehole and the screen, facilitating hydraulic connection between the aquifer and the observation well while minimizing the impact of the well on the aquifer. Above the filter pack, an impermeable material (typically bentonite, other clays, and concrete) is added for two reasons: to seal the casing to the rock material through which the well was drilled, and more importantly, to prevent water from filtering vertically up or down the borehole outside the casing. The casing is covered with a vented well cap, which keeps potential contaminants out of the well while allowing the air above the water in the well to maintain equilibrium with the atmosphere.[4,5] Inside a well-constructed observation well, the water level is free to fluctuate in response to natural and human-induced stresses on the aquifer system.

INFORMATION PROVIDED

Observation wells allow scientists to gain knowledge of the energy and mass of water beneath the surface of the earth, the degree of void interconnection within the underlying rocks, and rates and directions of flow.[6] Knowledge of the energy and mass contained in a groundwater system is critical to understanding and managing that system as a resource. Hydraulic head is a measure of the energy available to move water in the subsurface and, when coupled with saturated thickness and other aquifer characteristics, the mass of water present may be determined. A water level measured in an observation well under static, non-pumping conditions is a measure of hydraulic head in the aquifer at the depth of the open or screened interval.[3] Hydraulic head is the height at which a column of water stands above a reference elevation, most commonly sea level (Fig. 1). Water moves from points of high head to points of low head. The difference in hydraulic head divided by the distance between two observation wells in which the heads are measured is the hydraulic gradient, and hydraulic gradient is a

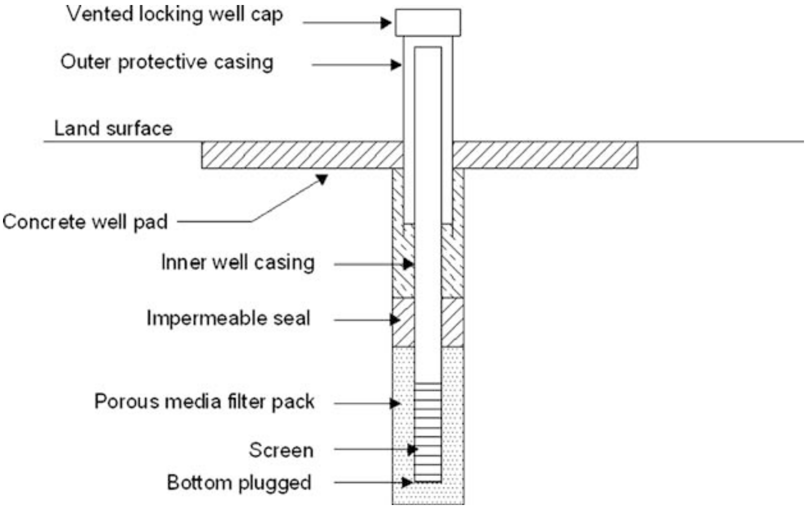

Fig. 1 Typical observation well design.

controlling factor for calculating the rate at which water moves in the subsurface. Water-level measurements made in two or more observation wells at the same time can define local hydraulic gradients. Water-level measurements made in three or more wells at the same time can define water movement direction and gradient. Water-level measurements made at different times in the same observation well can define temporal trends in water level in response to short- or long-term stresses such as pumping, changing land-use, or natural variations in climate.

Observation wells are a critical component of aquifer testing.[1,2,4,7–9] By relating the water-level response of the aquifer in the observation well to known stresses at differing distances, it is possible to compute hydraulic characteristics of the aquifer. These hydraulic characteristics, the interconnectivity of openings or "hydraulic conductivity," the amount of water stored or "storativity," and the amount of water that may leak vertically or "leakance," allows us to quantitatively test our understanding of how the system works. This understanding allows us to evaluate suitability of the aquifer for potential uses, especially with respect to computing how much water the aquifer will yield. This computation requires knowledge of the distance between the pumped well and the observation well, measured radially as a length, *r*, and it allows reconstruction of the cone of depression. The cone of depression is a roughly conical area of decreasing water levels in an aquifer outward from the well from which water is being withdrawn (Fig. 2). The cone of depression results from pumping a specified discharge, *Q* from the aquifer, and is related to the "interconnectivity" of the openings of the aquifer, or in scientific terms, the hydraulic conductivity. During an aquifer test, water level is measured on a high-frequency periodic basis (late in the test measurements may be taken less frequently) using a steel or electrical tape or continuously using an automatic sensing device. *Q*, *r*, and *h*—hydraulic head or water level—are essential for computation of the storativity, *S*, a measure of the storage capacity of the aquifer and the ability of the aquifer to provide water. Depending on the hydrogeologic conditions of the flow system (confined and unconfined), the proper equation with the radius squared reflects the quantitative relation between pumping and the exact symmetry of the cone (Fig. 2). Without observation wells, such computations would not be possible.

Observations wells are also critical components of local- to regional-scale groundwater-level monitoring networks.[1–3,6,10,11] Subsurface hydrologic systems typically are heterogeneous and complex. Comprehensive understanding of water-level conditions for an aquifer are derived through development of an observation well network in which information is gathered from many observation wells distributed across an area; water levels for locations between observation wells may then be derived by interpolation. These data provide the basis for generating 3-D maps of the water table or potentiometric surfaces, and are an important tool for water-resources planning and management. Because water levels vary with time, water-level network observation wells may be measured continuously or more commonly, only occasionally. Periodic water-level measurements are made at scheduled intervals, typically by manual means such as by steel or electric tape. Continuous groundwater-level data are measured by an automatic sensing device such as a pressure transducer or a float; these data are recorded by data loggers or recorders and retrieved periodically. Recently, acute responses of aquifers to intensive groundwater use and frequent drought have created a need for more rapid management decisions and action, and thus more timely data from observation wells. In response to this need, data from observation

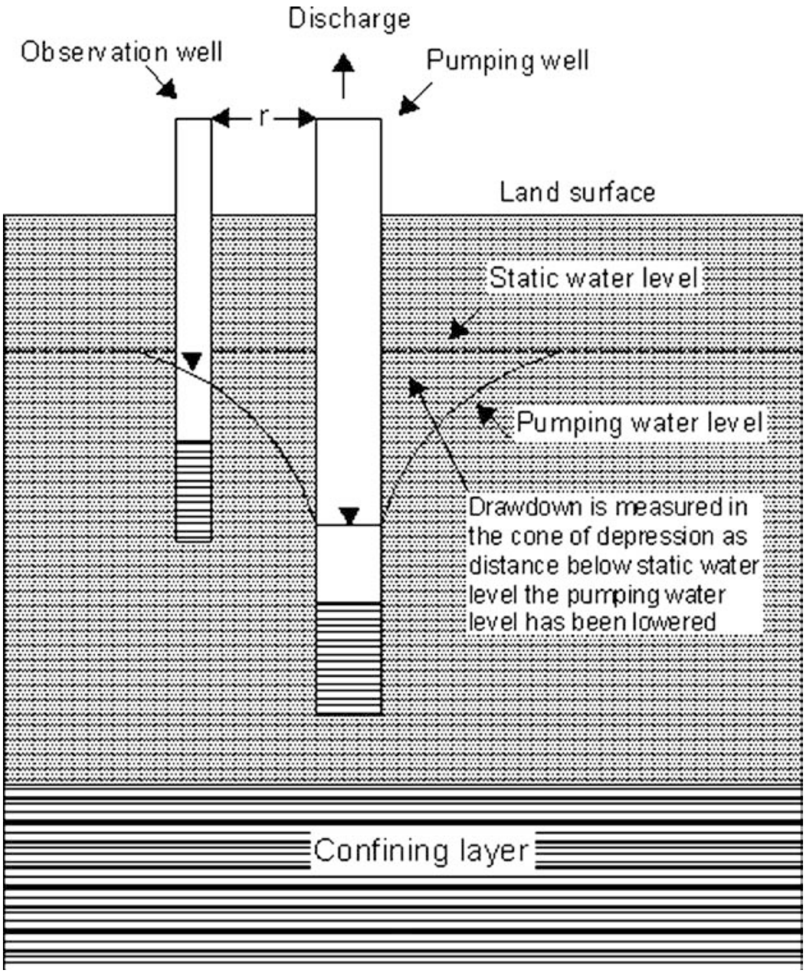

Fig. 2 Drawdown and cone of depression resulting from pumping groundwater. The observation well at radial distance *r* from the pumping well allows computation of the shape and dimensions of the cone, as well as important hydraulic characteristics of the aquifer.

wells are increasingly continuously measured at the well, transmitted via telemetric equipment (typically satellite or land-line), and processed at a central location to be made available on a real-time basis over the Internet.[11]

On-Farm Irrigation Flow Measurement

Lawrence J. Schwankl
Department of Land, Air and Water Resources (LAWR), University of California–Davis, Davis, California, U.S.A.

INTRODUCTION

Measurement of on-farm irrigation water plays a key role in irrigation water management. Efficient irrigation requires knowledge of both the crop water demand and the applied irrigation water. Measurement of the applied irrigation water at the farm level should, therefore, be done routinely as a component of good irrigation water management.

On-farm water measurements can be conveniently discussed as measurement techniques under pipeline flow conditions and under open-channel flow conditions. The following sections describe practical, on-farm, flow measurement techniques to measure flow in pipelines and open-channel situations.

PIPELINE FLOW MEASUREMENT

Pipeline flow conditions most common at the farm level are pumped groundwater and pressurized water deliveries from water providers such as irrigation districts. In some situations, water will be pumped by the grower from a canal or similar open-channel delivery source. The discharge pipe from the pump becomes a convenient location to measure flow rate.

Commercially available pipeline flow measurement devices most often require a full-pipe flow condition. They frequently measure flow velocity converted to a flow rate measurement using the pipe flow area.

Flowmeter manufacturers recommend installment flow conditions. This is usually specified as the length of straight pipe upstream and downstream of the flowmeter. Bends, elbows, tees, valves, etc., located too close to the flowmeter, disrupt the flow path, and lower the accuracy of the flow measurement.[1] The general recommendation is that there be at least an 8- to 10-pipe diameter length of straight pipe upstream of the meter, and at least 1-pipe diameter of straight pipe downstream of the meter. Always follow the manufacturer's recommendations.

The following are commonly used flow measurement devices for pipelines. There are numerous other pipeline flow measurement devices available.[2]

Propeller Flowmeters

The most common on-farm, pipeline flowmeter is the propeller meter (Fig. 1).[3] A propeller, mounted in the pipeline, rotates at a rate proportional to the water flow velocity. The propeller is connected to the readout device via a cable or shaft. A gear system, appropriate for the pipe size, translates the flow velocity into a flow measurement. The readout device provides a totalized flow, an instantaneous flow rate, or both. Manufacturers set the display units (e.g., gallons, cubic meters, ac-ft, etc.) based on user preference. The flowmeter units can be purchased frequently as flange-mounted or saddle-mounted devices. A propeller that occupies nearly the entire flow area is preferable to a smaller propeller, since it integrates the flow velocity across the pipe. Trash, such as weeds, in the water can entangle the propeller and adversely impact meter operation. A propeller meter should not be used under such water quality conditions.

Insertion Flowmeters

Insertion meters are devices mounted at a point on the inside wall of the pipeline. The measurement device is usually a small rotor, turbine, or an electromagnetic flowmeter (discussed in greater detail later). The devices are often mounted to the pipe using a threaded insert. The insertion flowmeters are either calibrated by the manufacturer or field-calibrated by the user, using a flow velocity profiling technique.

Insertion meters have the advantage of allowing relatively easy installation and removal, so they can be used at multiple pipeline locations. They also have the advantage of being usable on large pipe installations where other flowmeters (e.g., a propeller meter, electromagnetic meters) would be more expensive.

A disadvantage of insertion meters is that since they measure flow velocity at a single point in the pipeline, they can be severely impacted by flow conditions (e.g., bends or valves), which disrupt the water flow path.

Electromagnetic Flowmeters

Electromagnetic flowmeters (magmeters)[3] induce and measure a voltage in the water flowing through the

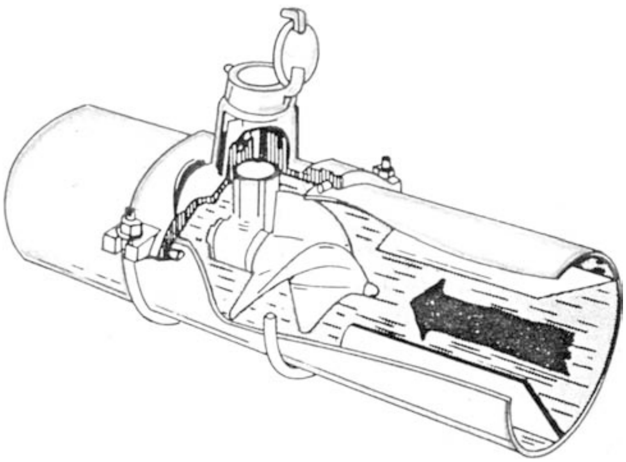

Fig. 1 Schematic of a propeller meter.

meter. The magnitude of the induced voltage is proportional to the water velocity. Most commonly, the meter is a tube (tube magmeter) through which the water flows. The tube magmeter contains magnetic coils to induce a voltage and electrodes to measure voltage, and electronics in the unit translate the voltage measurement to a flow reading. There are also electromagnetic meters that mount to a point on the inside pipe wall. These are insertion meters and can be moved to various pipeline measurement locations.

Electromagnetic meters are very accurate and the tube magmeters have no obstructions within the pipe to cause a pressure drop or become entangled by trash in the water. Electromagnetic flowmeter installations do not require as long a section of straight pipe upstream and downstream of the meter (see manufacturer's recommendations) when compared with propeller meters. Magmeters require an external power source, ranging from 240 V to battery-power, depending on the model and manufacturer. A disadvantage of electromagnetic meters has been their cost, substantially more than a similarly sized propeller meter, but the cost of some units has dropped significantly recently.

Acoustic Flowmeters

This group of flowmeters uses acoustic signals to measure flow.[3] Transit-time (ultrasonic) meters measure the alteration, caused by the flow velocity, in the transit time of an acoustic signal sent across the pipeline. Sensors are mounted to the outside of the pipeline, so the units are portable. Transit-time flowmeters, while accurate, are not widely used in on-farm applications due primarily to the cost.

Doppler flowmeters measure the velocity of particles in the water. The unit transmits known frequency acoustic signals and the returning signal's frequency is also measured. A change in the frequency is a function of the velocity of particles in the water reflecting the signal. The Doppler meter will not be accurate when used with very high quality water, but it can be used on many groundwater and surface water sources.

The major advantage of a Doppler meter is its portability. The sensor(s) mounts easily and quickly to the outside of the pipe and can, therefore, be used on even large diameter pipes. Flow in metal and plastic, but not concrete, pipe can be measured with a Doppler flowmeter. An external power source is required. Doppler flowmeters are more expensive than a propeller meter.

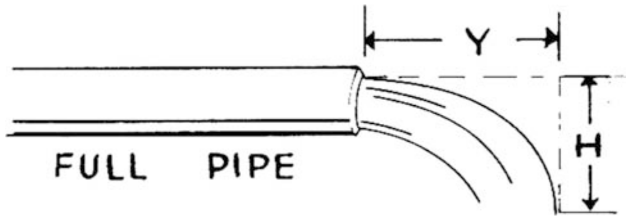

Fig. 2 Trajectory flow measurement method for a horizontal pipe.

Trajectory Methods

A low technology, but less accurate, method of estimating pipe flow rate is to measure the trajectory of the jet from the discharge end of a horizontal or vertical pipe. For a vertical pipe, the height of the jet above the end of the pipe is measured. For a horizontal pipe, the vertical and horizontal distances from the top of the pipe to the jet's upper surface are measured (Fig. 2). Tables are available to convert the distance measurements into a flow rate estimate.[3]

It is difficult to accurately determine the jet trajectory measurements. The flow trajectory measurement method is, therefore, only accurate as an estimate, but when no other flow measurement methods are available, it can provide useful information.

OPEN-CHANNEL FLOW MEASUREMENT

On-farm flow measurement in open ditches and channels is more difficult, and often less accurate, than flow measurement in pipelines. Weirs and flumes can be installed in permanent ditches and channels, but flow measurement in temporary ditches is more problematic. Temporary ditch flow measurement options include using float-velocity or current meter measurements.

The following are flow measurement options for use in on-farm open ditch and channel applications. Other flow measurement methods are also available.[3]

Float-Velocity Measurements

Measurement of channel flow rate using the float-velocity method[3] requires measuring both the velocity of an object, such as a stick or tennis ball, floating in the channel and the cross-sectional area of the ditch or channel. Since the floating object's velocity is not the same as the channel velocity, correction factors[3] are used to determine an average channel flow velocity.

Determining the velocity of the floating object is easily done, but determining the ditch cross-sectional area may be time-consuming. The resulting channel flow rate should be considered an estimate rather than an accurate measurement.

Current Meter Measurements

Current meters[2] can be used to determine the flow velocity at selected points in a channel. The velocity measurements, combined with cross-sectional area measurements, provide the channel discharge rate. The current meter is usually of one of the three types: (i) a mechanical meter with an anemometer or propeller device that rotates proportionally to the water flow velocity; (ii) a Doppler meter (see section on Acoustic Meters for pipelines); or (iii) an electromagnetic flowmeter. The current meter flow measurement is more accurate than the float-velocity method, but it is time-consuming.

Weirs

A weir[3–6] is a notch of particular shape through which water flows (Fig. 3). Generally, the notch shape is rectangular, trapezoidal, or triangular. A depth measurement a short distance upstream of the weir is recorded and a weir calibration equation translates the depth measurement to a flow rate.

A disadvantage of weir use is that sediment and trash will gather on the weir's upstream face. Weirs can also be difficult to install in temporary ditches or channels. For these reasons, they are not widely used for on-farm flow measurements.

Fig. 3 Trapezoidal weir installed in an earthen channel.

Fig. 4 Flume installed in a small concrete channel.

Flumes

A flume (Fig. 4)[2–8] is a device of particular cross-section, placed in the channel, constricting the channel sidewalls, raising the channel bottom, or both to force the water to accelerate. There are a large number of flume configurations commercially available, manufactured in metal or fiberglass, for installation in a channel. Installation ensuring that water does not erode and bypass the flume can be challenging in temporary ditch flow measurement applications.

The flume flow depth, upstream of the "throat" section, is measured and the flow rate is determined using the flume's calibration curve. The flume is often fitted with a stilling well to improve measurement accuracy. Continuous flume measurements can be recorded using a stage recorder or pressure transducer/data logger, installed on the stilling well.

Fig. 5 Ditch and siphon irrigation system irrigating an orchard.

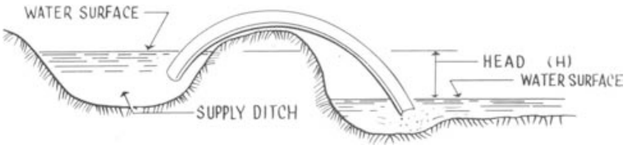

Fig. 6 Ditch to furrow siphon pipe irrigation showing the head difference.

Flumes are able to pass sediment and some trash, an advantage in on-farm flow measurement. They have applications in measuring both irrigation water applied to the field and tailwater runoff from fields. There are flumes available in a wide range of flow capacities, from very large to small enough to measure the flow rate in individual field furrows.

Siphon Flow Measurements

Ditch and siphon irrigation systems (Fig. 5) are common. The siphon discharge rate can be determined by measuring the difference in water surface elevation (head) of the supply ditch and the discharge point in the field (Fig. 6), and measuring the diameter of the siphon pipe. Siphon discharge rate tables are available to interpret the measurements.[3]

CONCLUSION

Methods and devices are available to measure irrigation flows under both pipeline and open-channel flow conditions. Pipeline flow measurement is often easier and more accurate than flow measurement in open ditches and channels, and pipelines usually provide a more permanent flow measurement installation location when compared with on-farm ditches. Selection of the flow measurement method is often based on the flow situation (e.g., pipeline vs. open channel), cost, and level of accuracy required.

Open-Channel Flow Rate Measurements

INTRODUCTION

Open-channel flow measurements require specialized training and equipment, and they are expensive to obtain. The majority of continuous streamflow records are not based on direct measurement of river discharge—they are derived from continuous measurements of river elevations or stage.[1] These stage data are converted into discharge by the use of a stage/discharge relation (rating) that is unique for each streamgaging location. Much of the effort and cost associated with streamgaging lies in establishing and updating this relation. Hydrologists visit streamgaging stations 6–10 times a year to make direct measurements of river depth, width, and velocity. From these data, they compute the open-channel flow rate. The range of measured flow rates and concurrent river stages are then used to build the rating curve for each site and to track changes to the rating curve.

Measurement of open-channel flow rate, also known as discharge, is usually determined by measuring two components—the cross-sectional area of the flow and the water velocity. Open-channel flow rate is expressed in the equation: $Q = A \times V$, where Q is discharge, A is cross-sectional area, and V is water velocity. The cross-sectional area is fairly simple to determine and is usually measured by taking soundings at multiple points in the cross section to determine the depth. Width is usually measured with a tape.

Water velocity can be measured using several types of instruments and techniques that include mechanical current meters, acoustic Doppler current profilers (ADCP), and low- and high-frequency radars. Several of these instruments and methods for measuring velocity and discharge are described below.

MECHANICAL METERS

Mechanical current meters are instruments designed to measure the velocity of moving water at a point in a river. A typical current meter has a horizontally mounted bucket wheel that is rotated by the moving water. The rate of rotation of the bucket wheel on the current meter is proportional to the speed of the moving water at that particular point (Fig. 1).[1] The current meter is held at a point for about a minute (to average turbulent flow fluctuations) while the revolutions of the cups on the meter are counted. Usually, two point velocities (or a single velocity) are measured vertically to define an average velocity for the water column. The discharges from the individual columns are then summed to obtain the total discharge.

ACOUSTIC DOPPLER CURRENT PROFILERS

An important development in open-channel flow measurement in the last ten years has been the deployment of ADCPs.[2] An ADCP uses acoustic energy—typically in the range 300–3,000 kHz—to measure water velocity throughout most of the water column by measuring the shift in the frequency of the acoustic signals reflected from materials suspended in and moving with the water. The ADCP determines water depth by measuring the time-of-travel of signals reflected from the channel bottom and measures boat velocity by using the Doppler shift of separate acoustic pulses reflected from the riverbed (Fig. 2). The channel width can then be computed using the instantaneous boat velocities and time between each measurement.

The ADCP has made three important contributions to direct open-channel flow measurements in streams. First, discharge measurements using a mechanical current meter require a minimum of 20 individual measurements across the river. These measurements typically take about two hours to complete, but during floods they can take as long as several hours to complete. The ADCP measurement can be done in a matter of minutes rather than hours.[3,4] Second, the ADCP allows measurements in environments where mechanical current meters are inappropriate or unreliable, such as in tidally affected flows, highly unsteady flows, and flood flows. Third, ADCPs are used to measure continuous profiles of water velocity (the vertical velocity distribution is no longer assumed but rather measured for all but the near bed and near-surface), thereby providing more accurate measurements of streamflow.

Fig. 1 Mechanical current meters—Price AA meter (left) and Pygmy meter (right).

ACOUSTIC FLOW MONITORS

Scientists have observed that sediment-laden flows, such as debris flows and turbulent flow in steep mountain channels, generate ground vibrations that can be detected by geophones located near the channels. Systems of geophones and instrumentation designed to measure these ground vibrations are called acoustic flow monitors (AFM).[5,6] Most debris flows cause the ground around the channel to vibrate with a peak frequency of 20–50 Hz, and water floods cause ground vibrations with peak frequencies greater than 100 Hz. Geophones located near channels can be programmed to detect vibrations in these frequency ranges and capture the full spectrum of vibrations. These ground vibrations caused by water and sediment flow can then be related to discharge.[7,8]

LOW- AND HIGH-FREQUENCY RADAR

U.S. Geological Survey (USGS) researchers are engaged in a series of proof-of-concept experiments to demonstrate the use of microwave and low-frequency radars to measure discharge directly—without having to place any instruments in the water. Surface velocity can be measured at various points across the river using the principal of Bragg scatter of a high-frequency (10 GHz) pulsed Doppler radar signal (Fig. 3). Cross-sectional area can be measured by suspending a conventional low-frequency (100 MHz), ground-penetrating radar (GPR) system over the water surface from a bridge or cableway and transiting it across the stream.[9] In the absence of a bridge or cableway, the GPR and radar systems have been mounted on helicopters and flown across the river, producing discharge values comparable to conventional discharge measurements.[10]

Fig. 2 Hydrologist measuring streamflow using an acoustic doppler current profiler.

SPACE-BASED PLATFORMS

Hydrologists have begun to consider the possibility of measuring and monitoring discharge from space.[11,12] Many important streams and rivers worldwide have no streamgages, and the ability to measure off-channel surface-water storage (wetlands, floodplains, lakes) and river discharge in virtually any location would provide new insight into the global hydrologic cycle and an understanding of the role of surface water in regulating the regional and global biogeochemical cycles. Such a space-based system might rely on radar altimetry for river stage and along-track interferometric synthetic aperture radar (SAR) measurements[13] of surface velocity along an entire reach of river. This requires some new thinking about the spatial utility of space-based remote sensing and the present in situ or cross-sectional basis for measuring river flow. Space-based technologies are unproven as tools for measuring discharge from great distances, but scientists are beginning to think about how to do it with support from the National Aeronautics and Space Administration (NASA).[14] Space-based instruments hold the promise to measure the elevations and perhaps even flow rates of the world's largest rivers. But far smaller streams (e.g., draining less than 10,000 km^2) around the world (including in the United States) present measurement needs that will challenge the resolution-cost trade-off capability of space-based sensors.

Fig. 3 Pulsed Doppler radar on top of equipment shelter, and UHF radar antenna to left of shelter on bank of San Joaquin River, CA, are used for surface-velocity measurements. Cable across channel is used to suspend Ground Penetrating Radar (GPR) system over the water to measure channel cross section. Non-contact methods of streamgaging show substantial promise, but much remains to be learned.

Open-Channel Spillways

Sherry L. Britton
Gregory J. Hanson
Plant Science and Water Conservation Research Laboratory (PSWCRL), Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Stillwater, Oklahoma, U.S.A.

INTRODUCTION

Provision must be made in the design of almost every dam to permit the safe discharge of water downstream. The function of the spillway is to safely convey this discharge past the dam without unacceptable damage. The high velocities and large levels of energy involved in flow over spillways, particularly during major floods, make their design of considerable importance. The design and capacity of spillways play an important role in the layout and economics of every dam project. Spillways are selected for a specific dam and reservoir on the basis of discharge requirements, topography, geology, dam safety, and project economics.

TYPES OF SPILLWAYS

The classifications of spillways are primarily based on their most prominent feature and/or function. This may include the type of discharge carrier or some other type of component.[1,2] Spillways are classified as controlled or uncontrolled depending on whether they are gated or ungated. Designation as a principal spillway generally indicates constant or frequent flow with an auxiliary spillway used to pass the infrequent larger flood events. Most spillways can be broken into two main categories: open-channel spillways and conduit spillways. Open-channel spillways include: a) straight-drop or free overfall spillways; b) chute spillways; c) cascade spillways; d) side-channel spillways; and e) unlined or vegetation lined earthen spillways. Conduit spillways include: a) siphon spillways; b) drop shaft or morning-glory spillways; c) tunnel spillways; and d) culvert spillways. The focus of this article is on open-channel spillways.

Straight-Drop Spillways

The U.S. Bureau of Reclamation[2] defines a straight-drop spillway as one in which the flow drops freely from the crest into a plunge pool or stilling basin (Fig. 1). Straight-drop spillways are used on thin arch or deck overflow dams, dams with a crest that has a nearly vertical downstream face, and with low earthfill dams.[3]

Hydraulic concerns of the straight-drop spillway are with the control and dissipation of energy in the downstream plunge pool or stilling basin. A minimum depth of tailwater is required for effective dissipation of excess flow energy to prevent downstream scour. The tailwater level in the downstream channel should be at approximately the same level as the water surface in the stilling basin.

Chute Spillway

A spillway that conveys water from a reservoir over a spillway crest into a steep-sloped open channel is known as a chute spillway[4] (Fig. 2). A smooth chute spillway conducts the overflow to an outlet energy dissipation basin. Chute spillways can be well adapted to earth or rock-fill dams when topographic conditions permit.[4] They are generally located through the abutment adjacent to the dam. However, they can be located in a saddle away from the dam structure. Such a location is preferred for earth dams to prevent possible damage to the embankment. The chute may be of constant width but is usually narrowed for economy and then widened near the end to reduce unit discharge.

Cascade Spillway

The cascade or baffle chute spillway uses steps or other appurtenances to dissipate energy in the spillway channel and thereby, reduce energy dissipation requirements in the outlet basin (Fig. 3). The cascade-spillway has greater flow depths than chute spillways requiring higher sidewalls. Spray action may be a concern due to air entrainment, and abrasion of the steps and other appurtenances can be a serious problem. Cascade-spillway use has increased recently due to the increased use of roller compacted concrete (RCC).

A major concern for cascade spillways is to provide a smooth transition flow from the spillway crest to the first few steps. This transition is commonly attained using a smooth ogee crest. Transitions for flatter

Fig. 1 Straight-drop spillway.

sloped spillways, 2.5 H:1 V or less, can also be attained by an arrangement of smaller steps at the crest of the cascade chute.[5] The energy loss for a cascade spillway is strongly dependent on the slope length. The energy loss due to the steps depends primarily on the ratio of critical depth of flow to the step height and on the number of steps.

Side-Channel Spillway

As defined by the U.S. Army Corp of Engineers,[6] a conventional side-channel spillway consists of an overflow weir discharging into a narrow channel in which the direction of flow is approximately parallel to the weir crest (Fig. 4). This type of spillway is used in circumstances similar to those of the chute spillway. Due to its unique shape, a side-channel spillway can be sited on a narrow dam abutment.

Fig. 2 Chute spillway.

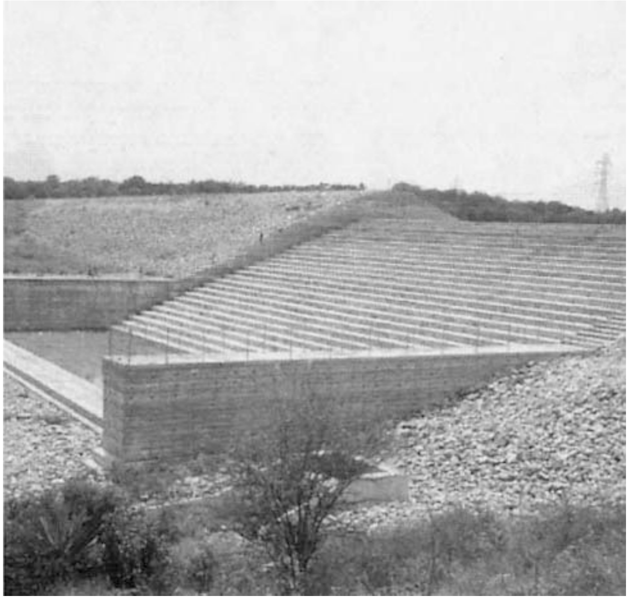

Fig. 3 Roller compacted concrete cascade spillway.

Earthen Spillway

Earthen spillways are typically excavated in native materials and vegetated with grasses adapted to the local area (Fig. 5). Earthen spillways are often designed as auxiliary spillways with the perspective that damage may occur during infrequent operation, but not to the

Fig. 4 Side-channel spillway.

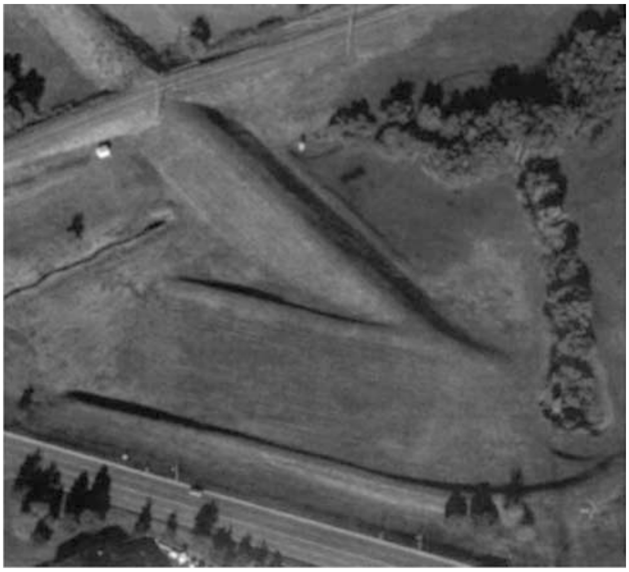

Fig. 5 Arial view of a vegetated-earthen spillway placed at dam abutment.

Fig. 6 Smooth flow over ogee spillway crest.

extent that it will lower the spillway crest or cause a catastrophic release of stored water. Often a saddle or low point on natural ground at the periphery of the reservoir will serve as the earthen spillway.

COMPONENTS OF SPILLWAYS

Spillways consist of three major components: entrance structure, conveyance channel, and outlet structure. An entrance structure is designed to control the discharge and admits reservoir water to the spillway. The conveyance channel carries the discharge from the inlet structure to the outlet structure. The outlet structure dissipates the energy of the high velocity flow from the conveyance channel and discharges it to the channel downstream.[1]

Entrance Structure

The design of the spillway entrance structure for small dams is not usually critical, and a variety of simple crest patterns are used. In the case of large dams, it is important that the water be guided smoothly over the crest of the structure with a minimum of turbulence (Fig. 6). Therefore, an ogee-crest design is often used. The ogee crest takes the form of the underside of the nappe of a sharp crested weir when the flow rate corresponds to the maximum design capacity of the spillway. This results in near-maximum discharge efficiency. Correct design of the spillway entrance will minimize cost while providing sufficient crest length to pass the design discharge. Also, it will result in acceptable energy heads and pressure levels on the spillway crest, and acceptable unit discharges for the conveyance channel and outlet structure.

Gates located at or near the crest are often used to control flow into the spillway. Types of gates may include flashboards, stop logs, lift gates, radial gates, rolling gates, and drum gates. A spillway using gates is often referred to as a controlled spillway. The use of gates allows for additional storage above the spillway crest and control of the timing and quantity of reservoir discharges. The disadvantages to gates are: they are expensive; they often require personnel at the structure for proper operation; and operational or structural failure may have catastrophic consequences.

The inlet structure has a significant effect on the spillway discharge. There are cases where there is a need for increased flow capacity with upstream head elevation restrictions. A labyrinth weir or box inlet weir may be used to increase the inlet capacity for a given range of reservoir water surface elevations. A labyrinth weir is folded in plan view, increasing the total weir length to 3–5 times the spillway width. The labyrinth weir capacity is typically twice the standard overflow crest of the same width for low head ranges.[7] The capacity of the box inlet weir is directly related to the perimeter of the overflow box that extends into the reservoir[8] (Fig. 7).

The discharge capacity of the standard ogee weir, labyrinth weir, and box weir, is given by the weir equation:

$$Q = \frac{2}{3}\left[C_{\mathrm{d}} L h \sqrt{2gh}\right]$$

Fig. 7 Chute spillway with notched box inlet.

in which Q is the discharge in cfs, C_d a dimensionless weir coefficient, L the length of weir in ft, g gravitational acceleration 32.2 ft sec^{-2}, and h the total head on the crest in ft (vertical distance from the crest of the spillway to the reservoir level). The coefficient C_d, varies with spillway type and head. A typical range of C_d for the ogee crest is from 0.55 to 0.75.

The typical entrance to earthen spillways as well as some other chute spillways consists of a forebay reach followed by a level crest prior to entering the conveyance channel. The discharge rating of these types of spillways is typically developed based on water surface profile calculation methods incorporating channel geometry and roughness conditions.

Conveyance Channel

With the exception of the straight-drop spillway that may be used for low dams, the water that passes the spillway inlet is carried to the downstream outlet structure by a conveyance channel. The material used to line the surface of the conveyance channel is dependent on frequency of use, erodibility of the natural materials, and overall spillway design. Principal spillway channels operate more frequently and are usually constructed of reinforced-concrete slabs 10–20 in. thick. Auxiliary spillways may also be lined to allow higher velocity flows and/or combination of the principal and auxiliary spillway functions into a single spillway. The high velocities and large levels of energy involved in flow over spillways may lead to problems with air entrainment, shock waves, cavitation, and abrasion. Abrasion may be a particular problem when entrained sediment is present.

Earthen spillways are unlined or vegetation-lined channels that are most often used as auxiliary spillways to pass infrequent flood flows. Damage may occur during operation, but it cannot be extensive enough to lower the spillway crest causing a catastrophic release of reservoir water (Fig. 8). The extent of damage that may occur in an unlined spillway is dependent on the duration and quantity of flow through the spillway, quality and maintenance of the vegetal cover, spillway geometry, and spillway geology.[9,10] Evaluation of expected erosion is the most difficult and critical problem encountered in the design of the earthen spillways. The designer must not only decide whether the channel materials will be eroded but also make reasonable estimates pertaining to the rate at which erosion will progress. Extensive exploration, testing of encountered materials, and geological profiles to a depth in excess of any anticipated scour are required to assist in the erosion estimates. Study of the history of erosion in the project area and research of erosion experiences at projects with similar facilities should be undertaken as part of the evaluation of expected erosion. The NRCS computer program ''Sites,'' uses a three-phase erosion model to predict erosion of vegetated-earthen spillways.[11]

Outlet Structure

Water returned to the river below the dam must be kept from scouring or eroding the riverbed or dam foundation. Plunge pools or stilling basins are therefore required to reduce the velocity of the water before returning it to the downstream channel. These energy dissipation structures may be an integral part of the

Fig. 8 Erosion damage of an auxiliary spillway after experiencing a flow.

Fig. 9 Energy dissipation basin.

dam or spillway. Two common structures used in dissipating the high energy of falling water are the apron-basin and the flip bucket. In the apron-basin type of structure, the high-velocity shallow flow coming from the dam is converted into a low-velocity deep flow by causing a hydraulic jump to occur on a horizontal or sloping concrete apron (Fig. 9). With a flip bucket, the toe of the dam is shaped to deflect the high-velocity flow upward away from the riverbed. The resulting ''flip'' breaks up the jet and dissipates the energy of the water. Additional energy is dissipated in a plunge pool downstream of the bucket.

FACTORS WHICH AFFECT SPILLWAY CHOICE AND DESIGN

Several factors should be considered when choosing a spillway. Singh and Varshney[1] list several factors such as safety considerations, hydrologic and site conditions, type of dam, purpose of dam and operating conditions, conditions downstream of the dam, and nature and amount of solid material brought by the river. Safety is the most important factor to consider for a spillway because improper design of spillways or insufficient spillway capacity may result in dam failures. Spillway design and capacity depend on inflow discharge (frequency and shape of hydrograph), the elevation of the spillway crest, storage of the reservoir at various levels, and the geological site conditions, which include slope stability, steepness of the terrain, or possibilities of scour downstream. The type, purpose, and conditions, downstream of the dam also influence the spillway design and capacity. Rising floodwaters downstream of the dam and erodible material can have major consequences if not properly considered. In addition, trees, floating debris, and suspended sediment can influence the decision in selecting a spillway.[1]

The required capacity (maximum outflow rate through the spillway) depends on the spillway design flow (inflow hydrograph to the reservoir), the normal discharge capacity of other outlet works, and the available storage. The selection of the spillway design flow is related to the degree of flood protection required that, in turn, depends on the type of dam, its location, and the consequences of a dam failure. A high dam storing a large volume of water located upstream of an inhabited area requires a much higher degree of protection from overtopping than a low dam storing a small quantity of water whose downstream reach is uninhabited. The probable maximum flood is commonly used for design of the former, while a smaller flood is suitable for the latter.

INTRODUCTION

Many aquatic organisms depend on dissolved oxygen (DO) for basic life functions. Dissolved oxygen is one of the factors that affect population diversity in surface waters. Aerobic bacteria, fungi, protozoa, and algae all carry out aerobic respiration and require DO to survive. Trout and other coldwater fish species require more DO than warm-water fish species. A DO concentration of $5\,mg\,L^{-1}$ is generally recommended for warm-water fish, and $6\,mg\,L^{-1}$ for coldwater fish.[1] Lower concentrations may be tolerated for short periods but result in stress on the fish.

The solubility of oxygen in water varies with water temperature and atmospheric pressure. Dissolved oxygen concentrations range from $14.6\,mg\,L^{-1}$ at $0°C$ to about $7\,mg\,L^{-1}$ at $35°C$.[2] Oxygen is less soluble in saline water than in pure water. Polluted waters usually have lower DO concentrations than pure water.

OVERVIEW

In ponds and lakes, photosynthetic activity from aquatic plants such as algae produce DO. At night, these same plants compete with aquatic organisms for DO. Biodegradation of organic matter can decrease DO concentrations. Organic wastes are subject to further bacterial decomposition once they enter the environment. If domestic or agricultural organic wastes enter water that contains DO, the aerobic bacteria will utilize the organic material as a food and energy source. During this process, the bacteria respire DO and produce carbon dioxide. If enough DO is removed, then concentrations can fall below values required for survival of aquatic organisms. Fish kills are sometimes the result of spills or unauthorized releases of organic-laden waste to surface waters.[3] During warm conditions, fish kills can occur immediately after the release. When an organic waste release occurs during cold conditions, DO concentrations may not be affected for several months until water temperatures increase, making it difficult to assess the exact cause and nature of the fish kill.

Fish kills are not always the direct result of organic releases. In some instances, the enrichment of waters by nutrients, a term called eutrophication, can lead to unwanted algal growth.[4] In many water bodies, phosphorus is the limiting nutrient for algal growth. A rapid release of dissolved phosphorus to surface waters can trigger algae blooms. Growing algae produces DO through photosynthesis, however, whenever the algae dies it is subject to decomposition that could lead to the decrease in DO.

DISSOLVED OXYGEN MEASUREMENT

Dissolved oxygen was originally measured using the Winkler (iodometric) method. The original Winkler method was based on the fact that oxygen oxidizes Mn^{2+} under alkaline conditions. The higher valence manganese then oxidizes I^- to free I_2 under acidic conditions. The amount of free iodine released is proportional to the DO concentration. Because nitrite ions interfere with the DO determination, several modifications to the original Winkler method have been developed. Nitrite interference is overcome by using sodium azide (NaN_3). Another modification includes using permanganate to oxidize any reducing agents present.

In recent years, electronic DO membrane electrodes have become more common. Membrane electrodes can be either the polarographic or galvanic type.[5] Both types utilize a sensing element composed of two metal electrodes. A voltage is passed across the electrodes, and the measured current is converted to a DO concentration. Membrane electrodes are especially useful in field applications. When electrodes are attached to a long cord, DO can be measured at various depths in ponds and rivers. Dissolved oxygen electrodes are usually calibrated against water samples that have been analyzed by using the Winkler method. Because DO electrodes are sensitive to temperature, an accurate temperature measurement must be made at the same time so that a correction can be applied. There are many brands of DO electrodes available commercially.

BIOCHEMICAL OXYGEN DEMAND

Organic wastes can enter surface water bodies from a variety of sources, including raw sewage spills, permitted publicly owned treatment works (POTWs), animal feeding operations, runoff from land application areas, or improperly designed septic tanks.[6] Environmental regulations exist to protect surface water bodies from unwarranted discharges that could threaten aquatic life or human health. Environmental permits for discharge of wastewater or stormwater runoff to surface water bodies often include such items as temperature and biochemical oxygen demand (BOD). BOD is an empirical test in which standardized laboratory procedures are used to measure the biologically available organic matter in a water sample. It is based on the amount of oxygen that would be consumed if an abundant aerobic bacterial population were present. BOD is defined as "the quantity of oxygen used by bacteria while stabilizing decomposable organic matter under aerobic conditions."[2,7] The BOD test is widely used to determine the concentration of domestic and industrial wastes, and is helpful in evaluating the BOD removal efficiency of wastewater treatment plants. Miner, Humenik, and Overcash[3] presented the conceptual reaction as follows:

$$BOD + O_2 \rightarrow CO_2 + H_2O + \text{Energy} \quad (1)$$

The standard BOD test is based on a 5-day incubation period, and is referred to as BOD_5. As a rule-of-thumb, BOD_5 is about 70–80% of the ultimate BOD (BOD_U).[2] Another reason for limiting the BOD test to 5 day is to avoid interferences from oxidation of ammonia to nitrite and nitrate, a process called nitrification. Nitrifying bacteria typically do not consume an appreciable amount of DO until 6–10 day after initiating the BOD test[8] (Fig. 1).

With samples that have a BOD less than $7\,mg\,L^{-1}$, the BOD is measured directly on the water sample.[2] For higher BODs, the wastewater sample is diluted because the BOD concentration exceeds the DO available. The dilution water reduces the toxicity of the wastewater and provides the DO needed for aerobic decomposition. Nutrients such as nitrogen, phosphorus, and trace metals are added to the dilution water, and it is saturated with oxygen before use. A buffer is added to maintain the pH in a range suitable for bacterial growth. The solution is "seeded" with the necessary microorganisms.[9] The seed source often consists of effluent from biological waste treatment plants.[5] The sample is incubated at a temperature of 20°C, and DO is measured initially and after 5 day. The 5-day BOD is determined by subtracting the two values. The DO is typically measured using either the Winkler method or a membrane electrode. Because the BOD concentration is rarely known before the test, several different dilutions are performed to cover the range of possible BOD values.

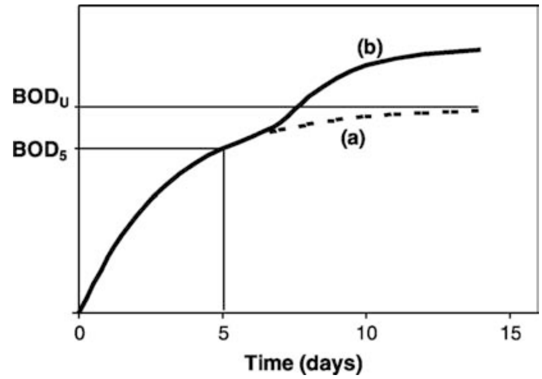

Fig. 1 The BOD curve showing (a) the normal curve resulting from oxidation of organic matter and (b) the curve if combined with nitrification of ammonia.

CHEMICAL OXYGEN DEMAND

The chemical oxygen demand (COD) test is used similarly to the BOD test to measure the concentration of a wastewater sample. In some cases, the COD data can be correlated with the BOD data, although this takes some experience to establish reliable correlation factors, which can range from 0.4 to 0.8. The COD test is used primarily to evaluate industrial waste, whereas the BOD test is used for biological waste.[2] Advantages of the COD test are that it can be performed in about 3 hr, as compared to 5 day for the BOD test, and it can be utilized in wastewater with high toxicity, where a BOD test cannot.

The COD test utilizes a strong oxidizing agent (usually potassium dichromate) under heated acidic (usually sulfuric) conditions in the presence of chromium and silver salts to convert organic matter to water and carbon dioxide. Unlike the BOD test, the COD test oxidizes all organic matter, including biologically resistant organic matter such as lignin. As a result, COD values are greater than BOD values. The COD test can be very accurate and precise for those samples with a COD of $50\,mg\,L^{-1}$ or greater.[2]

Inorganic ions such as chloride, bromide, and iodide can cause erroneously high COD values. Mercuric sulfate can be added to the sample to remove the chloride interference. A major disadvantage of the COD test is that disposal of hazardous wastes such as mercury,

Table 1 Typical BOD_5 and COD concentrations found in municipal, industrial, and agricultural waste products and wastewater

Source	Units	BOD_5	COD
Raw municipal wastewater	$mg\,L^{-1}$	200	450
Domestic sewage	$mg\,L^{-1}$	100–300	250–1,000
Beef feedlot runoff pond effluent	$mg\,L^{-1}$	—	1,400
Beef feedlot runoff pond sludge	$mg\,L^{-1}$	—	77,500
Dairy lagoon effluent	$mg\,L^{-1}$	350	1,500
Dairy lagoon sludge	$mg\,L^{-1}$	—	52,000
Swine lagoon effluent	$mg\,L^{-1}$	400	1,200
Swine lagoon sludge	$mg\,L^{-1}$	—	64,600
Milking center wastewater	$mg\,L^{-1}$	1,000	5,000
Cheese production wastewater	$mg\,L^{-1}$	3,200	5,600
Candy production effluent	$mg\,L^{-1}$	1,600	3,000
Synthetic textile effluent	$mg\,L^{-1}$	1,500	3,300
Slaughterhouse processing effluent	kg/1000 kg raw product	5.8–8.5	—
Vegetable processing effluent	kg/1000 kg raw product	7–55	14–96
Papermill effluent	kg/1000 kg pulp	60	—
Dairy cow manure (fresh, as excreted)	kg/d/640 kg animal	1.0	5.7
Beef cattle manure (fresh, as excreted)	kg/d/450 kg animal	0.6	2.5
Swine manure (fresh, as excreted)	kg/d/100 kg animal	0.2	0.6

Source: From Refs.[8,10].

hexavalent chromium, sulfuric acid, and silver can be a problem.[5]

Typical BOD and COD concentrations vary greatly among waste types. Waste streams from animal feeding operations have BOD concentrations greater than $5000\,mg\,L^{-1}$ compared to $200\,mg\,L^{-1}$ for typical municipal wastewater.[3] Typical BOD and COD concentrations for a variety of municipal, industrial, and agricultural waste sources are presented in Table 1. Chemical oxygen demand concentrations are typically about 2–5 times greater than BOD concentrations for the same waste product.

CONCLUSION

Dissolved oxygen is one of the most important water quality parameters for aquatic life. Because many municipal, industrial, and agricultural sources discharge wastewater to surface water bodies containing aquatic life, environmental regulations have been promulgated to limit the amount of oxygen-consuming organic waste products that can be discharged to a stream or lake. Methods for measuring the strength and concentration of these oxygen consuming waste products include the 5-day biochemical oxygen demand (BOD_5) and COD tests.

Pathogens: General Characteristics

Jeanette Thurston-Enriquez
Soil and Water Cons Research Unit, U.S. Department of Agriculture (USDA), Lincoln, Nebraska, U.S.A.

INTRODUCTION

The transmission of pathogens by water is a highly effective way of spreading infectious disease among large numbers of people. As early as 6000 years ago, the association of contaminated water and illness was documented in Sanskrit and Greek writings that described treatments for "impure water."[1] Today, waterborne disease outbreaks continue to be responsible for high morbidity and mortality worldwide (Table 1).[2,3]

CLASSES OF PATHOGENS ASSOCIATED WITH WATER

Due to the introduction of chlorination and filtration of drinking water supplies in the early 1900s, the waterborne outbreak paradigm in the United States shifted from bacteria, as the primary agents causing waterborne disease, to protozoan parasites and enteric viruses. Currently, these groups of micro-organisms and others cause water-related disease worldwide. Table 2 differentiates between the different types of micro-organisms: bacteria, viruses, protozoan parasites, blue–green algae, and helminthes. For each microbial group, examples of water-related pathogens and associated diseases are also listed.

CATEGORIES OF WATER-ASSOCIATED DISEASES

There are four disease categories related to water transmission of microbial pathogens: 1) waterborne; 2) water-washed; 3) water-based; and 4) water-related diseases.[4] Infectious agents that are excreted in the feces and transmitted by ingestion of contaminated water cause waterborne diseases. Classic examples of waterborne pathogens include *Cryptosporidium parvum* (cryptosporidiosis), poliovirus (polio), and *Vibrio cholera* (cholera). Water-washed infections occur in areas where personal hygiene and water availability is poor. Person-to-person transmission and contact with unclean household items effectively transmit water-washed pathogens such as *Trachoma* (eye infections) and *Shigella* (dysentery). Water-based diseases arise from infection with pathogens that spend all or a portion of their life in water. Examples of these include *Dracunculus medinesis* (dracontaiasis) and *Schistosoma* species (schistosomiasis). Unlike the other categories, water-related diseases are carried by water insects, as in the case of malaria, which is carried by mosquitoes.[2,4]

ENTERIC PATHOGENS

Micro-organisms that are excreted in the feces and infect the gastrointestinal tract are called enteric pathogens. Enteric pathogens cause a wide range of illness from asymptomatic (no clinical signs but microbe can grow and may be transmitted to susceptible individuals) to mild intestinal symptoms (diarrhea, fever, malaise, etc.) to paralysis. Enteric pathogens are probably the most important causes of water-washed and waterborne infections worldwide. Approximately 31%, 15%, and 10% of reported waterborne outbreaks are caused by enteric protozoan (*Giardia* and *Cryptosporidium*), viral, and bacterial agents, respectively.[5] However, the etiological agents responsible for approximately half of all reported outbreaks go unrecognized. The unidentified agents causing these outbreaks are thought to be enteric viruses due to epidemiological and clinical similarities.[6]

PATHOGEN CHARACTERISTICS THAT ENHANCE PATHOGEN SURVIVAL AND TRANSMISSION

Traits that may enhance pathogen survival and transmission in the environment may include numbers and location of pathogen reservoirs, concentration of pathogens excreted and mode of excretion, infectious dose, severity of illness, and individual pathogen traits. Because some pathogens, termed zoonotic, are able to infect humans and animals (domestic and wildlife) they can be distributed throughout the environment, contaminating land, air, and water (Table 3). Excretion of pathogens in the feces is another important characteristic since they can be released in very high

Table 1 Worldwide waterborne outbreak(s)

Country (year(s) of outbreak)	Disease (disease agent)	Number of cases (number of fatalities)
United States (1993)	Cryptosporidiosis (*Cryptosporidium parvum*)	>400,000 (>50)
England (1971–1980)	Giardiasis (*Giardia lamblia*)	60 (0)
Czech Soviet Republic (1979–1982)	Shigellosis (*Shigella*)	287 (not indicated)

Source: From Ref.[3].

concentrations. Table 4 lists the concentrations of enteric pathogens shed in feces.[7] Depending on the infectious dose, or the number of micro-organisms required to produce disease, numbers ranging from over 10^6 down to 1 infectious agent must be ingested. For example, ingestion of as little as 1 viral particle can induce illness in a susceptible individual compared to some bacterial pathogens that require ingestion of hundreds to thousands of organisms. Disease produced by enteric pathogens is generally mild, self-limiting, and in some cases, the infected individual may be shedding the pathogen without any symptoms (asymptomatic shedding). Fecally transmitted pathogens that produce mild symptoms, or are asymptomatic, enable the infected individual to effectively contaminate the environment, unlike other diseases that render the infected individual immobile. Genetically acquired microbial traits enable some microbial groups to be more resistant to heat, pH, or chemical (chlorine, ozone, etc.) and physical (ultraviolet light, gamma irradiation) disinfectants than others. Because of these differences, some pathogens survive longer in the environment than others. In general, enteric viruses and protozoan parasites survive longer in water subjected to environmental conditions and disinfected water than enteric bacteria.

ENVIRONMENTAL FACTORS AFFECTING PATHOGEN SURVIVAL

Unlike pathogens that need to be transmitted by direct or close contact to infected individuals (i.e., gonorrhea, human immunodeficiency virus, and herpes), enteric pathogens are hardy enough to survive conditions outside the body for long periods. Their survival depends on environmental conditions such as temperature, cell aggregation, sunlight exposure, pH, and presence of predatory organisms, inorganic or organic matter, and chemicals that may affect their survival. As temperature increases, the inactivation or dying-off of enteric pathogens increases. For example, *Giardia lamblia* cysts remain viable in water for 77 days and 4 days at 8°C and 37°C, respectively.[8] Since enteric pathogens infect the gastrointestinal tract they can withstand fairly low pH values, although high pH conditions may inactivate enteric viruses. Aggregation or adsorption to organic or inorganic matter may serve to protect or shield enteric pathogens from the effects of sunlight, chemical treatments, or predatory organisms. Also, macro invertebrates (nematodes and amphipods) and protozoa have been shown to ingest pathogens and protect them from the effects of water treatment.[9] Sunlight may decrease pathogen survival due to the effects of ultraviolet light damage. Ultraviolet light produces nucleic acid damage that can be repaired by some micro-organisms (bacteria) but not others (viruses).

PATHOGEN WATER ROUTES OF TRANSMISSION

Human and animal reservoirs of enteric disease can contaminate land, water, or air through several routes (Fig. 1). Fecal waste is deposited onto land in several ways: direct deposition by domestic animals and wildlife, piled for storage, piled (composting) or spread (land applied human biosolids) for treatment, and by agricultural practices (spraying, spreading, or injection of waste into/onto soil). Rain or other events that produce runoff from fecally contaminated sites increases the potential for transport of pathogens to surface waters that may be used for drinking, shellfish harvesting, irrigation, or recreational purposes. In addition, pathogens may be transported through soil and contaminate groundwater. Airborne transmission of pathogens via water droplets generated by human and animal activities or wind is another way by which pathogens in water may be transmitted. These water droplets may be transported naturally (surf droplets), by agricultural activities (spray irrigation), and other human practices (showers, cooling towers) through air and are capable of transmitting disease either through ingestion, inhalation, or contact.[2] Although considered foodborne, pathogens present in water used for harvesting vegetable crops or shellfish may increase the risk of illness through consumption of these products.

WATER TREATMENT

There are many treatment practices for the reduction of pathogens in water and waste. These include

Table 2 Types and characteristics of enteric and other pathogenic micro-organisms that can be transmitted by water

Types of micro-organisms associated with water	Microbial characteristics	Pathogens associated with water disease	Disease or complication
Bacteria	Prokaryotic, single-celled organisms Cell wall and membrane surrounding cellular components Reproduce via binary fission Susceptible to disinfectants and environmental conditions (compared to other water pathogens) Spores and dormant cells formed by some bacteria enable them to survive hash conditions (example *Clostridium*)	*Salmonella*	Diarrhea, typhoid
		Campylobacter	Bloody diarrhea
		Enterohemorrhagic Escherichia coli	Bloody diarrhea, hemolytic uremic syndrome
		Enteroinvasive E. coli	Dysentery
		Enteropathogenic E. coli	Diarrhea
		Enterotoxigenic E. coli	Diarrhea
	Size range 0.1–10 μm	*Shigella*	Diarrhea
Viruses	Obligate parasites (require a host for replication)	*Hepatitis A and E*	Liver disease
	Composed of protein outer capsid surrounding nucleic acid core	Enteroviruses (polioviruses, coxsackieviruses, echoviruses, and enterovirus types 68–71)	Febrile and respiratory illness, meningitis, diarrhea, encephalitis, and others
	Do not carry out metabolic functions	Rotaviruses (group A and B)	Diarrhea
	Nucleic acid may be double or single stranded	Human caliciviruses	Vomiting, diarrhea
	Long-term environmental survival due to simple structure and no requirement for nutrients	Astrovirus	Diarrhea
	Size range 0.01–0.1 μm	Adenovirus	Diarrhea, eye and respiratory infections
Protozoa	Single-celled eukaryotic organisms	*Giardia lamblia*	Diarrhea
	Complex structure	*Cryptosporidium parvum*	Diarrhea
	Sexual or asexual replication	*Cyclospora cayetanensis*	Diarrhea
	Some produce environmentally resistant stages (example *Cryptosporidium* oocysts and *Giardia* cysts)	*Microsporidia*	Diarrhea, kidney and respiratory infections
	Size range 1–100 μm	*Toxoplasma gondii*	Flu-like (adults), encephalitis, and ocular disease (children)
		Entamoeba histolytica	Amoebic dysentery
		Naegleria fowleri	Meningoencephalitits
Helminths	Multicellular, worms	*Ascaris lumbricoides*	Ascariasis
	Complex life-cycles (one or more hosts required)	*Necator americanus*	Hookworm
	Eggs are environmentally resistant	*Trichuris trichiura*	Whipworm
	Size range 1–10^9 μm	*Taenia saginata*	Beef tapeworm
		Schistosoma mansoni	Schistosomiasis
Cyanobacteria (blue–green algae)	Procaryotic single-celled organisms	*Anabaena*	All can produce toxins that can cause liver damage, neural damage, gastrointestinal symptoms
	Replicate by binary fission or fragmentation	*Nodularia*	
	Some species produce toxins	*Microcystsis*	
	Some are resistant to extreme environmental conditions	*Nostoc*	
	Size range 1–100 μm	*Alexandrium*	Possible carcinogens

Table 3 Examples of known and potential zoonotic enteric pathogens and their hosts

Zoonotic pathogens	Pathogen hosts
Bacteria	
E. coli	Humans, domestic and wild animals
Salmonella	Humans, domestic and wild fowl, and other animals
Viruses	
Caliciviruses	Humans and potentially cattle and swine
Hepatitis E	Humans and potentially swine and rats
Protozoa	
Cryptosporidium	Humans, domestic and wild animals
Giardia	Humans, domestic and wild animals

Table 4 Concentrations of enteric pathogens excreted in feces

Enteric pathogen group	Range of pathogen concentration (per gram of feces)
Bacteria	10^4–10^{10}
Viruses	10^3–10^{12}
Protozoan parasites	10^6–10^7

Source: From Ref.[7].

filtration (sand, activated carbon, flora), coagulation and sedimentation, disinfection, composting, and constructed wetlands. A multibarrier approach is used for the removal or reduction of pathogenic microorganisms in municipal wastewater. The general steps include: 1) removal or sedimentation of large debris (primary treatment); 2) biological degradation (trickling filters, aeration tank, lagoon) and/or disinfection (secondary treatment); and 3) a combination of physical (coagulation and filtration) and chemical (chlorine disinfection) steps in order to further reduce biological and chemical contaminants (tertiary treatment). Wastewater treatment has been shown to reduce bacteria by 99.99999%, viruses by 99.999% and protozoa by 99.993% (*Giardia* cysts) and 99.95% (*Cryptosporidium* oocysts).[10] Constructed wetlands have been applied as a low cost alternative to wastewater treatment. As water flows through the vegetated wetland absorption to flora, gravel or sand substrate, natural die-off, sedimentation, filtration, and predation occurs. For solid waste, compost piles can be used for the inactivation or reduction of pathogenic microorganisms. Temperature is the key factor controlling pathogen reduction in compost piles where it is suggested that 55°C must be maintained for at least 3 day and 15 day for static and aerated piles, respectively.[9] Difficulties in maintaining uniform temperature throughout the pile and regrowth of bacterial pathogens are two disadvantages for use of composting

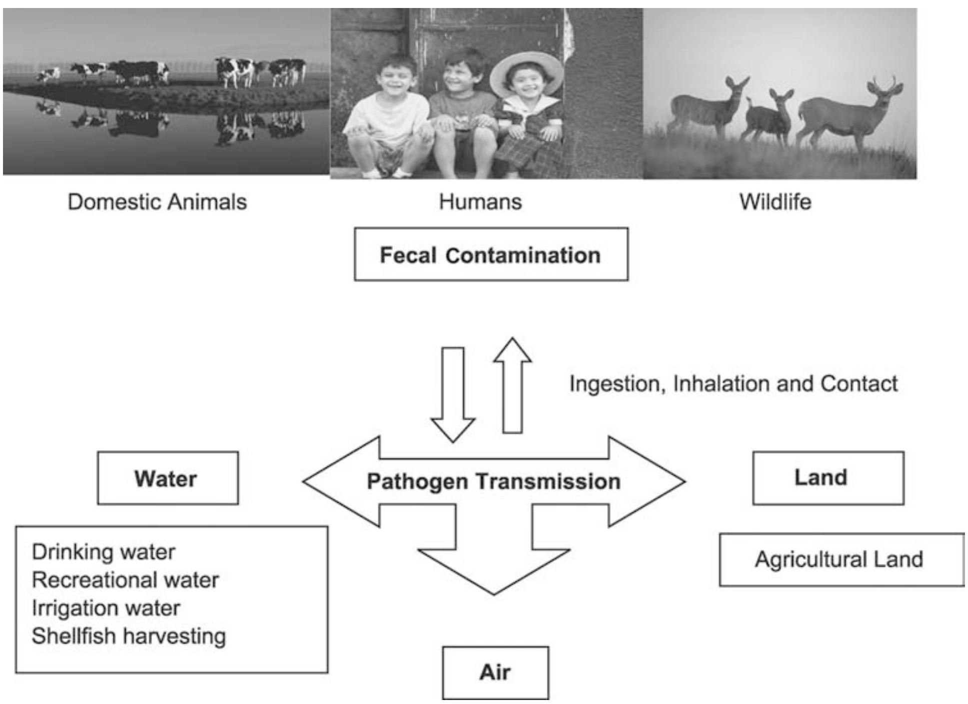

Fig. 1 Environmental routes of pathogen transmission.

for pathogen reduction.[9] Due to the different physical and genetic characteristics of pathogenic microorganisms, a combination of treatment or prevention practices may be necessary for their removal, death, or inactivation. For example, the ultimate barrier between pathogens and drinking water consumers is chemical or physical disinfection for inactivation of enteric viruses. Their small size (20–80 nm) enables them to bypass filtration processes, whereas filtration is required for the removal of protozoan parasites (>2 m in size) since they are highly resistant to most water disinfectants.

EMERGING PATHOGENS

Control of water transmission of pathogenic microorganisms continues to be a public health concern because there is an increasing immunocompromised (elderly, cancer, and AIDS patients) population and because a large percentage of waterborne outbreaks go unrecognized.[5,9,11] In fact, while less than 20 waterborne disease outbreaks are documented each year in the United States, it is estimated that the true incidence may be 10–100 times higher.[5] Even for well-established pathogens, the true incidence is unknown in the United States because: 1) reporting waterborne outbreaks and its agents is voluntary; 2) there is a lack of efficient detection methods for some important enteric pathogens; 3) contamination events in water are usually transient, thus etiological agents are not detected; and 4) individuals may not seek medical attention since acute gastrointestinal illness (AGI) is usually self-limiting and mild.[4,11] Furthermore, very little, if any, information exists on infectious agents that are newly recognized, or ‘‘emerging’’ in water supplies and their impact on waterborne disease outbreaks.

CONCLUSION

Water serves as a passive carrier for the transmission of disease. Human and animal populations may be exposed to pathogens through direct contact, ingestion, or inhalation of contaminated water. Enteric pathogens are the most important group of organisms relating to waterborne and water-washed diseases. They are excreted in high numbers in the feces and have traits that allow their survival and successful transmission in the environment. These traits should be considered when making decisions regarding strategies for limiting their transmission by water. A multi-barrier approach may be best for efficient removal of bacterial, viral, and protozoan pathogens.

Markus Flury
Center of Multiphase Environmental Research, Department of Crop and Soil Sciences, Washington State University, Pullman, Washington, U.S.A.

INTRODUCTION

This article covers transport of pathogens from different sources (e.g., land-applied animal or human wastes), either over ground or through the subsurface (soil, sediments, or rock formations), and the possible arrival of contaminating pathogens at surface or groundwater. Topics covered include the following: characteristics of pathogens and of the transporting pore space; mechanisms of transport; pathogen interactions with soil; measurement and modeling of pathogen transport; and practical aspects, including conditions favoring transport to water and their avoidance.

Transport and removal of pathogenic microorganisms are increasingly important, as humans intensify both their demands for freshwater and their disposal of wastes on land. Microbial transport is also important for the following processes: bioremediation of groundwater, e.g., the introduction of beneficial microbes to degrade chemical contaminants; filtration of wastewater, e.g., in buffer or filter strips along waterways, or in wetlands; and sand bed filtration of drinking water.

Pathogens are released to the environment from two major sources: 1) agricultural activities involving the disposal of animal wastes as manure or effluents and 2) human wastes disposed of via septic tank systems or land-applied sewage sludge (biosolids). Pathogens include helminths (not covered here), protozoa, bacteria, and viruses, each of which has distinct transport characteristics in surface and subsurface waters.

CHARACTERISTICS OF PATHOGENS AND PORES

The Pathogens

The size ranges of soil pores and soil biota vary over orders of magnitude[1,2] (Fig. 1). Viruses are in the range of nanometers, bacteria in the range of micrometers and protozoa in the range of micrometers to hundreds of micrometers. Pathogens may also form larger groups by clumping of bacteria or formation of virus aggregates.[3] This increases the probability of their removal by straining (see below).

Pathogens vary in their survivability in the environment. Bacteria are typically short-lived, but can reproduce and grow quickly as well. Oocysts of the protozoan *Cryptosporidium* (size 4–6 μm) are robust and persistent.[4] Viruses multiply only in host cells; for example, bacteriophages are viruses that infect and multiply inside bacteria, and human enteric viruses need humans to reproduce.

The Pore Space

In soil, the macropores (or drainable pores) have equivalent diameters $d > 30\,\mu m$,[1] are air-filled at field capacity, and provide the main drainage pathways during heavy rainfall or irrigation. At the wilting point (water potential of -1.5 MPa), only pores with $d < 0.2\,\mu m$ remain water-filled (Fig. 1).

Subsurface materials often have dual-porosity character,[4,5] with larger macropores (or fissures or conduits) embedded in a medium with finer pores, providing fast-track pathways (Fig. 2). Pathogen entrapment in soil can alter pore geometry by clogging of pores or formation of surface biofilms. An extreme example of this is the ‘‘biomat,’’ which forms in soils used for septic system disposal, made up of layers of intense microbial activity.

TRANSPORT AND FATE AT AND BELOW LAND SURFACES

Overland Flow vs. Infiltration

The first step controlling pathogen fate is at the land surface, where flow may separate into overland flow or infiltration (Fig. 3). Note that ‘‘overland flow’’ means (as it says) flow above the ground surface. ‘‘Runoff,’’ by contrast, may include both overland flow and subsurface flow submerged temporarily beneath the ground surface, which reemerges at lower

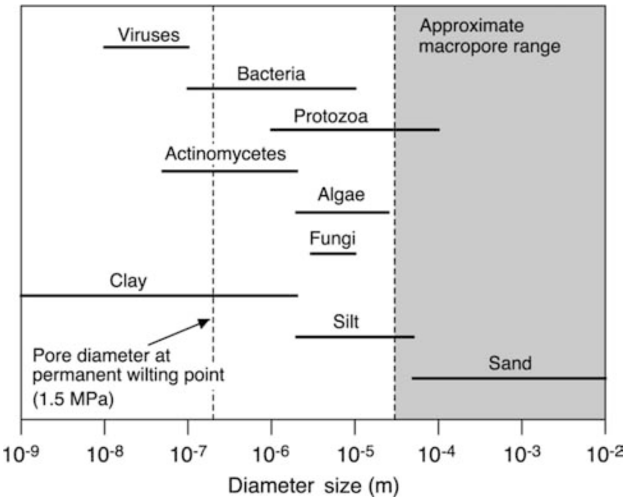

Fig. 1 Size ranges of soil particles and pores and of microorganisms. The vertical broken lines represent the equivalent diameters of pores, which empty at permanent wilting point (PWP), and at the transition between micropores and macropores. Under heavy rain or irrigation, water-filled macropores provide an efficient fast-track pathway for transport of pathogens or solutes (Fig. 2).

elevation—so-called ''through flow'' or ''interflow''. This distinction is important because the through flow is subject to the filtering action of soil, whereas overland flow is not (although it may be filtered by above-ground vegetation). Overland flow is most pronounced during heavy rainfall or irrigation and is encouraged by decrease in surface hydraulic conductivity, increase in slope or prior surface wetness,

Fig. 2 Illustration of macropore flow. This strongly structured, cultivated soil was flood irrigated with dye solution, causing preferential flow through macropores. This type of flow in ''dual-porosity'' soils, subsoils, or underlying rock (e.g., limestone with fissures or conduits) can fasttrack contaminants and pathogens to groundwater. (Photo courtesy of K.C. Cameron, Lincoln University, Canterbury, New Zealand.)

compaction of soil such as by animals in a stockyard, or by the presence of frozen surface soil.

Fate of Pathogens in Overland Flow

Pathogens can be filtered from overland flow by surface vegetation (e.g., in buffer or vegetated filter strips, which act as a ''line of defense'' between waterways and animal waste disposal sites). Die-off and waste sterilization result from prolonged surface exposure to desiccation, natural UV in sunlight, or freeze–thaw cycles, and predation by other microorganisms.

Fate in the Subsurface: Transport, Entrapment, and Survival

Within the soil, pathogens are present either in suspension in the aqueous phase (including the air–water interface), attached as single or multiple organisms on solid surfaces (including organic or clay particles in suspension in water), or in biofilms covering solid surfaces.[6]

Transport Processes

The main transport mechanism is passive convection with local flow of the soil solution. The transported microbes are carried either free floating (singly or in clumps), or adsorbed onto colloid particles (e.g., organic particles or clay).[2] However, some microbes can move actively: chemotaxis is movement along a chemical gradient, e.g., toward a food substrate. The rate of transport increases with soil wetness and as mean pore size increases and pores become more continuous. Preferential flow can occur during heavy infiltration via macropores in soil (Fig. 2), or fissures or conduits in rock formations (e.g., limestone in karstic formations).[7]

Microbes can travel faster than the mean pore-water velocity because of two differential flow effects.

1. Size exclusion: Microbes tend to be carried near pore centerlines and, because of their large size, cannot penetrate the ''slow flow'' zones next to pore walls, where flow is slowed by viscous drag.
2. Detouring effect: Microbes are swept preferentially through the larger pores, avoiding smaller pores.

As a consequence, microbes can travel faster than the average speed of the moving water, and so can precede the arrival of solutes or tracers.[5]

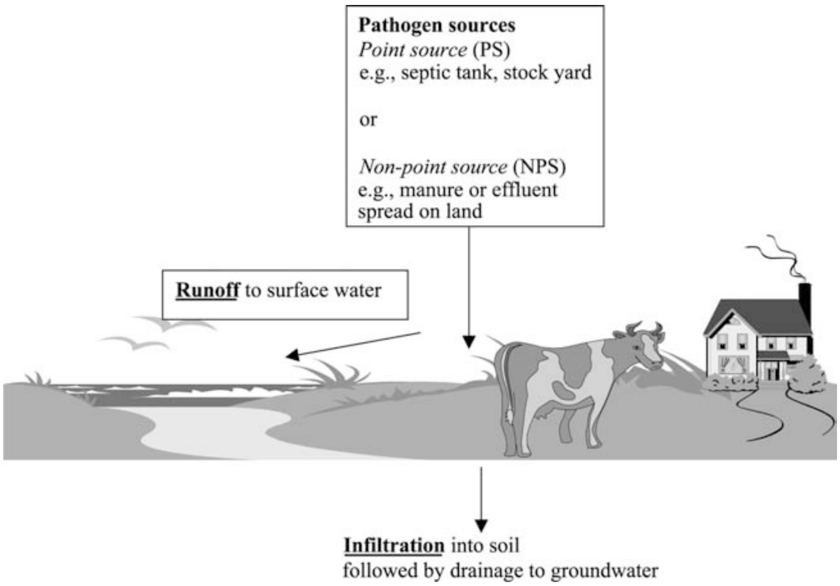

Fig. 3 Partitioning of water at the soil surface. Pathogens from agricultural or human wastes, or wild animals or birds, may be transported to surface or groundwater via overland flow, infiltration into soil followed by through flow, or drainage through soil. The partitioning is controlled by the rate of application of water or effluent vs. the soil's infiltration rate. Transport in drainage may be fast-tracked to groundwater through soil or bedrock, which has dual-porosity character, with large macropores or fissures (Fig. 2). Fortunately, most infiltrating water is filtered and disinfected by soils and sediments, which act as defensive barriers.

Entrapment and Survival

Microorganisms are subject to various processes that affect their transport and survival in the environment. These processes include the following:

- Cell multiplication and death: Inactivation (death or loss of viability) increases at high temperatures or when food sources (organic matter and nutrients) are scarce or aeration conditions are unfavorable. Certain microorganisms, such as bacteria, can multiply rapidly when conditions become favorable again. Viruses may be inactivated at certain surfaces, for instance, in the presence of iron oxides, which are common in soils.
- Predation: Microorganisms can feed on other microorganisms or otherwise inactivate them, e.g., some protozoans ingest bacteria and viruses.
- Straining: Microorganisms can get trapped in pore throats that restrict passage. This effect tends to become important when the microbe (or clump) diameter is >5% of the average grain diameter. Straining is a weak effect in sandy or gravelly soils or aquifers, where the sizes of pores are large compared to microorganisms.
- Filtration and attachment to solid surfaces: Microorganisms are removed from water by attachment (adhesion) to soil particle surfaces. Attachment is controlled by the surface properties of microbes and soil particles and the chemical composition of the water. Protozoa and bacteria can also actively bind to solid surfaces by using filaments or exudates.
- Sedimentation: Microorganisms can settle out of water under gravity. This mechanism is usually minor because most microorganisms have a density close to that of water and are approximately neutrally buoyant. Swimming capabilities of some microorganisms will also prevent settling by gravity.
- Detachment (release) from solid surfaces: Microorganisms can detach from solid surfaces when changes occur in the chemical or physical conditions that initially led to attachment, e.g., bacterial cells may be washed away from soil particle surfaces when water flow rates increase.
- Air–water interface trapping: Certain microorganisms (e.g., viruses) tend to attach to air–water interfaces or air–water–solid interfaces, an event that occurs in surface waters or unsaturated subsurface environments, such as soils.

Microbes are likely to be less efficiently removed from water moving in through flow than from deep percolation. First, through flow is likely to occur at higher soil water content, and indeed is often saturated flow, so there is less liquid–gas interface available for microbial removal. Also, travel is likely to be shorter for through flow than for deep percolation.

MEASURING PATHOGEN TRANSPORT

Measuring transport is complicated by the difficulty of microbial detection methods, especially for viruses. Methods include direct sampling for protozoa, bacteria, and viruses;[8] using viruses or bacteriophages as tracers, e.g., with dye attachment;[3,9] or using surrogate particles (e.g., fluorescent latex microspheres).[3] Measuring microorganisms via samples taken from subsurface environments requires special care to maintain the environmental conditions of the sample location, in order to avoid alteration of microbial communities.

MODELING

The difficulty of modeling transport processes in permeable media increases as we progress from water through solutes to microbes. For microbes, additional complexities include attachment and detachment (and their dependence on surface charges), multiplication and inactivation. In general, the modeling approaches consider convective and dispersive transport by moving water, coupled with terms for attachment/detachment and survival,[9,10] and with water flow separated into macropore flow and matric flow.[2,5]

AVOIDING WATER CONTAMINATION

A mechanistic understanding of the transport and fate of pathogens leads to the development of best management practices (BMPs) for avoiding water contamination. Historically, the single factor causing greatest risk of contamination is excess water from rainfall or snowmelt. This can fasttrack pathogens, either in overland flow to surface water, or via macropore or conduit flow to groundwater, bypassing the natural disinfection mechanisms present in the soil. Natural soils act as filters that protect groundwater from pathogens by removing them as described above. Degradation of soils by erosion or compaction will, however, reduce their natural disinfection capabilities.

CONCLUSION

Earth's natural subsurface materials play a critical "barrier" role in disinfecting water from pathogenic microorganisms. However, sometimes this barrier fails or is degraded, and pathogens migrate to and contaminate water resources. As humans intensify land use, understanding and avoiding pathogen transport to water are essential for sustainable development.

Pesticide Contamination: Groundwater

Roy F. Spalding
Water Science Laboratory, University of Nebraska, Lincoln, Nebraska, U.S.A.

INTRODUCTION

Trace concentrations of most of the commonly used pesticides have been confirmed in groundwaters of the United States. Since groundwater is the source of 53% of the potable water, the more toxic pesticides and their transformation products are a concern from the standpoint of human health. Others are a risk to the environment in areas where contaminated groundwater enters surface water. Through toxicological testing, the USEPA has established Maximum Contaminant Levels (MCLs) or lifetime Health Advisory Levels (HALs) for several pesticides (Table 1).

The EPA also has a separate list of unregulated compounds, including newly registered pesticides and their transformation products, such as acetochlor and alachlor-ESA, that are presently being evaluated or being considered for toxicological evaluation. Based on the results of the EPAs National Pesticide Assessment,[2] 10.4% of 94,600 community systems contained detectable concentrations of at least one pesticide. Evaluation of these results led to an estimated 0.6% of rural domestic wells containing one or more pesticides above the MCL.

PESTICIDE USE

In the United States about 80% of pesticide usage is in agriculture. The remainder is used by industry, homeowners, and gardeners. About 500 million pounds of herbicide, 180 million pounds of insecticide, and 70 million pounds of fungicide were applied for agricultural purposes in 1993.[3] Several maps of the United States delineate usage patterns of several pesticides.[4] The majority of the triazine and amide herbicides are applied to fields in the north central corn belt states of Michigan, Wisconsin, Minnesota, Nebraska, Iowa, Illinois, Indiana, and Ohio. Commonly used organophosphorus insecticides are more heavily applied to fields in California and along the southeastern seaboard than in the northern corn belt. Carbamate and thiocarbamate pesticides are heavily used in potato growing areas of northern Maine, Idaho, the Delmarva Peninsula, and vegetable fields of California and the southeastern coastal states. Fungicide use is concentrated in high humidity and irrigated areas of the coastal states and to some extent along the Great Lakes and Mississippi River Valley. The fumigants carbon tetrachloride and ethylene dibromide (EDB) were used heavily in the past at grain storage elevators throughout the Midwest and elsewhere in the United States.

ASSOCIATED PESTICIDE BEHAVIOR IN SOILS AND WATER

Although pesticide use is a dominant factor in groundwater contamination, leaching variability among pesticides exhibiting similar behaviors is striking and explains why several heavily used pesticides seldom if ever are detected in groundwater. In general, pesticides within a class have similar chemical characteristics upon which soil leaching predictions can be made based on persistence, solubility, and mobility. Pesticide class relationships with soils and water transport described in the following text are detailed in Ref.[5]. Individual frequencies of groundwater pesticide detection, in parenthesis next to commonly used products, are calculated from the Pesticide Groundwater Data Base (PGWDB)[4] and the National Water Quality Assessment (NAWQA) database.[6] High frequencies of detection identify those pesticides with a disposition to leach.

Insecticides

Chlorinated hydrocarbons are one of the oldest chemical classes of insecticides. Some of the best-known compounds include aldrin, dieldrin, DDE, DDT, endrin, and toxaphene. Although banned since the 1960s, their extremely persistent nature precludes their detection in very trace quantities in groundwater of the upper Midwest. On the other hand, heavily used organophosphates like malathion, methylparathion, disulfoton, and others have been extensively surveyed during several groundwater monitoring studies and have not been detected. The organophosphate insecticides, parathion (not reported (NR), <1),[a] terbufos (<1, <1), fonofos (<1, <1), and chlorpyrifos (<1, <1), which are heavily used on corn and sorghum, were also

[a] % occurrence from PGWDB, % occurrence from NAQWA data.

Table 1 U.S. maximum contaminant levels for drinking water

Organic chemical name	MCL (mg/L)	Organic chemical name	MCL (mg/L)	Organic chemical name	MCL (mg/L)
2,4,5-TP (Silvex)	0.05	Chlordane	0.002	Heptachlor	0.0004
2,4-D	0.07	Dalapon	0.2	Heptachlor Epoxide	0.0002
Alachlor	0.002	Dinoseb	0.007	Lindane	0.0002
Aldicarb	0.007	Diquat	0.02	Methoxychlor	0.04
Aldicarb sulfone	0.007	Endothall	0.1	Oxamyl (Vydate)	0.2
Aldicarb sulfoxide	0.004	Endrin	0.002	Picloram	0.5
Atrazine	0.003	Ethylene dibromide	0.00005	Simazine	0.004
Carbofuran	0.04	Glyphosate	0.7	Toxaphene	0.003
Carbon tetrachloride	0.005				

Source: From Ref.[1].

seldom detected. Diazinon (1.1, 1.3), the common garden insecticide, is occasionally detected in groundwater. Generally, the organic phosphates are rapid degraders and are strongly retained on soils.

For the most part, carbamates and thiocarbamates are very sparingly soluble and exhibit low to moderate soil retention; however, a small number have high solubility and low soil retention. Most carbamates are characterized as having short longevities. Generally, pesticides in this group having half-lives of 30 days or more have the potential to leach. The thiocarbamates butylate (<1, <1) and EPTC (2.6, <1) are extensively used in agriculture and have relatively short half-lives. Aldicarb (<1, <1) and carbofuran (14.7, <1) are at the high end for solubility and longevity in their class. Their metabolites have been frequently detected beneath high use crops, such as potatoes in the potato growing regions of the United States.

The pyrethroid insecticides have low solubilities, short half-lives, and high soil retentions that make them unlikely to leach. Yet, permethrin (<1, <1) is occasionally detected in very trace quantities in groundwater.

Fungicides and Fumigants

Fungicides are non-volatile organometallic compounds with low aqueous solubility that inhibit growth of actenomycetes and many fungi. The best-known fungicides zineb (not detected (ND), NR) and captan are zinc-based, and maneb (ND, NR) is manganese-based. Some, like bordeaux, are copper sulfate-based. Although their detection frequency is very low, fungicides have not been analyzed in many surveys.

Fumigants are very volatile halogenated compounds that generally are knifed below the soil surface. These compounds have high aqueous solubility and very low soil retention. The fumigants EDB and 1,3-dichloropropene have been frequently detected in the subsurface and in groundwater in high-use regions, such as California.[7] Ethylene dibromide and carbon tetrachloride were also used in grain storage facilities during the 1950s and 1960s. Spills, leaks, and improper handling resulted in 400 reported groundwater contamination sites in Kansas and Nebraska.

Herbicides

There are at least eight major chemical classes of herbicides. These include: quaternary N, basic, acidic, carboxylic acid, hydroxy and aminosulfonyl, amide and anilide, dinitroaniline, and phenylurea herbicides.[5] Several herbicide classes have similar behaviors with respect to soil and water.

Both quaternary N and dinitroaniline herbicides are very highly retained by soils and are not expected to be detected in groundwater. However, paraquat, pendimethalin, and trifluralin have been reported several times in groundwater. Their presence indicates that transport is dependent on factors not directly related to compound longevity, solubility, and mobility. Vertical transport by preferential flow through macropores is a commonly accepted mechanism used to explain these detections. In some instances, compounds have been described as preferentially transported attached to colloidal material.

Carboxylic, hydroxy, and aminosulfonyl acids, and thiocarbamate herbicides have very low to low soil retention and very short to moderate longevity. Thus, the more heavily used and persistent pesticides in these groups are the ones most generally detected in groundwater. They include the acids, dicamba (2.0, NR), picloram (2.5, <1), bromacil (1.8, 1.0), and dinoseb (1.4, <1).

Phenylurea herbicides have low to high soil retentions and short to moderate longevity. Linuron (16.7, <1) and diuron (<1, 1.9) are the most frequently detected in groundwater and both have moderately long half-lives ranging from 60 to 90 days.

Amide and anilide herbicides have low soil retention and short to moderate longevity. Several amide herbicides and their transformation products have been detected in groundwater. The commonly used amides in the Midwestern corn belt, namely alachlor (1.7, 2.7), metolachlor (<1, 12), propachlor (1.2, <1), and acetochlor (NR, <1), are the most frequent offenders because they are relatively persistent.

As suggested by the name, basic herbicides behave as bases. The group contains several subclasses including aniline, formamidine, imidazole, pyrimidine, thiadiazole, triazines, and triazole. Basic herbicides have low to high soil retention and very short to moderate longevity. Again, it is generally the most persistent and heavily used pesticides that are more frequently found in groundwater. The most frequently detected compounds in the group are the triazines, namely atrazine (5.6, 30), metribuzin (4.2, 1.9), cyanazine (2.0, 1.4), simazine (2.0, 14.8), and prometon (2.1, 11.6).

GROUNDWATER CONTAMINATION

It stands to reason that there are generally good associations between pesticide use and their detection in groundwater. Since groundwater flows very slowly at rates normally ranging from 0.1 ft/day to 3 ft/day, pesticide sources are generally very near the monitored well. Thus, high frequencies of triazine and acetamide detections are reported in the states of the northern corn belt. More fungicides and fumigants were detected in warm humid states of California and Florida where vegetable and fruit crops dominate the landscape. In an analysis of the 20 NAWQAs for pesticides, frequencies of pesticide detection in groundwater were significantly related to the estimated amount of agricultural use within a 1 km radius of the sampled site.[6] They also emphasized that pesticides were detected beneath both agricultural (60.4%) and urban areas (48.5%). Discontinued used pesticides have been detected numerous times in shallow aquifers.

In general, families of pesticides have similar chemical characteristics from which predictions have been made as to the product's potential for contamination of groundwater; however, differences in the leaching behavior of pesticides exhibiting similar chemistry can be appreciable and is the reason several heavily used pesticides are seldom, if ever, detected in groundwater.

MANAGEMENT OF POINT SOURCES OF GROUNDWATER CONTAMINATION

Important steps are being taken to reduce water quality pollution by pesticides occurring from spills and back siphoning events (point sources). Since it is easier to resolve point than non-point sources, laws have been enacted to eliminate contamination of surface water bodies, which may be in hydraulic contact with groundwater, from used pesticide containers and rinseate from chemical wash downs. Check valves are mandatory when pesticides are mixed and/or diluted and prevent backflow to groundwater. Soils at and adjacent to agrichemical supply facilities have been surveyed in several states and found to be highly contaminated with pesticide residues. The herbicides, atrazine, alachlor, metolachlor, cyanazine, and metribuzin are the worst offenders from the standpoint of pesticide mass in the soils at sites in Wisconsin and Illinois.[4] Many of these sites and those in other states are now involved in soil cleanups, which are designed to protect underlying groundwater from further pollution.

MANAGEMENT OF NON-POINT SOURCES OF GROUNDWATER CONTAMINATION

Normal farm chemical applications of pesticides are generally considered potential non-point sources of groundwater contamination because they are dispersed over large areas ranging from fields to watersheds. Management strategies are in place to reduce leaching of field applied chemicals.[8] These strategies vary from regulatory restrictions to outright bans on application in areas deemed more vulnerable to leaching. Integrated pest management, fostered by the office of pesticide management at the USEPA, is designed to reduce chemical applications. The practice of banding applications has reduced amounts applied. Both target more efficient pesticides and genetically engineered plants sensitive only to specific herbicidal action have been and are being developed. These new pesticides and pesticide–plant combinations require less chemical than in the past, and the altered plants allow for pest control with more environmentally sensitive chemicals. The USEPA has announced a plan to reduce the mass of applied chemicals from commonly used triazines and amides that are frequently detected in groundwater.

Irrigation Management

Irrigation practices can influence pesticide leaching. Atrazine was vertically transported deeper and faster when using flood rather than sprinkler irrigation.[9] Sprinkler systems allow for much more uniform and efficient water management practices than furrow irrigation, and recent studies have shown that they reduce chemical leaching.[10] In the Nebraska's Platte

Valley[11] and in the Walnut Creek watershed in Iowa,[12] peak herbicide concentrations were strongly related to rapid flushing beneath drainage areas where surface water ponds during heavy rainfall events on the cropped fields. Application of excess irrigation water also was reported to increase herbicide leaching.[9,11]

FUTURE RESEARCH

More research is necessary to evaluate the health risks of transformation products from heavily used pesticides that are frequently detected in groundwater. Research needs to focus on precision application of pesticides to specific field problem areas as a potential mechanism to reduce chemical application.

There is a need to evaluate the environmental cost/benefit of safer product replacements used in conjunction with genetically altered crops. As new products are registered to replace more persistent and mobile pesticides, long-term fate studies, including the monitoring of the transformation product impact, on groundwater quality are necessary.

Pesticide Contamination: Surface Water

Sharon A. Clay
Plant Science Department, South Dakota State University, Brookings, South Dakota, U.S.A.

INTRODUCTION

About 1000 million pounds of pesticide were applied in the United States in 1997.[1] This extensive use of pesticides has caused concern about pollution in the environment. Indeed, pesticides have been detected in groundwater, surface water, and rain. However, the amount found normally is less than 0.1% of the amount used and occurs in seasonal cycles. Management options that limit losses from target sites will be presented.

DETECTION FREQUENCY, CONCENTRATIONS, AND SEASONAL CYCLES OF PESTICIDES FOUND IN SURFACE WATER

Pesticide classification may be based on the type of pest controlled. Chemicals that control weeds (herbicides) accounted for 60% of the pesticide use in 1997.[1] Chemicals that control insects (insecticides) and plant diseases (fungicides) accounted for 13% and 7%, respectively, of the chemical use.[1] Rodenticides, fumigants, and nematicides represent other pesticide classes that account for the remaining 20% of use. In a typical year, agricultural lands receive about 80% of all pesticides applied while homeowners/gardeners (8%) and the commercial market (12%) apply the rest.

The United States Geological Survey (USGS) has sampled surface water for pesticide pollution since the late 1970s. Thousands of samples have been analyzed for about 100 pesticides or breakdown products (metabolites). Herbicides are the pesticide type most commonly found in rural streams.[2] Atrazine, a broadleaf herbicide ranked number one in total pounds applied in the United States from 1987 to 1997 (about 75 million lb/yr), has been detected most often.[1] Other herbicides found in surface water include simazine and cyanazine (used for broadleaf and grass control in corn) and alachlor and metolachlor (used for grass control in corn and soybean).[2] Most of these herbicides also ranked high in U.S. agricultural use between 1987 and 1997.[1] The amount of these herbicides found in streams has typically ranged from less than 1% of the amount applied (cyanazine, metolachlor, and alachlor) up to 3% (atrazine).[2] The five insecticides frequently detected were diazinon, carbaryl, chlorpyrifos, carbofuran, and malathion.[2]

Detection of cyanazine and alachlor in the U.S. environment will decline in the future. Cyanazine is no longer labeled for use in the United States as of 2002. Alachlor is being replaced by acetochlor. However, acetochlor was detected in surface water in its first year of general use (1994) with occurrence patterns similar to other herbicides of the same family.[3] The concentration detected was lower than alachlor due to lower application rates.

Pesticides have also been detected in urban streams.[4,5] In fact, the estimated contribution of insecticides to surface water contamination from urban and rural areas may be similar. Insecticides, such as malathion, carbaryl, and diazinon, are commonly used in urban settings for control of mosquitoes, turfgrass and garden insects, and termites.[4] Herbicides detected in urban streams were those commonly used for broadleaf weed control in lawns (i.e., 2,4-D, dicamba, and MCPA)[5] along with prometon and tebuthiuron, both used for total vegetation control in right-of-way areas.[4] Herbicides almost exclusively used in agricultural settings (atrazine, alachlor, metolachlor, and cyanazine) have also been detected in urban streams. Atmospheric depositions in sediment, rain, or snow or transport from agricultural watersheds upstream of urban settings are the most likely sources of these herbicides.

Pesticides in surface water have been detected throughout the year.[6] The greatest concentrations in rural streams are reported in the spring and early summer coinciding with agricultural applications.[7] The mean pesticide concentrations in most months are about 1 μg/L.[2] However, during peak usage, concentrations in some samples may exceed 12 μg/L. In urban streams, the mean pesticide concentration is fairly stable (<0.5 μg/L) throughout the year[2] but can differ by area of the country. In the southern United States, pesticides may be applied both earlier and later in the year due to the longer growing season compared to the northern tier of states.

PESTICIDE TOXICITY IN SURFACE WATER

The U.S. Environmental Protection Agency[8] has established pesticide concentration criteria values for some pesticides for the protection of aquatic health. Pesticides can be toxic to aquatic invertebrates such as plankton[9] and vertebrates such as frogs and fish, when above critical concentrations. The herbicides, atrazine [water quality criterion (WQC) = 1.8 μg/L] and trifluralin (WQC = 0.2 μg/L), and the insecticides, chlorpyrifos (WQC = 0.041 μg/L) and diazinon (WQC = 0.08 μg/L), were the pesticides that most often exceeded the aquatic health criteria in 37 rural streams.[2] In a survey of eight urban streams across the United States monitored from 1993 to 1995, 41 pesticides were detected. Simazine (WQC = 10 μg/L), prometon (no established criterion), atrazine, and diazinon were detected at all sites and 20 other pesticides were detected above their WQC in one or more of the streams.[4] The estimated number of days that the pesticide concentration exceeds the established standards varies by chemical.[2] Atrazine was estimated to exceed the standard in 15 rural streams from 1 day to 84 day (with an average of 36 day). In comparison, chlorpyrifos and azinphos-methyl (WQC = 0.01 μg/L) exceeded the standard in 8 streams, ranging from 1 day to 8 day (average of 3 day) and 1 day to 70 day (average of 13 day), respectively.

In addition, herbicides may be used to control plants in ponds and lakes. The reduction in vegetation may have an indirect effect on the number of weed-clinging invertebrates such as dragonflies or damselflies. However, removal of plants does not always decrease the numbers of aquatic organisms. For example, the number of aquatic organisms remain fairly constant or increase due to an increase in organisms that feed on plant debris after vegetation is controlled.[10]

FACTORS THAT AFFECT PESTICIDE MOVEMENT TO SURFACE WATER

Distance Between Application and Surface Water

The distance between pesticide application and surface water can greatly affect the likelihood of surface water contamination. In most cases, buffer zones of 50–100 ft are recommended on the pesticide label. Filter strips of grass or a dense cover crop at the field edge also reduces the pesticide concentration in the runoff in two ways.[11] First, filter strips slow water movement and allow soil particles to settle out of the runoff. Second, these areas normally are high in organic matter and can sorb the pesticide out of water. Herbicide concentrations have been reduced up to 64% after flowing through a filter strip compared to concentrations upstream of the filter strip area.[11]

Choice of Rate, Pesticide, and Application Timing

Some pesticides are much more vulnerable to movement into surface water. Pesticides that degrade quickly (days to a few weeks) are less likely to contaminate surface water than those that linger in the environment (months or longer). Applications to sandy soils with low organic matter are more likely to have runoff than loamy or clayey soils with more organic matter.

The higher the rate of application the more the pesticide available for runoff. For example, banding herbicides to only row areas and using cultivation to control weeds in interrow areas is one technique to reduce application rates. The amount of herbicide applied depends on the bandwidth. If the bandwidth is 10″ on a 30″ row, the amount applied is reduced by two-thirds compared to a broadcast application rate where the entire area is covered. Banding has been reported to reduce the amount of herbicide in runoff water up to 70%.[12] Applying the pesticide as a split application also reduces the amount of chemical present at one time and can reduce the potential risk of surface water contamination.

Pesticides that are applied at ounces per acre rather than pounds per acre are available. Examples of herbicides include the sulfonylureas and imidiazilinones. The low application rates of these herbicides reduce the total amount of herbicide applied to an area and therefore reduce the risk of contamination.

Rainfall After Application

The amount, intensity, and time of rainfall after application are all factors that affect the total amount and pesticide concentration in runoff. Generally, a large amount of pesticide is removed with the first rainfall after application.[13] If the soil is bare and crusted or has little or no plant canopy, the amount of runoff will be very large. Storms with high intensity rains also have more runoff than if the rain is slow and steady. The amount of water already present in the soil is another factor that affects runoff. There is little or no infiltration on saturated or very wet soils whereas dry soils will allow more water to infiltrate before runoff occurs.

Drift, Volatilization, and Atmospheric Transport

Drift is the transport of spray applications in the wind. The smaller the droplet size, the farther the droplets can travel. Very fine particles may move for miles before deposition occurs. These drops could land in lakes, streams, or other off-site areas. Wind speed also is an important factor in drift. Most applications should not take place when wind speeds are over 10 mph. Pesticides should not be applied when weather conditions that cause an inversion (warm air over cold air) are present. Fine spray droplets move much farther when an atmospheric inversion exists.

There are some factors that can be used to limit drift. Applying pesticides under low pressure in high amounts of water will increase droplet size, thereby decreasing the number of droplets available for drift. Larger droplets will also lower the pesticide concentration of individual droplets. There are nozzles specifically designed to limit the amount of fine particles in a spray pattern. Antidrift chemicals are available to be mixed with pesticide application. These chemicals reduce the number of very fine droplets in the spray pattern. Lowering the spray boom limits the amount of spray subjected to the wind. Shields for the boom or individual nozzles can be attached to limit wind interception with spray patterns.

Pesticides can volatilize (change from a liquid to a gas) or sublime (change from solid to a gas) from the soil surface. The amount volatilized is a function of the vapor pressure of the chemical and the environmental conditions. For example, EPTC, a grass herbicide, is highly volatile with most of the herbicide lost to the atmosphere within a few hours if not incorporated into the soil.[14] In contrast, atrazine is not very volatile but under the right conditions, 2% of the applied chemical can be lost through this mechanism.[15] This amount is about one-half the loss due to surface runoff on a regional scale. A pesticide applied to warm moist soils on windy days will have a greater loss than if the same pesticide is applied to cool dry soils.[14]

Pesticides attached to very small soil particles are also moved into the atmosphere.[16] Soil particles and aggregates that are less than 1 mm in diameter are considered wind-erodible.[17] In the Great Plains area of the United States, the loss of soil due to wind erosion is greater than the amount lost due to water erosion.[18] The small size soil particles make up about 50% of the soil mass in the top 0.5″ of soil, if the area has been chisel plowed. The amount of herbicide found on these particles can range from 50% to 200% more than the amount found on larger aggregates one day after application.[19] If there are windy conditions within days after application, the amount of pesticide lost could be very high. Shallow incorporation of pesticides limits pesticide losses into the atmosphere.

Concentrations of pesticides in the atmosphere can decrease by several methods. Dilution, removal in rain, snow, or by dry deposition, and photochemical degradation are the three ways in which pesticide concentrations can be reduced.[20] However, pesticides can move long distances from their sites of application.[21] For example, surface water and rainfall has been monitored in the remote pristine area of Isle Royale National Park, MI, located in Lake Superior.[22] Atrazine was detected in rainfall from mid-May to early-June, corresponding to peak application timing of atrazine in the U.S. Midwestern Corn Belt. Surface water of the lakes in Isle Royale National Park also contained atrazine at trace (part per trillion) levels. These levels are not high enough to be toxic to organisms, but their presence in this remote area point to the need to use caution in the use and application of pesticides.

CONCLUSION

Although other methods of pest control are important, pesticides continue to be an efficient, cost-effective method of management. The challenge is to select and apply pesticides in a manner that kills the target pest and does not harm non-target organisms or the environment. Sound and sensible management can reduce the probability of pesticides entering surface water. Precision application to only those areas needing treatment is one method to reduce the total amount of pesticide applied. Other techniques include using split applications, banding, and planting filter strips along streams and water courses.

Pfiesteria Piscicida

Henry (Hank) S. Parker
North Atlantic Area, Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Wyndmoor, Pennsylvania, U.S.A.

INTRODUCTION

Several highly publicized fish kills in 1997 in the Chesapeake Bay focused national attention on *Pfiesteria piscicida*, a toxic dinoflagellate already notorious for its role in major fish kills in North Carolina, and dubbed "the cell from hell" by researchers from that state. The economic, socio-political, and scientific consequences of the 1997 events may be felt for decades to come.

A discussion of *Pfiesteria* must first consider harmful algal blooms (HABs). Described as "episodes of rapid, explosive growth of populations of microorganisms . . . that make and secrete toxic biomolecules,"[1] HABs are generally attributable to photosynthetic microalgae; dinoflagellates are often implicated, with at least 85 toxic species identified to date.[2] Harmful algal blooms (also known as "red tides") have been reported since at least biblical times; however, it is widely believed that their frequency of occurrence and intensity have increased in recent years, resulting in increased mortalities of fish, marine mammals, and invertebrates, and toxic effects on humans.[3,4] There is growing concern that recent increases in HABs may be related to anthropogenic factors, including nutrient enrichment of coastal waters.

CHRONOLOGY AND IDENTIFICATION OF *P. PISCICIDA*

In 1988 scientists at the College of Veterinary Medicine, North Carolina State University (NCSU), were puzzled by deaths of fish in laboratory tanks.[5] The mortalities were initially attributed to an unknown contaminant. The scientists subsequently observed that a previously unknown dinoflagellate was abundant just before the onset of fish mortalities, but that the flagellated cells—"zoospores"—declined precipitously within 1–2 hr of the fish kill, suggesting "ambush-predator" behavior.[6,7] The disappearance of the zoospores was associated with the production of resting cysts or non-toxic amoeboid forms. After tanks were re-stocked with live fish, the zoospores re-appeared.

Three years after the fish tank mortalities, the NCSU researchers linked the deaths to similar fish kill events in the natural environment. The Albemarle-Pamlico estuarine system of North Carolina is the second largest estuary, by area, in the United States.[8] The estuary is of critical ecological importance, providing about half the nursery area for fish on the U.S. East Coast. Since at least the mid-1980s, the estuarine system had sustained major, unexplained fish kills. A massive kill occurred in 1991, resulting in the deaths of an estimated one million Atlantic menhaden, *Brevoortia tyrannus*. Water samples taken at the onset of and following mortality revealed the presence of the same dinoflagellates and patterns of abundance as observed in the culture tanks.

The NCSU scientists isolated the suspect dinoflagellates from several fish kills and conducted laboratory bioassays. They found that the isolates were lethal to 11 species of finfish, including several commercial species, and described the morphology, behavior, and preliminary life history of the organism. The organism was subsequently assigned to a new genus and species, *P. piscicida* gen. et sp. nov., and described as a polymorphic and multiphasic toxic dinoflagellate, with flagellated, amoeboid, and cyst stages.[9]

Since the identification of *P. piscicida*, the NCSU laboratory has identified a second toxic *Pfiesteria* species, *P. shumwayae*.[10] Although it was previously the convention to refer to similar toxic dinoflagellates as "*Pfiesteria*-like" organisms, scientists recently reached consensus that the term "toxic *Pfiesteria* complex" (TPC) should be employed to describe toxic species that are strongly attracted to live fish or fresh tissues; whose toxic activity is triggered by live fish or fresh tissues; and whose toxins can cause fish stress, disease, or death. Toxic *Pfiesteria* complex species currently known are limited to *P. piscicida* and *P. shumwayae*.

After its discovery in North Carolina, *P. piscicida* was identified in Delaware Bay in 1993 and documented in Chesapeake Bay in 1995, in a tributary of the Choptank River.[11] It was not until several major fish kill events in tributaries along the lower Eastern Shore of Chesapeake Bay in the summer and fall of 1997 that *Pfiesteria* was considered a problem for Chesapeake Bay. *Pfiesteria* was linked not only to fish mortalities but also to human health problems, engendering widespread media coverage.[12]

BIOLOGY OF *P. PISCICIDA*

Pfiesteria appears to be widely distributed in the U.S. Eastern and Gulf of Mexico coastal waters, from Delaware to Florida and Alabama. Toxic *Pfiesteria* complex species are eurythermal and euryhaline. *Pfiesteria* is a complex organism. Though often described as an alga, it is heterotrophic and not capable of photosynthesis except when zoospores ingest chloroplasts from algal prey, through a process known as kleptoplastidy.[13]

Burkholder and Glasgow[7] have described 24 stages in the life history of *Pfiesteria*. Individual stages range from 5 microns to 750 microns in size. In the absence of fish, all stages are non-toxic. Amoeboid stages subsist on microalgae; encysted stages lie dormant on the bottom, encased in a protective covering; and free-swimming cells are known as non-toxic zoospores. In the presence of fish, zoospores rapidly become toxic; toxicity is apparently triggered by chemical cues in live fish or their fresh tissues, secreta, or excreta. Cysts and amoebae may also be stimulated to give rise to zoospores that can become toxic as well. Released toxins may paralyze fish, disrupt osmotic balance, and degrade fish tissues, leaving open wounds or lesions.[14] This may lead to the death of the fish or render them susceptible to secondary infections. After the fish die, flagellated cells transform to amoeboid stages that feed on fish remains or, if conditions warrant, further transform into dormant, benthic cysts. Sexual reproduction, including gamete fusion and planozygote formation, has been observed. Cannibalism has not been observed.

FISH HEALTH AND *PFIESTERIA*

P. piscicida has been implicated as the causative agent for about half of all fish kills in the Albemarle-Pamlico estuarine system during 1991–1993.[15] Juvenile Atlantic menhaden appear to suffer a disproportionate number of *Pfiesteria*-related mortalities for reasons not yet fully understood. Lewitus et al.[11] concluded in 1995 that *Pfiesteria* was responsible for previously unexplained fish kills in Chesapeake Bay in 1988. It is now generally accepted that *Pfiesteria* was responsible for the fish kills in the lower Eastern Shore of Chesapeake Bay in 1997.

The most characteristic association of *Pfiesteria* with fish mortalities is the presence of large numbers of fish with open, bloody sores or lesions. Indeed, the presence of a high number of dead fish with lesions has been considered not only an indicator of the presence of *Pfiesteria* but also a confirmation that mortalities are attributable to *Pfiesteria*. Toxic stages of *Pfiesteria* have also been implicated in non-lethal pathologies of fish, including lesions, and researchers have observed that fish may recover from sublethal exposure to *Pfiesteria* toxins, but with possible long-term compromise to their immune systems.

Recent research confirms, however, that lesions in fish may be the result of an organism other than *Pfiesteria*, or a combination of organisms and host factors. Blazer et al.[16] determined that a high prevalence of menhaden with ulcerative skin lesions collected from Chesapeake Bay waters in 1997 was attributable to the fungal pathogen, *Aphanomyces invadans*. While not disputing that lesions associated with dead fish in acute fish kills may well be caused by *Pfiesteria*, the authors cautioned that the presence of lesions does not necessarily mean that *Pfiesteria* is responsible, or even present.

Similarly, Evans et al.[17] found that ulcerative lesions in Atlantic menhaden collected from Delaware inland bays could be attributable to multiple factors, including immunosuppression and increased susceptibility to infectious agents. They found an association between ulceration and *Acinetobacter* spp., a bacterial pathogen implicated in human skin infections, particularly in immunocompromised individuals, and produced skin lesions in experimentally inoculated fish. Further complicating understanding of the role of *Pfiesteria* in fish kills, conditions that appear to favor *Pfiesteria* outbreaks, including nutrient enrichment in poorly flushed embayments and estuaries, are also responsible for eutrophication and associated anoxic conditions that lead to fish stress or mortality. Because of these uncertainties, the NCSU laboratory applies a conservative protocol, based on Koch's postulates, to verify *Pfiesteria* involvement in fish kills and fish lesions.

EFFECTS ON HUMAN HEALTH

Scientists working with *Pfiesteria* cultures at NCSU first became concerned about potential toxic effects on humans in the early 1990s, when lab workers exhibited a range of disturbing symptoms including sores, headaches, respiratory problems, blurred vision, nausea, short-term memory loss, and difficulty in reading. Exposure appeared to be from dermal contact with toxin-containing water or inhalation of toxic aerosols. When Maryland fishermen exhibited similar symptoms during the 1997 *Pfiesteria* outbreaks in Chesapeake Bay, Maryland health officials undertook studies to improve understanding of *Pfiesteria* toxicity and effects on humans.[18] The researchers confirmed that direct exposure to *Pfiesteria* did result in many of the dermatological, cognitive, and neuropsychological symptoms reported earlier, but the studies raised as many questions as they answered. Understanding of the human health effects of exposure to *Pfiesteria* is

Nitrogen–Plant

particularly impeded by the absence of an assay to identify the toxin or of baseline profiles on humans prior to exposure. There is also insufficient knowledge of the exposure levels that lead to toxicity; which *Pfiesteria* life history stages are implicated in toxicity; the route of exposure to the toxins; and environmental persistence of toxins.

PFIESTERIA, AGRICULTURE, AND PUBLIC POLICY

The *Pfiesteria* outbreaks in Maryland's Chesapeake Bay in 1997 raised concerns that agricultural nutrients, particularly from the abundant poultry farms on Maryland's Eastern Shore, might be responsible for the conditions that led to the outbreaks. To address this issue, an ad hoc forum of scientists was convened in 1997, under the auspices of the University of Maryland Center for Environmental Science. The forum summarized its findings in a report entitled "The Cambridge Consensus," dated October 16, 1997.[19] While the forum did not specifically implicate agriculture, it did reach the following conclusions: 1) nutrient concentrations in tidal rivers of Maryland's Eastern Shore are higher than those of other rivers with similar salinity; 2) nutrient levels had increased in those rivers over the previous 12 yr; and 3) higher than normal levels of nutrients were discharged into those rivers in 1996 and early 1997 because of unusually high precipitation and runoff. The forum also concluded, based on review of research to date, that nutrient enrichment stimulates growth of non-toxic stages of *Pfiesteria* and its algal prey, but is not required for transformation of *Pfiesteria* to toxic stages.

Circumstantial evidence further implicated poultry farming in *Pfiesteria* outbreaks. It was reported that Maryland's Eastern Shore produces 800,000 tons of chicken manure annually;[20] that agriculture contributes 70% of the nitrogen and 83% of the phosphorus discharged to rivers of Maryland's lower Eastern Shore watershed; and that the practice by poultry farmers of routinely applying chicken manure to Eastern Shore soils used for growing grain (at levels based on the crop's nitrogen requirements) results in phosphorus inputs to Eastern Shore cropland at a rate approximately twice that of phosphorus removal by grain.[21] Annual net phosphorus surpluses are temporarily stored in the soil with the potential for runoff into adjacent water bodies.

Although Burkholder and Glasgow inferred that inorganic phosphate could directly stimulate toxic zoospores of *Pfiesteria*, and indirectly promote increased production of non-toxic zoospores, there is not yet conclusive evidence of a causative link between agricultural nutrients and *Pfiesteria* outbreaks. Nonetheless, Maryland officials have adopted a conservative strategy for nutrient management on poultry farms. The Maryland Water Quality Improvement Act of 1998 requires all but the smallest farmers in the state to prepare and implement nutrient management plans, including for phosphorus management on farmland receiving animal wastes, by 2005. On-farm phosphorus management presents challenges, particularly in no-till croplands on Maryland's Eastern Shore. In these areas, soluble phosphorus tends to accumulate on the soil surface with increased susceptibility to runoff. Nutrient management plans will likely involve reduced applications of both inorganic phosphorus fertilizers and poultry manures on croplands.

Advances in animal nutrition may also contribute to phosphorus management plans. One approach is to re-formulate poultry rations to include phytase, an enzyme that increases bioavailability of grain-based phosphorus in monogastric animals (including poultry). Alternatively, development of grains with a higher content of available phosphorus would reduce the need for phosphorus supplements in poultry feeds.

FUTURE RESEARCH NEEDS

Although our understanding of *Pfiesteria* has advanced considerably since the organism was first identified, there are still major gaps in our knowledge of the organism's biology, taxonomy, toxicity, and effects on fish and human health, and of the factors that stimulate its production and toxicity. A multidisciplinary workshop held in Baltimore, Maryland on October 28–30, 1997 identified major research needs for *Pfiesteria*. Key among these were the following:

1. Develop certified "pure" cultures of *Pfiesteria*-like organisms to enable comparable and transferable research among laboratories.
2. Distinguish among species of *Pfiesteria* and related taxa.
3. Develop molecular probes to rapidly detect *Pfiesteria* and toxins, including in different life history stages, and to better determine the fate of toxins.
4. Characterize the chemical composition of toxins.
5. Improve understanding of effects of *Pfiesteria* toxins on fish and human health.
6. Improve research cooperation among scientists and laboratories.

While there has been considerable recent progress in these areas, there are still substantial gaps in our knowledge. There is also a critical need for expanded research to better understand the relationships between agricultural practices and the conditions that encourage the development of HABs in general, and *Pfiesteria* outbreaks in particular, in coastal watersheds. Improved understanding of these relationships will enable the development of sustainable and affordable agricultural management practices and tools that will reduce negative impacts of agriculture on water quality.

Nitrogen–Plant

pH

William J. Rogers
Department of Life, Earth and Environmental Science, West Texas A&M University, Canyon, Texas, U.S.A.

INTRODUCTION

The pH of a solution is a measure and indication of how acidic or basic (alkaline) the solution is. The measurement of the pH of water is one of the most important and frequently used tests in water chemistry. An understanding of water pH is vital to understanding both the limitations and benefits of a particular water supply and its use in agriculture, industry, and domestic use. The measurement of the pH of water and wastewater is essential to understanding acid–base neutralization, water softening, precipitation, coagulation, disinfection, corrosion control, and scale control.[1] The pH scale ranges from a highly acid pH 0, corresponding to a solution with $(H^+) = 1$, to a highly alkaline pH 14, corresponding to a solution with $(H^+) = 10^{-14}$. Solutions with a pH from 0 to less than 7 are considered acidic and those from above 7 to 14 are considered alkaline. Solutions with a pH of 7 are considered neutral. Pure water has a pH of about 7, alkaline paint stripper and drain cleaners range in pH from 11 to 12 and battery acid from 1.5 to 2. There are no Primary Enforceable Drinking Water standards for pH but National Secondary Drinking Water Regulations, which are non-enforceable guidelines, recommend that pH levels be maintained between 6.5 and 8.5. EPA recommends secondary standards to water systems but does not require systems to comply. However, states may choose to adopt them as enforceable standards.

In general, pH is a measure of the activity of the hydrogen ions in a solution at a given temperature. We use the term activity because it is the amount of available hydrogen ions and not the concentration of hydrogen ions. For example, in pure water (H_2O) exists as

$$H_2O = H^+ + OH^-$$

The concentrations of the H^+ and the OH^- ions are equal and the solution is at equilibrium and is neutral. The pH of natural waters typically ranges from 4 to 9 and most are slightly basic due to the presence of bicarbonates and carbonates or the alkali and alkaline earth metals.[1]

The term pH is derived from the combination of "p" for the word "power" and "H" for the chemical symbol for hydrogen. pH is expressed as the negative log of the activity of the hydrogen ions in solution at a given temperature.

$$\mathrm{pH} = -\log_{10} a_{H^+}$$

Another way to express the pH mathematically would be as follows:

$$\mathrm{pH} = \log 1/H^+$$

where (H^+) is the amount of hydrogen ions in solution in moles per liter. In our pure water example, there are 0.0000001 mol per ions of hydrogen and a corresponding 0.0000001 mol per ions of OH^-. The pH of pure water is then

$$\mathrm{pH} = \log 1/0.0000001, \text{ or } 10^{-7}$$

and is considered neutral. It is important to note that the H^+ and OH^- ions which comprise the H_2O water molecule are continuously dissociating, similar to a game of musical chairs, and there may be an excess of one or the other of the ions. This excess determines the pH or strength of the acid or alkaline solution. If there is an excess of H^+ ions to the available OH^- ions in the solution, the pH would be <7 and considered acidic. If the reverse were true then the pH would be >7 and the solution considered alkaline or basic. For example, a pH of 8 would indicate a solution with $(H^+) = 10^{-8}$ or tenfold less than a pH of 7 and a pH of 9 $((H^{-9}) = 10^{-9})$ would indicate a solution one-hundredfold less than a pH of 7.

pH MEASUREMENT SAMPLING

pH measurements must be taken in the field or as close to the sample source as possible. The equilibria in a groundwater or surface water system is altered once the sample is taken. A pH measurement taken at the moment of sampling may be representative, or very close, to conditions found in the source media. However, if the sample is placed in a sample bottle and the pH is not determined until arriving at the laboratory, the pH may not be representative of the source media. Gains and losses of carbon dioxide, and reactions such as oxidation of ferrous iron can alter the pH by a full unit[2] representing a tenfold error. Accurate measurement of pH in the field should be standard practice for all groundwater and surface water samples.[2,3] Improved field instrumentation allows the sampler to take measurements directly from the source in many cases and any unneeded sample handling should be avoided. If samples are measured in a sample container, the sampler can expect to see some drift due to changes in temperature and carbon dioxide concentrations. If it is necessary to take measurements in a sample container, especially when working outdoors, the container can be placed in a container or other shield to reduce temperature changes.

pH MEASUREMENT

Measurement of pH is possible using pH indicator or litmus paper. This method provides an approximation of pH and has limited value. The pH indicator paper is immersed into the sample and the color change is compared to a color scale that indicates the approximate pH of the sampled media. The advances in pH meters and relatively low cost of these instruments have all but replaced this well-known and time-tested technique.

pH METERS

The pH meter measures pH using potentiometric electrodes that measure changes in potential (voltage) caused by differing concentrations of Hydrogen ions. The pH measuring system consists of three elements:

1. pH electrode.
2. Temperature compensation element.
3. pH meter (simply a volt meter).

pH ELECTRODES

Electrodes must be matched to the expected pH ranges and types of materials to be measured. The sampling of surface and groundwater poses a unique challenge in that the pH range is very narrow and the media may have a very low conductivity. The electrode must be calibrated and is essential to gaining and documenting instrument accuracy. Calibration adjusts the slope and offset based on the Nernst equation and is expressed as a percentage of a theoretically perfect slope. pH buffers are used as standards to calibrate your instrument. The following buffers are considered as standards:

- pH 1.68 at 25°C.
- pH 4.01 at 25°C.
- pH 6.86 at 25°C.
- pH 7.00 at 25°C.
- pH 9.18 at 25°C.
- pH 10.01 at 25°C.

Most of these buffers also have charts that give the expected pH at various temperatures. Each pH meter will include specific calibration instructions, but ideally, a two-point calibration using two buffers that bracket the expected pH range to be measured should be used. For the best accuracy, buffers are used that are no more than 3 pH units apart. pH buffers are always discarded after use and only fresh buffers are used. The electrode calibration should fall between at least 95% and 105%. Once the calibration has been conducted, the buffers can be used to recheck the instrument.

ELECTRODE CARE AND CALIBRATION

Electrodes must be replaced periodically. To prolong the life expectancy and to assure measurement accuracy the following steps should be taken:

- Rinse the probes with distilled water and then with water from the next sample.
- Stir samples consistently but then stop to take a measurement.
- Use shields or other methods to reduce temperature and other chemical changes.
- Avoid rubbing or wiping the electrode
- Store the electrode properly in pH 7 buffer with KCL or pH storage solution.

Note: Do not store the electrode in distilled or deionized water. Field instruments typically have a field cap or sleeve to store and protect the electrode. Typically, the storage cap or sleeve will have an adsorbent material that must be periodically recharged with storage solution.

Some fresh water samples will require the use of a low resistance glass electrode or the use of a reference electrode with a fast continuous leak rate. Some level of error is introduced and another option is the use of "pure water" measurement kits. This method uses a quality glass electrode, a pure water additive to increase the ionic strength on the media, and a set of

Nitrogen–Plant

diluted buffers that are similar to the ionic background of the pure water kit additive. Since there are variations in electrodes and instrument, it is advised that one pH instrument be used for all measurements if the results are to be compared. Prior to selecting a pH meter, it is necessary to determine the expected range of pH measurements, the media to be sampled, the expected temperatures, and the application (field or laboratory).

DATA RECORDING

Prior to use, the pH meter should be checked using two buffer standards that closely bound the expected range of pH observations. The time and location of the quality control test should be recorded in the field or laboratory notebook along with the required performance for the study. Time and location of the measurements should be recorded in the field book or logbook. Both the pH and the temperature indicated by the meter should be recorded.

ACCURACY, PRECISION, AND BIAS

Advances in pH meter technology have resulted in advertised field instrument accuracy (ability to measure a known concentration or standard) of ± 0.01 pH unit which is highly optimistic. Commercially available pH standards are typically available within 0.01 units, so it is very difficult to verify accuracy at less than 0.05 units and under most field conditions to much less than 0.02 pH units in the laboratory. More precise standards can be prepared in the laboratory[1] and instrument precision (ability to reproduce similar results) can be improved under controlled conditions. However, ± 0.1 pH units would be the expected accuracy under normal conditions. A synthetic sample of a Clark and Lubs buffer solution of pH 7.3 was analyzed by 30 laboratories with a resulting standard deviation of ± 0.13 pH units.[1] Based on these results and expected difficulties in measurement of water and poorly buffered solutions, reporting to the nearest 0.1 pH unit is advised. pH probes on potentiometers require continuous care and are subject to damage, especially if the probes are not well maintained. Therefore, it is critical that the pH meter be calibrated and checked prior to each usage.

CONCLUSION

The measurement of pH is essential in all water investigations. pH measurement in drinking and surface water poses a unique challenge due to narrow range of expected values. An understanding of pH is essential to the understanding of nutrient, contaminant transport, and response by susceptible species.[4] Species response to significant changes in pH typically cannot be attributed to that single environmental factor but may be a result of secondary effects such as the toxic levels of metals such as aluminum.[4,5]

Buffering capacity of the geological formations and surface and groundwater can also have a significant effect on the biological effects of such facts as acid rain or other factors that influence water pH levels. The importance of accurate pH measurement in all water measurement activities cannot be overemphasized.

Pharmaceuticals in Water Supplies

Klaus Kümmerer
Institute of Environmental Medicine and Hospital Epidemiology, University Hospital Freiburg, Freiburg, Germany

INTRODUCTION

Pharmaceuticals are applied in human and veterinary medicine and are excreted in urine and feces. The unchanged drugs or (still active) metabolites excreted by humans and animals end up in sewage and manure (Fig. 1). Unused medicines are sometimes disposed of down drains. Within the last decade, pharmaceuticals have been detected in sewage, surface water, ground water, and drinking water. This indicates that they are not fully eliminated by sewage treatment or in the aquatic environment.[1–4] We describe the occurrence, fate, and effects of pharmaceuticals in the aquatic environment.

SOURCES

Human Medicine

Pharmaceuticals, used in medicine, and their metabolites enter municipal sewage and sewage treatment plants (STPs). If the drugs and their metabolites are not eliminated during treatment, they can enter the aquatic environment and eventually reach drinking water (Fig. 1). Unused medicines are sometimes disposed down drains thus also ending up in effluent. The world wide use of antibiotics alone is estimated to be about 100,000 metric tons per year.[5] In general, the volume emitted by households owing to the use of pharmaceuticals outside hospitals is higher than that released by hospitals. Because of good manufacturing practice regulations, which apply to producers, emissions during manufacturing are probably low and occur locally in the event of an accident.

Many pharmaceuticals are biotransformed in the body. Metabolism in humans and animals and transformation in the environment modify the chemical structure of the active molecules, which, in turn, often results in a change in their physical-chemical and (eco) toxicological properties. Metabolism may lower activity or enhance water solubility; however, metabolism is frequently incomplete. Excretion rates range from 0% to 100%. There are two important pathways of metabolism. Phase I metabolites result from the modification of the active compound itself by hydrolysis (e.g., of ester bonds), oxidation, reduction, alkylation, and dealkylation. Phase II metabolites are phase I metabolites that have been modified by glucuronation or sulfatation (“coupling reactions”) to enhance excretion.

It has been assumed that approximately one-third of the pharmaceuticals sold in Germany and about 25% of those sold in Austria are disposed with household waste or down the drain. In the Netherlands, 8.3% of the pharmaceuticals prescribed are not used.[3] The compounds that are disposed with household waste end up on landfill sites. They can enter the landfill leachate. Pharmaceutical compounds have been detected in ground water near landfills and pharmaceuticals have been measured in the effluent from landfills.

Veterinary Medicine and Animal Husbandry

Drugs administered to animals are excreted in pure form or as metabolites.[6] Manure collected from large-scale livestock and farming operations is often spread on crop fields. That practice creates the opportunity for drugs and metabolites to enter surface water or groundwater resources via surface runoff and deep percolation. The wash off from topical treatment of animals (e.g., sheep) can enter soil or ambient waters directly. Compounds that enter the soil can perculate to ground water if they are not eliminated by sorption or degradation. Pharmaceutical use in aquaculture can degrade soil and water quality directly.

Occurrence and Fate in the Environment

Detailed investigations into the occurrence, fate, and effects of pharmaceuticals in the environment are available for several countries, mainly in Europe and North America.[1,2,4] Medical substances have been detected in the effluent from medical care units, municipal sewage, and the influent and effluent of STPs, in surface water, ground water, and in drinking water production (Table 1). More than 150 different

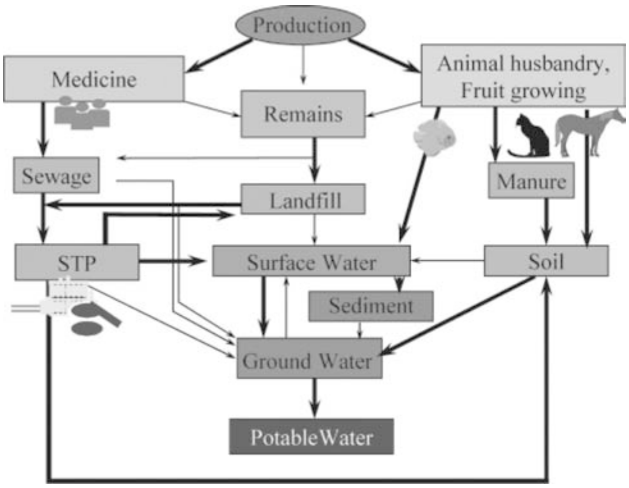

Fig. 1 Sources, distribution, and sinks of pharmaceuticals in the environment. *Source*: From Ref.[1].

drugs have been detected in sewage and in the aquatic environment.

The concentration of pharmaceuticals in water decreases only slightly along the way from STPs to ground water and drinking water.

Evidence suggests that the active substances of many pharmaceuticals are not completely eliminated during sewage treatment, or in the aquatic environment, or in the terrestrial environment.[1–4]

The active compounds often exhibit good water solubility because of their high polarity. Some are highly mobile in the aquatic environment, while others such as fluoroquinolones, tetracyclines, or mitoxantrone tend to sorb onto environmental matrices such as sewage sludge, sediments, particles in the water body, or in soils. The predominant processes by which pharmaceuticals are attenuated in the environment are sorption (e.g., quinoloness and tetracyclines) and degradation. Pharmaceutically active compounds often are molecules with different chemical functionalities within the same molecule. Under environmental conditions, these molecules can be neutral, cationic, anionic, or zwitterionic. Zwitterions are electrically neutral, i.e., the sum of charges is zero but they carry positive and negative charges at the same time. At pH values below and above this isoelectrical point, the molecules carry a net positive or negative charge. In other words, compared to most bulk chemicals, pharmaceutically active compounds are often complex molecules with special properties, e.g., dependence of log K_{ow} on pH.

EFFECTS

The active ingredients of medications have been selected or designed to act against organisms. The following properties influence their environmental impacts:

1. Effectiveness against bacteria.
2. Effectiveness against fungi.
3. Effectiveness against (non)target higher organisms.
4. Persistence.

Some compounds have effects in environmental organisms below the microgram per-liter-range. Hormones are bioactive in very low concentrations. Little information is available on the long-term effects of active substances in low concentrations on organisms in the aquatic and terrestrial environment. Effects on fish, Daphnia, algae, and bacteria have been demonstrated in low concentrations in chronic tests.[7]

Resistance

Antibiotics in subinhibitory concentrations can affect cell functions and change the genetic expression of virulence factors or the transfer of antibiotic resistance. In vitro experiments have shown that gentamicin in a concentration of 100 μg/L increases the transfer rate of resistance in staphylococci but does not select resistant bacteria. Other substances such as macrolides, quinolones, or vancomycin do not have such impacts.[8] The overall significance of antibiotics in the environment is still not clear.[9]

RISK AND RISK MANAGEMENT

The risk of adverse effects on humans through the ingestion of pharmaceuticals contained in drinking water seems to be negligible. The maximum possible intake within a life-span (2 L of drinking water per day over 70 yr) is far below the dosages used in therapy. Thus, the risks posed to humans from pharmaceuticals in the environment seem to concern environmental hygiene rather than toxicology and pharmacology. However, extrapolating effect data from high dose short-term ingestion during therapy to low dose long-term ingestion, i.e., ‘‘medication’’ via drinking water is still an unresolved issue both in toxicology and in ecotoxicology. Furthermore, assessments have so far been undertaken for single substances mostly and not for groups of similar acting compounds, or for mixtures of compounds from different groups such as antibiotics and cytotoxics. Such interaction is known from medical literature. Some of the compounds have carcinogenic, mutagenic, or reproductive toxic effects.

Table 1 Typical concentration ranges of pharmaceuticals in sewage and in the aquatic environment[a]

Water body/ concentration	>10,000 ng/L	>1,000 ng/L	>100 ng/L	>10 ng/L	<Detection limit
Hospital effluent	Antibiotics, antiepileptics	Cytotoxics			
Influent sewage treatment plant[b]	Analgesics	Cardiovascular active compounds, antiepileptics, cytotoxics			
Effluent sewage treatment plant[bc]	Iodinated x-ray contrast media	Cardiovascular active compounds, antiepileptics, analgesics, antibiotics	Antibiotics, iodinated x-ray contrast media	Cytotoxics	
Surface water	Iodinated x-ray contrast media	Cardiovascular active compounds, antiepileptics, analgesics, antibiotics, antidepressants		Cytotoxics	Antidepressants
Ground water		Cardiovascular active compounds, analgesics, iodinated x-ray contrast media			
Drinking water production			Analgesics, antiepileptics, iodinated x-ray contrast media, antibiotics	Cardiovascular active compounds	

[a]Most important groups are shown; analytical procedures for the detection of pharmaceuticals are available for about 150 compounds.
[b]Sometimes only one compound out of the group was detected, sometimes several. Detection limits are different; mostly they are in the range of 10–100 ng/L.
[c]The number of studies for effluents is about threefold those for influent.

As a means of risk management it has been proposed that sewage treatment plant effluent should be treated using (photochemical) oxidation processes, filtration, and reverse osmosis. However, none of these methods eliminates all compounds. The toxic properties of the resulting transformation products are not yet well assessed. Furthermore, additional advanced treatment will increase the cost of sewage treatment. It might be cost-effective to prevent the input of such compounds by prudent practice.

CONCLUSIONS

Pharmaceuticals are present in the aquatic environment. Concentrations are generally in the nanogram–microgram per litre range, which is below the therapeutical effect threshold.

However, knowledge on their effects and our understanding of such low environmental concentrations are poor. Risk assessments are based on the assumption that short-term high-concentration intake, i.e., within therapy, is comparable to the intake of a low concentration over a lifetime. Compounds that deserve our attention most are hormones owing to low effect thresholds, antibiotics, because they contribute to resistance and cytotoxics, owing to their mutagenic and carcinogenic properties.

The input of pharmaceuticals into the environment can be reduced by implementing prudent use and proper disposal. In the long run, pharmaceutical effectiveness can be improved and degradation properties could be enhanced.

Phosphorus: Inputs into Freshwater from Agriculture

Richard McDowell
AgResearch Ltd., Invermay Agricultural Centre, Mosgiel, New Zealand

INTRODUCTION

Eutrophication, the unwanted growth and die off of aquatic weeds and algae, is a major water-quality concern worldwide. Its economic impact on the fishing and water-treatment industries, in the eastern United States alone, have amounted to $2 billion in 10 years. Over the last 30–40 years, attention has centered on agriculture as the primary source of P loss to surface waters with P being a limiting nutrient for eutrophication. This attention is due to the identification and mitigation of point sources, and the intensification and specialization of farming. However, at the same time, as mitigating point sources of P losses, more than twice as much P has been applied to agricultural land than removed in crop grain or produce. Now many farms possess soil P concentrations well in excess of plant needs, resulting in an increased potential for loss. For the impact of P loss to be minimized, mechanisms must be understood and management must be adjusted accordingly.

LAND USE

Surveys of several watersheds have shown that P loss in runoff (overland and subsurface flow combined) increases as the portion of watersheds under forest decreases and agriculture increases.[1] Overland flow or surface runoff from forests, grasslands, and other non-cultivated land carries with it little sediment, so P losses are low and generally dominated by dissolved P, which is immediately algal-available[2] (Fig. 1). The cultivation of agricultural land greatly increases erosion, and with it, the loss of particle-bound P. Typically, particulate losses constitute 60–90% of P exported from most cultivated land.[2] Some of the particle-bound P is not readily available, but much of it can be a long-term source of P for aquatic biota.[3]

MECHANISMS OF P LOSS

In an agricultural landscape, P loss is greatest in areas where P is concentrated and water movement regularly occurs. Availability of P to water flow is determined by soil, crop, manure, and fertilizer management, while loss only happens if water flow (overland or subsurface) occurs. Areas where both high source and transport potential coincide are termed "critical source areas" (CSAs). These CSAs are usually small (<20% of land area) but can contribute most of the P exported from a watershed (90%).[4]

Availability and Release of P

In soils, P is associated with Al, Fe, Mg, and Ca. Aluminum- and Fe-P dominates as pH decreases, while Mg- and Ca-P dominate as pH increases. Organic P can form a significant part of soil P especially in acidic soils and soils that contain much organic matter. Compared with inorganic P, organic P is less available to aquatic organisms. However, organic P is an important source of P, which can be converted to orthophosphate by aquatic biota via phosphatase enzymes. In general, as P accumulates in the soil, more of it becomes available to flow. This is usually evident by a curvilinear (e.g., exponential) increase in water-soluble P or P loss in flow relative to soil test P (STP; e.g., Bray, Mehlich, or Olsen).

The rate at which dissolved P can come into flow will determine the P concentration in flowing water. Kinetic exchange experiments using ^{33}P have confirmed that P exchangeable within 60 sec is closely related to P in overland or subsurface flow. With time, P transport in overland flow becomes less related to this pool and more dependent on the slow diffusion of P from the inside of the soil aggregate.[5] Overall, soil P release to flow is a function of the surface area and the quantity of available soil P. Holford and Mattingly[6] showed that in near-neutral pH soils, P release and sorption were correlated to $CaCO_3$ surface area, but not to total $CaCO_3$ concentration.

Phosphorus fertilizer and manure management can greatly increase P losses. Kleinman et al.[7] showed that surface application of several manures, composts, and diammonium phosphate increased dissolved reactive (<0.45 μm) P in overland flow by 4–26-fold from unamended soil, and shifted P loss from particulate (90% in unamended soil) to dissolved (60% in amended soils) forms. Surface application of manure and mineral fertilizer concentrates P at the soil surface, where it is vulnerable to loss by overland flow. Depending on rainfall intensity and slope gradient, the depth of

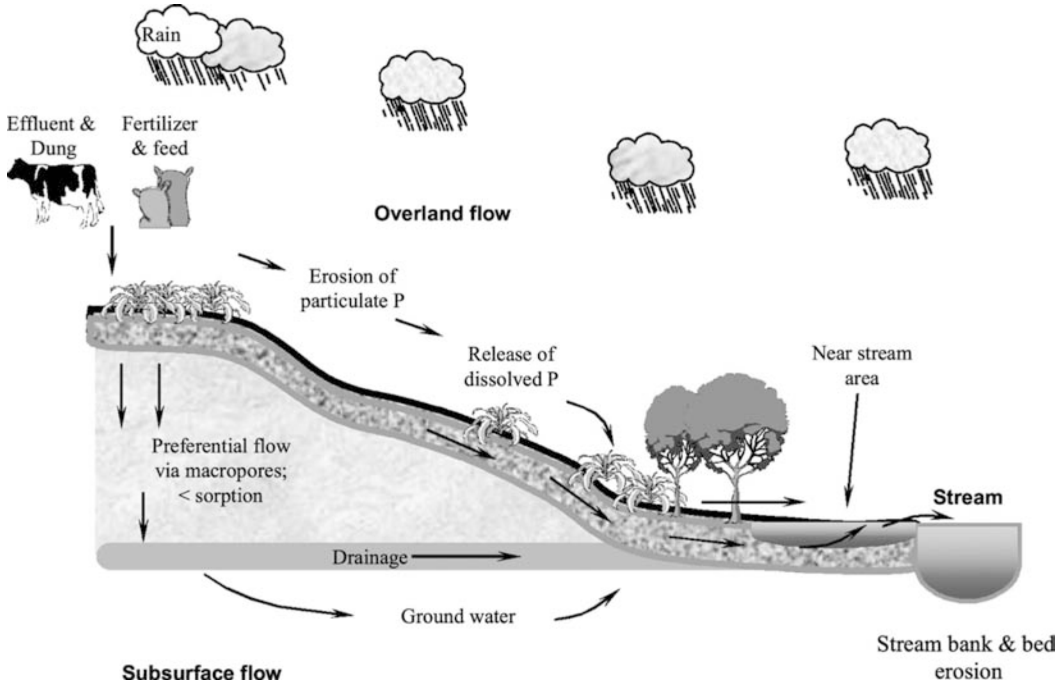

Fig. 1 Mechanisms of P loss from agricultural land to surface waters.

topsoil interacting with overland flow varies from c. 1 to 40 mm.[8] By injecting or knifing-in manure, P loss can be greatly deceased. In addition, by increasing the time between application and likely flow events, P loss can be further decreased. Following application, potential P loss is greatest and declines exponentially with time as P interacts with soil and is converted to more recalcitrant forms.[9]

While large manure application rates may increase soil-available P, additions maintaining STP within the range of plant responses (i.e., not in excess) may increase soil organic matter, may affect porosity, aggregate stability, infiltration, and, overall, may decrease P loss.[10]

The Transport and Loss of P

Volume of runoff, especially overland flow, will dictate the load of P lost from the landscape. Rainfall is the primary driving force behind P transfer, although some movement of P via wind erosion is also likely to occur in some regions. Increased net precipitation (precipitation–evapotranspiration) to a watershed increases the amount of discharge and the quantity of P lost by accelerating those transformations that occur before and after P reaches stream flow. Runoff from rainfall events can be divided into subsurface and overland flow (Fig. 1), depending on watershed characteristics (e.g., slope, soil type). Consequently, the locations of CSAs can vary with space and time. Some naturally wet areas, such as near-stream areas, are CSAs that can be actively losing P for much of the year and require targeted management.

Because of the greater kinetic energy and erosive power of high-frequency storms, more P is lost during overland flow in particulate forms than in subsurface flow. Although some subsurface flow pathways may be important under certain hydrological conditions, loss of P in subsurface flow is generally less than in overland flow, and decreases as the degree of soil–water contact increases, as a result of P sorption by P-deficient subsoils.[11] Exceptions occur where organic matter accelerates P loss together with Al and Fe, where the soil has a small P sorption capacity (e.g., some sandy soils), or where subsurface flow travels from P-rich topsoil via macropores or is intercepted by artificial drainage (Fig. 1).

During overland flow, soil and associated P are lost in order of increasing particle density and weight, while the opposite occurs for deposition during overland flow.[12] Thus, fine and/or light soil particles that contain many Al- and Fe-oxides and associated P or humic-associated P are transported before coarser and/or heavier sized particles. Eroded fine particles will be able to maintain P in flow for longer than coarser particles with less P in reserve. However, the concentration of P in water in equilibrium with fine particles can be much less (relative to the total concentration of P in the particle) than from coarse particles, which have a lower affinity for P and will release it faster.[13] Recent evidence suggests that the majority of concentration change during overland flow may be due to deposition and dilution, except in soils with a recent surface application of manure where most P is transported in light particulate organic matter, whose concentration varies little during flow.[13]

MANAGEMENT TO DECREASE P LOSS

Inputs of P from agricultural land to surface waters can range from 0.01 to 30 $kg\,ha^{-1}$. Depending on the eutrophic state (e.g., pristine-oligotrophic to severely impacted-hyperuutrophic), characteristics (e.g., bedrock), and dynamics of the receiving water body, even small amounts of P can induce a trophic response, whereby water quality as a result of eutrophication would either improve or decrease. However, linkages between CSAs and trophic responses across scales are uncertain, making critical P concentrations unclear. Consequently, management should be directed at decreasing P loss by as much as possible.

Effective management ultimately aims to balance P inputs with P removal in grain crops or produce at the farm gate. However, in areas of concentrated animal production, sufficient land may not be available for manure disposal, leading to an increase in soil P concentration.

Efficient management of P sources involves placing P away from CSAs that are likely to loose much P. Cultivation immediately after P application can decrease P losses if erosion is minimized. Periodic tillage of the soil may also decrease P loss by redistributing high-P topsoil throughout the root zone. As discussed, maximizing time between P application and rainfall events will decrease P loss. Furthermore, application of poorly water-soluble or slow-release fertilizers may help in situations where P application is likely to be soon followed by a rainfall event. The presence of crop covers and crop residues help decrease P loss by decreasing erosion and overland flow. Equally, anything that keeps surface roughness high or intercepts overland flow and encourages infiltration and sediment retention can be effective. Such measures include riparian zones, buffer strips, terracing, cover crops, contour tillage, and impoundments or small reservoirs. However, these measures are better at stopping particulate than dissolved P transport.

Other remedial measures include additives for manure to decrease P solubility and potential release to runoff, supplying animals with no more P than they actually need either in feed or supplements, use of soil testing to guide future P application (particularly as manure), identifying CSAs to target conservation measures, and redistribution of manure within and among farms.

CONCLUSION

The loss of P from agricultural land varies with use, management, watershed characteristics, and climatic variables. Although the amounts lost can greatly vary, a better understanding of the mechanisms behind P loss would allow for more targeted management that will enable agriculture to have less impact on surface water quality.

INTRODUCTION

Phosphorus (P) is an essential nutrient for growth and development of algae and other aquatic plants. However, P can cause water pollution if sufficient concentration (25–100 μg total P L^{-1}, eutrophic condition) is present in water. Eutrophication (nutrient-rich condition) can significantly increase growth of aquatic plants, algae, and sometimes strains of algae that cause taste, odor, or toxicity problems for drinking water supplies. During the night, when there is no photosynthetic activity to renew oxygen supplies for the dense concentrations of living cells, dissolved oxygen levels may become so depleted that fish and other aquatic animals cannot survive. Furthermore, many of the blue–green algae that cause the most serious water-quality problems require P inputs to grow and flourish, but they do not need high concentrations of N in lake water because they are able to utilize atmospheric N. Accelerated eutrophication of lakes, streams, and coastal waters remains a serious problem and has grown worse in many regions. Therefore, management plans for minimizing eutrophication should be designed to limit P inputs to surface water. Phosphorus occurs in water in many different forms that need to be evaluated to identify the overall effects of P on water quality. These include dissolved, bioavailable, particulate, and total P. Measuring these P forms in water is critical for distinguishing among them and assessing their effects on water quality.

PHOSPHORUS FORMS IN WATER

Dissolved P

Dissolved P is primarily the P fraction in the orthophosphate forms ($H_2PO_4^-$ and HPO_4^{2-}), which are immediately available for algae and plant uptake. Measuring this P fraction is important in determining the eutrophication potential of the water since dissolved P is a major portion of algae-available P (bioavailable P) in water. Dissolved P concentrations as low as 0.01 mg L^{-1} of lake water have been suggested as critical levels that can accelerate the eutrophication process in some relatively pristine lakes.[1] However, keeping runoff levels below 1 mg L^{-1} can help maintain acceptable levels of water quality in many lakes, streams, and coastal estuaries.

The dissolved P fraction can be conveniently separated from suspended P fractions by passing the water sample through a membrane filter (0.45 μm pore diameter) immediately after sample collection. Although this technique may not completely separate dissolved P from suspended P, it is easily replicated and provides a clearly defined analytical separation. Dissolved P in water is determined without any preliminary hydrolysis or oxidative digestion of the water sample. Samples should be kept refrigerated (4°C) and analysis is recommended within 48 hr, unless the sample is stored frozen at temperatures below −10°C. Also, low concentrations of dissolved P may be adsorbed onto plastic bottles, so acid-washed glass bottles are recommended unless the sample is to be frozen.[2] The molybdate colorimetric test used to determine dissolved P concentration in water is based on the fact that dilute orthophosphate solutions react with ammonium molybdate and potassium antimony tartrate in an acid solution to form an antimony-phospho-molybdate complex. When this complex is reduced by ascorbic acid, it takes on an intense blue color that is proportional to orthophosphate concentration.[3] Analytical procedures and additional information for the modern molybdate colorimetric test, including techniques for automated analysis, can be found in a standard methods textbook.[2]

Bioavailable P

A laboratory test for bioavailable P (BAP) measures the amount of dissolved plus the fraction of particulate P in water that is available for algae uptake,[4] and is an excellent indicator of the eutrophication potential of P in water. Briefly, a filter paper circle (5 cm diameter) with small pores (e.g., <5.0 μm) is immersed into a solution containing 10 g $FeCl_3 \cdot 6H_2O$ O in 100 mL distilled water. The filter papers are then air-dried and immersed for a few seconds in 2.7 M NH_4OH solution to convert $FeCl_3$ to Fe oxide. This iron-oxide filter strip has been shown to closely mimic the ability of algae to take up P in water. BAP in a water sample (50 mL) is then determined by shaking the sample with an iron oxide filter strip for 16 hr at 25°C on an end-over-end shaker. Phosphorus retained on the strip (BAP) is removed by shaking each strip with 40 mL of 0.1 M H_2SO_4 for 1 hr. Following neutralization, P is measured by the method of Murphy and Riley.[3]

There is a high correlation between BAP and dissolved P in runoff water from agricultural fields, and dissolved P comprises most of the BAP (Fig. 1). Since BAP in water is immediately available for algae uptake, the test would provide an indication of the eutrophication potential of the water body in the immediate future.

Total P

Total P in water provides an indication of short- and long-term water pollution potential. The United States Environmental Protection Agency (USEPA) has established total P concentrations of 25–100 $\mu g\,L^{-1}$ as critical levels for eutrophication of surface water. Total P consists of dissolved P and particulate P with dissolved P being an immediate concern and particulate P being a long-term P pollution concern.

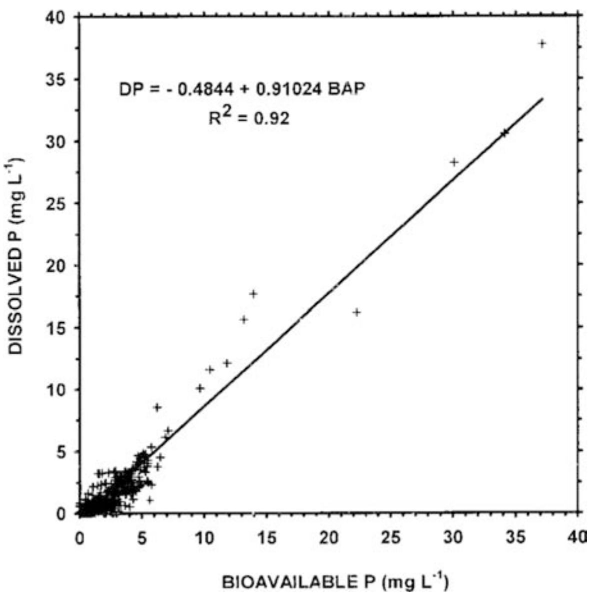

Fig. 1 Relationship between dissolved P and bioavailable P in runoff from fields with grain sorghum and winter wheat residues and receiving manure and fertilizer application. *Source*: From Ref.[5].

To determine total P concentration in water, an unfiltered water sample should be shaken to suspend any particulate matter immediately prior to measuring a subsample for analysis. Water samples for total P analyses can be frozen at temperatures below −10°C for long-term storage, or acidified (using HCl or H_2SO_4) to pH <2 and refrigerated (4°C) if analyzed within one month. Total P concentration in a water sample can only be determined colorimetrically when all P compounds (organic, condensed, and particulate) have been hydrolyzed to orthophosphate forms so that they will react with the molybdate reagent. This can be accomplished by several published methods, but they all require the use of heat and/or various strong acids to digest the water sample, thus oxidizing organic compounds and releasing the P as orthophosphate. Some methods also require strong oxidizing agents and thus may be dangerous. For example, perchloric acid digestion[6] is still known as a standard method for oxidizing resistant P compounds in water, but the heated mixture of $HClO_4$ and organic matter may react rapidly enough to produce a violent explosion unless organic matter is predigested. Preferred methods are sulfuric acid–nitric acid digestion, generally considered the most reliable procedure for potentially difficult samples, or persulfate digestion, which is simpler to use and provides good P recovery rates for most samples. Regardless of digestion method, at least 25 mL of shaken, unfiltered water sample should be digested if a large enough sample volume is available. Larger volumes (e.g., 100 mL) are recommended for digestion if the water sample is exceptionally clean and low P concentrations are expected. If total dissolved P is the only fraction of interest, then the water sample can be passed through a membrane filter (0.45 μm pore diameter) to remove particulate P before initiating a digestion process.

Sulfuric acid–nitric acid digestion takes several hours and may require the addition of at least one drop of 30% sodium peroxide to clarify relatively dirty samples during the digestion process so that residual color does not interfere with spectrophotometer analysis. Details of sulfuric acid–nitric acid digestion, persulfate digestion, and other methods, including techniques for automated versions of the P analyses are described in Ref.[2].

Particulate P

Particulate P consists of P fractions that are bound to soil particles and organic matter. This fraction is determined as the difference between total P and dissolved P in water. A small part (bioavailable particulate P) is immediately available to aquatic plants, but most particulate P must go through a chemical or biological reaction to become plant-available. Soil erosion increases particulate P in surface runoff, so reducing soil erosion is an important factor in minimizing particulate P loss. Particulate P can be a long-term environmental concern as the sediment-bound or organic P may eventually become available as dissolved P for algae uptake. Particulate P usually constitutes a major portion of total P in runoff from tilled soils, but a relatively minor P component in runoff from pastures, rangelands, and forests. Particulate P normally settles in the bottom of a water body, but can slowly release P to the overlying water. The sediments act as a P sink under aerobic conditions, but as a P source under anaerobic conditions.[7]

CONCLUSION

Phosphorus is an essential plant nutrient but excessive amounts can cause water quality deterioration. Measuring different forms of P in water can aid in determining the extent of short- and long-term water quality concerns. Dissolved and bioavailable P components are immediate water quality concerns as they are readily available for uptake by algae and other aquatic plants. Particulate and organic P fractions can cause water quality concerns over the long-term as P is slowly released in plant available forms to the surrounding water body. Total P consists of soluble plus particulate P and is an important component of water pollution assessment. The USEPA uses total P concentration as an indicator of eutrophication potential of surface water.

INTRODUCTION

The role of phosphorus (P) inputs in accelerating eutrophication of freshwaters is well documented.[1] The total load of P to a river can broadly be divided into point source inputs, typically dominated by sewage treatment effluents, and diffuse sources, often dominated by agriculture.[2,3] There is a general increase in P transport in the order of rivers draining forested–native ecosystems, intensively managed agriculture, and urban settings.[4] Point sources enter the river more continually through the year than do non-point sources, which are subject to large seasonal variation, typically as a function of overland flow.[5]

Changes in the forms and amounts of P during transport in streams and rivers can greatly influence the eventual impact of P loss on the degree of eutrophic response of receiving waters.[5,6] These changes are mediated by physical (sediment deposition and resuspension and flow regimes), abiotic (P sorption and desorption), and biotic (microbial and plant uptake) processes.[7,8]

RIVERINE PROCESSES

Physical Processes

Fluvial sediments are derived from the erosion of surface soils, gullies, ditches, and stream banks. Because surface soils generally contain the highest concentration of P in soil profiles, and erosion preferentially removes P-rich particles, eroded surface soil represents a major source of particulate P in riverine systems.[9,10] In areas with recent gully formation or bank erosion, subsoil is the dominant source of sediments. Consequently, sediments derived from these sources have low P content and high P sorption capacities.[11,12] As P release and sorption are largely related to particle size, with coarser-sized particles releasing P more readily than fine particles, which tend to sorb more P,[13] hydrologic processes controlling sediment particle size distribution have important implications to P fate in river systems.

Abiotic Processes

In fluvial systems with good hydraulic mixing (such as shallow flowing streams), P movement between sediment and water phases is mediated by the equilibrium P concentration at zero net sorption or desorption (EPC_0); P is released from sediment if the concentration of P in stream flow is less than its EPC_0, while the reverse is also true.[14] Other processes influencing sediment P release include a rise in stream water pH, P from dead phytoplankton, periphyton, or macrophytes, the hydrolysis of organic P species, and changes in sediment crystallinity and oxidation/reduction.[9,15] For example, the potential of stream sediments or bank material exposed to wetting–drying cycles causes a change in Fe-oxide crystallinity making P less easily released.[16,17]

BIOTIC PROCESSES

Uptake of P by aquatic biota can decrease dissolved P in the water column,[18] while bacteria can mediate a sizeable proportion of sedimentary P uptake and release (30–40%).[19,20] Biologically controlled P release during the decomposition of organic matter in sediments can be an important source of dissolved P at times of high temperature and low flow in areas with organic-rich sediments, such as streams draining forests.[21] Organic matter in sediments may also increase the blooms of bacteria and algae by preventing chelator limited growth.[22] The effect of biotic processes on riverine P transport varies greatly, reflecting seasonal cycles, management of stream-side land, sediment P forms, size of flow event, and streambed geology. However, during elevated flow, when P loads are often high, biotic processes have less effect on EPC_0, and physical and abiotic processes dominate.

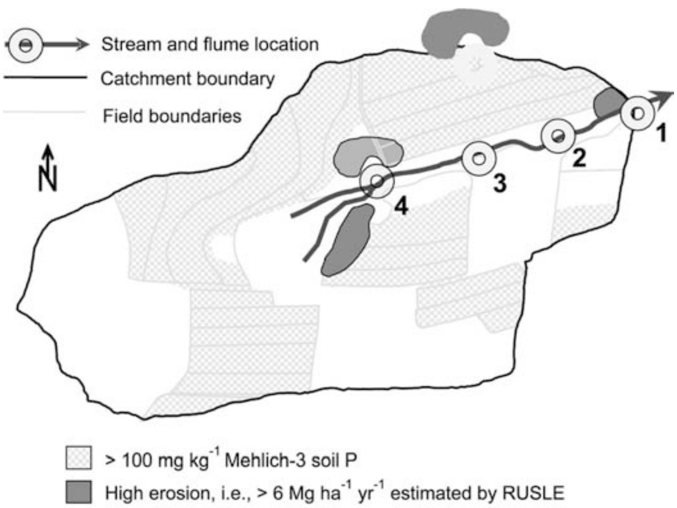
Nutrient Spiraling

The concept of P-spiraling, or the distance traveled downstream by one P molecule as it completes one cycle of uptake and transformations from dissolved to organic forms and back into flow, reveals significant information about the degree to which P changes during transport in rivers.[23] Lengths of P-spiraling vary from 1 to 1000 m, as a function of flow regime, season, bedrock geology, and sediment characteristics.[24,25] Similarly, interaction of ground water with stream flow within the hyporheic zone can cause increases or decreases in P concentrations depending upon streambed upwelling or infiltration of P-rich stream flow.

INTEGRATING RIVERINE PROCESSES AND LAND USE IMPACTS ON P TRANSPORT

The effects of riverine processes on P transport are illustrated by McDowell, Sharpley and Folmar[26] They found dissolved P concentrations in base flow increased from 28 to 42 $\mu g\,L^{-1}$ as one moved downstream in a 40-ha, agricultural watershed (Fig. 1). Base flow P concentrations were controlled by channel sediment P sorption (532 $mg\,kg^{-1}$ at flume 4 and 227 $mg\,kg^{-1}$ at the outlet) and EPC_0 (4 $\mu g\,kg^{-1}$ at flume 4 and 34 $\mu g\,kg^{-1}$ at the outlet). Storm flow trends were the opposite, with P concentrations decreasing downstream (304 $\mu g\,L^{-1}$ at flume 4 and 128 $\mu g\,L^{-1}$ at flume 1) due to the dilution of P derived from a critical source area, i.e., an area of high soil P and high erosion/runoff above flume 4 (Fig. 1).

In a much larger watershed, McDowell, Sharpley and Chalmers[6] examined the processes controlling sediment P release to the Winooski River, VT, the largest tributary to Lake Champlain (Fig. 2), revealing the complex interactions of local sources of P, sediment properties, and flow on riverine P transport. Input and delivery of fine sediment enriched with P was influenced by surrounding land use. Algal-available P of river sediments near agricultural land (3.6 $mg\,kg^{-1}$) was greater than that of sediments near forested land (2.4 $mg\,kg^{-1}$) (Fig. 2). Over the short term, river flow and sediment physical properties were responsible for particulate P loadings from the river to Lake Champlain. However, deposition of sediments downstream, near the outflow into Lake Champlain, resulted



Flume	Dissolved P		Stream sediment	
	Stormflow	Baseflow	P sorption max	EPC_0
	$\mu g\,L^{-1}$		$mg\,kg^{-1}$	$\mu g\,L^{-1}$
1	128	42	227	34
2	174	36	295	13
3	202	37	330	4
4	304	28	532	4

in a large pool of stored P within the river system. Over the long term, this pool is likely to release dissolved P to overlying waters.

DEFINING P-RELATED IMPAIRMENT IN FLOWING AND LAKE WATERS FOR TARGETED REMEDIATION

In order to prioritize and target watershed remediation to minimize P losses, water impairment must be quantified.[27] Background levels (i.e., regional nutrient criteria) of total P, total N, chlorophyll-*a*, sediment, and clarity in pristine surface waters are used as benchmarks for a given geographical area (Fig. 3).[28,29] While these criteria have regulatory applications under the Clean Water Act, they can also be used for voluntary planning and evaluation purposes.[30] These criteria are available for freshwater systems in the continental United States (Table 1). Similar approaches have been taken in Australasia and Europe.[3,31] In the European Union's Water Framework Directive, biological parameters are, however, the basis for measuring ecological status for the water with chemical parameters used only as support parameters. The E.U. classification system emphasizes if the ecosystem is in ecological balance and points out the effect of the pollution rather than providing a classification or ranking according to pollutant

concentration, which has been the basis for most previous classifications systems.

IMPLICATIONS TO WATERSHED MANAGEMENT

Aquatic ecosystems respond to P inputs on the basis of factors related to their physiography and flushing rates. Individual systems respond to discrete and sustained P inputs differently, and, indeed, it may not be possible to attain P loadings low enough to prevent periphyton blooms because of, for example, natural enrichment from P-rich rocks.

A certain degree of eutrophication can be beneficial. For example, fishery management often recommends a higher productivity to maintain an adequate phytoplankton–zooplankton–fish food chain for optimum commercial fish production. This food chain may be manipulated by stocking of water with certain fish species in addition to P load reductions, in efforts to reduce the incidence of algal blooms and improve overall water quality.[32]

CONCLUSION

Clearly, several interdependent riverine processes influence the amounts and forms of P transported from edge-of-field agricultural sources to the point of impact (i.e., river, lake, reservoir, and estuary). These processes will thus be critical in defining agricultural source management and in determining eutrophic response, and without information on the direction and magnitude of change in P transport in river systems, best management practices will not efficiently remediate against impairment of receiving waters.

Plant Water Stress: Exposure during Specific Growth Stages

Zvi Plaut
Volcani Center, Institute of Soil, Water and Environmental Sciences,
Agricultural Research Organization (ARO), Bet-Dagan, Israel

INTRODUCTION

Many yield determining physiological processes in plants respond to water stress. Most of these processes are dynamic and their activities may fluctuate with time according to internal and external factors. Yield integrates many of these physiological processes in a complex way and it is, thus, difficult to interpret how do plants accumulate, combine, and display the ever-changing and indefinite physiological processes over the entire life cycle of the crop. Moreover, as far as water stress is concerned, severity, duration, and timing of stress, as well as responses, which may take place after stress removal, and interaction between stress and other factors may be extremely variable. It would thus be very inconceivable, from a practical point of view, to study the response of physiological processes to the dynamic changes in plant water stress and accordingly conclude how the final yield will respond. The more pragmatic approach for determining the response of plant productivity to dynamic changes in water stress should thus be based directly on the yield or its components.

The timing of plant water stress, which is mostly the result of drought, and lack of available soil water, can either extend throughout the entire growth period or during specific stages of growth. The effect of stress during such stages on final yield is outlined in another article of this book.

HOW CAN CROP SENSITIVITY OF SPECIFIC STAGES BE EVALUATED?

The main objective in the determination of sensitive and insensitive growth stages is saving of irrigation water. This can be obtained either by withholding irrigation (or a sharp decrease in the amount of water applied) during insensitive growth stages, or by a slight but extended exposure of plants to water stress. The two approaches ought to be compared prior to making any conclusions concerning timing and quantities of water to be applied. In spite of the numerous studies on sensitivity of a wide range of crops to water stress at different growth stages (many but not all were outlined by Plaut, such a comparison was conducted in few investigations only).

Such a comparison was made by Plaut for three different crops: corn, sunflower, and tomatoes for processing.[1] The amount of water applied was reduced either by applying smaller quantities, but throughout the season, or by withholding irrigation at specific growth stages. In corn, yield losses were much more marked when the crop was subjected to water stress during flowering and early grain filling as compared to other growth stages, validating other studies, that this was a sensitive growth stage. However, slight and uniform water stress during the entire growth season resulted in less damage to yield than withholding irrigation at any (insensitive) growth stage although total amounts of applied water were similar (Fig. 1). In sunflower, as well, the withdrawal of irrigation water at any growth stage reduced yield more severely than uniform and extended light stress throughout the entire season. The response of tomatoes to the decrease in the amount of water applied was different (Table 1). The withdrawal of irrigation water at specific growth stages reduced fruit and total soluble solid (TSS) yields much less than decreases in crop irrigation coefficients throughout the season resulting in similar reductions of irrigation water.

The difference between the two groups of plants may be explained on the basis of being determinate. Corn and sunflower are distinct determinate plants and every plant bears a single reproductive organ, which is a distinct sink. Assimilates are mobilized from the source organs for an extended period and transported to this sink. Severe water stress, at any time even for a limited period, may upset the entire source to sink steady flow. Slight stress may cause less damage to this system so that source to sink flow may continue with no interruption. In tomatoes for processing, new sinks are continuously being formed, and any particular fruit is a sink for part of the entire source and for a limited time only. When stress is in operation, only the fruits, which serve as sinks at this particular time, will be affected. Moreover, newly formed fruits may even compensate for this loss, once stress is relieved, so that yield may be enhanced. It was also shown by Stirling, Black, and Ong[2] that pod yield of groundnuts were insensitive to early moisture deficits. Although growth was inhibited during exposure to stress, sink activity was maintained within the

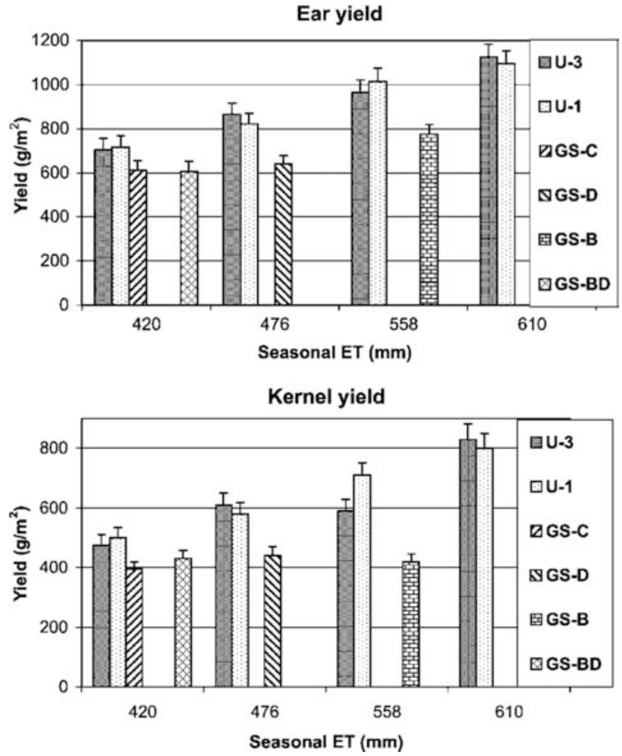

Fig. 1 The effect of deficit irrigation on corn ear and kernel yield. U-3 is the reduction in irrigation water throughout the season, 3 weekly applications. U-1 is as U-3 but 1 weekly application. GS-B, GS-C, and GS-D are withdrawal of irrigations at vegetative, flowering, and kernel filling stages, respectively. GS-BD is withdrawal of irrigation at stages B and D. The four groups of bars represent four levels of ET. Vertical bars are SE of the means.

expanding leaf, and it could rapidly recover when stress was released.

Our findings were recently verified with tomato plants, which were allowed to grow indeterminately as compared to others which were constantly pruned and grown as determinate plants (paper in preparation). It was similarly shown for determinate cultivars of beans that yield was reduced when exposed to stress during the growth stage of flowering and grain filling, while an indeterminate cultivar was more stress tolerant at the sensitive growth stage.[3]

Saving irrigation water by ''stretching'' the reduced quantities of water over an extended period can be obtained by scheduling irrigation according to soil water content, allowing low limits of pre-irrigation water content. When this irrigation strategy was compared with withdrawal of irrigation at specific growth stages, such as delay of irrigation until flowering or until midpod elongation, no difference in yield of soybeans was obtained during two seasons.[4] This suggests, at least for soybeans, that when grown in deep soil and fully recharged with water prior to planting, irrigation could be delayed, and the importance of critical growth stages is rather low.

There are crops in which no definite developmental stages can be recognized, like sugarcane. Following a short period of crop establishment and tillering, there is a long period of growth and sugar accumulation, which is one phenological period. In this crop, the effect of water stress appears to be primarily related to the degree of stress, relative to soil water content and ET demand, rather than to a specific crop factor.[5]

Water application at specific growth stages may also be of less concern in drought tolerant crops. As mentioned, sorghum is a good example for such a crop. An increase in yield may be obtained regardless when the water is applied and may result in increased number of grains and/or an increase in kernel weight, depending on when the water is applied.[6] Another drought tolerant crop, barley, did not show any preference of a particular growth stage, when the application of water was of largest benefit.[7] The highest yield was obtained when water was applied at all stages unless rainfall was sufficient.

Table 1 The effect of withholding irrigation water at specific growth stages and of reduced amounts of water throughout the season on tomato fruit and TSS yields. Four different groups are outlined, in which similar quantities of water were applied

Group	Amount of water applied (mm)	Crop irrigation coefficient	Growth stage of irrigation withdrawal	Fruit yield ($kg\,m^{-2}$)	TSS yield ($g\,m^{-2}$)
A	580	1.15	—	13.2	660
B	500	1.00	—	12.8	625
C	425	0.85	—	9.9	555
	420	1.00	Ripening	12.2	666
D	343	0.65	—	9.9	538
	339	1.00	Vegetative + flowering	10.8	533
	342	1.00	Fruit expansion	10.9	643

DEFICIT AND SUPPLEMENTAL IRRIGATION

Deficit irrigation is a deliberate under-irrigation of a crop. It may be practical under special conditions, mainly when water is very limiting. One would expect that irrigation timing at critical growth stages is of considerable importance under such conditions. Additional factors are also of importance in the planning of irrigation timing. When water is limiting, the highest yield and highest water use efficiency will usually be obtained when applied at low frequencies during an extended period. This was, for instance, shown for deficit irrigation of wheat when maximal yield was obtained with irrigation intervals of 4 weeks.[8]

Deficit irrigation is applied in desert areas, where ET is high and water is scarce. Corn is for instance grown in the African Sahel, as an important source of food. The optimal timing of deficit irrigation was studied in this area.[9] When 6–8 deficit irrigations were applied during the vegetative and reproductive phases, grain yield was reduced by 52% of the fully irrigated control. When only two deficit irrigations were applied during these growth stages (all the rest were full irrigations) grain yield decreased by 23–26% only. Yield reductions were mainly due to kernel number and less due to kernel weight.

Supplemental irrigation is generally given in addition to natural precipitation, when either no additional applications are needed, or when limited amounts of irrigation water are available. It is interesting that the timing of such irrigation was also not according to growth stages. Seed production of red clover, for instance, requires supplemental irrigation for maximal production. The timing of this irrigation was determined on the basis of crop water stress index (CWSI), and the fraction of available soil water consumed. The CWSI was found to be more consistent than fraction of soil water used, possibly because canopy temperature measurements integrate an entire plot, while soil moisture was based on single points. A single irrigation, which filled the entire soil profile applied at CWSI $= 0.28$ was sufficient to increase seed yield very remarkably.[10] White clover for seed production is also supplementary irrigated. It was recommended to apply a single irrigation during the period between haying and seed maturation as at this stage most of the available soil water is being utilized.[11]

In humid regions and under temperate climate, optimal seed production can be achieved for many years without any supplemental irrigation, or with a marked delay in water application. It was shown that maximal seed yield and the highest water use efficiency of white clover were obtained when the irrigation was delayed until 68% of available soil water was consumed. A single irrigation of bird's-foot trefoil increased seed yield over that which was obtained under maintenance of soil water close to field capacity due to frequent water applications.[12]

Plant Water Stress: Optional Parameters for Stress Relief

Zvi Plaut
Volcani Center, Institute of Soil, Water and Environmental Sciences, Agricultural Research Organization (ARO), Bet-Dagan, Israel

INTRODUCTION

The availability of irrigation water is diminishing in many parts of the world, which creates the need for optimization and increasing irrigation efficiency imperative. This was achieved in the past by irrigation scheduling, which covers two aspects; when to irrigate and how much water to apply. The main purpose of irrigation scheduling was to avoid harmful conditions of water stress and yet save irrigation water and other expenses in order to make water use most efficient. Higher efficiency of water use may still be attained, provided certain plant developmental stages are less sensitive to water deficit than others, so that restricting water supply during those stages may hardly affect productivity. Developmental stages of many crops, which are sensitive, and non-sensitive are outlined in another article.

PARAMETERS FOR WATER APPLICATION TO RELEASE STRESS

Although minimizing water application during non-sensitive growth stages may lead to savings in irrigation water, the overall efficiency of water use will depend on irrigation scheduling and on the amounts of water applied during the entire season. Optimal scheduling of irrigation is, however, of special importance during sensitive growth stages. Parameters based on aerial environment factors, soil, and plant factors were used and recommended as adequate for irrigation scheduling. In fact the subject of parameters for irrigation scheduling is beyond the scope of this chapter, we shall have to refer to it briefly, as it is very closely related to sensitivity to water stress at different developmental stages.

Plant Parameter

Plant water status, depends on water uptake and transpiration rates. Water uptake is a function of soil water content and availability, and transpiration is determined by aerial environment factors. There was thus, a tendency to base irrigation scheduling on parameters of plant water status, rather than on indirect parameters. Plant water potential (Ψ) was probably the most common plant parameter, which was practiced.[1] The use of midday leaf water potential was adopted for the timing of irrigation in cotton.[2,3] Different preirrigation levels of Ψ were examined as a guideline at which growth stage water application should be initiated.[4] Midday leaf water potential was also found to be most suitable as an irrigation-timing criterion for wheat,[5] provided measurements were conducted on cloudless days. The threshold Ψ for maximum water use efficiency was -1.82 MPa, and for maximum yield -1.44 MPa. Leaf water potential values were also used as thresholds for the timing of supplemental irrigation of corn.[6] Predawn water potentials may serve as a more adequate parameter of plant water status to be used for applying water. This is based on the assumption that predawn water potential integrates variation in soil moisture over the whole rootzone and is also less subjected to fluctuations in environmental conditions.

The Ψ serving as a threshold to be used for irrigation timing may sometimes vary during plant development. It was shown for grain sorghum that drought decreased leaf water potential only by 0.1–0.2 MPa during the vegetative stage, 0.3–0.4 MPa during the reproductive stage and exceeded 0.5 MPa during the grain filling stage.[7] This is an important finding suggesting, that preirrigation Ψ cannot always be a constant value for the entire life span of a given crop. Stomatal resistance was sensitive to small reductions in leaf water potential during the vegetative period, but became nearly insensitive during the reproductive period, suggesting that Ψ is not always the most suitable plant parameter for irrigation timing.

Irrigation timing can also be based on indirect plant parameters that respond to plant water status rather than on plant water potential. These include the use of stomatal aperture, growth rates of plant organs, and changes of trunk circumference. A particular indirect plant parameter for irrigation timing may be xylem cavitation. When the soil dries out, the water column within the xylem vessels will fracture or cavitate leading to the formation of a bubble, which gives rise to an acoustic emission.[8] The rate of occurrence of such acoustic events was suggested to be used as an indication of plant water status and for irrigation timing.

Soil Parameters

Another approach to determine the appropriate time for water application is based on soil water extraction and the remaining available soil water. Determining soil water potentials using different devices as tensiometers, psychrometers, resistance blocks, or dew point hygrometers can be used for this purpose. For instance, Irmak, Haman, and Smajstrla[9] who used a dew point soil hygrometer, showed for a heavy clay soil that water potential of −406 KPa at the depth of 0–30 cm left approximately 50% of available soil water, which was sufficient to provide maximum grain yield of corn. Soil water content, which can be determined gravimetrically, by neutron probes or by time domain reflectometry (TDR), can also be used for irrigation scheduling, and were in fact used in many studies.[10,11] The threshold of available soil water, which should serve for irrigation timing differs, however, among crops and for the same crop at various growth stages, as was shown elsewhere.

The number of irrigations to be applied during any growth stage and the amount of water per application will depend on the soil type and on ET conditions. Irrigation can be applied at higher frequencies than needed for maintaining soil water content above a recommended value, which is mostly in the range of 50% available soil water. The allowable soil water depletion or increase in plant Ψ becomes less important under such irrigation regimes. The continuous minimal soil water tension in the upper soil layers minimize the fluctuations in Ψ, which result in less inhibition of physiological processes and higher productivity. Although this can be performed using most irrigation methods, it is mostly common for high value crops like vegetables, potatoes, flowers, and fruit crops irrigated with drip irrigation. This was shown, for instance, for potatoes, tomatoes, sweet corn, and cashew[12–15] and for many additional crops. It was also demonstrated for other crops, like cotton that small quantities of water at high frequencies during their sensitive growth stages, resulted in an increased production.[16] A further increase in irrigation frequency up to 2–3 applications per week using drip irrigation was found to increase the yield very significantly.[17,18]

Agrometeorological Parameters

One of the most widely spread parameters for irrigation scheduling is probably the crop water stress index (CWSI), which was developed by several investigators and was outlined by Idso et al.[19] This index uses the difference between canopy and air temperatures ($T_c - T_a$), related to vapor pressure deficit of the air (VPD). An equation to calculate this CWSI is:

$$CWSI = \frac{(T_c - T_a)_a - (T_c - T_a)_p}{(T_c - T_a)_u - (T_c - T_a)_p} \quad (1)$$

where the subscript a, p, and u outside the parentheses stand for actual, potential [under no stress conditions, yielding lowest ($T_c - T_a$)] and upper ($T_c - T_a$), under no transpiring conditions. Although Idso presented the relationship between $(T_c - T_a)_p$ and VPDs under potential transpiration rates (fully irrigated) for 26 different species, the use of CWSI was limited to a few grain crops as wheat and corn,[20] for a limited number of forage legumes[21,22] and for some grasses.[23] The predicted ($T_c - T_a$) for severely stressed turf plants did not agree with measured values.[23] Values of CWSI of 0.25–0.30 or higher can be considered as fairly extreme conditions, and irrigation at values above those may lead to a decrease in yield. For corn, a decrease in grain yield was found when seasonal mean CWSI was higher than 0.22.[20] For wheat a CWSI of 0.30 was used.[24] For potatoes, which are more sensitive, a CWSI of 0.20 was scheduled for irrigation.[25]

Comparison and Interaction Between Parameters

Leaf water potential Ψ_l is directly affected by soil water potential Ψ_s in the absence of transpiration, so that

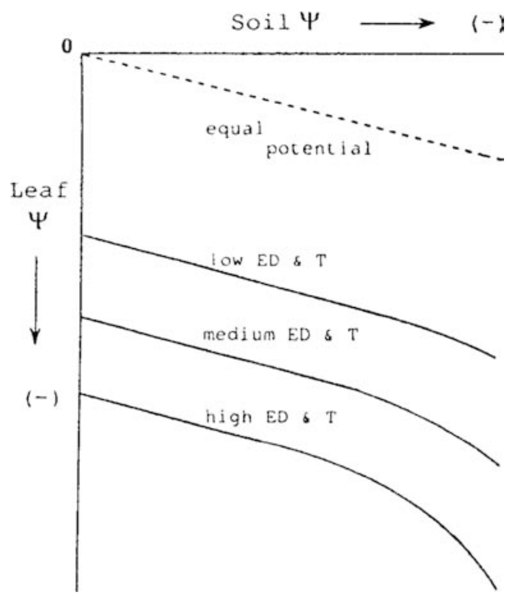

Fig. 1 Conceptual depiction of the influence of evaporative demand (ED) of the atmosphere and the resultant transpiration rate (T) on the relationship between soil Ψ and leaf Ψ over a range of decreasing soil Ψ. Dashed line indicate when soil and plant water potential are in equilibrium.

Nitrogen–Plant

Table 1 Summary of average irrigation amounts, ET estimates, and grain yields for a 3-yr period

Treatment		Irrigation		Estimated ET		Grain yield	
		Amount[a] (mm)	Relative[b]	Amount (mm)	Relative	Amount (kg/ha)	Relative
T1	40% D	345 a	1.00^{1}	477 a	1.00^{1}	11,700 a	0.96^{3}
T2	0.5 × ET	181 d	0.52^{7}	443 de	0.93^{7}	11,300 ab	0.93^{4}
T3	0.2 CWSI	248 b	0.72^{2}	467 ab	0.98^{2}	11,900 a	0.98^{2}
T4	0.4 CWSI	197 cd	0.57^{6}	447 cde	0.94^{6}	11,200 ab	0.92^{5}
T5	50 KPa	206 bcd	0.60^{5}	448 cde	0.94^{5}	12,200 a	1.00^{1}
T6	0.6 CWSI	157 d	0.46^{8}	431 e	0.90^{8}	10,600 b	0.87^{6}
T7	30 KPa	243 bc	0.70^{3}	462 abc	0.97^{3}	11,900 a	0.98^{2}
T8	C-M	231 bc	0.67^{4}	453 bcd	0.95^{4}	11,700 a	0.96^{3}

[a]Treatments with the same letter in each category do not differ significantly at the $\alpha = 0.05$ level. The applied irrigation, estimated ET, and grain yield LSD values were 49.2 mm, 18.4 mm, and 981 kg/ha, respectively.
[b]The maximum value is assigned a value of 1.00; other values are fractions of the maximum, e.g., applied irrigation for T2 is 181/345 = 0.52. Ranks are shown as superscripts, e.g., 1.00^{1} is the top ranking relative value.
Source: From Ref.[10].

predawn Ψ_l can be an estimate for Ψ_s. However, under active transpiration Ψ_l will depend on the rate of transpiration (T), on water conductivity within the soil (C_s), at the soil–plant interface (C_{sp}), and within the plant (C_p). It can be described by the following equation:

$$\Psi_l = \Psi_s - T(C_s + C_{sp} + C_p) \qquad (2)$$

Plants may thus be exposed to water stress, even when the soil is supplied with plenty of water and Ψ_s is high, if the transpiration demand and conductances are high. This implies that under such conditions plant water status cannot always serve for irrigation timing. Under conditions of low transpiration demand (cool and humid locations or time of the year), the threshold of Ψ_s would be lower than under high transpiration demand (Fig. 1). This suggests that it might be beneficial to schedule irrigation on more than one parameter. It was shown for instance that corrected data obtained for pan evaporation rates, soil water potentials, and CWSI were used in combination for scheduling tomato irrigation.[26] In wheat, significant yield losses were found when CWSI exceeded a threshold of 0.4–0.5, or rootzone water depletion above 50%.[27] A detailed comparison of different parameters, which could be used to determine critical stress and the need to apply water, was conducted on corn.[28] The compared parameters were: 40% depletion of available soil water (control), 0.5 predicted ET replacement based on a model, CWSI of 0.2, 0.4, and 0.6, soil water potential below −50 kPa and −30 kPa, and on a crop growth model. Maximal yield was obtained when −50 KPa was used as a parameter and this led to a reduction of 40% in irrigation water as compared to the control (Table 1).

Plant Water Use: Stomatal Control

James I.L. Morison
Department of Biological Sciences, University of Essex, Colchester, U.K.

INTRODUCTION

The term ‘‘plant water use’’ is commonly used, but it is unfortunate as it suggests that plants ‘‘consume’’ water in some biochemical processes.[1] However, less than 2% of the water that is taken up by plants is actually transformed during biochemical reactions, the rest (98% or more) is simply ‘‘lost’’ during transpiration, the process of evaporation from inside plants. Understanding and quantifying this transpiration is of critical importance in many applied and scientific disciplines, in particular in hydrology, crop science, forestry, ecology, meteorology, and climatology. Transpiration arises as an inevitable consequence of the need for plants to expose the surfaces of their photosynthetic cells to the air, to take up CO_2 during photosynthesis and therefore provide carbohydrate for growth. Aerial parts of terrestrial plants (and of emergent aquatic plants) are covered in impermeable materials; for leaves and photosynthetic stems this is the cuticle, a hydrophobic layer made up of lipids and waxes secreted to the outside of the epidermal cell layer that reduces the diffusional loss of water to the atmosphere to a very low rate in normal conditions. However, the cuticle is also impermeable to the diffusion of CO_2, so plants have ‘‘pores’’ in the cuticle with variable apertures in order to control CO_2 uptake and H_2O loss. These pores, termed stomata (single: stoma), are formed by a pair of specialized epidermal cells, the guard cells, which have both unusual anatomy and physiology. As well as determining CO_2 and H_2O exchange, stomata also influence the atmosphere-plant exchange of other gases, such as the phytotoxic pollutant, O_3. Stomatal apertures change over periods of minutes, and their size and shape vary between species and in different conditions.

STOMATAL ANATOMY AND DISTRIBUTION

Stomata occurred early in the development of terrestrial plants, with stomata being found in fossils from the Silurian period in the lower Paleozoic era (>400 million yr ago). Stomata occur on the spore capsules of mosses, on most aerial parts of terrestrial vascular plants, including leaves, green stems, fruits, and flowers, but not in submerged aquatic plants.[2] In the majority of plant species, the stomatal pore is elliptical, formed between a pair of semicircular guard cells (Fig. 1A–C), but the pore may become almost circular when fully open, with diameters of 5–50 μm, not only varying in size and shape between species but also varying with the conditions during leaf development. In grasses (Poaceae), the pore is a slit shape, formed between two elongated guard cells (Fig. 1D). In some species, there are well-developed subsidiary cells adjacent to the guard cells (Fig. 1A, B, and D). The pore may be sunken, with the guard cells recessed below the larger adjacent epidermal cells, particularly in plants of drier habitats. The numbers of stomata per unit leaf area (referred to as stomatal density or frequency) also vary with species and conditions, and range from 0 to 2000 or more stomata mm^{-2}. The proportion of the leaf area they cover is very small, about 0.5–3%. In herbaceous plants, stomata are found on both the upper (adaxial) and lower (abaxial) surfaces of leaves, which are termed amphistomatous, although there are usually more stomata on the lower surface. However, many tree species have stomata only on the lower surface (hypostomatous) and aquatic plants with floating leaves, such as water lilies have stomata only on the upper side (epi- or hyper-stomatous).

CONTROL OF TRANSPIRATION BY STOMATA

Leaf Scale

The diffusion rate of gases into or out of the leaf or other plant parts depends on the concentration gradient and the diffusive resistance of the pathway (a relationship known as Fick's Law). For water loss from the mesophyll cells inside the leaf, or CO_2 uptake by those cells, the major pathway is therefore from the mesophyll cell walls through the substomatal cavity to the pore, and then out through the layer of air immediately surrounding the leaf, to the mixed air stream (Fig. 2). Therefore, the stomatal pore offers a ‘‘resistance,’’ r_s, to diffusion, dependent on the aperture, shape, and number of stomatal pores. Note that although the pore area when open may only be at maximum a few percent of the total leaf area, the rates of evaporation can be about half that of a wet surface of similar dimensions (e.g., blotting paper); this is due

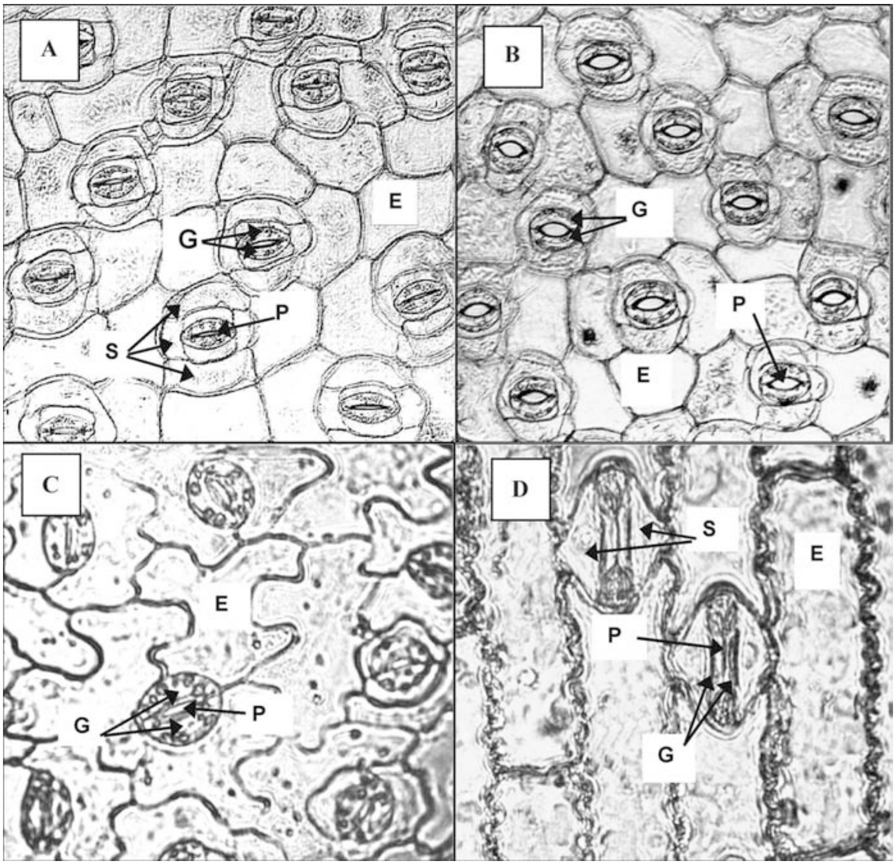

Fig. 1 Photomicrographs of stomatal and epidermal cells in (A and B) *Commelina communis*, (C) *Phaseolus vulgaris* (french bean) (D) *Zea mays* (maize). Guard cells indicated by G, subsidiary cells by S, pore by P, epidermal cell by E. Note chloroplasts evident in guard cells, particular in (C). Guard cell lengths approximately 45 µm in (A and B), 30 µm in (C), and 40 µm in (D). All from lower leaf surfaces.

to the ''edge effect'' of diffusion through multiple pores.[2] The ''boundary layer'' of air around the leaf also poses a resistance to diffusion (r_b), which depends on surface characteristics (presence of hairs, venation, etc.), leaf shape and size, and wind speed and turbulence. While the cuticle is relatively impermeable, some water is lost through it (varying with species) giving a ''cuticular resistance,'' r_c, in parallel to and usually much larger than, the stomatal resistance, r_s. There is also an internal resistance, r_i, for the pathway from cell wall to pore, but this is normally small compared to r_s and r_b. An equation for the rate of diffusion of water

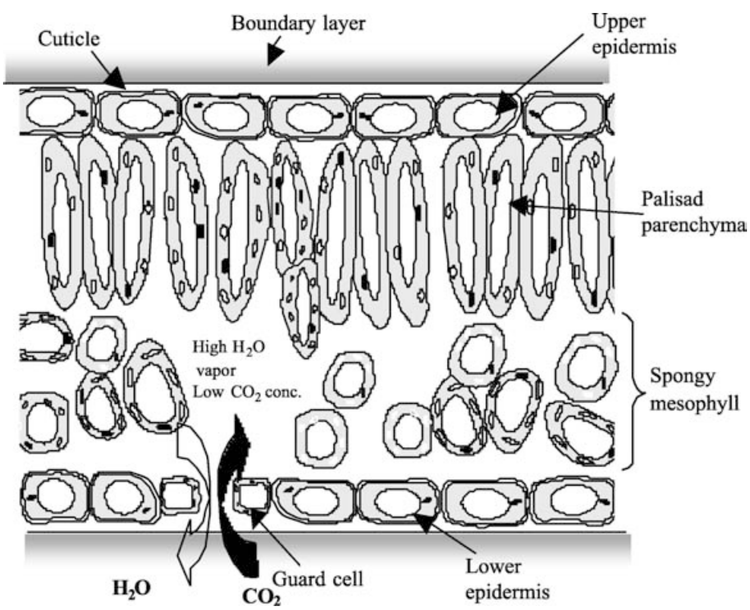

Fig. 2 Stylized cross-section of a leaf 1–2 mm thick, showing pathway for water vapor diffusion from the leaf internal cell spaces through the stomatal pore and boundary layer (size and thickness of various elements exaggerated for clarity, diagram courtesy of Dr. T. Lawson, University of Essex).

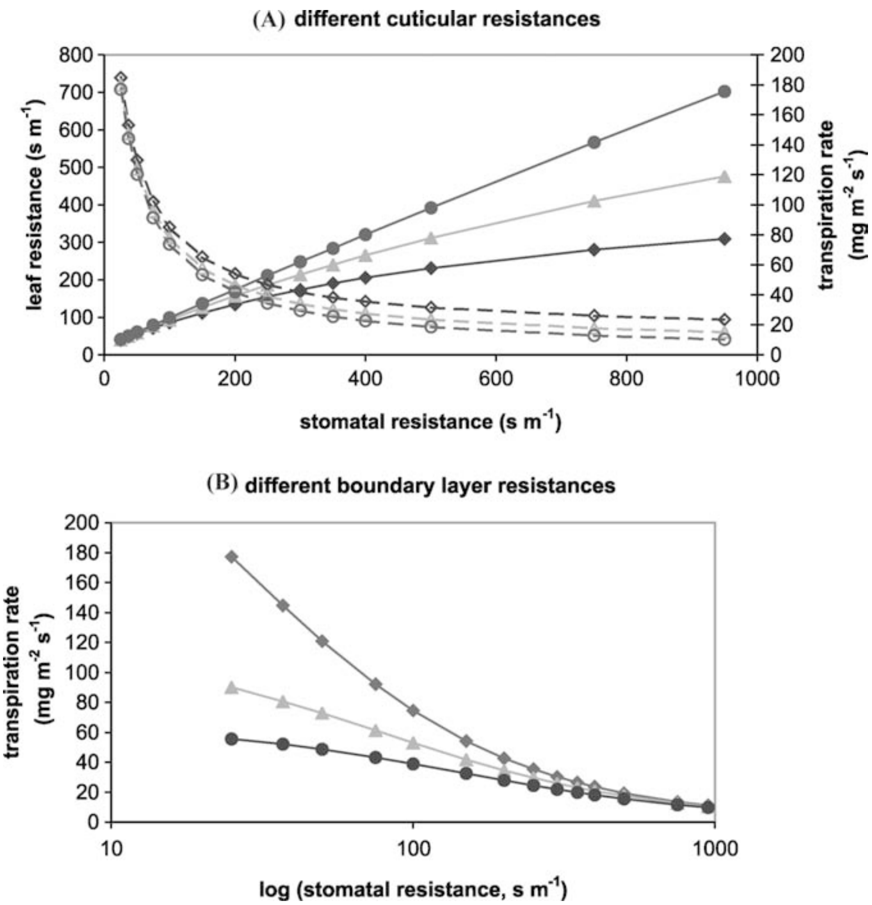

Fig. 3 Effect of changes in stomatal resistance on leaf resistance and transpiration rate. In (A) the diamond, triangle, and circle symbols are for increasing value of cuticle resistance (1000 sec m^{-1}, 2500 sec m^{-1}, and 20,000 sec m^{-1}, respectively). Open symbols and dotted lines are for transpiration rate. In (B) the diamond, triangle and circle symbols are for increasing boundary layer resistance (10 sec m^{-1}, 50 sec m^{-1}, and 100 sec m^{-1}).

from a leaf (E, mg m^{-2} sec^{-1}) can therefore be derived from the difference in water vapor concentration between the inside and outside of the leaf ($\chi_i - \chi_a$, g m^{-3}) and the leaf resistance, r_l (sec m^{-1}), which is given by the sum of the various resistances in series and/or parallel as appropriate as shown in Fig. 2:

$$E = \frac{\chi_i - \chi_a}{r_l} \tag{1}$$

$$r_l = \frac{r_c(r_s + r_i)}{r_c + r_s + r_i} + r_b \tag{2}$$

(For simplicity, these equations consider one side of the leaf only; see Ref.[3], which also gives typical values for the resistances.) Fig. 3A shows that if the cuticular resistance is very low, then r_l becomes curvilinearly related to r_s and Fig. 3B shows that r_b only influences E when $r_s < r_b$. Note that resistances are often replaced by their inverse, the ‘‘conductance,’’ g, ($g_l = 1/r_l$), as transpiration is approximately linearly related to stomatal conductance, g_s.

The aforementioned diffusion equations can be used for simple analyses, but in practice the leaf microclimate is not independent of the transpiration rate which affects the leaf temperature, and therefore the internal water vapor concentration, which determines the driving gradient for evaporation, and the long wave radiation balance. Because of this ‘‘feedback,’’ it is necessary to consider a more complete ‘‘energy balance’’ equation, such as the Penman–Monteith equation in order to examine the relative control that stomata exert on transpiration, compared to the other components. Analyses show (Fig. 4) that the important

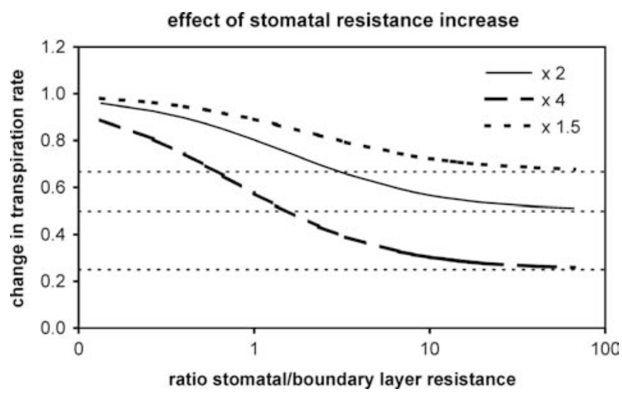

Fig. 4 Dependence of the change in transpiration rate caused by increases in stomatal resistances (increasing by 1.5, 2, and 4 times) on the ratio of stomatal to boundary layer resistance.

feature is the degree of ‘‘coupling’’ of the leaf to the air stream;[4] if the leaf has a small r_b compared to r_s, then the leaf is ‘‘well-coupled’’ and leaf temperature will not increase substantially, and changes in r_s will be reflected in E. This is typically the case with small, needle shaped leaves, at the top of the canopy with relatively high wind speeds. The opposite situation occurs with large, broad leaves within short, dense canopies, when E will not closely reflect changes in r_s. Indeed, it has recently been suggested that the evolution of larger planate leaves from the earlier leafless branched shapes became possible during the late Devonian period because of increased stomatal frequencies in response to declining atmospheric CO_2 producing greater evaporation cooling, and kept leaves below their lethal temperature limit.[5]

Vegetation Scale

The Penman–Monteith energy balance model has been used widely to quantify water loss from complete stands of vegetation (crops, pasture, and forests) by treating the canopy as a ‘‘big leaf.’’[4] This approach considers a canopy resistance, r_c as the sum of many individual leaf resistances, and a canopy aerodynamic resistance, r_a which reflects the pathway of air movement from outside the boundary layer of each leaf, to the mixed air stream well above the vegetation. However, there are many theoretical and practical problems in estimating the appropriate value for the resistances.[6,7] Nevertheless, as with individual leaves, the degree of coupling of the canopy to the airstream is important in determining the relative role of stomata in controlling water loss compared to the other components, although the feedbacks are more complex. First, there is likely to be evaporation from the soil surface, which acts to cool and humidify the air in the canopy. Secondly, the local air humidity is affected by the transpiration.[8] This also applies at the regional scale where the evaporation rate from the entire surface influences the heat and moisture transfer into the lower ‘‘atmospheric boundary layer’’ and changes the regional climatic conditions.[9]

STOMATAL PHYSIOLOGY

Stomatal pores open and close due to the changing turgor of the surrounding guard and epidermal cells. Guard cells have specially oriented cell wall fibers, which result in deformation and movement away of the central cell portions from each other when turgor increases. Cell turgor changes when the osmotic potential changes, caused by the uptake or loss of solutes, in particular K^+, which may be charge balanced by uptake of Cl^- or synthesis of malate^{2-} in the cells. One of the key steps in opening stomata, e.g., when a leaf is illuminated after darkness, is H^+ loss, due to a light-stimulated proton pump, which then hyperpolarizes the cell membrane, causing the influx of K^+. An intensive study over several decades has shown that the control of ion movement across the membrane is complex, with various ion channels that may be under the control of different environmental stimuli, and may be linked through key cell signaling mechanisms.[10] However, there are several questions still unresolved about stomatal metabolism, particularly the role of carbon metabolism.[11,12]

ENVIRONMENTAL EFFECTS ON STOMATA

Stomatal aperture is affected by many environmental and physiological variables; particularly, light, humidity, temperature, leaf, and soil water status (Fig. 5). Normally, stomata open (g_s increases, r_s decreases) in response to increasing light, but typically reach maximum aperture at approximately one-third of full sunlight. The response to light comprises at least two distinct effects in blue and red wavelengths. Stomata close in response to decreasing air humidity, with either linear or curvilinear response, when the humidity is expressed as the vapor pressure difference between the leaf and the air, i.e., the driving force for evaporation (discussed earlier). The humidity response is believed to be because of loss of turgor of the guard cells themselves, and is independent of the overall water status of the leaf. Stomata also close in response

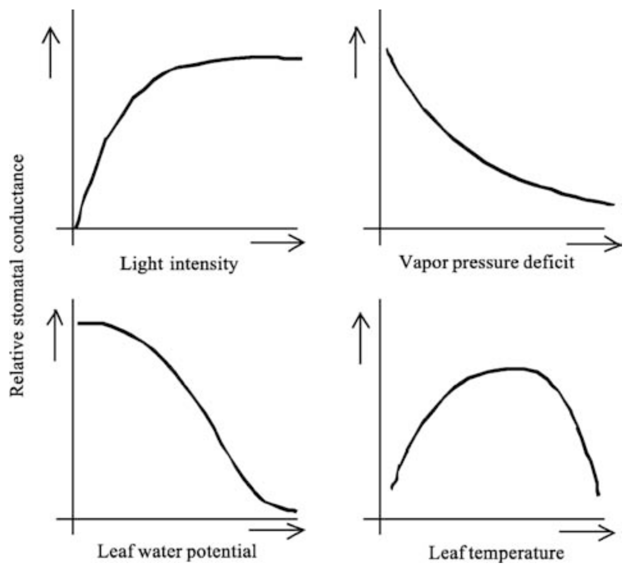

Fig. 5 Diagrams indicating generalized response of stomatal conductance to light intensity, leaf to air vapor pressure deficit, leaf water potential, and leaf temperature.

to a decline in leaf water status, but may show little effect at high water potential, until a threshold is reached. The soil water status also can have effects, and these are normally ascribed to the role of chemical "messengers" from the roots such as abscisic acid (ABA), synthesized or released in response to water shortage, which promote stomatal closure.[13,14] While normally stomata close in the long and medium term in response to reductions in water status, it should be remembered that with larger apertures, there is more transpiration, and inevitably a reduced water status, so a negative relationship can occur, at least in the short term.[15]

STOMATA LINK WATER AND CARBON FLOWS

Because stomata have a major control on plant gas exchange, they form the key linkage point between photosynthesis and transpiration, at all scales from that of individual leaves, to global carbon and hydrological cycles. Therefore, when plants are grown or measured across a range of different conditions (light or nutrient supply) there is a close linear correlation between photosynthetic CO_2 uptake and stomatal conductance.[16] For example, plants growing in shady, nutrient poor conditions, typically have low g_s and photosynthetic rate, compared to plants of open, fertilized habitats. This correlation results in a conservative "water use efficiency" (although note the difficulties with this term,[1]). However, plants of the different photosynthetic pathways do show characteristically different water use efficiencies, with C_4 having values 2–3 times that of C_3, and CAM plants being about 5–10 times C_3 species. This ratio emphasizes that the way that plants control the loss water is a key determinant of growth, reproduction, and survival.

Plant Yield and Water Use

M.H. Behboudian
College of Sciences, Institute of Natural Resources, Massey University, Palmerston North, New Zealand

Tessa Marie Mills
Environment and Risk Management Group, Horticulture and Food Research Institute of New Zealand, Palmerston North, New Zealand

INTRODUCTION

Water is the essence of life, and it plays vital roles in the biology of plants. In addition to its roles within the plant, evaporation of water from stomatal apertures provides for carbon dioxide entry into the leaf with carbon being fixed into organic matter through photosynthesis. Plants use a considerable amount of water to gain the required carbon, and "water use efficiency" (WUE) is the term used to quantify the yield, obtained through fixing of carbon, for the water lost. There are various ways, at the plant and farm level, to increase WUE as exemplified by the use of deficit irrigation (DI). The DI involves supplying less water to plant stands than the prevailing evapotranspiration (ET), a term combining transpiration (T) from plants and evaporation (E) from the soil. When yield is plotted against applied irrigation water, the relationship is called crop water production function (CWPF). Each point on CWPF could, therefore, relate to WUE. The availability of CWPF for each major crop in each region will facilitate the proper management of water resources. Many publications on various crops relate yield to water use and especially yield and applied irrigation water. A comprehensive coverage for various economically important herbaceous plants was given by Doorenbos and Kassam.[1] The following short treatment focuses on some basic definitions relating the yield to water use of crop plants.

WATER AND PLANT LIFE

Water has profound effects on plant function and distribution around the world. The ecological significance of water is due to its important physiological roles. Water is a plant nutrient (contributing the H atom), is a medium for all the biochemical reactions, acts as a solvent for many of important substances, hydrates most of the organic compounds in protoplasm, and acts as a medium for the diffusion and mass flow of solutes. It also maintains turgidity creating turgor pressure within cells.

Despite these vital roles, only a maximum of 5% of water absorbed from the soil remains in the plant with at least 95% being lost to the atmosphere through the process of transpiration.[2] Much more water is used by plants than dry matter is produced by them. Pimentel et al.[3] estimated that for the production of 1 kg of food or forage, the water use (in liters) of the following plants will be potatoes 500, wheat 900, alfalfa 900, sorghum 1110, corn 1400, rice 1912, and soybeans 2000. Therefore, plants differ in their efficiency of production in relation to water use, and the term WUE has been used to quantify this concept.

WATER USE EFFICIENCY

Leaves are the major sites of transpiration with at least 90% of water transpired through stomata and the rest through the cuticle.[4] The loss of water through open stomata will result in the diffusion of CO_2 from the air into the leaf. Therefore, CO_2 assimilation and final harvestable yield will be realized through the loss of water. Water use efficiency is defined as the total dry matter produced by plants per unit of water used:[2]

$$\mathrm{WUE} = D/W \qquad (1)$$

where D is the mass of dry matter produced and W is the mass of water used. D represents photosynthetic activity, because the C and O atoms of the CO_2 from the air account for most of the dry mass. The term W could be considered as equivalent to ET, which comprises non-productive E and productive T. Evaporation of free water from a leaf surface adds to E. The ratio D/T focuses on the physiological aspects of WUE. According to Postel,[5] the estimated WUE ($\mathrm{kg\,m^{-3}}$) for the following crops worldwide are wheat 0.8–1.0, rice 0.7–1.1, maize 0.8–1.6, other grains ~0.6–1.2, roots and tubers ~4.0–7.0, pulses ~0.2–0.6, soybean 0.4–0.7, other oilseeds ~0.2–0.6, groundnuts 0.6–0.8, vegetables and melons ~10.0, fruits (except melons) ~3.5, sugar cane 5.0–8.0, sugar beet 6.0–9.0, and tobacco 0.4–0.6. It is imperative that WUE be increased to accommodate partially for the rising demand for water by a rapidly expanding world population.

METHODS OF INCREASING WUE

There are several means for improving WUE. At the plant level, classical breeding and genetic engineering may be directed towards decreasing transpiration without a corresponding decrease in yield. Several possibilities for this are discussed by Richards et al.[6] such as early canopy development and introduction of short-season crops. At the field level, the following measures could be taken to save water: proper fertilizer application, suitable plant density, weed control, rainwater harvesting and conservation, tillage, mulching, double cropping to utilize the water remaining in the soil, and the possible use of antitranspirants and reflectants to reduce ET. Antitranspirants are best designed to either close stomata or form a cover over stomata in such a way that transpiration will be more reduced than photosynthesis leading to water conservation and increased WUE. However, despite decades of research no satisfactory compound has been introduced with these properties, and research on antitranspirants is practically abandoned.[2] Other possible measures at the farm level for increasing WUE are better control of water distribution system and judicious application of DI.

DEFICIT IRRIGATION

Deficit irrigation involves giving less water to the plant than the prevailing ET at selected times during the growing season. A short history of DI and its application to deciduous orchards, including some case studies, was reviewed by Behboudian and Mills.[7] If applied judiciously, DI saves water, decreases vegetative growth and, therefore, pruning costs in deciduous orchards, reduces leaching of biocides into the ground water, and might improve fruit quality while maintaining yield. Deficit irrigation is expected to be more successful in dry than in humid areas, because in the latter rain can interfere with achieving an intended low soil/plant water status.

Deciduous orchards may stand to benefit more from DI than do field crops, because fruits are strong sinks and, especially in high-density orchards, photosynthates would be more diverted towards fruits than towards the restricted roots or shoots whose seasonal growth would have already ceased. For field and annual crops, it is expected that conditions which decrease transpiration below its potential rate will also reduce biomass production below its potential rate.[8] The following relationship between yield and soil moisture deficit was quoted from the literature by Jamieson,[8] who also successfully tested it on peas, potatoes, wheat, barley, and maize:

$$Y = Y_0[1 - a(D_p - D_c)] \quad (2)$$

where Y is the yield, Y_0, the potential yield, D_p, the potential soil moisture deficit dependent on the

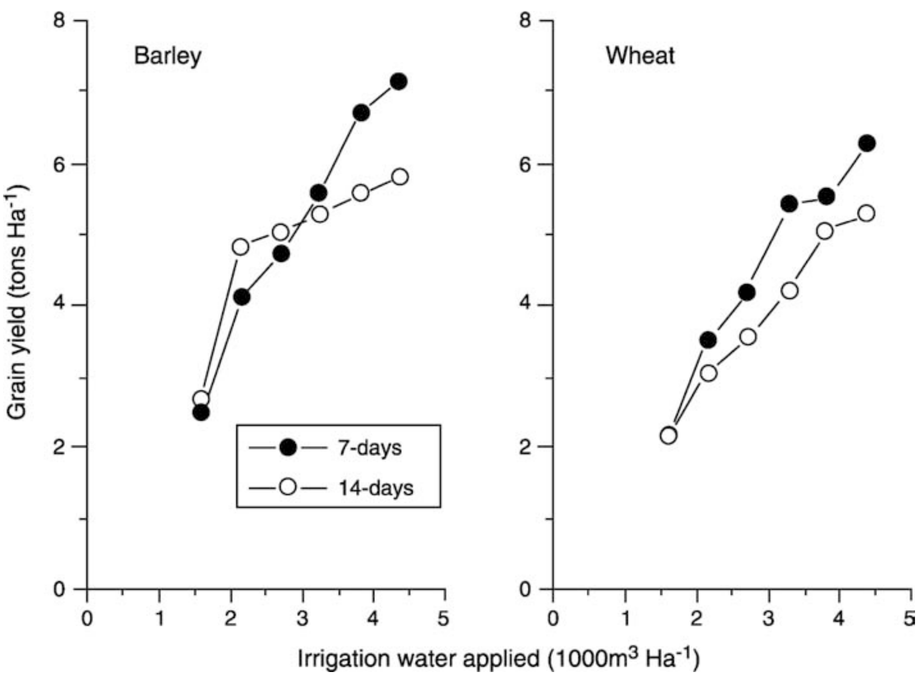

Fig. 1 The relationship between the amount of irrigation water applied and grain yield in barley and wheat (i.e., CWPF) at 7- and 14-day irrigation intervals. *Source*: The data are based on Ref.[12].

environmental conditions, and D_c, the threshold value of soil moisture deficit. The judicious application of DI involves avoiding development of water deficit during the most sensitive periods of crops to minimize the yield reduction which Eq. (2) estimates. For example, cereals are more sensitive to the timing of a water deficit than they are to the total reduction of irrigation water.[9] There are reports on DI application to annual crops without yield reduction as exemplified by the experiment of Heuer and Nadler[10] on cotton. Although plant growth expressed as plant height and accumulation of fresh weight were significantly decreased with DI, neither seed cotton yield nor lint quality were decreased. Agronomic practices need to be modified to realize the maximum potential of DI as outlined by Kirda and Kanber.[9] A more effective irrigation strategy could be followed by the consideration of CWPF for crops of interest.

CROP WATER PRODUCTION FUNCTION

The CWPF shows the relationship between yield and the amount of irrigation water. A quantitative treatment of this function with citation of the relevant literature can be found in Varlev, Dimitrov, and Popova.[11] An example of CWPF for barley and wheat is given in Fig. 1, which is based on the data of Fardad and Pessarakli.[12] The CWPF is an empirical relationship which should be determined for each crop in each area because yield is a function of various environmental and biotic factors. The relationship, therefore, does not follow the same pattern for all crops. Such CWPFs could be useful for planning and development of water resources and projections of agricultural production.

FUTURE PROSPECTS

Water availability for crop production will be a far more serious issue in 2025 than it is now.[5] Various measures could be taken to address this issue for increasing WUE on the global scale. Especially, rainfed land needs protection because it does not compete for water with agricultural, urban, and industrial users of water. Efficient channeling and storing of rainwater will be crucial. Improving irrigation efficiency such as delivering water directly to the roots of crops will greatly reduce evaporative losses. Increasing WUE of crops (as outlined earlier), shifting the mix of crops, and breeding for more drought and salt tolerance will have special value. These measures will be of vital importance for sustainable production of food for the growing world population. The on-going rise in the atmospheric CO_2 is expected to decrease transpiration and, therefore, to increase the WUE in the future.

Plants: Critical Growth Periods

M.H. Behboudian
College of Sciences, Institute of Natural Resources, Massey University, Palmerston North, New Zealand

Tessa Marie Mills
Environment and Risk Management Group, Horticulture and Food Research Institute of New Zealand, Palmerston North, New Zealand

INTRODUCTION

Critical growth periods may be defined as stages in a plant's development when active growth occurs. Plants are generally sensitive to water deficit (WD) during critical growth periods. Plant WD implies that the plant water status is less than the optimum value for growth and development. Plant demand for water is influenced by many factors including the evaporative demand of the aerial environment, soil characteristics, plant characteristics, and growth stage.[1]

Most plants experience WD at some stage during their life cycle. It may occur diurnally when the evaporative demand for water by the atmosphere is greater than the plant's ability to draw water from the soil, or seasonally as soil moisture is depleted due to transpiration and not renewed.[2] Water deficit typically results in a reduction in transpiration due to stomatal closure. If severe, this may also reduce photosynthetic rate and therefore carbon acquisition. This, in turn, may lead to reduced plant growth and biomass accumulation. The sensitivity of plant growth and the reduction in biomass accumulation during periods of WD are dependent on plant's developmental stage. Water deficit imposed during periods of active growth will impact upon the growth of the developing organ as cell turgor is required for cell growth.[3] Generally, however, not all organs of a plant undergo active growth at the same time. This results in different organs within the plant having different critical growth periods during the growing season. This difference allows the manipulation of plant WD to target particular plant organs with little carry over influence of WD on other plant parts. This phenomenon is demonstrated in Fig. 1,[4] where the clear separation of maximum shoot and fruit growth periods are illustrated for peach and pear.

MANIPULATION OF WATER AT CRITICAL GROWTH PERIODS—DEFICIT IRRIGATION

Water shortage is a major constraint to agricultural production in many areas of the world.[5] Additionally, 85% of the global water resource is used for irrigation of agricultural lands.[6] With increasing pressure on water as a scarce resource, there is a requirement to develop irrigation strategies that increase water use efficiency by plants to ensure productivity and reduced water usage. By understanding critical growth periods for separate plant organs, researchers are able to maximize irrigation efficiency and to minimize any detrimental impacts of WD on plant productivity.[7] Such irrigation strategies have been termed regulated deficit irrigation (RDI). Regulated deficit irrigation was initially developed to control shoot growth in peach trees (*Prunus persica*)[8] and thereby reduce pruning requirements and allow increased carbohydrate partitioning to fruit. Other benefits from RDI have now been realized including enhanced fruit quality[7] or greater economic yield.[9] Although RDI, if applied correctly, can increase crop profitability by reducing water use and increasing economic return, it may also have detrimental effects if applied at inappropriate times. For example, in apple (*Malus domestica*), WD at the time of flower initiation (early summer) may have a little impact on the crop currently being carried. However, the flower initiation may be disrupted, which results in a poor return bloom and low crop yields the following season.[10]

The impact of periodic WD varies enormously among plant types; thus, it is appropriate that annual crops and perennial crops be discussed in more detail separately. Annual crops will have no carry forward consequence of WD from the current season in subsequent seasons whereas perennial crops may.

CRITICAL GROWTH PERIODS IN ANNUAL CROPS

Water deficit studies have been conducted on many annual crops including peanut (*Arachis hypogaea*),[11] rice (*Oryza sativa*),[12] pearl millet (*Pennisetum glaucum*),[13] wheat (*Triticum aestivum*),[14] faba bean (*Vica faba* L.),[15] maize (*Zea mays* L.),[16] and pea (*Pisum sativum*).[17] The impact of such WD on crop quality

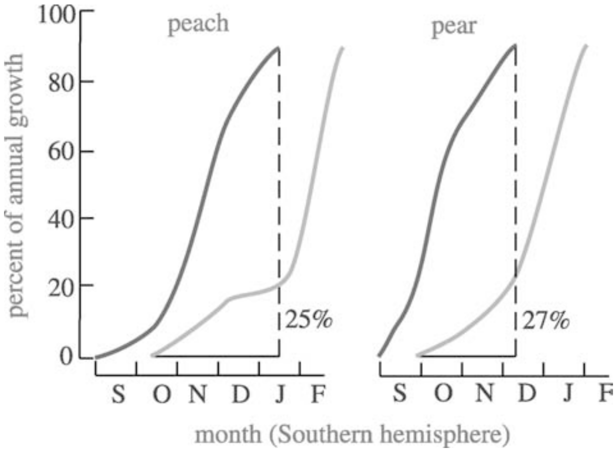

Fig. 1 The cumulative growth of annual shoots and fruit of "Golden Queen" peaches and "Bartlett" pears expressed as a proportion of total seasonal growth by these organs. *Source*: From Ref.[4].

and yield is highly dependent on the timing of the WD and how this aligns with critical growth periods. In wheat, the final yield was reduced whenever WD was imposed. However, the total reduction in yield was the greatest when WD was imposed during flowering. Water deficit at grainfill and tillering has much less impact on final yield. Differences in response to WD also occurred depending on wheat genotype. Water deficit during flowering in peanut resulted in fewer flowers produced per plant. However, a higher percentage of the flowers produced set fruit in plants having suffered WD, which ultimately increased peanut's total yield. The mechanisms for this increase in total yield are thought to be an increase in the promotion of root formation under drought as well as an inhibition of excessive vegetative growth. These two studies illustrate the variable nature of plant response at critical growth periods both within and between annual species.

CRITICAL GROWTH PERIODS IN PERENNIAL CROPS

Periodic WD has been used as a management tool in perennial crops for many years. Carry over influences of WD at critical growth periods are common in perennial crops and may modify plant morphology and increase plant's ability to withstand subsequent drought. Examples for major deciduous fruit crops are cited by Behboudian and Mills.[7] Again the impact of such periodic WD is strongly dependent on crop type and the productivity component of interest. For example, fruit yield may be reduced in apricot if WD is imposed during the late rapid fruit growth stage but is unaffected if WD is induced during the early rapid fruit growth stage as compensatory fruit growth occurs upon re-watering. Fruit quality attributes may also be modified and could result in increased yield under WD. For example, olive oil production was increased in plants subjected to WD following pit hardening.

CONCLUSIONS

Water deficit has its main effects during active periods of growth. It modifies plant organs differentially during a life cycle, depending upon how fast they are growing. Consequently, no generalizations can be made in regard to plant responses to WD at critical growth periods. The phenomenon of critical growth periods does, however, provide an opportunity for crop manipulation and enhanced crop performance under reduced irrigation strategies. With increasing pressure on water as a resource, strategies such as RDI need to be understood and embraced.

Plants: Osmotic Adjustment

James M. Morgan
Tamworth Centre for Crop Improvement, Tamworth, New South Wales, Australia

INTRODUCTION

Plant growth in general and crop production in particular normally occur in environments characterized by fluctuations in soil water supply and evaporative demand, which produce water stress of varying duration. Maintenance of metabolic processes usually depends upon minimization of water loss from cells, and this is often accomplished by intracellular accumulation of solutes such as potassium, amino acids (or derivatives), and sugars.[1–3] This type of adaptational response occurs widely in plants, fungi, microorganisms as well as some animal cells[1,2] and is usually known as osmoregulation, osmotic regulation, or osmotic adjustment. These terms are etymologically identical ("to adjust" means "to regulate" or "conform to a standard"), and are correctly used interchangeably though some have argued for a distinction.[4,5] The expressions can be taken to mean controlled (e.g., regulated by specific genes) change or maintenance of osmotica; generally the former in plants and the latter in animals, though in each, cell hydration is maintained to varying degrees. This may be expressed as volume maintenance (particularly in wall-less cells such as plant gametes and marine algae) or turgor maintenance (walled cells). Osmotic adjustment is also used to describe solute accumulations in plants where the control system (either genetical or physiological) is not clearly understood.

KEY CONCEPTS

The origin of relationships and theory may be found in earlier works.[6–9] At equilibrium, the cell water potential (φ_c) equals the water potential outside the cell (φ_e), and is the sum of the osmotic (π), pressure (P), and matric (τ) potentials.

$$\varphi_e = \varphi_c = \pi + P + \tau \tag{1}$$

Water stress occurs when φ_e is reduced through, for example, increased water deficits in the soil or atmosphere or increased salinity [Eq. (6)]. This may occur over short (e.g., diurnal) or longer time periods. A decrease in φ_e from zero (or a higher) (1) to a lower (2) level causes changes in π and P (assuming τ to be negligible—difficult to measure). The new value of π will be

$$\pi_2 = -\frac{n_2 RT}{V_2} = -\frac{(n_1 + n_a)RT}{V_2} = \frac{\pi_1 V_1}{V_2} + \pi_a \tag{2}$$

where V is the osmotic volume, n is the number of solute molecules, R the gas constant, T the absolute temperature, and subscript a indicates accumulation. The osmotic adjustment ($\Delta\pi_a$ or $-\pi_a$) is the difference between the osmotic potential attributable to concentration of π_1 by dehydration and the measured value, π_2 [(Eq. (5)].[4,8–10] The relative water content, $\zeta(\approx V_2/V_1)$, is normally used instead of V to calculate solute accumulation for plant tissue. At a particular stress level, its value depends upon the degree of osmoregulation according to

$$\frac{V_2}{V_1} = \frac{n_2}{n_1}\frac{\pi_1}{\pi_2} \tag{3}$$

When n does not change, ζ is inversely related to π. This relationship [or Eq. (2)] has been used widely to evaluate lines for genetical and yield studies in crop plants, often using a log transformation to test for linearity or ideal behavior.[6,8]

Two osmotic components are therefore important in influencing hydration and turgor; the initial osmotic potential, π_1 (i.e., at $\varphi_e = 0$ or $\zeta = 100\%$), and the solute accumulation, $\Delta\pi_a$. Both can be sources of adaptation to water stress in plants. In the short term, solutes accumulated during a stress episode may be retained after rehydration and this produces a decrease in π_1 ($\Delta\pi_{100}$). This is periodically used as a way of measuring osmotic adjustment, though the precise nature of the relationship with $\Delta\pi_a$ has not been well established experimentally. Repeated diurnal increases in $\Delta\pi_a$ due to fluctuations in vapor pressure deficit do not seem to produce long-term cumulative increases in $\Delta\pi_{100}$. The decrease in π_1, which is a "hardening" reaction, seems capable, therefore, of only limited variation. It is evident in plants that have been prestressed,[10] or in comparisons of glasshouse- and field-grown plants.[11] The value of $\Delta\pi_{100}$ is also calculated using π_1 and π_2, assuming no change in n_2.[4] It is compared with $\Delta\pi_a$ in Eqs. (4) and (5).

$$\Delta\pi_{100} = \frac{(n_2 - n_1)RT}{V_1} \tag{4}$$

while

$$\Delta\pi_a = \frac{(n_2 - n_1)RT}{V_2} \tag{5}$$

Thus, $\Delta\pi_{100} = \Delta\pi_a\zeta$.

COMPONENT SOLUTES AND GENETIC CONTROL

Numerous examples exist of genotypic variation between, and within plant species, including rice, wheat, sorghum, field peas, barley, and chickpeas.[4,10] There are, however, few instances where genetic control has been identified and pleiotropic effects investigated. Molecular approaches involving compatible solutes have not produced clearly demonstrable increases in osmotic adjustment.[12–14] However alterations in proline, betaine, and mannitol have been associated with differences in growth under saline conditions.[12,14] Greater success has been achieved using a phenocentric approach.[15]

In wheat, initial identification of large genotypic differences in the 1970s led ultimately to location of a gene (*or*) on chromosome 7AS.[8,16,17] There is evidence from mapping and breeding work of close linkage of *or* with an endosperm peroxidase, *Per A4*, locus, producing alterations in dough strength.[17,18] The gene effect is semiqualitative in that in leaves, responses of osmotic potential to water potential follow very different pathways.[8,11] Generally, genotypes with *Or* (dominant allele) show low or 0 $\Delta\pi_a$ with decline in φ_e from 0 MPa to near 0 P. Below this $\Delta\pi_a$ increases. Genotypes with *or* accumulate solutes from the commencement of stress (Fig. 1) with potassium the dominant component (and with some amino acid contribution).[19] The gene is also expressed in pollen grains, where it is dependent upon a supply of potassium, and involves volume regulation.[11] The response, which reaches a maximum at approximately 0.2 m*M*, shows a high affinity for potassium. Pollen expression enables visual identification of homozygous and heterozygous lines, and was used to produce a commercial cultivar in Australia (Mulgara) using backcrossing methods.[11,20] In rice, analysis using similar leaf tests (i.e., based on Eqs. 2 and 3) has identified a quantitative trait locus (QTL) in a region on chromosome 8 that is homoeologous with a region of chromosome 7AS in wheat.[14,21]

Considerable understanding of the osmoregulatory system comes from work on *Escherichia coli.*

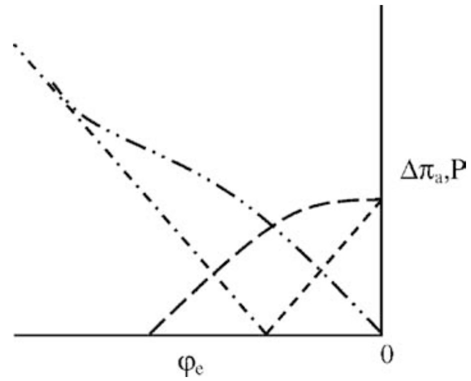

Fig. 1 Types of responses of $\Delta\pi_a$ and P to reductions in leaf water potential, φ_e, due to a single-gene difference in wheat. High osmoregulation (*or*) $\Delta\pi_a$ (–··–··–), P (– – –), and low osmoregulation (*Or*) $\Delta\pi_a$ (-·-·-), and P (- - -). *Source*: From Ref.[16].

The stress-induced K^+ accumulation is controlled by a single operon (*kdp*) which responds directly to turgor reduction. Potassium accumulation is the primary or initial stress response to restore turgor. Compatible solute accumulation (mainly betaine) is under separate control, and is induced by increased K^+ concentration.[22,23] As external stress increases, betaine progressively replaces K^+ as the main contributor to osmoregulation. The osmoregulatory system seems, therefore, to be controlled by the *kdp* operon.[23] This accords with the observation of single gene control at positive turgor in wheat. Also in various plant species, compatible solutes such as proline and amino acids tend to accumulate much later in stress development.[9,24–26] There is evidence that the effector of proline accumulation is π or a component of it, rather than φ_e.[27]

GROWTH AND YIELD RESPONSES

The relationship between osmoregulation and growth or yield may be broadly understood in terms of effects of positive turgor and hydration on cell expansion, metabolic processes such as photosynthesis (via stomatal resistance), and synthesis of growth regulators such as abscisic acid, which may in turn affect elongation and seed set.[4,10,28] Growth and yield response are dependent upon environmental conditions which reduce φ_e enough for expression of differences in osmotic adjustment. In leaves, the effect may be broadly or conceptually summarized by

$$\varphi_e = \varphi_s - RE_p \tag{6}$$

where φ_s is the soil water potential (water supply term), E_p is the evaporation rate (affected by evaporative demand), and R represents the resistance to water

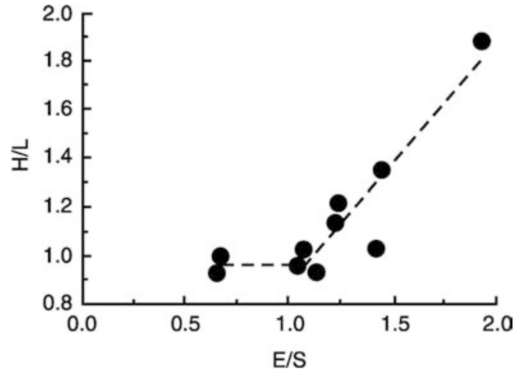

Fig. 2 Yield increase due to a gene conditioning high osmoregulation in wheat (H/L) is simply related to the ratio of evaporative demand (E) to soil water supply (S) for the period of net positive growth of the crop in the field. *Source*: From Ref.[20].

flow between the soil and the air.[7,9] In rainshelter experiments with wheat, where soil water supply was constant, both φ_e and difference in P due to osmotic adjustment were linearly related to evaporative demand, E. Growth or yield responses may not occur at high soil water deficit if E is low, even though biomass has been substantially reduced while a response can occur at low soil water deficit if E is high.[20] This scenario probably reflects the interaction of leaf area reductions due to soil or root stress,[29] and differences in growth reductions due to differences in leaf turgor responses. With gradual development of soil water deficit, it is probable that leaf area is adjusted to minimize stress in leaves. Lines with differing *or* alleles do not show differences in this effect. Where the effect of the *or* gene was measured using both recombinant inbred lines and backcross-bred lines, yield response (H/L, where H is the yield of lines with high osmoregulation, and L the yield of lines with low osmoregulation) forms a close ($r = 0.92$), simple relationship with water supply (S) and evaporative demand (E) when E/S is >1 (Fig. 2). For values below 1, $H/L = 1$.[20] Evidence of positive yield associations has also been found in lines of field peas and chickpeas.[30,31] In these studies, assessments of osmoregulation were based on Eq. 5, though positive relationships based on $\Delta\pi_{100}$ have also been found in sorghum.[32] Other attempts to associate genetic variability in solute accumulation with yield have mostly used cultivars or lines of differing genetic backgrounds to establish correlations, with questionable results as a consequence.[10,27,33]

CONCLUSIONS

As an adaptational trait, osmotic adjustment has proved effective in the improvement of wheat yields, by use of backcrossing techniques with gene identification in pollen grains. Modeling work suggests wide potential for yield improvement in environments where evaporative demand exceeds soil water supply during crop growth.[20] In this work, evaluation at a tissue/cell level has been a significant factor. From here it is possible to work "up" to growth and "down" to biochemistry. Correctly characterizing the osmoregulatory response to water stress is important, as it affects understanding of the chemistry, genetics, and yield relationships. A similar approach may prove productive in other crop species where genetic variation exists, especially in the *Gramineae*. However, success in some species may require an approach which combines molecular (e.g., gene markers) and phenotypically based techniques.[14,15]

Plants: Osmotic Potential

Mark E. Westgate
Department of Agronomy, Iowa State University,
Ames, Iowa, U.S.A.

INTRODUCTION

Inherent in the term ‘‘osmotic potential’’ is a measure of the capacity to do work. Typically in plant systems, that work involves the movement of water across cellular membranes and tissues for hydration, expansion growth, leaf movements, and stomatal opening. The osmotic potential of a cell is determined primarily by the concentration of solutes confined within the symplastic water volume (cytoplasm + vacuole). Therefore, solute transport across cellular membranes and cellular metabolism are essential components of osmotic regulation. Passive concentration of solutes due to dehydration or inhibition of metabolism under severe environmental conditions also can contribute to the ‘‘adjustment’’ of cellular osmotic potential. Whether active or passive, the accumulation of solutes has been shown to support expansion growth, maintain photosynthesis, and improve reproductive success under severe drought conditions in a number of plant systems. This article presents a brief overview of the physical origin of the term osmotic potential and its application to quantifying the response of plants to changing environmental conditions.

PHYSICAL DEFINITION OF OSMOTIC POTENTIAL

Solutes and Free Energy

The total amount of energy in the water molecules within a cell is partitioned between the energy associated with the molecular structure of the water, and energy that can be exchanged with the surroundings. Energy ‘‘tied up’’ in structure is the entropy, and the ‘‘exchangeable energy’’ is the free energy available to do work. Gibbs[1] defined this free energy term for any component of a system as its chemical potential, μ_j, which is a measure of the amount of work a mole of the component j can do. In the case of water, the chemical potential is given by

$$\mu_w = \mu_w^* + RT\ln(a_w) + \bar{V}_w P + Z_w FE + m_w gh \quad (1)$$

where μ_w is the chemical potential of water in the system (J mol^{-1}), μ_w^* is the chemical potential of the reference state for water (J mol^{-1}), R is the gas constant (J mol^{-1} K^{-1}), T is temperature (K), a_w is the activity of water (dimensionless), $\bar{V}_w$ is the partial molar volume of water (m^3 mol^{-1}), P is the hydrostatic pressure (MPa), Z_w is the charge number of water (dimensionless), F is Faraday's constant (C mol^{-1}), E is the electrical potential (mV), m_w is the mass per mole of water (g), g is gravitational acceleration ($\sim$9.8 m sec^{-2}), and h is vertical height (m). This equation formalizes a number of important points relative to the chemical potential of water in plant cells. First, the chemical potential cannot be measured directly, but is evaluated relative to an unknown reference energy state, μ_w^*. Second, it is affected by a number of physical factors, such as the presence of solutes ($RT\ln(a_w)$), atmospheric pressure ($\bar{V}_w P$), electrical charge ($Z_w FE$), and elevation ($m_w gh$). Third, chemical potential is quantified on a molar basis. The activity of water, $a_w = \gamma_w N_w$, is a product of the activity coefficient of water, γ_w (concentration^{-1}), and the mole fraction of water, $N_w = n_w/(n_w + n_s)$, where n_w and n_s are moles of water and solute, respectively. The partial molar volume of water, $\bar{V}_w = \partial V/\partial n_w$, describes the volume change associated with a change in the number of moles of water in the system. When solute is added to water, the free energy of the water per unit volume of the system decreases because the solute occupies space previously occupied by water. The additional solutes decrease the mole fraction of water, thereby decreasing the water activity term, $RT\ln(a_w)$.

Although the chemical potential of water in plants cannot be measured directly, it can be measured against a standard state (μ_w^0), which is defined as pure water, at atmospheric pressure, and at the reference temperature and gravitational level of the system. For pure water at atmospheric pressure, $P = 0$, $N_w = 1$, $z_w = 0$, and $h = 0$. Therefore, the standard state and the reference state for the chemical potential are equivalent.

$$\mu_w^0 = \mu_w^* + RT\ln(1) + \bar{V}_w(0) + (0)FE + m_w g(0) = \mu_w^* \quad (2)$$

Substituting μ_w^0 into Eq. (1), dividing by $\bar{V}_w$, and rearranging,

$$\begin{aligned}\Psi_w &= (\mu_w - \mu_w^0)/\bar{V}_w \\ &= (RT\ln a_w)/\bar{V}_w + P + (Z_w FE)/\bar{V}_w \\ &\quad + (m_w gh)/\bar{V}_w \end{aligned} \tag{3}$$

Eq. (3) defines the "water potential," Ψ_w, which is the maximum amount of work the water molecules in the system can do, relative to the standard of pure water.[1] By expressing the water potential per unit volume, $\bar{V}_w$, the water potential can be measured in units of pressure. Because water has no electrical charge ($Z_w = 0$), and gravitational effects on water are small (except in very tall trees!), the Ψ_w of plant cells is determined primarily by osmotic forces and pressure. So Eq. (3) can be simplified.

Plants–Pumps

$$\Psi_w = (RT\ln a_w)/\bar{V}_w + P = \Psi_s + \Psi_p \tag{4}$$

The osmotic forces are measured in the $(RT\ln a_w)/\bar{V}_w$ term in Eq. (4), and referred to as the osmotic potential, Ψ_s. As discussed below, this term includes solute and matric effects on water activity. Pressure effects on Ψ_w are measured in the second term on the right side of Eq. (4), which is referred to as the "pressure potential," Ψ_p. This term includes pressure generated internally by plant cells (turgor) and atmospheric pressure.

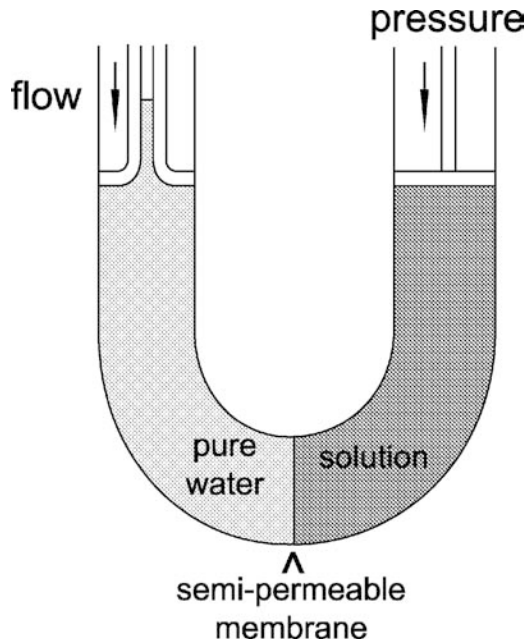

Fig. 1 Typical vapor pressure osmometer with a semipermeable membrane separating a chamber containing a solution from one containing pure water. Water flow from the pure water chamber across the membrane is monitored in the capillary at the top of the chamber. The amount of pressure applied to the chamber containing the solution to prevent water movement into it is equal to the solution osmotic pressure, π. *Source*: From Ref.[2], p. 33.

Osmotic Potential vs. Osmotic Pressure

In an ideal system with no solute/solvent interactions, the presence of solutes in water "dilutes" the chemical potential of the water because solute occupies space normally occupied by water. This dilution decreases the vapor pressure of the water at the surface of the solution. The decrease in vapor pressure is given by Raoult's law [Eq. (5)], which states that for dilute, ideal solutions the vapor pressure in equilibrium with a dilute solution is proportional to the mole fraction of the solvent, in this case water, N_w. That is, the vapor pressure decreases with N_w as solute is added.

$$e = e_o N_w = e_o(n_w/(n_w + n_s)) \tag{5}$$

where e is the vapor pressure of the solution, e_o is the vapor pressure of the pure water, N_w is the mole faction of water, n_w and n_s are moles of water and solute, respectively. The vapor pressure of dilute solutions is measured relative to pure water in "osmometers" like the one shown in Fig. 1. When pure water is separated from a solution by a membrane that is permeable to water, but not the solute, water moves across the membrane from the solution of higher chemical potential (larger N_w or higher Ψ_s) to the solution of lower chemical potential (smaller N_w or lower Ψ_s). This would be from the "pure water" side to the "solution" side in Fig. 1. Pressure applied to the solution side will stop the flow of water across the membrane. The amount of pressure that must be applied to prevent water movement is the "osmotic pressure" of the solution, relative to pure free water. The osmotic pressure, generally denoted as π, is present only when a balancing pressure is applied to the osmometer. On the other hand, the physical property responsible for the water movement across the membrane, the osmotic potential Ψ_s, is always characteristic of the solution. As more solute is added to the solution, its osmotic pressure increases according to the fundamental definition of osmotic pressure,

$$RT\ln a_w = -\bar{V}_w \pi \tag{6}$$

The Ψ_s of the solution, however, decreases since the addition of solutes decreases the mole fraction and, therefore, the activity of water according to Eq. (4). Thus, $\Psi_s = -\pi$. This mathematical equivalence has prompted many to use the terms osmotic pressure and osmotic potential interchangeably. Eq. (4) describes the general relationship between water potential and its component osmotic and pressure potentials

($\Psi_w = \Psi_s + \Psi_p$). The equation often used in place of Eq. (4) to quantify the components of water potential in plant cells and tissues is $\Psi_w = -\pi + P$, which has led to some confusion in the literature. This confusion has resulted primarily from the failure of authors to appreciate the distinction between osmotic pressure and osmotic potential, lack of regard for the proper sign convention for $-\pi$, and failure to recognize that P is cell turgor only when atmospheric pressure equals zero.

Osmotic and Matric Forces

Water molecules associated with the surfaces of colloidal particles, membranes, or cell walls have a decreased tendency to interact with water in the bulk solution. This interaction decreases the water activity (a_w) near these surfaces, as does the presence of solutes in the bulk solution. Such surface interactions do not alter the mole fraction of water, N_w, but they do decrease the activity coefficient of water, γ_w. Nobel[3] suggested that the individual contribution of surface interactions (matric forces) and solvent dilution (osmotic forces) on decreasing a_w could be considered as separate and additive components of the total osmotic potential of a solution. Recalling that $\Psi_s = (RT/\bar{V}_w)\ln a_w$ from Eq. (4), and that $a_w = \gamma_w N_w$, we have

$$\begin{aligned}\Psi_s &= (RT/\bar{V}_w)\ln(\gamma_w N_w)\\ &= (RT/\bar{V}_w)\ln\gamma_w + (RT/\bar{V}_w)\ln N_w\\ &= \Psi_m + \Psi_s^* \end{aligned} \tag{7}$$

where Ψ_m accounts for the effects of matric forces expressed through their impact on the activity coefficient, γ_w, and Ψ_s^* accounts for osmotic forces expressed solely via their impact on the mole fraction of water, N_w. This analysis assumes that these matric and osmotic forces are independent, and is not intended to define matric forces in all situations. But it is a useful approach to consider how matric and osmotic forces vary in tissues such as seeds, which undergo extensive dehydration and surface interactions begin to dominate water activity of the tissue.

PLANT CELLS AS OSMOMETERS

For dilute and ideal solutions of non-dissociating solutes, the relationship between the chemical potential and the mole fraction of water can be approximated by the van't Hoff equation [Eq. (8)]

$$\psi_s \sim -RTC_s \quad \text{or} \quad \pi \sim RTC_s \tag{8}$$

where C_s is the molar concentration of solute (mol m^{-3}), R is the gas constant (m^3 MPa mol^{-1} K^{-1}), and T is the absolute temperature (K). This relationship indicates that ψ_s is proportional to the solute concentration at constant temperature and pressure. Thus, if plant cells behave as perfect osmometers, i.e. no solutes cross the plasmalemma as water leaves or enters the symplasm, a known change in cell volume should lead to a defined change in cell ψ_s. Pressure–volume curves, such as shown in Fig. 2, generated by forcing water out of plant cells by pressurizing the atmosphere around them,[4] generally confirm that this relationship holds for plant tissues. They also provide information about several osmotic parameters of plant tissues. For example, an estimate of the osmotic potential at full cell hydration, ψ_s^0, and the symplasm volume of the tissue can be obtained by extrapolating the linear portion of the curve to the *Y*-axis and *X*-axis, respectively. The latter estimate, of course, assumes no water is expressed from the cell walls at high atmospheric pressures.

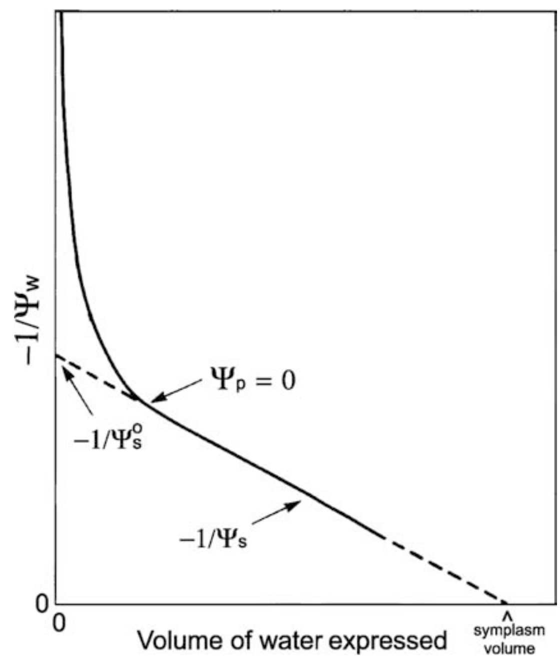

Fig. 2 A modified Hőfler diagram relating the change in tissue water potential (Ψ_w) to the volume of water expressed from the tissue. The initial change in Ψ_w is due to a decrease in Ψ_p and Ψ_s. Once Ψ_p reaches zero (incipient plasmolysis), further dehydration results in a linear decrease in Ψ_s. Extrapolating the linear portion of the curve to the *Y*-axis and *X*-axis provides an estimate of the osmotic potential at full hydration (and turgor), Ψ_s^0, and the volume of the symplasm. *Source*: From Ref.[3], p. 90.

CONTROL OF SOLUTE ACCUMULATION

Under well-watered conditions, values for tissue ψ_s generally range from -0.8 MPa to -1.3 MPa (Table 1).

Table 1 Typical osmotic potential values for various plant tissues. Tissues were sampled from plants grown under well watered (WW) or water stressed (WS) conditions. Osmotic potentials were measured on whole tissues or cell sap expressed from them

Less negative values can occur in stem and root tissues; much more negative values are observed in seeds as they desiccate during the later stages of development. Values in leaves vary during the day in response to photosynthetic activity. And ψ_s values can vary with development, as tissues increase in volume and differentiate into synthetic or storage organs. Under drought conditions, tissue ψ_s values invariably decrease throughout the plant due to the accumulation and passive concentration of solutes. This phenomenon, investigated by Meyer and Boyer[5] and Greacen and Oh,[6] has since been termed ''osmotic adjustment.'' Such solute accumulation has been shown to have a positive impact on expansion growth and reproductive success during drought in a number of plant systems.[7–9] Transgenic approaches are now being used to generate plants that overproduce ''compatible solutes,'' which are thought to improve plant tolerance to water deficit stress.[10] Whether this approach will actually lead to new genotypes with increased tolerance to abiotic stresses under field conditions, however, remains to be demonstrated.

Plants: Salt Tolerance

Michael C. Shannon
George E. Brown Jr. Salinity Laboratory, U.S. Department of Agriculture (USDA), Riverside, California, U.S.A.

INTRODUCTION

Salt tolerance is generally defined as the degree to which a plant endures salinity as a stressor. The components of salinity include the composition of the ions in the salt, e.g., sodium, chloride, calcium, and sulfate, and their concentrations. A plant may be exposed to salt continuously or intermittently and salt ions may affect the plant through their effects in the root zone as a component of the soil water or as a salt spray on leaf surfaces. Different plant species, and even sometimes varieties within a species, differ in salt tolerance. In addition, plants differ in their tolerance to salinity exposure depending on their stage of growth and different plant measurements can be taken as an index of salt tolerance. If salt stress becomes too severe, the plant may exhibit varying types of leaf burn and necrosis and will eventually die, but under moderately saline conditions it is very difficult to identify a salt-stunted plant from visual symptoms. Although scientists have studied the effects of salinity on plant growth, metabolism, and biochemistry, only a few genetic markers have been identified that have helped to improve salt tolerance in crops.

SALINITY EFFECTS AND MANAGEMENT

Plant salt tolerance can be described as a change in growth rate, leaf or root elongation rate, germination or emergence rate, and so forth. Salinity-induced growth decrease is measured as a function of salinity exposure. Roots are typically the sites of exposure in saline soils when plants are furrow or drip irrigated with saline water or are grown in saline soils, but foliage can be the site of salt exposure if the plant is subjected to sprinkler irrigation or ocean spray. Hurricanes can carry saline ocean water many miles inland and deposit salts on soils and plants. Another variable that affects salt tolerance is the timing of a plant's exposure to salt. Exposure may be continuous or intermittent with different starting and stopping points with respect to the stage of plant development. These factors, as well as salt composition and concentration, have significant and moderating effects on plant response, which is also strongly dependent on environmental factors and secondary stressors. Thus, it is not remarkable that despite the existence of thousands of research papers published on salt tolerance of crops and other plants[1] and literally tens of thousands more papers on the effects of salinity on plant growth, morphology, physiology, and biochemistry, there is yet much more information that is needed before a comprehensive, quantitative, and mechanistic explanation of salt tolerance can be proposed.

Salt tolerance of crops is most practically measured as a function of yield decline across a range of salt concentrations. A typical and adequate measure of salt tolerance can be usually formulated on the basis of a two parameter model;[2] the crop salt tolerance threshold (EC_t) and the slope (S) (Fig. 1). The crop salt tolerance threshold, defined as the salinity that is expected to cause the initial significant reduction in maximum expected yield (Y_{max}), is very sensitive to environmental interactions. The measurement of the threshold salinity value depends upon both on the accuracy of the salinity measurements and the method by which the measurements are integrated over time, as well as rooting depth and area, if exposed through the rooting profile. Because of this, there is a high degree of error in evaluating the slope at salt concentrations near the threshold; few salinity studies include enough replications to determine accurately the threshold value. Slope is simply the percentage of the yield that is expected to be reduced for each unit of added salinity above the threshold value. There is a tendency for slope to "tail-off" at the higher salt concentrations.

Soil salinity is usually and most easily measured as the electrical conductivity of a saturated soil paste extract (EC_e), in deciSeimens per meter ($dS\,m^{-1}$). Relative yield (Y) at any salinity exceeding the threshold (EC_t) can be calculated as:

$$Y = Y_{max} - S(EC_e - EC_t)$$

where S is the relative yield decrease per unit salinity increase and EC_t is the salinity threshold. Salt tolerance at high salinity has little economic importance

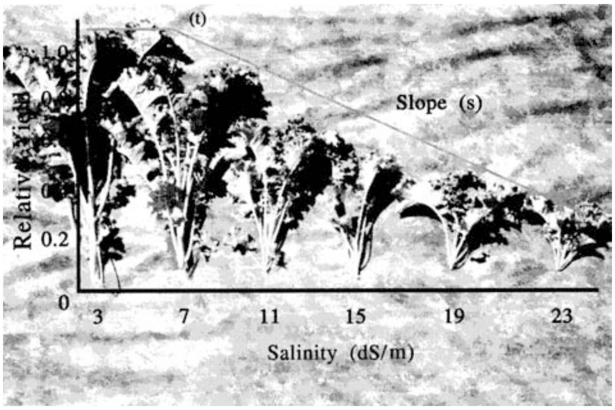

Fig. 1 Measurement of salt tolerance.

and measurements made at high salt concentrations may disproportionately skew the salt tolerance curve. For these reasons, the numerically most reliable value for crop salt tolerance response studies is the value at which yield is reduced by 50% (C50). The C50-value may still be estimated when too few data points exist to provide reliable information on the threshold. The set of equations developed by van Genuchten and Hoffman[3] takes advantage of the stability of the C50. The C50 value, together with an empirically-derived *p*-value that characterizes the steepness of the response function, may be obtained by fitting van Genuchten and Hoffman's function to observed salt tolerance response data.

Reliable data to describe the salinity functions can be obtained only from carefully controlled, monitored, and well-replicated experiments conducted across a range of salinity treatments. Data of this type have been compiled for 127 crop species which includes 68 herbaceous crops, 10 woody species, and 49 ornamentals.[4] This is a valuable resource database for growers concerned with the potential hazard of a given saline water or soil.

When high quality water is not available for irrigation and leaching, efforts to manage high salinity traditionally has been through crop substitution, i.e., the replacement of salt-sensitive crops with more tolerant ones. This practice has been traced back to the dawn of agriculture and is still probably one of the easiest and most often used strategies in dealing with salinity. Thus, barley (*Hordeum vulgare*, L.) may be substituted for wheat (*Triticum aestivum*, L.), cotton (*Gossypium hirsutum*, L.) for corn (*Zea mays*, L.), sugar beet (*Beta vulgaris*, L.) for lettuce (*Lactuca sativa*, L.), etc. Unfortunately, high value vegetable crops are typically more salt sensitive than most field crops. Harvest quality usually has a more significant impact on marketable yield of horticultural crops than it does for field crops. The salt tolerance tables developed at the USDA Salinity Laboratory in Riverside, California, have been valuable guides for extension personnel and growers in determining which crops can be grown based upon the anticipated soil salinity.[4]

Beyond crop selection, agricultural management techniques can be used to minimize and avoid salinity effects. Some of these practices include leaching, deep plowing, amendment application, careful choice of fertilizer source and type, installation of drainage, leveling operations, and irrigation techniques. Other management options include the use of drip or sprinkler irrigation to improve water application efficiency and elaborations in seed bed formation and planting design to facilitate removal of accumulated salts from the areas in which roots are developing and extracting water.[5] Some strategies which have not been researched and developed adequately include the manipulation of population densities to improve plant stand and the application of non-saline or more saline water dependent on the variable salt tolerance of plants during different growth stages.

More recently, crop breeding and genetic manipulation, using tools such as tissue culture and molecular techniques, have been proposed as adjunct strategies to deal with the salinity problem. In the last two decades especially, there has been great interest in breeding plants for improved salt tolerance.[6] Strategies that have been tried or suggested include conventional screening, selection, and breeding with established cultivars, introduction of high salt tolerance into cultivated species through introgression with tolerant wild relatives, or the domestication of salt-tolerant wild or halophytic species through genetic improvement of agronomic or horticultural characteristics. Some of these efforts have resulted in limited success, but major advances have not been noted.

Examples of screening and selection criteria that have been tried include selection during germination and emergence, resistance to salinity-induced reductions in plant height or weight, maintenance of high yield or quality under salt stress, and plant survival. Extensive efforts have also been made to identify reliable physiological or biochemical markers for salt tolerance. Such markers include capability to exclude ions (e.g., Na and Cl) from shoots or specific tissues, maintenance of nutrients (K, Ca, Mg, P, and NO_3) in plant tissues against high external salt concentrations, and ion selectivity (e.g., high K/Na, Ca/Na, or NO_3/Cl).[7,8] The accumulation of metabolic-compatible cellular osmoprotectants such as proline, glycine-betaine, and certain sugars and alcohols has also been proposed as indices for high salt tolerance, but the evidence that accumulation of compatible solutes offers a quantitatively measurable improvement in salt tolerance is not unequivocal.

Most recently efforts have been made to use molecular tools to improve the salt tolerance of plants, but specific genes that confer salt tolerance have proven to be elusive. Still there are increasing examples of success. Plants respond to two basic components of salinity—the ionic component and the osmotic component. The osmotic component is physiologically equivalent to dehydration or drought stress. Thus, plants grown in soils having high salinity have more difficulty in extracting water from the soil matrix. A gene for D-ononitol that confers drought tolerance in ice plant (*Mesambrythium* L.) has been found to improve drought tolerance in tobacco (*Nicotiana tabacum*, L.) under laboratory conditions.[9] Now several researchers are pursuing this strategy with other osmoprotectant genes and other species.

In an approach that focuses on ion regulation, the gene for an ion pump protein located in the vacuoles of Arabidopsis (*Arabidopsis Thaliana*, Heynh.) was transferred to tomato (*Lycopersicon esculentum*, Mill.). The transgenic tomatoes expressed increased salt tolerance in the greenhouse when grown in solutions equivalent to about one-third seawater.[10] The gene AtNHX1 is over-expressed in these plants making them more efficient at sequestering sodium in the vacuole and away from the sensitive metabolic machinery of the cytoplasm. Another Arabidopsis gene, AtHKT1, when inactivated has been shown to limit the transport of sodium through the root cell membrane barrier and effectively increase salt tolerance.[11] None of these approaches has thus far resulted in the improvement of salt tolerance in field-grown plants, however; there is room for optimism as more information is developed concerning the many mechanisms that plants use to respond to salt stress.

Platte River

William L. Graf
University of South Carolina, Columbia, South Carolina, U.S.A.

INTRODUCTION

The Platte River of central Nebraska is a braided stream draining 223,000 km^2 of the High Plains and Rocky Mountains. Formed by the confluence of the North Platte and South Platte rivers, the Platte River flows 500 km eastward across the state to join the Missouri River near Omaha. The river has played a key role in the economic development of the region, with its valley serving as part of the storied Oregon Trail, as part of the route of the first transcontinental railroad, and as the location of about 500,000 ha of irrigated agriculture. The river also provides habitat for whooping cranes (and other species not discussed here), an endangered bird species. The fundamental issue in the management and use of the river is how to resolve the conflict between demands on the river resource for water supply and for support of imperiled species.[1]

The root of the conflict over water resources along the Platte River is a difference in philosophical perspectives on water: first, water as a commodity, and second, water as an ecosystem component. For most of the past century and a half, society has viewed the river as a conduit for water as a commodity, with all of the discharge of the river assigned to users with legally vested water rights. To exercise these rights, water users and government agencies have constructed an elaborate water-control infrastructure, including dams and diversion works that control the flow of the river. The flows, in turn, have resulted in geomorphic and riparian vegetation adjustments. The decline in the whooping crane population was partly the result of continent-wide influences such as habitat destruction and hunting,[2] but the shrinking population of whooping crane was particularly noticeable along the Platte River. Recognition of the important role of the river in health of wildlife populations led to a more recent perspective on its water as an ecosystem component. While changes in water flows have had detrimental effects, the water-control infrastructure also offers opportunities through regulation of the flow to restore some of the ecosystem functions and to enhance crane habitat.

EFFECTS OF WATER DEVELOPMENT IN THE PLATTE RIVER BASIN

The Platte River flows across the hundredth meridian, a north–south line which marks the western edge of the region of rainfall abundant enough to sustain humid-region agriculture. The agricultural development of the areas associated with the river therefore required the creation of an extensive system of dams, diversions, and canals. Withdrawal of water from the river at local diversions began in the mid-1800s, and small headwaters dams created relatively small water storage reservoirs beginning in 1900. The construction of very large dams and reservoirs began in 1909 and ended in 1958. By the 1960s, the infrastructure was capable of exerting major changes in the flow of the Platte River. In the central reaches of the Platte River, annual peak flows declined to a mere 20% of their predam magnitudes, and mean daily flows declined to only 30% of their predam magnitudes.[3] The number of pulse flows declined, and their timing changed.

The flow changes on the Platte resulted in dramatic changes in the river's geomorphology and riparian vegetation.[4] Photographs taken in the middle 1800s show the river channel as a ribbon of sand as much as 2 km across, with wooded islands scattered along its course. Timber cutting by pioneers along with prairie fires probably reduced the riparian forest that had previously existed along the channel margins. The earliest aerial photography shows that this open condition continued at least until the late 1930s (Fig. 1). The completion of the dams in the system, with associated changes in flows, resulted in a shrinkage of the channels of the river, and a few small channels replaced the broad braided system. In many reaches of the river, woodland areas that once were limited to islands expanded to cover much of what had been active channel areas. Under predam conditions large annual floods maintained a wide, barren active channel, and periodic pulse flows swept away seedlings of cottonwood and willow each year. Under postdam conditions, the small annual floods could maintain only narrow channels, and the lack of pulse flows allowed the expansion of woodland cover. A positive

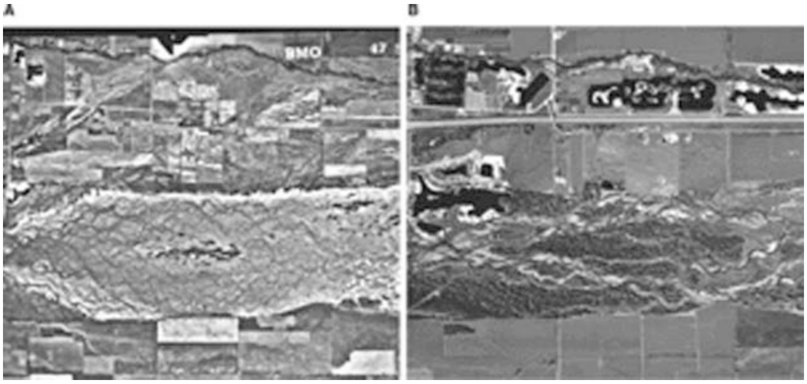

Fig. 1 Aerial photographs of the Platte River near Kearney, Nebraska, showing geomorphology and vegetation changes as a result of flow controls. Left image: 1938 (black and white); right image 1998 (IR false color). (From imagery by U.S. Geological Survey.)

feedback resulted, whereby the new vegetation trapped and stabilized sediment on expanded islands and bars, further restricting channels.

WHOOPING CRANES AND THE PLATTE RIVER

The physical changes in the Platte River had potentially negative effects for the population of whooping cranes. Whooping cranes historically visited the Platte River twice each year during their migrations from their wintering grounds in the southern United States and northern Mexico to summer breeding areas in north central Canada, and then back again. The cranes favored the Platte River as a stopover during migration because the river offered preferred habitat: shallow water, bars separated from the river banks by flowing water for protection from predators, long sight lines, and nearby food sources, often grains.[5] The postdam changes in the river's geomorphology and vegetation reduced the useful habitat for cranes because the character of the river changed. The creation of narrow channels, loss of bars, and expansion of woodland were contrary to suitable crane habitat. These local changes, combined with other continent-wide influences, resulted in the vitual disappearance of whooping cranes by the early 1940s, when the migrating population dwindled to 15 birds with virtually no use of the Platte River. Conservation measures, begun in the 1940s, resulted in a gradually increasing population, so that in 2003, 194 birds were in the migrating population. As the population expands and conservation efforts are undertaken in other areas, the Platte River, midway in the biannual migration route, is increasingly important. The recreation of predam conditions would be helpful in supporting the expanding whooping crane population.

RESTORATION OF THE PLATTE RIVER

The future of agriculture in the Platte River Valley depends on treating the river's water as a commodity, and the sustainability of the future population of whooping cranes depends on the availability of suitable habitat that results from treating the river as an ecosystem. The restoration of the river to include suitable crane habitat, while maintaining the water-supply functions of the stream, is the objective of the Central Platte River Recovery Implementation Program. The program includes federal, state, local, and private interests, all engaged in research and decision making for the river. The basic strategy for restoration is to replicate in miniature the predam flow regime to maintain a geomorphology and vegetation community similar to original predam conditions. The magnitudes of flows introduced to the river to improve habitat will be smaller than in predam conditions, recognizing the value of the water for agriculture. Instream flow recommendations by federal agencies include recommended low flows, annual pulse flows, and once-every-five-year peak flows. These efforts, along with some vegetation clearing, are attempts to recreate and maintain increased areas of suitable habitat for whooping cranes. It is too soon to determine the success of the program, but active proposals include the purchase of water to operate the system for the benefit of crane habitat.

CONCLUSIONS

The Platte River experience has important general lessons for similar rivers that serve as economic resources as well as valued habitat. First, water is the key to understanding the changes in habitat that have been detrimental to wildlife populations. Second, environmental rehabilitation depends on restoring the physical integrity of the system, with the biological system to follow. Third, change is an integral part of any river system, and the rehabilitated Platte River will not be a static arrangement. Commodity and ecosystem perspectives on the river will need to coexist rather than continue as exclusive viewpoints.

INTRODUCTION

Environmental pollution is one of the foremost ecological challenges. Pollution is an offshoot of technological advancement and overexploitation of natural resources. From the standpoint of pollution, the term environment primarily includes air, land, and water components including landscapes, rivers, parks, and oceans. Pollution can be generally defined as an undesirable change in the natural quality of the environment that may adversely affect the well being of humans, other living organisms, or entire ecosystems either directly or indirectly. Although pollution is often the result of human activities (anthropogenic), it could also be due to natural sources such as volcanic eruptions emitting noxious gases, pedogenic processes, or natural change in the climate. Where pollution is localized it is described as point source (PS). Thus, PS pollution is a source of pollution with a clearly identifiable point of discharge that can be traced back to the specific source such as leakage of underground petroleum storage tanks or an industrial site.

Some naturally occurring pollutants are termed geogenic contaminants and these include fluorine, selenium, arsenic, lead, chromium, fluoride, and radionuclides in the soil and water environment. Significant adverse impacts of geogenic contaminants (e.g., As) on environmental and human health have been recorded in Bangladesh, West Bengal, India, Vietnam, and China. More recently reported is the presence of geogenic Cd and the implications to crop quality in Norwegian soils.[1]

The terms contamination and pollution are often used interchangeably but erroneously. Contamination denotes the presence of a particular substance at a higher concentration than would occur naturally and this may or may not have harmful effects on human or the environment. Pollution refers not only to the presence of a substance at higher level than would normally occur but is also associated with some kind of adverse effect.

NATURE AND SOURCES OF CONTAMINANTS

The main activities contributing to PS pollution include industrial, mining, agricultural, and commercial activities as well as transport and services (Table 1). Uncontrolled mining, manufacturing, and disposal of wastes inevitably cause environmental pollution. Military land and land for recreational shooting are also important sites of PS contamination. The contaminants associated with such activities are listed in Table 1. Contamination at many of these sites appears to have resulted because of lax regulatory measures prior to the establishment of legislation protecting the environment.

CONTAMINANT INTERACTIONS IN SOIL AND WATER

Inorganic Chemicals

Inorganic contaminant interactions with colloid particulates include: adsorption–desorption at surface sites, precipitation, exchange with clay minerals, binding by organically coated particulate matter or organic colloidal material, or adsorption of contaminant ligand complexes. Depending on the nature of contaminants, these interactions are controlled by solution pH and ionic strength of soil solution, nature of the species, dominant cation, and inorganic and organic ligands present in the soil solution.[2]

Organic Chemicals

The fate and behavior of organic compounds depend on a variety of processes including sorption–desorption,

Table 1 Industries, land uses, and associated chemicals contributing to points, non-point source pollution

Industry	Type of chemical	Associated chemicals
Airports	Hydrocarbons	Aviation fuels
	Metals	Particularly aluminum, magnesium, and chromium
Asbestos production and disposal	Asbestos	
Battery manufacture and recycling	Metals	Lead, manganese, zinc, cadmium, nickel, cobalt, mercury, silver, and antimony
	Acids	Sulfuric acid
Breweries/distilleries	Alcohol	Ethanol, methanol, and esters
Chemicals manufacture and use	Acid/alkali	Mercury (chlor/alkali), sulfuric, hydrochloric and nitric acids, sodium and calcium hydroxides
	Adhesives/resins	Polyvinyl acetate, phenols, formaldehyde, acrylates, and phthalates
	Dyes	Chromium, titanium, cobalt, sulfur and nitrogen organic compounds, sulfates, and solvents
	Explosives	Acetone, nitric acid, ammonium nitrate, pentachlorophenol, ammonia, sulfuric acid, nitroglycerine, calcium cyanamide, lead, ethylene glycol, methanol, copper, aluminum, *bis*(2-ethylhexyl) adipate, dibutyl phthalate, sodium hydroxide, mercury, and silver
	Fertilizer	Calcium phosphate, calcium sulfate, nitrates, ammonium sulfate, carbonates, potassium, copper, magnesium, molybdenum, boron, and cadmium
	Flocculants	Aluminum
	Foam production	Urethane, formaldehyde, and styrene
	Fungicides	Carbamates, copper sulfate, copper chloride, sulfur, and chromium
	Herbicides	Ammonium thiocyanate, carbanates, organochlorines, organophosphates, arsenic, and mercury
	Paints	
	Heavy metals	Arsenic, barium, cadmium, chromium, cobalt, lead, manganese, mercury, selenium, and zinc
	General	Titanium dioxide
	Solvent	Toluene, oils natural (e.g., pine oil) or synthetic
	Pesticides	Arsenic, lead, organochlorines, and organophosphates
	Active ingredients	Sodium, tetraborate, carbamates, sulfur, and synthetic pyrethroids
	Solvents	Xylene, kerosene, methyl isobutyl ketone, amyl acetate, and chlorinated solvents
	Pharmacy	Dextrose and starch
	General/solvents	Acetone, cyclohexane, methylene chloride, ethyl acetate, butyl acetate, methanol, ethanol, isopropanol, butanol, pyridine methyl ethyl ketone, methyl isobutyl ketone, and tetrahydrofuran
	Photography	Hydroquinone, pheidom, sodium carbonate, sodium sulfite, potassium bromide, monomethyl paraaminophenol sulfates, ferricyanide, chromium, silver, thiocyanate, ammonium compounds, sulfur compounds, phosphate, phenylene diamine, ethyl alcohol, thiosulfates, and formaldehyde
	Plastics	Sulfates, carbonates, cadmium, solvents, acrylates, phthalates, and styrene
	Rubber	Carbon black
	Soap/detergent	
	General	Potassium compounds, phosphates, ammonia, alcohols, esters, sodium hydroxide, surfactants (sodium lauryl sulfate), and silicate compounds
	Acids	Sulfuric acid and stearic acid
	Oils	Palm, coconut, pine, and tea tree
	Solvents	
	General	Ammonia
	Hydrocarbons	e.g., BTEX (benzene, toluene, ethylbenzene, xylene)
	Chlorinated organics	e.g., trichloroethane, carbon tetrachloride, and methylene chloride

(Continued)

Plants–Pumps

Table 1 Industries, land uses, and associated chemicals contributing to points, non-point source pollution *(Continued)*

Industry	Type of chemical	Associated chemicals
Defense works		See "Explosives" under "Chemicals Manufacture and Use, Foundries, Engine Works, and Service Stations"
Drum reconditioning		See "Chemicals Manufacture and Use"
Dry cleaning		Trichlorethylene and ethane
		Carbon tetrachloride
		Perchlorethylene
Electrical		PCBs (transformers and capacitors), solvents, tin, lead, and copper
Engine works	Hydrocarbons	
	Metals	
	Solvents	
	Acids/alkalis	
	Refrigerants	
	Antifreeze	Ethylene glycol, nitrates, phosphates, and silicates
Foundries	Metals	Particularly aluminum, manganese, iron, copper, nickel, chromium, zinc, cadmium and lead and oxides, chlorides, fluorides and sulfates of these metals
	Acids	Phenolics and amines
		Coke/graphite dust
Gas works	Inorganics	Ammonia, cyanide, nitrate, sulfide, and thiocyanate
	Metals	Aluminum, antimony, arsenic, barium, cadmium, chromium, copper, iron, lead, manganese, mercury, nickel, selenium, silver, vanadium, and zinc
	Semivolatiles	Benzene, ethylbenzene, toluene, total xylenes, coal tar, phenolics, and PAHs
Iron and steel works		Metals and oxides of iron, nickel, copper, chromium, magnesium and manganese, and graphite
Landfill sites		Methane, hydrogen sulfides, heavy metals, and complex acids
Marinas		Engine works, electroplating under metal treatment
	Antifouling paints	Copper, tributyltin (TBT)
Metal treatments	Electroplating metals	Nickel, chromium, zinc, aluminum, copper, lead, cadmium, and tin
	Acids	Sulfuric, hydrochloric, nitric, and phosphoric
	General	Sodium hydroxide, 1,1,1-trichloroethane, tetrachloroethylene, toluene, ethylene glycol, and cyanide compounds
	Liquid carburizing baths	Sodium, cyanide, barium, chloride, potassium chloride, sodium chloride, sodium carbonate, and sodium cyanate
	Mining and extracting industries	Arsenic, mercury, and cyanides and also refer to "Explosives" under "Chemicals Manufacture and Use"
	Power stations	Asbestos, PCBs, fly ash, and metals
	Printing shops	Acids, alkalis, solvents, chromium (see "Photography" under "Chemicals Manufacture and Use")
Scrap yards		Hydrocarbons, metals, and solvents
	Service stations and fuel storage facilities	Aliphatic hydrocarbons
		BTEX (i.e., benzene, toluene, ethylbenzene, xylene)
		PAHs (e.g., benzo(a) pyrene)
		Phenols
		Lead
Sheep and cattle dips		Arsenic, organochlorines and organophosphates, carbamates, and synthetic pyrethroids
Smelting and refining		Metals and the fluorides, chlorides and oxides of copper, tin, silver, gold, selenium, lead, and aluminum
Tanning and associated trades	Metals	Chromium, manganese, and aluminum
	General	Ammonium sulfate, ammonia, ammonium nitrate, phenolics (creosote), formaldehyde, and tannic acid
Wood preservation	Metals	Chromium, copper, and arsenic
	General	Naphthalene, ammonia, pentachlorophenol, dibenzofuran, anthracene, biphenyl, ammonium sulfate, quinoline, boron, creosote, and organochlorine pesticides

volatilization, chemical and biological degradation, plant uptake, surface runoff, and leaching. Sorption–desorption and degradation (both biotic and abiotic) are perhaps the two most important processes as the bulk of the chemicals is either sorbed by organic and inorganic soil constituents, and chemically or microbially transformed/degraded. The degradation is not always a detoxification process. This is because in some cases the transformation or degradation process leads to intermediate products that are more mobile, more persistent, or more toxic to non-target organisms. The relative importance of these processes is determined by the chemical nature of the compound.

IMPLICATIONS TO SOIL AND ENVIRONMENTAL QUALITY

Considerable amount of literature is available on the effects of contaminants on soil microorganisms and their functions in soil. The negative impacts of contaminants on microbial processes are important from the ecosystem point of view and any such effects could potentially result in a major ecological perturbance. Hence, it is most relevant to examine the effects of contaminants on microbial processes in combination with communities. The most commonly used indicators of metal effects on microflora in soil are: (1) soil respiration, (2) soil nitrification, (3) soil microbial biomass, and (4) soil enzymes.

Contaminants can reach the food chain by way of water, soil, plants, and animals. In addition to the food chain transfer, pollutants may also enter via direct consumption or dust inhalation of soil by children or animals. Accumulation of these pollutants can take place in certain target tissues of the organism depending on the solubility and nature of the compound. For example, DDT and PCBs accumulate in human adipose tissue. Consequently, several of these pollutants have the potential to cause serious abnormalities including cancer and reproductive impairments in animal and human systems.

SAMPLING FOR PS POLLUTION

The aims of the sampling system must be clearly defined before it can be optimized.[3] The type of decision may be to determine land use, how much of an area is to be remediated, or what type of remediation process is required. Because sampling and the associated chemical and statistical analyses are expensive, careful planning of the sampling scheme is therefore a good investment. One of the best ways to achieve this is to use any ancillary data that are available. These data could be in the form of emission history from a stack, old photographs that give details of previous land uses, or agricultural records. Such data can at least give qualitative information.

As discussed before, PS pollution will typically be airborne from a stack, or waterborne from some effluent such as tannery waste, cattle dips, or mine waste. In many cases, the industry will have modified its emissions (e.g., cleaner production) or point of release (increased stack height), hence the current pattern of emission may not be closely related to the historic pattern of pollution. For example, liquid effluent may have been discharged previously into a bay, but that effluent may now be treated and perhaps discharged at some other point. Typically, the aim of a sampling scheme in these situations is to assess the maximum concentrations, the extent of the pollution, and the rate of decline in concentration from the PS. Often the sampling scheme will be used to produce maps of concentration isopleths of the pollutant.

The location of the sampling points would normally be concentrated towards the source of the pollution. A good scheme is to have sufficient samples to accurately assess the maximum pollution, and then space additional samples at increasing intervals. In most cases, the distribution of the pollutant will be asymmetric, with the maximum spread down the slope or down the prevailing wind. In such cases more samples should be placed in the direction of the expected gradient. This is a clear case of when ancillary data can be used effectively. A graph of concentration of the pollutant against the reciprocal of distance from the source is often informative.[4] Sampling depths will depend on both the nature of the pollution and the reason for the investigation. If the pollution is from dust and it is unlikely to be leached, only surface sampling will be required. An example of this is pollution from silver smelting in Wales.[5] In contrast, contamination from organic or mobile inorganic pollutants such as F compounds may migrate well down to the profile and deep sampling may be required.[6,7]

ASSESSMENT

In order to assess the impacts of pollution, reliable and effective monitoring techniques are important. Pollution can be assessed and monitored by chemical analyses, toxicity tests, and field surveys. Comparison of contaminant data with an uncontaminated reference site and available databases for baseline concentrations can be useful in establishing the extent of contamination.

However, this may not always be possible in the field. Chemical analyses must be used in conjunction with biological assays to reveal site contamination and associated adverse effects. Toxicological assays can also reveal information about synergistic interactions of two or more contaminants present as mixtures in soil, which cannot be measured by chemical assays alone.

Microorganisms serve as rapid detectors of environmental pollution and are thus of importance as pollution indicators. The presence of pollutants can induce alteration of microbial communities and reduction of species diversity, inhibition of certain microbial processes (organic matter breakdown, mineralization of carbon and nitrogen, enzymatic activities, etc.). A measure of the functional diversity of the bacterial flora can be assessed using ecoplates (see http://www.biolog.com/section_4.html). It has been shown that algae are especially sensitive to various organic and inorganic pollutants and thus may serve as a good indicator of pollution.[8] A variety of toxicity tests involving microorganisms, invertebrates, vertebrates, and plants may be used with soil or water samples.[9]

MANAGEMENT AND/OR REMEDIATION OF PS POLLUTION

The major objective of any remediation process is to: (1) reduce the actual or potential environmental threat; and (2) reduce unacceptable risks to man, animals, and the environment to acceptable levels.[10] Therefore, strategies to either manage and/or remediate contaminated sites have been developed largely from application of stringent regulatory measures set up to safeguard ecosystem function as well as to minimize the potential adverse effects of toxic substances on animal and human health.

The available remediation technologies may be grouped into two categories: (1) ex situ techniques that require removal of the contaminated soil or groundwater for treatment either on-site or off-site; and (2) in situ techniques that attempt to remediate without excavation of contaminated soils. Generally, in situ techniques are favored over ex situ techniques because of: (1) reduced costs due to elimination or minimization of excavation, transportation to disposal sites, and sometimes treatment itself; (2) reduced health impacts on the public or the workers; and, (3) the potential for remediation of inaccessible sites, e.g., those located at greater depths or under buildings. Although in situ techniques have been successful with organic contaminated sites, the success of in situ strategies with metal contaminants has been limited. Given that organic and inorganic contaminants often occur as a mixture, a combination of more than one strategy is often required to either successfully remediate or manage metal contaminated soils.

GLOBAL CHALLENGES AND RESPONSIBILITY

The last 100 yr has seen massive industrialization. Indeed such developments were coupled with the rapid increase in world population and the desire to enhance economy and food productivity. While industrialization has led to increased economic activity and much benefit to human race, the lack of regulatory measures and appropriate waste management strategies until early 1980s (including the use of agrochemicals) has resulted in contamination of our biosphere. Continued pollution of the environment through industrial emissions is of global concern. There is, therefore, a need for politicians, regulatory organizations, and scientists to work together to minimize environmental contamination and to remediate contaminated sites. The responsibility to check this pollution lies with every individual and country although the majority of this pollution is due to the industrialized nations. There is a clear need of better coordination of efforts in dealing with numerous forms of PS pollution problems that are being faced globally.

Porous Pavements

Bruce K. Ferguson
School of Environmental Design, University of Georgia, Athens, Georgia, U.S.A.

INTRODUCTION

The underlying cause for nearly all urban stormwater problems is the loss of the soil's water-retaining function, because rain water is denied access to it by impervious pavements or rooftops. Porous pavements restore that function by bringing water back into contact with the underlying soil, or emulate that function by filtering and storing water in the pavement structure. Unlike stormwater detention and infiltration basins, which mitigate stormwater problems downstream from urban developments, porous pavements reduce or eliminate the problems at the source by changing the way urban structures are built and the way they operate hydrologically.

Porous paving materials have been in existence since approximately 1970. Since then laboratory research, field monitoring, and on-the-ground experience have been documented in many countries. As porous paving materials become increasingly used, their potential cumulative effect can be great, because pavements are the most ubiquitous structures built by mankind: they occupy two-thirds of the potentially impervious surfaces in urban watersheds.

POROUS PAVEMENT CONSTRUCTION

The hydrologic and structural success of porous pavements depends on correct selection, design, installation, and maintenance. Failures—clogging and structural degradation—result from neglect of one or more of these steps. Construction of porous pavements is not more difficult than that of dense pavements, but it is different, and its different specifications and procedures must be strictly adhered to for successful performance.[1]

Porous pavements are made in the same types of structural layers as dense pavements: surface course, base course, and subgrade (Fig. 1). Each layer has multiple structural and hydrologic functions. Alternative materials can be selected for each layer by applying physical principles that are well known in all pavement design. Part or all of a porous pavement's base course functions as a reservoir while water infiltrates the subgrade or discharges laterally.

The dominant component in most porous paving materials is aggregate such as crushed stone. Although aggregate is a simple material, its physical character greatly influences the success of the pavement. Most importantly, it must be single-sized or "open-graded," having a narrow range of particle sizes. Clean, open-graded aggregate has open voids between particles, giving a porosity of 30–40% and permeability usually over 1000 in./hr. As long as the particles remain angular, open-graded aggregate obtains structural stability from particle-to-particle interlock.

To preserve the surface infiltration rate against sedimentary clogging, a porous pavement's surface must be designed, paradoxically, as if to discharge constant runoff. Sediment must be prevented from washing on, and sediment and debris must be allowed to wash off. Surface drainage should be away from the pavement edge in every possible direction: on the downhill side, if necessary, numerous large curb cuts should be added; on the uphill side, if necessary, a swale should be added to prevent off-site sediment from washing onto the pavement surface. These provisions limit most porous pavements to letting in only the rain water that falls directly upon the pavement, and not the stormwater runoff from the surrounding earthen slopes.

ALTERNATIVE PAVING MATERIALS

In Table 1, a list of alternative porous paving materials is given. The "soft" category includes crushed shell, wood chips, and rubber particles. Decks are surrogates for pavements that are commonly porous and permeable. Each material has its own advantages and disadvantages for specific applications and requirements for design, construction, and maintenance.[1]

None of the material types—porous or dense—should be spread thoughtlessly everywhere. An urban development site should be analyzed in detail to identify pavement settings where different, optimally suited materials can be placed. Universally accessible pedestrian routes require surface textures different from those of "general" routes. The driving lanes of streets and parking lots and the portions of parking lots near building entrances have heavy traffic that require frequent braking and turning, which in turn require greater surface stability than that in parking stalls and areas distant from entrances. In "calmed" traffic areas, coarse surface textures and perceptible traffic noise may be desirable. Steep slopes have demanding

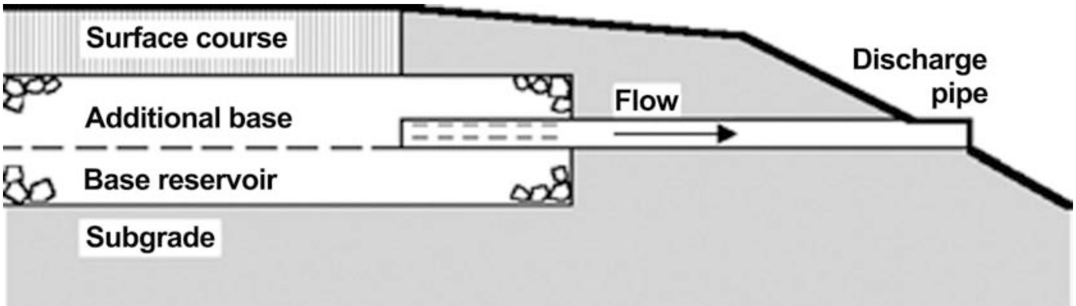

Fig. 1 Common components in porous pavement construction.

requirements for surface and subsurface stability. Unreliable maintenance discourages the use of living turf. In all pavements, areas can be distinguished, with different requirements for hydrology, appearance, subsurface tree rooting, and cost.

WATER-QUANTITY EFFECTS

During a rain storm, small pores in porous pavements completely retain the first water, to be evaporated later. Over the course of a year, more than half of the total rain water amount may be thus captured and evaporated gradually.[2] When further rain water fills and connects a pavement's voids, the water flows into the base reservoir, where it is stored in and transmitted through the large void spaces between aggregate particles.

Soil infiltration from the reservoir reduces surface stormwater volume and restores natural subsurface flow paths. The native soil infiltration rate depends largely on soil texture. Compaction during construction greatly reduces infiltration rate, but it is commonly necessary to stabilize the subgrade structurally. Compaction and the resulting reduction in infiltration rate are most likely to be required in the case where the subgrade is plastic clay or fill soil, the pavement base course will be too thin to compensate structurally for soft wet soil, or the surface course will be of a type that is sensitive to movement (asphalt, concrete, blocks, and grids). Compaction might be omitted, and the native infiltration rate preserved, where the subgrade is native cut (and therefore has in situ compaction and stability); an adequately thick base course will compensate for soft subgrade; and the surface course will be of a type that tolerates movement (e.g., aggregate, turf, and geocells).

Where slowly permeable soil prohibits significant infiltration, a porous pavement can perform detention and water-quality treatment comparable to those of off-pavement reservoirs and ponds. If a lateral outlet (perforated pipe) is added at the bottom of the reservoir, then the pavement performs treatment and detention and only incidental soil infiltration. If an outlet is added at the top of the reservoir, or if water is allowed simply to overflow at the pavement surface, water in the reservoir is permanently in contact with soil and infiltrates; only excess water discharges laterally.

Hydrologic modeling can be used to design a pavement reservoir and its outlet pipes to store and infiltrate a desired amount of water and to produce a desired discharge rate from a given storm.[3,4] In hydrologic models requiring assignment of a surface runoff coefficient or runoff curve number, it is reasonable to assign to most porous pavements a value equivalent to that of grass on the same soil and slope, rather than the high values characteristic of impervious surfaces.

Table 1 Alternative porous paving materials

Material	Distinctive characteristics
Porous aggregate	Inexpensive and very permeable
Porous turf	Living and dynamic
Plastic geocells	Recycled
Open blocks and grids	Sturdy, attractive, and reliable
Porous concrete	Quality depends on installer
Porous asphalt	Technology is advancing
"Soft" paving materials	Organic and recycled
Decks	Adaptive to site

WATER-QUALITY EFFECTS

Porous pavements are effective filters and degraders of the urban pollutants commonly associated with pavement use. Oil leaked from automobiles is degraded (broken into chemically simpler constituents) by a biotically diverse micro-ecosystem that exists on the abundant surface area within a porous pavement's voids. The community's habitat is aerated and occasionally moistened. The community blooms to feed on oil when it is provided. The oil's constituents go off as carbon dioxide and water and very little else; essentially no oil is discharged from the bottom of the pavement.[2]

The metal ions released by automobile corrosion and wear, such as those of lead, zinc, and cadmium, cannot be degraded, but they can be captured and prevented from moving downstream and accumulating inadvertently in the environment. Voids in porous pavements trap metal ions by capturing the minute sediment particles to which the ions are characteristically attached. Most of the capture occur near the pavement surface, in the first sufficiently narrow voids that the particles encounter during their infiltration and percolation. The amounts of solids and metals discharging from the bottom of a pavement are less than one-third of those from the surfaces of nearby dense pavements. Elevation of metal levels in the underlying subgrade has been essentially undetectable.[5]

Beneath a porous pavement, almost all subgrade soils further protect the quality of water before it percolates into aquifers.[6] Natural clay particles have electrochemically active surfaces that interact with the dissolved chemicals in percolating water; naturally occurring soil microbiota degrade complex chemicals into simpler constituents. A soil's cation exchange capacity (CEC), multiplied by the thickness of the soil mantle, indicates the relative renovation capability of a soil profile. It takes only a few inches of most kinds of soil to trap and transform oils and metals. Where a natural subgrade's CEC is too low to assure treatment, a "treatment liner" of soil with higher CEC can be installed. If a liner of this type will be required, any hydrologic modeling must be redone taking into account the new artificial layer's infiltration rate.

COSTS AND BENEFITS

A porous pavement is both a pavement structure and a stormwater control facility. Compared with a dense pavement, it can provide the same structural pavement function while reducing or eliminating the need for downstream facilities such as detention ponds, which involve additional costs of land acquisition, excavation, piping, and outlet structures. Comparing a porous pavement's cost with that of a dense pavement requires consideration of the cost of both the pavement structures and the associated stormwater control facilities. A systematic way to make this comparison is to allocate the cost of a porous pavement's surface course to the pavement structure, and the cost of its base course to stormwater control. Using this accounting, for example, a porous asphalt pavement structure in the mid-Atlantic area of the U.S.A. is slightly less expensive than an equivalent dense pavement, and the porous pavement's stormwater control is less expensive than equivalent off-pavement control required for a dense pavement's runoff.[7]

In addition to controlling urban stormwater hydrology, properly applied porous pavements can also enlarge urban tree rooting space, reduce the urban heat-island effect, reduce traffic noise, increase driving safety, and improve appearance.[1] Therefore, selection and implementation of porous pavements are integral parts of the multifaceted concerns of urban design, and all of their effects are considered together in evaluations of costs and benefits.

CONCLUSIONS

Porous pavements are becoming increasingly common because of public concern about and legal requirements for urban stormwater management. Suppliers are changing their industrial processes to make the materials widely available. The transition to new materials is gradual because many regulatory agencies are slow to approve new construction practices. Nevertheless, this technology's environmental and economic advantages encourage increasing awareness and adoption.

Precipitation: Distribution Patterns

Gregory L. Johnson
National Water and Climate Center, U.S. Department of Agriculture (USDA), Portland, Oregon, U.S.A.

INTRODUCTION

Precipitation formation and distribution are largely controlled by two factors: the availability of atmospheric moisture, and the presence of upward vertical motion. Warmer air can hold more moisture than colder air, which often means tropical areas have more precipitation than colder regions, although this is not always true. Continental interiors usually have less precipitation than nearby coastal areas, also due to less available atmospheric moisture. It is estimated that only 15% of globally evaporated water each year comes from continental areas, with the remainder from the world's oceans.[1] Locations with predominant rising air, such as the forced lifting over mountain areas, usually have more precipitation than nearby lower elevations. There are clear exceptions to these general patterns, however, which result from a sometimes complicating set of factors.

LATITUDINAL AND LAND–OCEAN EFFECTS

The general precipitation characteristics mentioned earlier must be considered in light of the global circulation patterns that transfer energy, as well as moisture, poleward from the equator. Fig. 1 illustrates the chief latitudinal and vertical flow patterns that consist largely of three cells from the equator to each pole. This meridional circulation system was first depicted by Bergeron.[2] Rising air is noted in equatorial regions and at approximately 60° latitude, leading to relatively more precipitation in those regions. Conversely, subsidence is common at approximately 30° latitude and at the poles, which are the locations of the major desert regions.

These global circulation patterns in both the oceans and the atmosphere are modified by the shape and position of continents. The flow in the major oceans is largely anticyclonic, and the associated atmospheric flow transports tropical water and atmospheric moisture poleward along the east sides of continents. Therefore, eastern portions of North and South America, Africa, Australia, and Asia have relatively greater precipitation than their western regions, especially at latitudes of approximately 25–45°, and during their respective summers. In the winter, polar air shifts southward and intensifies the atmospheric thermal boundary and, thus, upper air steering winds. This typically moves the jet stream, with its associated storminess and greatly enhanced precipitation, to the west coast of the continents at 40–60° latitude. This produces, for instance, very wet winters along coastal areas of the Pacific Northwest northward to Alaska, as well as in southern Chile.

At middle and high latitudes, precipitation is chiefly the result of large-scale weather systems. These synoptic-scale (>500 km or so) systems often have rather long lifetimes (days), and can produce precipitation over a wide area, although generally there are regions of enhanced precipitation within these broad areas associated with the position of the upper air jet stream. These systems are more common in the cold season months. In the warm season, precipitation usually is of smaller spatial scale (such as individual thunderstorms), resulting in precipitation signatures that are of considerably smaller spatial dimensions (10–100 km), and often with accompanying shorter time durations. There are exceptions to these spatial rules, as well, such as organized tropical systems (storms and hurricanes) that occasionally impact midlatitude areas, and thunderstorm complexes (such as the mesoscale convective complexes, or MCCs common over the U.S. Midwest in the summer), which can have spatial scales approaching those of synoptic systems.

In the tropics, typical areal dimensions of thunderstorms can be as little as 2 km^2. Average durations at a location often are less than 1 hr, and whole storms generally last less than 3 hr.[3] Tropical storm systems can have much longer durations and larger spatial dimensions, but are quite infrequent in most locations, and usually contribute only a relatively small percentage to the average annual precipitation except in a few regions. These systems do follow rather common transit routes, however, such as from off the African coast westward to the Caribbean and the southeastern coast of the United States; and from the Mexican coast westward across the Pacific south of Hawaii to east Asia. In these regions, tropical storms can contribute more significantly to annual precipitation, even on a 30-yr average basis. Another region of enhanced convection is the intertropical convergence zone

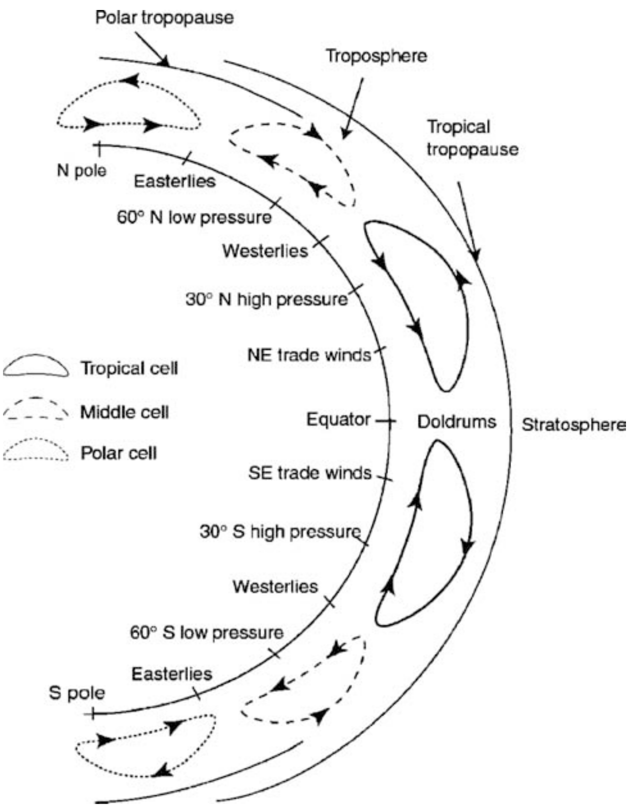

Fig. 1 Vertical distribution of the three major atmospheric cells in each hemisphere responsible for poleward energy transfer and atmospheric circulation systems (after Ref.[2]).

(ITCZ). This is a semipermanent (at climatic time scales) region of surface convergence, clouds, and enhanced precipitation associated with the equatorial trough, in the general region across the Pacific, Indian, and (to a somewhat lesser extent) Atlantic Oceans. Northeast and southeast trade winds converge at the ITCZ, and in the Pacific, it is commonly 5–10° north of the equator.

GLOBAL PRECIPITATION PATTERNS

The result of these and other forcings is a global precipitation structure as very generally depicted in Fig. 2. Equatorial regions are generally the wettest, but note the extremely wet coastal regions of southern Alaska and western Canada, and also southern Chile. The great deserts are generally in the region of 20–30° latitude, and along west coasts or in continental interiors. This general map, of course, fails to show much of the great spatial variability that exists even in small regions.

SPACE AND TIME SCALES OF PRECIPITATION

The matching of space and time scales of precipitation processes is an important consideration in the determination of precipitation patterns. Over short time-averaging periods precipitation generally has high spatial variability. A snapshot image of precipitation coverage over the continental United States in Fig. 3 is derived from compositing all doppler weather radar reflectivity coverages. At once this springtime image reveals a number of different precipitation processes, including organized precipitation structure along the Atlantic seaboard associated with an upper level trough and a surface cold front. Other areas of precipitation exhibit greater spatial variability, and cover

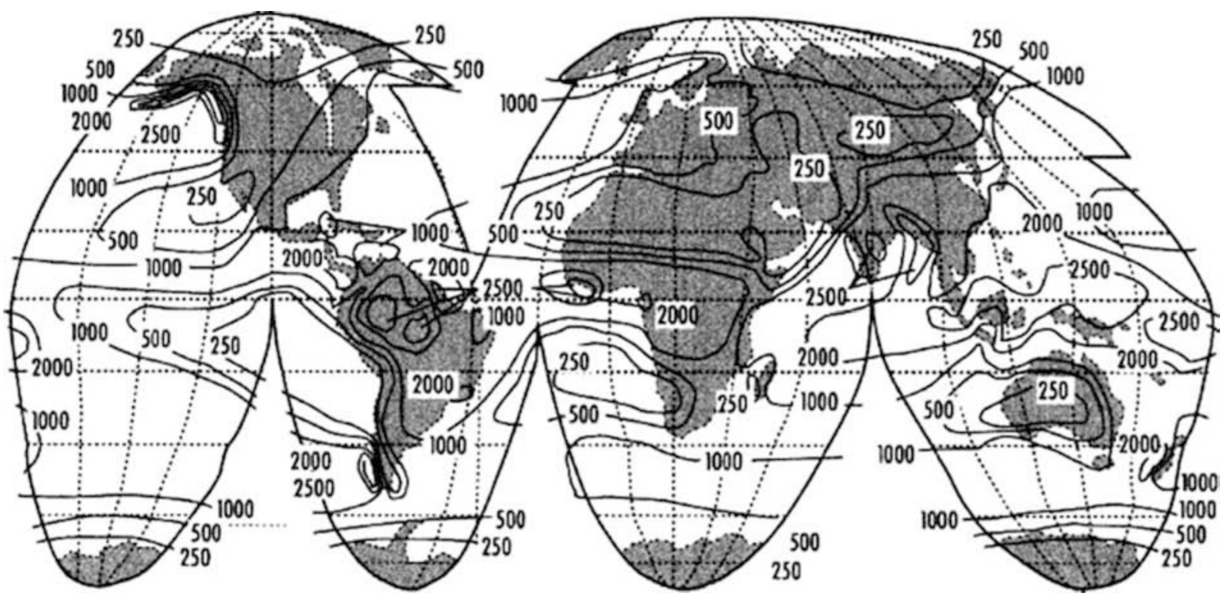

Fig. 2 Global mean annual precipitation isohyets (mm).

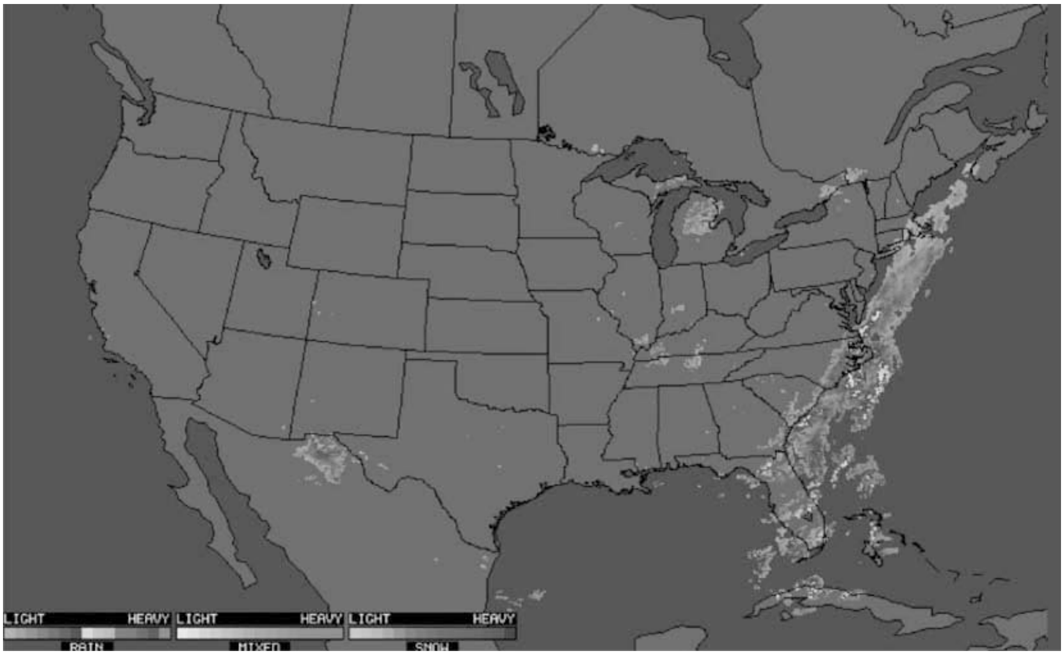

Fig. 3 Composite radar reflectivity image of the United States, showing precipitation areas, 2000 UTC, April 25, 2001.

much smaller spatial domains. Isolated subtropical showers with more inherent randomness in their locations are evident off the northeast coast of Mexico. A small area of organized convection is at least partially due to the presence of mountains in extreme north-central Mexico. A large portion of the country is dry.

In contrast, at longer time scales, precipitation patterns begin to emerge that reveal more consistency in moisture-availability and lifting-mechanism-presence. For instance, at monthly time scales, weather features that exhibit consistency over 30-day periods emerge. Any given month, representing just one sample of 30 days, can show features that may be associated with large-scale forcings like El Niño, or upper air patterns that become relatively ''locked in'' for that month. In contrast, a 30-yr average, or longer, will reveal precipitation processes that are even more consistent. Take for example the contrasting images of mean July precipitation (based on 30 yr of data) vs. the map of July, 1993 precipitation over the continental United States (Fig. 4). The mean map (top) reveals numerous features, including the moist eastern half of the country, especially along the Southeastern coast; the extreme dryness in California and most of the West coast; the summer Monsoon circulation creating precipitation over Arizona, New Mexico, and Colorado, with mountain enhancement, as well; and two smaller regions with relatively drier July weather compared to surrounding areas, in southern Missouri–northern Arkansas, and across most of Michigan. These relative minima are explained by a relatively greater frequency of surface high pressure over the cooler Great Lakes, which suppresses summer thunderstorm and shower activity over Michigan; and by the Ozark Mountains inhibiting northward-flowing moist air from the Gulf of Mexico, as well as slightly interrupting the dynamics of thunderstorm development.

In contrast, the bottom map (July 1993) depicts processes that were dominant over this 31-day period only. Note the fairly large region of enhanced precipitation in the Iowa–Nebraska–Kansas–Missouri area that was associated with a stationary frontal system for much of the month, and moisture-feedback processes that helped generate excessive precipitation for many weeks. To the south, a similar-sized area with very little precipitation covered much of Texas. The area with near-zero precipitation in California expanded to include much of Nevada and Arizona, as well, and another region with enhanced precipitation covered much of eastern Montana and the Dakotas. July, 1993 thus represented both an accentuation of the mean map (top), as well as at least two regions with significantly anomalous rainfall—abnormally large rainfall amounts over the Midwest to Plains region, and the dryness from eastern Texas to northern Georgia.

These maps also reveal differences in small-scale variability. Over the relatively short time period of a single month (e.g., July, 1993) the map appears ''speckled'' with precipitation values. Particularly in regions not directly under the influence of major synoptic forcing there is a great deal more variability between individual climate stations than in the 30-yr mean map (top), in which most of this small-scale

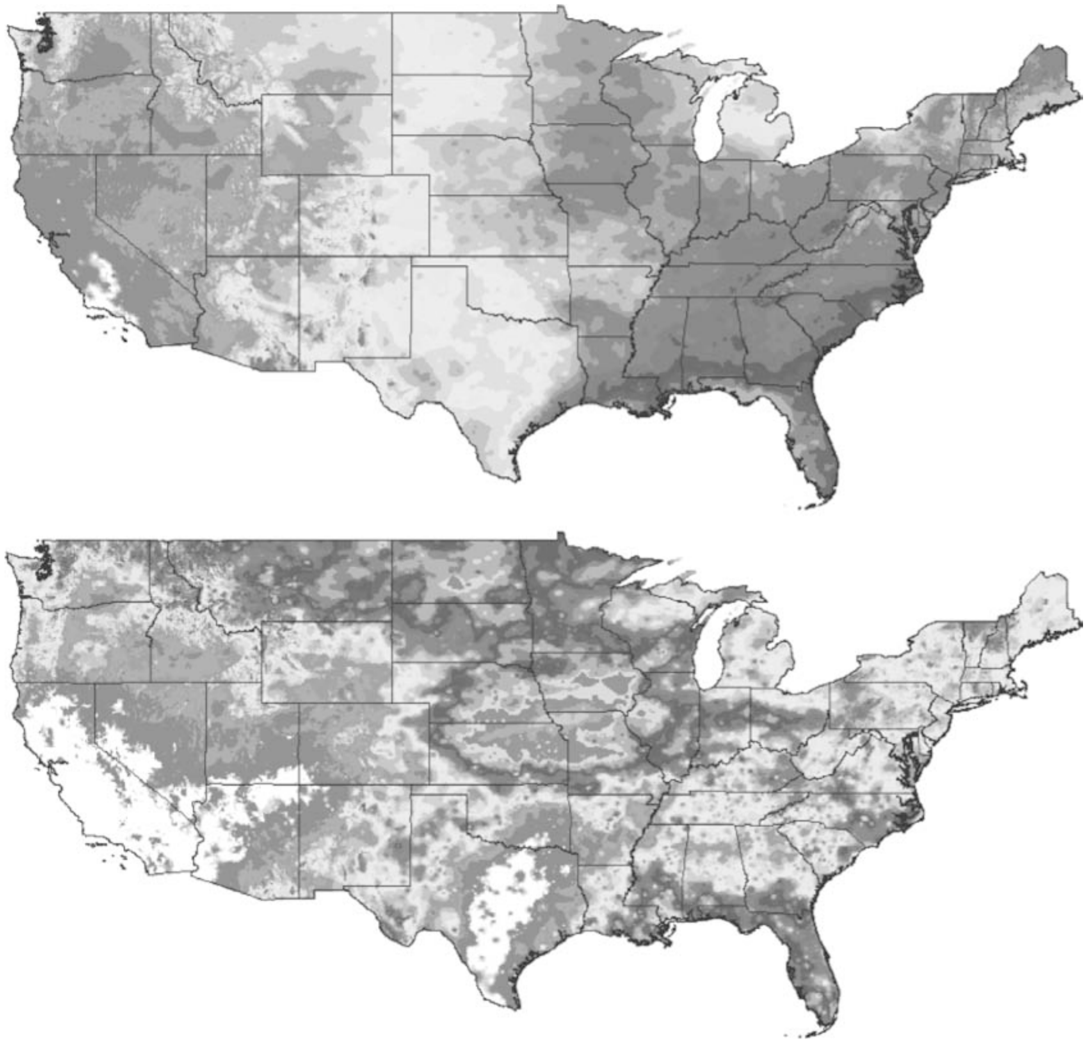

Fig. 4 Mean 1961–1990 July precipitation (top) and July 1993 precipitation (bottom). Maps created using the PRISM modeling system of the Spatial Climate Analysis Service, Oregon State University.

variability associated with a limited sample size is removed. The 30-yr mean map thus represents only very consistent and dominant precipitation forcings.

At the average annual time scale, with a 30-yr averaging period, consistent precipitation patterns are clearly in evidence (Fig. 5), while the small-scale variability shown in the July, 1993 map, and somewhat distinguishable even in the 30-yr mean July map, are now clearly absent. Note the significantly greater detail and spatial variability depicted in this map compared to the generalized global precipitation map shown in Fig. 2. Other atmospheric forcings are at work, as well, and include.

Orographic Enhancement

Air flow over mountain barriers creates forced uplift and, typically, an increase in precipitation, called orographic enhancement. This increase in precipitation with elevation is largely local, however, with regional or national relationships often insignificant or nonsensical. For instance, elevation increases from the Mississippi River westward to the Rocky Mountains across the Plains, but precipitation decreases westward across this region. In mountainous regions, precipitation–elevation relationships can be different from one mountain barrier to the next, with the upwind barrier often having more precipitation enhancement than succeeding ridges downwind. Orographic enhancement is controlled by a number of factors, including wind direction relative to the barrier, wind speed, available atmospheric moisture, elevation increase, and slope angle.

Significant orographic enhancement is noted on this map (Fig. 5) over much of the western United States, and in some of the highest mountain terrain in the southern Appalachians and in New England.

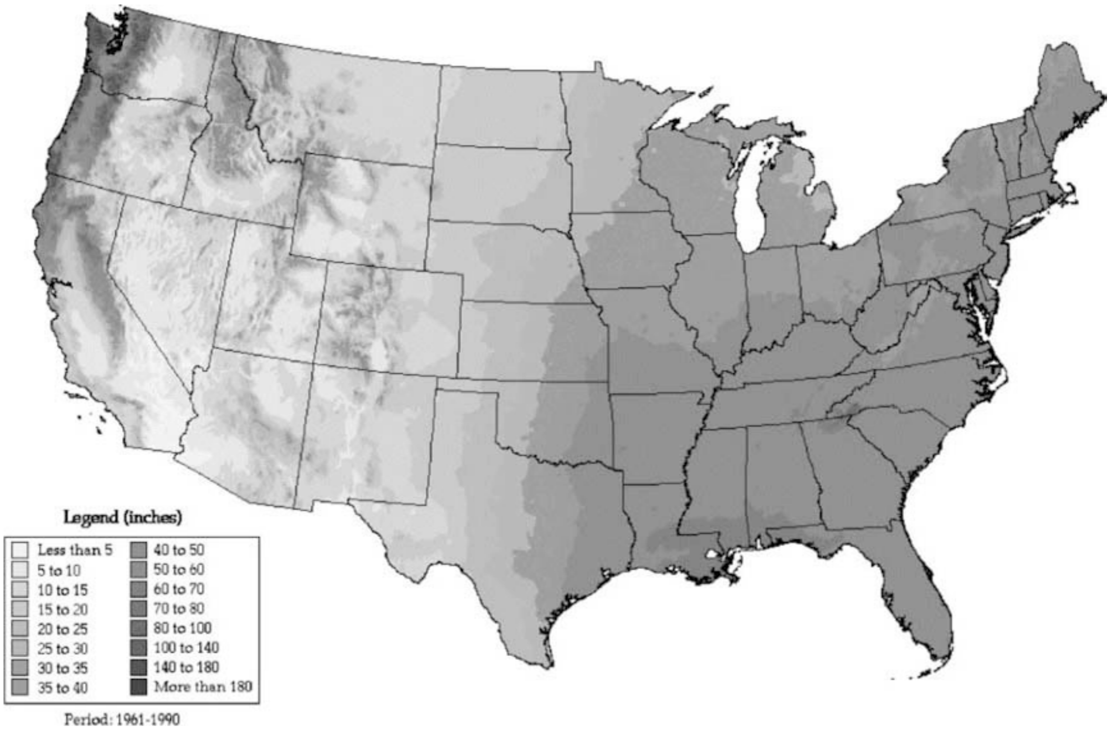

Fig. 5 Mean annual precipitation of the United States (in.), 1961–1990. derived using the PRISM modeling system.

Over much of the western United States, between the Cascade/Sierra Nevada ranges and the Rocky Mountains, this mean annual precipitation map looks very much like an elevation map. The mountains are very effective at ''scouring'' what moisture is available in the air flow. In some cases, as over much of Idaho, the terrain contains many successive mountain barriers with very small spacing between them. In this case, the entire region acts as an elevated terrain feature with fairly consistent precipitation enhancement over the area.

There are elevational limits to orographic enhancement. Across most of the continental United States, precipitation increases with elevation to approximately 3000 m in southern latitude areas, and around 2500 m to the north. In Alaska, it is conjectured that precipitation is a maximum above 2000 m. In regions where the trade wind inversion is prevalent, such as many oceanic areas 10–30° latitude either side of the equator (e.g., Hawaii), precipitation is maximized at levels as low as 1000 m, with highest mountain elevations sometimes extremely dry.

Other Causes of Vertical Motion

There are factors other than topography that can control vertical motions and, thus, precipitation distribution. These include sea breezes that often create areas of surface convergence and, necessarily, upward vertical motions some distance (typically 10–50 km) inland from the immediate coastline. Peninsular Florida in the warm season is a good example of this phenomenon. On many afternoons, in the absence of any other synoptic forcings, an onshore airflow will develop that penetrates approximately 30-km inland, creating a convergence zone where storms develop and precipitation enhancement is noted.

In midlatitudes, jet stream dynamics create and strengthen storm systems and vertical motions. These are strongest when thermal contrasts between the poles and tropics are greatest, in the respective hemispheric cold seasons.

Convective instability creates upward vertical motions that can create significant precipitation. These precipitation processes are most common in the tropics and in the warm season at midlatitudes, and are the result of local heating (both sensible and latent). Their space and time dimensions are typically quite small.

PRECIPITATION MAPPING

Climatologists and, in particular, climate mapping specialists, study these precipitation processes and build them into precipitation distribution models. These models objectively determine precipitation amounts and patterns by quantifying causative processes, such as orographic enhancement. One example of this is the parameter–elevation regressions on independent slopes model (PRISM), used to create the maps shown in Figs. 4 and 5.[4] This model distributes point precipitation values, usually at a time step of 1 mo or longer, to a grid by estimating many of the factors discussed earlier, and others. PRISM has been successfully used to develop maps in the new, digital Climate Atlas of the United States,[5] as well as many other products.

CONCLUSION

The distribution of precipitation over the landscape is dictated by processes that enhance upward vertical motion in the presence of sufficient moisture. Longer time averaging periods reveal only the most consistent processes, while at successively shorter time periods spatial heterogeneity and inconsistencies increase. Due to a multitude of factors that control these processes, including the shape and size of land and water areas, latitude and topography, precipitation distribution pattern determination is usually less than straightforward.

Precipitation: Forms

Richard T. Wynne
National Weather Service, National Oceanic and Atmospheric Administration (NOAA), Amarillo, Texas, U.S.A.

INTRODUCTION

In nature, water can take solid or liquid form under many situations in the atmosphere and on the surface of the earth. Precipitation is a special category or subset of the conditions under which water exists. Specifically, water particles, in either liquid or solid form, to be defined as precipitation that must both 1) fall from the atmosphere and 2) reach the ground. This definition would then include rain, drizzle, snow, sleet, and freezing rain and exclude other forms of water in the atmosphere such as clouds, fog, dew, rime, or frost in that it must fall from the atmosphere. It also eliminates forms such as virga since precipitation must reach the ground.[1]

BEGINNINGS OF THE PROCESS

What determines the type of precipitation? The vertical temperature and moisture profiles of the atmosphere are important factors. If ice crystals encounter warm and cold layers of air on the way to the ground, then the form of precipitation could change. Vertical motions of the air are also factors since they will affect the path of the water particles on the way to the ground. No matter what the type of precipitation we see at the ground, the process usually begins in clouds. Tiny droplets join to form much bigger drops, which, begin to fall earthward. At lower temperatures, clouds may consist of ice crystals that form from the freezing of water droplets or sublimate directly from water vapor into solid ice crystals. The crystals begin to collide and aggregate to form snowflakes that start to fall toward the earth. The process, however, is just beginning. The temperature and moisture structure of the atmosphere determines which form of precipitation is observed at the ground.

COMMON FORMS OF PRECIPITATION

In the warm season of the year, *rain* is usually the most common form of precipitation. When a deep, moist layer of air is at the earth's surface with the temperature above 0°C, rain occurs if the drops survive to the surface. If ice or snowflakes enter this warm surface layer and it is sufficiently deep, then the ice melts into liquid drops and arrives at the surface as rain. When the surface air is very dry as it is often in the western Great Plains, one may see rain shafts extending below the cloud bases but evaporating before reaching the ground. This feature is identified as virga and is not considered to be precipitation.

Ice crystals can carry a thin coating of water even at temperatures well below freezing. As a result, cloud ice crystals will join together when they collide and form flakes. Once these flakes become heavy enough, they will fall toward the earth. During the winter season, the entire layer of air may be below 0°C and the flakes will reach the ground as *snow*.

Sometimes, a warm layer of air will ride over a very cold layer of air where temperatures are below freezing. When this happens, the drops can freeze into pellets of ice and is termed *sleet* in most parts of North America. These ice pellets tend to bounce when they land on a solid surface and remain intact. On the other hand, snow on its way to the ground may encounter an air layer just warm enough to melt the smaller snowflakes producing a mixture of snow and rain at the surface. This is termed sleet in some parts of the world.[2]

As stated earlier, water-coated ice crystals can join together to form snow. These ice crystals may also fall through a cold air layer freezing the outer coating. The precipitation then becomes snow pellets, sometimes called *graupel*. Graupel is opaque and, like ice pellets, bounces when it hits a solid object. Often, it will break up following impact unlike ice pellets.

Drizzle is another form of precipitation since it falls to the ground. Numerous, very small drops that are affected easily by air currents, but do eventually fall to the surface, are classified as drizzle. Fog, which often accompanies drizzle, is not considered to be precipitation since it does not fall. In observing, drizzle drops are considered to be less than 0.5 mm.[3] Drops larger than this size are classified as raindrops. Sometimes, while making an observation, it is difficult to tell if light rain or drizzle is occurring. A rule-of-thumb many observers use is to observe an open surface of water such as a puddle of water if one is available. If the water surface is being disturbed by the precipitation, then it is considered to be light rain. If the water surface remains undisturbed, it is classified as drizzle. Drizzle usually forms in shallow, stratiform low cloud layers. Typically, the weather system is non-convective, or does not have much vertical development. Warm frontal systems usually have a gentle sloping structure. Air and moisture is lifted slowly and fewer collisions between water particles occur. Many times, drizzle forms in advance of a warm front.

Hail is another common form of precipitation. Hail most often accompanies strong thunderstorms where violent downdrafts and updrafts exist nearly side-by-side. Hail formation can begin as ice crystals fall through a moist air layer where liquid water coats the ice particles. The ice particles are then caught in an updraft and carried to great altitudes where the water coating freezes. Once again, the frozen particle falls toward the earth and is coated with a layer of liquid water and carried upward in another updraft. This cycle continues and layer after layer of ice builds up on the original particle. Strong updrafts can result in large hail sizes. Finally, the hail becomes too heavy to be held by the updrafts and it falls to the earth.

CONCLUSION

Many forms of precipitation have been identified. Only the most common ones have been reviewed here. To be classified as ‘‘precipitation,’’ the liquid or solid form of water must both fall from the atmosphere, and, it must reach the ground. The temperature and moisture structure of the column of air through which the particle falls often determined what form it will be in when it reaches the ground. Ongoing research continues on the use of temperature and moisture profile of the atmosphere to predict what type of precipitation can be expected. Weather models now give a ‘‘first guess’’ as to what these profiles will look like in the future and to predict the weather type.

Precipitation: Measurement

Marshall J. McFarland
Texas A&M University, Stephenville, Texas, U.S.A.

INTRODUCTION

The objective of precipitation measurement is to determine the spatial and temporal distribution of precipitation, primarily rain and snow, but including all forms of precipitation. Measurement requirements depend on the scope and purpose of their use. For climatological and hydrological purposes, such as water supply assessment, precipitation measurement seeks to determine the amount of water that reaches the earth surface over a given area, usually for a 24-hr period with an area of $100\,km^2$ or greater. For stormwater runoff and flash flood forecasting, precipitation amount and rate measurements are needed on a time scale of minutes to an hour for areas of tens of square kilometers. For microwave circuit design, rainfall rate along a narrow transmission path is needed on a time scale of a few minutes. Precipitation is usually measured with gages of various designs that meet specific needs over a wide range of geographic locations. Precipitation may also be indirectly measured or inferred with remote sensing technology with sensors operating in visible, infrared, microwave, or gamma ray portions of the electromagnetic spectrum. Remote sensing technology is beyond the scope of this report. A review of the measurement of precipitation is given in Ref.[1].

PRECIPITATION GAGES

Development of Precipitation Gages

Rain gages were used in India in the 4th century B.C., Palestine in the 1st century B.C., China in the 13th century, and Korea in the 15th century.[2,3] The gages used in Korea were cylindrical about 30 cm deep and 15 cm diameter, so would have about the same characteristics and accuracy as many of the gages in widespread use today. Rain gages were first used in Europe in the 17th century and included a tipping-bucket gage developed by Sir Christopher Wren and modified by Robert Hooke in 1678.[3] Numerous designs of gages were developed around the world in the 18th century. In 1802, Dalton (cited in Ref.[3]) described the function and basic design of the rain gage:

> "The rain gage is a vessel placed to receive the falling rain, with a view to ascertain the exact quantity that falls upon a given horizontal surface at the place. A strong funnel, made of sheet iron, tinned and painted, with a perpendicular rim two or three inches high, fixed horizontally in a convenient frame with a bottle under it to receive the rain, is all the instrument required."

Virtually any open container will collect rain and snow, but few will collect the "exact quantity" of rain or snow that would fall on the horizontal surface in the absence of the gage. The measurement of the exact quantity of rain and snow that falls on a given horizontal surface has been the subject of considerable research and development in the past several hundred years. In 1769, it was established that gages elevated above the surface caught less rainfall than gages near the surface,[4] which was subsequently shown in 1861 to be due to effects of wind.[5] Ground level gages were developed in 1842 to avoid the effects of wind.[4] In the late 1800s, Nipher developed the first shielded gage, a design still in use, to decrease the influence of wind on the collection of snow.[5]

Standard Precipitation Gages in the United States

Two similar designs of non-recording rain gages are used in the climatological network of the National Weather Service.[6] The standard gage has a 20.3-cm (8 in.) orifice diameter, a funnel, a measuring tube, and an outer container. The measuring tube holds 5.08 cm precipitation; overflow collects in the outer container. A calibrated measuring stick is inserted into the measuring tube and is read to the nearest 0.01 in. (0.254 mm). The funnel and measuring tube are removed when snow is expected. The snow is melted for equivalent water measurement. A 10 cm scale version of the standard gage is also in use, with measurements read from a calibrated scale on the clear plastic side.

The National Weather Service has two types of weighing gages that record rate and amount of precipitation,[6] with an accuracy of 0.01 in. (0.254 mm). The collection portion of the gage is similar to the standard gage, but the funnel directs the catch to a collector mounted on a weighing mechanism. The Belfort (Fischer and Porter) recording gage converts the weighed precipitation to a punched tape output.

The Universal recording gage converts the weighed precipitation to a strip chart or to direct current (dc) voltage for telemetry.

Tipping bucket recording precipitation gages are used, especially with automatic weather stations, to record precipitation rate and amount. The collector portion of the gage is a scale design of the standard gage. The funnel directs the catch to one of two buckets balanced on a fulcrum, each with a typical capacity of 0.01 in. (0.254 mm). When the bucket fills, it tips and discharges the water into a container and rotates the other bucket under the funnel. The time of the tip is recorded electronically when a magnet trips a switch.

Orifice Design for Precipitation Gages

Any open container will collect precipitation. If the requirements for accuracy are not precise, then virtually any open container will be satisfactory. Indeed, for extreme rainfall events when the daily or storm event rainfall exceeds the capacity of the gage, ''bucket surveys'' are used to estimate the total rainfall. The rainfall depth in any open container, such as a barrel or a bucket, will be measured. Rain gages for individual's use, as opposed to gages in networks, may be of any design and any design may be satisfactory if precision is not an issue. Common designs are clear plastic gages with square or cylindrical orifices, with imprinted measurement scales on the collection tube. Orifice widths or diameters range from about 2 cm to 10 cm. The larger diameter orifice gages may have a funnel; smaller diameter gages do not, but may be wedge or cone shaped to increase the accuracy for measurement of lower rainfall amounts. The diameter or width of the orifice does not have a significant effect on the amount of rainfall collected by the gage.[7–9]

Effects of Wind on Precipitation Measurement

Any object placed above ground level will result in increased wind speed over the top of the object. When the object is a rain gage, the increased air flow over the top of the collector will deflect rain and snow particles from their original path. This results in an undercatch of precipitation,[10,11] especially for snow.[12,13] As the gage gets larger, the effects of the wind increase. The height of the gage is also a major factor, because the wind speed increases rapidly with height above the surface. A large gage mounted on a post will catch less precipitation than a smaller gage mounted on a rod or open stand. The measurement error associated with large gages above ground level with moderate wind and light snow may exceed 50%. Several approaches have been used to reduce the effect of wind on the catch of precipitation. Shields of vertical metal or wood slats surrounding the gage will deflect the wind downward and away from the gage orifice. Shielded gages are in widespread use for snow measurement networks (e.g., SNOTEL—SNOw TELemetry[14]) in the United States, but are not routinely used in the National Weather Service climatological network. Ground level or pit gages installed at the surface will eliminate wind effects, but create other problems such as splash effects, and collection of blowing leaves, drifting snow, or surface water in the gage. Pit gages are used for reference purposes, but are not used in measurement networks. Low bushes and/or 50% snow fence around the gage will also reduce the effects of wind on the precipitation catch by the gage.[15,16]

Precipitation Measurement Errors

Precipitation gages are subject to measurement errors from wetting, evaporation, condensation, rain splash, and snow plugging and capping. Rainfall that adheres to (wets) the surface of the gage will not be measured in the collection tube. The collected precipitation in the collection tube is subject to evaporation, especially in hot and dry conditions. Condensation that forms dew and frost on the gage may add a few mm depth to the precipitation total. Rain may splash out of the gage, especially for designs that have a shallow funnel with a slope of less than 45° from the vertical and designs with open collector tubes when the gage nears its capacity. Wet snow will stick to the inside of the gage orifice and may prevent additional snow from entering the gage. Small diameter (or width) gages and gages with shallow funnels are especially susceptible to snow plugging and capping.

Another source of measurement error arises from a combination of wind with sloping terrain with the precipitation event. The precipitation caught by a gage with a horizontal orifice will deviate from the precipitation that is actually incident upon the terrain. For precise measurements, a pit gage or a gage with an orifice parallel to the terrain slope will provide precipitation measurements that are more representative.[17]

DIRECT MEASUREMENTS OF SNOW

The measurement of snow in mountainous areas is complicated by inaccessibility for daily observation, lack of ideal exposures for gages, measurement errors with gages, sloping terrain, variable exposures due to trees and natural topographic features, and redistribution of snow by wind. Snow measurements are made by direct methods such as gages, core extractions, and depth measurements with a stick; and by indirect methods such as weighing snow pillows and remote sensing from air and space craft.[14] A white-painted wooden board is used for snow depth measurements. The snowboard is placed horizontally on the ground surface or flush with the snow surface in a representative location. The observer records the 24-hr depth accumulation with a ruler, then cleans and replaces the snowboard. The federal snow sampler is used to extract cores from the total snow pack. The sampler is a light-weight graduated aluminum tube that is forced into the snow pack.[18] The snow water equivalent is obtained by weight. Core samplers are used to take snow measurements at monthly or longer intervals along predetermined transects known as snow courses. A snow pillow is a hydraulic weighing platform of rubber or stainless steel. The snow that accumulates on the pillow or a series of pillows is weighed with the use of a pressure transducer so the water equivalent may be transmitted via telemetry.[19]

CONCLUSION

The basic technology of precipitation measurement with gages has not changed in the past several hundred years. A precipitation gage is basically an open container that ideally catches the precipitation that would accumulate on a horizontal ground surface at the gage location. Measurement errors, needs for rainfall intensity measurements, and problems with snow measurement have resulted in a wide variety of gage designs. When precision is not required, virtually any open container will serve the purpose. For hydrology and climatology, standardized gage designs and measurement procedures are necessary. New technology, especially in remote sensing, will continue to evolve and to increase our knowledge of the spatial and temporal distribution of precipitation.

Precipitation: Modification

George W. Bomar
Texas Department of Licensing and Regulation, Austin, Texas, U.S.A.

INTRODUCTION

The water resources of any nation are one of its most precious treasures. However, increases in population and economic growth place greater demands on this valued asset. We are continually reminded that water, while indispensable for personal and economic well being, is a finite resource. We are made all the more keenly aware of its value when deviations in the normal patterns of rain (and snow) foment drought, which places even greater strain on the available water supply.

Traditionally, sources of fresh water are regarded as either surface or groundwater, which are replenished, of course, by precipitation yielded by various species of cloud formations. To augment the supply of water from those sources, dams are constructed to confine more of the streamflow above the surface or wells are drilled to capture greater quantities of water from subterranean *aquifers*. Seldom is the atmosphere viewed as yet another repository of substantial amounts of water—albeit in the form of vapor—waiting to be harvested.

Today, careful and well-designed efforts to manage *atmospheric* water resources are proliferating worldwide. Through the responsible use of new weather-modification, or *cloud-seeding* technologies, those who manage the development of atmospheric water are confronting the challenge of finding new fresh-water sources with increasing success.

GROWING ATMOSPHERIC WATER

Exceedingly tiny cloud droplets materialize in the atmosphere when moist air is sufficiently cooled to its dew point. These minuscule droplets, which typically number in the trillions in a swelling cumulus cloud, may collide with one another to grow larger and larger droplets, which might eventually become big and heavy enough to fall as rainwater. For this to happen, the cloud must persist for a prolonged period. Most clouds do not live long enough to develop a significant load of rain.

Nature facilitates the rain-making process by capitalizing on the role of *supercooled* droplets to grow raindrops much more readily. In growing taller, an increasingly buoyant convective cloud (cumuli) moves more of its water mass into colder (higher) regions of the atmosphere. Though the air is colder than 32°F, the tiny cloud droplets do not immediately freeze into ice, but rather remain in liquid form (supercooled).

Meanwhile, innumerable microscopic particles, such as soil, dust, sand, and salt, start the rain-production process by acting as "seeds" or crystalline skeletons on which these very tiny, supercooled droplets can freeze to form either snowflakes or soft ice (graupel). These seeds become de facto *ice nuclei*, around which more and more supercooled cloud water converges to grow larger and larger raindrops.

Cloud seeding involves the release of artificial ice nuclei to grow even more, and larger, water droplets out of this usually abundant supply of supercooled cloud water. The artificial seeds are of one of two types: 1) glaciogenic (ice forming); and 2) hygroscopic (water attracting). The most common type of glaciogenic seed is silver iodide, who crystalline structure most closely resembles that of a natural ice crystal. Another well-used glaciogenic material is dry ice, which almost instantaneously produces large numbers of small ice particles when dropped in pellet form into clouds with supercooled water. In clouds that never develop vertically, such that the cloud's water mass is never chilled to the point of becoming supercooled, hygroscopic seeding agents work well in growing large raindrops. The hygroscopic seeds are usually small salt particles, such as potassium chloride.

SEEDING TECHNIQUES

Timing and targeting the artificial seeds in promising clouds are the two most critical factors in successful cloud seeding. Seeding must be done opportunistically and precisely, in the right locations when the time is ripe.

For seeding convective clouds, which tend to grow dynamically in a matter of minutes, aircraft are the favored method of delivery. Specially-equipped aircraft, bearing racks containing flares (pyrotechnics) of seeding materials or wing-mounted generators for releasing solutions of artificial ice crystal, can release the seeds straight into the rising air current (updraft) below the bases of developing clouds. In some instances, aircraft can get seeding material into the core region of supercooled clouds by dropping flares from above the tops of those clouds.

In mountainous terrain, where moisture-laden clouds tend to ‘‘hug’’ ridge lines, aircraft usually cannot safely navigate to dispense seeding materials. Because the flow of moist air feeding the clouds is often quite predictable, it is possible to disperse the seeds using a network of ground-based generators. These generators can be manually operated, even remotely controlled, to regulate the flow of seeding material at prescribed levels and for predetermined durations.

ASSESSING THE IMPACT

The true measure of any endeavor, including weather modification, is the answer to the daunting question: Are the results from the effort worth the resources needed to produce those results? Assessing cloud-seeding activities is a formidable challenge because the impact of the seeding must be separated from the highly variable, natural occurrence of rain, snow, and hail from cloud formations. Many methods and types of data have been used to evaluate cloud-seeding efforts, with each having its own strengths and weaknesses. Some assessments are made using direct evidence: measurements of rain, hail, snow. Others are based largely on secondary evidence: insurance statistics and crop yields. Ultimately, the efficacy of any particular evaluation will depend on the type and amount of data available for analysis.

Many weather-modification projects, past and ongoing, have furnished evidence that seeding, when performed timely and in a well-targeted fashion, has altered the behavior of cloud formations in such ways that the objectives of the projects (rain enhancement, snowpack augmentation, hail suppression) have been achieved. Benefits, when quantified, have far outpaced the costs to conduct the operations.

The ultimate way to evaluate a weather-modification project is through randomization: Storms are randomly selected for seeding—or to be left untreated. Then, the two groups are compared to discern differences in behavior, during and following seeding. The drawback to such an analytical approach is that only about half of all storms get treated, reducing the overall effect as well as the benefit-to-cost ratio.

Still, with the promise of success, the technology will continue to be applied in many different climatic regimes. As research techniques improve, and as better seeding technologies are developed, better and more consistent results are sure to be achieved.

Precipitation: Remote Sensing Measurement

Marshall J. McFarland
Texas A&M University, Stephenville, Texas, U.S.A.

INTRODUCTION

The objective of precipitation measurement is to determine the spatial and temporal distribution of precipitation, primarily rain and snow. Historically, precipitation has been measured with gages, which capture samples of the precipitation for direct measurement. Gage measurements of precipitation have limitations, especially for operational meteorological and hydrological purposes such as short period weather and flash flood forecasting. These limitations include:

1. The density of measurements in most gage networks is not sufficient for assessment of precipitation from thunderstorms in small watersheds. More-or-less typical precipitation networks for climatological purposes have a gage density of about one gage every 30 km (900 km^2 area). The highest precipitation intensities in a thunderstorm cell occupy a much smaller area, so could easily be missed in a fixed gage network.
2. Many areas of interest are not suitable for direct measurement of precipitation with gages. These areas include mountains (for water supply assessment) and oceans (for earth heat and moisture budgets).
3. The cost of direct measurements (including equipment, maintenance, personnel, data acquisition and processing) precludes expansion of gage networks for operational uses.

Remote sensing of precipitation is widely used to obtain increased spatial and temporal accuracy. With remote sensors, the precipitation is not captured or directly measured. The precipitation is inferred from physical, statistical, and/or empirical relationships between precipitation characteristics and the emitted or reflected radiation from the earth and atmosphere. Remote sensors that record naturally emitted radiation are referred to as passive, while active remote sensors record reflections of radiation emitted from the sensor. Precipitation estimation with weather radar is an example of an active remote sensor. Cloud information from visible and near-infrared imagery obtained from earth satellite sensors is an example of passive remote sensing. The sensors may be land-based, or mounted on aircraft or earth satellites. A summary of measurement of precipitation is in Ref.[1].

ESTIMATION OF PRECIPITATION WITH WEATHER RADAR

Weather radar operates in the microwave portion of the electromagnetic spectrum, usually at wavelengths from 3 cm to 10 cm. At these wavelengths, large cloud water droplets, raindrops, hail, snow particles, and other solid forms of precipitation reflect emitted radiation. The backscattered radiation, known as the reflectivity, Z, is highly correlated with the characteristics of the precipitation in the volume of the radar beam. For spherical raindrops, the reflectivity is a function of the sixth power of the raindrop diameter. Reflectivity of rainfall within and below a cloud volume is primarily a function of the numbers and diameters of the larger raindrops.

The relationship between the radar reflectivity and the rainfall rate is a power function, $Z = aR^b$, where a and b are empirically fitted variables.[2] The variables a and b of the Z–R relationship change with type of precipitation, precipitation intensity, raindrop shape, presence of liquid films on frozen forms of precipitation, and ambient conditions within the cloud. The value of a is typically 200 and will range from 100 in stratiform rainfall to 400 for intense convective rainfall. The value of b is nearly constant at 1.6, with a usual range of 1.3 to 1.6.[3] With constant values of a and b, radar estimates of precipitation should be within a factor of two about 75% of the time.[4]

Several sources of error in the estimation of precipitation with radar are present. Any change in the relationship between reflectivity and rainfall will change the accuracy of the rainfall estimation. A major source of error is inherent in the geometry of the radar beam as it intersects a cloud. Normally, the radar scans at low elevation angles, such as 0.5–1.5°, within about 75 km of the radar location. Consequently, the precipitation is fairly close to the earth surface. If the fall speeds of the precipitation particles differ from terminal velocity as a result of updrafts or downdrafts, the radar estimation will be an overestimation or an underestimation. For heavy rainfall intensity in a strong downdraft, the underestimation could be nearly 50%.[3]

Due to earth surface curvature, the radar beam intersects cloud volumes at increasing elevations with increasing range from the radar location. At increasing range, the radar estimate of rainfall rate could be an underestimation if the cloud volume in the radar beam is above a layer where precipitation rate is still increasing through growth of raindrop size through processes of coalescence and collision. With increased range, the radar beam may intersect the 0°C isotherm, where melting of snow begins to occur. With initial melting, a snowflake becomes covered with a film of water before collapsing into a smaller raindrop. Water covered snow is much more reflective than the raindrops below the layer of melting snow. As a result, a "bright band" about 100 m deep with a reflectivity typically two to five times greater than that of the rainfall below will appear in the radar display of the return.[5] If the radar beam includes cloud volume above the bright band, the reflectivity will decrease due to the very low reflectivity of the snow. Generally, the precipitation rates will be underestimated when the radar beam is above the freezing level.

Other sources of error include incomplete beam filling by the cloud, false echoes, and anomalous propagation, and intervening clouds and precipitation. Rain drops on the radome will also attenuate the backscattered radiation.

For maximum accuracy of radar estimates of precipitation rate and amount, the variables in the *Z–R* relationship should be calibrated on a real-time basis. This is possible with a network of automatic, recording rain gages that is connected to the radar processing system through telemetry, modem, or other means of communication. The spatial and temporal accuracy of radar is combined with the point accuracy of gages in this method. Two approaches have been demonstrated. The deterministic approach is to use rainfall rate information from point gages to calibrate the values of the *a* and *b* variables in the *Z–R* relationship or to determine the ratio of gage to radar estimation of rainfall. The adjusted values are then used to adjust the radar estimates of rainfall for the areas between gages. A statistical approach combines the radar and gage spatial information to interpolate and extrapolate the gage measurements throughout the area.[6–8]

VISIBLE AND INFRARED ESTIMATION OF PRECIPITATION FROM SATELLITE IMAGERY

Earth satellites with sensors operating in the visible, near-infrared, and thermal-infrared portions of the electromagnetic spectrum provide several methods of estimation of precipitation.[9] The simplest is perhaps the areal extent of snow, which is readily apparent in visible and near-infrared imagery. Another method has been developed for convective rainfall. Methods of estimating convective rainfall rates and/or amounts are based on the premise that the intensity of convective rainfall is correlated with the visible brightness and radiative temperature of the cloud tops (10.5 μm to 12.5 μm wavelength). Colder and brighter cloud tops represent both deeper and more intense convection, which is highly correlated with precipitation intensity and amount. The relationships between satellite-derived variables of cumulonimbus cloud top features and rainfall features are developed from radar and gage measurements.

Several advanced methods for estimation of rainfall from satellites with visible and thermal-infrared sensors have been developed. The life-history techniques incorporate information about the life cycle of the convective cloud into the rainfall estimation method[10–12] for scales from individual convective cloud to synoptic systems. The methods are based on similar assumptions that convective cloud development follows an established pattern, raining convective clouds have cloud top temperatures colder than a threshold (e.g., −19°C), rainfall rate is proportional to the cloud area, rainfall intensity is inversely proportional to the temperature of the cloud top, and rainfall distribution in time is a function of the stage of the life cycle of the cloud.

PASSIVE MICROWAVE MEASUREMENT

Snow pack properties, such as depth, snow water content, and age, may be developed with the use of passive microwave radiometers on earth satellites. Passive microwave radiation sensors operate in similar wavelengths as weather radar, which is active microwave radiation. Passive microwave sensors record the radiation naturally emitted by the earth surface and atmosphere, which is proportional to the product of the emissivity and the first power of the temperature at microwave wavelengths (the Rayleigh–Jeans approximation to Planck's Law[13]). Consequently, the recorded radiation is referred to as the brightness temperature. The emissivity is an inverse function of the dielectric constant of the emitting surface. The value of the real component of the complex dielectric constant, the permittivity, is in the low single digits for air, dry soils, and ice and snow. The permittivity of water ranges from about ten to twenty in the microwave wavelengths of the sensors (e.g., 0.81 cm to 1.55 cm), so the addition of water to dry soil decreases the brightness temperature. The brightness temperature of a land surface is decreased by the loss factor, which is also a function of the dielectric constant. The loss factor is high for water but very low for ice and snow. A dry snowpack will scatter, or attenuate, the brightness temperature proportional to the snowpack depth. Typically, the snowpack properties are retrieved with multiple linear regression for the multiple wavelengths and both polarizations of the radiometer.[14]

The atmosphere is essentially transparent to emitted microwave radiation from the earth surface except when convective clouds with rainfall are present. Tropical rainfall over oceans is determined from the emitting and scattering characteristics of the precipitating clouds.[15] At the microwave wavelengths of the passive microwave sensors on earth satellites, the precipitating clouds appear as warm areas over a very cold background.

TERRESTRIAL GAMMA SNOW MEASUREMENT

The water equivalent of a snowpack can be determined by measuring the attenuation of naturally occurring gamma radiation emitted from potassium, uranium, and thorium isotopes in the upper 20 cm of soil.[16] Water mass (not necessarily liquid) in the soil and snow attenuates the gamma radiation, so differences in the radiation emitted from bare ground and snow-covered ground are used to determine the snow water content and other properties. The gamma radiation sensors are flown on aircraft to determine snowpack properties, primarily in the Great Plains of the northern United States and southern Canada.

CONCLUSION

Remote sensing of precipitation is in widespread use in meteorology, climatology, and hydrology. In remote sensing of precipitation, the precipitation is not captured or otherwise directly measured. The interactions of the precipitation with radiation in the electromagnetic spectrum are measured with sensors, and then translated into precipitation characteristics with the use of physical, statistical, and empirical relationships. Precipitation estimation with weather radar is a good example of a remote sensor system. Microwave radiation is emitted from an antenna at the radar site. As the radiation pulse intersects a cloud, some of the radiation is scattered back towards the antenna by snow, water, and ice. The reflectivity is correlated with the precipitation characteristics, which have been determined with precipitation measurements from gages. Information on clouds and precipitation may be obtained from visible, near-infrared, thermal-infrared, microwave, and gamma ray portions of the electromagnetic spectrum. The sensors may be at fixed locations, or may be mounted on ships, aircraft, or earth satellites.

Precipitation: Simulation Models

Timothy O. Keefer
Southwest Watershed Research Center, U.S. Department of Agriculture (USDA), Tucson, Arizona, U.S.A.

INTRODUCTION

The variability of precipitation across a range of spatial and temporal scales, from short-duration high-intensity down-bursts within a localized storm to the seasonal and annual variations at a single location and across the globe is obvious to a casual weather observer. Frequently, in the planning and management of agricultural and engineering activities, precipitation information that reflects this natural variability is needed. Examples include irrigation design and application, evaluation of agricultural runoff for soil erosion and water quality, cropping and seeding patterns, sizing and placement of culverts and dams, scheduling and selection of agricultural and construction equipment. The demands of the particular use of the information vary from within-storm intensities to daily amounts to regional and seasonal accumulations each with different precision. Generally, the source of such information is the precipitation data measured and recorded at a point. Precipitation information for a particular location may not be adequately known or available in the specific time-frame required because of short or non-existent records of measurements, inaccurate or inconsistent data, or budgetary constraints.

An alternative approach is to use a precipitation simulation model which generates sequences of synthetic precipitation which share the same statistical properties as the observed time series. Three broad categories of precipitation simulation models exist in various degrees of mathematical and statistical complexity which relate to the type of precipitation simulated. Low-resolution, large-area precipitation data can be generated by 3-dimensional dynamic-numerical general circulation models (GCMs); rainstorm event occurrence and intensities are simulated by spatial-temporal models; daily precipitation occurrence and amount are modeled by a family of fairly simple stochastic/statistical algorithms. The latter of these are often part of a larger model called a weather generator, which simulates other weather related land/atmosphere variables such as solar radiation, temperature, or soil moisture. The generated synthetic sequences of precipitation are used for a variety of purposes such as: analysis for water resource engineering applications, climate change scenarios, and as input to other hydrological or natural resource models. This differentiates these models and their results from the class of models which are used in weather prediction and forecasting. All three categories of models are valuable tools for scientific research and agricultural, engineering and hydrological applications. The selection of any one type should fit the intended analysis, level of complexity and scale of required results. Overviews of various precipitation simulation models are Ref.[1] for GCMs, Ref.[2] for rain storm modeling, and Ref.[3] for daily precipitation.

MODELS AND APPLICATIONS

General Circulation Models

General circulation models (also referred to as global climate models and sharing a common acronym, GCM) use the same fundamental equations of conservation of mass, energy and momentum as do numerical weather prediction (NWP) models. These dynamic meteorology models, and similarly structured regional climate models (RCM), attempt to numerically solve systems of simultaneous non-linear differential equations which themselves are intended to represent the complex physical processes involved in atmospheric dynamics. Whereas NWPs use observations of recent atmospheric dynamics as boundary conditions for model runs and produce weather prediction in the short term (1–10 days), GCMs use arbitrary boundary conditions and alternative atmospheric parameters to simulate climate for the past, current or future. One result of GCM simulations is precipitation over an area, called a grid, which may be on the order of $10^5\,km^2$, whereas for an RCM the spatial resolution may be 10^1–$10^3\,km^2$.

Precipitation is generally simulated in these models by convective processes resolved from radiation, temperature, pressure, and humidity simulated at various atmospheric layers within a gridbox. These simulations of precipitation are useful for evaluating changes in vegetation and surface water resources under different possible climate change scenarios. To increase the resolution of the GCM simulation, downscaling by statistical techniques or incorporating an RCM into the GCM achieves finer resolution precipitation output applicable to soil moisture and runoff analysis for subgrid scales. Excellent sources of information about and applications of the models are available at WEB sites such as Intergovernmental Panel on Climate Change,[4] American Institute of Physics,[5] and NASA's Goddard Institute for Space Studies.[6]

Spatial-Temporal Rainstorm Models

Stochastic simulation models of rain storm events in space and time attempt to reproduce the statistical properties of the event across a range of temporal and spatial scales. Two of the most advanced modeling concepts are: i) stochastic representation of the physical process of rainstorm temporal and spatial evolution and ii) scale-invariance or self-similarity of the spatial rainfall field. The stochastic approach defines the arrival of the rain cells within a rain storm by a point cluster process[7] represented by one of two common models, the Neyman–Scott process or the Bartlett–Lewis process. The former uses a Poisson distribution for the cluster centers, a random number of cells and a distribution of the distance of cell from the cluster center. The latter assumes a Poisson process for arrival of storms, and distributions for the number of cells per storm, intercell intervals, duration and intensity within a cell. For each characteristic, a statistical distribution must be assumed and numerous parameters identified. Alternatively, scale-invariant models[8] exploit the properties of multiplicative random cascades developed in turbulence theory. Observations of rainfall fields suggest that there are certain spatial and temporal properties that behave similarly over a range of scales differing only by a scale parameter. Thus a hierarchy of attributes (e.g., rainfall intensity) can be developed such that larger areas of lower intensity have embedded within them smaller areas of higher intensity and these in turn have even smaller areas of yet higher intensities. Applications of these models are design storms for engineering and water resources and continuous time hydrologic modeling.

Other statistical storm models of simpler structure are derived empirically. One method is to disaggregate daily rainfall amounts to within-storm intensities for the duration of a storm. These models have parameters that are location specific. Another approach is the regionalization of probabilities associated with storm interarrival time, duration, and amount.

Daily Precipitation Models

Daily precipitation simulation models are the most common for use in a variety of agricultural and engineering applications. These models describe the occurrence (wet) or non-occurrence (dry) of precipitation on a day and subsequently the amount of precipitation given the day was wet. The occurrence process is modeled most frequently by a first-order, two-state Markov chain. Linked to this occurrence process is a statistical description of precipitation on a wet day, often a gamma or exponential distribution.[9] This family of fairly simple models of daily precipitation is referred to as chain-dependant processes. Equations for these models are given in a companion article, *Precipitation: Stochastic Processes*, and are not duplicated here. The models can be parsimonious in the necessary parameters, are easily parameterized with a sequence of observed daily precipitation (a commonly recorded observation for many stations) albeit for many years. Seasonal variation of model parameters can be accomplished by writing them as Fourier series or by assuming they vary step-wise on a monthly or seasonal basis. The structure of the model provides simple generation of multiple realizations of daily time series. Model output is generally used as input to hydrologic, natural resource, or agricultural models requiring daily time step precipitation. The model parameters are location specific with limited transferability to neighboring locations that do not share the same stochastic precipitation structure, e.g., to a location with a large elevation change. Another limitation of the model is the underestimation of interannual variability. One approach to resolve this has been determining the appropriate order of the Markov chain indicating that for particular seasons and geographic locations a second-order or higher conditional dependence may be required, although not all such variability is explained. Markov chains of more than two states may explain more of the variability and a continuum of states may be best.

Other methods to model daily precipitation occurrence have been advanced, among them: alternating renewal process, discrete auto-regressive moving average, Markov–Bernoulli process, dependence on weather type, Markov-renewal. Some recent weather generator models use multivariate techniques to simulate precipitation conditioned on other weather variables or simultaneously with other weather variables or using semiempirical distributions. Although numerous inter-comparisons have been done, no single model provides simplicity, ease of parameterization, and the best fit for all weather types and locations.

An example of a particular precipitation simulation model is provided. The Markov chain-mixed exponential model (MCME) is used to simulate daily precipitation for two stations with different climates in the western United States. This model is the precipitation algorithm embedded in the U.S. Department of Agriculture-Agricultural Research Services (USDA-ARS) weather generator, Generation of Weather Elements for Multiple Applications (GEM).[10] This model is an enhanced version of a series of weather generators developed by the USDA-ARS.[11] Daily precipitation model parameters are estimated from an observed time series of daily data. The optimized parameters are used in the model in conjunction with a random number generator to synthesize a 30-yr period of daily precipitation occurrence and amount. Daily values are summed to seasonal values and the annual averages and variances of these are compared to observations. Fig. 1 shows the results for Tombstone, Arizona plotted as a cumulative distribution function for two 3 month seasons, United States Department of Agriculture, January, February and March (JFM) and October, November and December (OND); Fig. 2 is the same for Eugene, Oregon. The mean is fairly well preserved for both seasons and both the amount and number of occurrences at Tombstone, but the variance is underestimated especially for JFM. The mean is not as well preserved at Eugene, and the variance is underestimated for OND. This is one of the limitations mentioned previously and it may be due to low-frequency ocean-atmospheric signals, such as the El Niño-Southern Oscillation, which have varying influences seasonally and regionally and which are not adequately identified in the daily parameters.

CONCLUSION

Precipitation simulation models generate synthesized sequences of precipitation at a range of spatial and temporal scales. Three broad categories are general circulation models, stochastic spatial-temporal rainstorm models, and daily precipitation models. Model selection and use should be justified by the desired resolution of results and ability to fully estimate the required parameters. Future developments to precipitation simulation models will be downscaling techniques which link regional and local scales, improved algorithms to more faithfully represent the stochastic and physical dynamics of precipitation, and the inclusion of low-frequency oscillations and spatial distribution of parameters in daily precipitation models.

Precipitation: Stochastic Properties

David A. Woolhiser
Colorado State University, Fort Collins, Colorado, U.S.A.

INTRODUCTION

As one observes the evolving patterns of radar images of precipitation on television or the internet, it becomes clear that it is a stochastic process—a process occurring in time (and space) and governed by probability laws. We can only make probabilistic statements because even if we have perfect knowledge of weather variables at some point in time, we cannot predict their values for some future time with certainty.

Day-to-day variations in weather variables, especially precipitation and temperature, have a major influence on agricultural and engineering decisions. Choices of crops to grow, as well as planting, tillage, spraying and harvesting dates are all weather and climate related, and estimates of rainfall probabilities for the next few days can be helpful in guiding decisions. Engineering design of agricultural or urban drainage facilities, control of erosion by structural means, or agricultural management methods must be based upon information on the statistical characteristics or rainfall. Computer models of the growth and yield of major crops such as wheat, corn, soybean and cotton are dependent on real or simulated precipitation data.

PRECIPITATION AS A STOCHASTIC PROCESS

Although precipitation varies widely in space and time, a description of the process at a given location is essential for many agricultural and engineering applications and is not as difficult as describing both spatial and temporal characteristics. Symbolically, we can describe the daily precipitation process for year, τ and day, n as:

$$\begin{aligned} Z_\tau(n) &= Z_1(1), Z_1(2), Z_1(3), \ldots \\ &\quad Z_1(365), Z_2(1), Z_2(2), \ldots, Z_M(365); \\ \tau &= 1, 2, \ldots, M; \quad n = 1, 2, \ldots, 365. \end{aligned}$$

where Z is the amount of precipitation on day n of year τ, the maximum n is either 365 or 366 and M is the number of years. The process, $Z_\tau(n)$ can be written as the product $X(n)Y(n)$ where $X(n) = 0$ if day n was dry and $X(n) = 1$ if day n was wet. $Y(n)$ is a random variable denoting the depth of precipitation if the day was wet.

The occurrence process, $X(n)$, usually exhibits the phenomenon of persistence, which means the probability of measurable precipitation on a given day depends on what happened on the previous day or days. In many cases, persistence can be adequately described by a first order, two state Markov chain where the occurrence of precipitation on day n only depends on whether the previous day (day $n - 1$) was wet or dry, or:

$$\begin{aligned} p_{i,j}(n) &= P\{X_\tau(n) = j | X_\tau(n-1) = i\}; \\ & i, j = 0, 1; \quad n > 1 \\ p_{i,j}(1) &= P\{X_1(1) = j | X_{\tau-1}(365) = i\} \end{aligned}$$

The $p_{i,j}(n)$ are called transition probabilities.

In some climates, particularly when precipitation is caused by slowly moving fronts, a second-order Markov chain may be required.

$$\begin{aligned} p_{i,j,k}(n) &= P\{X_\tau(n) = k | X_\tau(n-1) = j, X_\tau(n-2) = i\}; \\ & i, j, k = 0, 1; \quad n > 2 \end{aligned}$$

Although other occurrence processes may be superior for some climates, the simplicity of the first or second order Markov chain is an advantage for most applied purposes.

As an approximation, the amount of precipitation on a wet day n, is often assumed to be independent of the amount (or occurrence) of precipitation on day $n - 1$. Several distribution functions have been used to describe $Y(n)$, but the most common is the gamma distribution:

$$f_n(y) = \frac{\beta(n)^{\alpha(n)} y^{\alpha(n)-1} e^{-\beta(n)y}}{\Gamma[\alpha(n)]}; \quad y, \alpha(n), \beta(n) > 0$$

where $f_n(y)$ is the probability density function on day n, $\alpha(n)$, $\beta(n)$ are parameters specified for day n, $\Gamma[\alpha(n)]$ is the gamma function and e is the base of natural logarithms.

Another density function commonly used is the three parameter mixed exponential:

$$f_n(y) = \frac{\alpha(n)\exp[-y/\beta(n)]}{\beta(n)} + \frac{[1 - \alpha(n)]\exp[-y/\delta(n)]}{\delta(n)}$$

where $\alpha(n)$ is a weighting function with values between zero and one and $\beta(n)$ and $\delta(n)$ are the means of two exponential distributions.

Because of seasonal variations, the parameters of these distributions must vary within the year. This variability can be accommodated by estimating the parameters for fixed periods such as seasons (spring, summer, fall, and winter), months, or weeks. An alternative approach is to use finite Fourier series to provide a daily variation with only a small number of parameters—annual means and the amplitudes and phase angles of significant harmonics. For example, eight parameters are required to specify a first order Markov chain for four seasons, twenty four parameters are required for monthly representation, and eighteen parameters for a Fourier series representation with five harmonics for P_{00} and three harmonics for P_{10}.

EXAMPLES, PARAMETERS OF STOCHASTIC MODELS

These Markov transition probabilities and the daily rainfall amount distribution will exhibit dramatic differences seasonally and spatially. Figs. 1–3 illustrate the stochastic daily rainfall characteristics for three general climatic types in the United States. The stations represented, Portland, Oregon, Waterloo, Iowa and Walnut Gulch, Arizona—are examples of Mediterranean, continental, and monsoon climates, respectively. Fig. 1 shows the variability of the dry–dry transition probabilities, $P_{00}(t)$. The most striking feature is the nearly opposite behavior of this parameter for Portland and Walnut Gulch. Because the probability of a wet day following a dry day is $1 - P_{00}(t)$, Fig. 1 illustrates that the driest period in coastal Oregon occurs at the same time as the wettest (monsoon) period in southeastern Arizona. Oregon, of course, has a much higher frequency of precipitation in the winter than Arizona. The Corn Belt (Waterloo) has the greatest probability of a wet day following a dry day in early June.

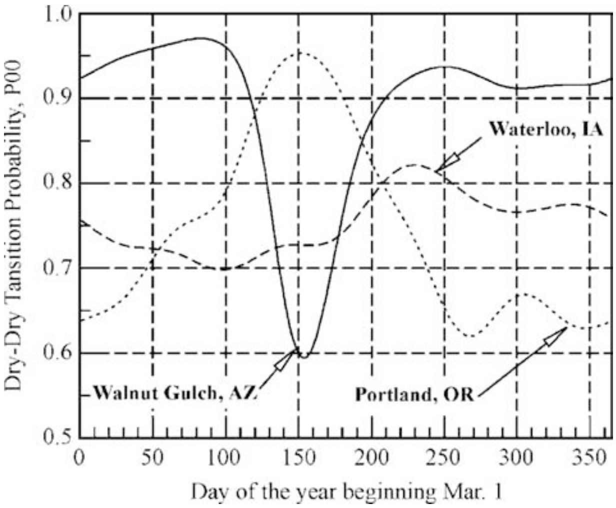

Fig. 1 Seasonal variation of the dry–dry transition probability.

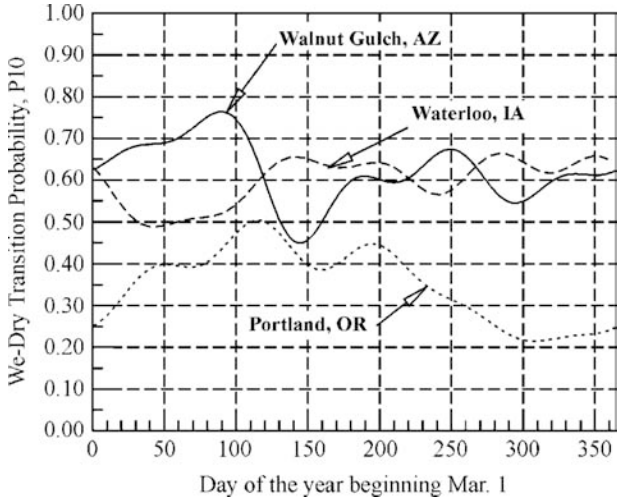

Fig. 2 Seasonal variation of the wet–dry transition probability.

Fig. 2 shows the variations in the wet–dry transition probabilities, $P_{10}(t)$. The probability of a wet day

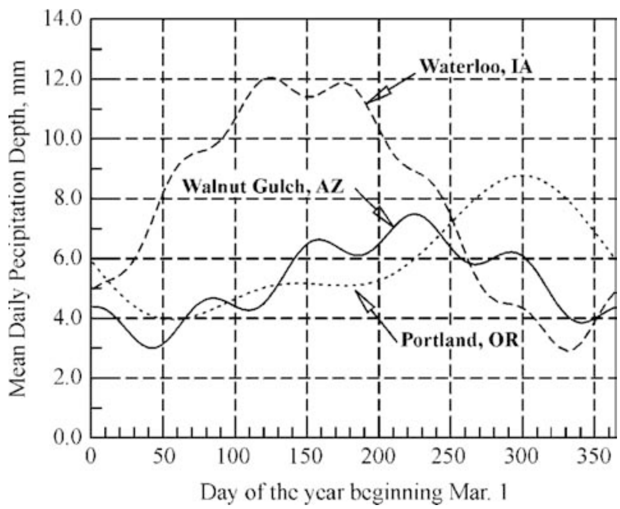

Fig. 3 Seasonal variation of the mean daily rainfall depth.

Plants–Pumps

following a wet day is $1 - P_{10}(t)$, so the lowest vales of $P_{10}(t)$ have the highest persistence. As expected, coastal Oregon has the highest persistence, with the probability of a wet day following a wet day as high as 0.79 in early January. Walnut Gulch has the lowest persistence in June just before the higher persistence during the monsoon season. $P_{10}(t)$ shows less variability for Waterloo, with the highest persistence in April.

Fig. 3 shows the seasonal variation of the mean daily precipitation depth on a wet day. Waterloo shows the greatest mean depth during the summer growing season while the daily precipitation depth at Portland peaks during the winter. Walnut Gulch exhibits a complex pattern with the greatest depth in the fall when the remnants of hurricanes can intrude into Arizona. Secondary peaks occur during the monsoon season (mid summer) and the winter.

PRECIPITATION DATA SOURCES

Micro-computers have facilitated the delivery of climate information to users. Historical weather data are widely available from the world-wide-web. The site of the Climate Prediction Center of the U.S. National Weather Service[1] is particularly helpful. In the United States, personnel at Regional Climate Centers can provide assistance. The web sites of these centers can be found by searching the web for "Regional Climate Centers." Micro-computer programs and data-bases are also available for the contiguous United States[2,3,4] and provide an easy method to obtain simulated daily data for virtually any location in the United States. The CLIMWAT[5] database has monthly precipitation data from 144 sites around the world. Such models have limited application in mountainous regions because most weather stations are located in the valleys and the data for these stations are not valid for higher elevations. Analysis of precipitation data from raingage networks in mountainous regions has shown some regularity, with the frequency of precipitation and mean daily amounts increasing with elevation.

OTHER SOURCES OF INTER-ANNUAL STOCHASTIC VARIATIONS

Although the assumption of year-to-year stationarity for daily precipitation models is adequate for many purposes, it has been found that such models do not preserve the variance of annual precipitation totals. Although model simplifications may account for some of this variance reduction, large-scale interactions between the atmosphere and oceans play a substantial role. It has been demonstrated by many studies that the El Nino-southern oscillation phenomenon or ENSO affects precipitation regimes in several continents. For example, during El Nino years the southwestern United States typically has wetter than normal winters, while the Pacific Northwest has drier than normal winters. The opposite effect occurs during La Nina years. An excellent documentation of this phenomenon for the United States is available from the National Oceanic and Atmospheric Administration (NOAA).[6] Other factors that may affect daily precipitation include random explosive volcanic events, changes in radiation received due to changes in the angle of the earth with the sun, global warming, etc.

The additional randomness due to ocean-atmosphere interactions or other causes has been incorporated into stochastic precipitation models by estimating monthly parameters separately for months classified in the lower 30%, middle 40%, and upper 30% of the climatological distributions of total precipitation.[7] The transitions between each of these classes are described by a first-order, three-state Markov chain.

Precipitation: Storms

Clayton L. Hanson
U.S. Department of Agriculture (USDA), Boise, Idaho, U.S.A.

INTRODUCTION

Precipitation includes all water particles, whether liquid or solid, that fall from clouds and reach the ground. Precipitation includes both liquid (drizzle and rain), freezing (freezing drizzle and freezing rain) and frozen (snow, ice crystals, and hail) water.[1] For precipitation to occur, air must be cooled sufficiently to cause condensation and droplet growth. The mechanism that causes precipitation is adiabatic-expansion cooling as air is lifted in the atmosphere. When cooling is sufficient, vapor condenses on nuclei that are generally small particles of dust or salt, and combustion products that are always present in the atmosphere to form either ice crystals and supercooled liquid cloud droplets, or only liquid cloud droplets. Clouds that extend above the 0°C level are referred to as cold clouds and those that do not extend above the 0°C level are called warm clouds. Ice particles grow to sufficient mass to fall as precipitation in cold clouds by three processes; vapor condensation, collisions with supercooled droplets, and aggregation with other ice particles. In warm clouds, droplets grow large enough to fall as precipitation through the coalescence process where larger particles (which fall faster than small particles) collide and coalesce. As shown in Fig. 1, air is generally lifted by four means: 1) frontal convergence (cyclonic convergence); 2) orographic lifting; 3) thermal convection; or 4) tropical cyclones (hurricanes).[2–4]

FRONTAL CONVERGENCE

Precipitation caused by frontal convergence occurs when the general atmospheric circulation brings air masses of different temperatures and moisture from high-pressure regions (cold, relatively heavy air) to low-pressure regions (warm, relatively light air) which forces the air to rise, producing adiabatic cooling. Areas of high pressure at the surface are associated with converging air on the west side of high altitude troughs and areas of low pressure at the surface are associated with diverging air on the east side of the troughs. These cyclonic systems are usually larger than 500 km across and in the mid-latitudes, the air is lifted at the frontal surface as shown in Fig. 1A. Non-frontal convergence generally occurs in the tropics within a mass of warm, moist air.

The area of contact is called a cold front when a cold air mass replaces a warm air mass, and is a warm front when a warm air mass replaces a retreating cold air mass. Cold fronts generally move faster then warm fronts, so when a cold front overtakes a warm front, the colder air stays at the surface with the warm air lifted above to form an occluded front as shown in Fig. 1A. If a front is not moving, it is called a stationary front.

Typically, cold fronts have relatively steep slopes of 1 in 50 to 1 in 150, whereas warm fronts have slopes of 1 in 100 to 1 in 300.[3] As cold fronts are usually steeper and move faster than warm fronts, the band of weather associated with cold fronts is narrower, more severe and of shorter duration than that of warm fronts. When cold fronts move slow and have stable, warm air ahead of the front, stratus-type rain clouds form in a wide band over the front. When cold fronts move rapidly, the weather associated with these fronts is generally of shorter duration and more severe than that of slower moving cold fronts. When the warm air ahead of cold fronts is moist and unstable, a squall line of showers and thunderstorms may form 50–400 km ahead of the front. The weather associated with squall lines is often more severe than that of the subsequent cold front.

Because warm fronts are flatter than cold fronts, clouds and precipitation are generally widespread, up to several hundred kilometers ahead of the front with the heaviest amounts of precipitation extending cyclonically 50–250 km north and westward of the center of the cyclone. If the warm air above a warm front is moist and relatively stable, the precipitation is gentle and increases as the front approaches. Thunderstorms can be embedded in the clouds when the warm air above a warm front is moist and unstable.

As a frontal system moves, the associated cold front overtakes the warm front and is forced up over the cold air that forms an occluded front. Occluded fronts typically form when frontal systems are at their maximum intensity, which results in widespread cloudiness and precipitation with the maximum precipitation to the north of the low pressure center.

The two major sources of moisture in the United States are from the Pacific Ocean and the Western Atlantic-Gulf

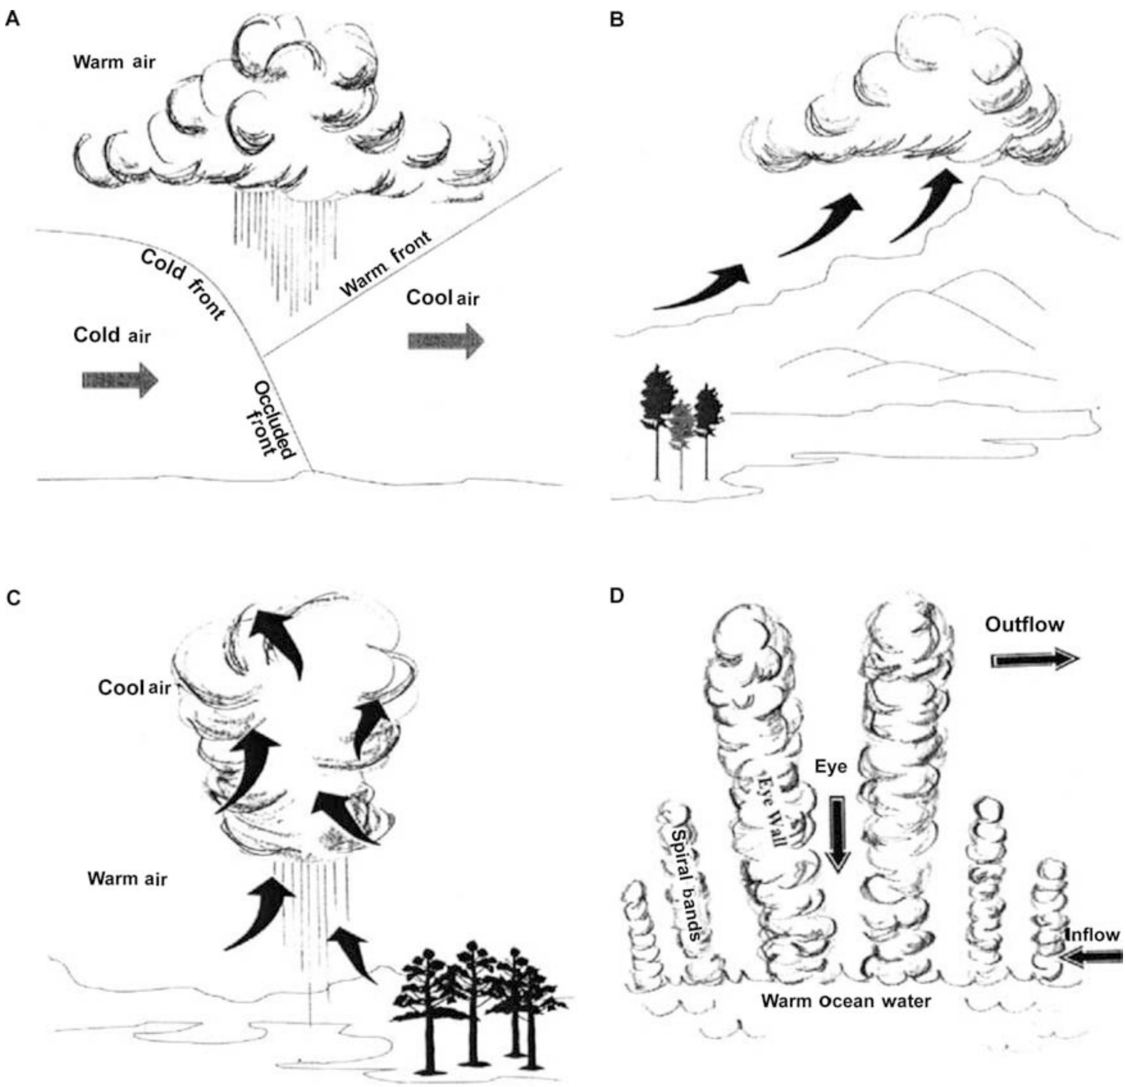

Fig. 1 The primary methods by which air is cooled to saturation by adiabatic cooling are (A) frontal convergence; (B) orographic lifting; (C) thermal convection; and (D) tropical cyclones. (The illustrations are not to scale.)

of Mexico region. The Gulf of Mexico is the primary source of moisture for the large frontal systems that develop in the Great Plains of the United States.

OROGRAPHIC LIFTING

Orographic precipitation results when moist air is forced to ascend over natural barriers such as the coastal hills and mountains along the West Coast of the United States (Fig. 1B). As air is forced up the windward side of barriers, it cools until the air reaches saturation, at which time water vapor begins to condense into liquid water droplets. If the upward airflow is strong enough, precipitation can develop, and this precipitation usually increases with elevation. This process continues until the air is either too dry to produce more precipitation or the air moves over the barrier. After the air moves over the barrier, it warms and precipitation becomes less as the air moves down slope (subsidence), which results in a ''rain shadow'' on the leeward side of barriers, e.g., the semi-arid and arid regions of central Oregon and Washington, and western Nevada. Orographic precipitation is the greatest during the winter in mid-latitudes when atmospheric flow is strongest; however, convective precipitation in summer months is enhanced over barriers due to diurnal winds which tend to move up slopes during the day.[3–5]

THERMAL CONVECTION

Convective precipitation, which is generally associated with air mass showers and thunderstorms, is most prominent in mid-latitudes during the summer (Fig. 1C). Thunderstorms cause some of the most severe precipitation events that often include high-intensity precipitation, hail and damaging winds. For convective activity to develop, the atmosphere has to be conditionally unstable, there has to be some triggering mechanism to release the instability, and there has to be an adequate supply of moisture in the atmosphere. Some lifting mechanism such as upper air systems, frontal lifting, orographic lifting, and/or very strong day time heating is required to release atmospheric instability. As the air is lifted, it cools to the dew point and condensation forms a cloud that results in latent heat being added to the air, which lifts it even more rapidly. When the rapidly uplifted air reaches high altitudes, ice crystals and water drops grow big enough to overcome the updraft, and they fall as rain and/or hail. Single thunderstorm cells can range in size from a few kilometers to 20 km and lines of thunderstorms along a cold front can be several hundred kilometers long.[3–5]

The Rapid City, SD storm of June 9–10, 1972 is a good example of the flooding that can occur due to the precipitation produced by convective thunderstorms that are aided by orographic lifting. The primary atmospheric phenomenon that contributed to these severe storms was the strong low-level easterly airflow that forced moist air upslope over the Black Hills and the unusually light winds aloft over the Black Hills. These light winds at higher levels did not move the thunderstorms away from the hills, which resulted in concentrated rainfall along the eastern slopes of the Black Hills. At one location in the Black Hills, this storm produced 380 mm of precipitation in about 6 hr.[6]

TROPICAL CYCLONES

Tropical storm systems can produce significant amounts of precipitation and cover relatively large surface areas.[4,5,7] These systems typically affect the United States between June and November, with peak activity in the late summer. Atlantic tropical systems originate as tropical waves off the west coast of Africa where the sea-surface temperature is at least 26°C and move westward toward the Caribbean in the predominate easterly winds (trade winds) that flow across the ocean. Some of these systems develop into hurricanes, which means that they have sustained winds in excess of 33 m sec^{-1}. Larger hurricanes can sometimes have radii in excess of 500 km, and their movement is much less directed by winds aloft, thus making prediction of their movement difficult.

The quantity of precipitation that falls from tropical systems is a function of storm movement, relative location to the storm center, and storm movement relative to land masses. Even relatively weak tropical cyclones have sometimes produced extremely heavy rainfall. Precipitation around a tropical cyclone, particularly one that has become fairly well organized and concentric, usually comes from rain bands rotating cyclonically around the low-pressure center. These bands of showers and thunderstorms typically increase toward the center of the storm and are maximized in the eye wall of organized hurricanes where a solid circle of severe thunderstorms is usually located (Fig. 1D). Often, the heaviest precipitation is from these ''eye wall thunderstorms'' and from rain bands that are generally to the east of the center of the cyclone.

In the southeastern United States, tropical storms are responsible for 5–30% of the normal precipitation in the summertime.[4] Tropical cyclone activity in the eastern Pacific Ocean sometimes produces heavy precipitation in the Southwest where desert locations in Arizona and southern California can sometimes receive most of their annual precipitation from the remnants of these storms.

INTRODUCTION

In current agronomic practices, inputs such as fertilizer, pesticides, and water are applied uniformly across a field regardless of their need and their management is normally based on average responses of these inputs to crop yield across the field. However, with current emphasis on quality and efficiency of food production, it is imperative that inputs be managed according to specific needs across the field. This type of farming is known as *precision farming*, a generic term that describes the way whereby inputs to a farming operation are managed. Perhaps a better descriptor for this type of farming is *site-specific management*, which can now be implemented due to commercially available hardware that allows farm equipment to variably apply products across a field using onboard computers.

PRECISION FARMING

Precision farming refers to the practice of applying agronomic inputs across a farm, mainly fertilizers and other chemicals, at variable rates based on soil nutrients or chemical tests, soil textural changes, weed pressures, and/or yield maps for each field in the farm. In large fields (e.g., >40 ha), crop yield and thus crop-water use are notoriously variable. The sources of this variation are related to soil physical and chemical properties, pests, microclimate, genetic and phenological responses of the crop, and their interactions. The technology for crop yield mapping is more advanced than current methodologies for determining and understanding causes of yield variability. Prevailing and traditional management practices treat fields uniformly as one unit. However, recent reports (e.g., Refs.[1–3]) show that to understand underlying soil processes that explain crop yield variability, research must be done at the landscape level and using appropriate statistical tools for large scale studies (e.g., Refs.[1,3,4]).

Precision farming must incorporate the inherent spatial and temporal variability of soil physical (e.g., crop water supply factors), chemical, and biological factors within a field for input management. Accurate representation of spatial and temporal variability in a field requires taking and analyzing many samples. Sampling is normally done on a grid with a scale that can vary from one to several hundred meters.[5] Once properties are measured, geostatistical tools (e.g., semivariogram, kriging, cokriging, etc.) and other spatial statistical tools (e.g., autocorrelation, crosscorrelation, state–space analysis, etc.) can be used to establish statistical relations in space and to minimize the number of soil samples to characterize and map fields.[2,3,6] The number of samples required a priori to determine spatial and temporal variability is perhaps the single largest deterrent in the application of precision farming practices to manage and improve crop-water use.

CROP YIELD AND WATER USE

There is a linear relation between crop yield and water use when the only limiting factor is water (e.g., Ref.[7]). Precision farming has the potential for improving water use efficiency on large fields provided there is a quantitative understanding of what factors and where in the field they affect crop-water use. We know that crop-water use is a function of many biotic and abiotic variables, including managed inputs, and harvestable yield is a manifestation of how these variables and inputs interact and are integrated during the growing season. However, it is difficult to determine a hierarchy on the contribution of each input and variable to the measured yield using classical statistics.[2,3] Often, variables that affect water supply to the plant would contribute to yield at a high level assuming an adequate plant stand and weed control. The cause and effect relation between a single state variable and crop yield is site specific and is difficult to establish without considerable sampling of the soil and/or crop. The establishment of response functions, i.e., crop-water use as a function of variable x_i, only gives a partial answer to explain crop-water use and yield based on inputs. The general idea of precision farming is to optimize input application to the measured crop yield at each sampling location. This is a simple premise; however, the decisions for variable-rate application of any agronomic input must consider temporal and spatial variability of the soil's properties affecting crop growth, water use, and yield. Soil factors that affect stored water, such as depth to root restricting layer and soil textural differences, must be considered in any precision farming operations that attempt to improve crop-water use and yield related to agronomic inputs.

There is very little information published on crop-water use across large fields at the landscape level and in the context of precision farming (e.g., Refs.[1,8,9]). An exception is a study[1] where cotton-water use was measured along a 700-m transect with the objective to 1) illustrate the landscape pattern of cotton-water use and 2) determine the underlying soil processes governing cotton lint yield variability. In this study, state–space analysis[1,3] was used to formulate management decisions that may improve crop-water use and, thus, yield using precision farming practices.

LANDSCAPE CROP-WATER USE

To illustrate the concept of crop-water use in a large field we use the study of Li et al.[1] In 1999, a field experiment was conducted near Lamesa, Texas on a research farm of Texas A&M University on the southern edge of the High Plains of Texas. The soil is classified as an Amarillo sandy loam. The field was 60 ha with slopes ranging between 0.3% and 6.3%.[1] To assess the effect of soil water, NO_3-N, and topography on cotton lint yield across the landscape, two irrigation levels were used. The irrigation treatments consisted of water applications at the 50% and 75% potential evapotranspiration (ET) with a center pivot LEPA irrigation system.[10] At each irrigation level, one transect was established following the circular pattern of the center pivot. The two transects were instrumented with 50 neutron access tubes each 15 m apart, and volumetric water content (θ_v) was measured periodically throughout the growing season. At each point θ_v was measured in 0.3-m depth increments to 2.0-m depth using a neutron probe calibrated for this soil. In addition, at each transect point soil texture, soil and plant N–NO_3, leaf area index, lint yield, slope, plant density, and other parameters were measured.[1]

Statistical Calculations

It has been shown that the use of classical statistics, such as regression analysis and analysis of variance, fails to completely explain the cause and effect between, for example, crop yield and measured soil variables in precision farming experiments.[1–4,11] Instead, there are other more appropriate statistical tools for relating the variability of soil and plant parameters measured in space and time. For example, the structure of the spatial variance between measurements may be derived from the sample *semivariogram*, which is the average variance between neighboring measurements spatially separated by the same distance. Spatial structure between variables is often determined using *autocorrelation* and *crosscorrelation* functions. Autocorrelation measures the linear correlation of a variable in space along a transect. The crosscorrelation is the comparison of two variables measured along a transect and is used to describe the spatial correlation between two landscape variables, i.e., where one variable, the tail variable, lags behind the head variable by some distance. The spatial association between several variables can be described using *state–space* analysis, which is a multivariate autoregressive technique.[1–4,6,11]

Plants–Pumps

SPATIAL ANALYSIS OF CROP-WATER USE

To illustrate the variability of crop-water use or ET, values measured along the 50% irrigation transect were selected.[1] In Fig. 1, the relation between the scaled ET and elevation both as a function of distance along the transect is shown. The ET data are scaled to the maximum of 426 mm of water measured 210 m from the south end of the transect. These results show that higher ET was measured at lower elevations and ET

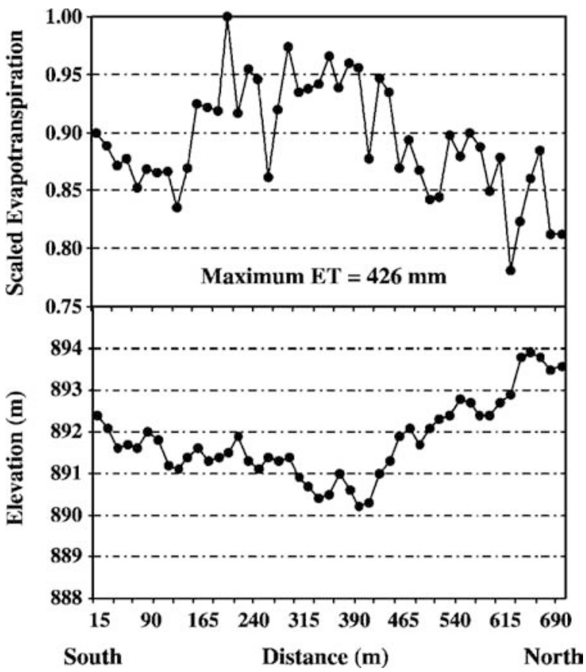

Fig. 1 Scaled ET and elevation as a function of distance along a 700-m transect.

decreased at higher elevations. Spatial crosscorrelation between lint yield and soil water, lint yield and site elevation, and soil water and site elevation are shown in Fig. 2. For a 95% confidence interval, the cotton lint yield was positively crosscorrelated with soil θ_v across a lag distance of ± 30 m. Lint yield and θ_v were negatively crosscorrelated with elevation at a lag distance of ± 30 m. These results show the effect of topography on θ_v and crop-water use measured along the transect. Similar results are given in other reports.[1,8,9,11] In this example, the crosscorrelation between θ_v and elevation shows the spatial structure of measured variables and further shows that more water was stored in lower elevations resulting in higher ET.

Linear regression analysis between θ_v and lint yield and relative site elevation is shown in Fig. 3, and the state–space analysis for the relation between lint yield and three measured parameters is shown in Fig. 4. Results in Fig. 3 show the shortcomings of using an inappropriate statistical tool to understand underlying processes explained with the state–space analysis. This analysis (Fig. 4) quantified how cotton lint yields varied as a function of distance and showed that by using θ_v, soil NO_3–N, and elevation, the variation in lint yield can be explained with a high level of confidence.

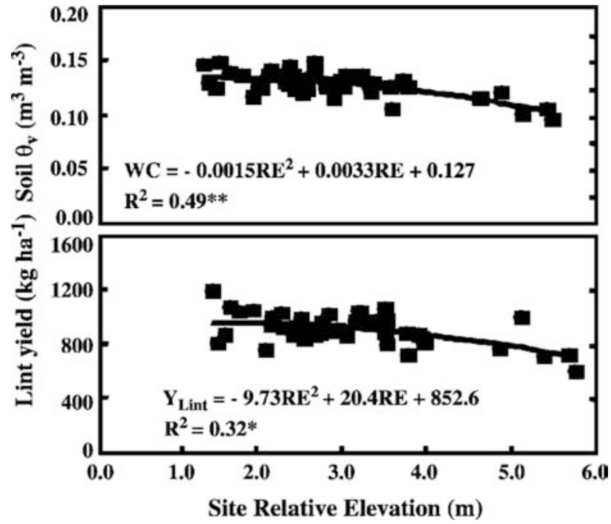

Fig. 3 Soil water content (θ_v) and cotton lint yield as a function of site relative elevation.

Benefits of precision farming to improve crop-water use may be obtained by an economic analysis of maximizing crop yield as a function of application of N fertilizer and irrigation water as given by the state–space equation. In the example given, decision can be made to apply more N fertilizer to lower areas of the field that also hold more water and increase crop-water use and yield. With the introduction of variable rate planters it will be possible in the near future to discriminate site locations and plant more ''drought'' tolerant varieties or change the seeding rate in areas that are prone to have less soil water. This implies the delineation of management zones within a field that are defined based on potential crop-water use and their

interaction with other input variables to maximize economic yield across the field. This type of precision farming is not currently practiced but remains within the realm of possibilities that this type of farming has to offer.

INTRODUCTION

Precision conservation is defined as 'a set of spatial technologies and procedures linked to mapped variables directed to implement conservation management practices that take into account spatial and temporal variability across natural and agricultural systems.'[1,2] Precision conservation is related to the emerging field of precision agriculture, but it has a broader scope and scale when applied to the conservation of agriculture, forest, rangeland, and other ecosystems (Fig. 1). Whereas many precision agriculture applications focus on maximizing crop production and profitability, precision conservation focuses on ecosystem sustainability. The geographic extent to precision conservation encompasses agricultural fields and their surrounding landscapes, and it evaluates management practices across several scales from site-specific to sub-watershed and watershed levels to reduce the amount of eroded sediment, nutrients, and agrochemicals that accumulate in waterways (Figs. 1 and 2).[1,3,4,5]

The emerging field requires the integration of spatial technologies (global positioning systems (GPS), remote sensing (RS), and geographic information systems (GIS)) and analytical approaches. These spatial technologies and analytical approach capabilities are used to implement precision conservation practices that contribute to effective soil and water management in agricultural and natural ecosystems. Precision conservation can account for variability in topography, length, slope, hydrology, soil cover parameters, and other chemical and physical properties to implement best conservation and management practices. These procedures can reduce the transport of nutrients and sediments from fields to surrounding areas; help manage off-site areas, buffer areas, water channels and other areas of a watershed, and contribute to minimizing the entry of agrochemicals into water.

The need to evaluate and account for spatial erosion variability is widely reported by Wheeler,[6] Mitasova et al.,[7] Wang et al.,[8] and others. Therefore, the Universal Soil Loss Equation (USLE) was initially developed as a tool to assess soil erosion by slope sections[9] and now it is used extensively at a watershed scale.[5,10–12] Erosion and off-site transport of soil particles, nutrients, and chemicals can significantly impact water bodies. These processes alter the physical and chemical properties of site-specific soil, remove essential nutrients and soil organic matter, and reduce productivity.[13–15] Availability of data are making a more spatially detailed assessment possible, which[5] is making precision conservation feasible. Precision conservation is increasing the ability to analyze numerical relationships across landscapes to evaluate site-specific erosion patterns across fields and to develop erosion probability maps.[16,17] Precision conservation tools are used to assess how this spatial erosion variability is affecting site-specific yields and how conservation practices can increase/sustain these yields.[18–20]

ELEMENTS OF PRECISION CONSERVATION

Global positioning, remote sensing, and geographic information systems provide the mechanisms and frameworks for collecting, managing, and processing mapped data used for precision conservation. Global positioning systems technology enables precise positioning within a few meters using standard handheld devices and within a few centimeters using more sophisticated equipment. The spatial resolution of the data has increased from an acre per pixel to a few feet for satellite imagery, a few inches for aerial photography, and millimeters for digital, in-field photos. Remote sensing technology utilizes satellite, aerial, and ground-based imagery to characterize landscape conditions. Geo-referenced RS data can be used to monitor landscape erosion potential, to assess risk, and to develop best management scenarios from field to watershed and regional scales.

Global positioning systems technology is helping to encode, store, use, analyze, and display information needed to run detailed models. This allows for the

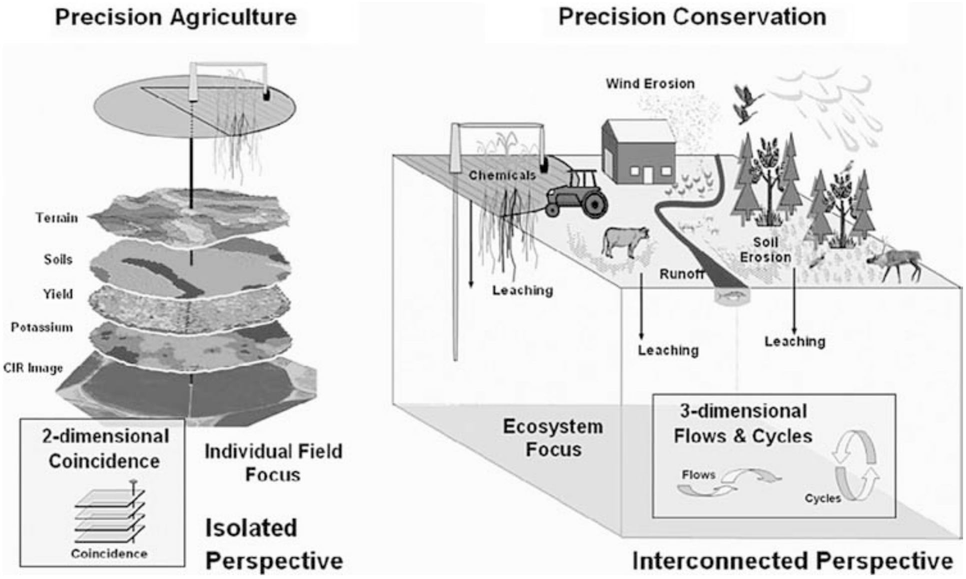

Fig. 1 The site-specific approach can be expanded to a 3-D perspective that assesses inflows and outflows from fields to watershed and regional scales. *Source*: From Ref.[1].

development of geo-registered map layers that can be mathematically analyzed to discover spatial relationships among landscape characteristics and erosion, which are needed to apply precision conservation management practices. These new technologies allow users to link results from analysis with management actions at precise locations in fields and to buffer areas and their surrounding landscapes.

Precision conservation is a new way of conceptualizing and utilizing the spatial information contained in mapped data for the purpose of management and conservation of the landscape using digital representations

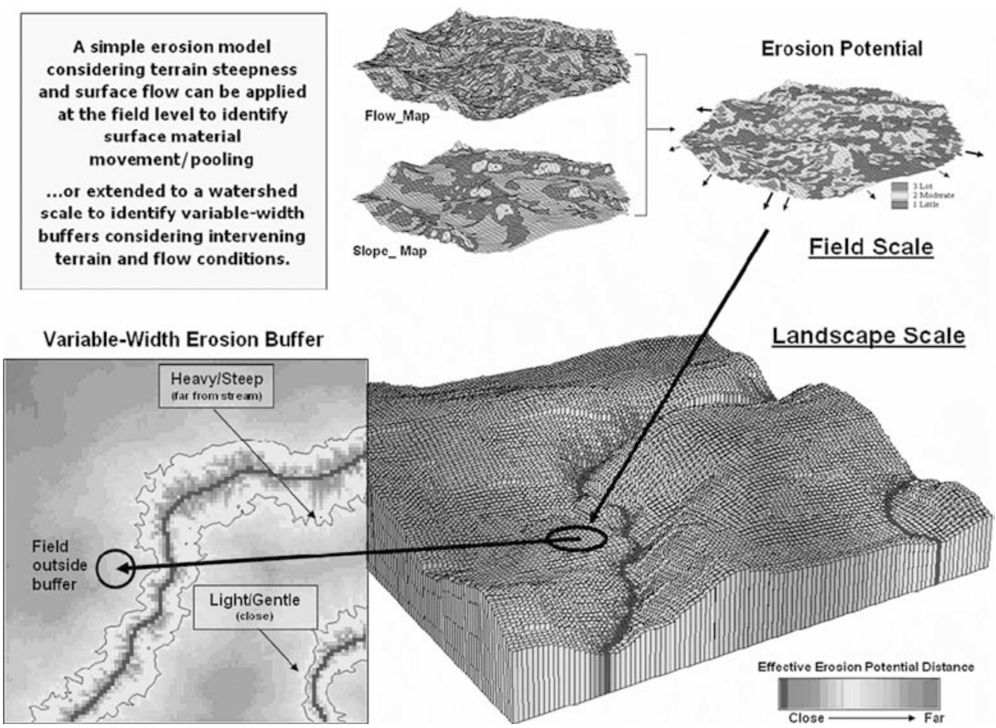

Fig. 2 Application of a simplified erosion potential model at the field and watershed scales.

that are linked to databases and a multitude of new processing capabilities. Spatial analysis is a recently issued approach that extends the basic set of discrete map features of points, lines, and polygons to map surfaces that represent continuous geographic space as a set of contiguous grid cells. Spatial statistics seek to uncover numerical spatial relationships within and among mapped data layers with the potential to integrate site-specific management actions with site-specific conservation practices that can contribute to watershed sustainability (Fig. 2).

Now that software and technologically advanced computers are readily available and the necessary data sets are arriving online to evaluate the surface flow of water over a terrain surface, our scientific understanding of calibrations and weights of spatial models is emerging as the most limiting factor in precision conservation. Berry et al.[1,2] presented an example of how a simple model of surface flow over an elevation map can be used to determine an erosion potential map (Fig. 2). The analyses show that the gray tone (ridges) will be the location with minimal flows, while the red areas (depressions) will be the locations collecting the larger amount of water flow. Berry et al.[2] used this analysis to show how this erosion potential model can be applied to a larger watershed scale to identify effective erosion buffers around waterways that takes into consideration the intervening terrain to derive variable-width buffers (Fig. 2).

EXAMPLES OF PRECISION CONSERVATION APPLICATIONS

Emerging ideas and applications served as the focus of a symposium on ‘Precision Conservation in North America,’ at the 2004 annual meeting of the Soil Science Society of America. At the symposium, several researchers presented papers describing how precision conservation can be applied to soil management systems;[18,20] landscape positioning;[21] and the interactions with nutrient distribution, nutrient application to reduce NO_3–N leaching losses,[22,23] and soil organic C sequestration potential.[24–26] The concept of precision conservation was also used and applied with conservation planning.[3,27] Precision conservation was applied to erosion probability maps,[16] erosion variability,[5] identifying spatial patterns of erosion,[17] and the effect of erosion patterns on yield productivity.[19] Precision conservation concepts were also applied to precision irrigation.[28]

Delgado and Bausch[22] showed how precision conservation techniques can be used to identify this spatial variability and how to improve management to increase the synchronization of the applied nitrogen with plant nitrogen uptake to reduce NO_3–N leaching. Spatial variability can also be managed using site-specific management zones to reduce NO_3–N leaching from the field.[23] The general principles for managing nitrate leaching have been discussed in detail by Meisinger and Delgado.[29]

Precision conservation approaches have been adapted by the USDA in guiding its conservation actions with private landowners.[4,24] Precision conservation is contributing to the use of tools to develop management plans that are site-specific and account for spatial variability in more detail than previously possible.[3,4,27] Precision conservation tools also can be used to assess the effects of best management practices at a watershed scale using grid-based analysis of spatially distributed impacts across a watershed.[5] These new capabilities provide the means for identifying areas of high erosion impact with detailed models of erosion, addressing issues of scaling in more detail,[5,17,30] and identifying areas of nitrate leaching.[22] Berry et al.[1,2] reported that the off-site flows needed to be taken into consideration in precision conservation across the landscape, because these off-site flows interconnect fields and natural ecosystems.

CONCLUSION

Precision conservation utilizes a set of technologies and procedures that link mapped variables with analytical capabilities to appropriate management actions. It requires the integration of the spatial technologies of GPS, RS, and GIS with the ability to analyze spatial data. Precision conservation will continue to evolve to link new technologies in order to assess how management practices can be more effective across different erosion risk landscape scenarios to reduce the off-site transport of nutrients. Precision conservation will contribute to conserve the sustainability of the system and even to improve the system’s physical and chemical properties, which increase productivity. Precision conservation will be a crucial science influencing to the sustainability of our biosphere in this century.

Professional Societies

Faye Anderson
School of Public Affairs, University of Maryland, College Park, Maryland, U.S.A.

INTRODUCTION

Professional societies play a vital role in every discipline as they function to serve the individual interests of their members, represent their collective interests, and communicate information about the discipline to a wider audience. Professional societies can be viewed as individual membership organizations because professionals pay annual dues to join these organizations. Individuals join professional societies for the career opportunities accompanying membership, and many join more than one society. These opportunities include attending conferences at reduced costs, subscribing to journals, gaining leadership experience, and access to professional networks. Most professionals state their reasons for joining as gaining access to the most up-to-date information in their profession and networking with colleagues about common challenges, problems, and solutions.

Water-related professional societies foster scientific research, disseminate cutting-edge information, advocate for water resources, facilitate employment opportunities, and work to influence the future course of the profession. Common activities often include publishing journals and newsletters, conducting conferences and workshops, maintaining listservers and websites, and providing various networking opportunities for their members. Members are elected to run these organizations through a Board of Directors. This Board typically works alongside a headquarters office staff, which includes an Executive Director. Due to the large number of associations, association management has grown to have its own professional societies, e.g., the American Society of Association Executives.[1]

Agricultural water is an important societal resource, ultimately affecting every person on Earth through food systems. Water resources professionals in agriculture-related fields work in a wide variety of capacities—federal government, state and local government, universities, extension offices, non-profit organizations, agribusiness, etc.—and on a wide variety of issues—irrigation methods, water quality, non-point source pollution, soil, drought, water conservation, etc. These sectors and disciplines often come together under the broader umbrella of a professional society's mission, and sometimes more narrowly defined interests form their own professional society as well. The majority of these societies are non-profit organizations and membership fees vary widely. Some societies have tens of thousands of members and others just a few hundred. These professional societies serve both the individual needs of their members and the collective needs of the profession. Some societies have a code of ethics. Professional societies will often draft position or white papers on key issues affecting water resources. As agricultural water resources increasingly face stress and water professionals confront multiple demands in the workplace, these professional societies will continue to serve important functions for both their memberships and society.

U.S. PROFESSIONAL SOCIETIES

Many agricultural water professional societies are based in the United States and predominantly serve the interests of U.S.-based professionals by focusing the majority of their efforts on domestic agricultural water issues and concerns. Due to the large number of professional societies, there is substantial competition for both professional influence and members.[2]

American Agricultural Economics Association

The American Agricultural Economics Association (AAEA)[3] is a professional society for those interested in agricultural economics issues, including those related to rural communities and natural resources. AAEA strives to keep its members abreast on the latest agricultural economics research developments and policy issues. Its official mission is to enhance the skills, knowledge, and professional contributions of those economists who serve the society in solving problems related to agriculture, food, resources, and economic development. The AAEA publishes the *American Journal of Agricultural Economics*, *CHOICES* magazine and a newsletter. It conducts an annual meeting and several workshops and smaller meetings each year. Water resources are an important component of this agricultural economics organization's natural resources agenda and there is some activity related to aquaculture as well.

American Geophysical Union

American Geophysical Union (AGU)[4] is an international scientific society with over 35,000 members in 115 countries. Formed over 75 years ago, AGU is devoted to advancing the understanding of earth and its environment in space and making the results available to the public. AGU publishes many newsletters, books, and journals, including the well-respected *Water Resources Research*, which is popular with many agricultural researchers.

American Institute of Hydrology

The American Institute of Hydrology (AIH)[5] was formed in 1981 to provide certification, training, and education for hydrologists. It is the only national and international professional organization that certifies Professional Hydrologists and Professional Hydrogeologists.

American Society of Agricultural Engineers

American Society of Agricultural Engineers (ASAE)[6] is a professional and technical organization dedicated to the advancement of engineering, applicable to agricultural, food, and biological systems. Founded in 1907, ASAE has grown to over 9000 members and has an active Soil and Water division. Their Hancor Soil and Water Engineering Award recognizes outstanding contributions to the field.

American Society of Agronomy

The American Society of Agronomy (ASA)[7] is dedicated to the development of agriculture enabled by science, in harmony with environmental and human values. ASA publishes *Agronomy Journal*, *Journal of Environmental Quality*, and *Journal of Natural Resources and Life Sciences Education*. The ASA has an environmental quality division and a committee on water management on agricultural lands and sustainable agriculture. The Crop Science Society of America[8] and the Soil Science Society of America[9] share a close working relationship and related interests with the ASA, including sharing the same Headquarters office and staff. However, each of these Societies is autonomous, has its own bylaws, and is governed by its own Board of Directors.

American Society of Civil Engineers

American Society of Civil Engineers (ASCE)[10] is widely considered the leading source of technical and professional information in the field of civil engineering. ASCE publishes dozens of journals, including the *Journal of Irrigation and Drainage Engineering*. ASCE has a Water Resources Planning & Management (WR) division and the Environmental & Water Resources Institute (EWRI). The ASCE awards the Royce J. Tipton Award in recognition of contributions to the advancement of irrigation and drainage engineering.

American Water Resources Association

American Water Resources Association (AWRA)[11] has a broad-based membership representing every sector of the water resources profession. AWRA publishes the *Journal of the American Water Resources Association* and *Water Resources Impact*. It also has an active Agricultural Hydrology Committee and sessions dealing with agricultural issues at its annual meetings and specialty conferences.

American Water Works Association

American Water Works Association (AWWA)[12] is an international non-profit scientific and educational society dedicated to the improvement of drinking water quality and supply. Founded in 1881, AWWA is the largest organization of water supply professionals in the world and is dedicated to the promotion of public health and welfare in the provision of drinking water of high quality and sufficient quantity. Its Government Affairs office is very active in policy processes, including those concerned with agricultural water and water conservation issues.

Irrigation Association

Since 1949, the Irrigation Association (IA)[13] has represented the widely varied interests of its membership in irrigation, drainage, and erosion control. Primarily a trade association, IA has led the advances in water-use efficiencies for irrigated agriculture, landscape, and golf course applications and offers many training opportunities to its membership. The IA awards annual prizes for technological innovations and helps define research priorities relating to irrigation.

National Ground Water Association

National Ground Water Association (NGWA)[14] seeks to enhance the skills and credibility of all ground water professionals, develop and exchange industry knowledge, and promote the ground water industry and understanding of ground water resources. NGWA publishes an extensive list of publications and has a multitude of professional educational opportunities. It also manages the National Ground Water Educational Foundation.

Society of Range Management

The Society of Range Management (SRM)[15] works to promote and enhance the stewardship of rangelands to meet human needs based on science and sound policy. The SRM has over 4000 members organized into geographic sections and has a Watershed/Riparian Committee.

Society of Wetland Scientists

The Society of Wetland Scientists[16] was founded in 1980 to promote wetland science and the exchange of information related to wetlands. With over 4000 members, the society has regional chapters, holds annual meetings, publishes a journal *Wetlands*, and organizes professional certification programs.

Soil and Water Conservation Society

The Soil and Water Conservation Society (SWCS)[17] has approximately 10,000 members and is very active in agricultural water issues. The mission of SWCS is to foster the science and the art of soil, water, and related natural resource management to achieve sustainability. The SWCS serves to both promote and practice an ethic recognizing the interdependence of people and the environment. The Society acts as an advocate for both the conservation profession and for science-based conservation policy. Its members help carry out this mission through 80 geographic chapters, including student chapters. The organization plays an active role in the Farm Bill and other pieces of relevant agriculture and water legislation, and often publishes white papers on agricultural water-related policy issues. The SWCS publishes the *Journal of Soil and Water Conservation* and *Conservation Voices*, and organizes annual meetings.

U.S. Committee on Irrigation and Drainage

The U.S. Committee on Irrigation and Drainage (USCID)[18] was organized in 1952, as a non-profit professional society. Its multi-disciplinary membership shares an interest in irrigated agriculture—its planning, design, construction, operation and maintenance of irrigation, drainage and flood control works; agricultural economics; water law; and environmental and social issues. The USCID represents the United States on the International Commission on Irrigation and Drainage (ICID). The ICID is an international organization of more than 70 countries founded in 1950. It operates as a non-governmental organization devoted to the development of the science and technique of irrigation engineering worldwide.

Water Environment Federation

Since 1928, the Water Environment Federation (WEF)[19] has sought to promote and advance the interests of water quality industry and to benefit society through protection and enhancement of the global water environment. The WEF mostly focuses on domestic and industrial wastewater issues, yet it has a non-point source committee that addresses agriculturally related issues. Its research foundation, the Water Environment Research Foundation, provides research grants to study both point and non-point sources of water pollution.

INTERNATIONAL PROFESSIONAL SOCIETIES

Increasingly, the above professional societies are incorporating more global water and agricultural issues into their activities and are attempting to attract more foreign members to help sustain their organizations. A few agricultural water-related professional societies have a specific international focus in both mission and membership base. The broad ranges of water and agricultural challenges facing many areas of the world, as well as the needs for networking working professionals across geographic regions, often drive the activities of these international-focused societies.

International Erosion Control Association

International Erosion Control Association[20] has 2400 members and provides education, resource information, and business opportunities for professionals in the erosion and sediment control industry. It offers a professional certification program.

World Association of Soil and Water Conservation

The World Association of Soil and Water Conservation (WASWC)[21] has 500 members and its philosophy is that the conservation and enhancement of the quality of soil and water are a common concern of all humanity. The WASWC strives to promote policies, approaches, and technology that will improve the care of soil and water resources and to eliminate unsustainable land use practices. It has a quarterly newsletter and also publishes books. Its meetings are usually held in conjunction with the International Soil Conservation Organization and the Soil and Water Conservation Society's meetings.

Other associations with relevant international interests include the International Association for Environmental Hydrology, the International Commission of Agricultural Engineering (CIGR), the International Association for Hydraulic Engineering and Research, the ICID, the International Soil Conservation Organization, and the International Society of Soil Science.

CONCLUSION

Increasingly, professional societies build partnerships with organizations having similar agriculture and water-related interests, such as federal and state agencies (e.g., the U.S. Department of Agriculture), environmental groups (e.g., American Rivers), research institutes (e.g., International Water Management Institute), and other professional societies. These partnerships facilitate work on common goals and access each other's resources. Water-related professional societies are even partnering to form broader alliances to further their common interests, such as Water Associations Worldwide[22] and several environmental societies collaborating under the umbrella of the Renewable Natural Resources Foundation.[23]

The number and diversity of agricultural water professional societies reflects the interdisciplinary nature of the discipline. All of the above water-related professional societies have interests in agricultural water issues, and have information and activities of interest to those working in agricultural water fields. This is exhibited in the articles published in their journals, the sessions held at their meetings, and the content of their professional education opportunities. In many ways, the current interests of members and the critical challenges confronting society serve to motivate these professional societies' activities. Further information on the specific activities of any professional society can be found on their respective websites and by contacting them directly.

Plants–Pumps

Psychrometry: Accuracy, Interpretation, and Sampling

Derrick M. Oosterhuis
Altheimer Laboratory, University of Arkansas, Fayetteville, Arkansas, U.S.A.

INTRODUCTION

Thermocouple psychrometers are generally considered to be reliable and accurate for measurement of plant and soil water potential (ψ).[1–3] However, the rigorous requirements for using these highly sensitive instruments are frequently misunderstood by users, often leading to frustration and erroneous data.[4] The use of psychrometry in soil and plant water relations has been comprehensively reviewed.[5–8]

ACCURACY OF PSYCHROMETER MEASUREMENTS

The accuracy and reliability of psychrometric measurements of leaf ψ have been demonstrated in many studies. Comparisons of psychrometers with Scholander-type pressure chambers for measurement of leaf ψ have generally exhibited close agreement.[2,3,9] At high water potentials, the psychrometric ψ tends to be more negative than the ψ measured in the pressure chamber, but as the water ψ decreases, pressure chamber values become more negative[2,7] due to resistance to water movement through the xylem towards the cut surface as a result of compression of the vascular tissue.[10] Psychrometric ψ measurements on excised tissues are generally more negative than those of in situ values, with deviations from the 1:1 relationship being greatest at high ψ values with errors often exceeding 0.3 MPa.[11] The source of error for the lower ψ values was associated with evaporative water losses during tissue sampling. A field comparison of the main commercially available thermocouple psychrometers showed differences between the types of psychrometers,[12] attributed to the size of the tissue sample used[13] and evaporative losses.[14] The screen-caged psychrometer most closely correlated with the pressure chamber measurements of ψ. Measurement of leaf ψ with the end-window and leaf-cutter types of psychrometer were similar but slightly more negative and variable than the larger screen-caged psychrometer, while the C-52 sample chamber (Wescor Inc, Logan, UT) was the most variable of the psychrometers tested.

INTERPRETATION OF PSYCHROMETRIC WATER POTENTIAL MEASUREMENTS

Despite widespread acceptance of thermocouple psychrometry, results have not been always satisfactory due to substantial variability in the ψ measurements. Prerequisites for accurate and reliable measurement of ψ with psychrometers include scrupulously clean psychrometers, careful calibration, precise temperature control, proper measurement techniques, and correct interpretation of data. Some of the more common and important sources of errors are discussed below.

Temperature gradients between the reference junction and the sensing-junction can cause errors in the measuring circuit, which are ultimately included in the wet bulb temperature depression. These ‘‘zero offsets’’ are easily measured on the microvoltmeter prior to Peltier cooling and can then be compensated for to eliminate them from the measurement of ψ.[4] Equations are available for correcting these temperature gradients if so desired.[15,16] The achievement of complete vapor equilibrium within the sample chamber is essential. Insufficient equilibration can result in excessively low ψ measurements, whereas excessively long equilibration periods can result in non-representative ψ values due to metabolic changes in the sample tissue.[2,3] Careful interpretation of the microvolt output following Peltier cooling[17] is important, and psychrometer users should be aware of the possible shapes of the microvolt output and the interpretation thereof to obtain the corresponding sample ψ.[4,9,17] Adsorption of water by thermocouple psychrometer assemblies can cause erroneously low ψ measurements[18] because many of the materials used in the construction of thermocouple psychrometers act as vapor sinks and adsorb more water than required to saturate the volume of air within the sample chamber.[19,20] These errors may be largely overcome by covering both the inside of the chamber and the neoprene O-rings with a thin coating of Vaseline.[4,5] Errors due to adsorption of water by the psychrometer assembly are negligible when sufficient tissue is used, but significant with small volumes of tissue.[18]

To achieve a given level of statistical precision for a given experiment and measurement technique, some knowledge of the sources of variation is essential to determine the number of samples and replications needed. An understanding is required, therefore, of the sampling error due to instrument variation, leaf-to-leaf, and plant variation so as to devise a sampling scheme (discs per leaf, leaves per plant, and number of replications) that minimizes the variability, achieves maximum efficiency, and gives the required precision. For example, total error (experimental + sampling) is significantly larger ($P < 0.05$) for stressed than for well-watered wheat leaves.[21] This will vary with species and should be considered for each experiment. Savage, Cass, and de Jagger[22] provided a statistical assessment of errors encountered during the use of thermocouple pychrometers for ψ measurement.

An underlying requirement often overlooked in psychrometric measurement of ψ is the need for consistency in all procedures from one sample to the next. Strict adherence to experimental protocol will greatly enhance the reproducibility of the data and will ensure more meaningful and reliable results with less variability.

SAMPLING FOR SOIL OR PLANT PSYCHROMETRIC MEASUREMENTS

Accurate measurement techniques for ψ measurement are of little use if the soil or plant sample is not representative of the water status of the biological system being measured. The water potential of the excised plant sample or excavated soil sample must show little, if any, change prior to being sealed into the psychrometer sample chamber.[23] Oosterhuis and Wullschleger[7] reviewed the use of thermocouple psychrometers for the measurement of ψ in leaf discs and highlighted the precautions necessary during tissue sampling and the interpretation of results for accurate psychrometric measurement of ψ. A similar review for sampling soil material is not available.

Water lost by evaporation following sample excision, particularly from succulent and turgid leaf samples, could result in a decrease in measured ψ. However, leaf ψ can rise within a few minutes after excision because xylem tension is released,[24] followed by a rapid decrease in ψ dependent on the evaporative demand. Thus, ideally, samples should be punched directly from attached leaves into the psychrometer chamber with only one sample being taken from each leaf.[5] The leaf-cutter psychrometer was developed[25] with these concepts in mind. Precautions are needed to reduce evaporative losses after excision especially under conditions of high evaporative demand. Leaves with waxy cuticles may require the use of abrasion to reduce cuticular resistance and vapor pressure equilibration times.[14,26]

Tissue-sample size can affect the measurement of leaf ψ,[13,24] although results are inconclusive as to the optimal size which should be used with a particular psychrometer chamber volume. The relative amount of the chamber volume occupied by leaf tissue and air is important as this introduces problems associated with vapor pressure equilibration. The larger the volume of the psychrometer sample chamber, the larger the leaf material sample, i.e., the chamber should be filled with as much leaf material as practically possible. This will also reduce the problems associated with sources and sinks of water vapor on the chamber walls.[5] Excessively small samples may require longer vapor pressure equilibration times because less tissue is available to contribute water vapor. Most data suggest that the measured leaf ψ is higher in tissue having a high cut surface area (A) to sample volume (V) ratio,[24,27] although the opposite has been reported.[13] Nevertheless, the area of the cut surfaces represents a potential site for excessive evaporation losses, and the A/V ratio gives some indication of the possible extent of these losses. Using the largest possible leaf disc to fill the chamber will ensure that the A/V ratio is minimized and the effects of evaporative losses concomitantly reduced.

For in situ soil ψ measurement, psychrometers should be placed in horizontal positions because vertical gradients are more pronounced than horizontal gradients. Furthermore, soil ψ measurements may be compromised if psychrometers are used in the upper 0.3 m of the soil.[28]

CONCLUSION

With good techniques and adequate precautions during sampling, precise measurement techniques, and careful interpretation of the recorded data, thermocouple psychrometers offer a convenient, accurate, and reliable method of measuring ψ. The most important sampling procedures include consistency of technique, prevention of evaporative losses during collection and sealing in the psychrometer chamber, and careful sample selection. Measurements of water potential with thermocouple psychrometers compare favorably with those made using the pressure chamber. Close attention should be paid to careful cleaning and calibration, achievement of complete vapor pressure equilibration, and prevention and detection of temperature gradients.

Psychrometry: Theory, Types, and Uses

Derrick M. Oosterhuis
Altheimer Laboratory, University of Arkansas, Fayetteville, Arkansas, U.S.A.

INTRODUCTION

Measurements of water potential (ψ) and its components are being increasingly used to characterize plant and soil water relations. The psychrometric technique has a number of advantages compared to other methods including the ability to facilitate a large number of samples and also allows the determination of the components of ψ. Reviews of psychrometry in soil and plant water relations have been published,[1–3] the use and construction of these instruments have been documented,[1,4,5] and concerns about their use for measuring soil and plant ψ have been addressed.[6]

THEORY OF THERMOCOUPLE PSYCHROMETERS

The Concept of Water Potential

The use of thermodynamic principles to express the water relations of soil and plant tissue[1,2] is well recognized. The free energy of water in the soil–plant–atmosphere continuum influences both the movement of water along energy gradients and water availability in the plant. Application of these concepts has proven extremely meaningful, since the chemical potential of water and dissolved solutes greatly affects cell growth.[2] The chemical potential of water is related to the change in the free energy of the system and can be expressed in terms of the partial water vapor pressure.[7] In an isothermal system, the volumetric ψ (MPa) is given by the Kelvin equation:

$$\psi = (RT/V_w)\ln(e/e_0) \quad (1)$$

where R is the universal gas constant ($8.3143 \times 10^{-6}\,\mathrm{m^3\,MPa\,mol^{-1}\,K^{-1}}$), T the absolute temperature (K), V_w the partial molar volume of pure water ($1.805 \times 10^{-5}\,\mathrm{m^3\,mol^{-1}}$), and e and e_0 are the partial and saturated vapor pressures of water (relative humidity of the air in the psychrometer chamber expressed as a fraction). Therefore, the ψ of a system can be determined if the equilibrium water vapor pressure (e/e_0) is measured at a known temperature and pressure. The thermocouple psychrometer is based upon this concept and upon the principle that the vapor pressure above a solution or segment of plant tissue is related to its water potential according to Eq. (1).

Principles of Operation of Thermocouple Psychrometers

Two fundamental designs of thermocouple psychrometers have been used to determine water potential in plant tissues,[8,9] and a number of modifications and advances have been suggested for both. The Spanner-type psychrometer, however, has certain advantages over the Richards and Ogata instrument[4,10,11] and is more widely used. The thermocouple is usually constructed from chromel and constantan wire of approximately 25-μm diameter[1] to meet the requirements of both high temperature sensitivity and small junctions. The typical Spanner psychrometer (Fig. 1) consists of a thermocouple sensing-junction (constantan–chromel) and two reference junctions (copper–constantan and copper–chromel).[1]

Three primary methods of using thermocouple psychrometers are currently available including the psychrometric,[8] dew point,[12] and isopiestic methods.[13] For the psychrometric method, a sample is sealed into the chamber, allowed to reach both temperature and vapor pressure equilibrium and then the wet bulb temperature of the air in the chamber is measured relative to the dry bulb temperature. This method requires that water be condensed onto the sensing junction by applying an electric cooling current.[14] This Peltier cooling current continues until the sensing-junction temperature is below the dew point temperature of the chamber air and water condenses on the thermocouple junction.[1,8] When the current is discontinued, the droplet evaporates and the voltage output is monitored (Fig. 2). In the dew point method, the depression of the dew point temperature is measured, again related to the relative humidity within the chamber, and hence, to the ψ of the sample at the prevailing temperature.[15] The isopiestic variation is a null method of measurement in which the vapor pressure of a sucrose solution is balanced against the water potential of the sample.[13] The isopiestic and the dew point methods involve no net transfer of water once condensation has occurred. Although each of these methods has its advantages,

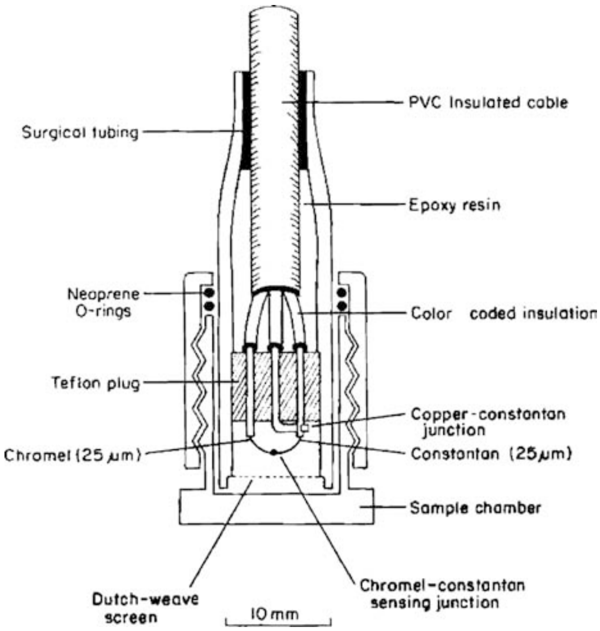

Fig. 1 Diagrammatic representation of a spanner-type end-window. Thermocouple psychrometer used for measuring leaf-disc water potential. *Source*: From Ref.[3] with permission.

the psychrometric and dew point techniques are more widely used, with the former method being the more popular and easily available commercially. Both techniques use identical sensors but different microvoltmeter circuitry. In this review, thermocouple psychrometers are used as a collective term for both thermocouple psychrometers and dew point hygrometers.

TYPES OF THERMOCOUPLE PSYCHROMETERS

Many different thermocouple psychrometer designs have been developed for soil or leaf ψ measurement, and a number of these are commercially available.[16]

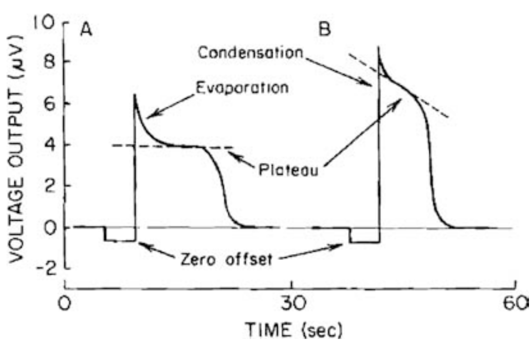

Fig. 2 A typical chart-recorder trace during the determination of relatively high (A) and low (B) leaf-disc water potential. *Source*: From Ref.[3] with permission.

These include the end-window psychrometers, leaf-cutter psychrometers, and screen-caged psychrometers, the leaf in situ psychrometers, self-standing aluminum insulated psychrometers, porous ceramic shield psychrometers, and a multichambered psychrometer apparatus. The majority of these instruments use a small soil or plant tissue sample for determination of ψ. All of these commercially available psychrometers are generally used without modifications except for leaf in situ psychrometer which should be modified by insulating the housing assembly with a covering of foam insulation and reflective aluminum tape for temperature control.[17] In situ measurements of ψ can be made of leaves in the field using the leaf in situ psychrometer attached directly to an intact leaf,[17,18] in tree trunks with screen-caged thermocouple psychrometers inserted into the trunk,[19,20] or in the soil using ceramic or screen-caged psychrometers buried in the soil at right angles to the soil surface.[21]

USE OF THERMOCOUPLE PSYCHROMETERS

Preparation of Psychrometers

The thermocouple junction is normally protected by a stainless steel housing. New psychrometers should be thoroughly cleaned with a solution of boiling 10% acetone or a jet of steam to remove any oil or debris, which may have accumulated during construction. All psychrometers and sample chambers must be scrupulously cleaned before and after use by repeated flushing of the psychrometer and the sample chamber with deionized water. If possible, the psychrometer should also be periodically inspected under a dissecting microscope to check the cleanliness and physical state of the thermocouple junction. The use of a detergent or steam may help to remove stubborn deposits. After cleaning, the psychrometers and sample chambers should be partially dried with filtered, compressed air and then placed in an oven (<30°C) for few hours. After drying, the psychrometers should be allowed to cool to prevent possible condensation before being stored in their sample chambers or in clean plastic bags.

Calibration of Psychrometers

Accurate calibration of thermocouple psychrometers is essential for accurate and reliable measurements of water potential and its components. The procedure consists of placing a filter paper disc in the sample chamber of a previously cleaned psychrometer using forceps. A small quantity of the appropriate standard solution ($0.1\,mol\,kg^{-1}$, $0.3\,mol\,kg^{-1}$, $0.5\,mol\,kg^{-1}$, $0.7\,mol\,kg^{-1}$, and $1.0\,mol\,kg^{-1}$ NaCl or KCl solutions), sufficient to saturate the filter paper, is added to the filter paper disc in the sample chamber with a syringe or eye dropper beginning with the most dilute calibration solution. The microvolt output (water potential) is then determined using an appropriate microvoltmeter, after a 4-hr vapor pressure equilibration in a constant temperature water bath (i.e., 25°C). Each standard is measured in turn after careful washing and drying of the psychrometers between measurements. A calibration curve is then constructed from conversion tables[22] by which future measurements of the microvolt output can be converted to the equivalent leaf ψ. Use of a computer greatly facilitates these conversions. If a psychrometer is in constant use, it should be recalibrated every few months.[1]

Temperature Control, Thermal Gradients, and Zero Offsets

Thermocouple psychrometers are typically placed in isothermal water baths to minimize temperature-related errors in ψ measurements. Failure to understand and adequately qualify these errors can seriously affect the accuracy of experimental results. Temperature gradients within the psychrometer can arise from thermal fluctuations in the environment, heat produced by sample respiration, and heating of the reference junctions during the Peltier cooling operation.[23] These gradients can introduce systematic error either through temperature differentials between the sensing junction and the sample, or by causing temperature-induced zero offsets within the thermocouple measuring circuit. Thermocouple psychrometers measure the relative humidity of the air in equilibrium with the sample, and therefore any difference in temperature between the sample and chamber air will introduce significant error. This error results from the fact that the air in the chamber and the sample come to the same vapor pressure, not the same relative humidity.[23] The error in ψ introduced is approximately $7.77\,\mathrm{MPa}\,^{\circ}\mathrm{C}^{-1}$.[24] Commercial psychrometers which utilize leaf-disc samples do not currently allow for the measurement and correction of this error.

Transient electrical zero offsets are another source of possible error in the use of thermocouple psychrometers. Observed zero offsets at the microvoltmeter are generally interpreted as originating within the sensing head of the psychrometer. However, zero offsets can also originate from other locations within the psychrometer circuitry, i.e., at the connection of the meter or the data logger and these should be insulated from direct solar radiation or air currents by enclosing the connectors with a plastic shield.[6] Poorly earthed equipment and the proximity of AC main cables to the hygrometer output leads may cause significant zero offsets and error in ψ. Shielding the wire does not eliminate the problem, but spatial isolation from other electrical equipment within at least a 2-m radius minimizes these errors. Some long-term drift can be tolerated, but short-term fluctuations should be kept to a minimum, less than 0.0005°C for proper precision.[1]

Vapor Pressure Equilibration

It is essential that the vapor pressure within the sensing head of the psychrometer must be in dynamic equilibrium with that of the sample under the established isothermal conditions for precise ψ measurement.[6] This usually occurs within 2–4 hr at 25°C in an isothermal water bath. Failure to achieve complete vapor equilibrium within the sample chamber due to an insufficient equilibration period can result in excessively low ψ measurements. In contrast, non-representative ψ values can also result from long equilibration times due to metabolic changes, i.e., starch hydrolysis, in the sample tissue.[25,26] Error associated with equilibration times can also result from changes in cellular turgor which accompany growth when the leaf-disc tissue is separated from its water source.[27] This error is greatest when sampling from young, actively growing tissues, but is presumable of only minor concern with mature tissues. Psychrometer chambers with rubber seals or dirty or oxidized metal surfaces can display equilibration characteristics dominated by the chamber material.[28] High leaf cuticular resistance may necessitate longer equilibration times[29] or cuticular abrasion.[30]

Measurement Procedure

After psychrometer selection, initial preparation and calibration, the actual measurement procedure involves tissue sampling, equilibration in an isothermal water bath, and recording of the voltage output. The psychrometer-sample chamber assembly is placed in an isothermal water bath for an appropriate vapor pressure equilibration time (4 hr is usually sufficient). The psychrometric mode is then used and water condensed on the measuring junction by applying a 5-mA Peltier cooling current for 15 sec. These are the recommended and most widely used values; however, optimum cooling times and cooling currents may vary with the tissue and condition of measurement.[31] The voltage output should be monitored continuously during evaporation with an appropriate dedicated microvoltmeter (e.g., from J.R.D. Merrill Specialty Equipment, Logan, Utah, or Wescor Inc., Logan Utah) and a chart recorder.[32] Care is required in analysis of the voltage output plateau[31] since it indicates the equilibrium ψ of the sample in the psychrometer chamber.

Interpretation of the Psychrometer Output Plateau

Accurate determination of leaf ψ with thermocouple psychrometers requires reliable and accurate determination of the plateau voltage output following the Peltier cooling (Fig. 2). Immediately following the termination of cooling, psychrometer output sharply increases, reaches a peak or plateau, followed by a relatively rapid decline as water on the sensing junction evaporates back into the air of the chamber. The plateau represents the wet bulb temperature of the psychrometer when the evaporation of water from the junction reaches a steady state with the vapor pressure of the air in the chamber. If the leaf or soil sample has a relatively high ψ, then the plateau may be horizontal and easy to interpret (Fig. 2A), whereas with drier samples, the plateau becomes increasingly transient and interpretation more subjective (Fig. 2B).[32] Although several approaches for determining the plateau can be used, the one most typically used is to extrapolate the plateau back to intersect the vertical line corresponding to the beginning of the evaporation period. The voltage corresponding to this intersection point is then used to calculate ψ. Caution should be exercised to ensure that identical methods of interpretation are used in psychrometer calibration and in the measurement of sample ψ.

CONCLUSIONS

Psychrometry is an extremely useful technique for measuring water potential of plant or soils if proper sampling and measurement precautions are taken. Calibration and cleaning of the instruments are fundamental steps in thermocouple psychrometry. Major concerns during measurements include achievement of complete vapor pressure equilibration, prevention and detection of temperature gradients. With good calibration and cleaning techniques, precise measurement techniques, and careful interpretation of the recorded data, thermocouple psychrometers offer a convenient, accurate, and reliable method of measuring ψ.

Pumps: Displacement

Dorota Z. Haman
Agricultural and Biological Engineering, Institute of Food and Agricultural Sciences, University of Florida, Gainesville, Florida, U.S.A.

INTRODUCTION

A displacement pump is a device that traps a fixed amount of water at the intake conditions (lower elevation or pressure) and either transports it to a discharge elevation and/or compresses it to the discharge pressure. This article deals with screw pumps and three types of reciprocating positive displacement pumps: piston, plunger, and diaphragm.

SCREW PUMPS

Screw pumps are the oldest of the positive displacement pumps. It is known that they were used in ancient Egypt to lift water from the Nile. The Cochleon or Egyptian Screw was composed of tubes wound round a cylinder (see Fig. 1). As the entire unit rotates, water is lifted within the spiral tube to the higher elevation.

Later, other designs of screw pumps were used where a spiral groove was cut on the outside of a solid wooden cylinder and then the cylinder was covered by boards or sheets of metal closely covering the surfaces between the grooves. Although the screw pump is said to have been invented by Archimedes and has been named after him, there is no record of Archimedes himself claiming its invention. The invention was attributed to him by Diodorus who lived 200 yr later. He claimed that Archimedes invented the screw pump in Egypt suggesting that Greeks adopted the pump from Egypt where the first records of the pump can be found. An astronomer of Alexandria, Conon of Samos, also called Conon of Alexandria, who was a close friend of Archimedes, is believed to have invented or adopted the screw pump from lower Egypt. Archimedes demonstrated and fully explained its properties and the screw pump eventually became known as the Archimedean screw.[1] Screw pumps have been used since then in many applications and are still used today.

The simplest, single screw pumps also called ‘‘progressive cavity’’ or Archimedean pumps are often used in land drainage since they can pump large volumes of water over levees. Large pumps of this kind, powered by the windmills, have been employed by the Dutch to drain polders since 1634. The Archimedean screw turned in a brick-lined casing enclosing approximately one half of the screw, but open at the top. When it has reached the top of the screw, the water flowed over a low sill to the tail race. A sluice door or trap, which is closed by its own weight as soon as the screw stops, prevented the water in the storage basin from flowing back to the polder (Fig. 2).[2]

The diameter of a typical drainage pump is 0.3 m or greater and the length is up to 15–18 m. The screw is normally arranged at an angle of 30°. The greater the angle of inclination, the lower the output. The output lowers approximately 3% for every degree increase over a 22° inclination. At 30° angle, 15 m long screw can lift water to 7.5 m. The output depends also on the level of water in the intake reservoir and the ratio of the diameter of the screw shaft to the outside diameter of the screw flights. It is also limited by the rotational speed which for a single screw pump is between 30 rpm and 60 rpm.

Modern Archimedean screw pumps can have efficiencies up to 75%. For practical purposes they are no longer than approximately 15 m but they can have very large diameters in order to increase the capacity of the screw. If the required lift is larger than 7.5 m, a number of screws arranged in series can be used. In addition, single, double, and triple flights are often used (Fig. 3). Flights are also known as helixes. With each increase in flights, there is a 20% increase in capacity. The three-flight pump can handle the most capacity in the least amount of space. Finally, the clearance between screw flights and trough will impact the output of the pump.[3]

Modern screw pumps fall into two basic categories: rigid screw pumps and eccentric screw pumps. Rigid pumps can be subdivided into single screw pumps described above and intermeshing screw pumps with two or more screws. The eccentric pumps can come in two basic configurations. In one, the rotor thread is eccentric to the axis of rotation and meshes with internal threads of the pump housing (stator). In the other, the stator wobbles along the pump centerline. Multiple-screw pumps are available in a variety of configurations and designs. All employ one driven rotor in mesh with one or more sealing rotors. They can be single-ended, or more commonly double-ended.[4]

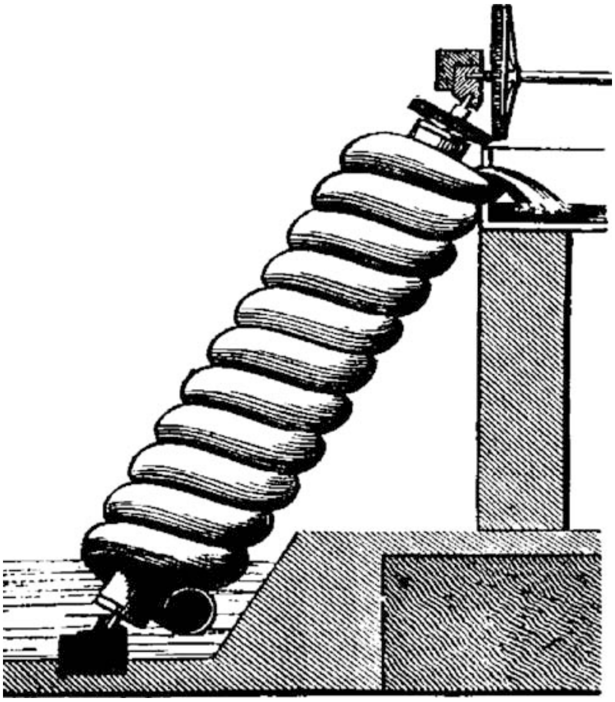

Fig. 1 Egyptian screw pump. *Source*: From Ref.[1].

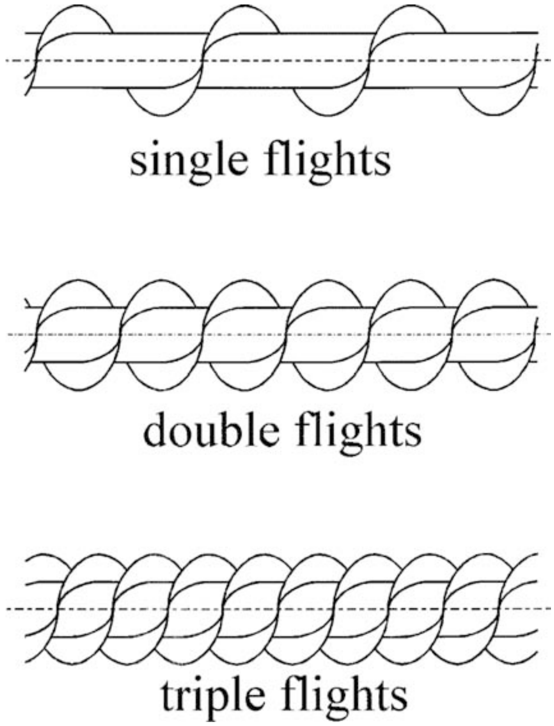

Fig. 3 Various types of flights in a screw pump.

The multiple rotor pumps can be further divided into timed and untimed categories. Timed rotors rely on internal or external set of timing gears for phasing the mesh of the threads and for supporting the forces acting on the rotors. Untimed rotors rely on precision and accuracy of the screw itself for proper mesh and transmission of rotation.[4]

Screw pumps are a unique type of rotary positive displacement pump in which the flow through the pumping elements is truly axial. The water is carried between the screw threads on one or more rotors. It is then displaced axially as the screws rotate and mesh. In other types of rotary pumps, the liquid is forced to travel circumferentially, however, the screw pump has an axial flow pattern and low internal velocities. They are true positive displacement pumps and they will deliver a definite amount of water with every revolution of the rotors. Due to relatively low inertia of rotating parts, some screw pumps can operate at higher speeds than other pumps often up to 10,000 rpm. They are self-priming and flow characteristic is essentially independent of pressure.

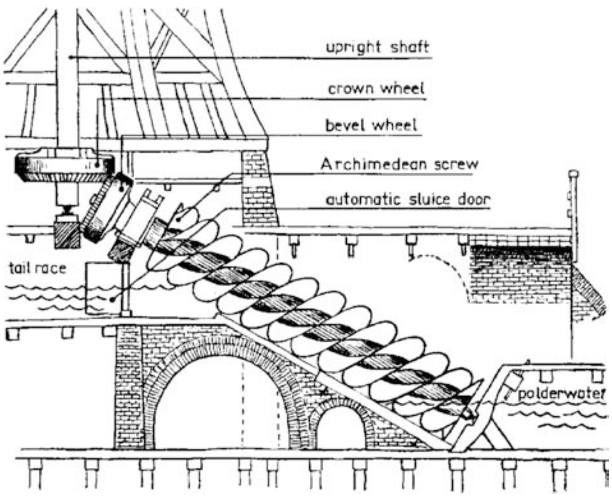

Fig. 2 Archimedean screw pump used in a Dutch windmill. *Source*: From Ref.[2].

Commonly, screw pumps are used today in pumping wastewater and storm water due to their large capacity and low heads and no need for screening the debris. Modern screw pumps consist of revolving shaft fitted with one, two, or three helical blades to rotate in an inclined trough and push the wastewater up the trough. This type of pump can pump large solids without clumping and can operate at a constant speed over a wide range of flows with good efficiencies.

The capacity of any screw pump is the theoretical capacity minus the internal leakage. In order to find the capacity of a screw pump the speed of the pump must be known. The delivered capacity of any rotary screw pump can be increased in several different ways. The capacity of the pump depends on several factors: diameter of the screw, speed of the screw, and the number of flights mounted on the screw shaft.[4]

The advantages of screw pump include: 1) wide range of flows and pressures; 2) wide range of liquids

Plants–Pumps

and viscosities; 3) Built-in variable capacity; 4) High speed capability allowing freedom of driver selection; 5) low internal velocities; 6) self-priming with good suction characteristics; 7) high tolerance for entrained air and other gases; 8) minimum churning or foaming; 9) low mechanical vibration, pulsation-free flow, and quiet operation; 10) rugged, compact design—easy to install and maintain; and 11) high tolerance to contamination in comparison with other rotary pumps.[4]

There are also some disadvantages to screw pumps. Their cost is relatively high due to close tolerances and running clearances. Performance characteristics are sensitive to viscosity change and high-pressure capability requires long pumping elements.[4]

RECIPROCATING PUMPS

Reciprocating pumps like screw pumps are among the oldest types of pumps used. Early reciprocating pumps consisted of a piston that moves back and forth within a cylinder. A primitive, piston pump has its origin in a syringe that was used in ancient Egypt. The forcing pump was greatly improved and described by Greek inventor Ctesibius (200 B.C.) the son of a barber in Alexandria who is considered the inventor of a piston forcing pump for pumping water (Fig. 4).

Pumps, utilizing a piston-and-cylinder combination, were commonly used in Greece to raise water from wells. The pumping action is due to the mechanism that is literally forcing slugs of water from the intake pipe to the outlet. Due to the forcing action of the mechanism, the pump head curve for this pump is almost flat. The other similar type of reciprocating pump is a plunger pump where the piston is replaced with a plunger that fits the cylinder less tightly than the piston. Plunger pump (Fig. 5) was invented later and patented by Sir Samuel Moreland in 1675.[1]

Positive displacement, reciprocating pumps are usually selected for low-flow-rate/high-pressure applications. Since most of the water pumping applications require high flow rate, as for example in irrigation systems, reciprocating pumps have limited use in water pumping applications. However, piston and diaphragm pumps are ideal for pumping water using solar energy. Solar water pumps utilize DC electric power from photovoltaic panels and they must work during low light conditions at reduced power, without stalling

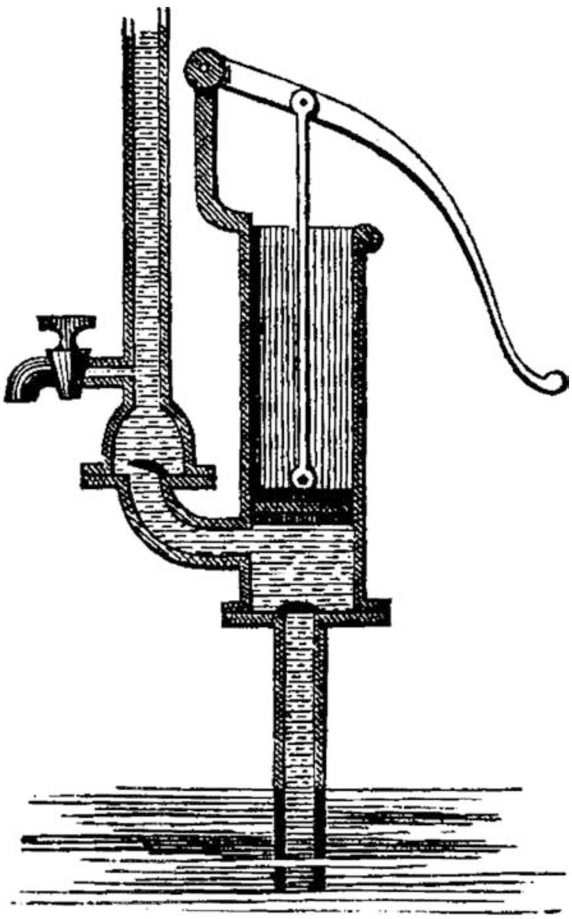

Fig. 4 Early piston pump. *Source*: From Ref.[1].

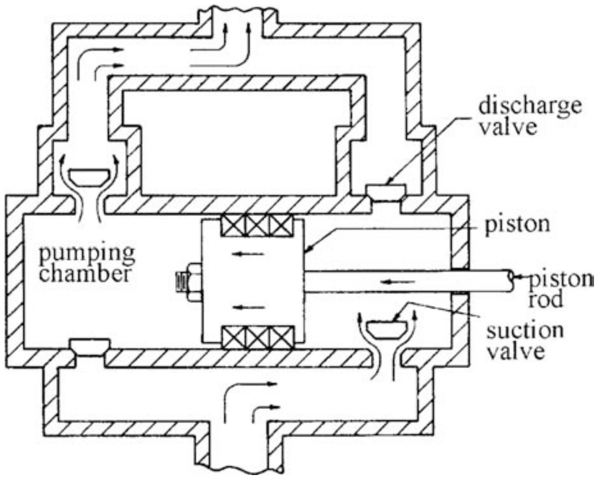

Fig. 6 Schematic of a double-acting piston pump.

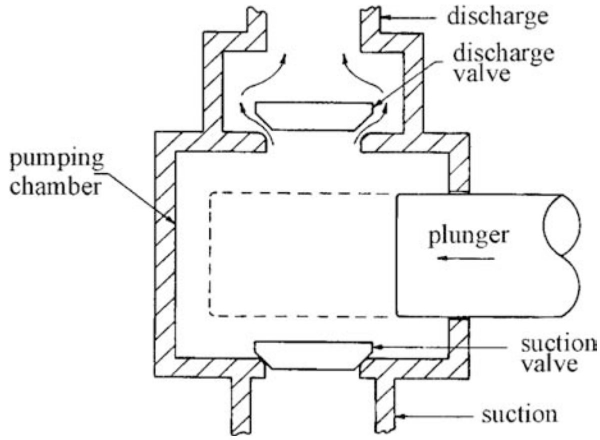

Fig. 7 Schematic of a plunger pump.

or overheating. Positive displacement pumps seal water in cavities and force it upward. As a result, lift capacity is maintained even while pumping very slowly. These pumps are used for pumping water for domestic supply, livestock, and small irrigation systems where electricity is not readily available.

A modern reciprocating positive displacement pump (also called power pump) is one in which a plunger or piston displaces a given volume of water for each stroke. All power pumps have a fluid-handling portion, called the *liquid end* consisting of displacing device such as piston or plunger, a fluid holding cylinder, suction and discharge valves, and a packing seal. The liquid end must have a driving mechanism to provide force to the plunger or piston.

A piston is a cylindrical disk, mounted on a smaller diameter rod and usually fitted with some type of sealing rings that move with the piston whereas a plunger is a smooth rod, similar to a piston. The sealing rings in the plunger pump are stationary and the plunger slides through the rings. Schematics of a double-acting piston pump and a plunger pump are given in Figs. 6 and 7, respectively.[5]

A modern power pump is a constant speed, constant torque, and nearly constant-capacity reciprocating pump whose plungers or pistons are driven through a crankshaft from external source. It can have a vertical or horizontal construction. Horizontal construction is used on plunger pumps up to 150 kW and piston pumps rated to 2200 kW. Maximum number of plungers in a horizontal pump is usually no more than five whereas horizontal piston pumps usually do not exceed three pistons. Vertical construction plunger pumps are larger (up to 1100 kW) and contain 3–9 plungers. Plungers are used in pumps producing pressures

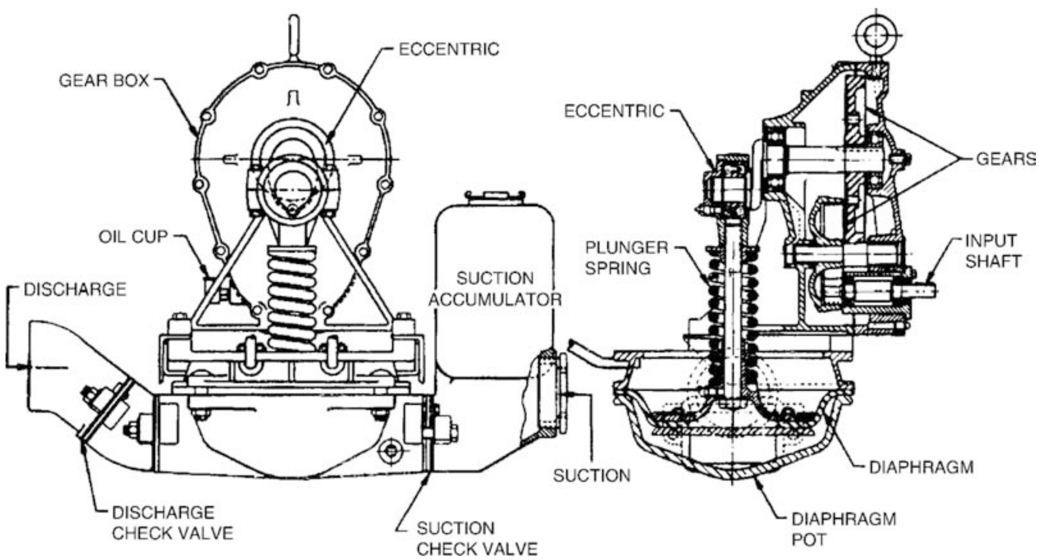

Fig. 8 A schematic of a diaphragm pump. *Source*: From Refs.[4–6].

between 7000 kPa and 200,000 kPa while maximum pressure developed by a piston water pump is approximately 13,800 kPa.[6]

Mechanically and hydraulically driven diaphragm pumps are positive displacement pumps with flexible membranes that operate in a similar manner to a piston or plunger pump. (Fig. 8). A diaphragm is a flexible disk or tube which isolates water from the piston, plunger, hydraulic liquid, or compressed air that are used to actuate the diaphragm. Diaphragm pumps do not have seals or packing and can be used in applications requiring zero leakage. They do not require priming and can be run dry without damage.

Mechanically driven diaphragm pumps operate by reciprocating movement of plunger rod. The force on the central part of the diaphragm creates the suction and discharge pressures. Hydraulically actuated diaphragm pumps, where reciprocating piston forces hydraulic fluid in and out of the chamber behind the diaphragm, is also a positive displacement pump. Air operated diaphragm pumps are displacement pumps but they should not be considered as positive displacement pumps since the maximum pumping pressure cannot exceed the pressure of the compressed air powering the pump.

The disadvantages of diaphragm pumps are that they are not manufactured for operating pressures above 860 kPa and they are not practical for pumping rates above 16 L m^{-3} (58 m^3 hr^{-1}).[7]

A most common disadvantage of all reciprocating pumps is pulsation. This can be minimized in some modern pumps by increased number of pistons, plungers, or diaphragms that operate out of synchronization with each other.[8] In addition, the initial cost of a reciprocating pump is larger than the cost of a centrifugal pump.

Pumps: Internal Combustion Engines

Hal Werner
Agricultural and Biosystems Engineering, South Dakota State University, Brookings, South Dakota, U.S.A.

INTRODUCTION

Internal combustion engines or electric motors power most water pumps. This section will present information on the use of internal combustion engines.

The most common internal combustion engines are diesel and natural gas with propane and gasoline used less frequently. Choosing a particular power unit fuel may be governed more by necessity rather than desire. For example, natural gas is not an option unless gas service is located near the pumping site because of the high cost of extending natural gas lines. Other considerations are discussed in this article.

Advantages of using an internal combustion engine for water pumping include variable speed allowing for varying pump output and, except for natural gas, portability between pumping sites.

Disadvantages of internal combustion engines are high repair and maintenance costs, susceptibility of units to cooling and lubrication failure, and the need for right-angle drives when using deep well pumps.

Depending on actual local fuel prices, natural gas and diesel generally have the lowest pumping costs for a given installation. Diesel engines are often the highest initial cost and servicing for diesel engines may not be readily available in some areas. Gasoline engines generally require more frequent overhaul and repair but fuel may be more readily available. Few gasoline engines are rated for continuous duty service needed for pumping water.

Thermal efficiency is the rate at which an engine can convert energy in the fuel into mechanical power. For well-maintained engines, the thermal efficiency of diesel engines is highest followed by natural gas and propane. Gasoline engines have the lowest efficiency.

Several factors need to be considered when selecting an engine for pumping water. Engineering considerations include the type of pump, pump speed, and horsepower requirements. Economic considerations include cost of the equipment, cost of the fuel, hours of operation, and labor requirements. Other factors to consider include fuel availability or cost for service, need for portability, safety controls, and any peripheral equipment such as a generator.

POWER REQUIREMENTS

The power needed to drive a water pump is determined by the following factors. Flow rate (Q) is the amount of water pumped per time period. Total head (TH) is the amount of head (pressure) that the pump supplies to the flow delivered. Total head includes static head or vertical lift, delivery pressure, friction losses, and other miscellaneous losses. Total head is also called total pumping head or total dynamic head (TDH). Finally, the efficiency of the pump (E_p) and drive unit (E_d) is used to calculate power needs. In general form, the equation to calculate pump power (P) is:

$$P = \frac{(C \times Q \times \mathrm{TH})}{(E_p \times E_d)} \tag{1}$$

where C is a coefficient to convert the units to the desired units of power. Power is often expressed in units of kilowatts or horsepower.

It is very important to size the power unit large enough to meet the power required for the pump. It is crucial not to overload the power unit and thereby shorten its life, or worse, have it fail completely. While electric motor sizes can be matched to the pump power needed, engines are generally sized larger to account for rating methods. Engine ratings may be designated as intermittent, automotive, industrial, or continuous. Engines used for pump powering should be selected using an industrial or continuous rating that provides for the continuous, constant load of a water pump. If no continuous rating is available for the engine, the output power rating of the engine should be reduced by at least 20% to avoid overloading.

Additionally, most engines are rated for a standard operating condition that does not reflect varying conditions found for most installations. For example, most are rated as bare engines at sea level and 16°C (60°F). Below are some of the derating factors that should be applied to engines:

- For each 300 m (1000 ft) above sea level deduct 3%.
- For each 5.5°C (10°F) above 16°C (60°F) deduct 1%.
- For radiator and fan deduct 5%.

- For accessories (alternator, etc.) deduct 5%.
- For drive losses (right angle, belt) deduct 5%.

Neglecting to derate an engine for the various factors could result in overloading and premature failure of the unit. Finally, add power for any other options that the engine supplies, such as hydraulic motors or a generator set that provides power for auxiliary electric motors.

A right-angle drive system is required when engines power deep well pumps. A right-angle gear drive unit is the most common drive with belt drives uncommon and less desirable. It is critical that drive shafts and couplers be properly aligned when connecting engines to drive units and pumps. It may be desirable to install a clutch between the engine and the pump to allow for running the engine and auxiliary equipment without operating the pump.

If possible, direct connect the pump to the engine to avoid drive unit losses. This requires that the engine speed be matched to the desired pump speed for the proper output. This speed may be different from the highest rated power for the engine and must be considered when sizing the engine since power output varies with engine speed. It may be desirable to operate the engine at a slower speed than the maximum rated speed to prolong life. Fuel efficiencies are also often higher at speeds less than the maximum rated speed.

Tractors are occasionally used to drive pumps. It is critical to derate the tractor engine for continuous operation since they are rated for intermittent operation. Also apply an additional derating factor (about 5%) to cover the losses between the engine and the power take off (PTO) shaft if the power rating is not given for the PTO output. Standard tractor PTO speeds are 540 rpm and 1000 rpm. Few modern pumps operate at those speeds; thus a gear or belt speed increaser will generally be required. Retrofit tractor engines with safety controls to protect the engine from hazards such as loss of pump pressure, coolant temperature, and oil pressure.

Two types of safety equipment are essential for engines. First operator safety is imperative. All shafts, belts, and fans must be shielded. Also pump and pipe fittings must be secure and rated for the operating pressure to prevent failure.

The second type of safety equipment protects the pump from damage if a malfunction occurs. These safety controls should shut down the engine whenever a condition exists that could damage the engine. Most important is a device to shut off the engine in case of excessive engine temperature, either high coolant or oil temperature. It may also be desirable to provide oil level protection. For centrifugal or deep well pumps, protection must be supplied for a loss of pressure at the pump discharge or in a downstream pipeline. A drop in pressure may overload the engine and result in premature failure. Finally, the engine and pump should be protected from loss of water, e.g., loss of prime of a centrifugal pump.

Another option is to automate the controls for the engine. A variety of features are available including remote monitoring, remote starting and stopping, and controls to interlock peripheral equipment like chemigation application units. The interlock feature shuts down the engine when the secondary unit malfunctions.

ENGINE FUEL USE

The fuel-to-power conversion efficiency of internal combustion engines varies from less than 20% to nearly 40%. As a result considerable heat energy must be dissipated from the engine to prevent overheating. Engines use three cooling options. The radiator and fan option is common and is similar to units on most cars and trucks. Air-cooled engines use a high capacity blower and shrouds to direct cooling air over the engine. Heat exchangers are similar in principle to radiators except no fan is used and water from the pumping source circulates through a heat exchanger instead.

Estimates of hourly fuel use for internal combustion engines can be made using the table below. Divide the total energy requirements of the pump [using Eq. (1) given previously] by the values from the table to estimate the fuel use for the pumping station. Actual fuel use may be different from the estimated depending on the relative performance of individual engines and pumps. Energy use for electricity is included in the table for reference. The cost of operation can be estimated by multiplying the fuel use by its cost.

Maintenance of internal combustion engines is crucial to long life and efficient operation. Monitor oil levels and regularly change oil. Insure that safety devices are functioning properly. Conduct maintenance on a planned schedule, and keep records of service and maintenance.

Fuel	Power output per unit of energy
Diesel	11.79 MJ/L (16.66 hp hr/gal)
Propane	6.51 MJ/L (9.20 hp hr/gal)
Gasoline	8.14 MJ/L (11.5 hp hr/gal)
Natural gas	7.79 MJ/m^3 (82.2 hp hr/1000 ft^3)
Electricity	3.16 MJ/kW hr (1.18 hp hr/kW hr)

CONCLUSION

Internal combustion engines are excellent choices to power water pumps. The engine needs to be matched to the pump requirements to insure efficient operation and long life. Options to consider for each engine include a clutch, auxiliary generator, and automated controls. Safety devices must be provided to protect both the opartor and the equipment. Proper maintenance is essential to guarantee long engine life.

Rainfall Shelters

Arland D. Schneider
Hedges Engineering and Consulting, Sumner, Washington, U.S.A., and
U.S. Department of Agriculture (USDA), Bushland, Texas, U.S.A.

INTRODUCTION

Rainfall shelters (shelters) have been used during the past 50 yr to exclude rainfall and other precipitation from research plots and lysimeters. They bridge the gap between the controlled environment of a greenhouse or growth chamber and uncontrolled field conditions. Meteorological variables such as radiation and wind are altered under the shelter,[1] but with limited rainfall duration, the effect on crop growth is minimal. The main limitation of rainfall shelters is the small crop area that requires careful extrapolation of results to field areas.

Foale, Davis, and UpChurch[2] identified the following six subsystems or components of rainfall shelters: site, tracks, shelter structure, drive (mechanism), power supply, and controller. Auxiliary components include in-shelter irrigation systems and cranes for weighing lysimeters. Rainfall shelter subsystems and features are illustrated in Fig. 1, and the references provide examples of various types of shelters.

RAINFALL SHELTER SUBSYSTEMS

Site

The site needs to be representative of the soil to be studied, and the surrounding area must be similarly and uniformly cropped for accurate evapotranspiration measurements.[2] The area needs to be well drained with surface runoff from adjacent areas excluded. Since plot areas are small, isolating individual blocks of soil with vertical walls of plastic film or concrete may be desirable.[2] Utilities such as electricity and telephone service are also desirable, and a water supply of adequate quantity and quality must be available for irrigated experiments. Overall shelter design should allow all or most of the research area to be planted, cultivated, and harvested with farm machinery.

Tracks

Most rainfall shelters have two tracks, but some also have a center track to reduce the structure span or to support a center drive mechanism.[3,4] The center track restricts access to the research area and is not recommended, except for unusual conditions. Tracks may be at ground level for low structures or for structures with support walls (Fig. 1).[5] Tracks may also be elevated to eliminate the support walls, and secondary walls may then be suspended from the structure roof (Fig. 1).[3,4] Foundations for the tracks may be continuous footings or individual piers located along the tracks. Tracks are generally single, I or C section beams of rolled-steel, but angles, railway tracks, and welded-up sections have also been used. In addition to the load of the structure, the tracks must resist upward wind forces and lateral forces in one or both directions.

Structure

Structures consist of the framing, covering, truck assemblies, and any walls or doors. Maximum length is about 30 m, and is governed by the length of time to cover the research area during intense storms. Dual shelters that cover the research area from both ends are sometimes used to increase the length of the research area.[3] Foale, Davis, and UpChurch[2] provide design information for minimizing the shading from the second shelter. Maximum width has normally been about 12 m, but wider spans are possible with heavier structures and tracks.[6] The height of the structure largely determines the wind loading, and Foale, Davis, and UpChurch[2] provide excellent wind design information for rainfall shelters. Some structures are designed to be easily moved from one location to another where crop rotations or insect and disease populations require frequent changes in the research location. For example, the shelter by Kvien and Branch[7] was mounted on standard automobile tires rather than tracks and rollers to allow easy movement across a field area.

Construction materials range from light aluminum trusses with fiberglass covering to heavy steel beams and columns.[5,8] The structures are usually covered with fiberglass, aluminum, or steel sheeting. Unless the shelters are in locations with extended daytime rainfall, the light transmittance of the covering is not considered. Walls are omitted on some structures for low crops, but are needed for tall crops, and a taller shelter allows personnel to work inside the shelter.[5]

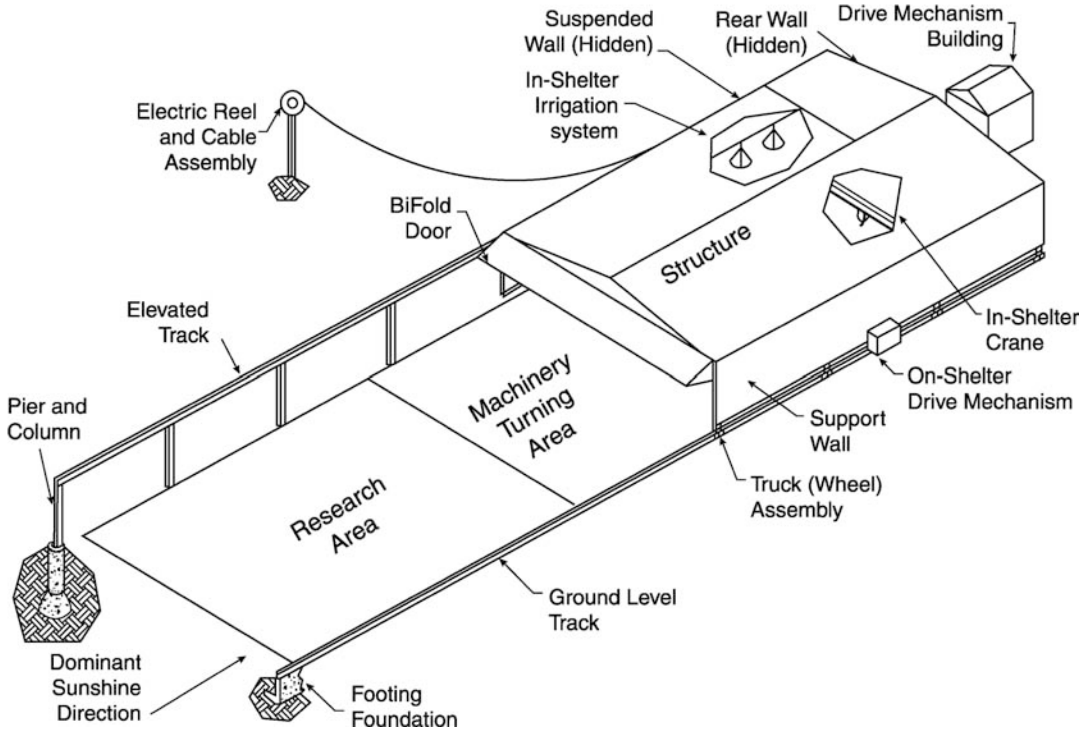

Fig. 1 Illustration of rainfall shelter subsystems and features. All items would not be used on a single shelter.

With ground level tracks, walls are attached to the load-bearing columns, and with elevated tracks, the walls are suspended from the roof trusses or beams. On many shelters, walls are placed along the rear end of the structure to exclude blowing rain from the research area. On some more recent shelters, bifold doors originally designed for aircraft hangers have been installed on both ends of the structure.[5,8] With both doors open, wind forces in the direction of travel are greatly reduced in comparison to having a permanent rear wall. Truck or roller assemblies are generally placed under the columns of structures with support walls or under the beams or trusses of structures without support walls.

Drive Mechanism

Rainfall shelter drive mechanisms can be classified by the location and type of the drive. Most drive mechanisms have been permanently installed at the rear of the parked structure (Fig. 1).[6] Another approach is to install the drive mechanism entirely on the structure.[5,8] The on-structure location eliminates the separate building to house the drive mechanism and the long drive shaft spanning the distance between the two tracks.

Rain shelter drive mechanisms are of four basic types: cable and drum,[6,9] sprocket and chain,[10] rack and pinion,[3,11] and rack drive.[5,8] The cable and drum mechanism is simply a closed-loop cable passing over a drive drum at the rear end of the shelter and an idler pulley at the opposite end of the tracks. A sprocket and chain drive can use either a closed-loop chain similar to the cable and drum or a drive sprocket traveling along a fixed chain. The rack and pinion is an excellent, but expensive, drive because the machined rack must run along the full length of travel. A rack drive is similar to a rack and pinion, but it utilizes a specially designed drive sprocket that allows a tensioned roller chain to be used in place of the rack. Flexidyne drives now allow the use of independent drives on each side of the structure thus eliminating the long drive shaft across the structure.[5,8]

Power Supply

Alternating current (a.c.) electricity from a reliable utility grid is the preferred power supply because it allows the use of larger motors and heavier structures.[5,6] For starting and reversing the larger motors, three-phase a.c. is preferred to single-phase a.c.[6] If a.c. power is unreliable, especially during storms, it can be used to charge batteries that then power a direct current (d.c.) system.[2] At remote sites without a.c. power, solar battery chargers can be used, or charged batteries can be transported to the shelter.

Control System

A rain shelter control system consists of a rain sensor for initiating movement of the shelter, controls for starting and stopping motors, and mechanisms for safe operation of the shelter and auxiliary components. Initially, rain sensors were collectors with float-activated microswitches or water-activated electrodes.[9,11] Rainfall of sufficient intensity would initiate a control sequence and cause the shelter to move over the research area. After sufficient drainage from the collector through a capillary drain, the shelter would be returned to the parked position. Resistance circuit boards provide the same function with rainfall decreasing the resistance between electrodes and absence of rainfall causing the resistance to return to the normal larger value.[11] The electric pulses from tipping bucket rain gages have also been used to initiate the control sequence.[3,6] After a sufficient time without pulses from the rain gage, the shelter is returned to the parked position. Rain sensors designed for lawn sprinkler systems have been used on rainfall shelters, but they do not accurately sense the end of rainfall.[5]

Rain shelters have been traditionally controlled with timers, relays, and microswitches that followed some logic sequence to start and stop the drive motors.[3,9] The controllers were usually designed by individual researchers to meet the unique features of the shelter. More recently, programmable controllers with input from a rain sensor, microswitches, and transducers have been used to control the shelter motors.[5,6] The control program with complex logic can be developed on a computer, and then downloaded to the controller. Programmable controllers are especially well suited to controlling several motors and meeting numerous failsafe conditions normally required of a complex shelter. Typical failsafe conditions include locking out the drive motors when the doors are closed or when an in-shelter crane scale is attached to a lysimeter.

Auxiliary Components

The most common auxiliary components are in-shelter spray irrigation systems[12] and cranes for weighing lysimeters.[5] Spray systems suspended from the structure frame can be designed for uniform, multiple treatment, or line source irrigation. A bridge crane inside the shelter structure can be substituted for a gantry crane and used to lift, move, and weigh lysimeters. Weighing the lysimeters inside the structure eliminates wind effects on measurements and increases accuracy.[5]

INTRODUCTION

As farmers grow plants in a wide range of environments, rainfed-farming systems are highly diverse, ranging from intense production systems with high capital, equipment, and management investments to systems that consist of reseeding forage species with grazing animals harvesting the crop. Regardless of the size of the enterprise or the crop grown, a key to the success of rainfed-farming systems is soil water management. Crop plant productivity in rainfed systems is greatly determined by the amount and/or seasonal distribution of soil water and by the physiological capability of the plants to use that water. Systems that have been developed to increase crop yields include soil management techniques that optimize root zone water content and crop management techniques that best utilize the stored soil water plus seasonal precipitation. Continued increases in productivity of rainfed-farming systems will require a combination of improved soil and crop management practices. For a more in-depth treatment of the subject of rainfed-farming characteristics than space allows here, the reader is referred to Loomis and Conner[1] and Gimenez, Orgaz, and Fereres.[2]

SOIL MANAGEMENT

Under rainfed conditions, there are two water-related problems that farmers have to contend with; either not enough or too much water. For some farmers, particularly in humid areas, both of these problems can occur during the same growing season. Optimizing soil water content and using methods that minimize the effects of excess or ill-timed rain are important for timely application of agronomic practices, plant health, and, in many cases, crop quality.

SOIL MANAGEMENT UNDER CONDITIONS OF EXCESS WATER

A significant amount of land used for farming in humid regions is prone to excess water, at least during some part of the growing season. For most crops, a long period of excess water causes root damage or death because of lack of soil oxygen. Many common crops cannot survive flooded conditions for more than a few days. In addition, saturated soil conditions can increase severity of plant disease.

Agricultural soils prone to prolonged periods of excess water are generally relegated to grazing land or actively drained with subsurface drain lines. More recently, subsurface drainage has been replaced by controlled drainage, or water table management, to allow for better water management of the crops. With this, the same drain-line systems are used, but ditch outlets are controlled to keep ditches partially filled much of the time keeping the soil saturated deep in the profile. Controlled drainage conserves water for periods of low rain and reduces nitrate contamination of surface and ground water.

Excess precipitation often creates the most problems by affecting farming operations. Wet soils or long periods of rain can delay tillage, planting, farm chemical applications, and harvesting. Operating equipment on wet fields can severely damage soils by compaction and rutting. To help overcome crop losses because of too much rain, technological advances have been made in field equipment such as large tires and high horsepower tractors and harvesters that allow for field operations under wetter soil conditions. In addition, the post-harvest technologies of grain drying or ensiling forage and grain crops when animals are a part of the farm enterprise allow for earlier harvesting (which reduces the amount of time the crop is at risk from too much rain).

SOIL MANAGEMENT PRACTICES TO INCREASE PLANT AVAILABLE WATER

Water that falls on an agricultural field can become unavailable to crops in three ways, previously illustrated using the hydrologic balance.[3] It can run off the field before it enters the soil, it can enter the soil and drain below the rooting zone, or it can evaporate from the soil surface. In water-deficit conditions, management techniques to reduce these losses can have profound effects on crop productivity.

Reducing Runoff/Increasing Rainfall Infiltration

Techniques that farmers use to reduce water loss via runoff were originally designed to control soil erosion. By protecting the soil surface, those farming practices that increase the long-term sustainability of land for crop production and enhance environmental quality also increase the amount of rainwater that enters the soil.

Farming practices that have long been used to reduce runoff losses include terracing, strip cropping with alternating bands of sod and row crops, and contour plowing. These practices keep water from moving quickly down slopes, allowing it time to seep into the soil. A more recent practice, rapidly growing in use among farmers, is conservation tillage or any cropping system that keeps 30% of the soil surface covered with plant residues. Residues increase rainfall infiltration by acting as small barriers that slow water movement down slopes. Residues on the surface also absorb the force of raindrops that fall to the soil, reducing the packing effect of raindrop impact on the soil surface. If the surface layer of soil becomes packed, infiltration slows and more water is susceptible to runoff.

Increasing the Soil's Capacity to Provide Water

On many soils throughout the world, crop plants often become water-stressed because soil physical properties reduce the volume of soil that roots can grow into. Compaction is common throughout the world and can be caused by animal or machinery traffic, or be a natural characteristic of the soil. Current management systems to loosen compacted soils generally consist of some form of tillage. This can range from lightweight surface tillage implements designed to loosen and crumble compacted surface soils to large, energy-intensive tillage tools designed to loosen compacted subsoil layers. Relieving compaction stress generally results in increased crop yields, especially in rainfall-limited seasons and environments. Similarly, eliminating chemical restrictions to root growth, such as liming acid subsoils, increases the volume of soil for roots to extract water.

The capacity of the soil to provide water to plants can also be increased by enhancing soil water holding capacity with soil organic matter. Adding large amounts of organic material has resulted in crop yield increases in soil inherently low in organic matter. In conservation tillage, and especially no-tillage, improvements in yield can occur because the slowly decomposing residues that are left on the surface build soil organic matter near the surface and thereby increase water-holding capacity of the soil.

Reducing Soil Water Evaporation

A common method used to reduce soil water evaporation, especially in semiarid areas, is conservation tillage. Stirring and mixing the soil with tillage implements aerates the soil and exposes moist soil to the atmosphere where the soil water can quickly evaporate. Keeping the ground covered with plant residues also reduces evaporation rates by keeping soils cooler so there is less energy at the soil surface for evaporation. In addition, plant residues that are left on the soil surface act as a physical barrier to water vapor movement from the soil to the air.

CROP MANAGEMENT

In most rainfed-farming situations, variability in rainfall from year to year is more detrimental to the cropping system than is the lack of rainfall. Since farmers cannot plan for a specific amount of water for their crop each year, they tend to be cautious and limit inputs to levels that optimize a historically normal rainfall year. This management, quite different from irrigated farming where yield can be more accurately predicted, does not allow for the most efficient use of water in most years.

Water use efficiency (WUE) is calculated as the product of aboveground biomass of the crop and its harvest index divided by the sum of evaporation and transpiration (ET) ($WUE = biomass \times harvest index/ET$). Harvest index is the ratio of harvested product to the aboveground biomass. Production practices differ between forage and grain crops partially because of the differences in the contribution of harvest index to WUE and yield.

Biomass production of plants is closely related to the amount of water transpired; so forage production practices generally attempt to maximize early-season vegetative growth. To accomplish this, forages are usually solid seeded at high populations. This planting practice maximizes early season vegetative growth, minimizes E, and results in many roots across the entire surface layer so that more of the stored soil water is used. Grain crop species planted for forage are generally seeded at higher populations than when grown for grain; an example would be corn (*Zea mays* L.).

For grain crops, rainfed-farming practices must be designed so that the water needs of the crop are met during both the vegetative and the reproductive growth stages. Maximizing early-season vegetative growth, as is done with forages, can have a detrimental effect on yield in some environments if stored soil water is exhausted during that growth stage and rainfall during reproductive growth is not enough to prevent water stress of the crop. To reduce early-season water use, summer-seeded grain crops are generally planted at lower plant densities and often in wide rows. This increases the amount of water available per plant, and stores water in the soil for the reproductive stage. Some grain crops are solid-seeded such as wheat (*Triticum aestivum* L.), but they avoid excessive early-season water use by being grown in cooler climates or are planted so that vegetative growth occurs during the time of year when air temperatures are cool.

Farmers often grow a mix of crop species and cultivars under rainfed conditions. Growing crops with a range of maturities spreads the risk of water-deficit stress during the growing season. This practice is especially valuable for crops that have extremely sensitive periods to water-deficit stress, like silking in corn. Planting genotypes with a range in maturity ensures that not all of the crop will be in the sensitive period should short droughts occur. In addition, a wide range of maturities allows for more timely management at critical times during the growing season and at harvest. Similarly, planting dates of crops can be spread out to ensure a range of crop growth stages throughout the season.

Farmers generally apply less fertilizer to rainfed than to irrigated crops. Lower amounts of relatively immobile nutrients like phosphorous and potassium are applied because crop productivity is generally less under rainfed conditions than under irrigated, so lower amounts of these nutrients are removed from the fields with the harvest. Nitrogen fertilization schemes for grain crops under rainfed conditions generally include lower amounts early in the season, especially in semi-arid and arid areas, because fast vegetative growth may deplete all of the soil water and result in drought stress during reproductive growth. In more humid areas, N amounts are generally recommended based on yield potential for average rainfall years.

Pests can reduce crop transpiration by competing for water resources (weeds), by reducing root numbers (insects and diseases), and by damaging leaves (diseases and insects). Insects and diseases that attack seeds and fruits can also reduce water-use efficiency by lowering harvest index. Pests are generally managed through crop rotations, mechanical means, and with pesticides, often using the principles of integrated pest management (IPM). With IPM, multiple methods of pest management are employed and applications of pesticides are based on in-field determinations of pest populations and economic thresholds. Where grown, new crop genotypes with insect and/or broad-spectrum herbicide resistance simplify pest management decisions.

CONCLUSION

New rainfed-farming practices will likely be combinations of soil and crop management practices. For example, farmers in the southeast United States traditionally grew soybean [*Glycine max* (L.) Merr.] in 76-cm wide rows (or wider) with conventional tillage practices and in-row subsoiling. Many hectares of soybean in the area are now being produced with conservation tillage in narrow rows (25-cm wide or less) and with deep tillage implements that loosen the entire surface horizon of soil. Yield increases with this conservation tillage system were realized in research[4] and by early farmer adopters of the technology, but the system gained rapid popularity with growers when new soybean genotypes became available that tolerated broad-spectrum herbicides. Integrating soil and crop management practices into systems that reduce water losses and increase the ability of crop plants to use soil water will continue to be a high priority of research to improve rainfed farming.

Rainwater Harvesting

K.F. Andrew Lo
Department of Natural Resources, Chinese Culture University, Taipei, Taiwan

INTRODUCTION

Water is a limited resource. Even if water is a renewable resource, it is, at the same time, finite. Its availability is largely dictated by climate. Low precipitation and high evaporation often mean small amounts of useable water. In recent years, much progress in efforts to improve living conditions has been achieved through technological solutions. Total water use in the world has quadrupled during the past 50 years. At present and in the future, livelihood conditions for the burgeoning populations can only be marginally improved through the construction of dams, reservoirs, and conveyance structures. New approaches are needed for the proper management and use of water resources.

Among the various alternative technologies to augment water resources, rainwater harvesting is a simple, decentralized solution and imposes insignificant impact on the environment. It is an important water source in many areas with significant rainfall but lacking any kind of conventional, centralized supply system. It is also a good option in areas where good-quality fresh surface water or groundwater is lacking. Rainwater harvesting systems have been used since ancient times and evidence of roof catchment systems dates back to early Roman times. In the Negev Desert in Israel, in Libya and Egypt, in Mexico, and in the Andes Range in South America as well as in the Arizona Desert in North America, stone dams and tanks were built to divert and store rainwater for irrigation purposes.

ADVANTAGES OF RAINWATER HARVESTING

Rainwater harvesting systems can provide water at, or near, the point where water is needed or used. The systems can be both owner-operated and utility-operated, and owner-managed and utility-managed. Rainwater collected using existing structures (rooftops, parking lots, playgrounds, parks, ponds, and flood plains) has few negative environmental impacts compared with other water resources development technologies.[1] Rainwater is relatively clean and the quality is usually acceptable for many purposes with little or even no treatment. The physical and chemical properties of rainwater are usually superior to sources of groundwater that may have been subject to contamination.

Other advantages of rainwater harvesting include the following:

1. Rainwater harvesting can coexist with, and provide a good supplement to, other water sources and utility systems, thus relieving pressure on other water sources.
2. Rainwater harvesting provides a water supply buffer for use in times of emergency or breakdown of public water supply systems, particularly during natural disasters.
3. Rainwater harvesting can reduce storm drainage load and flooding in cities.
4. The owners who operate and manage the rainwater catchment system are more willing to exercise water conservation.
5. Rainwater harvesting technologies are flexible and can be built to meet almost any requirements.

TYPES OF RAINWATER HARVESTING SYSTEMS

Collection systems can vary from simple households to large catchment systems. The categorization of rainwater harvesting systems depends on factors such as the size and nature of the catchment areas and whether the systems are in urban or rural settings.[2]

Simple Rooftop Collection Systems

The main components of a simple rooftop collection system are the cistern itself, the piping that leads to the cistern, and the appurtenances within the cistern (Fig. 1). The materials and the degree of sophistication of the whole system largely depend on the initial capital investment. Some cost-effective systems involve cisterns made with ferrocement. In some cases, the harvested rainwater may be filtered or disinfected.

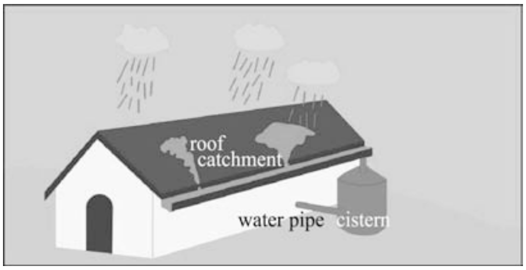

Fig. 1 A simple roof catchment system (illustrated by Chia-Ming Lin).

Large Systems for Educational Institutions, Stadiums, Airports, and Other Facilities

When the systems are larger, the overall system can become more complicated (e.g., rainwater collection from roofs and grounds of institutions, storage in underground reservoirs, and treatment and use for non-potable applications) (Fig. 2).

Fig. 2 An indoor storage system in a monastery in China (photographed by K. F. Andrew Lo).

Rooftop Collection Systems for High-Rise Buildings in Urbanized Areas

In high-rise buildings, roofs can be designed for catchment purposes and the collected roof water can be kept in separate cisterns on the roofs for non-potable uses.

Land Surface Catchments

Ground catchment techniques (Fig. 3) provide more opportunity for collecting water from a larger surface area. By retaining small creek and stream flows in small storage surfaces or underground reservoirs, can meet water demands during dry periods. However, there is a possibility of high seepage loss to the ground. The marginal quality of the water collected is suitable for use mainly in agriculture.

Collection of Stormwater in Urbanized Catchment

The surface runoff collected in stormwater ponds/reservoirs from urban areas is subject to a wide variety of contaminants. Keeping these catchments clean is of primary importance; hence the cost of water pollution control can be considerable.

DESIGN AND MAINTENANCE OF RAINWATER HARVESTING SYSTEMS

Typically, a rainwater harvesting system consists of three basic elements: the collection system, the conveyance system, and the storage system.

Catchment Surface

The effective catchment area and the material used in constructing the catchment surface influence collection efficiency and water quality. Materials commonly used for roof catchment are corrugated aluminum and galvanized iron, concrete, fiberglass shingles, tiles,

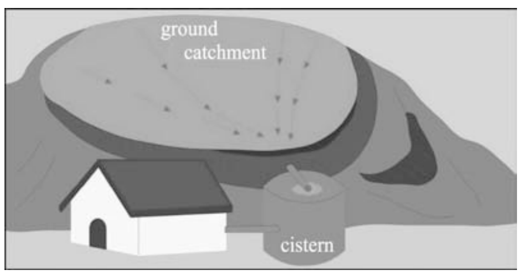

Fig. 3 A land catchment system (illustrated by Chia-Ming Lin).

and slates. Mud is used primarily in rural areas. Bamboo roofs are least suitable because of possible health hazards. The catchment surface materials must be non-toxic and must not contain substances that impair water quality. Roofs with metallic paint or other coatings are not recommended because they may impart tastes or color to the collected water. Catchment surfaces and collection devices should be cleaned regularly to remove dust, leaves, and bird droppings to minimize bacterial contamination and to maintain the quality of collected water. Roofs should also be free from overhanging trees because birds and animals in the trees may defecate on the roofs.

When land surfaces are used as catchment areas, various techniques are available to increase runoff capacity: 1) clearing or altering vegetation cover; 2) increasing the land slope with artificial ground cover; and 3) reducing soil permeability by soil compaction. Specially constructed ground surfaces (concrete, paving stones, or some kind of liner) or paved runways can also be used to collect and convey rainwater to storage tanks or reservoirs. Care is required to avoid land surface damage and contamination by people and animals. If required, these surfaces should be fenced to prevent people and animal entry. Large cracks in the paved catchment because of soil movement, earthquakes, or prolonged exposure should be repaired immediately. Maintenance, typically consisting of the removal of dirt, leaves, and other accumulated materials, should take place annually before the start of the major rainfall season.

Conveyance Systems

Conveyance systems are required to transfer the rainwater collected on catchment surfaces to storage tanks. This is usually accomplished by making connections to one or more downpipes connected to collection devices. The pipes used for conveying rainwater, wherever possible, should be made of plastic, polyvinyl chloride (PVC), or other inert substance because the pH of rainwater can be acidic and may cause corrosion and mobilization of metals in metal pipes.

When it first starts to rain, dirt and debris from catchment surfaces and collection devices will be washed into the conveyance systems. Relatively clean water will only be available sometime later in the storm. The first part of each rainfall should be diverted from the storage tank. There are several possible options for selectively collecting clean water for the storage tanks. The common method is a sediment trap, which prevents debris entry into the tank. Installing a first-flush (or foul-flush) device is also useful to divert the initial batch of rainwater away from the tank.[3]

Rainwater pipes must be permanently marked in such a way that there is no risk of confusing them with drinking water pipes. Gutters and downpipes need to be periodically inspected and carefully cleaned. A good time to inspect gutters and downpipes is while it is raining, so that leaks can be easily detected.

Storage Tanks

Various types of rainwater storage facilities can be found in practice. Storage tanks should be constructed of inert material. Reinforced concrete, fiberglass, polyethylene, and stainless steel are suitable materials. Ferrocement tanks and jars made of mortar or earthen materials are commonly used. As an alternative, interconnected tanks made of pottery or polyethylene may be suitable. They are easy to clean. Bamboo-reinforced tanks are less successful because they may become infested with termites, bacteria, and fungi.

Precautions are required to prevent the entry of contaminants into storage tanks. The main sources of external contamination are pollution from debris, bird and animal droppings, and insects. A solid and secure cover is required to avoid breeding of mosquitoes, to prevent insects and rodents from entering the tank, and to keep out sunlight to prevent algae growth inside the tank.[4] A coarse inlet filter is also desirable for excluding coarse debris, dirt, leaves, and other solid materials.

All tanks need cleaning and their designs should allow for thorough scrubbing of the inner walls and floors. A sloped bottom and the provision of a pump and a drain are useful for collection and discharge of settled grit and sediment. Chlorination of the cisterns or storage tanks is necessary if the water is to be used for drinking and domestic uses. Cracks in the storage tanks can create major problems and should be repaired immediately.

The extraction system (taps/faucets, pumps) must not contaminate the stored water. Taps/faucets should be installed at least 10 cm above the base of the tank because this allows any debris entering the tank to settle on the bottom.[5] If it remains undisturbed, it will not affect the quality of the water. The handle of taps might be detachable to avoid misuse by children. Periodic maintenance should also be carried out on pumps used to lift water.

CONCLUSION

In the future, water scarcity in both developing and developed countries is inevitable.[6] The challenge of meeting the water demand can be largely met by appropriate understanding, study, and application of rainwater harvesting. Rainwater harvesting is about to come of age.[7] It has an appropriate image about it that meshes well with the gentler ideas of the late 20th century. Because the technique makes use of an untapped resource—precipitation that would otherwise be evaporated before it had a chance to play a useful role in feeding the human population—it looks like getting something for nothing. Making use of such a resource has certain poetry to it, particularly in a field where the resource itself can never be increased or decreased; unlike food, water cannot be grown to order, even given the right soil and the right fertilizer. But, like food, water can be harvested more efficiently. Doing so is a major priority for the 21st century.

Rangeland Management: Enhanced Water Utilization

Darrel N. Ueckert
W. Allan McGinty
Texas A&M University System Agriculture Research and Extension Center, San Angelo, Texas, U.S.A.

INTRODUCTION

Rangelands occupy almost half of the earth's land surface and are a major source of the meat, fiber, and water necessary to sustain the world's burgeoning human population. Water is the driving force of rangeland ecosystems and must be used efficiently because most rangelands are in climatic regions where water is scarce and limits plant growth. Healthy rangelands conserve water and nutrients, but rangelands in many regions have deteriorated and are dysfunctional. Excessive losses of soil and nutrients to the erosive forces of water and wind can further reduce the productivity of these vast landscapes for hundreds of years. Ecologically sound rangeland management involves working with the natural ecological processes of energy flow, hydrologic cycles, and biogeochemical cycles. Practices useful for enhancing the efficiency of water utilization on rangelands include proper grazing management, control of undesirable weeds and woody plants, ripping, contour furrowing, pitting, and reseeding.

HYDROLOGICALLY FUNCTIONAL RANGELANDS

Healthy rangelands have high rainfall infiltration rates because of good soil structure, meaning that the soil particles are held together in water-stable clusters (aggregates) by roots, fungal hyphae, byproducts of organic matter decay and microbial synthesis, and resistant humus components.[1] Water-stable aggregates do not readily disperse during rainfall events; hence, they do not plug up the large soil macropores. Pore space in a soil increases with aggregation, and this aids rainfall infiltration. Healthy rangelands support a variety of plant species with the genetic potential to grow an abundance of foliage (which becomes litter after it dies) and deep root systems capable of extracting water and nutrients from a large volume of soil. They have a sufficient amount of vegetative cover (standing live and dead plants and litter) to protect the soil surface aggregates from being dispersed by raindrops and to provide resistance to surface runoff. Vegetative cover also ameliorates the extremes of soil temperature, reduces evaporation of soil water, and provides a microenvironment favorable for decomposition of organic matter, which in turn contributes to the formation of water-stable soil aggregates.[2]

HYDROLOGICALLY DYSFUNCTIONAL RANGELANDS

The direct and indirect effects of drought and excessive grazing by livestock or wildlife can render rangelands dysfunctional relative to conserving water and nutrients and yielding the products needed by society.[2] These effects seriously diminish the production of foliage and deposition of litter, the depth and branching of plant root systems, soil aggregation, and infiltration rates, while increasing the losses of water and nutrients from the landscape as surface runoff. The kinetic energy of raindrops hitting bare soil, as well as excessive hoof action, break soil aggregates into small particles that move with water into the large soil pore spaces, plugging them or seriously reducing their volume and the capacity of the soil to absorb and store water. Over time, plant composition changes and cover decreases as the productive, palatable, deep-rooted plants die and are replaced by lower densities of smaller, less palatable, less productive, shallow-rooted plants.[3,4] The result is reduced microorganism activity, less aggregate formation, a harsher environment for seed germination, more soil exposed to raindrop impact, fewer roots to exploit soil water and nutrients, decreased rainfall infiltration, and accelerated surface runoff and erosion. The downward spiral of deterioration eventually leads to desertification.[2] Weeds, woody plants, and succulents [e.g., cactus (*Opuntia* spp.)] often increase in or invade deteriorated rangelands and compete with the remaining forage species for the diminished supply of soil water and nutrients.

MANAGEMENT TO ENHANCE WATER UTILIZATION

Ecologically sound rangeland management means working with natural ecological processes (energy flow, the hydrologic cycle, and biogeochemical cycles) to manage vegetation and soils to achieve and maintain high infiltration rates and to minimize loss of water, soil, and nutrients in runoff.[5,6] Proper grazing management is the basic tool for achieving efficiency in water and nutrient utilization on rangelands. Control of weeds and woody plants can make more water available for desirable plants. Water conservation practices, such as ripping, contour furrowing, or pitting, may be necessary to reverse the downward spiral toward desertification on severely deteriorated rangelands and reseeding may be necessary to introduce plants that can efficiently use the available water.

Grazing Management

Excessive grazing affects plants directly by altering their physiology and morphology and indirectly by altering microclimate, soil properties, and the competitive interactions among plants.[3] Without sufficient leaf surface area, plants cannot efficiently capture the energy from sunlight via photosynthesis and root growth will be reduced. Over time, the composition of the vegetation changes, rainfall infiltration declines (Fig. 1), surface runoff increases, and plant production decreases. Grazing management involves balancing the number of animals with the forage supply, selecting the appropriate kinds and classes of animals to be grazed, controlling the timing of grazing, and distributing grazing evenly across the landscape.[7] Achieving the proper level of utilization of plants and maintaining an acceptable minimum amount of litter is the most important management decision, regardless of whether rangeland is grazed continuously or in a complex grazing system. The minimum amounts of litter needed to sustain productivity of shortgrass, mid-grass, and

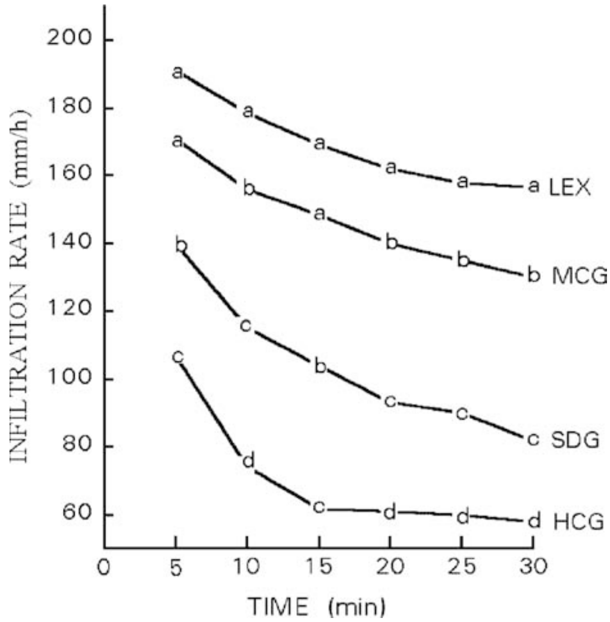

Fig. 1 Mean infiltration rates for four grazing treatments 6 years after they were initiated on the Edwards Plateau, Texas. LEX = livestock exclosure; MCG = continuously grazed at moderate intensity; SDG = short duration rotation (14-pasture, 1-herd; 4 days on, 50 days rest) stocked at 1.75 times the moderate intensity; HCG = continuously grazed, stocked at 1.75 times the moderate intensity. Means within a time period with different letters are significantly different at $P \leq 0.05$.[2]

tall-grass rangelands are 340–560 kg/ha, 840–1120 kg/ha, and 1350–1680 kg/ha, respectively.[8] "Take half and leave half" is the guiding principle for determining stocking rates. Under most management systems, 50% of the forage produced during the year should remain ungrazed. Twenty-five percent of the year's forage growth will be lost to trampling, insects, and other

Fig. 2 Controlling young redberry juniper (*Juniperus pinchotii* Sudw.) plants with 1% picloram (4-amino-3,5,6-trichloro-2-pyridinecarboxylic acid) high-volume foliar sprays prevents development of juniper woodlands which intercept and transpire large amounts of water and cause deterioration of the herbaceous understory.

Rainfall–Satellite

animals, or rendered ungrazable due to livestock dung or urine. The remaining 25% of plant growth can be utilized by livestock.[8] Rangeland vegetation and precipitation records should be continually monitored, and livestock and wildlife numbers should be adjusted annually or even seasonally to achieve proper use.

Management of Undesirable Vegetation

Excessive grazing, drought, climatic changes, and a reduction in the frequency and intensity of fire predispose many rangelands to invasion by weeds, woody plants, and succulents that have little or no value to grazing animals or humans. These plants intercept or transpire large quantities of water that might otherwise be used by desirable forage plants. The efficiency of water use on rangelands can be increased by controlling undesirable vegetation.[9,10] Herbicidal, mechanical, prescribed burning, and biological control methods, or appropriately timed and sequenced combinations of these methods, coupled with proper grazing management can provide effective, cost efficient, and ecologically practical solutions to noxious plant problems.[11] Rangelands should be monitored annually for noxious plants, and control programs should be initiated before these plants mature, thicken, utilize excessive amounts of water, and cause deterioration of desirable vegetative cover[12] (Fig. 2).

Special Water Conservation Treatments

Severely deteriorated rangelands, especially in arid and semiarid regions, often recover slowly or not at all after initiation of proper grazing management or the total removal of livestock because of the lack of vegetative

Fig. 3 Ripping reduces runoff, enhances rainfall infiltration, and provides a seedbed for germination and establishment of new plants. Three months after ripping (A) and 5 years after ripping (B) severely deteriorated rangeland (Tulia loam soil; 3–4% slope) in the southern rolling plains, Texas.

cover, poor soil aggregation, low infiltration rates, and the resultant harsh environment for plant establishment and growth. Mechanical land treatments such as ripping, furrowing, and pitting can expedite natural recovery of these desertified rangelands[5,13] by increasing resistance to surface runoff, shattering compacted soil layers, and thereby increasing water infiltration and retention. Mechanical treatments that effectively increase deep infiltration or percolation of precipitation in saline soils can leach soluble salts below the root zone and thus increase the availability of water to plants. The objective of using these mechanical treatments is to facilitate the establishment of dense patches or bands of vegetative cover that will persist and continue to conserve water and nutrients naturally, long after the soil disturbance has disappeared. The full potential of these practices will only be realized if treated areas are initially protected from grazing to allow the establishment of vegetative cover and afforded proper grazing management thereafter.

Ripping (also referred to as subsoiling or deep chiseling) involves pulling a heavy shank equipped with a broad lifting tip 40–60 cm deep through the soil on the contour.[13] Space between rips is usually 3–9 m. Ripping fractures impervious soil layers (which increases porosity and the rate of infiltration), causes uplifting of the soil (which resists surface runoff), leaves a furrow in the center of the uplift (which will retain water), and the soil disturbance provides a seedbed for new plant establishment. Ripping facilitated infiltration of water from a 5 cm convection thunderstorm to a depth of 100–125 cm, compared to only 10–13 cm on adjacent, unripped rangeland. Increased forage production after ripping (Fig. 3) would support a cow/calf unit year long on 9 ha, compared to 32 ha without ripping.[14]

Contour furrowing involves pulling disk plows or other tillage implements to create depressions or grooves in the soil surface 10–20 cm deep, 15–75 cm wide, and 0.6–3 m apart.[13] These soil depressions increase on-site water retention and the displaced soil provides resistance to surface runoff. Furrowing implements can be designed with rippers in front of the disks and dikers that dam up the furrows at selected intervals. Seeders can also be attached that deposit seed on or into the disturbed soil during the furrowing process to establish plant species that can make beneficial use of the water retained in the furrows.

The most effective rangeland pitting has been done with disk plows equipped with eccentric or deeply notched disks or disk plows with eccentric furrow wheels that alternatively raise and lower the disks. These create thousands of small basins or pits across the landscape, which function similarly to contour furrows.[13] Seeders can also be attached to pitting implements. Pits installed with implements that utilize spike teeth tend to fill in with soil within about a year.

CONCLUSION

Maintaining good vegetative cover, litter, and soil aggregation is critical for the efficient utilization of water on rangelands. Proper grazing management budgets about half of the annual plant production to be left to maintain a healthy hydrological cycle. Management of undesirable plants can decrease wasteful interception and transpiration of water and increase availability of water for beneficial plants. Mechanical water conservation treatments can effectively reduce surface runoff and increase infiltration, but their long-term effectiveness hinges upon the establishment and maintenance of dense patches or bands of vegetative cover.

INTRODUCTION

To supplement water supplies, there has been considerable interest in using vegetation management (brush control) to increase stream flow and water yields (runoff + deep percolation) from watersheds. One option on rangelands[1,2] is to replace deep-rooted woody brush species, which may intercept a substantial amount of precipitation and have high whole-plant transpiration rates due to high leaf areas, with shallow-rooted herbaceous vegetation that usually intercepts less precipitation and has less leaf area. The amount of increased stream flow and/or water yield, if any, on treated watersheds depends on several factors, including the pre- and post-treatment vegetation types or land use,[3] treatment method or soil,[4] climate,[5] and time since treatment imposition.[6] Wilcox[7] presents a perspective on the mechanisms of how brush clearing could affect streamflow. Several field and modeling studies in Texas have shown water yield increases associated with brush removal (Table 1). Based, in part, on these studies, a study was conducted to use a hydrologic simulation model to evaluate changes in stream flow and water yield associated with brush removal on several watersheds.[11] This report uses results from that work to present a case study of how brush clearing can influence rangeland water yield.

CASE STUDY

Methods

Eight Texas watersheds investigated in this study were: Canadian River above Lake Meredith, Wichita River above Lake Kemp, Upper Colorado River above Lake Ivie, Concho River, Pedernales River, several watersheds above the Edwards Aquifer recharge zone, Frio River above Choke Canyon Reservoir, and Nueces River above the junction with the Frio River. For ease of simulation, several of these watersheds were further subdivided, resulting in 17 modeled watersheds.

The Soil and Water Assessment Tool (SWAT) model used in this study[12] is physically based, uses readily available inputs, and is capable of simulating long periods. A GIS interface was developed[13] that creates SWAT model input data files from map layers and associated relational databases. Model inputs included daily precipitation totals and maximum and minimum temperatures; a United States Geological Survey (USGS) Digital Elevation Model at a 1:24,000 scale; and a USDA-Natural Resources Conservation Service soils database.

Because of the need to discriminate brush land use by species and cover density, current, detailed, and accurate land use data for these watersheds were required. These data were developed by classifying 1999 Landsat data. Scenes were radiometrically and precision-terrain corrected and then classified using >1100 ground control points (GCPs), where land use (e.g., brush species and cover density) and areal extent were recorded. Land use was classified as heavy (>30% canopy coverage) cedar, mesquite, oak, or mixed brush; moderate (10–30%) cedar, mesquite, oak, or mixed brush; light (<10%) brush; open range, cropland, water, barren, urban, and other. Classification accuracy, determined from the GCP data, was approximately 70%.

Model Calibration

Plant growth parameters (e.g., maximum leaf area index, base temperature, canopy height, albedo, and rooting depth) for each land use were input for two model simulations. For the first, i.e., the "with brush" condition (calibration), we used the classified land use layer created for this study (and associated model

Table 1 Estimated annual water yield increase (ML per hectare of treated land) resulting from brush removal at selected locations in Texas. N. Concho water savings are based on model simulations

Location	References	Land use change	Increase
Seco Ck.	[6]	Remove all juniper (3-yr post-treatment avg.)	0.3
Sonora	[8]	60% juniper/40% grass–100% grass	0.9

[a]Calculated from ratio of average runoff to precipitation and from measured increase in runoff.

inputs for each land use) and assumed[14] existing brush sites were in fair hydrologic condition (50–75% ground cover). For the second, the ''without brush'' condition, areas with heavy and moderate brush land use (excluding oak) were changed to a grassland with no brush by adjusting land use input files (e.g., rooting depth, leaf area, etc.) and were assumed[14] to be in good hydrologic condition (greater than 75% ground cover). The fraction of each watershed where brush removal was simulated varied from 26 to 74%. All other model inputs were held constant.

The model was calibrated by adjusting runoff curve number, soil evaporation compensation factor, shallow aquifer storage, shallow aquifer re-evaporation, and channel transmission loss to match USGS measured monthly stream flow from 1960 through 1998 for various locations in each watershed. The fraction of base flow and surface runoff in each watershed was estimated using a base flow filtering algorithm.[15]

Measured annual average stream flows varied from 2.4×10^3 ML to 6.2×10^5 ML (10^6 L) because of differences in precipitation (annual averages ranged from 430 mm to 861 mm) and watershed area (1.3×10^4 ha to 2.2×10^6 ha). Correlation coefficients between predicted and measured monthly stream flow for each watershed varied from 0.26 to 0.99, and averaged 0.8. Correlations tended to be lower in watersheds with less precipitation. The average percentage error between predicted and measured average annual stream flow was 9%. Thus, the calibrated model accurately predicted measured stream flow.

Simulated Effects of Brush Control

Average annual stream flow, per unit treated area, increased in all watersheds due to brush control (without brush) and increases were closely related to annual precipitation (Fig. 1). Scatter about the regression line was due to variation in soils, type and density of brush removed, and topography across watersheds. The estimated annual precipitation associated with a zero stream flow increase in Fig. 1 (ca. 450 mm) is very similar to previous estimates.[5]

Annual water yield increases for sub-basins in the Wichita River watershed (used for illustrative

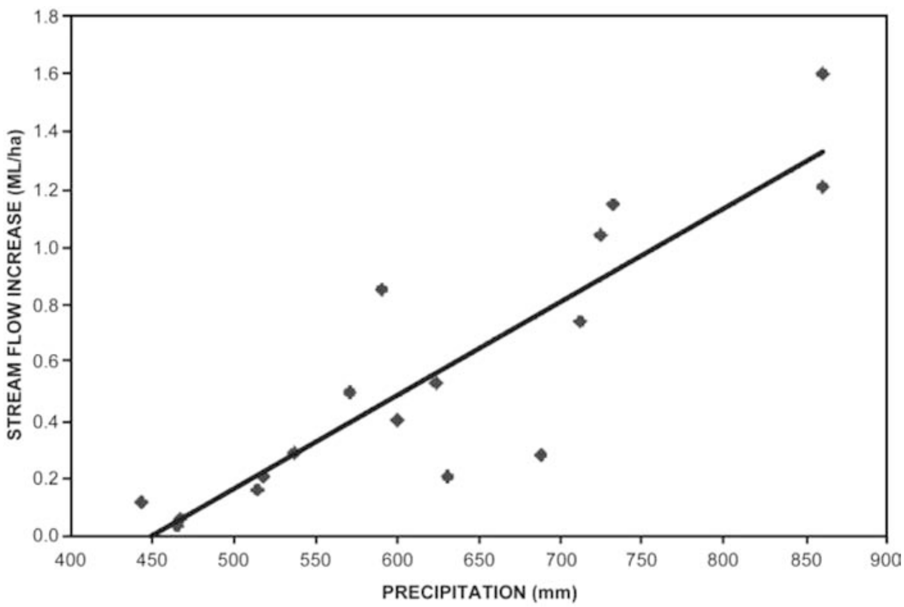

Fig. 1 Average annual increase in stream flow, per unit area treated for brush removal, vs. average annual precipitation in selected Texas watersheds.

purposes), per treated area, varied from 0.2 to 1.1 ML/ha (results not shown). The large range of annual water yield increases across sub-basins in this watershed was due, again, to differences in soils, type and density of brush removed, precipitation, and topography. For most watersheds, sub-basin water yield increases increased with increasing precipitation. All watersheds showed large variability across sub-basins (results not shown). These results highlight the need for high spatial resolution of model inputs and simulation units to precisely identify where brush control would yield maximum benefits.

CONCLUSION

Field research has shown that vegetation management (brush control) may increase stream flow and water yield from watersheds. In this study, we used satellite imagery to classify brush cover into species and density categories and used a hydrologic simulation model to simulate the effects of brush removal on stream flow and water yield in selected watersheds in Texas. All watersheds showed an increase in stream flow as a result of removing brush and large spatial variability of water yield increases.

Results from this study will be used, along with other considerations (e.g., economics and wildlife), to prioritize watersheds and areas within watersheds for imposition of brush control programs to increase water supplies. This study demonstrates how research tools can be applied to address policy questions.

INTRODUCTION

Rangelands are found in a variety of climate and moisture regimes and may include natural grasslands, savannas, shrublands, deserts, tundra, alpine ecosystems, marshes, and meadows. Most rangelands, however, are found in relatively dry climates where potential evapotranspiration is significantly greater than precipitation. For this reason, our discussion of water balance on rangelands will be generalized for dryland conditions. In water-limited rangelands, most of the incoming precipitation returns to the atmosphere via evapotranspiration. Of the other components, runoff will account for most of the remaining. Water moving to groundwater is generally relatively small.

WATER BALANCE

Water balance is an expression of how precipitation is partitioned after it arrives on the land surface. The relative proportions of its components define the water budget of a region. The water balance is driven by another fundamental physical relationship: energy balance. Together, these two relationships determine global vegetation patterns. The following equation presents a simplified interpretation of the water budget:

$$P = \mathrm{ET} + R + G + \Delta S$$

where P = precipitation, ET = evapotranspiration, R = runoff, G = groundwater recharge, ΔS = change in soil water.

Evapotranspiration comprises all those processes by which water changes phase from a liquid to a gas. These processes include: a) evaporation from plant or litter surfaces (commonly referred to as interception loss); b) evaporation from the soil; and c) transpiration from the plant. Where snow constitutes a significant portion of the total precipitation on rangelands, sublimation, which is the transfer of water from solid to vapor state, may be substantial and is included in this term. *Soil water* is the amount of water in the soil. Water that moves beyond the root zone is considered to be *groundwater recharge*, because eventually it will move to an underlying water body. *Runoff* is water that travels from the hillslope toward the stream channel, the portion of which (not captured by soils or evaporated en route) becomes streamflow.

EVAPOTRANSPIRATION

Because the different components of evapotranspiration can be difficult to separate, we often measure total evapotranspiration. At the plant community level, total evapotranspiration may be measured directly through knowledge of the energy budget. As an example, the Bowen ratio methodology,[1] which is based on calculations of the energy budget, has been commonly used to estimate evapotranspiration from rangeland plant communities. Alternatively, evapotranspiration can be determined by difference using the water budget approach, where all the components of the water budget except evapotranspiration are measured directly, and evapotranspiration is assumed to be the difference between the sum of these components and the total water budget.

Interception Loss

Interception loss is that component of precipitation that is captured by the vegetation canopy or underlying litter layer and subsequently evaporates, thus never reaching the soil surface. On rangelands, interception loss may be and often is substantial. On a percentage basis, drylands lose considerably more water via interception than do more humid environments.[2]

Interception losses from rangelands may range from 1% to 80% of the annual water budget, but generally are between 20% and 40% (Table 1). Actual amounts depend on the character of the vegetation and precipitation. For example, evergreen shrubs, such as juniper, capture a higher percentage of precipitation because they are continuously foliated, have a large leaf area, and a leaf shape conducive to interception. In addition, these shrubs lay down a thick litter layer that captures considerable water. Interception loss is generally small in arid shrublands because of lower canopy cover. In grasslands, interception loss may be as high or higher than in shrublands if cover is extensive. The vegetation canopy has only a finite capacity to capture water—therefore the percentage of precipitation intercepted for individual storms is highly variable. For small storms, most water may be intercepted, whereas for very large storms the amount intercepted may (on a percentage basis) be quite small.

Evaporation from Soil

Evaporation from a bare soil is a multistage process.[16] Initially, after the soil is wetted, evaporation is relatively constant and limited only by the evaporative demand (which is regulated by meteorological conditions, such as radiation, wind, and air humidity). As the soil dries and its water content decreases, the evaporation rate progressively decreases. Evaporation from bare soil is limited to about the top 15 cm.

The relationship between evaporation from the soil and transpiration is of special ecological importance as it determines how much water is available to plants. The amount of evaporation depends on how much of the soil surface is bare. Where only small amounts of bare soil are found, soil evaporation will be low. But in regions where much of the soil is bare, such as arid and some semiarid rangelands, the percentage of evaporation is likely to be very high. Reported values of soil water evaporation range from 30% to 80% of the water budget (Table 2).

Table 1 Measured values of interception loss, expressed as a percentage of precipitation, for selected U.S. rangeland shrubs and grasses

	% Interception

Sideoats grama (*Bouteloua curtipendula*)	18[13]

Transpiration from Plants

Transpiration is the evaporation of water from the vascular system of plants into the atmosphere. The process begins with the absorption of soil water by plant roots and ends with its evaporation from stomatal cavities. Because the water is pulled through the plant by the potential energy gradient, transpiration is primarily a physical process. Plants exert physiological control through modification of the size of the stomatal openings.

The amount of transpiration depends on the amount of water that is available to the plant. Whereas evaporation from soils is primarily limited to water in the very uppermost layers, the water transpired by plants may be drawn from substantially greater depths, depending on the depth and development of plant roots. The plant roots may also redistribute water within the profile by removing water from a wet area of the soil and releasing it into a dry area—a process known as *hydraulic lift*.

RUNOFF

Runoff from rangelands is normally small but can nevertheless be very important. It is a principal agent of erosion, contaminant movement, and geomorphic change on many rangelands. Additionally, it serves a vital ecological function of redistributing and concentrating the limited water and nutrient resources in semiarid landscapes. Runoff generally accounts for less than 10%, and most often below 5%, of the annual water budget, and most of this occurs as flood flow. The actual percentage depends partly on the scale of observation. For example, on piñon-juniper rangelands, it has been demonstrated that at a very small scale (1 m^2), up to 100% of the precipitation from a particular storm may run off—while at the hillslope scale, runoff from the same storm will amount to only about 5% of the water budget.[18] The difference is due to the fact that as the scale increases, so too does the opportunity for storage. Similarly, in the many desert landscapes, runoff as a percentage of the water budget will decrease with scale because of transmission losses in the alluvial stream channels.[19]

Source: Modified from Ref.[17].

Runoff from rangelands most often occurs as *Horton overland flow*,[20] but it may travel other pathways as well, including saturation overland flow, shallow subsurface flow, and groundwater flow. *Horton overland flow* results when precipitation intensity exceeds soil infiltration capacity. *Saturation overland flow* is relatively uncommon on rangelands but may be observed when soils become saturated, because of either a rising groundwater table or a perched, saturated zone. Frozen soil runoff is a special type of saturation overland flow whereby a frozen soil layer forms an impeding horizon while the soil above it is unfrozen and saturated. *Shallow subsurface flow*, sometimes referred to as interflow or throughflow, is that portion of runoff that travels laterally through the soil, generally because of some impeding soil horizon. *Shallow subsurface flow* is more common in humid environments, but it can be important in semiarid environments, especially when macropores are present in the soil.[21] *Groundwater flow* is generally the source for the base flow of a stream (prolonged flow, not attributable to a specific precipitation event).

GROUNDWATER RECHARGE

Groundwater recharge, especially deep recharge, is generally very small in rangeland environments. However, it can be exceedingly important, especially with respect to long-term contaminant transport. Commonly, in arid and semiarid landscapes, only a few millimeters or less of water will move beyond the root zone each year—because in most cases the soils have the capacity to absorb all or most of the precipitation. Owing to the high evaporative demand in these regions, most water stored in the soil will eventually be evaporated or transpired. In some cases, however, the capacity of the soil to absorb water is overwhelmed, and substantial groundwater recharge does occur. In other cases, groundwater recharge may occur where there is an accumulation of water in concentrated locations, such as snow drifts or stream channels. In still other situations, surprisingly high groundwater recharge may occur in very dry environments if permeability is relatively high, owing to either the presence of fractures[22] or very sandy soils.[23]

SOIL WATER

The soil storage term ΔS, in the equation, is the difference between the amount of water stored within the plant root zone at the beginning of the period for which water balance is being calculated and the amount at the end. The magnitude of ΔS depends on weather patterns during that period, the duration of the period, and the storage capacity of the soil. For relatively short periods, the weather patterns are critical because they determine the initial and final S values (for periods of several years, ΔS becomes insignificant). The storage term is important because it determines, to some extent, the way incoming water is partitioned among the remaining terms. Where soils have a high storage capacity, flow to groundwater will tend to be much lower. The incoming water is instead available for plant uptake, enabling more plant production; and it also affects the rates of organic nutrient release to the soil and of carbon mineralization.

The storage capacity of a soil depends mostly on the depth of the soil, the coarse-fragment content, and the texture. Sandy soils hold about 60 mm of water per meter of soil, while finer-textured soils can store up to 200 mm. Deep, rock-free soils of medium texture may store over 300 mm of water. The ability of a soil to store water will decrease in direct proportion to the amount of coarse fragments in that soil. For example, a sandy soil with 50% rock content would be expected to store about 30 mm of water per meter of soil.

CONCLUSIONS

On rangelands, the water balance is driven and defined to a great extent by the fact that potential evapotranspiration is much greater than precipitation, which in turn contributes to a large soil water deficit. As a rule, therefore, evapotranspiration is the largest component of the water balance equation; the other components are generally quite small (nevertheless, they may be exceedingly important). In addition, both the magnitude and the definition of the different water balance components, particularly runoff, are very much scale-dependent.

Newer measurement technologies allow us to estimate more precisely than ever before the water balance components. It is now possible to directly measure plant-community-level evapotranspiration, soil water evaporation as a percentage of transpiration, interception loss during an actual rainstorm, groundwater recharge, and runoff—all at multiple scales. Application of these technologies promises to help us gain the vital information required to develop workable strategies for solving the growing problems of rangeland degradation.

Rainfall–Satellite

INTRODUCTION

Improvements in irrigation techniques, sustainable farming methodologies, and drought and pest resistance have made a tremendous impact on global agricultural production. During the last three decades, production of food crops, such as grain and cereal, doubled and tripled resulting in a 19% per capita increase in food for direct human consumption.[1–3] During the same time, the percentage of the world's hungry and malnourished people dropped from 35% to 20%, and per capita food supplies rose from 2135 cal per day to 2750 cal per day.[4] Despite these vast improvements, more than 800 million people globally are still undernourished, and one-third of all children—two of every five in South Asia—are malnourished.[5]

INCREASING NEEDS AND INCREASING EFFICIENCIES

In the next few decades, as world population increases to between 7 and 10 billion people, global demand for food is projected to grow twofold, with even greater increases in the developing world.[6] In the past, increases in food production were achieved by placing more land under cultivation. Since the mid-1960s, however, the rate of growth of the world's cultivated lands grew at a declining rate, averaging only 8%. In many industrialized nations, agricultural area actually decreased due to competition with urban sprawl.[7] As a result, recent increases in production have been more a factor of higher efficiency and productivity rather than expansion of land under cultivation.

Much of that efficiency and productivity is due to modern irrigation techniques. Since the turn of the century, land under irrigation globally grew fivefold, and doubled in the last 25 yr, to approximately 275 million ha.[8–10] Today, 40% of the world's food is produced on irrigated fields, which cover only 17% of the world's cultivated land. Rain-fed agriculture—which accounts for 83% of the world's farmland—produces the remaining 60% of agricultural production.[11,12]

WATER SCARCITY AND AGRICULTURE

While highly productive from a per hectare point of view, water scarcity remains the single biggest threat to future food production. Agriculture today is the largest single consumer of freshwater globally, responsible for 93% of global consumptive use of water today.[13] Land under irrigation, which accounts for 17% of cultivated land (about 270 million ha), uses more than two-thirds of global water withdrawals.[14,15] Moreover, at existing rates of use, crop demands for 2025 could require an additional 200 cubic miles of water—a volume nearly equal to the annual flow of the Nile River 10 times over.[16] Many freshwater sources, however, including aquifers, rivers, and lakes, are stressed far beyond their limits. Eight percent (8%) of food crops globally is grown on farms using groundwater at a rate faster than the aquifer can recharge. Moreover, many large rivers, such as the Jordan and Rio Grande Rivers, are so heavily diverted that little if any water reaches the rivers' mouths. Significantly, as much as one-third of the world's population today lives in regions experiencing moderate to high water stress.[17]

IMPROVING WATER MANAGEMENT AND USE TECHNOLOGIES

Accordingly, developments in the use and management of water resources are essential if we are to continue meeting the needs and demands of the world's population. The use of existing technologies and methodologies must be expanded to regions stressed by water scarcity. Drip irrigation, for example, which saves water and reduces soil salinity, could be used on a much broader scale. Farmers using drip irrigation typically can reap two or three harvests every year. Studies conducted in Israel, Jordan, Spain, and the United States show that drip irrigation can reduce water use by 30–70% while increasing crop yield by 20–90%, as compared to flooding methods.[18,19]

Likewise, research into technology designed to reduce water use, as well as to reuse and recycle wastewater, should be pursued. Precision irrigation systems, which supply water only when and where needed, are now being designed. Low-energy sprinklers, already in use, allow plants to absorb as much as 95% of the water flowing through the sprinkler. Wastewater is being treated for use on cultivated fields—treated wastewater in Israel, for example, accounts for 30% of the country's agricultural water supply and is expected to rise to 80% by 2025. Moreover, gains in rain-fed agricultural production is also being targeted with a range of improved small-scale and supplemental irrigation systems.[20–22]

These and many other improvements in water use and management are currently being researched and developed throughout the world at government and academic institutions, as well as private operations. While far from comprehensive, the following is a short list of non-commercial institutions (i.e., universities, government agencies, etc.) from around the world that are dedicated to tackling the issue of water scarcity in agriculture.

RESEARCH ORGANIZATIONS

The Dryland Agricultural Institute at West Texas A&M University (http://www.wtamu.edu/research/dryland/), located in Canyon, Texas, assists researchers, educators, extension workers, and administrators to develop practical and workable strategies for improving the sustainability of dryland agriculture systems worldwide. The Institute's chief areas of research include: efficient water use; wind and water erosion; soil fertility and organic matter; drought-resistant germplasm; deficit irrigation; pest management; and rangeland management.

The Agricultural Research Service (ARS) is the principal research agency of the United States Department of Agriculture (USDA). It oversees the Water Quality and Management National Program (WQMNP) (http://www.nps.ars.usda.gov/programs/programs.htm?NPNUMBER=201), which cooperates with the Cooperative State Research, Education, and Extension Service; Economic Research Service; and National Agriculture Statistics Service to provide research, technology transfer, education, extension, and economic assessments for the Natural Resources Conservation Service within the USDA. Specifically, the WQMNP is tasked with developing innovative concepts for determining the movement of water and its associated constituents in agricultural landscapes and watersheds, and to develop new and improved practices, technologies, and strategies to manage the U.S.'s agricultural water resources. The WQMNP research is conducted throughout the United States at various locations on: economical irrigated crop production; precision irrigated agriculture; water conservation management; irrigation and drainage in humid areas; wastewater reuse; erosion on irrigated land; salinity and trace element management; and drainage management.

The Agricultural Research Organization (ARO) (http://agri.gov.il/) of the Israel Ministry of Agriculture is responsible for planning, organizing, and implementing the greater part of Israel's agricultural research effort. The ARO, based in Bet Dagan, Israel, focuses on solving current problems in agricultural production, introducing new products, processes and equipment, and researching Israel's future agricultural development. Within the ARO, the Institute of Soil, Water, and Environmental Sciences (http://agri.gov.il/SoilScience.html) carries out research to ensure optimal use of two of Israel's limited natural resources: soil and water. Research areas include: water scarcity and quality; the need for more economically and environmentally sound irrigation; management of agrochemicals and cropping; energy saving; and the development of efficient and environmentally friendly greenhouse management schemes.

The Australian Commonwealth Scientific and Industrial Research Organisation: Land and Water (CSIRO) (http://www.clw.csiro.au/) is dedicated to creating the knowledge, the strategies, and the tools to manage land and water in Australia and internationally. It is divided into five divisional research programs: Remediation of Contaminated Environments, Sustainable Agriculture, Sustainable Catchment and Groundwater Management, Tropical Land and Water Management, and Waterway Management and Landscape Function. Based in Glen Osmond, Australia, the Sustainable Agriculture Program identifies, tests, and develops soil and water management practices necessary to underpin sustainable production systems for use in agriculture and horticulture in Australia. The emphasis of the program is on the identification and introduction of systems, which are ecologically suited to the climatic conditions and which do not lead to degradation of the soil and water resources. The program also addresses issues relating to the sustainable use and cycling of wastes in rural areas.

The International Water Management Institute (IWMI) of Sri Lanka (http://www.cgiar.org/iwmi/) is a scientific research organization focusing on issues of sustainable and productive use of water resources, particularly as they relate to agriculture, water scarcity, and food security in the developing world. The IWMI works with partners in the Global South to develop tools and methods to help these countries eradicate poverty through more effective management of their water resources. One of the Institute's four core programs concerns Irrigation and Water Resources (IWR). The Program focuses on integrated approaches for managing water resources, assessing the performance of irrigated agriculture, contributing to improving irrigation system design and operation, and documenting the impacts of water management interventions.

CONCLUSION

The future ability of agricultural production to meet global needs is inextricably linked to improvements in water management techniques. Knowledge of irrigation practices, integrated water management systems, and other agricultural methodologies must continue to progress to ensure improvements of agricultural sustainability and productivity. Moreover, the negative impacts on the environment and agriculture that can result from unsound agricultural practices must be better understood and minimized. Research conducted at these and other institutions is indispensable to the progressive development of such knowledge and, therefore, must be encouraged and supported if we are to achieve our needs as well as our full potential.

Residential Irrigation Water Use and Control

Michael D. Dukes
Agricultural and Biological Engineering Department, University of Florida, Gainesville, Florida, U.S.A.

Rainfall–Satellite

INTRODUCTION

As urban areas grow throughout the country, limited water resources will be stretched to fulfill urban, agricultural, and other needs. Studies have indicated that half to two-thirds of water use in urban areas is used in landscape irrigation. This has been a problem for many years in the arid states, but is becoming problematic in the humid regions of the U.S.A. as well. Some reasons for the large amount of water used in urban areas include improper irrigation system design, large high quality landscapes, improper irrigation system maintenance, and improper irrigation management practices.

Proper irrigation management should consist of supplying the amount of water according to plant needs throughout the year. Historically, a soil water budget approach has been the recommended procedure for landscape irrigation.[1] This method is often not practical for homeowners to carry out. General irrigation guidelines, based on historical average weather data, are typically available through the cooperative extension service. One study involving residential homes showed that the amount of irrigation water used could be reduced by 16% by setting time clocks according to seasonal turfgrass demands.[2] Alternatively, new "smart" irrigation controllers have become available that bypass timed irrigation events based on soil moisture sensors placed in the irrigated area, or that perform a running soil water balance calculation based on estimated evapotranspiration (ET). These controllers have the potential to save substantial amounts of water compared with typical management practices.

RESIDENTIAL IRRIGATION WATER USE

A recent study across the U.S.A. indicated that 58% of potable water is used for landscape irrigation.[3] It was also found in this study that homes with buried sprinkler systems used 35% more water than homes without these systems and that homes with irrigation timers used 47% more water than homes without timers.[3] In a landscape and irrigation study, which was aimed at determining residential irrigation water use in central Florida, that 62% of potable water was used for landscape irrigation during the 29-month monitoring period.[2] The current Florida population of 16 million is projected to exceed 20 million by 2020.[4] Most new homes in Florida come with an in-ground irrigation system and a time clock controller. Proper irrigation system design and management have become critical, as water use has grown.

Barnes[5] found that residential irrigation rates in Wyoming were 122–156% of seasonal ET rates. A study using soil moisture sensors to control residential or small commercial irrigation systems used 533 mm of water for irrigation when compared to the theoretical requirement of 726 mm.[6] Aurasteh, Jafari, and Willardson[7] reported that homeowners with in-ground irrigation systems used an average of 38% more water than the estimated water requirements. Residential landscape water use research in Florida revealed that typical homeowners used an average of 142 mm of water per month, which was 37% higher than reference ET measurements and 82% higher than estimated turfgrass needs for the irrigated area.[2] Homeowners using irrigation time clocks, set to seasonal plant water requirements, used 16% less irrigation water on average. Typically, homeowners irrigated too much in the late fall and winter. This often occurred because of the lack of knowledge about the necessary length of irrigation run times for specific plant material, or because it was inconvenient to adjust the irrigation time clock.[2] As irrigation management appears to be a major reason for water waste, several steps have been taken to reduce water waste.

SOIL WATER BALANCE

A calculated amount of water in the plant root zone has been recommended for many years in a basic irrigation management strategy to determine when to irrigate and how much to irrigate. Change in water storage within the plant root zone is equal to inputs of irrigation and precipitation minus ET, runoff, and drainage. By tabulating historical rainfall and ET data and assuming a fraction of runoff, general guidelines can be generated for irrigation required based on an "average" weather year. However, actual weather conditions can vary substantially from the "average" year, making irrigation predictions inaccurate.

IRRIGATION CONTROL WITH FEEDBACK

In an irrigation system with feedback, data from soil or plant sensors are used to initiate and terminate the irrigation cycle. The dynamic nature of this control methodology allows for a rapid response to irrigation needs.

Irrigation with soil moisture sensors can consist of a sensor that has a user adjustable threshold setting where the scheduled time-based irrigation event is bypassed, if the soil moisture content exceeds the user adjustable threshold. This type of control is "bypass" control. The soil moisture sensor(s) should be installed in the root zone for each irrigation zone. If the sensor system contains only one soil moisture probe, then that probe should be installed in the driest irrigation zone of an irrigation system, and all other irrigation zones should have their run times reduced to minimize overwatering. Frequent irrigation events can be programmed into the irrigation timer and the sensor will allow irrigation, as conditions in the root zone dictate in response to rainfall and ET. The second type of soil moisture control is "on-demand" control, where the soil moisture-based irrigation control system consists of a stand-alone controller and multiple soil moisture sensors. Under "on-demand" soil moisture-based control, high and low limits are set such that irrigation occurs only within those limits.

Many types of soil moisture sensors have become commercially available. Historically, tensiometers have been recommended, but these devices require more maintenance than is acceptable for home irrigation. Newer sensors rely on the ability of the soil to conduct electricity and the fact that this property is strongly correlated to soil moisture content.

ET-BASED CONTROL SYSTEMS

Although ET-based control systems have been available for many years, until recently the technology has not been reliable or inexpensive enough for residential irrigation applications, as in the case of soil moisture-based control systems. The oldest type of these systems consists of a complete weather station that is interfaced with a controller for a large irrigated area. This type of system is fairly common on golf course irrigation systems. However, a complete weather station costs several thousand dollars and requires frequent maintenance for accurate measurements. Based on the meteorological parameters measured by the weather station, ET is calculated, and then a running soil water balance is calculated by the controller. Newer ET-based controllers have been introduced by several manufacturers and are being marketed for use in residential applications.

There are a couple of approaches to ET-based control at the residential home level. Meteorological data are used to calculate the ET value for a hypothetical grass surface for the site from where the meteorological data are collected. This ET value for a specific location is then sent to individual controllers mounted at a residence via wireless communication such as a paging network. Thus, the ET controller adjusts the irrigation run times or watering days according to climate throughout the year. The second type of approach for ET controllers is to use a preprogrammed crop water use curve for different regions. The curve is modified by a sensor, such as a temperature or solar radiation sensor, mounted with the controller to measure on-site weather conditions and modify the generalized crop water use curve based on this measured weather parameter. Several laboratory studies have shown that ET controllers can adjust irrigation in response to plant needs,[8,9] but few studies exist that demonstrate the controllers in comparison to actual homeowner irrigation or non-irrigated test plots. Results from the two demonstration studies with ET controllers in California indicate that some irrigation savings is possible with these controllers, but more detailed comparisons are needed.[10]

CONCLUSIONS

Preliminary research has shown that soil moisture-based controllers and ET-based controllers can or have the potential to reduce residential irrigation consumption. However, these control systems need to be evaluated across geographical regions and even against one another in comparative studies to determine not only the most effective in terms of water savings, but also the reliability of the technology. One challenge for ET-based controllers in humid regions is to adequately account for precipitation in the soil water balance calculations.

Reverse Osmosis

Mark Wilf
Hydranautics, Oceanside, California, U.S.A.

Rainfall–Satellite

INTRODUCTION

Osmosis is a natural process involving fluid flow across a semipermeable membrane barrier. It is selective in the sense that the solvent passes through the membrane at a faster rate than the dissolved solids. The difference of passage rate results in solvent solids separation. The direction of solvent flow is determined by its chemical potential, which is a function of pressure, temperature, and concentration of dissolved solids. Pure water in contact with both sides of an ideal semipermeable membrane at equal pressure and temperature has no net flow across the membrane because the chemical potential is equal on both sides. If a soluble salt is added on one side, the chemical potential of this salt solution is reduced. Osmotic flow from the pure water side across the membrane to the salt solution side will occur until the equilibrium of chemical potential is restored. Equilibrium occurs when the hydrostatic pressure differential resulting from the volume changes on both sides is equal to the osmotic pressure. Application of an external pressure to the salt solution side equal to the osmotic pressure will also cause equilibrium. Additional pressure will raise the chemical potential of the water in the salt solution and cause water flow to the pure water side, because it now has a lower chemical potential. This phenomenon is called reverse osmosis (RO). The reverse osmosis technology developed about 50 yr ago, as a scientific experiment, is used extensively today to reduce salinity of various water sources and produce potable water in commercial systems. Other applications include production of low salinity water for industrial applications and reclamation of waste streams. The economics of RO technology is very competitive in comparison with other salt reduction processes and, in some cases, the cost of producing potable water using RO can be lower than water supplied from natural sources, if pumping water over long distances is required.

OSMOTIC PRESSURE

The osmotic pressure, P_{osm}, of a solution can be calculated by measuring the concentration of dissolved salts in solution:

$$P_{osm} = 1.19(T + 273)\sum(m_i) \tag{1}$$

Where P_{osm} is the osmotic pressure (in psi); T, the temperature (in °C); and $\sum(m_i)$, the sum of molal concentration of all constituents in a solution. An approximation for P_{osm} may be made by assuming that 1000 ppm of total dissolved solids (TDS) equals about 11 psi (76 kPa) of osmotic pressure. The mechanism of water and salt separation by reverse osmosis is not fully understood. Current scientific thinking suggests two transport models: porosity and diffusion. That is, transport of water through the membrane may be through physical pores present in the membrane (porosity), or by diffusion from one bonding site to another within the membrane. The theory suggests that the chemical nature of the membrane is such that it will absorb and pass water preferentially to dissolved salts at the solid/liquid interface. This may occur by weak chemical bonding of water to the membrane surface or by dissolution of water within the membrane structure. Either way, a salt concentration gradient is formed across the solid/liquid interface. The chemical and physical nature of the membrane determines its ability to allow for preferential transport of solvent (water) over solute (salt ions).

WATER AND SALT TRANSPORT

The rate of water passage through a semipermeable membrane is defined in Eq. (2):

$$Q_w = (\Delta P - \Delta P_{osm})A = (\mathrm{NDP})A \tag{2}$$

where Q_w is the rate of water flow through the membrane, ΔP, the hydraulic pressure differential across the membrane, and ΔP_{osm}, the osmotic pressure differential across the membrane. A represents a unique constant for each membrane material type, and NDP is the net driving pressure or net driving force for the mass transfer of water across the membrane.

The rate of salt flow through the membrane is defined by Eq. (3):

$$Q_s = \Delta CB \tag{3}$$

where Q_s is the flow rate of salt through the membrane, ΔC is the salt concentration differential across the membrane, and B represents a unique constant for each membrane type.

Eqs. (2) and (3) show that for a given membrane:

- Rate of water flow through a membrane is proportional to net driving pressure differential (NDP) across the membrane.
- Rate of salt flow is proportional to the concentration differential across the membrane and is independent of applied pressure.

Salinity of the water that passes through the membrane, the permeate, C_p, depends on the relative rates of water and salt transport through reverse osmosis membrane:

$$C_p = Q_s/Q_w \tag{4}$$

The fact that water and salt have different mass transfer rates through a given membrane creates the phenomena of salt rejection. No membrane is ideal in the sense that it absolutely rejects salts.

COMMERCIAL REVERSE OSMOSIS TECHNOLOGY

The semipermeable membrane for reverse osmosis applications consists of a multilayer film of polymeric material composed of a skin layer 0.1–0.2μm thick and spongy supporting layer approximately 0.1 mm thick cast on a fabric support. The commercial grade membrane must have high water permeability and a high degree of semipermeability, i.e., the rate of water transport must be much higher than the rate of transport of dissolved ions. The membrane must be stable over a wide range of pH and temperature, and have good mechanical integrity. The stability of these properties over a period of time at field conditions defines the commercially useful membrane life, which is in the range of 3–5 yr. There are two major groups of polymeric materials that can be used to produce satisfactory reverse osmosis membranes: cellulose acetate (CA) and polyamide (PA). Membrane manufacturing, operating conditions, and performance differ significantly for each group of polymeric material.

CELLULOSE ACETATE MEMBRANE

The original CA membrane, developed in the late 1950s by Loeb and Sourirajan, was made from cellulose diacetate polymer.[1] Current CA membrane is usually made from a blend of cellulose diacetate and triacetate. The membrane is formed by casting a thin film acetone-based solution of CA polymer with swelling additives onto a non-woven polyester fabric. Two additional steps, a cold bath followed by high temperature annealing, complete the casting process. After processing, the cellulose membrane has an asymmetric structure with a dense surface layer of about 0.1–0.2 μm which is responsible for the salt rejection property. The rest of the membrane film is spongy and porous and has high water permeability. Description of manufacturing process of CA membranes and its properties can be found in number of publications.[2]

COMPOSITE POLYAMIDE MEMBRANES

Composite PA membranes have been developed in the early eighties by Cadotte and coworkers.[3] Commercially it is manufactured in two distinct steps. First, a polysulfone support layer is cast onto a non-woven polyester fabric. The polysulfone layer is very porous and is not semipermeable, i.e., it does not have the ability to separate water from dissolved ions. In a second, separate manufacturing step, a semipermeable membrane skin is formed on the polysulfone substrate by interfacial polymerization of monomers containing amine and carboxylic acid chloride functional groups. The resulting composite membrane is characterized by higher specific water flux and lower salt passage than CA membranes. Polyamide composite membranes are stable over a wider pH range than CA membranes. However, PA membranes will degrade more rapidly by free chlorine than are CA membranes. Consequently, CA membranes are used today almost exclusively in commercial composite membrane elements. The structures of CA and PA polymer are shown in Fig. 1A and B.

RO MEMBRANE MODULE CONFIGURATIONS

The membrane module configuration used almost exclusively for commercial reverse osmosis desalting applications is the spiral wound configuration. In a spiral wound configuration two flat sheets of membrane are separated with a permeate collector channel material to form a leaf. This assembly is sealed on three sides with the fourth side left open for permeate to exit. A feed/brine spacer material sheet is added to the leaf assembly. A number of these assemblies or leaves are wound around a central plastic permeate tube. This tube is perforated to collect permeate from the multiple leaf assemblies. A diagram of the spiral membrane leaf assembly is shown in Fig. 2. The typical industrial spiral wound membrane element is approximately 100 cm or 150 cm (40 in. or 60 in.) long and

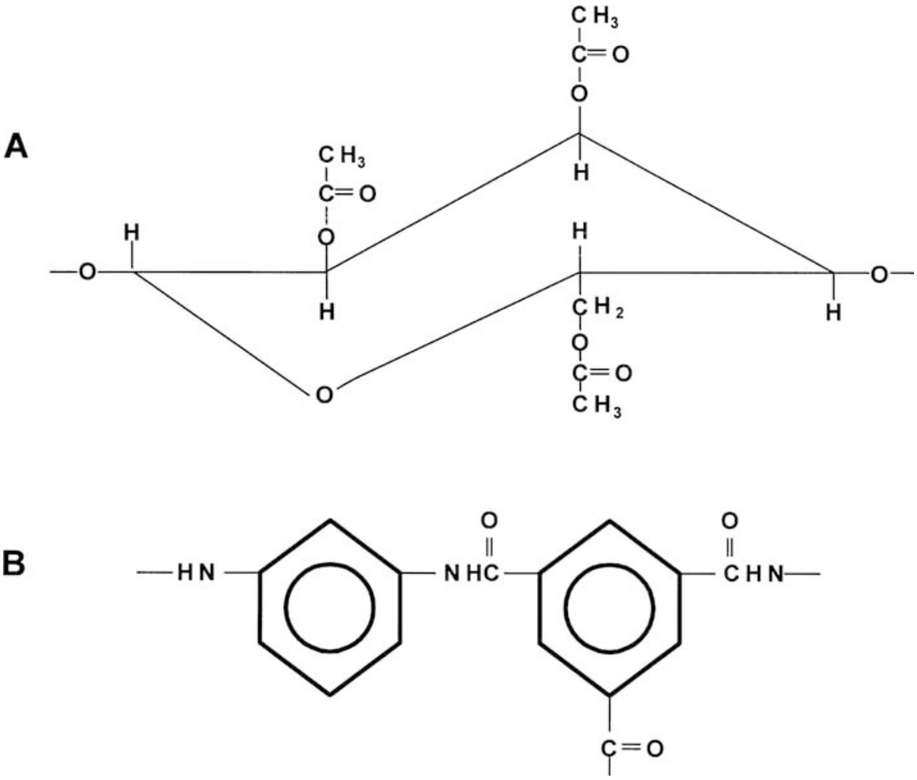

Fig. 1 Chemical structure of cellulose triacetate (A) and polyamide (B) membrane material.

10 cm or 20 cm (4 in. or 8 in.) in diameter. The feed/brine flow through the element is on a straight axial path from the feed end to the opposite brine end, running parallel to the membrane surface. The feed channel spacer induces turbulence and reduces concentration polarization (excess salt concentration at the membrane surface). The structure of the corresponding modules configurations is shown in Fig. 3.

RO SYSTEM CONFIGURATION

RO systems consist of the following basic components: feed water supply unit, pretreatment system, high pressure pumping unit, membrane element assembly unit, instrumentation and control system, permeate treatment, and storage unit and cleaning unit. The membrane assembly unit (RO block) consists of a

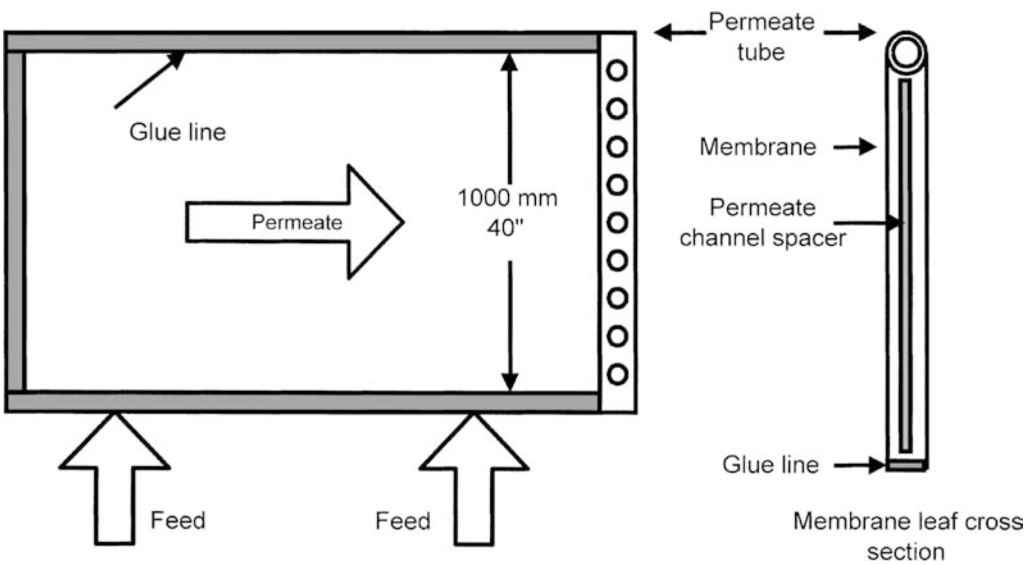

Fig. 2 Conventional spiral wound module configuration.

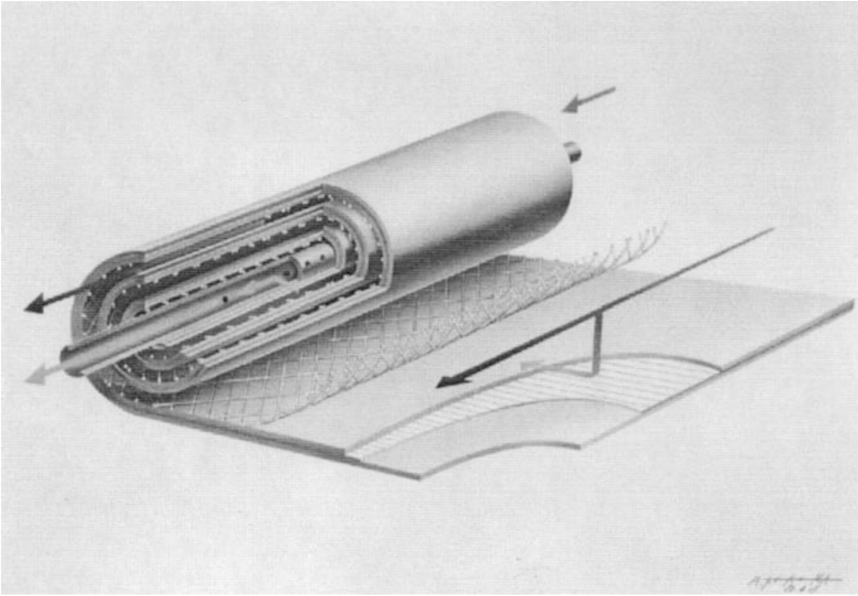

Fig. 3 Membrane schematic showing materials and flows.

stand supporting the pressure vessels, interconnecting piping, and feed, permeate, and concentrate manifolds. Membrane elements are installed in the pressure vessels. Each pressure vessel may contain 1–8 membrane elements connected in series (Fig. 4). A system is divided into groups of pressure vessels, called concentrate stages. In each stage, pressure vessels are connected in parallel with respect to the direction of the feed/concentrate flow. The number of pressure vessels in each subsequent stage decreases in the direction of the feed flow, usually in the ratio of 2:1, as shown in Fig. 5. Thus, one can visualize that the flow of feed water through the pressure vessels of a system resembles a pyramid structure: a high volume of feed water flows in at the base of the pyramid, and a relatively small volume of concentrate leaves at the top. The decreasing number of parallel pressure vessels from stage to stage compensates for the decreasing volume of feed flow, which is continuously being partially converted to permeate. The permeate of all pressure vessels in each stage, is combined together into a common permeate manifold. The objective of the taper configuration of pressure vessels is to maintain a similar feed/concentrate flow rate per vessel through the length of the system and to maintain feed/concentrate flow within the limits specified for a given type of membrane element. A picture of the actual RO unit is shown in Fig. 6. The concentrate from the first stage becomes the feed to the second stage; this is what is meant by the term ''concentrate staging.'' The flows and pressures in the multistage unit are controlled with the feed and concentrate valves. The feed valve, after the high-pressure pump, controls feed flow to the unit. The concentrate valve, at the outlet of RO block, controls the feed pressure.

FEED WATER PRETREATMENT

The extend of pretreatment process depends on the quality of raw water, which is usually associated with its origin: surface or well water. The initial removal of large particles from the feed water is accomplished using mesh strainers or traveling screens. Mesh

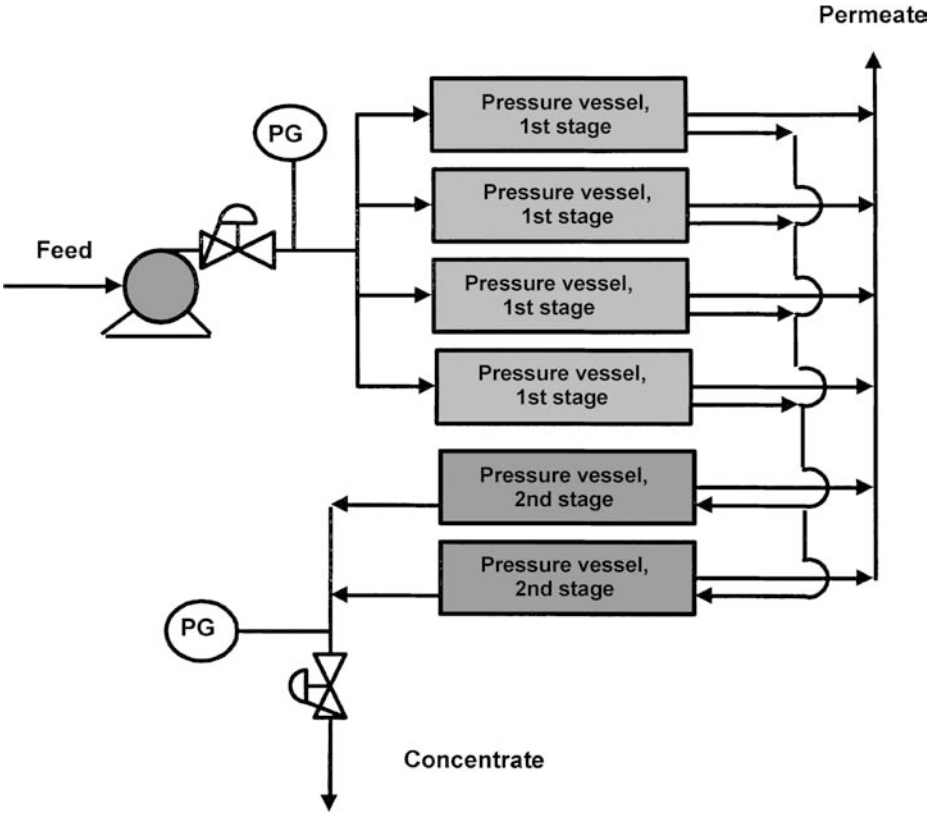

Fig. 5 Flow diagram of a two-stage RO system.

strainers are used in well-water supply systems to stop and remove sand particles that may be pumped from the well. Traveling screens are used mainly for surface-water sources, which typically have large concentrations of biological debris. It is a common practice to disinfect surface feed water in order to control biological activity. Biological activity in well water is usually very low, and in majority of cases, well water does not require chlorination. In some cases, chlorination is used to oxidize iron and manganese in the well water before filtration. Settling of surface water in a detention tank results in some reduction of suspended particles. Addition of flocculants, such as iron or aluminum salts, results in the formation of corresponding hydroxides; these hydroxides neutralize surface charges of colloidal particles, aggregate, and adsorb to floating particles before settling at the lower part of the clarifier. To increase the size and strength of the flock, a long chain organic polymer can be added to the water to bind flock particles together. Use of lime results in increase in pH, formation of calcium carbonate and magnesium hydroxide particles. Well water usually contains low concentrations of suspended particles, due to the filtration effect of the aquifer. The pretreatment of well water is usually limited to screening of sand, addition of scale inhibitor to the feed water, and cartridge filtration. Surface water may contain various concentrations of suspended particles, which are either of inorganic or biological origin. Surface water usually requires disinfection to control biological activity and removal of suspended particles by media filtration. The efficiency of filtration process can be increased by adding filtration aids, such as flocculants and organic polymers. Some surface water may contain high concentrations of dissolved organics. Those can be removed by passing feed water through an activated carbon filter. Depending on composition of the water, acidification and addition scale inhibitor may be required. Recently, new pretreatment equipment has been introduced to the RO market. It consists of backwashable capillary microfiltration and ultrafiltration membrane modules. This new equipment can operate reliably at very high recovery rates and low feed pressure. The new capillary systems can provide better feed water quality than a number of conventional filtration steps operating in series. The cost of this new equipment is still relatively high compared to the cost of conventional pretreatment, and therefore is mainly used for treatment of heavily fouling streams, such as municipal wastewater effluents.

RO APPLICATIONS

The majority of applications involve production of potable water from brackish or seawater streams.

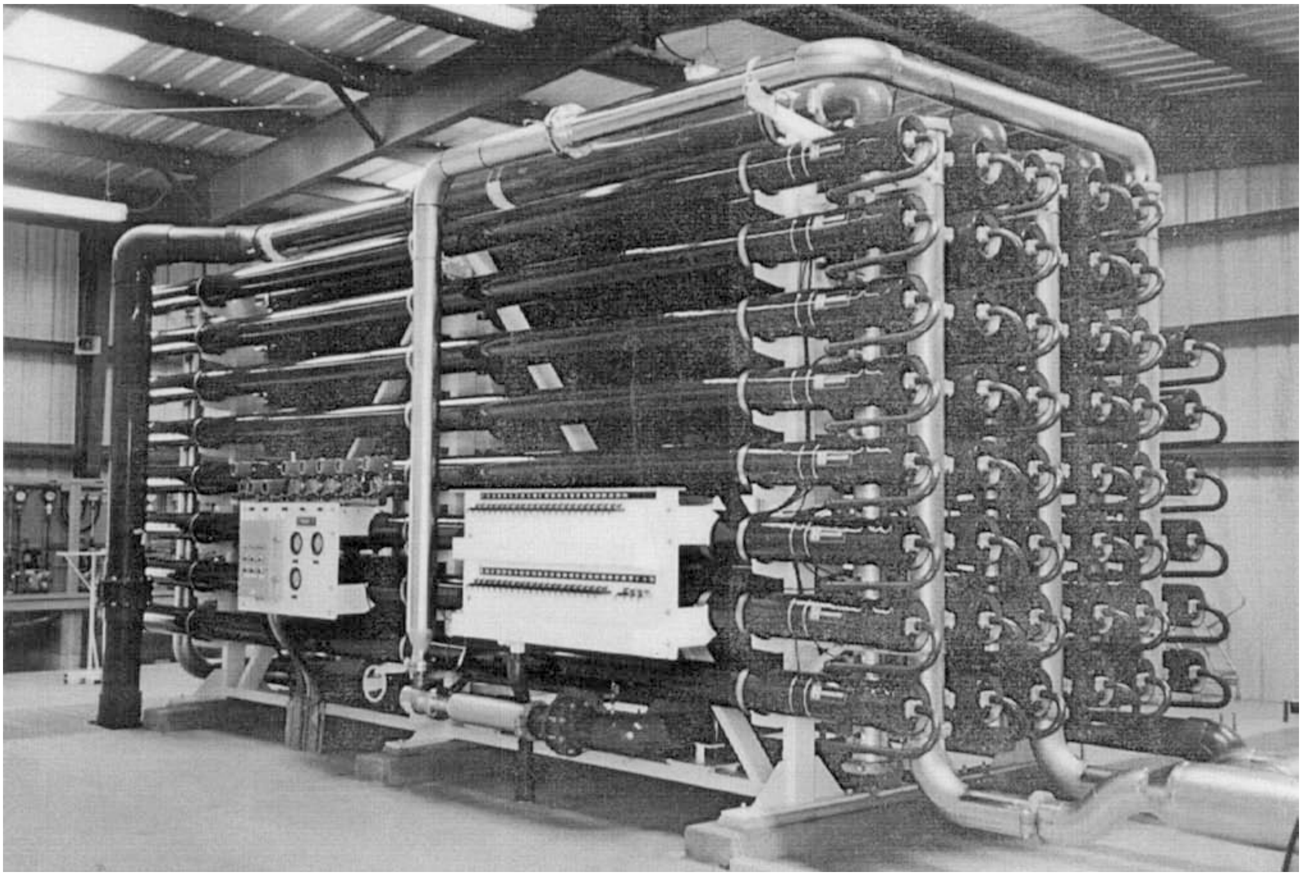

Fig. 6 Commercial RO train.

Reverse osmosis technology is also used in industrial applications to reduce water salinity prior to ion exchange equipment. Another growing area of application is reclamation of municipal wastewater. These applications usually involve integrated membrane technology, where the secondary municipal effluent is treated with macrofiltration or ultrafiltration prior to reverse osmosis unit. Municipal wastewater reclamation produces water for number of applications including industrial (cooling water makeup), agricultural (irrigation), and aquifer injection (prevention of sweater intrusion). The cost of reverse osmosis process decreased significantly in the last decade. The current cost of desalting of brackish water is in the range of \$0.25–\$0.35 m^{-3} (\$0.95 m/1000 gal–\$1.32/1000 gal). For recent large seawater projects the water cost as low as \$0.54 m^{-3} (\$2.04/1000 gal) has been reported.[4,5]

Richards' Equation

Graeme D. Buchan
Centre for Soil and Environmental Quality, Lincoln University, Canterbury, New Zealand

INTRODUCTION

Darcy's law is the basic law governing the flow of water (or other liquids) in permeable materials, and it tells us that the flow velocity q (m sec^{-1}) at any point (e.g., in soil, porous rock, concrete, timber, or other material) is proportional to the gradient of the water potential at that point. However, Darcy's law tells us only about the flow at individual points and is sufficient to describe only steady flow processes. To model unsteady flows (where the moisture distribution changes with time), we must also know the relationship between velocities at neighboring points. If the neighboring velocities are unequal, their 'mismatch' must be compensated by a filling or emptying of pores between the points. The additional equation required to complete the mathematical description of flow is the so-called *continuity equation*. Basically, this equation ensures that matter is not created or destroyed, and so is also called the conservation equation. When Darcy's law is combined with the continuity equation, we obtain Richards' equation, first derived by the physicist Lorenzo Adolph Richards in 1931.[1]

Richards was a pioneering soil physicist who contributed enormously to soil water physics in the United States in the period c.1930–1960.[2,3] His contributions to theory included the conceptual extension of Darcy's Law to unsaturated flow,[1] as part of his development of Richards' equation. On the experimental side, he: invented the tensiometer;[2,4] developed the pressure-plate apparatus[5] to measure water desorption from soil; developed the thermocouple method for measuring the vapor pressure (or "water activity") in soil or biological materials; and helped establish the relationship between the permanent wilting point for plants and the soil water content at 15 bar suction. He also investigated salt-affected soils.

THEORY

We need a mathematical description of water flow in permeable materials. The resulting equations can then be used to model flow in: 1) soil or sediments, including phenomena such as infiltration, drainage, drying by evaporation, or water flow towards roots; 2) groundwater, including aquifers; and 3) other materials, during wetting or drying processes (e.g., timber, concrete, foodstuffs, or granular or powder materials).

Darcy's Law

First, we limit attention to flow in unsaturated materials. The saturated case will be described later as a special case. Also, for simplicity, assume that liquid flow is initially in the horizontal (x) direction (Fig. 1). Darcy's law states that the flow velocity q at any point is proportional to the gradient $\partial H/\partial x$ of hydraulic head H.

$$q = -K\partial H/\partial x \quad (1)$$

Here H (m) is the water potential expressed in terms of the equivalent height or head of a column of water, and K (m sec^{-1}) is the hydraulic conductivity of the material. In saturated soil, water is under positive pressure, so $H > 0$. In unsaturated soil, where the water is under suction, H becomes negative:

$$H = -\psi \quad (2)$$

where ψ (intrinsically positive) is the so-called matric suction, a measure of the energy status of the water.[4] For vertical flow, gravity enters as an additional driving force, and H has two components:

$$H = -\psi + z \quad (3)$$

where z (the vertical coordinate, Fig. 1) represents the gravitational potential. Extending Darcy's law to three dimensions gives:

$$q = -K\nabla H \quad (4)$$

where ∇ represents the 3-D gradient (a vector quantity). Eq. (4) assumes an isotropic material, i.e., that K is equal for all flow directions.

K is a function of soil wetness, and may be written in one of two ways. First, in the "mass picture" we write $K = K(\theta)$ where θ (m^3 m^{-3}) is the volumetric water content. However, $\theta = \theta(\psi)$ is related to the suction ψ. The $\theta(\psi)$ relationship is known as the soil moisture characteristic (SMC).[4,5] Thus, in the "energy picture," K is expressed instead as $K(\psi)$.

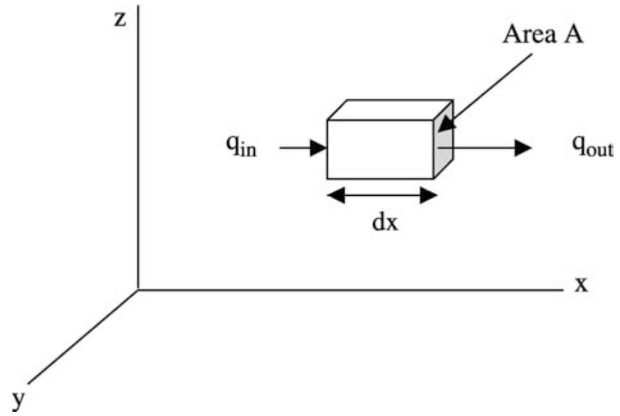

Fig. 1 Horizontal flow of a liquid across an imaginary volume element in a permeable material, with volume $V = A\,\mathrm{d}x$. In unsteady flow, the velocities q_{in} and q_{out} are unequal, and the continuity principle implies a net filling or emptying of pores in the element.

For vertical flow, Eq. (1) becomes [using Eq. (3)]:

$$q = -K\partial H/\partial z = K\partial\psi/\partial z - K \qquad (5)$$

The two terms on the right side of Eq. (5) mirror the two head components in Eq. (3), and represent, respectively, the suction-driven and gravity-driven components of flow. For horizontal flow, only the first term applies.

Eq. (1) gives the flow velocity q at any point. In order to describe transient (non-steady) processes, we need to introduce the continuity equation.

The Continuity Equation

Consider an imaginary small cubical volume in the material (Fig. 1), with entry velocity q_{in} and exit velocity q_{out}. The mismatch of these two velocities must be balanced by a change in the volumetric water content θ in the cube.

$$V\partial\theta/\partial t = A[q_{\text{in}} - q_{\text{out}}] = -A\,\mathrm{d}x\partial q/\partial x \qquad (6)$$

Since $V = A\,\mathrm{d}x$, then

$$\partial\theta/\partial t = -\partial q/\partial x \qquad (7)$$

The corresponding equation for vertical flow is $\partial\theta/\partial t = -\partial q/\partial z$. In 3-D analysis we replace $\partial q/\partial x$ with $\nabla \cdot q$, which is a measure of the so-called *divergence* of the water flux at the point. (The divergence is, as its name suggests, the net outflow through the surfaces of a tiny volume surrounding the point.) Then:

$$\partial\theta/\partial t = -\nabla \cdot q \qquad (8)$$

Eq. (8) is the continuity equation.

Richards' Equation

We can now combine Darcy's law with the continuity equation. For vertical flow, combining Eq. (5) and the vertical (z) form of Eq. (7) one can derive:

$$\partial\theta/\partial t = -\partial/\partial z(K\partial\psi/\partial z) + \partial K/\partial z \qquad (9)$$

This is Richards' equation for vertical flow. Note that, mirroring Eq. (3), Eq. (9) contains both a suction-driven and a gravity-driven flow term. Extending Eq. (9) to isotropic 3-D flow, we add horizontal (x and y) terms.

$$\partial\theta/\partial t = -\nabla \cdot (K\nabla\psi) + \partial K/\partial z \qquad (10)$$

However, we have a problem. Eq. (10) cannot be solved immediately as it contains two unknowns, both θ and ψ. To eliminate one unknown, we exploit the relationship between θ and ψ, i.e., we assume that the SMC $\theta(\psi)$ is known. There are two options.

(1) *The energy picture*. Here we retain ψ as the unknown, and solve Eq. (10). Since $\theta(\psi)$ and $K(\psi)$ are both highly non-linear functions, and also may be based on experimentally derived data rather than analytical functions, analytic solution of Richards' equation is not generally possible, except in special cases.[6] Hence, numerical solution is required. Note that Eq. (10) is first order in the time derivative ($\partial/\partial t$) and second order in space derivatives ($\partial^2/\partial x^2$ etc). Hence, solutions generally have the space variables (x, y, or z) paired with $\sqrt{t}$.

(2) *The mass picture*. Here we retain θ as the unknown.

$$\partial\theta/\partial t = \nabla \cdot (D\nabla\theta) + \partial K/\partial z \qquad (11)$$

In Eq. (11), the substitution $D = -K\,\mathrm{d}\psi/\mathrm{d}\theta = D(\theta)$ has been used. D is called the "hydraulic diffusivity," because Eq. (11) now looks like a diffusion type equation. However, the water transport described by Eq. (11) is not a true diffusion process. It is a mass flow process.

To summarize, in the "energy picture," water potential ψ is the dependent variable; while in the "mass picture," θ becomes the dependent variable, and the mass flow equation takes the apparent form of a diffusion equation.

APPLICATIONS AND COMPLICATIONS

Richards' equation is the foundation of all mechanistic models used to simulate the dynamics of water (or other liquid) in permeable materials, including soils, rocks, aquifers, or industrial materials. Because Richards' equation is so generic, any model based on it should be able to simulate any flow process, in either unsaturated or saturated material, assuming that appropriate values for the equation parameters have been determined for a particular application. In soils, processes in the unsaturated (or vadose) zone include: infiltration of water into the soil;[4] its redistribution once inside the soil; water uptake by root fibres;[7] and drying by evaporation. Processes in saturated materials include the flow of water beneath the water table in soil drainage systems, and groundwater flow in aquifers (permeable rock, gravels, or other sediments).

Saturated Flow

In saturated flow in a stable material, Richards' equation [Eq. (10)] simplifies, because $\theta = \theta_{sat}$ is now constant in time, so that $\partial\theta/\partial t = 0$. If the water is under positive pressure (e.g., in soil submerged beneath the water table), we replace the suction ψ with the pressure head H (>0). Also, for a uniform isotropic material, $K =$ constant. Then Richards' equation, Eq. (10), becomes Laplace's equation:

$$\nabla^2 H = 0 \tag{12}$$

Eq. (12) can be used to solve the flow regime in groundwater systems.[4]

Relevance to Solute Transport

An analog of Richards' equation can also be developed for the movement of solutes in permeable materials. However, the solute transport equations are complicated by the additional flow processes that occur. While Richards' equation describes only the convection (by mass flow) of water in a material, solutes do not just "convect" with the bulk flow of water. Differences in solute concentration also cause solutes to "diffuse" (by molecular diffusion) and "disperse" (via the microscopic irregularities in water flow).[4]

Complications

The above analysis neglects: 1) hysteresis, i.e., the dependence of the $\theta(\psi)$ and $K(\psi)$ relationships on the "history" of how the material reached its current state of wetness, via drying or wetting actions; and 2) anisotropy, or the dependence of the hydraulic conductivity K on flow direction. These topics are discussed in Ref.[4].

Ring and Tension Infiltrometers

Laosheng Wu

Dong Wang
Department of Soil, Water and Climate, University of Minnesota, St. Paul, Minnesota, U.S.A.

INTRODUCTION

Field characterization of soil hydraulic properties is an important first step in solving soil water and solute transport problems. Ponded ring infiltrometers and tension infiltrometers are experimental devices designed for in situ measurement of soil hydraulic parameters. According to Green and Topp,[1] double ring infiltrometer is one of the most popular methods for estimating saturated hydraulic conductivity. Tension infiltrometers are also gaining more popularity in estimating soil hydraulic properties and in documenting macropore and preferential flow.[2] This entry provides a brief overview of the recent development and application of ring and tension infiltrometers for soils and hydrologic studies.

RING INFILTROMETERS

Infiltration is the process of water entering the soil surface. One of the most common devices for measuring infiltration rate and water intake capability at the soil surface is ring (cylinder) infiltrometer made of either metal or plastic and coming in various sizes. Depending on their configuration, ring infiltrometers can be classified as single- and double-ring infiltrometers. In a single-ring infiltrometer, water is filled and the infiltration rate from the ring into the soil is measured. In a double-ring infiltrometer, an outer ring is used to provide a buffer zone to reduce lateral flow so that the inner ring will measure ‘‘true’’ vertical (1-D) flow, and infiltration rate is measured only in the inner ring (Fig. 1). The ponding level in the outer ring is kept as close as possible to the level in the inner ring. The rate of water intake can be measured either manually or automatically using electronic pressure transducers.

A typical infiltration curve has a very high initial infiltration rate due to the high initial hydraulic gradient. As the wetting front extends deeper into soil, the hydraulic gradient decreases with time, and so does the infiltration rate. By assuming that the water flow in a soil profile is a piston-type flow and the soil in the wetted region has a constant water content or matric potential (h_o), hydraulic conductivity (K_o), water diffusivity (D_o), and matric potential head at the wetting front (h_f), Green and Ampt[3] showed that the infiltration rate (i) can be calculated as

$$i = -K_o \frac{h_f - h_o - L}{L - 0} = \frac{K_o}{L}(\Delta h + L) \tag{1}$$

where $\Delta h = h_o - h_f$, L is the depth of the wetted zone. It can be shown that the infiltration rate (i) decreases as time (t) increases:[4]

$$i = \Delta\theta (D_o/2t)^{1/2} \tag{2}$$

where $\Delta\theta = \theta_w - \theta_i$ is the difference in volumetric water content between the wetted zone (θ_w) and the initial profile (θ_i); $D_o = K_o \Delta h / \Delta\theta$ is soil water diffusivity.

Based on the 1-D Richards' equation with approximations, Philip[5] also showed that the infiltration rate can be estimated as:

$$i = \frac{1}{2} S t^{-1/2} + A \tag{3}$$

where S is called sorptivity, and A is a constant that approaches saturated hydraulic conductivity under ponding conditions.

TENSION INFILTROMETERS

Tension infiltrometers are devices that can be used to estimate soil hydraulic properties and structural characteristics based on infiltration measurement at the soil surface. Depending on soil conditions, the physical appearance of tension infiltrometers can vary considerably. They may be called tension infiltrometers[6] where a relatively small contact disk is used at the soil–water interface or disk permeameters[7] where a relatively large disk is used. The most important difference

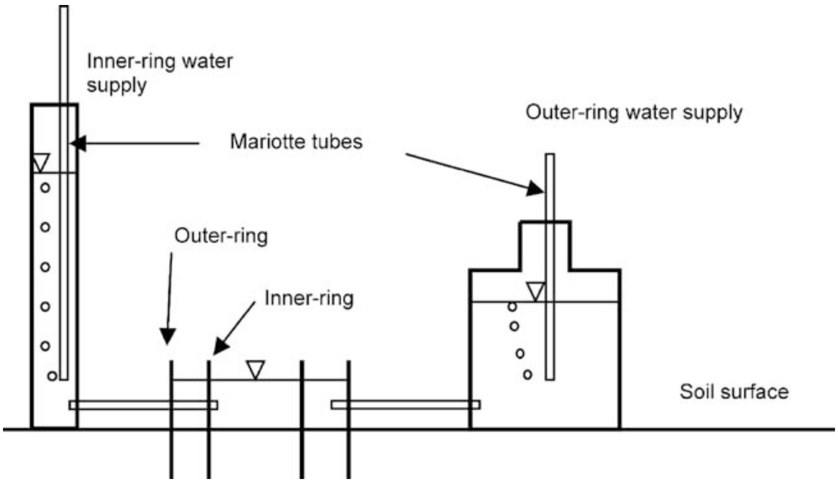

Fig. 1 Schematic of a double-ring infiltrometer.

between ring and tension infiltrometers is that for ring infiltrometers water is usually supplied with a positive head, whereas for tension infiltrometers the infiltration water at the soil–water interface is under tension. Because of the negative pressure head at the soil–water interface, in designing tension infiltrometers, it is usually necessary to place a porous membrane between the infiltrometer and the soil surface that prevents air entry from this interface into the water supply. Most tension infiltrometers or disk permeameters consist of three components: 1) a circular disk or plate connected to the water supply at the top and to a porous membrane at the bottom; 2) a water supply tube or reservoir that supplies the infiltration water; and 3) a bubbling tube or tower that is connected to the water supply tube for air supply and is used to adjust the water tension at the soil–water interface with a single

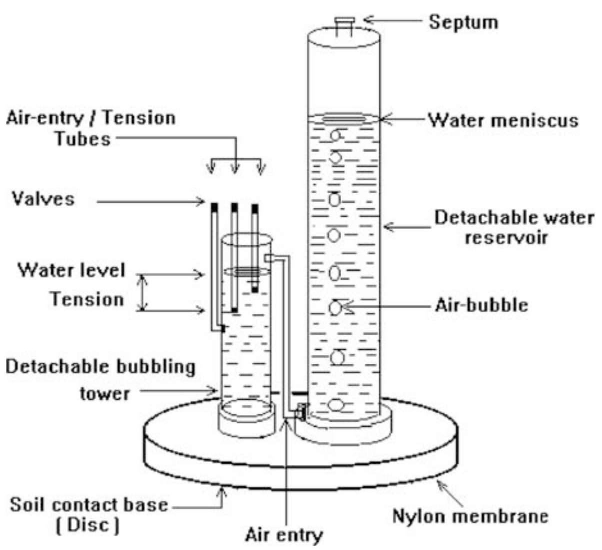

Fig. 2 Schematic of a tension infiltrometer. *Source*: From Ref.[8].

or multiple air entry tubes with preselected settings for water tension (but only one will be open at one time) (Fig. 2).

The most widely used method for parameter estimation based on tension infiltrometer measurement is to use the approximate steady-state solution of water flow from a shallow circular pond by Wooding:[9]

$$i(h_t) = K_s\left(1 + \frac{4}{\pi r_o \alpha}\right)\exp(\alpha h_t) \quad \text{for large times} \qquad (4)$$

where $i(h_t)$ is the steady-state infiltration rate under a given supply tension h_t, r_o is the radius of the infiltrometer disk, K_s is the soil hydraulic conductivity under saturated conditions, and α is the empirical parameter. Because the only unknowns in this equation are K_s and α, they can be solved by making measurements at a fixed radius with multiple tensions or at a fixed tension with various radii.

Because the determination of steady-state infiltration rate can be subjective and limited by experimental conditions, methods using early-time infiltration data to estimate soil hydraulic properties are needed. Wang Yates, and Ernst[10] proposed an alternative procedure requiring only early-time infiltration data and the measurement of water content increase during the infiltration event. The first step is to solve for soil sorptivity (S) from the transient tension infiltration data using an approximate infiltration equation by Warrick:[11]

$$i(t) \approx S/2\sqrt{t} + D_e S/r_o \qquad \text{for small times} \qquad (5)$$

where $i(t)$ is the transient infiltration rate, and D_e is an effective diffusion coefficient, which is a constant for a given set of h_t and r_o. A non-linear regression between $i(t)$ and $t^{1/2}$ would provide a satisfactory estimation of sorptivity. The second step is to solve for K_s from a relationship developed by Youngs[12] using S and the measured water content increase during the infiltration:

$$K_s = 342.25 \frac{\eta \rho g}{\sigma^2 (\theta_o - \theta_i)^2} S^4 \quad \text{for small times} \tag{6}$$

where η is water viscosity ($10^{-2}\,\mathrm{g\,cm^{-1}\,sec^{-1}}$), ρ is the density of water ($1\,\mathrm{g\,cm^{-3}}$), g is the gravitational acceleration ($980\,\mathrm{cm\,sec^{-2}}$), σ is the surface tension of water ($72.75\,\mathrm{dyn\,cm^{-1}}$ or $\mathrm{g\,sec^{-2}}$), and θ_o and θ_i are, respectively, the final and initial water content. The final step is to solve for α from White and Sully[13] using the S and K_s values as:

$$\alpha = \frac{(\theta - \theta_i) K_s}{b S^2} \qquad b \approx 0.55 \tag{7}$$

APPLICATIONS AND LIMITATIONS

While the purpose of the ring infiltrometer measurement is to evaluate the water intake capability of a soil, the infiltration rate measured from infiltrometers is not always directly applicable in practice since the field infiltration problems are mostly 1-D or vertical infiltration rate. The flow from a ring into the soil is a 3-D problem.[14–16] Many factors, including ring geometry, soil conditions, and time during the measurement sequence, can affect the vertical infiltration rate measured by ring infiltrometers. Lateral divergence of flow by capillary forces can lead to overestimation of vertical infiltration. The extent (degree) of this overestimation also depends on the ring size. Wu et al.[16] showed that in both single- and double-ring infiltrometers, the possibility of overestimation decreases as the ring size increases. As one might expect, overestimation of vertical infiltration caused by lateral flow is more significant in a fine-textured soil than in a coarse-textured soil. Bouwer[17] indicated that the final infiltration rate gives true vertical infiltration rate correctly only if $h_{cr}/d = 0$, where h_{cr} is called critical matric head and d is ring diameter.

Ring insertion depth and soil layering also affect the infiltration rate measurement. Since the flow from a ring infiltrometer is confined to a vertical direction before the wetting front reaches the ring insertion depth, there can be no overestimation. However, lateral flow occurs when the wetting front passes the insertion depth. Numerical experiment by Wu et al.[16] showed that the infiltration rate decreases as the insertion depth increases for a 12-hr infiltration simulation. Restricting layers deeper in the profile can also cause lateral flow. The significance of this effect depends on the position of restricting layers. In addition, many non-systematic errors (including soil surface disturbance, water quality, temperature, and biological factors) can influence infiltration measurement.[18]

Theoretically, the true final vertical infiltration rate should be equal to the field-saturated hydraulic conductivity.[18] Reynolds and Elrick[15] developed a solution for steady-state water flow rate from a single-ring infiltrometer by accounting for the soil initial matric potential head, the radius of the ring, and the ring insertion depth. By modifying the Reynolds and Elrick method and using a scaling approach, Wu and Pan[19] developed a generalized infiltration curve for single-ring infiltrometers. By applying their solution to soils with different initial and boundary conditions and rings with various geometries, they found that the dimensionless infiltration curves were close to each other for their test soils. They further applied the generalized infiltration equation to measure the field saturated hydraulic conductivity (K_s) using the infiltration data from single-ring infiltrometers, and found that the K_s values from the new method were comparable with the values measured by other methods.[20]

Tension infiltrometers are commonly used to estimate soil-saturated hydraulic conductivity. Depending on the water supply tension, soil sorptivity and a macroscopic capillary length[2] may also be estimated. While the steady-state method requires the tension infiltration to reach the steady-state rate, alternative methods need accurate measurements of transient infiltration rate for a preselected tension. Experimentally, the decision on when a steady-state flow may have reached is prone to subjective decisions and sometimes it is limited by the total amount of water available in the water supply tube, as in the case of coarse soils. For soils with fine textures or low infiltration rate, infiltrometers with automated recording mechanisms such as the one described by Ankeny Kaspar, and Horton[6] may be required because of the extended time needed to reach steady-state flow. Besides the drastic differences in infiltration rate for different types of soil, the size of infiltrometer disk and supply tension also affect the time needed to approach the steady-state condition and possibly the accuracy on parameter estimation.[21] The use of automated recording can provide a more detailed and accurate measurement of the transient infiltration from a tension infiltrometer, which would enable the application of other methods for parameter estimation, such as numerical inversion.[22]

In addition to their application for measuring water flow and soil hydraulic properties, with tracers tension infiltrometers can be used to measure solute exchange coefficients between the mobile and immobile water content.[23,24]

Riparian Geomorphology

Ashley A. Webb
Research and Development Division, Forests NSW, Coffs Harbour Jetty, New South Wales, Australia

INTRODUCTION

Geomorphology is the study of the morphology of landforms and the processes responsible for their evolution, while the term riparian refers to landforms within and adjacent to permanent, intermittent or ephemeral streams, which include the channel bed, banks, and floodplain.[1] Riparian vegetation is vegetation growing within the riparian zone, while large wood is defined as organic material >0.1 m diameter, including logs, pieces of timber, live trees, branches, and rootwads located within the riparian zone. Riparian geomorphology is therefore the study of the dynamic and complex relationships that exist between vegetation, large wood, and the formation and morphology of stream channels and floodplains. It is a cross-disciplinary field combining aspects of the disciplines of fluvial geomorphology, biogeography, and riparian ecology.

Essentially, while riparian vegetation and large wood exert influence on the morphology of the riparian zone, the distribution of riparian vegetation species, including grasses, sedges, shrubs, and trees is in turn influenced by the hydrogeomorphic characteristics of the stream channels and floodplains they inhabit. Riparian vegetation communities generally exhibit a degree of zonation, which refers to the lateral, vertical, and longitudinal distribution of vegetation species within the riparian corridor[2] (see Fig. 1). Such zonation of species is due to their relative tolerance of the varying frequency, magnitude, and duration of, and sediment deposited by, floods experienced at different elevations above or away from the streambed or at various locations on the floodplain. The zonation of vegetation may also be a function of succession that refers to temporal variations in the structure and composition of the vegetation community. The distribution of large wood within the riparian zone is influenced by the distribution of vegetation from which it is recruited, the dominant recruitment processes (e.g., windthrow, bank erosion, landslides), and the hydrogeomorphic processes responsible for its storage and/or transport.[3]

Riparian vegetation and large wood exert a significant influence on fluvial processes and channel and floodplain morphology.[4] This influence is greatest when the ratio of vegetation size to channel size is at a maximum and declines when channel width exceeds the mean height of vegetation growing adjacent to the stream.[5] Several mechanisms including bank erosion control, sediment storage patterns, bed stability, resistance to flow, and floodplain hydraulics are linked to the influence of riparian vegetation and large wood on stream morphology.[6] The remainder of this entry discusses these mechanisms in greater detail.

BANK EROSION CONTROL

Live riparian vegetation is effective in stabilizing streambanks as roots are able to bind bank sediment, thus increasing its cohesion and reducing erosion and lateral migration rates. Trees, shrubs, grasses, and sedges may all contribute to the cohesiveness of sediment. For example, in a study of anastomosed channels in Alberta, Canada, it was concluded that bank sediment with 16–18% by volume of roots and a 5 cm thick root mat, was 20,000 times more resistant to erosion than comparable bank sediment without vegetation.[7] Similarly, Australian research indicated that the addition of *Eucalyptus camaldulensis* (River Red Gum) or *Melaleuca ericifolia* (Swamp Paperbark) roots to an otherwise degraded streambank profile increased bank stability to mass failure by up to 60%[8] (see Fig. 2).

Large wood too can impact upon rates of streambank erosion to both positive and negative degrees. Individual pieces of large wood aligned with the mainstream flow direction and positioned adjacent to streambanks can serve to defend the banks from erosion and reduce channel migration. In some cases, such pieces of large wood in the Californian Redwood forest streams were reported to be several channel widths in length.[3] Large wood may also become incorporated in the bank or floodplain sediments, serving to reduce erosion. Conversely, individual large wood pieces or large wood accumulations aligned transverse to the mainstream flow direction may become outflanked and direct flows onto streambanks, leading to increased bank erosion.[3]

SEDIMENT STORAGE

Both large wood and live riparian vegetation contribute to sediment storage within channels. Riparian

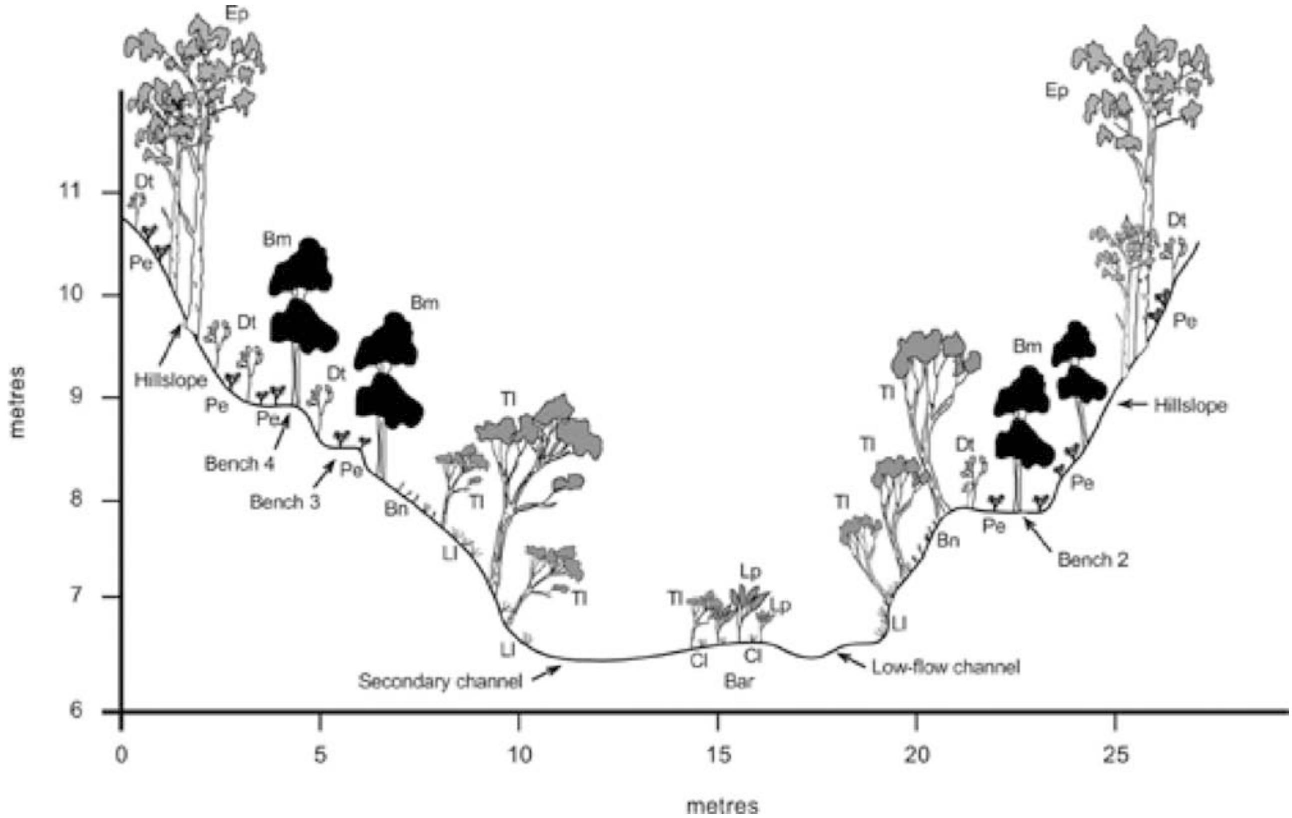

Fig. 1 Zonation of riparian vegetation on Mogo Creek near Sydney, Australia. Vegetation symbols are not to scale. Ep, *Eucalyptus punctata*, Bm, *Backhousia myrtifolia*, Tl, *Tristaniopsis laurina*, Dt, *Dodonaea triquetra*, Lp, *Leptospermum polygalifolium*, Pe, *Pteridium esculentum*, Bn, *Blechnum nudum*, Ll, *Lomandra longifolia*, Cl, *Cyperus lucidus*. *Source*: From Webb, A.A. Episodic erosion, riparian vegetation colonisation and the late Holocene stability of sand-bed, forest streams in southeastern Australia. PhD thesis, University of Sydney: Sydney, Australia, 2002.

vegetation, by colonizing recent deposits within stream channels and by reducing streambank erosion, reduces the amount of sediment transported through a river reach. In this way, riparian vegetation serves to reduce in-stream sediment loads. While trees contribute to the storage of considerable volumes of sediment in some channels, in others the role of grasses and sedges may be just as important.[9] Large wood also plays a major role in maximizing sediment storage within stream channels. Obstructions on the channel bed provide suitable sites for sediment deposition by increasing channel roughness, reducing flow velocity and, therefore, reducing sediment transport capacity.[3] In general, the relative amount of sediment stored by large wood is inversely proportional to channel size (and usually catchment area) and, on lower order streams, the sediment stored by large wood can exceed the annual sediment flux.[10]

BED STABILITY

Log steps are individual pieces of large wood that span the active channel bed, forming a natural wooden drop structure. The small vertical falls created are responsible for the dissipation of a lot of stream energy and are most commonly found on lower order, steep channels.[3,10] In addition to providing storage sites for sediment, large wood and vegetation in channels are important for creating hydraulic diversity. This includes a greater diversity of runs, riffles, hydraulic jumps, and pools. Step pools formed downstream of log steps and scour pools formed around and under immobile pieces of large wood (see Fig. 3) are important for creating slow water habitat.[11]

RESISTANCE TO FLOW

Live riparian vegetation and large wood can contribute to channel and floodplain stability by increasing channel roughness thereby reducing flow velocity, stream power, and bank shear stress. The blockage ratio or the proportion of a channel cross-section taken up by large wood or vegetation is important in determining the degree of resistance to flow. The blockage ratio is dependent on the relative size and volume of the wood

Fig. 2 Roots of river red gum (*Eucalyptus camaldulensis*) trees contribute to streambank stability: Murray River, Australia. (Photo by author.)

as well as its orientation to the mainstream flow direction. To have a significant impact on bankfull flow hydraulics, research has shown that large wood would have to occupy greater than 10% of the channel cross-section.[12]

CHANNEL AND FLOODPLAIN MORPHOLOGY

Vegetation can have marked impacts on the morphology of stream channels. In general, streams with heavily vegetated banks have smaller width to depth ratios than those with unvegetated banks.[5] However, in some instances, vegetation (including large wood) within the channel may divert flows against streambanks leading to localized bank erosion and channel widening. The influence of riparian vegetation on channel morphology and pattern dates back to the Permian. Sedimentary evidence from the Karoo Basin of South Africa indicates that following the Permian–Triassic extinction and concomitant changes in plant ecosystems, there was a basin-wide change from

Fig. 3 Scour pools formed beneath channel-spanning pieces of large wood are an important source of fish habitat, Wheeny Creek, Australia. (Photo by author.)

meandering to braided river systems. This was attributed to an increased supply of bedload due to catastrophic extinction of terrestrial plant life and decreased resistance of the channel boundary due to the loss of channel-margin vegetation.[13]

Vegetation may also play an active role in shaping the morphology of floodplains. Vegetation often acts as a nucleus for bar and bench sedimentation and also influences the development or destruction of floodplain landforms. On low gradient streams, the formation of flood chutes and meander cutoffs can be attributed to the presence of dense vegetation in the riparian zone creating significant backwater effects and diverting floods through the neck of floodplain loops.[14] Smaller scale landforms can also be induced on forested floodplains, such as scour holes formed around tree stumps/roots and mounds/hummocks formed on nuclei of shrubs, rushes, or grasses.

CONCLUSIONS

Riparian geomorphology is a term used to describe the study of the complex and dynamic interactions that exist between riparian vegetation, large wood, and the morphology and evolution of stream channels and floodplains. The geomorphology of riparian zones exerts influence over the distribution or zonation of vegetation species and the large wood that it recruits. Conversely, riparian vegetation and large wood can significantly influence the geomorphology of channels and floodplains through mechanisms including bank erosion control, sediment storage patterns, bed stability, resistance to flow, and floodplain hydraulics. This influence is greatest when the ratio of vegetation size to channel size is at a maximum and declines when channel width exceeds the mean height of vegetation growing adjacent to the stream.

Worldwide, a number of river systems have been subjected to extensive clearing of riparian vegetation and the removal of large wood, which has resulted in a plethora of documented environmental impacts including increased flow velocity, spatially extensive bed degradation, massive channel enlargement, and loss of fish habitat.[15] In recent decades, our understanding of riparian geomorphic processes has increased dramatically, primarily due to advanced studies of riparian vegetation, large wood, and geomorphic interactions in forest streams. Knowledge of such processes will become increasingly important as river managers attempt to rehabilitate our river systems from the impacts of human disturbance.

River Channelization

Nicola Surian
Dipartimento di Geografia, University of Padova,
Padova, Italy

INTRODUCTION

Channelization includes those methods of engineering (resectioning, straightening, construction of levees, diversions, etc.) that modify existing river channels or create new channels, often changing the relationship between river channels and floodplains. The most common purposes of channelization are flood control, land drainage improvement, creation of new spaces for urbanization or agriculture, maintenance or improvement of navigation, and reduction of bank erosion. Channelization is carried out both on very large rivers and small streams; it is widespread in lowland rivers, but also many upland (mountain) rivers have experienced this type of human intervention.

Human impact on rivers has a long history. For instance, the Yellow River, in China, has been regulated for at least 4000 yr and most alluvial rivers in Europe have been channelized during the last 2000 yr. Nowadays, channelization is much more widespread in those countries that have undergone a remarkable economic development during the last century or so (e.g., United States, European countries, Japan). In the United States, the federal government has been rechanneling rivers since the 1870s and more than 8000 miles of streams and rivers have been channelized during the 1950s and the 1960s for agricultural purposes.

Often channelization has induced severe effects on the environment (e.g., channel dynamics, groundwater resources, aquatic and riparian ecology, etc.) as well as on human structures (e.g., bridges, roads). For this reason, in some countries, especially in those strongly affected by channelization, there have been some changes in the attitude about stream management through a more careful use of traditional methods, through the use of different approaches (in particular geomorphological and ecological ones) and the restoration (or rehabilitation) of existing channelized rivers.

TYPES OF CHANNELIZATION

Channelization is carried out through different engineering methods that can be used one by one or by more than one method at the same time, according to river characteristics (e.g., channel cross section, channel gradient, bed and bank material, vegetation) and purposes of intervention (flood control, urbanization, agriculture, navigation). The most commonly adopted methods are briefly described.

Resectioning by Widening and Deepening

Widening and deepening increase the channel cross section; therefore, channel capacity to contain flows is increased and floodplain is inundated less frequently (flood control and agricultural purposes). In some cases this type of intervention is adopted to lower the water table for the improvement of agriculture. Channels are commonly designed with trapezoidal cross sections, but rectangular sections can be used where banks are stable (e.g., concrete banks) and triangular sections in small ditches.

Straightening

Straightening implies the cut of river bends (meander cutoff in the case of a meandering river); it produces shortening of the river channel, increasing of the gradient, and increasing of the flow velocity. The purpose is to reduce flood heights.

Levees (or Embankments)

The aim of levees is to increase channel capacity so that flood flows are confined and do not inundate the areas adjacent to the channels (floodplains), which would be inundated under normal conditions. Levees generally have a trapezoidal section and can be built close to channel banks (in this case levees must be quite high) or more far apart (for instance including the ‘‘shifting belt’’ or the ‘‘erodible corridor’’ of the river). This type of intervention, which is used both in rural and urban areas for flood control, requires extensive maintenance of the structure itself (geotechnical properties of materials may decay through time) as well as of the river channel [aggradation of the river bed may occur once the flows have been confined within embankments; e.g., several lowland rivers in the Po Plain (Italy) or braided rivers in New Zealand].[1]

Flood Walls and Lined Channels

This type of method is commonly used in urban areas where other kinds of channelization are limited or where access for maintenance is restricted.[2] Lined channels generally have a rectangular cross section with vertical sides made of concrete. This type of channelization produces a remarkable decrease of channel roughness, an increase of flow velocity, and, consequently, a decrease of water level for a given discharge.

Bank Protection Structures

Groynes are structures built transverse to the river flow and extending from the banks into the channel. The aim of these structures, which deflect the direction of the flow, is to protect the banks from erosion processes and, in some cases (groynes can be either impermeable or permeable), to induce sediment deposition behind the structures. The use of revetments is another technique adopted to prevent bank erosion. Different materials (concrete, gabions, synthetic materials, live or dead vegetation) are used for revetments.

Diversion Channels

New channels can be constructed to divert flows out of the existing channel (e.g., the Danube River in Vienna). Diversion channels are usually aimed at flood control (for instance where river channel cannot be resectioned or where levees cannot be built or built higher) and agriculture improvement.

Culverts

This type of channelization has often been used for urban streams, but also for small rural/mountain streams. In the latter case large-diameter concrete pipes are used. Culverting of a stream is most likely the ‘‘hardest’’ type of channelization since it implies the disappearance of the stream below ground surface for short or longer reaches.

EFFECTS OF CHANNELIZATION

Several studies have documented that channelization may have different effects on channel morphology, riparian and floodplain ecology, human infrastructures, etc. (Table 1). Such effects regard not only the channelized reaches of a river but, quite often, also

Table 1 Examples of studies documenting the effects of channelization

Location	Effects (channel morphology, ecology, structures, etc.)	References

the upstream and downstream reaches (e.g., nickpoint migration; increased flood discharges in the downstream reaches). In some cases the effects of channelization have been really dramatic since early channelization projects were designed with little or no consideration of sediment transport and river dynamics.[3] The effects of channelization may be grouped into the following categories: river morphology and dynamics; hydrology; ecology; human structures and activities. Since in many situations channelization is not the only human impact on rivers and their drainage basins, it is worth noting that most of these effects are often the results of a combination of such impacts (channelization, dams, sediment mining, land use changes).[4]

River Morphology and Dynamics

River morphology and dynamics can be significantly affected by channelization (Fig. 1). Since the different types of channelization (see previous section) imply

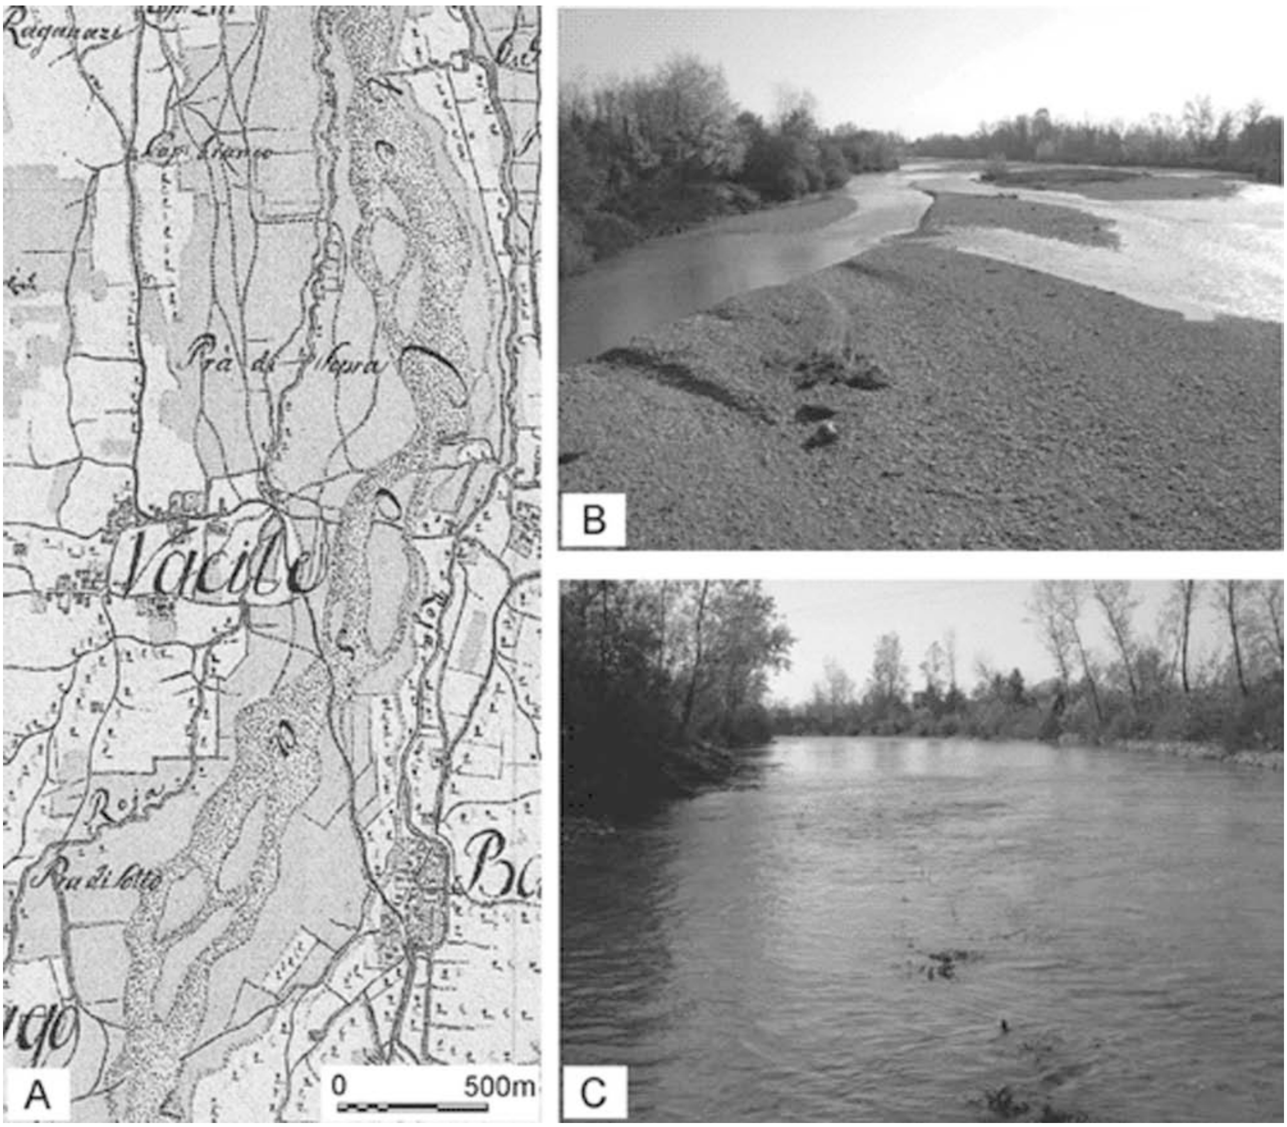

Fig. 1 Channelization of the Cosa Torrent (Tagliamento River basin, Italy): the braided reach of this torrent has been channelized at different degrees (strong channelization in the upper reach, softer channelization in the downstream reach): (A) old map (1805) showing the braided morphology of the Cosa Torrent prior to channelization; (B) conservation of the braided morphology in the downstream reach where levees were constructed 150–200 m apart; (C) disappearance of the braided morphology (nowadays the channel is only 35 m wide) following several channelization works (straightening, construction of levees, etc.).

changes in the morphological and hydraulic characteristics of a river (width, depth, slope, bed and banks roughness), morphological adjustments are likely to take place to attain a new equilibrium condition. As regards bed-level adjustments, river incision, due to increased stream power, is a common phenomenon, but also bed aggradation is not infrequent (e.g., in downstream reaches or following a period of channel incision). ‘‘Classical’’ examples of channel evolution due to channelization, and in particular to straightening, are those documented in the southeastern United States.[5] Other remarkable effects are those produced by the construction of levees (or by incision induced by other types of channelization[6]): such construction dramatically changes sediment fluxes, reducing sediment deposition in the floodplain.

Hydrology

Channelization works affect river and floodplain hydrology. As for floods, channelization generally produces higher velocity in the channelized reach (therefore lower water stage) but can induce increased flood discharges in the downstream reaches due to reduction (or elimination) of floodplain storage and to an increased hydraulic efficiency of the channels. Deepening of the channel or incision induced by channelization may strongly affect hydraulic relationships between the river and its floodplain. In the case of unconfined aquifer, the lowering of the water table is likely to occur, whereas in the case of confined aquifer an increase of stream flows may take place.[7] In coastal reaches, changes of water-table levels can produce soil salinization due to variations in salt wedge position. In very low gradient rivers, overbank flows, which under natural conditions are due to backwater effects and are fundamental from an ecological point of view, can be significantly reduced or eliminated. In addition, there are several examples of the effects of channelization on water quality.[2]

Ecology

River channelization frequently has serious effects on aquatic and riparian ecosystems, but may have far-reaching effects extending into the floodplain. Both flora and fauna along the river are affected by changes induced by channelization, such as morphological (e.g., disappearance of pool-riffle sequences), sedimentological (e.g., more uniform grain-sizes), and hydrological changes (e.g., changes in water levels and temperatures). A detailed reconstruction of riparian vegetation recovery patterns following stream channelization has been carried out in West Tennessee.[8] Floodplain ecosystems may be affected since hydrological and sedimentary connectivity between the river and its floodplain may dramatically change (decrease of overbank flows, lowering of water tables, etc.). Wetland environments, which are often drained for agriculture, are frequently affected by channelization.[9] Finally, it is worth pointing out a recent study, on the Spoon River (Illinois), describing stream aggradation induced by channelization and the likely positive effects for the river ecology.[10]

Human Structures and Activity

In addition to several beneficial effects for human activities (urbanization, agriculture, navigation), channelization may have some negative effects for man. The most common effects, frequently induced by channel instability (e.g., incision or bank erosion), are damage to transportation and communication infrastructures and loss of land. In some cases such effects have been evaluated in terms of economic costs.[11] As for floods, it should not be forgotten that channelization itself induces an increase of human occupation and activities in floodplains and therefore an increase of flood risk.

CONCLUSIONS

Channelization, which includes a series of engineering methods to modify river channels, or create new channels, is widespread throughout different environmental settings and aims at flood control, land drainage improvement for urbanization and agriculture, maintenance or improvement of navigation, and reduction of bank erosion. Most of the published studies have focused on negative effects of channelization, but it must be recognized that there are several situations where channelization has been necessary and useful.

In many countries, especially in those most affected by channelization and related effects, river management approach has undergone some changes in the last decades. There is more awareness that traditional engineering methods are not always the best practice for rivers and related environments, and that remarkable adjustments may take place in channelized rivers, especially in higher-energy reaches. Nowadays river managers not only have ‘‘softer’’ techniques (e.g., bioengineering techniques) at their disposal but also geomorphic and ecological knowledge allowing more comprehensive approaches to manage fluvial environments (e.g., basin-based approaches and capability to predict the potential effects of channelization). There are also increasing number of examples concerning enhancement, rehabilitation, or restoration of existing channelized rivers.[3]

River Channels

Paul F. Hudson
Department of Geography and the Environment, University of Texas at Austin, Austin, Texas, U.S.A.

INTRODUCTION

The earth's surface is organized into an integrated system of watersheds drained by rivers that function to transport water and sediment. In addition to their role in removing runoff and sediment, rivers perform important ecological functions, represent valuable habitat to aquatic flora and fauna, are laterally connected with riparian ecosystems, and represent a longitudinal corridor between terrestrial and marine settings. Since the beginning of civilization, humans have depended on rivers as resources for food and water, irrigation, and transportation. Humans have compromised the ecological functioning of many rivers because of exploitation related to irrigation, commerce and navigation, and flood control.[1,2] Changes to river channels frequently occur because of modifications to the physical controls on river channels, sediment, and streamflow. Modification to the streamflow and sediment regime occurs indirectly because of land degradation or dams within the upper basin, or by direct engineering modifications to the main-stem channel. Changes in these physical controls have significant implications to the morphology, behavior, and ecological viability of rivers and are likely to be somewhat unique to each river basin. Nevertheless, to understand the magnitude, timescale, and character of river response, it is essential to understand the fundamental processes controlling river channel morphology.

Rivers exhibit significant variability in form and behavior, and develop a channel pattern in response to hydraulic and sedimentary controls.[1] Classification of river channel patterns is essential for understanding how fluvial processes alter rivers, and for effective restoration and management. The coarsest level of river classification is based on whether a river is bedrock confined or is free to adjust its channel within its floodplain, also known as an alluvial channel. Rivers in contact with resistant bedrock are not able to dynamically adjust their channel, such as a river flowing within a narrow canyon, and are commonly dominated by much older structural controls such as folds and faults. Alluvial channels, alternatively, flow within a bed of their own sedimentary deposits, alluvium, and are therefore free to adjust their channels in four dimensions: slope, planform, width, and depth.[1] Alluvial river channels have been classified according to several criteria, including whether a channel is dominated by suspended or bedload,[3] has single or multiple channels, and by planform (overhead) pattern.[5] The latter is the most utilized approach, with the three dominant channel patterns being braided, meandering, and anastomosing. The planform approach to channel classification is also common because of its ease of application using a variety of data types and geographic techniques, such as maps, air photos, satellite imagery, and GISs (geographic information systems). Meandering rivers are the most studied because elements of their channel geometry exhibit systematic empirical relationships between different morphological elements, such as the relationship between meander bend wavelength and the spacing of pools and riffles (Fig. 1).

PROCESS: DEPOSITION AND EROSION

River channel patterns are ultimately controlled by a unique combination of hydraulic and sedimentary controls. However, at a fine scale, channel adjustment occurs because of the process of fluvial erosion and deposition. Deposition of sediment, bedload or suspended load, results in channel bed aggradation (vertical adjustment), and the formation of channel bars (lateral adjustment). Deposition becomes dominant when sediment load increases relative to discharge, resulting in the capacity of the channel to transport the load supplied being exceeded. Deposition also occurs if the channel competence decreases relative to sediment size. Excessive channel bed aggradation has significant consequences to the style and behavior of alluvial channels, and over historical timescales has frequently occurred because of land use change triggering excessive soil erosion. Such changes also have negative consequences to the ecological functioning of channels, a topic that has become a major area of research by fluvial geomorphologists.[2]

Channel erosion occurs by two distinct processes, entrainment of channel bed sediment (scour) or mass wasting of channel banks, which results in channel banks collapsing into the channel bed. Channel scour occurs when shear stress, controlled by channel slope

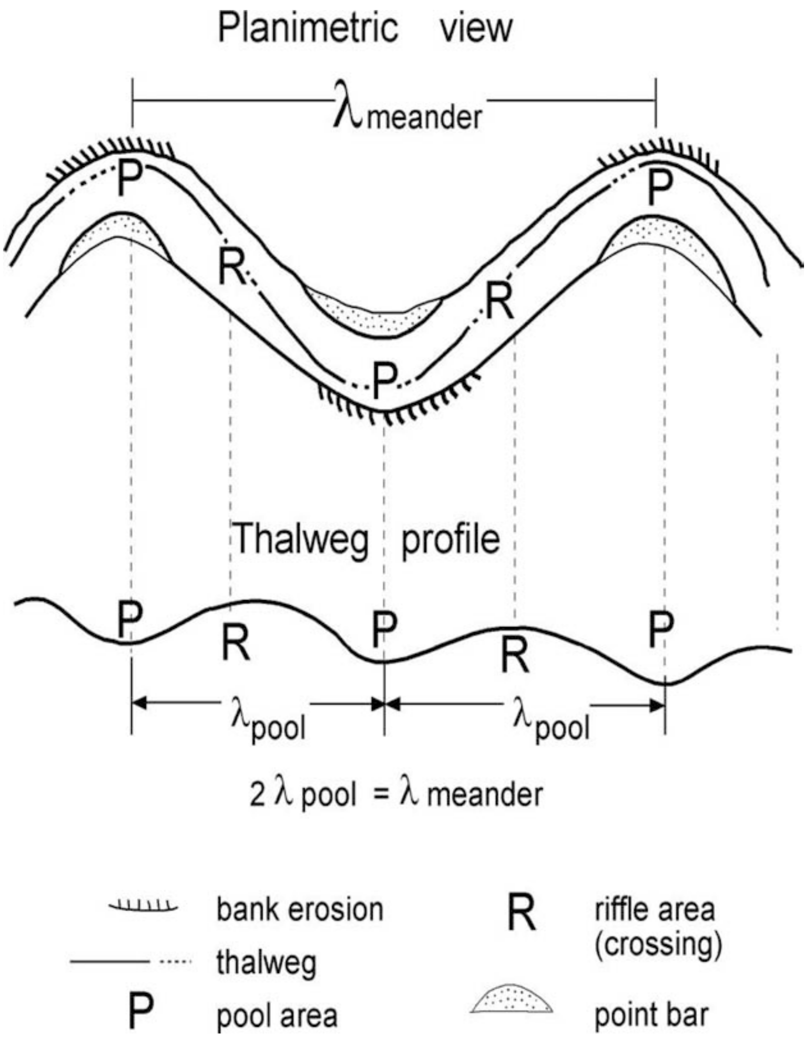

Fig. 1 Geomorphic characteristics of meandering rivers. *Source*: From Ref.[4].

and flow depth, exceeds the critical or threshold shear stress required for channel bed sediments to be entrained. The energy required to erode is largely dependent on sediment size, but factors such as packing and particle shape are also important.[1] Entrainment and channel scour are velocity-dependent, and are greatest during large streamflow events. During large streamflow events, channel banks in small rivers are often eroded directly by fluvial abrasion. However, most rivers' channel banks are eroded primarily by mass wasting, which is fundamentally a gravity-driven process. Mass wasting results in bank material collapsing into the river after the bank height becomes unstable. In most cases, channel bank erosion is a two-part process, whereby channel bed scour adjacent to the channel bank results in over-steepening, and subsequent bank collapse. Because this often occurs during or shortly after large streamflow events, saturation of the bank material is also important, which reduces the shear strength of bank material by increasing the weight and decreasing cohesion of bank material. The resistance of bank material to erosion is largely dependent on the cohesion of bank material, a function of the silt–clay within the bank material.[6] Most channel banks, however, have heterogeneous deposits, with coarse-grained channel deposits being capped by fine-grained flood deposits.[1]

Erosion and deposition, therefore, occur over very short periods, ranging from instantaneous to single-event timescales. However, the location of erosion and deposition within a river reach often occurs in rather predictable locations influenced by the planform channel geometry.

CHARACTERISTICS OF ALLUVIAL CHANNELS

The characteristics of alluvial channels may be considered from the standpoint of control and response (Table 1). While the three types of alluvial channels considered here each have unique characteristics, there are also several common features, providing a

Table 1 Characteristics of river channel patterns

Characteristics		Anastomosing	Meandering	Braided
Control	Gradient	Low	Moderate	High
	Energy	Low	Moderate to low	Moderate to high
	Flow variability	Low	Moderate	High
	% silt-clay in banks	High	Moderate	Low
	Dominant sediment load	Suspended	Suspended and bed load	Bed load
Response	Sinuosity	High	High to moderate	Low
	Width: depth ratio	Low	Moderate	High
	Lateral migration	Rare	Common	Common
Planform depiction				

framework for comparisons between anastomosing, meandering, and braided rivers. Having an understanding of the characteristics of channel patterns is important because it can be used to understand and predict the behavior of an individual river system, as well as providing a guide for more effective river management and river restoration projects.[2,7]

Meandering rivers have a single channel with a sinuosity (ratio of channel length to valley length) ranging from about 1.5 to 3.5. Meandering rivers are the most studied of any channel type, in part because their meander bend geometry is directly linked to stream energy.[8] Thus, the size of meander bends is scale-dependent, and there are close relationships between channel width and radius of curvature, meander bend wavelength, and the spacing of pools and riffles.[4] Similarly, the planform geometry of meandering rivers is associated with a systematic pattern of erosion at channel cutbanks and pointbar deposition on the inside of meander bends (Fig. 1). The energy regime (the product of slope and streamflow) of meandering channels is generally moderate to low. Meandering rivers with high amounts of silt–clay in the bank material are associated with relatively stable banks and with low rates of lateral migration.[3,6] The cohesion provided by silt–clay in the bank material increases bank stability, resulting in narrower and deeper channels (low w/d ratio), and such rivers would generally be associated with low-energy (low gradient) settings. High-valley gradients are often associated with an increase in sinuosity and lateral migration rates.[9] If such rivers also have sandier channel banks (low % silt–clay), it has been shown to result in unstable banks and frequent channel adjustment.[3] Meandering channels are dominant within large low-energy river valleys and the lower reaches of large drainage basins,[10] but meandering rivers can also be found in high mountain valleys where the gradient and sediment load are not too high.

Braided rivers have multiple channels separated at low flow by channel bars or islands, resulting in a high thalweg sinuosity.[7] At higher flows, channel bars and islands are inundated, reducing sinuosity as flow is contained within defined floodplain channel banks.[5] Braided rivers are generally associated with high rates of bedload transport, which may include either cobble, gravel, or sand bed channels. The flow regime displays greater variability than that in either meandering or anastomosing (Table 1) and commonly results in frequent reworking of channel bars. Many braided rivers have relatively stable vegetated channel islands, but these features are not considered permanent and are much younger than adjacent floodplain deposits. The high bedload of braided rivers requires a wide channel bed, resulting in high w/d ratios, and high channel gradient for transport (Fig. 2). Channel erosion rates can be locally high, but because of the absence of a planform pattern of erosion, such as within meandering rivers, cross-valley rates of erosion are variable. Deposition occurs on the downstream end of bars, and braided rivers are not associated with significant pointbar deposits.

Anastomosing rivers are characterized by a floodplain having multiple channels flowing within cohesive deposits.[7] Such rivers are associated with very low rates of channel migration, and instead are dominated

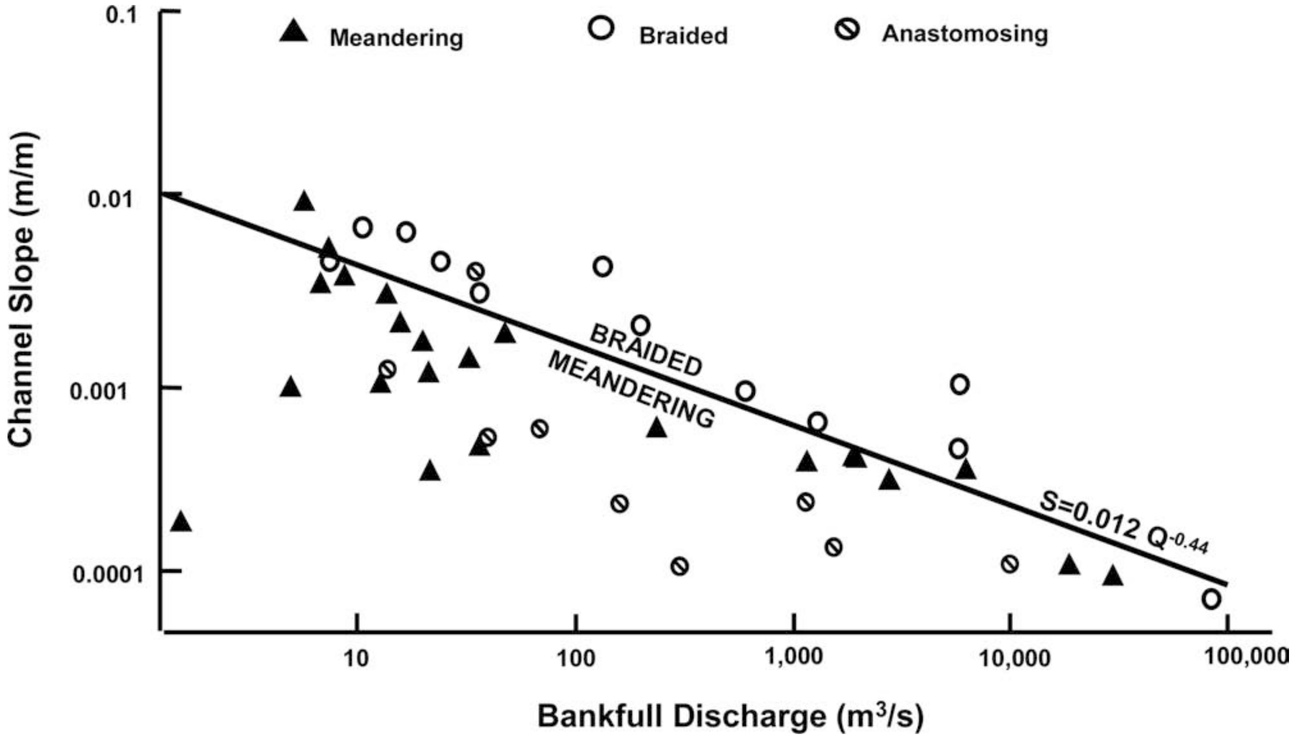

Fig. 2 Distinguishing river channel patterns based on hydraulic controls. *Source*: Modified from Ref.[5].

by avulsions, which occur when a channel abruptly switches courses. Anastomosing channels are low-energy channels,[10] which are dominated by fine-grained suspended sediment loads, cohesive channel banks, low w/d, and low channel gradients (Table 1). Anastomosing channels are not as common as meandering and braided channels, and have received considerably less attention from the research community. Nevertheless, fluvial geomorphologists and sedimentologists are currently debating as to whether anastomosing channels represent a true ‘‘end member’’ channel type, or whether there is a continuum of channel patterns from braided, to meandering, to anastomosing.

CONTROLS ON CHANNEL PATTERN

Alluvial rivers differ markedly in morphologic characteristics, and as suggested above, the controls that determine channel pattern. Understanding controls on channel pattern is critical to interpreting the fluvial geologic record, and for understanding the magnitude of channel change and timescale for channel adjustment when disturbances are introduced into a drainage system. Two broad approaches have generally been utilized to understand controls on alluvial channel patterns: hydraulic and sedimentary.

The hydraulic approach primarily utilizes bankfull discharge and slope and was championed by various works of Leopold.[5,8] The hydraulic approach has been successful at distinguishing between broad channel patterns (Fig. 2). For a given streamflow and sediment load, braided rivers are associated with a greater slope than meandering or anastomosing, which are generally associated with very low gradients. Anastomosing rivers are associated with low stream power, primarily owing to low valley gradients.[10] Essentially, the approach by Leopold and Wolman[5] suggests that a transition occurs, from meandering to braided, when a specific energy threshold is crossed. The general framework has stood the test of time fairly well because discharge and gradient relate directly to stream power. Along a river valley, a meandering to braided transition frequently occurs when slope exceeds a threshold value (Fig. 3), which is commonly because of geologic controls. More recent hydraulic approaches have utilized valley slope (e.g., Ref.[11]) rather than channel slope, because channel slope and channel pattern are interrelated.

A sedimentary approach was endorsed by Schumm,[3,6] who considered whether rivers were dominated by suspended or bedload transport, and the cohesion (% silt–clay) of bank material. It is important that the sedimentary approach be considered within the context of channel resistance to erosion.

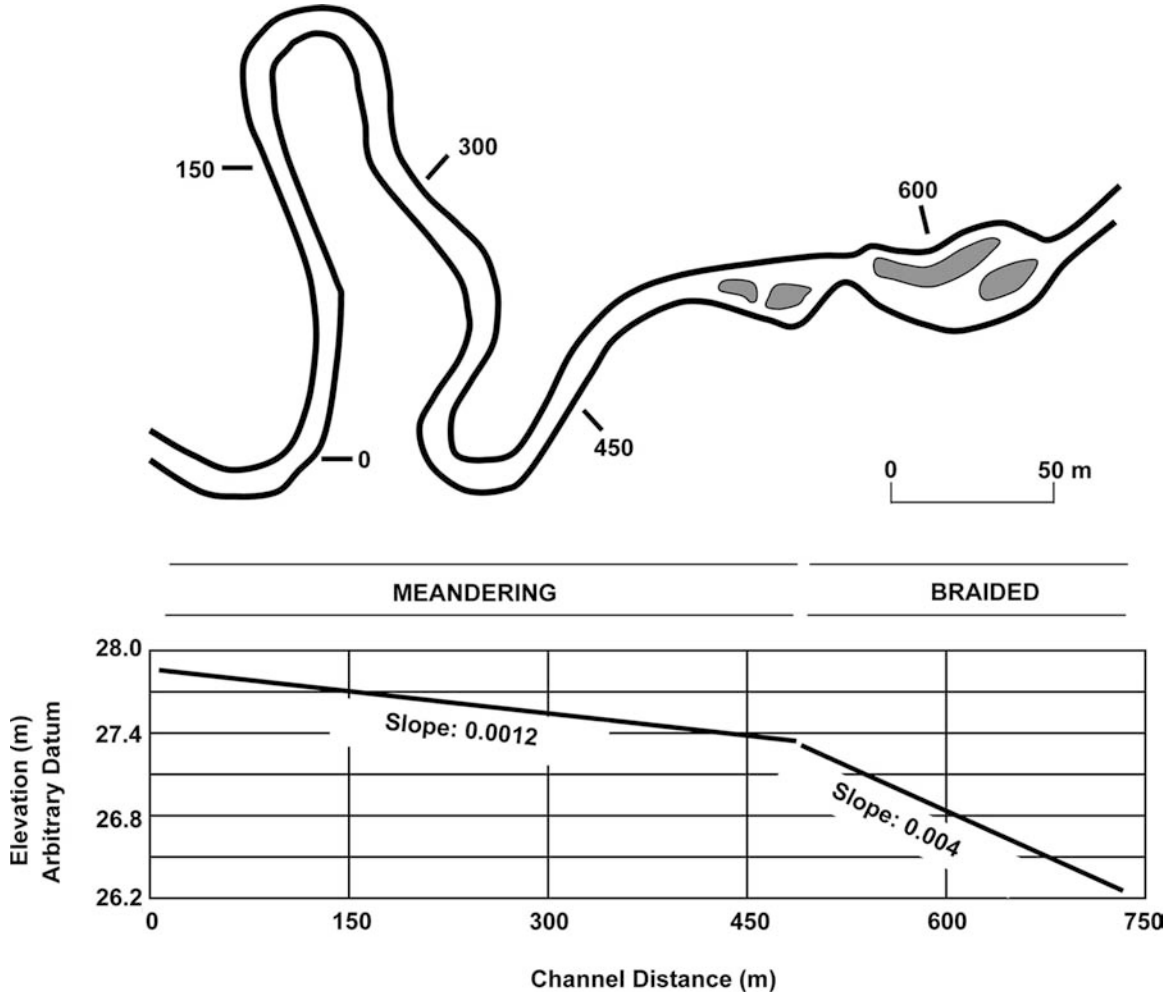

Fig. 3 Plan and long profile (slope) of Cottonwood Creek, Wyoming (U.S.A.). The river changes its channel configuration from meandering to braided because of an increase in slope. *Source*: From Ref.[5].

An increase in bedload or bed material size represents an increase in resistance to the hydraulics of streamflow. Similarly, an increase in the silt–clay of bank material represents an increase in cohesion, increasing bank resistance to erosion. While both approaches have been found effective, more recent work has sought to combine these two approaches. A study by van den Berg,[11] for example, combined stream power and bed material size and found that cobble bed braided rivers were associated with higher stream power than gravel bed braided rivers. Thus, resistance to streamflow provided by coarser bed sediments requires an increase in gradient (energy) for transport. Such an approach directly considers channel pattern with respect to flow competence, or the ability of a channel to entrain and transport its sediment, which relates to the fundamental processes of erosion and deposition (discussed above).

Additional influences on channel pattern include neotectonic controls.[9] While neotectonics would appear to represent a distinct control, it should actually be considered from the standpoint of either a hydraulic or sedimentary control. Neotectonics represent a hydraulic influence in the case of causing a reach-scale change in valley gradient, with valley slope usually being greater on the downside of a fold axis (hinge point), but lower on the downthrown block of a normal fault. Such changes in valley slope commonly result in an adjustment of sinuosity. Neotectonics also influences sedimentary controls, principally by emplacing bedrock or older deposits not associated with the contemporary hydrologic regime into the active channel. This produces a reach-scale change in bed sediment that can result in a local adjustment of channel planform and w/d ratios. During the past decade, there has been a much greater appreciation of the importance of neotectonics to alluvial river channels. Predictably, this occurs within high relief settings along active margins, but even low-energy coastal plain settings along passive margins commonly present significant neotectonic influences on river channel patterns.[9]

ENVIRONMENTAL CONSIDERATIONS

River channel change is environmental change. This is appreciated when evaluating the response of rivers to various human impacts, such as land use change and engineering. The potential impact of a specific human disturbance to an alluvial channel should be considered from the standpoint of its influence on channel controls, namely discharge (Q) and bedload (Q_{bl}). Schumm[3] developed a framework that can be used to consider the impact of specific human disturbances to channel morphology (Table 2). For example, an increase in discharge and bedload would result in an overall larger channel, manifested by an increase in w/d, sinuosity, and meander wavelength (Table 2, a).

River engineering occurs in several forms, but most commonly involves a direct modification to the channel, or direct alteration of the discharge and sediment regime. The two major ways in which this has occurred is through channel straightening and in the construction of dams and reservoirs, both of which were common for flood control and navigation from the 1930s to the 1970s. River straightening results in an abrupt increase in channel slope, and channels frequently respond by upstream incision of knick points (a local steep section of channel) and channel widening.[2] This frequently disturbs downstream aquatic habitat by reducing channel complexity, principally pool and riffle environments. Dam and reservoir construction has largely reduced downstream flow variability and sediment loads. The geomorphic effect is variable, but commonly results in downstream channel incision and a reduction in channel w/d (Table 2, b). Additionally, this disconnects the channel from the floodplain, altering riparian ecosystem processes.[7] The distance downstream that such actions influence the channel is largely governed by dam management and also the characteristics of tributaries that enter downstream of the dam.[1]

Table 2 River channel response to changes in bedload and discharge

b.	$Q^-, Q_{sb}^- \rightarrow w^-, d^\pm, (w/d)^-, \lambda^-, S^+, s^\pm$
c.	$Q^+, Q_{sb}^- \rightarrow w^\pm, d^+, (w/d)^\pm, \lambda^\pm, S^+, s^-$
d.	$Q^-, Q_{sb}^+ \rightarrow w^\pm, d^-, (w/d)^\pm, \lambda^\pm, S^-, s^+$

Q: streamflow (discharge); Q_{sb}: sediment bedload; w: channel width; d: channel depth; (w/d): channel width to depth ratio; λ: meander wavelength; S: channel sinuosity; s: channel slope

Land use change as a result of urban sprawl or conversion to agriculture has had a profound impact on alluvial river channels. The process of urbanization frequently introduces a specific sequence of changes to a river channel that occurs over a period of several decades. Most commonly, this includes initial incision and bank widening upstream owing to increased peak discharge and a reduction in sediment load (e.g., Table 2, c), with increased sedimentation and flooding downstream.[1] These changes are also responsible for significant channel degradation and loss of associated riparian habitat. Agriculture and logging have impacted many rural streams, and are largely associated with increasing runoff and peak discharge events. Associated with this has been an increase in sediment loads, particularly suspended sediment loads, because of an increase in soil erosion. These upper basin land use changes were manifested in downstream channel adjustments. This was widespread in the Midwest and Eastern U.S.A. from the mid-1800s to the early-1900s. Improvements in land management, particularly after the 1930s, have resulted in landscape and channel stabilization. Importantly, the consequence of this legacy of land mismanagement to river channels has resulted in a broader appreciation for effective watershed management, and in particular, has heightened our understanding of the linkages between upper basin controls and downstream fluvial processes and aquatic ecosystems. The scientific framework developed by fluvial geomorphologists from the mid-1950s to the 1990s is beginning to be applied by agencies charged with river management and restoration.

Largely in recognition of human impacts on river channels, there is increasing interest in river restoration.[2,7,12] The degree to which a river is restored to its predisturbance form depends largely on present human interests in a particular river. Rural rivers may be restored to their "natural" form, such as along the Kissimmee River in Florida (U.S.A.) where cutoff meander bends were reconnected. However, in urban areas where most river restorations occur,[12] rivers are often aesthetically restored, but the demand for channel stability dictates that rivers must not be allowed to act natural, ultimately requiring considerable channel engineering.

SUMMARY

Understanding controls and characteristics of alluvial river channels is increasingly recognized as vital to understanding broader riparian environments. Because alluvial river channels include several modes of adjustment, a change in hydraulic or sedimentary controls can have significant consequences to the physical integrity of a river, and the associated ecology of its channel and floodplain. For decades, separate disciplines studied rivers for distinct reasons, but there is increasing recognition of the need for an interdisciplinary approach to river management and restoration, particularly within geomorphology, biology, and engineering.

INTRODUCTION

In arid and semiarid regions, the limited availability of water is the major constraint to agricultural development. These regions are increasingly suffering from shortage of water. Moreover, due to human population explosion in most of these areas, the demand for water continues to grow. Indeed, of the 9.4 billion expected total world population by 2050, 8.2 billion will live in developing countries, of which 3 billion will reside in arid and semiarid environments.[1] Therefore, competition for water among different sectors will be heightened, and the share of water for agriculture will be shrinking. The limited renewable water resources and the need for higher agricultural productivity means that developing alternative water resources is necessary in dry areas.

One of the inefficiently used resources in arid and semiarid regions is rainfall surface runoff. Rainfall in these regions is generally low and erratic, and it is characterized with seasonal and spatial uneven distribution. Due to the absence of proper management, much of the rainfall is lost to deep seepage, evaporation, and/or unutilized surface runoff. The variability in rainfall results in crop productivity failure and is considered the most common and unpredictable problem that farmers in arid and semiarid regions have to face year after year.

The gross volume of rainfall received annually by vast dry areas may be substantial. Any significant increase in the quantity of water available to crops in arid and semiarid regions may improve the reliability and sustainability of agricultural production systems in these regions. Such increase can be induced by water harvesting, which offers an efficient approach for confronting the seasonality, uneven spatial distribution, and ineffectiveness of rainfall in dry regions. Among numerous examples in various locations around the world is a productivity analysis done for an agricultural area in the hot arid tropics of India. This study indicates considerable improvement in gross monetary returns under diversified cropping systems adopted due to improved dry-land farming technologies including water harvesting through creation of farm ponds.[2]

BACKGROUND

Water harvesting is not a new development but rather an ancient method of water supply.[3–5] Fraiser[6] reported several examples from the literature of early water harvesting structures. Researchers found such structures that date back over 9000 yr in the Edom Mountains in southern Jordan. Some other evidence was identified of simple forms of water harvesting practiced in the Ur area in Iraq at around 4500 B.C. The term was probably cited for the first time in the literature by Geddes in 1963 defining it as the collection and storage of any form of water, either runoff or creek flow, for productive use.[7] This definition, as well as others, focuses on surface runoff as the key factor in water harvesting, the source of runoff being mainly rainfall and snowmelt flowing from slopes and in ephemeral streams.[8]

During the past 40 yr, water harvesting has been receiving renewed attention.[9] Boers and Ben-Asher[10] reviewed the achievements in this field during the 1970s. Research during that period emphasized two aspects: surface runoff inducement, as well as runoff collection and conservation. Considerable research was done on methods to reduce surface storage and infiltration losses. Runoff farming and the issue of relative sizes of the catchment area and storage reservoir have recently concentrated thorough investigation efforts.[11–13] However, very little was done concerning the more fundamental physical and hydrologic modeling aspects of water harvesting. Nevertheless, this field is currently capturing significant attention.[14–16]

The goal of this chapter is to provide an overview of various water harvesting methods and to present a case study on the application of reservoir siting in a dry marginal area of Lebanon using the hydro-spatial AHP method that was developed for that purpose.

OVERVIEW OF WATER HARVESTING METHODS

Classification of Water Harvesting Techniques

Boers and Ben-Asher[10] defined three main characteristics of water harvesting. First, it is applied in arid and semiarid regions where runoff is intermittent; second, it depends upon local water such as surface runoff, creek flow, springs, and soaks; and third, it is relatively small-scale in terms of catchment area, storage volume, and investment. Other important elements in the definitions of water harvesting are the form of runoff, the use of runoff, and the harvesting technique itself.[8]

Most authors have their own classifications of water harvesting techniques. However, there is a general consensus in the literature[8] that the methods of water harvesting can be divided into two main categories:

Macrocatchment, or runoff farming, where surface runoff water collected from a relatively large area is conveyed by means of small channels, waterways, and/or small diversion dams to a storage reservoir or to a cultivated field.

Microcatchment, where a within-field system is used to harvest water for one or several trees or bushes from a relatively small area.

According to Fraiser,[6] there are three basic types of water harvesting systems: the Direct Water Application System (DWAS), the Supplemental Water System (SWS), and the Combination System (CS). In the DWAS the runoff water is stored in the soil profile of the crop growing area during the precipitation event. This approach includes two major configurations:

Floodwater irrigation, a system in which runoff is diverted directly from small natural drainage channels using water spreading techniques.

Microcatchment irrigation, where a microcatchment consists of a small prepared runoff collecting area directly upslope of the growing area.

In the SWS, the collected water is stored offsite in a storage facility and applied later to the crop area using some form of irrigation system. In the CS, the runoff water is applied first to the crop area, where some water infiltrates into the soil profile, and then the excess water is diverted into a storage facility for later application.

Water Harvesting Planning and Design

There is no standard procedure to simply select a water harvesting technique for immediate implementation. Siegert[9] stated that apart from basic technical considerations concerning topography and soil characteristics, the selected method must be compatible with local lifestyles, social systems, and willingness of the beneficiaries to adopt it. Unless people are actively involved in development projects that are aimed to help them, such projects are doomed to fail. Samra et al.[17] considered that rainwater harvesting systems should be site-specific, environmentally sound, compatible with indigenous traditional knowledge, present minimum social conflicts, and meet multiple objectives.

A prerequisite to designing any water harvesting system is the identification of suitable areas for applying water harvesting technology. Site selection for the needed storage facilities is the most important step in water harvesting system design. It requires the knowledge of climate, topography, natural vegetation cover, land use, soil characteristics, agricultural practices and socio-economics of the area.[18] El-Awar et al.[15] added that comprehensive hydrologic analysis of candidate watershed(s) is a key element in successful planning of water harvesting systems.

Collection of the necessary data and information has been traditionally performed through available reports, maps, or other sources such as surveys and field investigations. However, on regional level the accomplishment of data collection can hardly be made by such traditional means because it would be too expensive and time consuming. Remote Sensing (RS), defined as the science of deriving information about Earth resources from satellite images and aerial photos, can be utilized for timely and accurate data collection. The main advantage of satellite imagery is that it provides information about natural resources and land cover patterns quickly and inexpensively. Digital Geographic Information Systems (GIS) designed for data mapping, displaying, management, and analysis can improve the decision making process in water harvesting system planning by conducting analyses otherwise rendered impractical and infeasible. GIS-hydrologic model combinations can be used for predicting surface runoff and other hydrologic parameters needed for water harvesting design purposes.

In the context of water harvesting planning, Giraldez et al.[19] mentioned that several hydrologic models have been proposed for evaluating water harvesting systems from the simple Shanan and Schick[20] model to the more detailed model of Illangasekare and Morel-Seytoux.[21] Kutsh[22] introduced an equation based on empirically derived parameters to approximately determine the quantity of water held back by water harvesting structures. These empirically derived parameters are the water harvesting area (WHA), the water losses in the WHA, and the water losses from the terraces and slopes of the command area. Karmieli et al.[23] developed an empirical model to predict runoff yield in the Negev Desert. The equation assumes a linear relationship between annual rainfall and runoff in a given watershed taking into account the reduction in runoff efficiency with the increase in catchment size. Samra et al.,[17] while presenting the process of hydrologic design for water harvesting structures, mentioned several methods to estimate the peak runoff and the runoff volume. For the computation of peak runoff, they recommend the use of the Rational Method as well as several other empirical formulae developed under different situations. With respect to the computation of runoff volume, they suggested the use of the SCS Curve Number Method. El-Awar et al.[16] used RS and GIS techniques conjunctively with hydrologic modeling and the Analytic Hierarchy Process (AHP) for siting small water harvesting reservoirs in dry marginal areas.

In summary, water harvesting planning consists of the following steps:

- Collection of needed data on hydrology, soil characteristics, land cover, and topography of the investigated area using technologies such as RS.
- Utilization of a computer based analytical environment for data capturing, storage, manipulation, and analysis such as GIS.
- Comprehensive hydrologic analysis of the investigated area based on collected hydrologic data and hydrologic modeling.
- Use of decision making tools for evaluating the different alternatives of water harvesting systems, including site selection and storage volume.

HYDRO-SPATIAL AHP METHODOLOGY FOR SITING WATER HARVESTING RESERVOIRS IN DRY AREAS: A CASE STUDY

Hydro-Spatial AHP is a methodology for locating and ranking suitable sites for small water harvesting reservoirs. This methodology is based on quantifying the overall site suitability for such reservoirs through a Reservoir Suitability Index (RSI) calculated for potential candidate sites. This index is developed using hydrologic modeling in conjunction with GIS and AHP. The resulting procedure excludes sites where reservoirs cannot be built, due to any physical constraints and/or restrictive land use policies and regulations, and ranks the rest of the sites based on their respective RSI values.

AHP, originally developed and introduced by Saaty,[24] has been widely used for quantitative assessment and ranking of different alternatives.[25] GIS technology is used in this work for building and managing the needed digital spatial database to provide the site attributes required for the decision process. Hydrologic modeling is used to determine the potential runoff volume that represents a major decision criterion in the hierarchical ranking process of different candidate sites.

Site attributes, related to different decision criteria, are determined through hydrologic modeling and GIS applications. Both techniques are used simultaneously for estimating the necessary spatial hydrologic parameters. The AHP decision procedure uses the calculated attributes in order to rank potential sites based on their suitability for water harvesting reservoirs.

The RSI is based on a set of selection criteria defined by experts and discussed below. The methodology used for RSI computation can be represented by the following steps: 1) identification of selection criteria; 2) development of a hierarchy structure; 3) deciding on the Relative Weights (RWs) of elements in different levels of the hierarchy structure; 4) determination of related site attributes through GIS and hydrologic modeling; 5) calculation of the RSI for all tested locations; and 6) ranking these locations based on the calculated values of their indexes.

(1) Selection criteria: The first step is to define the selection criteria. Such criteria are used to compute the RSI and rank the sites that are under investigation. The major selection criteria in this case study are potential storage and land cover characteristics of candidate sites.

(2) Decision hierarchy structure: The selection criteria are arranged in a multilevel hierarchical decision structure. The first level of this structure represents the ultimate objective of the decision process. The major selection criteria are placed in the second level of the hierarchy structure. These major criteria are further detailed and categorized into different subcriteria within subsequent higher levels of the structure. The highest level contains attributes or attribute classes that are determined through hydrologic modeling and GIS applications. Classification of attribute values into a finite number of classes would save on the efforts needed for the evaluation of a large number of tested sites.

The hierarchy structure that is developed for this work is shown in Fig. 1. Its first level contains the RSI, which is calculated for all candidate sites. The major decision criteria that are used to calculate the RSI value are arranged in the second level of the structure. These criteria are the potential storage and land cover characteristics of the candidate sites. In the third level,

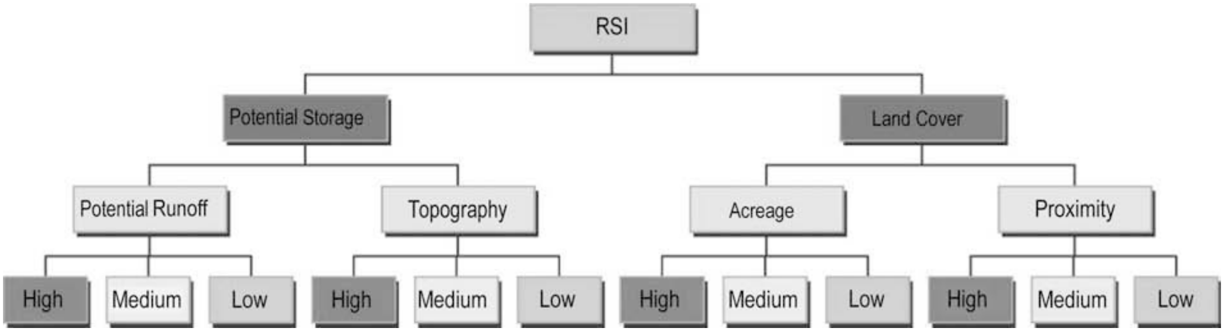

Fig. 1 Hierarchy structure for water harvesting reservoir siting.

potential surface runoff as well as topographic and soil characteristics are assessed. These represent the component subcriteria that are used to evaluate the potential storage. Land cover is subdivided into two level-3 subcriteria: the proximity to benefiting agricultural lands, and the total acreage of such benefiting areas. The fourth level, which is the last level, contains the attribute classes that are related to the major criteria and subcriteria of the second and third levels, respectively. The values of these attributes are extracted from the developed GIS and hydrologic model for the area. These values are grouped into a number of classes based on value ranges of different selection criteria and subcriteria.

(3) RWs: Related selection criteria, subcriteria, and attribute classes are compared to each other in pairs in order to develop RWs for all elements in the decision hierarchy structure. All pairs of attribute classes that belong to the same subcriterion are compared to each other. Experts qualitatively judge all attribute classes for their RWs in influencing the corresponding subcriterion in the neighboring upper level of the hierarchy structure. This qualitative judgment is quantified by fitting different degrees of preference, or significance, into a numerical scale. Table 1 shows the scale used to represent different preference degrees in this case study.

The degrees of preference of certain classes over the others are represented by their corresponding numerical values that fill the cells of a decision matrix. The decision matrices of all comparisons of attribute classes of level 4 are shown in Table 2.

The matrix provides a format for quantitatively comparing the weight or the importance of each attribute class relative to other classes that belong to the same subcriterion. The numerical values in the matrix cells represent the preference of one attribute class against another. For example, the first row of Table 2 shows that high potential runoff level is preferred five times and nine times more than the medium and low levels, respectively. It is noted that the diagonal cells of the decision matrices are always filled with values of unity because they represent the self-comparison of attribute classes. The RW of an attribute class is considered as the normalized eigenvalue of the class row within the comparison matrix. The eigenvalue is calculated as the Nth root of the product of all the elements of the class row, where N is the total number of elements in that row. The computed eigenvalue is normalized by dividing it by the summation of the eigenvalues of all the rows of the matrix.[26] The RWs of the subcriteria and major criteria applied in this work have been developed using the same procedure. The corresponding decision matrices are presented in Tables 3 and 4.

(4) Site attribute determination: The site attributes related to different selection subcriteria are determined through GIS and hydrologic modeling applications. A digital GIS is built for the entire investigated area. Different data layers of the GIS database are used directly in computing the needed site attributes. The GIS database is also used indirectly in this process by providing the needed input data for the hydrologic model to determine the potential surface runoff at the candidate sites. The developed site attribute classes are

Table 1 Numerical scale for qualitative preferences

Degree of preference	Corresponding numerical value
Indifference	1
Weak preference	3
Strong preference	5
Very strong preference	7
Absolute preference	9

Table 2 Decision matrix for attribute classes of level 4 of the hierarchy structure

	High	Medium	Low	Eigenvalue	RW
High	1	5	9	3.557	0.735
Medium	1/5	1	5	1.000	0.207
Low	1/9	1/5	1	0.281	0.058

Table 3 Decision matrix for level-3 subcriteria of the hierarchy structure

	Runoff	**Topography**	**Soil**	**Eigenvalue**	**RW**
Runoff	1	8	9	4.160	0.798
Topography	1/8	1	3	0.721	0.138
Soil	1/9	1/3	1	0.333	0.064
	Area	Proximity		Eigenvalue	RW
Area	1	7		2.65	0.875
Proximity	1/7	1		0.38	0.125

assigned their respective RWs that are used to calculate the RSI values at different sites.

(5) RSI computation: The RSI of a potential reservoir site is computed through the application of the following formula:

$$\mathrm{RSI} = \sum_{i=1}^{N_2} \mathrm{RW}_i \left[\sum_{j=1}^{Ni_3} \mathrm{RW}_j \mathrm{RW}_k \right] \tag{1}$$

where RW_i is the relative weight of level 2 major criterion i, RW_j is the relative weight of level 3 subcriterion j, RW_k is the relative weight of level 4 attribute class k, N_2 is the total number of level 2 major selection criteria, Ni_3 is the total number of level 3 subcriteria that belong to level 2 major criterion i.

The above equation represents the ratings approach of the AHP decision process.[26] The RWs of each group of level 3 subcriteria are multiplied by the RWs of their respective level 4 attribute values, aggregated together, and multiplied by the RW of the corresponding major selection criterion of the second level of the hierarchy structure. This equation is applied to calculate the RSIs of all potential sites of water harvesting reservoirs.

(6) Ranking of potential reservoir sites: The computed RSI values are grouped into several classes, and the investigated potential sites are ranked based on their respective RSI classes. Ranking the potential sites with respect to reservoir suitability helps in assigning priorities for different sites in the terminal stages of the decision process. The final phase of this process consists of producing an RSI map showing the ranks of all potential reservoir sites under analysis.

Table 4 Decision matrix for level-2 major criteria of the hierarchy structure

	Potential storage	**Land cover**	**Eigenvalue**	**RW**
Potential storage	1	4	2	0.800
Land cover	1/4	1	0.5	0.200

APPLICATION AND RESULTS

Pilot study area: This study focuses on Irsal, a remote Lebanese highland region located in the Northeastern dry marginal lands of the western slopes of the anti-Lebanon mountain range. The region is characterized by its semiarid weather with dry hot summers and cold winters, and its average annual precipitation is about 300 mm. This low precipitation depth, coupled with its non-uniform temporal and spatial distributions, has a magnified effect on the water resources budget in the region.

Decision criteria: All decision criteria and their respective RWs used in this work were based on indigenous knowledge and expertise in the pilot area as well as relevant literature.[15,27] Threshold values that define attribute class limits within the fourth level of the decision hierarchical structure (Fig. 1) were selected on the same bases as well. An interactive participatory approach was followed to make use of local farmers' experience to improve different criteria and attribute class limits extracted from the literature. Local expertise had also been heavily used in assigning the RWs of different attribute classes in the hierarchy structure.

All subwatershed outlets in the study area were considered as potential reservoir sites. The selection criteria were used within the hierarchy structure to calculate the RSIs of the potential sites under consideration. The land cover criterion in the decision hierarchy structure represents the proximity of a potential reservoir site to stone fruit orchards and other agricultural lands in the area, as well as the acreage of these benefiting areas. In other words, this decision criterion assesses the potential site based on the need for water in its vicinity.

The potential storage decision criterion is composed of the site topographic and soil characteristics, in addition to potential runoff component subcriteria. Potential surface runoff within individual subwatersheds was estimated by means of the Soil Conservation Service (SCS) Curve Number method. Watershed Modeling System (WMS), a comprehensive hydrologic modeling environment with GIS capabilities, was used to determine these estimates. A composite (area-weighted) curve number was derived for each subwatershed. The needed hydrologic and basin data were extracted from topographic, subwatershed, and land cover GIS overlays that were imported into WMS and processed for that purpose. HEC-1 model, interfaced with WMS, was used for runoff calculations. Runoff volumes from individual storms were determined, then routed and summed to estimate the potential annual runoff for all subwatershed outlets. Based on their individual values, these potential annual runoff volumes were classified into high, medium, and low classes.

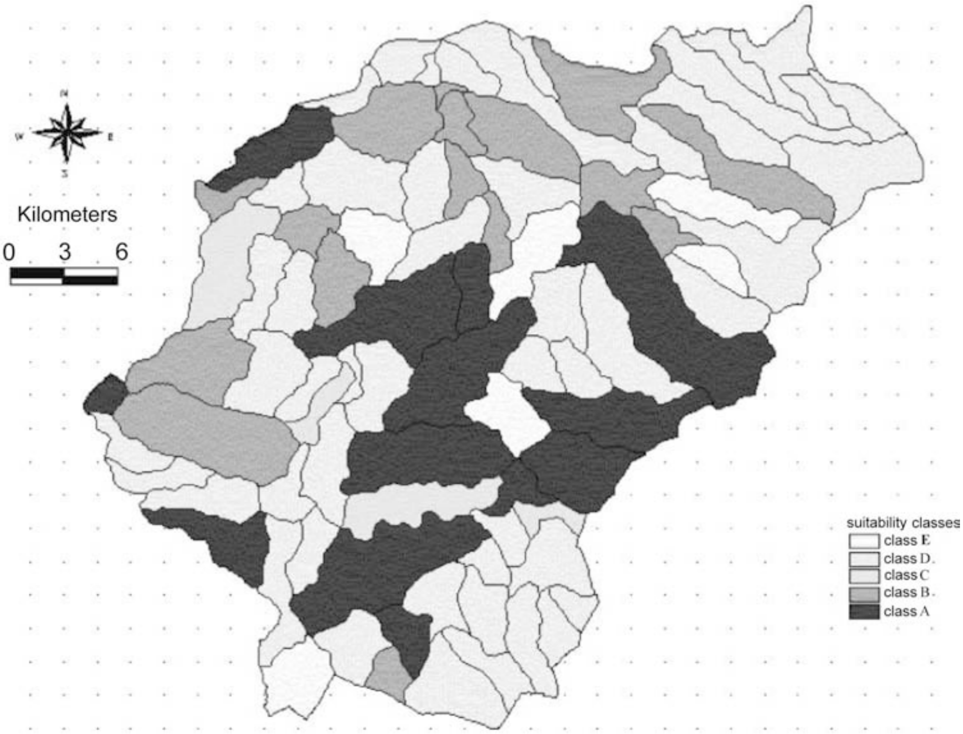

Fig. 2 RSI map.

The topographic and soil characteristics subcriteria were used in this study as indicators of the site potential storage capacity. Candidate sites with very steep or very mild slopes were considered to have relatively low storage capacities. Prevailing slopes of the investigated subwatershed outlets were determined from the topographic and subwatershed digital maps. Soil characteristics classification was based on the sites' soil texture and clay content. The needed information was extracted from relevant GIS data layers, and three soil permeability classes—high, medium, and low—were considered. Subwatershed outlets found to be on cracked limestone layers were excluded from further consideration.

Ranking of potential sites: The RWs of the attribute classes developed from GIS and hydrologic modeling applications were used within the decision hierarchy structure, and Eq. (1) was applied to calculate RSI values for all subwatershed outlets. Finally, RSI map was created for the considered RW combinations. Fig. 2 presents the RSI map that was developed. Five reservoir suitability classes, based on individual RSI values, were assigned for the considered subwatersheds. The highly suitable class was given the first rank (class A) and the suitable, moderately suitable, and weakly suitable classes were given the second, third, and fourth rank, respectively. The subwatersheds of the excluded sites were ranked as non-suitable (class E).

CONCLUSION

The Hydro-Spatial AHP methodology for small water harvesting reservoir siting combines the capabilities of GIS, hydrologic modeling, and AHP approaches. The application of the methodology shows that it works efficiently for siting small water harvesting reservoirs. Moreover, the methodology is highly flexible regarding the number, types, threshold values, and RWs of decision criteria on which the reservoir siting process is based.

The use of the same clearly defined hierarchical structure of decision criteria to rank all candidate sites insures the general objectivity of the methodology. However, the development of the criteria RWs is based on subjective expert preferences. Therefore, special care should be taken in developing these RWs that should always be defendable and subject to cross checking.

Sacramento–San Joaquin Delta

Mark J. Roberson
Keller-Bleisner Engineering, LLC, Sacramento, California, U.S.A.

INTRODUCTION

The Sacramento–San Joaquin Delta is the largest estuary on the west coast of North America. It serves as a major water supply conveyance facility for over 20 million Californians; provides habitat for many species of birds, mammals, and plants; and supports agricultural and recreational activities. It is the terminus of several primary rivers: the Sacramento, the San Joaquin, and the eastern tributaries of the Cosumnes, Mokelumne, and Calavaras. These watersheds drain 40% of the State's land area. Recreational uses of the Delta include boating, fishing, hunting, and wildlife viewing. Agricultural uses include the irrigation of a wide variety of tree, vine, vegetable, and row crops.

DELTA LANDS

The Delta of California covers an area of about 700,000 acres with about 60% of the land use dedicated to agriculture. In Table 1, current land use in the Delta is compared with historic native state. Following the 1849 gold rush many miners became farmers and through reclamation turned much of the Delta's swampland into productive agricultural lands. Due to the continual threat of flooding, more and more time and money was spent protecting lands through levees and drainage systems. Currently there are 57 reclaimed islands surrounded by levees designed to prevent high flow events from inundating low-lying areas. Large areas of the Delta are covered by organic soils that are up to 60 ft deep. Oxidation of organic soils has resulted in as much as a 15-ft loss in elevation.[1] Due to the drop in land elevation, there is increased pressure on the levees during flooding events.

WATER DEVELOPMENT

The first large-scale impact to the Delta was from sediment that originated from hydraulic gold mining in the Sacramento River watershed. The federal government stopped this form of mining in the 1884 but the residual transport of sediments continues. In addition to sediments, mercury, which was used to extract gold also made its way into the Delta. In some Delta channels, the sediment filled the river bottom channels to the point where navigation was impossible. The bed of the Yuba River, a tributary to the Sacramento River, was raised some 60 ft over a period of less than 30 yr.[2] Sediments also reduced the capacity for the Delta to contain floodwater and thus enhanced the need for levee protection.

In 1921 the State initiated the first water plan to address water supply and flooding issues. This plan was partially carried out by the Federal government through the Central Valley Project in 1933 and the State Water Project in 1951. Combined, these projects deliver, through pumping plants or direct diversions, over 7 million acre-ft of water annually (Table 2) to customers north and south of the Delta. Much of the controversies surrounding the Delta begin with how to use the Delta for conveying and protecting the drinking water supply and restoring its ecological health.

Flow control on the upstream watersheds and the construction of upstream and Delta levees has altered channel hydraulics and eliminated nutrient enriching flood-events. The Delta levees keep water moving through the Delta, preventing flooding of the natural floodplain and subsequent deposition of sediments (Fig. 1).

WATER QUALITY

Water quality in the Delta is influenced by two sources: the San Francisco Bay and the upstream watersheds. Tidal exchanges in the Bay-Delta bring salt water deep into the upper reaches of the Delta. Prior to the development of the Central Valley Project and the State Water Project, salt water would travel as far as Sacramento—nearly 70 mi upstream of the San Francisco Bay. With the advent of flow control on the rivers feeding the Delta, the extent of tidal action is much less and salinity intrusion is confined to only a small portion of the Delta. This has helped the water users maintain consistent water quality but it has removed an important component of the estuary's ecosystem. The water quality in the Sacramento, Cosumnes, Mokelumne, and Calavaras watersheds is excellent, however, multiple urban and agricultural use impairs the water quality as it reaches the Delta.

Table 1 Acres of emergent marsh in regions of the Sacramento–San Joaquin Delta

Region	Historic—1906	Current—1993	Percent change
North	53,660	4,460	−91
East	7,600	1,270	−83
South	470	650	38.3
Central and West	31,170	5,040	−86
Total	98,900	11,600	−89

Source: CALFED Bay-Delta Program, from USGS maps.

Water quality in the San Joaquin River watershed is heavily impaired by agricultural practices on the west side of the San Joaquin Valley with the main constituents of concern being naturally occurring.

One of the engineered functions of the Delta is to serve as a conveyance facility, moving water from the Sacramento Valley to the west side of the San Joaquin Valley and Southern California. Water moving through the Delta is pumped into the Delta–Mendota or the California Aqueduct at maximum rate of 11,000 cubic ft per second. During periods of low inflow to the Delta (summer, following a low precipitation winter) the export pumps can dewater many of the channels and sloughs. This dewatering results in ocean water or poor quality San Joaquin River water entering the export pumps and subsequently being delivered to the west side and Southern California.

Upstream water quality issues are typical of most major watersheds in the United States: nutrients, sediments and pesticides from agriculture operations, dairies and urban runoff containing household chemicals move downstream into the Delta. However, the drainage from the Westside of the San Joaquin Valley may pose the greatest challenge due to selenium, boron, and elevated levels of salinity. Unlike farm chemicals, selenium and boron are both naturally derived from the native soil that was formed from marine sediments. Common agricultural practices on the Westside soils include irrigation that solubilizes selenium and boron coupled with subsurface drainage that quickly moves the constituents to the San Joaquin River. In 1981 the U.S. Fish and Wildlife Service noticed deformities among the bird population in wetland refuges that received drainage water from the Westside. The deformities were eventually traced back to the elevated selenium concentrations that were as high as 1000 ppm when the known toxicity level to birds is less than 10 ppb. Although great strides have been made in reducing the concentration of selenium in drainage water, the levels are still too high for resident bird populations. The long-term effects of elevated selenium levels on Delta resources is still under investigation.[4]

Table 2 Delta flow components and comparisons, 1000 acre-ft for the period of 1980–1991

Inflows	Outflows
Sacramento River; 17,220	Outflow to Bay (21,020)
San Joaquin River; 4,300	Tracy Pumping Plant (2,530)
East Side Rivers; 1,360	Harvey Banks Pumping Plant (2,490)
Precipitation; 990	Consumptive use and channel percolation (1,690)
Yolo Bypass; 3,970	Contra Costa Pumping Plant (110)
Total; 27,840	Total (27,840)

Fig. 1 Salinity control gates at the Suisun Marsh protect the brackish water marsh in the west side of the Delta. The Suisun Marsh is the largest contiguous water marsh in the United States and contains 12% of California's remaining natural wetlands.[1] (Photo by Mark J. Roberson.)

Another constituent of concern is mercury that was used in gold mining operations in the Sacramento River watershed. Transported on sediments to the Delta the mercury containing sediments are found in marshes, on Delta islands, and in protection levees constructed using dredge material. Although the elemental form of mercury is used to extract gold, biotransformations of released mercury make it more available for biological uptake and food chain accumulation.

ECOLOGICAL RESOURCES

In the early 1900s striped bass and shad were introduced and have proliferated due to the abundant food sources. In the late 1990s the Chinese Mitten crab, thought to have originated from ship ballast, multiplied quickly feeding on indigenous Delta species. Plant life in the Delta is a diverse mixture of riparian scrub and woodland as well as emergent and seasonal wetlands. Migratory and resident bird populations are prolific due to the abundant food sources and protective habitat.

Delta fish species are numerous with some completing their life cycle within the Delta whereas others may simply pass through to upstream rearing habitat. The Delta smelt and the split-tail are two species that complete their lifecycle within the Delta. The split-tail rely on shallow warmer water for feeding and reproduction whereas the smelt require high freshwater flows particularly during the late winter and spring. Due to upstream flow control and export pumping, these habitats have been dramatically reduced. There are numerous salmon runs in all the primary watersheds.

The numerous channels, sloughs, and islands within the Delta serve as nesting and feeding grounds for residential and migratory birds. All anadramous fish from these watersheds must migrate through, or spawn in, the Delta.

RESTORATION EFFORTS

The CALFED Bay-Delta Program was established in 1995 to address ecosystem, water quality, water supply reliability, and levee and channel integrity issues of the Bay-Delta system. The Ecosystem Restoration element of CALFED lists the following stressors to the Delta's ecosystem: water diversions, channelization, levee maintenance, flood protection, rock placement for shoreline protection, poor water quality, legal and illegal harvest, wake and wake erosion, agricultural practices, conversion of agricultural lands to vineyards, urban development, habitat loss, pollution and the introduction of non-native plants and animals.

IMMEDIATE ISSUES OF CONCERN

The CALFED Bay-Delta program has identified nine major issues, requiring immediate attention during the first seven years (2000–2007) of program implementation. To refine the understanding of the issues, adaptive management during project implementation is envisioned.

- The impact of introduced species and the degree to which they may pose a significant threat to reaching restoration objectives.
- Recognition that channel dynamics, sediment transport, and riparian vegetation are important elements in a successful restoration program and the need to identify which parts of the system can be restored to provide the desired benefits.
- Development of an alternative approach to manage floods by allowing rivers access to more of their natural floodplains and integrating ecosystem restoration activities with the Army Corps of Engineers' Comprehensive Study of Central Valley flood management programs.
- Increasing the ecological benefits from existing flood bypasses, such as the Yolo Bypass so that they provide improved habitat for waterfowl, fish spawning and rearing, and possibly as a source of food and nutrients for the estuarine foodwebs.
- Thoroughly testing the assumptions that shallow water tidal and freshwater marsh habitats are limiting the fish and wildlife populations of interest in the Delta.
- A better understanding of the underlying mechanisms of the X2 salinity standard in the Delta and the resultant effects on aquatic organisms.
- A need to better understand the linkage between the decline at the base of the estuarine foodweb and the accompanying decline of some, but not all, species and trophic groups.
- Clarifying the extent to which entrainment at the Central Valley Project and State Water Project pumping plants affects the population size of species and invertebrates.
- Clarifying the suitability and use of the Delta for rearing by juvenile salmon and steel head.

Saline Seeps

Ardell D. Halvorson
Agricultural Research Service (USDA-ARS-SPNRU), U.S. Department of Agriculture, Fort Collins, Colorado, U.S.A.

INTRODUCTION

Saline seeps occur frequently in dryland farming areas throughout the Great Plains of North America and southern and western Australia and have been reported elsewhere.[1,2] This article addresses saline seeps in the Great Plains.

WHAT IS A SALINE SEEP?

Saline seep describes a soil salinization process resulting from dryland (rainfed) farming practices that allow water from precipitation to move through salt laden subsoils in the recharge area that eventually resurfaces at a downslope topographic area (Fig. 1). Saline seeps have intermittent or continuous saline water discharge at or near the soil surface downslope from recharge area. Crop growth in the saline seep area is reduced or eliminated because of increased soil salinity (Fig. 2). Saline seeps differ from other saline soil conditions by their recent and local origin, saturated root zone, shallow water table, and sensitivity (short-term response) to precipitation and cropping system water-use.

CAUSES OF SALINE SEEP

Saline seeps generally result from a combination of geologic, climatic, hydrologic, and cultural (land-use) conditions. The primary cause is a change in vegetation from grassland to a less water-use efficient cropping system, such as crop-fallow, that allows precipitation in the recharge area to move through the root zone and subsoil dissolving salts, and providing seepage water. The water accumulates above a geologic layer of less permeability forming a perched water table or accumulates in a layer of greater permeability that is underlain by less permeable material. The water then moves laterally downslope to a point where the water is forced to the soil surface or the permeable layer surfaces or is exposed on a side slope position. Many different geologic situations exist that can result in saline seep formation.[1] Other factors contributing excess water for saline seep development include: above normal precipitation; restricted surface and subsurface drainage; large snow drifts; gravelly and sandy soils; natural drainageway obstructions; artesian water wells; leaky livestock ponds; crop failures; and water conservation practices, such as level bench terraces.

SALINE SEEP WATER QUALITY

Water quality associated with saline seeps is usually unsuitable for human and livestock consumption due to high concentrations of dissolved salts and often high nitrate-N levels. Total salt concentration makes it unsuitable for irrigation. Calcium, magnesium, and sodium are the dominant cations and sulfate the dominant anion associated with saline seeps in the northern Great Plains.[3–5] Soils in seep areas are in equilibrium with gypsum, lime, and other Ca–Mg sulfate minerals.

SALINE SEEP CONTROL

Early detection is important to timely implementation of farming practices to reduce the severity or eliminate the saline seep problem.[1,6] Visual indicators of impending saline seep problems include vigorous weed growth following crop harvest in areas that would normally have dry soil; salt crystals on soil surface; prolonged soil wetness after rain; tractor wheel slippage or bogging down of implements in areas of the field that would normally be dry; excessive crop growth with lodging; infestation of salt tolerant weeds; stunted or dying trees in a shelterbelt; and poor seed germination. Crop root zone soil salinity can be readily assessed and mapped with portable field salinity detection equipment. Salinity in normal productive soils is generally low in the top meter, increasing with depth. Developing saline seeps have slightly increased levels of salinity at the soil surface that increase rapidly with depth. Developed saline seeps have high salinity at the soil surface that decrease with increasing soil depth.

Understanding the geology and circumstances causing a saline seep to form helps in designing effective control measures. Locating the saline seep recharge area is important to develop control measures. Generally, recharge areas are located at a short distance

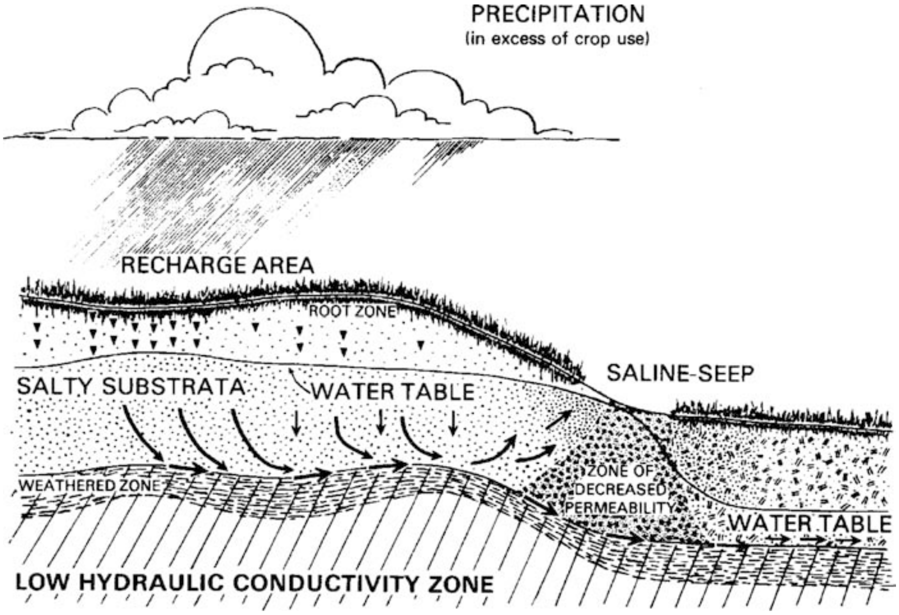

Fig. 1 Example diagram of geologic conditions contributing to saline seep formation in the northern Great Plains of U.S.A.

(180–600 m) upslope from the seepage area. The recharge area is usually located directly upslope or at an angle across the slope from the seepage area. Soil survey maps can be helpful in locating sandy or gravelly areas. Geologic maps may provide information on subsurface stratification, permeable, and impermeable layers. Soil profile information can help to identify recharge areas. Using a soil probe, one can often identify wet soil areas going upslope from the seep area in the direction of the recharge area. Deep coring can be used to examine and sample the soil profile at greater depths.

Visual assessment of recharge area location includes identifying the upslope area, direction of seep expansion, and contributing factors such as bench terraces, cropping system, and surface water collection areas. Saline seeps in glaciated areas generally expand laterally and upslope toward the recharge area. In non-glaciated areas, they tend to expand laterally and downslope away from the recharge area. Seep areas should show signs of drying up within 2 yr or 3 yr after implementing control measures (more intensive cropping systems, growing alfalfa, or high water-use crops) in the recharge area if the recharge area was correctly identified.

Fig. 2 Typical saline seep area developed on a hillside in eastern Montana, U.S.A.

Since saline seeps are caused by water moving below the root zone in the recharge area, there will be no permanent solution to the saline seep problem unless control measures are applied to the recharge area. There are two general procedures for managing seeps: 1) mechanically draining ponded surface water where possible, and/or intercepting lateral flow of subsurface water with drains before it reaches the seepage area; and 2) agronomically using the water for crop production.

Drainage

In recharge areas with small depressions that temporarily collect runoff water after a rainfall or snowmelt, surface drainage may reduce the contribution of water to the perched water table. Drainageways should be kept open to prevent ponding of water. In areas with level bench terraces, use of such water conservation practices may need to be evaluated if saline seeps are a problem. Drainage studies show that hydraulic control of the seep area can be achieved when subsurface interceptor drains are installed on the upslope side of the seep area. Disposal of the saline water, usually high in nitrate, is often a problem because of downstream surface or groundwater pollution. Other legal and physical constraints also come into consideration when disposing the seep water. The economics of dryland farming systems generally does not allow installation of costly drainage systems.

Agronomic Control

The best approach for controlling saline seeps is to use the water for crop production while it is a relatively non-saline resource in the root zone of the recharge area.[1,6–8] Planting crops and utilizing cropping systems in the recharge area that will effectively use available soil water supplies will achieve hydraulic control of many seep areas. This requires delineation of the recharge area followed by adoption of cultural practices that maximize soil water-use and minimize deep percolation. Planting deep rooted crops like alfalfa in the recharge area has been effective.[9] Intensifying crop rotations from crop–fallow to rotations that have less fallow or no fallow in the rotation improves crop water-use efficiency and reduces the amount of water moved below the root zone. Intensive, flexible cropping systems that use good soil and crop management practices to improve crop production and water-use are economically feasible. Fallow should be considered only when soil water and expected growing season precipitation are not sufficient to produce economical yield levels.

RECLAMATION

Once a saline seep area is brought under hydrologic control and the water table has been lowered sufficiently (>1.5 m) to stop movement of salts to the soil surface, reclamation of the seep area can begin. Research and farmer experiences show that reclamation occurs quite rapidly.[1,6,10] The rate of reclamation depends on the amount of precipitation received to leach the salts from the root zone. Because Ca–Mg sulfate type salts have accumulated in the seep area, the soil in the seep area is normally not dispersed by Na, thus permeability is maintained without need for gypsum application. Practices that enhance water movement through the soil profile need to be used. When soil salinity has been lowered sufficiently, normal crop production practices can be utilized. In the northern and central Great Plains, near normal crop production has been achieved on former saline seep areas.

SOCIOECONOMIC CONCERNS

Saline seeps present socioeconomic concerns because they do not respect property lines. A recharge area can be located on one farmer's property with the seepage area on another farmer's property. Seep discharge can contaminate streams, natural drainageways, and/or farm ponds. When a recharge area is on an adjacent farm, co-operation of landowners is needed to correct a saline seep problem. Formation of salinity control districts has been effective in getting farmers and government to work together. Changes in government farm programs that allow more intensive cropping practices helps farmers deal with saline seeps more effectively today. Development of conservation tillage and no-till farming practices makes it more feasible to implement economical intensive cropping systems that utilize available water supplies efficiently. Saline seep is not just an individual farmer problem. Any loss of farmland decreases the nation's food and tax base.

Saline Water

Khaled M. Bali
Cooperative Extension Imperial County, University of California–Davis, Holtville, California, U.S.A.

INTRODUCTION

The word salinity refers to the presence of salts in waters and soils. It refers to more than just sodium or chloride, the two elements of table salt. Magnesium, calcium, carbonate, bicarbonate, nitrate, and sulfate can all contribute to salinity. The suitability of water for drinking, irrigation, or wildlife depends on the type and concentration of dissolved salts in water. The salinity of water is usually expressed in terms of a measured parameter that is affected by all the dissolved salts in water. Electrical conductivity (EC) is the parameter that is most currently used and expressed in decisiemans per meter ($dS\,m^{-1}$); another is total dissolved salts (TDS) expressed as the mass of dissolved salts per unit volume of water. One decisiemans per meter is approximately equal to a TDS of $640\,mg\,L^{-1}$. Other terms that are commonly used to express water or soil salinity are given in Table 1.

SOURCES OF SALTS

The primary source of salts in waters and soils is chemical weathering of earth materials (rocks and soils). Natural secondary sources of salts along coastal areas include atmospheric deposits of oceanic salts, and seawater intrusion into groundwater basins and into estuaries. Atmospheric salt deposition also occurs in the interior of continents. The deposition rate decreases with distance from the ocean from values as high as $200\,kg\,ha^{-1}\,yr^{-1}$ to $20\,kg\,ha^{-1}\,yr^{-1}$ in the interior. Other secondary sources of salts found in soils are saline water from rising groundwaters, inland saline lakes and playas, leaching of saline lands, and natural salt deposits.[1,2]

The ocean is the primary source of salts found in natural salt deposits. These were laid down under the direct influence of an ocean during earlier geologic periods and subsequently uplifted. More commonly, however, the direct source of salts is surface and groundwater. All of these waters contain dissolved salts, the concentration depending upon the salt content of the soil and geologic materials with which the water has been in contact. There are other sources of salts which are the result of human activity: they include irrigation and drainage water, chemical fertilizers, animal wastes, sewage sludges and effluents, and oil- and gas-field brines.

Most waters on earth are salty because oceans contain approximately 97% of the water on earth and most of the fresh water is frozen in glaciers. The salinity of the Pacific Ocean is approximately $35{,}000\,mg\,L^{-1}$. Because of the high salinity of ocean waters and the volume of fresh water frozen in glaciers, only a small fraction of earth's water is available for drinking, irrigation, environmental, and recreational uses.

SOLUBILITY OF SALTS

What kinds of salts are commonly found and what are their solubility in water? Listed in the order of their solubility, they are the chloride (Cl^-), sulfate (SO_4^{2-}), bicarbonate (HCO_3^-), and carbonate (CO_3^{2-}) salts of sodium (Na^+), potassium (K^+), magnesium (Mg^{2+}), and calcium (Ca^{2+}). The chloride salts are more soluble than the sulfate salts, which in turn are more soluble than the bicarbonate/carbonate salts. Likewise, sodium salts are more soluble than magnesium salts, which are more soluble than calcium salts (Tables 2 and 3).

SALINITY MEASURMENTS

The salinity of water is closely related to its EC. Electrical conductivity is easy to measure in the laboratory. Salts ionize when dissolved in water, i.e., the salts dissociate or disintegrate into the elements that make up the salt. For example, the sodium chloride crystals in the saltshaker do not just become smaller when put into water. They totally disintegrate to the point where the sodium and chloride in the salt crystal become individual ions of sodium and chloride in the solution. These ions are electrically charged: sodium is positively charged and chloride is negatively charged. If one places bare wires of an electrical cord plugged into a wall socket into a solution of dissolved salt, the ions will carry the current. The saltier the water, the more current that will be carried and the lower the electrical resistance to alternating current. For safety and other reasons, this method is not used to measure the EC of a water sample. Instead, the sample is put into a small EC cell, which contains two electrodes, and

Table 1 Salinity conversion table

1 ppm = $1\,mg\,L^{-1}$ (for low concentrations)
1 ppb (part per billion) = $1\,\mu g\,L^{-1}$
1 ppm = 1000 ppb
$1\,mg\,L^{-1} = 1000\,\mu g\,L^{-1}$
$1\,dS\,m^{-1} = 1\,mmhos\,cm^{-1}$
$1\,dS\,m^{-1}$ = 640 ppm; EC (electrical conductivity) less than $5\,dS\,m^{-1}$
$1\,dS\,m^{-1} \approx$ 800 ppm; EC greater than $5\,dS\,m^{-1}$

Note that EC is affected by temperature. EC_{25} is most commonly used to express the EC at 25°C (77°F). Measurements made at other temperatures should be adjusted to EC_{25} using the following equation: $EC_{25} = EC_T - 0.02\,(T - 25)EC_T$.

the source of the alternating current is applied to the electrodes and the electrical resistance is measured with a resistance meter.[3]

DRINKING WATER QUALITY STANDARDS

Drinking water quality standards and guidelines are regulated by the U.S. Environmental Protection Agency.[4] The primary regulations include maximum contaminant levels (MCL) for inorganic chemicals such as lead and nitrate, organic chemicals, turbidity, coliform bacteria, and radiological constituents. The World Health Organization[5] has set similar standards for drinking water quality. The salinity of water used for drinking in the United States does not usually exceed $1000\,mg\,L^{-1}$ (or approximately $1.5\,dS\,m^{-1}$). Reverse osmosis can be used to lower the concentration of salts in drinking water. Drinking water that does not contain salts does not taste good as well.

WATER QUALITY GUIDELINES FOR IRRIGATION

Many crops are adversely affected at salinity levels greater than about $4\,dS\,m^{-1}$ in the water extract obtained from a saturated-soil paste. Decline in crop yield occurs if salt accumulates in the root zone to a level such that the crop is no longer able to extract enough water from the soil solution. If water uptake is significantly reduced, plant growth will be reduced. In general, salinity problems are more severe during the early stages of growth. Decline in crop yield can be predicted from average root zone salinity.[6]

Table 2 Solubility of salts

carbonate < bicarbonate < sulfate < chloride
calcium < magnesium < sodium

Table 3 Common names of salts (listed in the order of decreasing solubility)

Symbol	Common name
NaCl	Table salt
$NaHCO_3$	Baking soda
$NaCO_3$	Washing soda
KCl	Potash
$MgSO_4 \cdot 7H_2O$	Epsom salt
$CaSO_4 \cdot 2H_2O$	Gypsum—calcium sulfate
$MgCO_3$	Magnesite
$CaCO_3$	Calcite (soil lime)

In general, vegetable and tree crops are more sensitive to salinity than field crops.

The effects of salinity effects are not limited to crop damage. Salinity can also have a major impact on soil structure and infiltration rate. Good quality water (low salinity) is good for crop production, but it may reduce the rate at which the water penetrates into soil. To evaluate the suitability of water for irrigation,[7,8] one needs to know the water quality related problems that may cause decline in yield[6] or reduction in soil permeability to water and air.[9]

Salinity Effects on Plants

Crops vary in their salt tolerance. Each crop has a unique threshold salinity, or maximum soil salinity it can tolerate without a yield reduction. The yield decline per unit of salinity (slope) greater than the threshold salinity also differ among crops. These thresholds and slopes are known as the salt tolerance coefficients.[6] Salinity increases the energy crops need to expend to maintain turgor pressure and not wilt. This reduces the energy available for plant growth.

Sodium Adsorption Ratio

Sodium adsorption ratio (SAR) is commonly used as an index for determining sodium hazard in soils. Sodium adsorption ratio is usually determined for irrigation water or soil solution (extract of a completely saturated soil sample). The presence of excessive exchangeable sodium (Na) in soil solution may cause clay particles to swell. Clay swelling makes soil less permeable to water and to air, and can result in soil crusting and hard setting for sandy loam and loamy soils, and poor tilth for a broad spectrum of soil textures.[9] The Na hazard depends on the total salt concentration in the soil solution as well as on individual concentrations of calcium (Ca), magnesium (Mg), and sodium (Na). The effect of these individual ion concentrations is quantified by SAR, which is defined as

$$\mathrm{SAR} = [\mathrm{Na}]/(([\mathrm{Ca}] + [\mathrm{Mg}])/2)^{0.5}$$

where [Na], [Ca], and [Mg] are the concentrations of sodium, calcium, and magnesium, respectively, all concentrations are expressed in mmol of charge per liter (mmol L^{-1}), or in the non-SI unit of meq L^{-1}.

The effect of SAR on water infiltration rate depends on the salinity of irrigation water. For a given SAR, water infiltration rate increases as the salinity of irrigation water increases. For a given salinity, water infiltration rate decreases as the SAR of irrigation water increases.

Specific Ion Toxicity

Salinity can affect crop growth through specific-ion toxicities and osmotic effects. Specific-ion toxicity occurs when the concentration of one ion is high enough to cause toxicity.[6] Boron, chloride, and sodium are some of the ions that impede plant growth and development. Specific-ion toxicity causes leaf burn on the tips and margins of crop leaves.

Soil Salinity and Water Potential

Water movement in soil is often considered in terms of driving force. Water moves from where its energy status is high to where it is low. The energy status of water is commonly described by the total water potential which consists of pressure, capillary (or matric), osmotic, and gravitational potentials. The capillary or matric potential is due to cohesion–adhesion forces in the soil matrix. Osmotic or solute potential is due to the concentration of salts in soil solution.

Total water potential (H) can be expressed by

$$H = h_p + h_m + h_s + h_g$$

where h_p, h_m, h_s, and h_g are pressure, matric, solute, and gravitational potentials, respectively. Pressure and gravitational potentials can be either positive or negative. However, matric and solute potentials are always zero or negative.

Most plant roots can extract water from the soil when matric potential is between -5 bar and 0 bar. Almost all crops cannot extract any water from the soil when the matric potential is about -15 bar. This point is called permanent welting point (PWP), and its value depends on soil texture and crop type.

The higher the negative value of matric potential, the harder it is for plant roots to extract water. The presence of salts in the soil–water system adds another force that the plant has to work against to extract water. Solute or osmotic potential is zero when the concentration of salts in soil–water system is zero. Osmotic potential becomes more negative due to the increase in soil salinity. Therefore, salinity increases the total negative potential of soil water making it harder for the plants to extract water from soil solution.

Water movement from soil to plant depends on total water potential of soil water. At any particular soil moisture content, the higher the concentration of salts, the harder it is for the plant to extract water from the soil. The approximate relationship between soil solution's osmotic potential and soil salinity at 25°C (77°F) is

$$h_s = -0.4\mathrm{EC}$$

where h_s is soil solution's osmotic potential (bar) and EC is soil solution's salinity in dS m^{-1} (mmhos cm^{-1}).

Salton Sea

Timothy P. Krantz
Salton Sea Database Program, University of Redlands, Redlands, California, U.S.A.

INTRODUCTION

California's largest lake, the Salton Sea, is situated in the southeast corner of the state in a closed basin at the bottom of a 7851-mi^2 watershed. Over 85% of the water entering the Salton Sea results from agricultural run-off with less than 3% of inflow from annual precipitation. The Salton Sea supports a thriving fishery and provides important habitat for millions of migratory birds. More than two-thirds of bird species in the continental United States have been recorded at the Salton Sea and adjacent areas. The long-term viability of the Salton Sea ecosystem is threatened by increasing salinity and eutrophication resulting from the nutrient-rich agricultural drainage. More imminently, the viability of the Salton Sea is threatened by proposed water transfers and reductions of inflow, potentially concentrating pre-existing salts and causing the sea to recede by as much as one-third of its surface area and more than half its total depth.

GEOGRAPHIC SETTING

The Salton Sea is located in the southeastern desert of California. It lies in the Salton Trough—a closed basin, including the Coachella and Imperial valleys of California, and the Mexicali Valley of Mexico. The Salton Sea is located at 227 ft below mean sea level (msl). The shallow nature of the sea, with a surface area of 367 mi^2 (951 km^2) and a depth of 51 ft (15.5 m), renders it very sensitive to even slight changes of inflow. The sea is sustained by 1.34 million acre ft (af) of inflow, mostly agricultural run-off diverted from the Colorado River (Fig. 1).

The Salton Sea is situated in the Colorado Desert in one of the most arid regions of the United States. Annual precipitation is less than 3 in. (7.6 cm), and mean monthly temperatures in July are 92°F (33.3°C), with maximum temperatures exceeding 100°F (37.7°C) on more than 110 day yr^{-1}. Potential evaporation is estimated at 5.78 ft (1.76 m) per year.[1]

GEOLOGY AND GEOMORPHOLOGY

The Salton Basin was once connected to the Gulf of California and characterized by a shallow marine environment.[2] For the past several million years, as the Colorado Plateau was uplifted, the sediments that once filled the Grand Canyon were deposited in the Gulf of California, eventually building a huge delta, blocking off the Salton Basin from the ocean.[3] The deltaic dam is now 40 ft above sea level, with a drainage divide about 17 mi south of Mexicali, Mexico.

Once separated from the Gulf of California, the Salton Basin would periodically dry out as the Colorado River drained directly into the Gulf of California. At other times, the river would change course and fill the basin, sometimes to its brim, spilling over into the Gulf of California covering more than 2200 mi^2. These prehistoric inundations have been called Lake Cahuilla or Lake LeConte. The Lake Cahuilla shoreline was established by locating geomorphological features with global positioning systems and plotting these in a geographic information system (GIS).[4] Further evidence of Lake Cahuilla has been obtained from archaeological sites along the ancient shoreline, including fish traps, bones, and other lake-related remains. The periodicity of Lake Cahuilla episodes has been estimated based on carbon dates of the travertine deposits and other organic archaeological evidence, indicating that the lake was full most of the time over the past 1300 yr of record.[5–7]

HYDROLOGY OF THE SALTON SEA

The present-day Salton Sea was formed in 1905 when flood flows on the Colorado River rushed into a temporary diversion channel, quickly deepening and widening to capture the entire flow of the river until the breach was finally filled in 1907. Far from being an "accidental lake," it was human intervention that prevented the next stand of Lake Cahuilla from being formed.

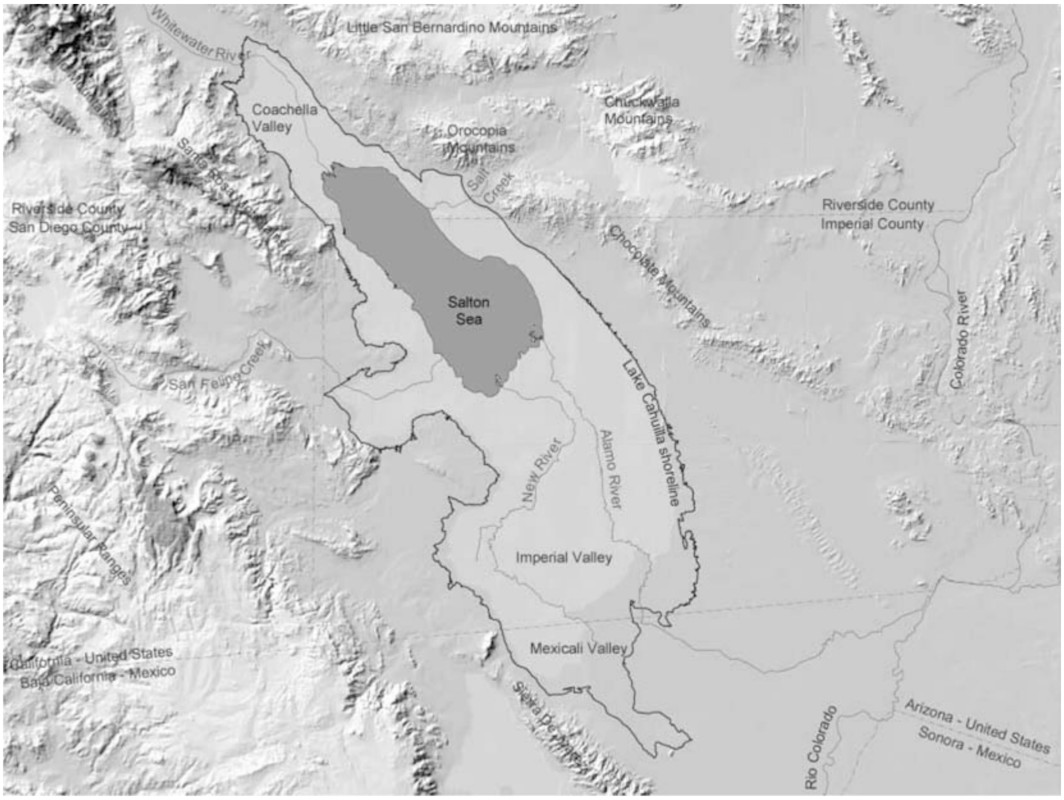

Fig. 1 The Salton Sea lies in a closed basin, sustained largely by agricultural run-off from the Imperial Valley. Lake Cahuilla was the prehistoric high stand of a lake that occasionally filled when the Colorado River would drain into the basin.

After an initial high stand of the Salton Sea from the 1907 flood at about −195 ft msl, the sea receded to about −250 ft msl by 1920. Since then, with the expansion of agriculture in the Imperial and Coachella valleys and increased agricultural run-off, the surface elevation of the sea has risen to its current elevation of about −227 in. The elevation of the sea has remained relatively stable at its current level since the 1980s, indicating that the inflow of about 1.34 million af is equal to evaporation at that elevation—or about 15% of the total volume of the sea lost to evaporation each year.

Approximately 4.5 million tons of salts are added to the sea annually. Because evaporation is the only outlet for the sea, the dissolved salts, nutrients, and minerals that enter the sea remain there, and have accumulated over the past century to the point at which the sea is now about 25% saltier than the ocean, at about 44,000 mg L^{-1}.[8]

BIOLOGICAL RESOURCES

The nutrient-rich agricultural drainage that sustains the Salton Sea also supports an incredible diversity of life. More than 400 species of invertebrates, mostly single-celled plankton, have been identified in the sea.[9] These provide the food base supporting a highly productive fishery, with an estimated 200 million fish—one of the most productive fisheries in the world.[10]

The Salton Sea is of critical importance for many species of migratory birds. The sea supports over 90% of the North American population of eared grebes, with as many as three million individuals during migration, as many as 30,000 American white pelicans and 2000 brown pelicans, more than 120,000 shorebirds of 44 species, 25,000 snow and Ross' geese, the largest breeding colony of gull-billed terns in Western North America, and 45% of endangered Yuma clapper rail habitat.[11]

ENVIRONMENTAL THREATS

Increasing Salinity

Increasing salinity may cause the fishery to collapse as it approaches 60,000 mg L^{-1}.[12] At the present rate of salt loading of about 4.5 million tons per year, the Salton Sea would reach the 60,000 mg L^{-1} threshold in about 50 yr, assuming inflow remains at its present level of 1.34 million af per year.[8]

Pilot-scale solar evaporation ponds to remove salts from the sea have been constructed and are operational. The solar ponds, if fully implemented, would provide an outlet for concentrated salts in the sea, requiring approximately 100,000 af of water to be removed from the sea each year—the amount containing the equivalent of the annual salt load from inflow.[8]

Eutrophication

Nutrient loading from agricultural run-off has created eutrophic conditions at the Salton Sea. Productivity and biomass are very high, leading to oxygen depletion caused by decay of accumulated senescent biological material. These anoxic conditions have contributed to extensive fish kills over the past few decades, leading to further oxygen depletion.[13] Eutrophic conditions worsen during summer months, when high biological productivity and warm water temperatures conspire to greatly reduce dissolved oxygen throughout the water column. One event, in August 1999, resulted in the death of six to seven million fish over a period of several days. Chemical limnological data taken at the time indicated a complete loss of dissolved oxygen from top to bottom in portions of the sea coincident with that event.[14]

Reductions of Inflow

Inflow at the present elevation is about 1.34 million af per year. Proposed water transfers of as much as 300,000 af from the Imperial Irrigation District to metropolitan water users in Southern California, together with other potential reductions of inflow, may reduce total inflow to the Salton Sea by as much as 500,000 af.

With reduced inflows, salinity increases rapidly, the contracting lake concentrating salts already in residence while more salts continue to enter the sea in agricultural run-off. With a reduction of inflow by 300,000 af per year, salinity would reach the 60,000 $mg\,L^{-1}$ threshold for the fishery in about 12 yr; and with a reduction of 500,000 af, salinity would reach the limit of tolerance of the fishery in just 7 yr.[15]

The collapse of the fishery would represent a serious adverse environmental impact. The death of 200 million fish would have a cascade effect on the rest of the ecosystem, causing the demise of fish-eating bird populations, exacerbating eutrophication from decomposition of the dead fish, and creating a huge breeding ground for flies and other pathogens in their rotting carcasses.

Many species of birds would be critically impacted. Ground-nesting bird colonies on Mullet Island—the only island in the sea—would be exposed to coyotes, cats, and other predators with a draw down of only 7 ft. Many other species would experience substantial whole-species population decline.

Other potential impacts of reduced inflows to the Salton Sea include collapse of lake-related economies, such as boating, hunting, fishing, and property values; degradation of air quality as a result of exposure of as much as 120 mi^2 of fine lake bottom sediments to the desert winds; loss of agricultural productivity from salt and dust deposition; and increased respiratory disease and human health problems as a result of airborne sediments.

CONCLUSION

The Salton Sea is characterized by contrasts. It is California's largest lake, situated in one of the hottest, most arid regions of the United States. Sustained in large part by agricultural run-off, the nutrient-rich inflows support one of the most productive fisheries in the world, in turn supporting millions of migratory birds. At the same time that agricultural drainage is the life's blood of the Salton Sea, it also causes hyper-eutrophic conditions that lead to occasional fish kills and bird die-offs that the sea experiences today.

Increasing salinity will cause the collapse of the fishery within 30–50 yr at present rates of salt loading and inflow, if salinity control measures, such as solar evaporation ponds, are not undertaken. With reduced inflow as a result of water transfers or other actions, the Salton Sea may drop by more than half its depth, exposing more than 100 mi^2 of land, and become a biologically "dead" sea—a North American version of the "Aral Sea."

Satellite Sensing: Atmospheric Water

Vincenzo Levizzani
National Council of Research, Institute of Atmospheric Sciences and Climate, Bologna, Italy

INTRODUCTION

The World Meteorological Organization (WMO) has recognized the availability of water as the most crucial problem of mankind in the new millennium. Local and global changes in the water cycle will affect entire populations and the quality of life on the surface of our planet. The United Nations[1] reports that the global freshwater consumption rose sixfold between 1990 and 1995—more than twice the rate of population growth. If we are to continue with present trends, two of three people on the planet will live in conditions of water stress by 2025. In view of this problematic frame, a global rainfall measurement system in support of weather and climate forecasting is vital for an accurate monitoring of the hydrological cycle and for risk/hazard management.

These requirements can only be met by establishing a global rainfall measurement system from space using remote sensing techniques, which apply to all conditions, including lands and oceans, deserts, and scarcely populated areas, and have the necessary space–time resolution for fine-scale to global-scale applications. An overview of satellite rainfall measurements is given (see Ref.[2] for a more complete review). Starting from visible/infrared (VIS/IR) techniques (‘‘VIS/IR Methods’’), the evolution is followed into the passive microwave (PMW) methods (‘‘PMW Techniques’’) and the newest technology of space-borne precipitation radars (PRs) (‘‘Active Sensing’’). A final brief overview of global methods and the future is provided in ‘‘Conclusion.’’

VIS/IR METHODS

A rather complete overview of VIS/IR methods is given in Refs.[3,4]. Such methods are based on the very crude assumption that rainfall mostly comes from the coldest/highest clouds. This is true for the towering convective clouds of thunderstorms. However, cloud systems are very much heterogeneous and normally mixed, especially at midlatitudes. Cirrus cloud shields are often very high and cold, and produce false rainfall signals. Moreover, the distinction between convective heavy precipitation and stratiform low rainrates is difficult to achieve by means of only a cloud top characterization in the VIS/IR, which does not dwell on the necessary knowledge of the cloud structure underneath.

Cloud models are used to introduce the physics of clouds into the retrieval process for a quantitative improvement deriving from the overall better physical description of the rain formation processes. Cloud top temperature is related to rainrate and rain area via a one-dimensional cloud model in the Convective Stratiform Technique (CST).[5] Local minima in the IR temperature are sought and screened to eliminate thin, non-precipitating cirrus. Precipitation is assigned to convective areas by means of the cloud model. To every other element colder than the stratiform threshold, a fixed stratiform rainrate is assigned.

VIS/IR techniques are used as an effective method to build a global rainfall climatology. The Global Precipitation Climatology Project (GPCP) of WMO’s Global Energy and Water Cycle Experiment (GEWEX) makes available several continuously updated datasets at daily, 5-day (pentads), and monthly time scales.[6] An example of global precipitation estimate is given in Fig. 1.

PMW TECHNIQUES

At PMW frequencies, precipitation particles are the main source of attenuation of the upwelling radiation. Thus PMW techniques are physically more direct than those based on VIS/IR radiation. The emission of radiation from atmospheric particles results in an increase of the signal received by the satellite sensor, while at the same time scattering caused by hydrometeors reduces the radiation stream. The type and size of the detected hydrometeors depend on the frequency of the upwelling radiation. Above 60 GHz, ice scattering dominates and the radiometers can only sense ice while rain is not detected. Below about 22 GHz, absorption is the primary mechanism affecting the transfer of PMW radiation, and ice above the rain

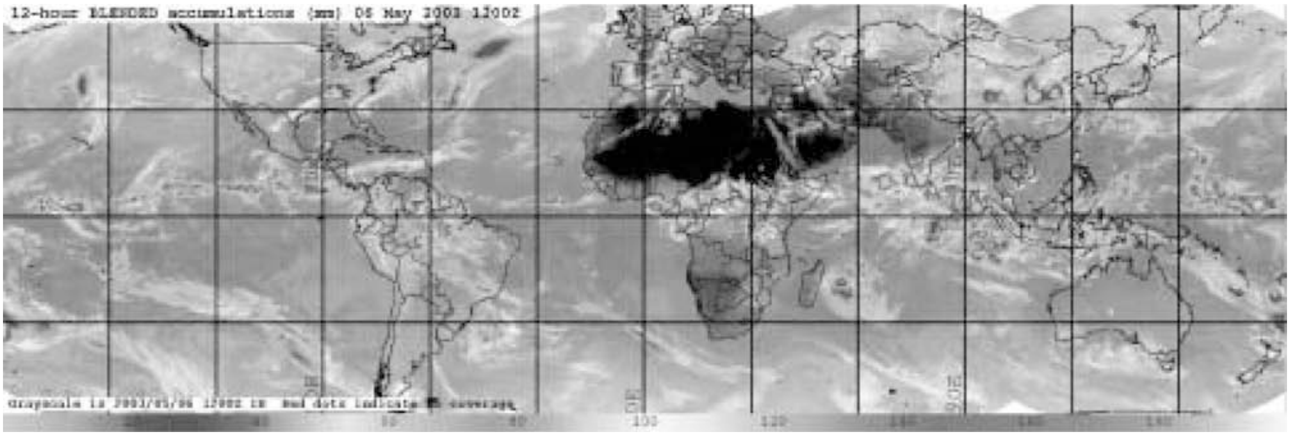

Fig. 1 Twelve-hour rainfall accumulation using a combination of VIS/IR and PMW data from several satellites. The scale is in millimeters of rain. The map was obtained by the Naval Research Laboratory, Monterey. (Courtesy of Dr. F. Joseph Turk.)

layer is virtually transparent. Between 19.3 and 85.5 GHz, the common PMW imagers' frequency range, radiation interacts with the main types of hydrometeors, water particles, or droplets (liquid or frozen). Scattering and emission happen at the same time, with radiation undergoing multiple transformations within the cloud column in the sensor's field of view (FOV). At different frequencies, the radiometers observe different parts of the rain column.

The most physical approaches are based on time-dependent cloud radiation models that take full account of precipitation microphysics. These techniques simulate the physics of the cloud system in the PMW characterizing the vertical sources of radiation that contribute to the top-of-the-atmosphere (TOA) PMW brightness temperatures (T_B) measured by the satellite radiometer. Vertically, angularly, and spectrally detailed radiative transfer models (RTMs) are applied to the highly resolved thermodynamic and microphysical output of the cloud model. Weighting functions, which are essentially vertically resolved radiative structure functions describing the process by which radiation originates and reaches the satellite radiometer, are found. The functions are then subdivided into individual contributions by the various hydrometeor species generated by the cloud model. An example of such model is given in Ref.[7], where a time-dependent cloud radiation model that establishes microphysical settings as a base of precipitation retrieval from PMW is proposed.

ACTIVE SENSING

The launch of the Tropical Rainfall Measuring Mission (TRMM) in November 1997 as a joint effort between the National Aeronautics and Space Administration (NASA) and the National Space Development Agency (NASDA) of Japan opened up an entirely new perspective in rainfall measurements from space. The payload[8] consists of five instruments: the TRMM Microwave Imager (TMI), the Precipitation Radar (PR), the Visible and Infrared Radiometer System (VIRS), the Clouds and Earth's Radiant Energy System (CERES), and the Lightning Imaging System (LIS).

The PR, the first of its kind to be flown on board a spacecraft, operates at 13.8 GHz. The instrument provides the vertical distribution of rainfall for the investigation of its three-dimensional structure, obtaining quantitative measurements over both lands and oceans, and improving the overall retrieval accuracy by the combined use of the radar, and the TMI and VIRS instruments. An example of the multisensor view of cloud systems by means of the TRMM instrument package is given in Fig. 2.

CONCLUSION

Recently lunched and planned satellite missions and sensors are rapidly changing the way mankind understands the global water cycle because its key components will be soon monitored and, most important of all, quantified. Multispectral observations are now provided, among others, by NASA's Moderate Resolution Imaging Spectroradiometer (MODIS)[9] on board the Earth Observation System (EOS) and by the Spinning Enhanced Visible and InfraRed Imager (SEVIRI) on board EUMETSAT's Meteosat Second Generation (MSG).[10] Missions to be launched during the first decade of the millennium will focus on multisatellite

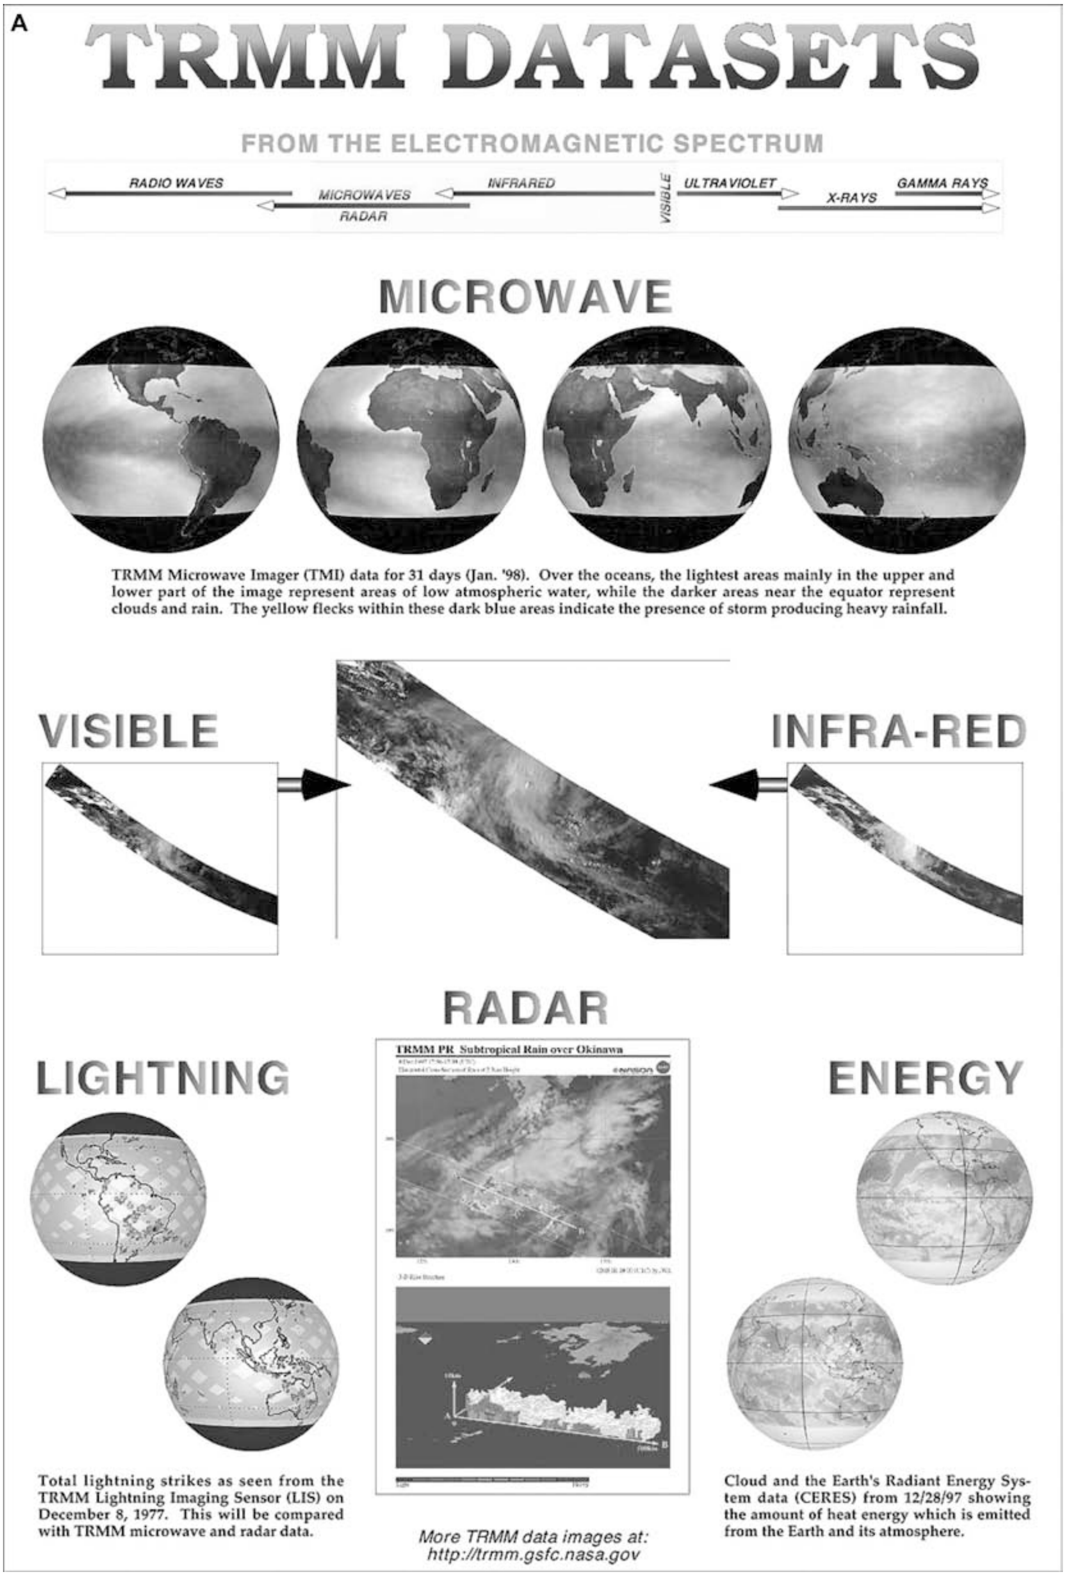

Fig. 2 (A) Data types from the sensor package on board the TRMM. (B) TRMM swath over hurricane Floyd. The outer swath is the Visible and Infrared Scanner and the inner swath is the PR coverage. Two vertical cross sections of PR scanning are shown with radar reflectivity indicated in color. The position of the most active convective cells is highlighted by the higher reflectivity values. strategies to ensure global monitoring of clouds and precipitation:

- The A-train[11] with the CloudSat spacecraft that will fly the first space-borne millimeter wavelength radar. The CloudSat radar will observe, starting in 2004, jointly most of the cloud condensates and precipitation, and provide profiles of these properties with a vertical resolution of 500 m. The satellite constellation will include the EOS Aqua and Aura at each end of the constellation, CloudSat, a second NASA mission that flies an aerosol lidar (CALIPSO), and another small satellite, PARASOL, carrying the POLDER polarimeter inserted in the formation between the larger EOS spacecraft. TRMM has quantified how much precipitation falls in the tropical atmosphere, but at present, we cannot estimate within a factor of 2 the mass of water and ice in these clouds and how much of this water and ice is converted to precipitation. We also cannot say with any certainty what fraction of global cloudiness produces precipitation that falls to the ground.
- The Global Precipitation Measurement (GPM) mission scheduled for 2008 will consist of a ''mother ship'' with an advanced double-frequency PR and a PMW radiometer that will fly in formation with seven or eight ''drones'' hosting a PMW radiometer. The drones will calibrate their rainfall estimates with the precise measurements of the main ship, thus ensuring a 3-hr global coverage.

These missions will further advance our capacity of quantitative rainfall measurements from space by improving current global products (e.g., Refs.[12–15]). Pending issues on the role of clouds and precipitation on global climate changes are also at hand. The direct and indirect effects of anthropogenic and natural aerosols have to be quantified.[16] An example of aerosols depressing precipitation formation is shown in Fig. 3.

The era of single-sensor, single-mission strategies for observing the water cycle is certainly finished, and the space agencies and research institutions are conceiving truly international missions that will be flown to link clouds and precipitation physics into new

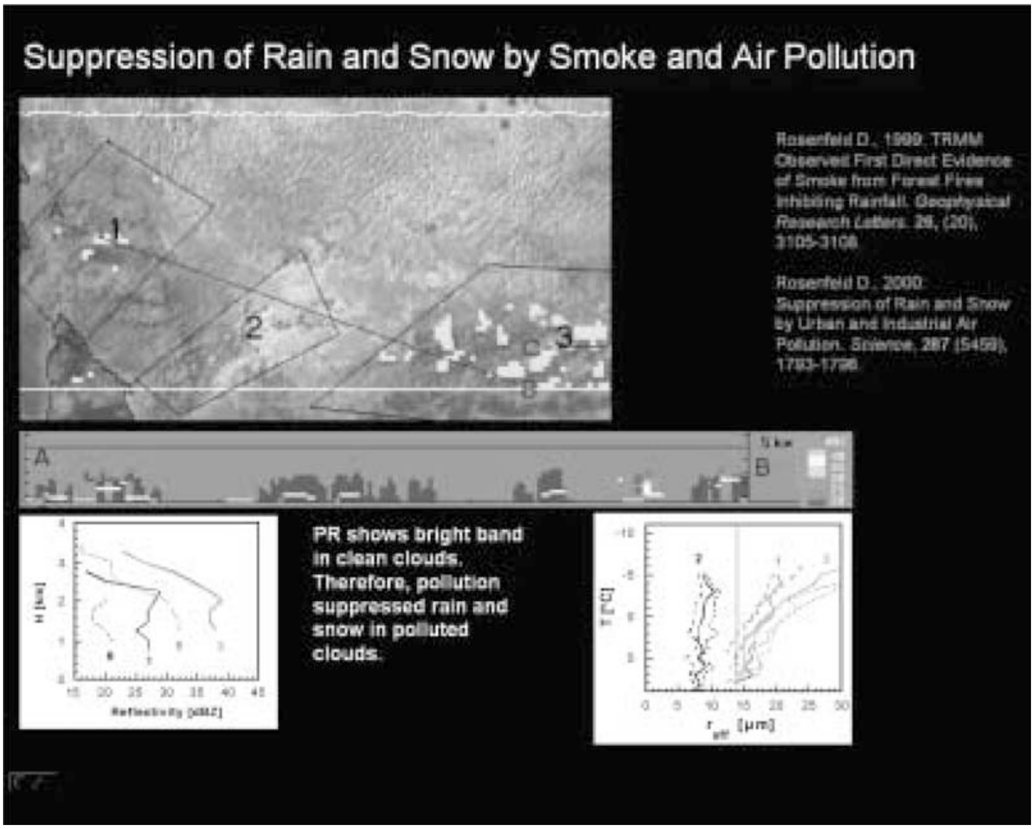

Fig. 3 Image of TRMM VIRS and PR over Australia showing the rainfall suppression effects by anthropogenic aerosol particles from industrial pollution. The area delimited by boxes 1 and 3 is not affected by the presence of aerosol particles, whereas in area 2, there is a heavy load. The PR swath shows precipitation in areas 1 and 3, whereas no precipitation is detected in area 2. The reason is that small aerosol particles from industrial pollution coalesce small droplets that do not develop into precipitation drops as it happens in unperturbed air masses. This is confirmed by the dimensions of cloud particles at the cloud top (bottom of figure), whereas in area 2, all the particles are below 15 μm size; those in areas 1 and 3 are above this threshold, which is the precipitation threshold. This discovery opens up new perspectives in quantifying human intervention in climate change. (Courtesy of Prof. Daniel Rosenfeld, Hebrew University of Jerusalem.)

algorithms that dwell on cloud physics and meet the requirements of nowcasting, weather forecasting, climate, and hazard management.

Scaling Processes in Watersheds

Ole Wendroth
Department of Plant and Soil Sciences, University of Kentucky, Lexington, Kentucky, U.S.A.

David A. Robinson
Geophysics, Stanford University, Stanford, California, U.S.A.

INTRODUCTION

Soils play a vital role in controlling both hydrological and ecological processes in watersheds, including water storage and dynamics, biogeochemical cycling, and transport as well as biomass production. The objective of this entry is to discuss scaling issues of soil-water processes in watersheds and to identify relevant research questions. Although the origin of the term "process" (Latin: *procedere*, to advance) refers to space, process is nowadays more generally used in a temporal context to describe dynamic phenomena. Here, the term is used with respect to both space and time. Compared with the rapid temporal variation of weather, and atmospheric conditions affecting processes in watersheds, soil development occurs extremely slowly. Conversely, owing to an infinite number of possible combinations of the five soil-forming factors—climate, organisms, topography, parent rock, and time[1]—inherent soil spatial variation occurs over a variety of scales, from the pore to sample, to profile–plot–field–watershed–landscape, and region. Water sculpts soils across scales from pore connectivity to landscape flow paths and is the main carrier of solutes in watersheds.[2] Soils, as a major interface, and control on processes, deserve our considered attention in unraveling the dynamics of watershed processes, especially when considered as a unique and complex material with regard to their transport properties.[3]

To describe soil spatial heterogeneity, and in particular assign a value to land, soil scientists have stratified soils into subdivisions, i.e., mapping units that are not necessarily related to watershed structures. Unfortunately, subjective boundaries between these mapping units are artificially introduced that exist only conceptually. In reality, soils and their variability have to be understood as continuous bodies in space and time[4] and there is a significant scientific need for measurement methods that can quantify soil properties across the landscape.

HOW TO SAMPLE A PROCESS AND IDENTIFY AN APPROPRIATE SAMPLING SCALE

Regardless of scale, sampling a process requires the identification of a system's continuous change in space or time. This requirement implies that the system's state is observed at the grain level (Fig. 1), i.e., the finest level of temporal or spatial resolution at that scale, in sufficient resolution. At this level, measurements made in space or time help identify the continuity of the process. Measurements are taken over a domain, called the extent.[5] In this domain, changes over short distances in space or time are expected to vary less than changes observed over large distances or the entire domain. Hence, we can distinguish between structured variation, i.e., the signal, and random variation, i.e., the noise of the process. The variogram[6] or the autocorrelation function are ecologically relevant measures of environmental structure and appropriate tools to determine if the sampling design (volume, size, distance, time interval) is appropriate at the particular space–time scale combination.

To identify a process, it is necessary to determine the range of spatial or temporal representation for the set of measurements of a variable for identifying its process. The range of representation or crosscorrelation is also essential for relating different variables sampled in space and time to each other, even though they may not be measured at exactly the same location or time.

For many watershed processes, the variance increases indefinitely with distance.[6] For soil-water content, this behavior may not be true: At the pore scale, variance of soil-water content is greater than that at larger scales, where the combination of volume fractions, solid, water, and air become more homogeneous.[7] In this example, increasing the volume of observation causes the variance of soil-water content to decrease until we arrive at a stable mean and variance, manifesting the representative elementary volume (REV). Further increase of the sampling

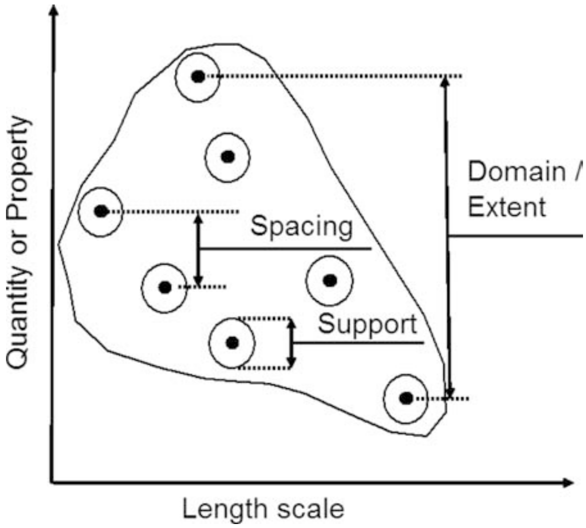

Fig. 1 The scale triplet: spacing, extent, and support. *Source*: Adapted from Ref.[33].

volume to larger scales may not alter the variance further, but we miss essential information about spatial and temporal information within that volume. For this reason, ref.[8] suggested adding space and time components to the REV paradigm. Adding such components is an essential task for scaling soil-water properties and processes in watersheds. Soil-water content as the relevant state-variable governing water and solute fluxes changes its variability structure with its magnitude and spatial observation scale.[9] In a numerical study of parameterizing soil as a Miller-similar medium, ref.[10] showed that moving from water saturation to dryness, the spatial variance and correlation length of fluxes decreased until a threshold water content was reached. At this threshold value, corresponding to a matric potential close to field capacity, soil-water content, water flux density, and other relevant hydraulic state variables behaved in a spatially homogeneous manner. As the soil-water content decreased further, the variances of soil water and associated fluxes became larger owing to the increasing impact of soil textural variability. Ref.[11] verified these findings at the field scale for soil-water matric potential in a sandy loam and a clay soil.

Therefore, the question of whether the observational scale for soil-water content is appropriate or not is not easily answered! However, identifying the spatial change of variability structure, on the one hand, and the variables that are associated with soil-water status, on the other, such as infiltration, runoff, drainage, and evapotranspiration in space and time, is an important objective that can be accomplished with the existing tools.

IMPLICATIONS OF SCALING

Scaling has been widely used in soil science for characterizing the spatial variability of soil hydraulic property functions,[12,13] water infiltration,[14] internal drainage,[15] and soil chemical processes such as Cadmium sorption.[16] One objective for the scaling of soil properties and functions is to describe spatially variable systems with a reference parameter or function, and estimate the spatial distribution of complex non-linear multiparameter functions using scaling factors[17] relative to this reference. If chosen appropriately, the set of scaling factors conserves the spatial variability of processes without having to deal with multiple parameter sets.[18] These scaling factors can then be used as coregionalizable information, i.e., their spatial or temporal autocovariance functions are determined for quantifying their process through time and space, and they simplify the handling of spatially varying input parameters in water balance and transport models. However, we have not exhausted the opportunities yet to apply the spatial or temporal distributions of scaling factors for soil-water and chemical processes, and their auto- and crosscorrelation lengths relative to other, often already existing, soil information.

Soil physical properties are difficult to obtain for large areas in an efficient manner, and at a scale relevant for important transport processes. Therefore, indirect observations are an opportunity to estimate the spatial distribution of physical properties that relate to transport processes for large domains or at large scales, and transfer the spatial distribution of transport rates to other scales and domains. Ref.[19] estimated the distribution of hydraulic conductivity scaling factors based on field drainage rates observed over two days after a long rainfall period. This and similar procedures demonstrate an important need for instrumentation that can measure spatial, root zone, soil-water content, with its associated relevance for water fluxes, profile average hydraulic conductivity, and ecohydrological relationships and their functional continuity across watersheds and landscapes.

ASPECTS OF SCALE TRANSITIONS

For many soil-water related observations that are taken across different size areas or time increments in watersheds, the size of an individual observation is similar, owing to available instrumentation. Studying soil-water content and deriving fluxes across a soil profile, on the one hand, or in a plot or across a soil landscape, on the other, is often based on the same type of instrument and the same volume of an individual observation. Upscaling information from small observational domains to larger ones can be accomplished through data aggregation, geometrical averaging, etc.[20] Ref.[21] studied the impact of data aggregation and sampling density on the error variances of spatial estimation using block kriging. However, characteristics and processes in watersheds are not strictly additive over different scales.[2]

A question relevant for scale transitions would be: What are the typical processes that can be studied and measured at particular space–time scales, and what variables and processes are related that need to be included when an attempt is made to transfer these processes to other scales or domains? Fig. 2 is an illustration of some examples for soil-water processes typically occurring across a range of space–time scale combinations and their relation to other variables and processes within and across watersheds.

Recent technological developments provide fundamental opportunities to explore soil-water processes in watersheds at space–time scale combinations that we have not been able to study in the past, except for relatively small spatial scales. These opportunities are especially important at the interface between soil and atmosphere, where a strongly pronounced spatial and relatively small temporal heterogeneity meets the large temporal variability and relatively minor spatial variability. Gas infrared analyzers for CO_2 emissions[22] and lidar scanners for water vapor fluxes[23] allow measurements over relatively large areas at short time intervals. These tools are essential for improving our concepts of upscaling and transferring information from one domain to another. Within short time intervals, magnitudes of fluxes can be measured over large areas with high spatial resolution and their spatial and temporal continuity. It is an important multidisciplinary task for research in watersheds to develop or adapt similar measurement methods for hydrology, to understand the relation between underlying soil variables at the land surface such as soil hydraulic conductivity, water content, evaporative fluxes, vegetative surface cover, soil temperature, and soil texture. The use of geophysical methods may contribute to a better understanding of the spatial variability of state and rate variables at the land surface.[24]

Physically based concepts derived at the sample and profile scale are often used in models to describe processes at a larger scale for the reason that concepts for these local processes simply do not exist for larger scales. For example, ref.[25] derived effective hydraulic

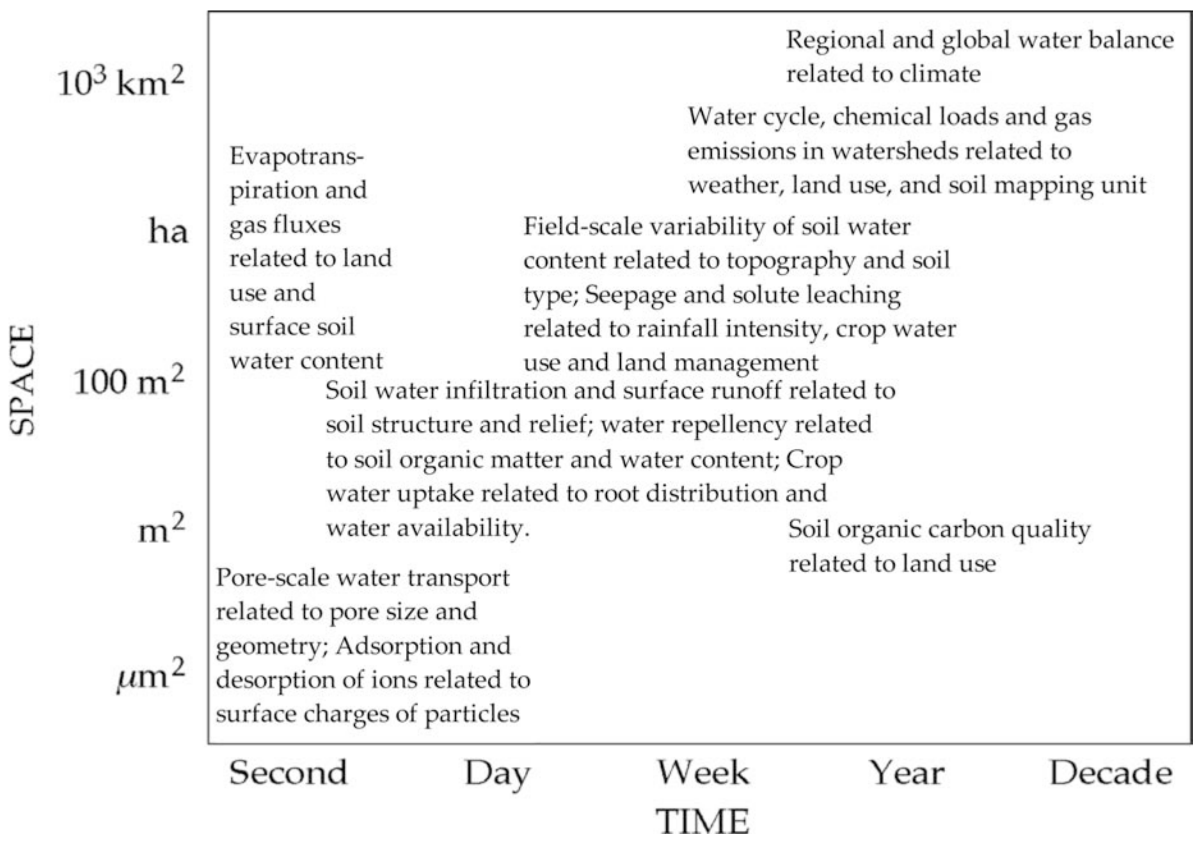

Fig. 2 Examples for processes occurring at different combinations of space and time scales in relation to other characteristics and properties.

soil parameters at large scales from inverting water transport models originally developed for small scales. Ref.[26] combined a large-scale water transport model with a small-scale model describing soil salinization processes (UNSATCHEM[27]) and successfully described long-term and large-scale development of soil salinity for a region within the Californian Central Valley. Approaches like these are very promising for scenario calculations on effects of land use change upon important watershed processes. However, we cannot simply downscale information from large scales like this ($60\,km^2$) to the field, plot, or local scale, for which many transport theories were originally developed. Ref.[28] pointed out that with increasing awareness of watershed pollution, soil landscapes have to be characterized at finer scales to minimize unfavorable transport to ground and surface waters. For this purpose, the concept of pedotransfer functions[29] needs to be reconsidered. The use of pedotransfer functions extrapolates locally specific physical properties to qualitative, ill-defined soil mapping units, without accounting for spatial auto- and crosscorrelation lengths, ignores spatial continuity of processes, and therefore remains insensitive to small-scale processes in watersheds and soil landscapes.[30]

Commonly occurring soil hydrological phenomena appear to differ whenever their spatial and temporal resolutions change. The fact that we cannot quantify preferential transport at a regional scale, i.e., preferential flow is not manifested in large-scale effective parameters, does not mean that it does not occur within the domain considered. Ref.[31] pointed out that there is no physical justification for effective parameters. Instead, there is a need to identify land surface variables whose patterns can be associated with transport rates and fluxes at continually smaller scales.

Downscaling may be impossible for many watershed processes, as many large-scale processes simply do not reflect processes occurring at smaller scales.[2] We have to accept this constraint. Instead, hydrologists and soil scientists need to identify the space and time scales at which land use and management affect the relevant transport properties in watersheds, and to derive strategies to maintain this information from small to large scales. Remote sensing of the land surface at increasingly finer resolutions will support this scale transition greatly,[32] while conserving information relevant for pollution studies in watersheds.

CONCLUSION

Soil-water relations control many hydrological and ecological processes in watersheds. Scaling factors are widely used to describe the heterogeneity of watersheds and soil landscapes. Local observations can be upscaled by aggregation; however, processes are not simply additive across scales and there is a real need for more spatially distributed measurements. Watershed management requires process understanding at fine scales. Downscaling from large to small scales cannot be accomplished without additional small-scale observations that conserve the variability pattern and continuity of relevant transport processes.

Seas: Dead and Dying

Andrey G. Kostianoy
Ocean Experimental Physics Laboratory, P.P. Shirshov Institute of Oceanology, Russian Academy of Sciences, Moscow, Russia

INTRODUCTION

About 97% of earth's water is salt water in oceans and seas. Nearly 70% of the world's fresh water is frozen in the Antarctic and Greenland ice sheets, glaciers, and permanent snow cover and ice. About 30% of all fresh water is groundwater. Lakes and rivers contain only about 0.25% of all fresh water. All over the globe, water is being diverted for industrial, agricultural, and household uses, and many lakes are suffering from the resulting lack of inflow. In 2002, the United Nations Environment Program (UNEP) announced that about three billion people would face severe water shortages by 2025, if the present consumption rates persist. Shallowing, desiccation, and degradation of certain freshwater and salt lakes and inland seas are among the major environmental problems at the beginning of the 21st century. There are clear indications that the growth of human population and the increasing use of natural resources, especially water, combined with climate changes, exert a considerable stress on closed or semienclosed seas and lakes. In many regions of the world, marine and lacustrine hydrosystems are or have been the objects of severe or fatal alterations ranging from changes in regional hydrological regimes and/or modifications of the quantity or quality of water resources, deterioration of geochemical balances (increased salinity, oxygen depletion, etc.), mutations of ecosystems (eutrophication, decrease in biological diversity, etc.) to the socioeconomic perturbations, which have been the consequences or may soon be in the near future.

Here, we address several examples of critical inland water bodies all over the world; "critical" meaning that the lake or inland sea is facing either a severe anthropogenic pressure in some form or a rapid change of its physical conditions owing to climate change.

CRITICAL SEAS AND LAKES

A significant fall in the water level and/or increase in salinity of many large saline lakes and inland seas have taken place worldwide during the past century.[1,2] Examples include in North America—Great Salt Lake (Utah), Walker and Pyramid lakes (Nevada), Owens and Mono lakes and the Salton Sea (California), Dead-moose (Canada); in South America—Llancanelo (Argentina); in the Middle East—the Dead Sea (Israel/Jordan/West Bank) and Lake Van (Turkey); in the Central Asia—the Aral and Caspian seas, Lake Sarykamysh and Kara Bogaz-Gol Bay (Turkmenistan), Lake Balkhash (Kazakhstan), Lake Issyk-Kul (Kyrgyzstan); in China—Lop Nor and Qinghai Hu lakes; in Africa–Lake Chad and Lake Elmenteita (Kenya); in Japan—Lake Biwa; and in Australia—Keilambete, Eyre, Corangamite, Gnotuk, and Bullenmerri lakes. The most striking examples include: (i) the Lop Nor Lake in China, which completely dried up by 1972; (ii) the Aral Sea, which is following such a fate; (iii) the Dead Sea, whose level dropped 14 m from 1977 till the beginning of the 21st century; and (iv) Lake Chad, which at the same time shrunk to about 5% of its size in 1963.

Northern and northwestern China has been experiencing a desiccation process since 1950s owing to a decrease in precipitation by at least 30%.[1] As a result lake Lop Nor vanished completely in 1972 and became nuclear testing site; the depth of the lake Ohlin at the head of the Yellow River dropped by over 2 cm annually; the Qinghai Hu lake water level decreased by an average of 10 cm/yr between 1959 and 1982 owing to a decrease in rainfall, groundwater supply, and the unsustainable use of the water for irrigation (the total drop since 1908 reached 11.7 m, the lake salinity increased from 5.6 to 12 g/L since 1950). Because of rapid population growth, the surface of Ebi Nor, the largest salt lake in northwest China's Xinjiang Uygur Autonomous Region, has shrunk to 530 km^2 in the past five decades (its surface was 1200 km^2 in the 1950s). As a result, many plant and animal species living in and around the lake have been extirpated.

Once the fourth largest inland water body with a surface area of 66,000 km^2, total volume of 1070 km^3, and maximum depth 69 m, the Aral Sea was about the size of the Netherlands and Belgium taken together.[1–6] Many fish species were living in the brackish (10 g/L) water, 12 of them were very important for fisheries (yearly catches of 44,000 tons). But over the past 45 yr, the freshwater discharge into the Aral Sea from the Amu Darya and Syr Darya rivers (formerly 50 km^3/yr) has been decreasing because of diversions for irrigation and ceased almost completely.

As a result, the Aral has split into two subsidiary bodies, its surface level has dropped by almost 23 m (in the Large Aral), the sea has shrunk by a factor of four in its original size and a factor of 10 in its volume, and the salinity exceeded 82 g/L in the western Aral Sea and is even higher in the eastern part (150 g/L). The desiccation and salinization of the sea have led to desertification and degradation of the regional ecosystem, and had severe impact on the quality of life and health of the local population.

The Dead Sea is a deep salty terminal lake at the border between Israel, Jordan, and the West Bank. The Dead Sea waters are probably the saltiest (340 g/L) and densest (1.237 g/cm^3) lake/sea waters in the world.[7] Its level is determined by the balance between river runoff, precipitation, and evaporation. Since the 1960s, the hydrological regime of the Dead Sea has been strongly influenced by use of its watershed by Israel, Syria, and Jordan. Moreover, Israel and Jordan are using the seawaters for mineral production at salt evaporation ponds located south of the sea, responsible for 25–30% of the total Dead Sea evaporation. As a result, evaporation exceeded fresh water inflow to the sea. Since 1977, the length of the sea decreased from 80 to 50 km and the level has dropped by 14 m at rates of 0.6–1.0 m/yr.[7] Plans have been developed to construct a pipeline to bring water from the Red Sea into the Dead Sea to stabilize or raise the water level. The pipeline, referred to as the "Peace Conduit" project, would bring about 450×10^6 m^3 of Red Sea water into the Dead Sea annually.[2]

Global warming (during the 20th century, the mean land surface temperature in Africa has increased by 0.9°C) and withdrawal and/or diversion of water from inflowing rivers are the reason for the water level drop in several African lakes.[1,2] Lake Chad, once one of the largest on earth, has been a source of freshwater for irrigation projects in Chad, Niger, Nigeria, and Cameroon. Since 1963, the lake has shrunk to nearly a twentieth of its original size (from ~25,000 to ~1,350 km^2), owing to both climatic changes (including a 50% decline in rainfall) and high agricultural water (between 1983 and 1994, irrigation water use increased fourfold). Lake Victoria, shared by Kenya, Uganda, and Tanzania, with a surface area of 68,000 km^2, is the world's second largest and the largest African body of fresh water in terms of surface area.[1] It is of great socioeconomic importance for 20 million people living in the basin. Over the past few decades, Lake Victoria has been a subject to drastic ecological and water quality changes owing to pollution (including sewage discharges and agricultural runoff); sediments resulting from soil erosion in the catchment area because of deforestation and overgrazing; and industrial pollution from many local industries. All these factors have resulted in the eutrophication of the lake because of the increase in nutrient supply to the lake, algal blooms, and massive fish deaths.

A number of lakes in the North America have also experienced desiccation in the past century.[1] For instance, the Pyramid Lake in Nevada experienced a 21 m level drop since 1910, accompanied by a salinity increase from 3.8 to 5.5 g/L between 1933 and 1980. In California, Owens Lake (once 280 km^2) dried almost completely and Mono Lake's level dropped 17 m from 1919 to 1982 owing to diversions of their tributary system. Even the world's largest freshwater system, the North American Great Lakes, may be shrinking. In 2002, the aggregate level of the five Great Lakes was at the lowest in more than 30 yr. Since 1997, Lakes Huron, Michigan, and Erie have dropped over 1 m, and an additional drop of 0.5–1 m has been predicted. These changes are attributed to decrease in precipitation; enhanced evapotranspiration and reduced ice cover because of higher temperatures; and irreversible loss of water for urban and industrial uses (for example, Chicago sends its used water taken from the lakes to the Mississippi basin after treatment, instead of back to the Great Lakes).

CONCLUSIONS

In 1986, the International Lake Environment Committee and UNEP started a project called "*Survey of the State of World Lakes*," aimed at collecting and analyzing environmental data on 217 lakes, including 64 from Asia, 61 from North America, 56 from Europe, 20 from Africa, 12 from South America, and 4 from Oceania.[8,9] The results have indicated that environmental problems, common for the lakes in all continents, may be classified in the following categories:[9] (i) lake shallowing and salinization owing to overuse of water from lakes and/or tributary rivers, resulting in a degradation of water quality and lake ecosystems; (ii) accelerated sedimentation in lakes and reservoirs resulting from anthropogenic or natural soil erosion; (iii) lake water acidification resulting from acid precipitation, which may result in the extinction of ecosystems, and contamination of water with toxic agricultural and/or industrial chemicals; (iv) eutrophication owing to inflow of nitrogen and phosphorus compounds or other nutrients in the discharged water or waste water inflows, strongly affecting biodiversity; and (v) in extreme cases, a complete collapse of aquatic ecosystems and desiccation of lakes. In addition, shallowing and desiccation of inland seas often lead to nonhydrologic consequences, such as air pollution from dust storms caused by wind erosion of exposed lakebeds.

One of the principal tasks for future research is the delimitation of the anthropogenic and natural climate change impacts on lakes. Climate change is the reason for the water level drop in only a few cases. Shallowing or desiccation of lakes has caused local climate changes in numerous drainage basins, and if the present climatic trends persist, global climate changes could trigger almost untenable environmental effects for people and aquatic ecosystems.

Increased fresh water consumption for agricultural, industrial, and urban uses and uncontrolled irrigation pose a serious threat to inland seas, lakes, rivers, and wetlands as well. Regular measurements of the sea/lake level are practically absent in many regions such as Central Asia and Africa. Monitoring of the evolution of these water bodies may be accomplished by satellite altimetry from the TOPEX/Poseidon, Jason-1, ERS-1, ERS-2, GFO, and Envisat.[10]

Degradation of many inland water bodies is a continuing global environmental problem and its social and economical implications have attracted the growing attention of many individuals and organizations, resulting in many national and international research projects.

Sediment Budgets

Desmond E. Walling
Department of Geography, University of Exeter, Exeter, Devon, U.K.

INTRODUCTION

The sediment budget concept represents a means of expressing the principle of conservation of mass or mass balance that characterizes the operation of erosion, transport, and deposition processes within the environment. The concept can be applied to a range of spatially defined environmental systems, including drainage basins, beaches, dunefields, lakes, and glaciers, and to smaller subsystems within these, such as a slope, an alluvial fan or a channel reach within a drainage basin. The mass balance equation for a given system or subsystem takes the form:

$$\text{Output} = \text{Input} \pm \Delta\ \text{Storage}$$

Sediment budgets can be established at different spatial and temporal scales, ranging, for example, from a global representation of land erosion and land–ocean sediment transfer involving annual fluxes, to the evolution of a sand or gravel bar within a river channel during an individual event. Their potential value lies in two main applications. First, they can provide a conceptual framework for developing an improved understanding of the interaction of erosion, transport, and deposition processes, by quantifying the fluxes involved and demonstrating the importance of sinks or stores. Second, they can provide a useful management tool for assessing changes resulting from human activities, and for informing the design of sediment management and control strategies and the prediction of the likely impact of future environmental change. From a water science perspective, it is appropriate to emphasize the sediment budgets of drainage basins and this entry will focus on this aspect. Some workers interpret the term ''sediment'' to embrace both particulate (or clastic) and dissolved material (or solutes), but here attention will be limited to clastic material or sediment sensu stricto. This contribution will briefly review the development of sediment budget studies, provide examples of sediment budgets developed for particular drainage basins, and discuss their implications and practical application, and finally outline the problems associated with establishing reliable catchment sediment budgets and thus using the sediment budget as a management tool.

THE DEVELOPMENT OF SEDIMENT BUDGET STUDIES

Although it has been suggested that the origin of the sediment budget concept, as applied to drainage basins, can be traced back to the early 20th century and the work of Gilbert, when investigating the fate of mining-derived sediment within the Sacramento River basin in California, credit is more usually attributed to Jackli[1] and Rapp,[2] who were among the first to attempt to document rates of sediment mobilization and transfer within small drainage basins. Their work was expanded upon by several subsequent workers, including Dietrich and Dunne,[3] who produced a detailed sediment budget of the 16.2 km^2 Rock Creek catchment in the Oregon Coast Ranges. Much of this early work focused on mountain or steepland catchments and emphasized the geomorphic evolution of the basins, linking weathering and soil development to slope stability, mass movements, sediment storage, and the sediment flux at the catchment outlet. It was, however, the work of Meade and Trimble[4–7] on drainage basins and river systems in the eastern and central United States that demonstrated the wider relevance of the concept, by highlighting the importance of alluvial storage within the channel and floodplain systems of drainage basins. By focusing attention on the important role of such storage in influencing the relationship between upstream erosion or sediment mobilization and downstream sediment yield, their work clearly demonstrated the value of the sediment budget concept for understanding erosion and sediment delivery in drainage basins.

EXAMPLES OF CATCHMENT SEDIMENT BUDGETS

Fig. 1, which presents results from the classic work of Trimble[7] on the 360 km^2 catchment of Coon Creek,

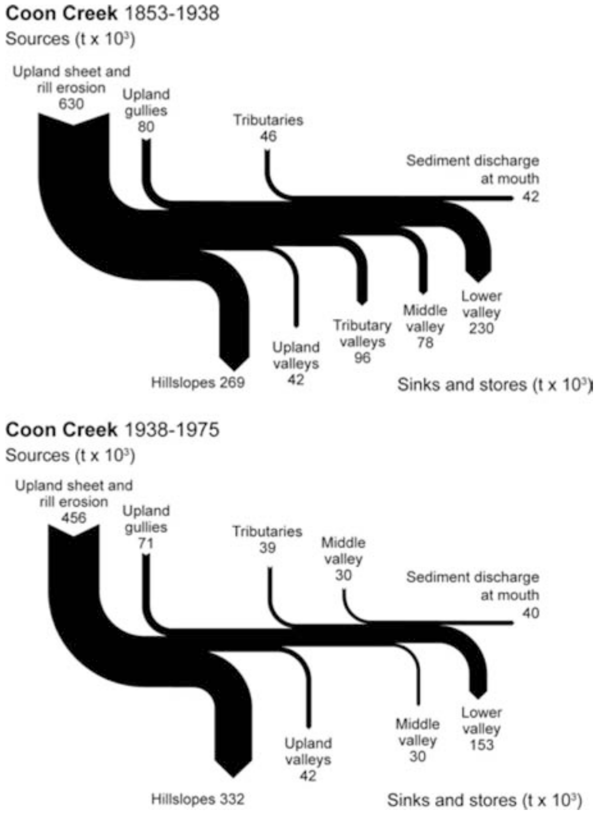

Fig. 1 The sediment budgets for Coon Creek, Wisconsin, U.S.A., for the periods 1853–1938 and 1938–1975 produced by Trimble. The fluxes shown are mean annual values. *Source*: Based on data presented in Ref.[7].

Wisconsin, U.S.A., provides a useful demonstration of the nature of a catchment sediment budget and the way in which it integrates consideration of sources, sinks, and output. In this study, separate budgets were developed for the period of poorly managed agriculture and severe erosion, that followed land clearance and the expansion of agriculture in the latter half of the 19th century and the early part of the 20th century, and for the subsequent period, when soil conservation measures were introduced to control erosion and soil degradation. A key feature of the budgets for both periods is the relatively small proportion of the sediment mobilized within the basin by erosion that actually reaches the basin outlet (i.e. ca. 5–7%). This emphasizes that measurement of the sediment yield at a basin outlet may provide a poor indication of the overall amount of sediment mobilized and moved through a basin and that the key to understanding the system lies in identifying and recognizing the importance of the sediment sinks or stores. Fig. 1 shows that during both periods, large amounts of sediment were being stored in the colluvial deposits associated with the hillslopes within the upland areas and in alluvial sinks within both the tributary valleys and the main valley of Coon Creek. Comparison of the sediment budgets for the two periods shows that although the implementation of soil conservation measures after 1938 greatly reduced upland erosion rates, producing a ca. 25% reduction in sediment mobilization from the slopes, the sediment yield at the basin outlet changed very little, owing to the increased efficiency of sediment transfer through the channel system (i.e. reduced deposition) and the remobilization of sediment that had accumulated within the middle valley during the preceding period of accelerated erosion. Evidence of the importance of sediment storage and remobilization, such as that provided in Fig. 1, emphasizes the key role of sediment sinks in controlling the sediment response of a drainage basin.

From a management perspective, a sediment budget similar to that presented in Fig. 1 affords a useful means of identifying the most important sediment sources that would need to be targeted in any attempt to reduce downstream sediment fluxes and to optimize the use of the resources available for implementing control measures. It also emphasizes that control of upstream erosion may not necessarily result in a significant reduction of the downstream sediment yield, if sediment is remobilized from intervening stores. Knowledge of the sediment budget of a drainage basin is also important in predicting the likely impact of future climate change on its downstream sediment response, since this could change significantly if hydrological changes resulted in the remobilization of sediment from existing sediment sinks, for example, through changing channel morphology and increased channel migration and erosion.

The precise form taken by the sediment budget of a catchment will reflect a wide range of controls, including the local topography and the hydrologic regime. Fig. 2 serves to show the potential nature and extent of such variability by depicting the key characteristics of the sediment budgets of four small drainage basins on the Russian Plain documented by Golosov and his co-workers.[8] These are all relatively small basins, heavily impacted by land use activities and associated soil erosion. The emphasis of the investigation was on establishing the proportion of the sediment mobilized within the catchments by sheet, rill, and gully erosion that reached the basin outlet. In this environment, sheet (i.e. slope) and rill erosion are generally more important than gully erosion as a sediment source and there is little evidence of sediment storage on the lower parts of the slopes. Slopes are frequently convex, terminating at the margins of balkas or flat floored, gully-like features, which dissect the landscape. Even in this relatively homogeneous area, the proportion of the sediment mobilized by erosion within the individual catchments that reaches the basin outlet ranges from 0 to 89%. In most of the basins, both the

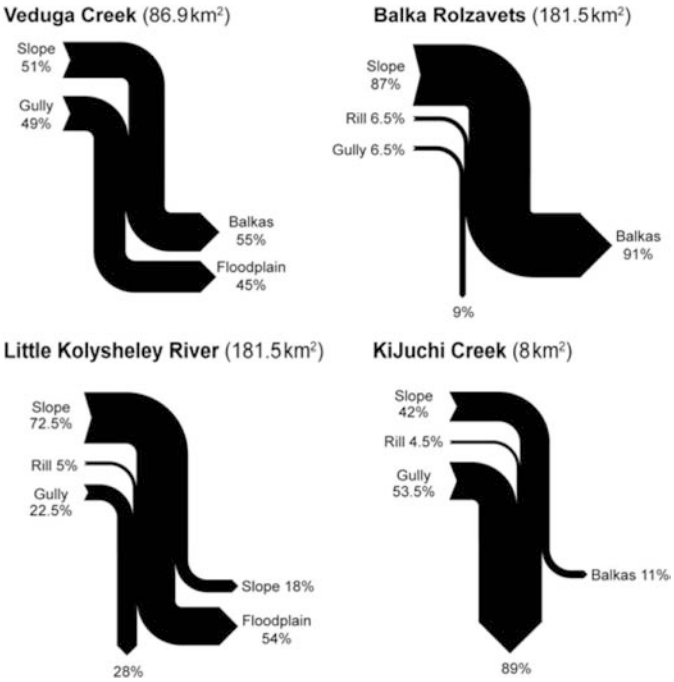

Fig. 2 The sediment budgets for four drainage basins on the Russian Plain, established by Golosov and his co-workers. *Source*: Based on data presented in Ref.[8].

balka bottoms and the river floodplains constitute major sinks for sediment moving through the system and as with Coon Creek (see Fig. 1), the sinks are a very important component of their sediment budgets.

As the scale of the drainage basin considered increases, deposition of sediment on the river floodplains in the lower parts of the basin will commonly assume increasing importance as a sediment sink. Work within the catchments of the Rivers Ouse and Wharfe in Yorkshire, U.K., reported by Walling and his co-workers[9] has, for example, shown that as much as 30–40% of the sediment delivered to the main channel system is deposited on the adjacent floodplains and does not reach the basin outlet.

Many of the sediment sinks operating within a drainage basin are likely to be long-term sinks. For example, the sediment deposited on the lower parts of a slope will commonly remain in near-permanent storage, unless there is a significant change in the pattern of erosion. Prosser and co-workers[10] have estimated that as much as 80% of the sediment eroded from large coastal catchments in Eastern Australia, as a result of land clearance by European settlers, remains stored in their channels and floodplains. However, some sinks may be more readily remobilized and therefore operate as shorter-term stores. This was the case with the middle valley sink depicted in Fig. 1. Furthermore, at the annual timescale, sediment deposited within the channel system may accumulate during one period of the year, only to be remobilized and flushed out by high flows during a subsequent period. In this situation, storage is clearly temporary.

The residence time concept proposed by Madej,[11] although primarily applicable to coarse sediment stored in river channels, provides a useful basis for characterizing the timescales of sediment storage associated with a sediment budget. In her study of Redwood Creek in Northwest California, Madej estimated the residence time (years) of coarse sediment stored in individual reaches by dividing the storage (m^3 per unit length of valley) by the downstream transport rate (m^3 per year). A similar approach could be applied to the overbank deposits in a reach of river floodplain by estimating the total mass involved and relating this to the deposition flux and the rate of removal by erosion associated with channel migration.

ESTABLISHING A CATCHMENT SEDIMENT BUDGET

While the sediment budget concept undoubtedly represents a valuable tool for both understanding and managing the sediment response of a drainage basin, its value is potentially compromised by the difficulty of establishing a reliable sediment budget for a catchment, and particularly for anything other than a fairly small catchment. Traditional monitoring techniques are not well suited to documenting the spatially and temporally variable processes involved. Recent advances in the use of environmental radionuclides to document rates and patterns of soil redistribution on the slopes of a drainage basin and of sediment deposition within floodplain systems, as well as in the

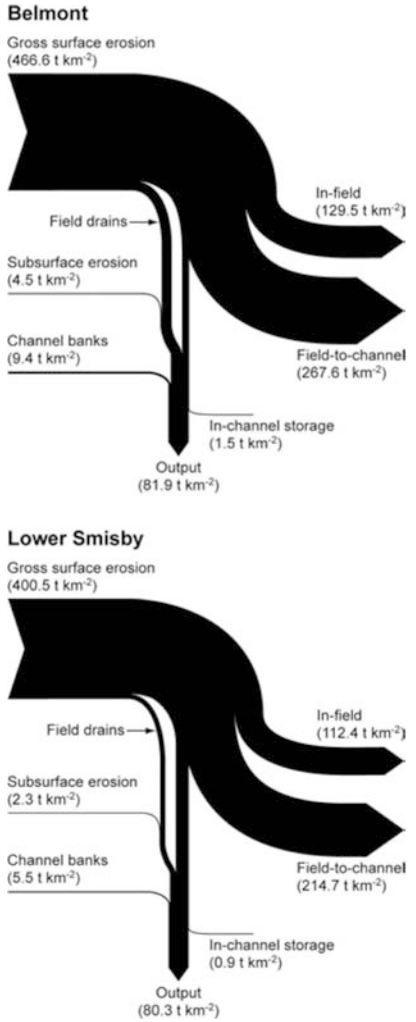

Fig. 3 The sediment budgets established for the Belmont catchment (1.5 km^2) in Herefordshire, U.K., and the Lower Smisby catchment (2.6 km^2) in Leicestershire, U.K., by Walling and co-workers. *Source*: Based on data presented in Ref.[14].

application of sediment source tracing or ''fingerprinting'' techniques to establish sediment sources, must be seen as greatly increasing the ability to assemble the information necessary to establish a reliable sediment budget.[12,13] Fig. 3 presents the sediment budgets established for two small agricultural catchments, in the U.K. using these novel approaches.[14] In this case, subsurface field drains represent an important transfer pathway for sediment and they have been incorporated into the sediment budget.

CONCLUSION

This entry has traced the development of the sediment budget concept as applied to drainage basins, provided examples of catchment sediment budgets and their use, and emphasized the problems of assembling the information necessary to establish a reliable sediment budget for a catchment. Sediment problems in catchments and river systems are attracting increasing attention in many areas of the world and the establishment and analysis of catchment sediment budgets is likely to play an increasingly important role in informing the design and implementation of effective sediment control strategies. In view of the importance of fine sediment as a vector for the transport of many contaminants, such as pesticides and heavy metals, the value of the sediment budget concept extends well beyond sediment per se.[15]

Sediment Load

Xi Xi Lu
David L. Higgit
Department of Geography, National University of Singapore, Singapore, Singapore

INTRODUCTION

"Sediment load," strictly speaking, refers to the nature of the material being moved by a stream or river, though in practice the term is used widely in the literature to indicate the quantity of sediment moving through a river section in a given time interval. Some authorities[1] prefer the term "sediment discharge" and its units are normally expressed as t/yr. This refers to the solid part of the total material load carried in rivers, as distinct from material transported in solution, termed the dissolved load. A standard definition of dissolved load refers "to the constituents in a representative water sample that passes through a 0.45-μm membrane filter."[2] The size criterion is necessary because colloids are transitional between the suspended and dissolved loads. Summerfield[3] prefers the terms "mechanical" and "chemical" to refer to the solid and dissolved components, which together can be used to infer denudation rates. As sediment discharge varies enormously among river basins of different sizes, the flux is often expressed as a specific sediment yield (t/km^2/yr). Numerous empirical studies have demonstrated that specific sediment yield is negatively correlated with basin area and have noted that the amount of material transported through the river section is often a small fraction of that mobilized on basin slopes by erosion processes.[4]

Following Einstein,[5] sediment load can be divided into wash load and bed-material load components. Wash load is that part found significantly in suspension and travels at approximately the same velocity as the flowing water. At non-flood discharges, suspended sediment is generally up to about 0.35 mm in particle diameter.[6,7] The bed-material load moves close to the boundary by rolling, sliding, or saltation (jumping), and consists of sand size or larger sediment (>0.35 mm particle diameter). Particles move slower than the flowing water because of collisions with the bed and other particles. This distinction between wash load and bed-material load is, in principle, similar to subsequent classifications based on the predominant transport mode or field measurement method: suspended sediment load and bedload.[8] Generally, bedload can be considered as a synonym of bed-material load, and suspended load as a synonym of wash load, although part of bed-material load can be temporarily suspended in rivers during turbulent mixing processes. Suspended sediment and bedload have distinctive characteristics in terms of source areas, material properties, transport dynamics, and the nature of measurement techniques.

SUSPENDED SEDIMENT LOAD

Suspended sediment load accounts for more than 90% of the total sediment load for most rivers. If the stream is small and/or well mixed, a grab-sample near the water surface in the center of the stream can be sufficient to represent suspended sediment concentration. In larger rivers where suspended sediment is nonuniformly distributed, two kinds of sampling methods are recommended: depth-integrating and point-integrating.[1] Depth-integrating samplers are designed to have continuous intakes as the sampler is lowered at a constant speed (normally equal or less than 0.4 times the stream velocity) from the water surface to the streambed and back, providing a discharge-weighted sample over the vertical profile. Point-integrated samplers sample at a designated depth by opening and closing electronically. Sampling is problematic in rivers with coarse sediment, weak turbulence, or shallow depth, because the instrument cannot sample near the bed where suspended bed-material load is highest. An indirect method to monitor suspended sediment concentration continuously is the turbidity meter. Readings should be calibrated against measured concentrations, which are influenced by sediment size, shape, and mineralogy.

Following Langbein and Schumm,[9] numerous attempts have been made to explain the global patterns of sediment yield in terms of climate and/or vegetation[10–12] or topography[13,14] Sediment discharge is a function of five interrelated variables—climate, geology (soil) and topography, vegetation, and disturbance, both natural and imposed. Natural disturbances include fire, vegetation disease, slope failure, and volcanic activity, whereas imposed disturbances include construction, agriculture, urbanization, and many other land-use and water-use practices. Suspended sediment in the major rivers is derived mainly from upland sources by interrill, rill, and gully erosion, and by the entrainment of stored bottomland sediment, especially that of channel banks and bed. As fine-grained materials can be readily transported in suspension, sediment load is generally supply limited and dominantly controlled by factors influencing slope erosion in the drainage basin. The Asian rivers, in particular, Ganges/Brahmaputra and Yellow River (Huanghe), have higher sediment loads compared to other rivers (Table 1). Human activity is influential in accelerating soil erosion by deforestation, expansion of agriculture, and inappropriate soil management (e.g., Huanghe), while conversely sediment load is decreased by building reservoirs and dams, river-diversion projects, and other structural intervention such as dredging (e.g., Colorado, Nile). These anthropogenic influences complicate the identification of controlling factors on sediment load.

Numerous attempts have been made to estimate the global sediment load delivered to oceans. Generally, there are two kinds of methods for predicting sediment fluxes: one based on compilation and extrapolation of available sediment yield data,[15] and the other based on modeling the empirical relations between sediment yields and environmental parameters.[9,16] Estimates vary ranging from $<10 \times 10^9$ t/yr[17] to $>50 \times 10^9$ t/yr (Table 2).[20,21] Moreover, the links between upland erosion and downstream sediment load, expressed by sediment delivery ratios, are complicated by changes in sediment storage and remobilization.[22] Thus calculations of the total amount of sediment reaching oceans can be overestimated. Attention should also be paid to sediment yield estimates across regions or within large river basins.[23]

BEDLOAD

Bedload sediment is more difficult to measure accurately. Large temporal and spatial variations in sediment movement and the migration of bar and dune forms impose challenges for representative sampling.

Table 1 Suspended sediment loads for the 25 largest world rivers

River	Drainage area ($\times 10^6$ km^2)	Water discharge (km^3/yr)	Sediment load ($\times 10^6$ t/yr)	Specific sediment yield (t/km^2/yr)
Amazon	6.15	6300	900	146.3
Zaire	3.82	1250	43	11.3
Mississippi	3.27	580	210	64.2
Nile	2.96	30	0	n.d.
Parana	2.83	470	92	32.5
Yenisei	2.58	560	13	5.0
Ob	2.50	385	16	6.4
Lena	2.50	514	12	4.8
Changjiang (Yangtze)	1.94	900	478	246.4
Amur	1.85	325	52	28.1
Mackenzie	1.81	306	100	55.2
Ganges/Brahmaputra	1.48	971	1670	1128.4
Niger	1.21	192	40	33.1
Zambesi	1.20	223	20	16.7

Source: From Ref.[16].

The extensive time and energy needed to execute comprehensive bedload sampling has prompted surrogate-monitoring methods. Direct bedload sampling strategies include trapping in pits or baskets or the use of pressure-difference samplers (the Helley–Smith is the most well-known sampling device). Indirect sampling includes the use of tracer techniques such as painted pebbles emplaced on the streambed. Visual identification of tracer particles is impaired by the burial as the channelbed is scoured and aggraded. Retrieval rates can be improved by inserting a small magnet within particles that can be detected using a magnetic susceptibility probe. Real time information on tracer movement (and by implication the hydraulic conditions under which transport initiates) can be achieved by radio tracking representative particles. At a larger scale, bedload transport can be estimated from the accumulated sediments in reservoirs, lakes, or monitored reaches. Alternatively, bedload as well as total sediment load can be estimated from suspended sediment load data based on assumptions about material type in the channel.

Bed-material load is often assumed to be of minor importance (less than 10% of total sediment load) in most large rivers and in many cases has not been measured or estimated. However, in headwater regions, bedload may dominate sediment load and represent a hazard to water resource development and exert a strong influence on river channel morphology and its ecological function. The channelbed functions as a temporary storage site for bedload though this does not preclude the legacy of past processes (e.g., glacial deposits) influencing bed material composition. The movement of bedload can be viewed as being controlled by three basic independent variables—the fluxes of water as the transport medium, the availability of sediment for transport, and the energy gradient (essentially land-surface slope). From this set several dependent variables characterizing flow, fluid, and sediment properties can be identified (Table 3). The two variables used most often to predict bedload transport rates are bed shear stress and the stream power per unit bed area.[25,26] However, few available empirical equations can provide satisfactory prediction owing to the complexity of riverbed materials and inherent variability of transport.[27]

CONCLUSIONS

Fluvial sediment load has significant implications for river channel management. Channel form and geometry are conditioned by water discharge and sediment load regimes over longer term periods, while in the short term the deposition of sediment can cause local problems of siltation in reservoirs and around water intakes. Furthermore, sediment-associated transportation of nutrients and contaminants contributes to water quality problems. The chemical composition of fluvial sediment has generated research interest in both the ability to link sediment to source areas through fingerprinting techniques[28] and in the role of fluvial sediment flux in biogeochemical cycles. In particular, the impact of human-induced environmental change on sediment flux is an important concern. Globally, soil erosion appears to be accelerating (through agricultural expansion, forest clearance) while sediment flux

Table 3 Variables influencing the bedload transport

Flow properties	Fluid properties	Sediment properties	Other properties

Scaling–Soil Water

from large rivers to the coastal zone is decreasing (through dam construction and water diversion).[29] Syvitski et al.[30] estimate a reduction of 1.4 billion tones per year compared to prehuman sediment loads, which has major implications for coastal retreat and marine biology.

Selenium

Dean A. Martens
Southwest Watershed Research Center, Agricultural Research Service (USDA-ARS), U.S. Department of Agriculture, Tucson, Arizona, U.S.A.

INTRODUCTION

Selenium (Se) is an essential nutritional element, but excessive Se can be toxic to animals and humans. Selenium has an atomic number of 34, an atomic weight of 78.94 and occupies a position in Group VIA of the periodic table between the metal tellurium and the non-metal sulfur. Selenium's chemical and physical properties are intermediate between those of metals and non-metals (Table 1). Selenium has a valence of -2 in combination with hydrogen or metals, and in oxygenated compounds it can exist as the $+4$ or the $+6$ oxidation states giving rise to an array of Se compounds.[1] Six stable Se isotopes occur with varying degrees of abundance: ^{74}Se (0.87%), ^{76}Se (9.02%), ^{77}Se (7.58%), ^{78}Se (23.52%), ^{80}Se (49.82%), and ^{82}Se (9.19%) and a short-lived isotope (^{75}Se) used in neutron activation, radiology, and tracer applications.[2] The average Se concentration in the earth's crust is about 0.05–0.09 mg kg^{-1}.[3] Selenium concentrations range from 0.004–1.5 μg g^{-1} in igneous rocks to 0.6–103 μg g^{-1} in shales of the cretaceous period.

FORMS OF SELENIUM

Important properties of elements, e.g., their bioavailability and toxicity, depend on their chemical form or speciation. Chemical speciation involves the quantification of chemical forms, or species that comprise the total element concentration. Selenium can exist in the (+6), (+4), (0), and (-2) oxidation states, the major feature of Se chemistry that affects the Se solubility and movement in nature. The distribution of the valence states depends on microbial activity, solution pH, and redox conditions. Selenium in the (-2) oxidation state exists as hydrogen selenide (HSe^-) and as a number of metallic selenides. Heavy metal selenides are the most insoluble forms of Se. H_2Se is a toxic gas at room temperature and is thermodynamically unstable in aqueous solutions. Elemental Se(0) exists as several allotrophic forms and is very stable and highly water insoluble. Thermodynamic calculations show that Se(-2) should be found in reducing environments, Se(+4) species in moderately oxidized environments, and the Se(+6) species in oxidizing environments.[4] In waters, dissolved inorganic Se is normally present as (+6) selenate (SeO_4^{2-}) and as (+4) selenite (SeO_3^{2-}).[4]

Inorganic Se

The soluble inorganic Se forms, selenite and selenate, account for the majority of the total Se concentration of waters, although particulate Se(0) smaller than 0.45 μm may also be present.[5] The proportion of selenate/selenite present in waters is generally predicted by the pH–redox status of the system. Selenate is stable under alkaline and oxidizing conditions and selenite is stable under mildly oxidizing conditions.[6] Although, measurement of pH–redox status is a good predictor of Se species,[7] actual speciation must be analyzed as exceptions to the thermodynamic predictable Se species have been reported[8] due to the influences of biological activity.

The ratio of selenate to selenite present in natural waters is also affected by the different adsorption kinetics of selenate vs. selenite. Selenite has a strong affinity for a variety of common minerals at pH values < 7, where as selenate does not;[9] selenite also has a strong affinity for particulate organic matter.[10] Constituents adsorbing selenite include Al and Fe oxides, clay minerals, and calcite. Also microbial populations selectively assimilate selenite over selenate.[11] Due to the many mechanisms for selenite removal from waters, selenate is the major soluble Se species in natural waters.[11]

Another important factor controlling the ratio of selenate to selenite in natural waters is the microbial activity. Microbial activity has been reported to quickly reduce selenite[12] and selenate[12] as well as tellurate, tellurite, vanadate, molybdate, arsenate, and chlorate[12] suggesting that microbial reductions are important for changing the solubility and availability of elements, especially Se.

Organic Selenium

Selenium is required as an essential micronutrient for a host of mammals, birds, fishes, algae, and bacteria.[13] The Se analog of cysteine, selenocysteine

Table 1 Chemical properties of selenium[2]

Property	
Atomic number	34
Atomic mass	78.96
Density ($g\,cm^{-3}$)	4.79
Melting point (°C)	217
Boiling point (°C)	685.4
Atomic radius (um)	0.117
Hardness, relative units	2
Electronegativity, relative units (Li = 1)	2.4
Latent heat of fusion, $J\,g^{-1}$ ($cal\,g^{-1}$)	6.91 (16.5)
Heat of vaporization ($J\,g^{-1}$)	272.98 (65.2)
Thermal conductivity, W (m °C)	0.293–0.766

(SeCys), plays a critical role in the enzyme glutathione peroxidase (EC 1.11.1.9)[14] and regulates ribosome-mediated protein synthesis.[15] Selenium containing organic compounds noted includes selenomethionine, selenocystathionone, dimethylselenopropionic acid, methylselenomethionine, trimethylselenonium ion, and the volatile organics dimethyl selenide (DMSe) and dimethyldiselenide (DMDSe).[16,17] Selenium toxicity through enhanced incorporation of SeCys into protein disrupts the three-dimensional structure and impairs function due to pH differences between sulfhydryl and selenol bridges.[18] In a tragic event that emphasized the need to monitor Se levels in waters generated by agriculture, the inadvertent concentration of Se from agricultural drainage conveyed to evaporation ponds in San Joaquin Valley, California resulted in the formation of organic Se compounds from the assimilation of inorganic Se from the drainage waters[19] that resulted in death or impaired reproduction in aquatic wildlife[19] Selenomethionine has been reported to be the most toxic organic Se compounds ingested by waterfowl,[20] although no other organic Se compound has been tested for waterfowl toxicity.

Volatile Species

A major mechanism for Se cycling in the environment is the biological volatilization of assimilated inorganic Se. Challenger and North[21] first confirmed microbial volatilization of DMSe and since, other Se gases as hydrogen selenide (H_2Se), methaneselenol (CH_3SeH), and dimethyl selenenyl sulfide (CH_3SeSCH_3) have been identified. The two major Se gases of environmental importance are DMSe and DMDSe[22] and are important in fossil fuel emissions, during plant growth[23] and from soil microorganism exposed to inorganic Se as selenate or selenite.[24] Atmospheric Se gases are subject to several important processes such as reaction with hydroxyl radicals and ozone,[25] converted into particles[26] and then removed from the atmosphere by dry or wet deposition. The biological emissions of volatile Se forms are as great as emissions from anthropogenic sources[22] and are an important mechanism for Se cycling.

Elemental Selenium

Elemental Se is allotrophic, not measurably soluble in water, and can exist as gray hexagonal, red monoclinic, and vitreous amorphous forms. In reducing environments, Se speciation is predicted by thermodynamics to be H_2Se, but this species is extremely unstable and is oxidized to elemental red Se. Microbial dissimilatory reduction of selenate or selenite to insoluble Se(0) forms can result in higher concentrations than predicted by the speciation and chemical reactivity of the soluble forms. Although anaerobic conditions have been reported to be necessary for the Se reduction to occur by facultative anaerobes,[27] recent research has found certain bacterium can reduce selenate under microaerophilic conditions to Se(0).[11]

In environmental systems, there are three major transformation mechanisms for Se: oxidation/reduction, mineralization/immobilization, and volatilization with the kinetics of each a function of the Se species, microbial activity, and pH–redox conditions. With the toxicity of Se at only approximately 50 times the dose required as an essential element, knowledge of the transformation mechanisms involved with cycling and processes of Se is vital for prevention of additional problem areas associated with water cycling.

Software Development

Matthias Langensiepen
Department of Modeling Plant Systems, Institute of Crop Science,
Humboldt University of Berlin, Berlin, Germany

INTRODUCTION

Water science encompasses a large number of academic disciplines ranging from basic natural to applied socioeconomic sciences. Understanding water-related system processes can become a daunting task and frequently involves several disciplines. Modeling and software development have become increasingly popular in dealing with the associated complexities, because hypotheses and theories are thereby made subject of objective and time-efficient examination. Thorough planning of the underlying model and software development processes increases the effectiveness of seeking problem solutions in water science. Principles, processes, and tools of modern software development are described in the following.

THE MODEL DEVELOPMENT CYCLE

A model is defined as any structure that a person can use to simulate or anticipate the behavior of something else.[1] Different types of models have evolved in the history of water science, ranging from physical representations of real systems to sophisticated algebraic frameworks.[2,3] Engineers often apply set modeling procedures to solve their problems. These procedures are commonly performed to get a practical job done and not to question their underlying theories. Science-oriented models, in contrast, serve as logical testing frameworks for checking the validity of hypotheses and given theories. Science and engineering models thus follow quite different aims and require the application of corresponding modeling procedures.[4]

When scientific problems are observed, hypothetical solutions are often communicated and discussed in a linguistic form. Languages, however, are opaque to nascent human intuition because they evolve through long-term tradition. It is only the non-linguistic medium of algebraic and symbolic notations that empowers the time-efficient mathematical logic for testing scientific hypotheses.[5] The purpose of scientific software development is to implement mathematical models arising from this process and to provide communication bridges between computers, users, and models. Consequently, knowledge is processed by the software development cycle (Fig. 1).

Initialization and Abstraction

The software development cycle is initiated by problem observation. Characterizing the variability of pressure-flow distribution in soils or understanding the coordination of stomatal conductance in plants are typical examples of current problem observations in water science. Based on past experience and intuition, a researcher would then start formulating hypothetical solutions for these problems. The process would likely lead to the construction of a mathematical model that might be implemented as a software simulation. Since model and software development often involve more than one person who wish to attain specific goals, predefining the functionality of the future model is a useful step before it is actually encoded into executable software.[6] The procedure of defining these so-called use cases helps keeping research and development processes focused.[7,8] A model simulating groundwater flow, for instance, would have much different use case requirements than software solutions for regional precipitation and water balance models.

After having completed the initial exploration phase, sharpened concepts in the form of software requirements may be written as executable acceptance tests.[9] Such tests however do not remain static but constantly evolve throughout the software development process. Each time functionality is added to the software, a corresponding test is added that specifies the new behavior. All tests are executed again then to ensure that the simulation system maintains its integrity. It is in these tests in which other programmers may also receive documentation about how the code is actually working.[7]

The next step of the software development cycle—problem abstraction—reduces search by dividing a problem into smaller subproblems that are mapped into a hypothetical solution structure. Since elements in the problem space and their representations in the solution space are defined as ‘‘objects,’’ object-oriented programming is a useful method for processing scientific knowledge.[10,11] Object-oriented programming lets developers describe their problems in terms of problems, rather than

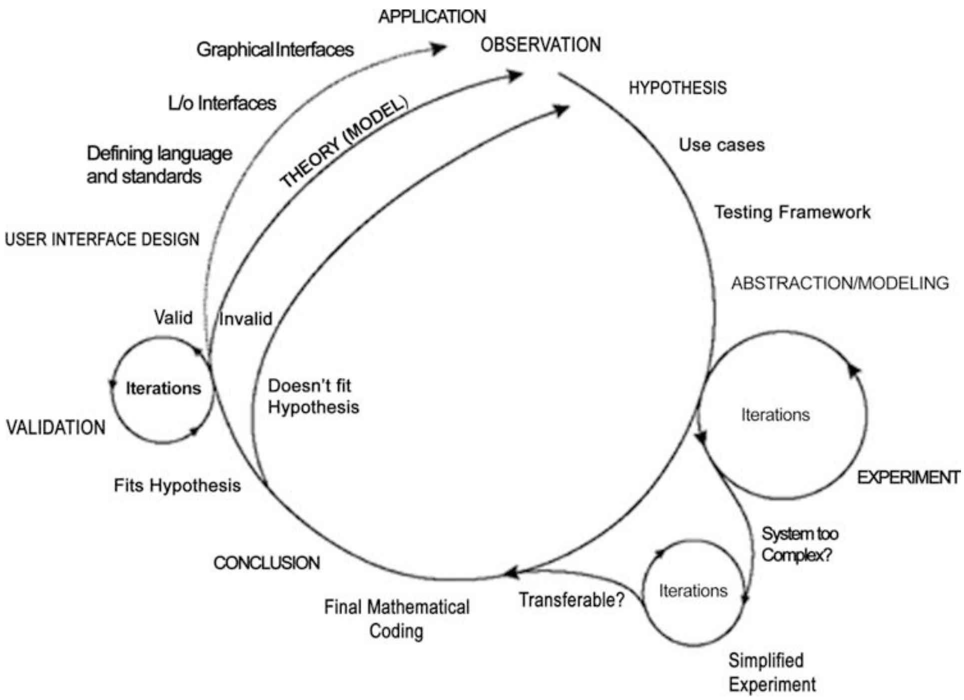

Fig. 1 The software development cycle. (Solid line: model development and software implementation. Dotted line: practical application of validated simulation models.)

in terms of the computer where the solution is executed.[11] Older, so-called imperative languages such as FORTRAN, Delphi, Pascal, or C are still in widespread use. They operate on a higher level of machine language abstraction and force software developers to think more in terms of machine code. This shortcoming is one of the reasons why today's software development technologies make increasing use of the object-oriented programming paradigm.[7,11,15]

Software objects have type names, consist of data storing fields, and use methods to communicate with their environment. A water-catchment system, for instance, could be divided into different functional units like soil patches, streams, plant communities, microclimate regions, etc. Each of these objects would carry a type name, have data fields, and provide methods, which serve as interfaces that communicate with their environment. The objects would possibly contain or be related to other objects. A plant species could, for example, inherit common features of its plant family. It could also be composed of different functional objects like leaves, roots, cells, and transport pathways, etc. that form its general behavior. Careful design of the inter-relations between objects strongly affects the reusability and maintainability of simulation software.[15]

Experimentation and Validation

Every experiment needs an assumption about how a set of problems can be possibly solved. The rigidity of the initialization process makes the experimental validation of these guesses highly efficient. Hypotheses are mathematically expressed, integrity is maintained through test-driven development, and alternative solutions are made available through object-oriented system design. This information is also useful in setting technical requirements for the execution of an experiment, which typically loops through several iterations to capture the temporal and spatial variabilities that are common in water science.

It might happen that the system under observation might prove to be too complex. The functioning of a watershed, for example, involves a large number of processes that as a whole become easily unwieldy. It is a typical procedure then to carry out simplified experiments under isolated conditions. Rain shelters, canal models, wave generators, and growth chambers are typical examples for such conditions. Fitting results of such simplified experiments back into their original model framework often poses a vexing statistical problem known as the ''complexity paradox:'' The closer a model captures the full range of processes and parameters in a system, the more difficult it is to ascertain whether or not the model faithfully describes that system.[12] Judging on the right scale of observation is difficult, therefore, and is often matter of dispute.

Hypothesis testing and validation are the final steps of the scientific knowledge transformation process, where experimental results are compared against their related model outputs. They are fundamentally

Scaling–Soil Water

statistical processes, where systematic and random patterns in the experimental and modeled results are characterized. Prediction errors are frequently quantified by the root mean square error (RMSE) between observations and model outputs. The mean square error (MSE $=$RMSE^2) can additionally be decomposed into a bias and variance component to illustrate the different error sources. Histograms and residual plots are suitable for illustrating the shape of the error distributions and their variance structures.

It has to be mentioned in this context that it is generally difficult to judge the validity of models in water science, because most system processes take place in natural environments, which, as specified, cannot classify as closed systems.[12]

Design and Application

Once a model has been validated through experimentation and manifested as software, it is often applied in practical situations. To make a scientific model useful for such applications, graphical and language interfaces must be added that serve as communication bridges between users and the complex model interior. A vast amount of options exist about possible ways of using and arranging graphical elements like window frames, menus, buttons, dialogs, slide bars, pictures, and so on. To make the usage of these elements ergonomic, it is advisable to take appropriate time for structuring and designing them. User interface design is a very dynamic process with quite substantial changes long after the behavior of a mathematical model has stabilized.

Model design also requires careful planning of electronic data exchange and storage formats. Today's models have increasingly become components of larger simulation frameworks or connect with other models through local area networks or the internet. They retrieve and store data in various binary or ASCII formats that comply with certain standards to facilitate data exchange. Extended Markup Language (XML), for instance, is a new industry-standard, extensible, and system-independent way of exchanging data, which has the potential to become extremely popular among model developers.[13,14] Besides, there is a whole class of programming languages like Python or Perl that is increasingly used for web application and web service development.

The software development cycle is terminated by the practical application of a model. Yet, this does not let a developer off the hook, because changing requirements, observations, and applications almost certainly lead to new iterations of the development cycle. It is at this late stage, where skillful planning of the software system really pays off: The reusability of model components is directly related to the developer's ability to decompose a system into objects (i.e., problem abstraction).[11,15]

TOOLS FOR SOFTWARE DEVELOPMENT

A large number of computer languages and tools have evolved during the history of computing, which makes choices of appropriate development environments difficult. When starting to get acquainted with software development, it is advisable to choose a modern language for which basic integrated development environments (IDEs) can be freely downloaded from the internet. A basic IDE consists of a source code editor, a visual source code generator for window elements, language dependent helper entries, a variable watching facility, and a debugger with basic functionality for stepwise execution of a program. More sophisticated IDEs offer a larger range of options for debugging, refactoring, code construction, documentation, and deployment to speed up development time.

There is a large choice of developer tools on the market fulfilling varying purposes in model development.[16] Many tools support the Unified Modeling Language (UML), which is a family of graphical notations for drawing diagrams of software concepts based on the object-oriented approach.[17,18] The diagrams are on a conceptual level and do not provide insight into the actual code. Translation tools are available that enable code generation from such UML models and visa versa (round-trip engineering). Model navigation and versioning are two other important tool features that enable developers to follow subsequent iterations and to navigate through classes and diagrams. Automated generation of HTML documentation is another important option of development tools aimed at simplifying model usage and exchange. Large-scale software projects benefit from class and pattern repositories that are managed by appropriate developer tools. Finally, XML support is increasingly getting important due to the popular role of this document exchange format in software development.

CONCLUSIONS

Software development plays an increasingly important role in water science serving as an effective knowledge transformation and communication tool. The model development cycle offers a formalized approach for testing research hypotheses about water-related system processes. The success and lifetime of a simulation model is determined by adherence to basic software design principles, among which two principles play a dominant role and certainly also apply to science in general: travel light and embrace change![19]
