PALEOCLIMATE MODELING, QUATERNARY

Introduction

Climate models have proven to be very powerful tools in the study of past, present, and future climate. Particular emphasis has been placed on paleoclimate modeling of the Quaternary. The Quaternary is conventionally defined as the Pleistocene plus the Holocene. This modeling has served two basic roles. First, it has helped us to understand the forces driving the diverse phenomena that occurred during this geologic period. Second, by understanding how climates of the recent past differed from those of the present-day, we can both shed light on how climate may change in the future and help to validate our models by seeing how well they simulate a different climate, especially one for which considerable proxy data exist that enable climate reconstruction over much of the globe.

While many diverse paleo-modeling studies have been made for the Quaternary, two major foci can be identified. The first concerns the phenomena for which this period is best known – the cyclical appearance and subsequent disappearance of massive continental ice sheets over much of North America and Europe. Topics here include ice sheet inception, interactions between ice sheets and climate at the Last Glacial Maximum (LGM), and simulation of entire ice sheet cycles. The second major focus is simulation of the mid-Holocene climatic optimum at about 8–6 kyr B.P. While these two themes have drawn the most attention, numerous

other facets of Quaternary climate have also been addressed, e.g., the last interglacial at around 120 kyr B.P., the Younger Dryas cold event at around 11–12 kyr B.P., quasi-cyclical Heinrich and Dansgaard-Oeschger events, and the study of past abrupt climate changes in general (e.g., Bradley, 1999). Much attention has recently been paid to climatic changes over the past 2,000 years, for example “mega-droughts” over continental interiors (see *Climate variability and change, last 1,000 years*).

A variety of different types of climate models has been used for these simulations of Quaternary climate. Probably the best-known of these are the so-called “general circulation models,” or GCMs (also popularly known as “global climate models”); indeed these types of models will be the primary (but not sole) focus of this chapter. Originally, these only modeled the atmosphere, with the state of the ocean, land surface, and cryosphere specified. More recently, a major push has occurred toward modeling of the entire climate system, with fully coupled ocean-atmosphere GCMs that frequently also include such features as an interactive land surface (including dynamical vegetation components), explicit simulation of sea ice, and most recently, chemistry of the oceans and atmosphere, with particular emphasis on the carbon cycle. These more comprehensive models are frequently referred to as “earth system models,” or ESMs, though it is important to remember that their core component is still a GCM.

A number of earlier studies used a much simpler climate model known as the “statistical dynamical model” or SDM. In recent years, a new, hybrid model has been developed that combines features of the GCM and SDM into a robust model that can be used to simulate long periods of time; these are known as “earth models of intermediate complexity,” or “EMIC.” Finally, a very different type of model, based on the concepts of low-order dynamical systems, has been used to study long term climate changes, such as the Pleistocene ice sheet cycles. These low order paleoclimate dynamical models, or PDMs, have considered the role of such factors as internal non-linear oscillations and external forcings due to Milankovitch orbital cycles (e.g., Berger, 1977) in explaining the ice sheet cycles (as do EMICS).

In the remainder of this entry, we explore in more depth how different climate models have been applied to key problems of Quaternary climate. Since all of these specific Quaternary issues/problems are explored in some detail in other entries of this encyclopedia, key results are summarized rather than explained in detail. The thrust here is rather to explain how one goes about doing this paleoclimate modeling, using an evolutionary time-frame, and emphasizing strengths and weaknesses of the models.

Model descriptions and evolution

The GCM

The core of the GCM is essentially the same type of model that is used for modern day weather forecasting; the major distinction is in how the model is used. For weather forecasting, the model is started from a set of initial conditions and run forward in time for a few days (usually 10–14). For climate studies, the model is used to generate a climatic state for a given set of boundary conditions and forcings. The model must be spun-up for a period of months to centuries, both to remove the effect of what are now arbitrary initial conditions and to come into quasi-equilibrium with the imposed boundary conditions and forcings. The model run is then continued for a period

ranging from a few years to centuries – the model at this point is generating a series of daily weather patterns, which are then used to generate the desired “climatic statistics” in much the same way that real climate statistics are generated from daily weather observations.

The original GCMs (dating back to the 1970s) were mostly atmosphere-only models; the state of the ocean was prescribed by imposing known (for present-day) or reconstructed (for past times) sea surface temperatures (SST). The state of the land surface was prescribed through very simplistic formulations that specified a surface albedo and a crude representation of water availability (and hence surface evaporation); snow cover was either specified or simulated using simple models. The cryosphere (that is sea ice and continental ice sheets) were imposed, again based on observations or past reconstructions. These early GCMs were constrained both by lack of sufficient physically-based knowledge (especially how to deal with the ocean, cryosphere, and land surface) and, very importantly, by limitations on computational resources to run these computer-intensive models. Over the past four decades, both our understanding of the physics and computational resources have increased tremendously; as of this writing (early 2006) GCMs that contain fully-interactive atmosphere, ocean, ice, and land surface components are in wide use. It is, however, fair to say that the atmosphere component is still the best understood (and hence best modeled), though the other components are rapidly catching up. Furthermore, while the greatly enhanced computational resources we now enjoy mean that the GCM can include all relevant components of the climate system, they still cannot be run for very long time spans (e.g., thousands to tens of thousands of years). See McGuffie and Henderson-Sellers (2005) and Washington and Parkinson (1986) for a more detailed discussion of the GCM.

Other models (SDM; low order dynamical; EMIC)

Around the time that GCMs were first used to address questions of Quaternary climate, the SDM was also in vogue, and used to address the same questions. Unlike the GCM (which is a daily weather model used to generate climate statistics), the SDM attempts to solve the questions by providing appropriate physical quantities on seasonal to annual climatic time-scales. The problem is that key physical processes involved in describing individual weather systems (especially those responsible for rain and snow at mid and high latitudes) must be heavily parameterized, that is, explained in terms of basic quantities like temperature and large-scale circulation (Figure P10). Thus, these models, as such, contributed little to direct understanding of Quaternary climate, though as described below, they did make substantial contributions to low order dynamical models, and, especially, to the recent develop of the EMIC. Saltzman (1978) provides a review of the SDM.

Low order dynamical models differ from the other climate models discussed here in that the major goal is not to simulate a specific climate state, but rather to directly simulate the way in which climate changes over long timescales. These models attempt to define the important feedbacks involved in long-term climate change and then to show how both linear and non-linear interactions, as driven or modulated by external forcings, account for the known record of climate change, especially when the climate changes are expressed as a time series averaged either globally or over key geographic regions. Saltzman (2001) provides an extensive review and discussion of these models; for our present purposes, it suffices to say that they

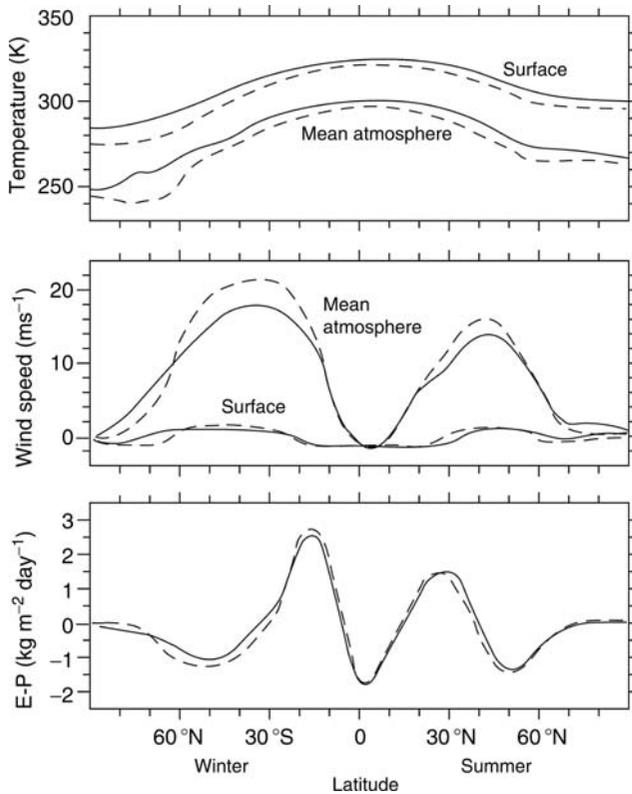

Figure P10 The distribution of zonally-averaged potential temperature (*top panel*), zonal wind (*middle panel*), and evaporation-precipitation difference (*bottom panel*), as simulated by an atmospheric SDM for modern conditions (*full line*) and for 20 ka glacial conditions (*dashed line*) (after Saltzman and Vernekar, 1975).

have demonstrated the important ways in which the state of the oceans, the carbon cycle (i.e., atmospheric carbon dioxide), and the extent and volume of the ice sheets themselves interact non-linearly to describe how the Pleistocene ice ages occur. Furthermore, they show how such key external forcing agents, especially Milankovich orbital cycles, could act as a pace-maker, that is, phase-lock the otherwise arbitrary ice sheet cycles into the specific time frame given by the paleorecords. An additional key feature of these models is that they are computationally very cheap, and therefore can easily be run for thousands or even millions of years.

The most recent addition to the suite of models is the EMIC. This type of model has been developed specifically to address many of the limitations of the above modeling approaches, and therefore draws upon each of them. These models attempt to explain important physical processes with sufficient rigor (drawing upon concepts adapted from both the GCM and SDM), while at the same time being simple enough that, like the low-order dynamical system models, they can be integrated over geologic timescales (at least those spanning thousands of years, Figure P13). Conceptually these models would seem to offer much, and therefore demonstrate considerable promise. However, since they have only been developed over the past few years, the “jury is still out” on how useful they will ultimately prove to be. One key disadvantage of these models is that they have low spatial resolution compared to the GCM (on the other hand this is a key feature that allows very long

runs to be made with them). Claussen et al. (2002) provide an excellent description of one widely used EMIC.

One final modeling approach that has recently been developed and employed is the use of regional climate models (RCM), which have very high spatial resolution (e.g., Giorgi et al., 1990). For many problems, this high resolution is desired or even essential, a good example being the need to resolve mountainous topography (or the full structure of an ice sheet, see Figure P12). Even modern GCMs are typically run for paleoclimate studies at a horizontal resolution no greater than 150 km in latitude and longitude, and many present-day studies are still made with a resolution no greater than 300–400 km. Past studies frequently used even lower resolution GCMs. The drawback to the much higher resolution RCM is inherent in the name; because of computational cost, they can only be run for limited areas, and must be forced at their lateral boundaries, usually from a GCM when conducting paleoclimate studies. Essentially then, the RCM can be thought of as providing a physically based downscaling of GCM results.

With this modeling background developed, focus now shifts to modeling of specific issues of Quaternary climate; emphasizing the use of the GCM, but bringing in other models as appropriate.

Historical development of Quaternary modeling

Some of the earliest GCM and SDM modeling studies involved simulating the impacts of the massive ice sheets of the Last Glacial Maximum (LGM) on the atmosphere (SDM – Saltzman and Vernekar, 1975; GCM – Gates, 1976). Though crude by present-day standards, this work did demonstrate that the climate at the LGM was significantly colder and generally drier than at present, and that orbital forcing played at least some role in accounting for the ice age cycles. Subsequent work generally advanced in two areas: exploration of the physical mechanisms responsible for the relatively cold, dry LGM climate, and snapshot simulations of the climate state every few thousand years from the LGM until the present.

The need to provide specified sea surface temperatures (SST) for the early generation GCM provided the original motivation for the CLIMAP (Climate: Long-range Investigation, Mapping, and Prediction) program, which, in the late 1970s and early 1980s, used all available deep sea core data, especially oxygen isotope data, to develop SST reconstructions for the LGM (CLIMAP group, 1981; Manabe and Broccoli, 1985). These CLIMAP LGM SST became the standard for virtually all GCM work of the LGM, and indeed, with some modification, continue to be used at present. They also engendered considerable controversy when modeling studies using CLIMAP SST yielded significant discrepancies with tropical terrestrial LGM reconstructions from proxy data. Suspicion arose that CLIMAP was flawed over large sections of the tropical Pacific, and much work has gone into resolving this issue, which even at this writing has not been fully resolved (see for example Crowley, 2000; and Toracinta et al., 2004). The controversy does provide an excellent example of the iterative nature by which reconstruction of past environments and paleoclimate modeling work hand in hand.

Another significant development that began in the 1980s was the concept of analyzing GCM time slices through the late Quaternary (especially from the LGM to the present, Figure P11), that is, GCM “snapshots” of simulated climate every few thousand years. The first sets of snapshots

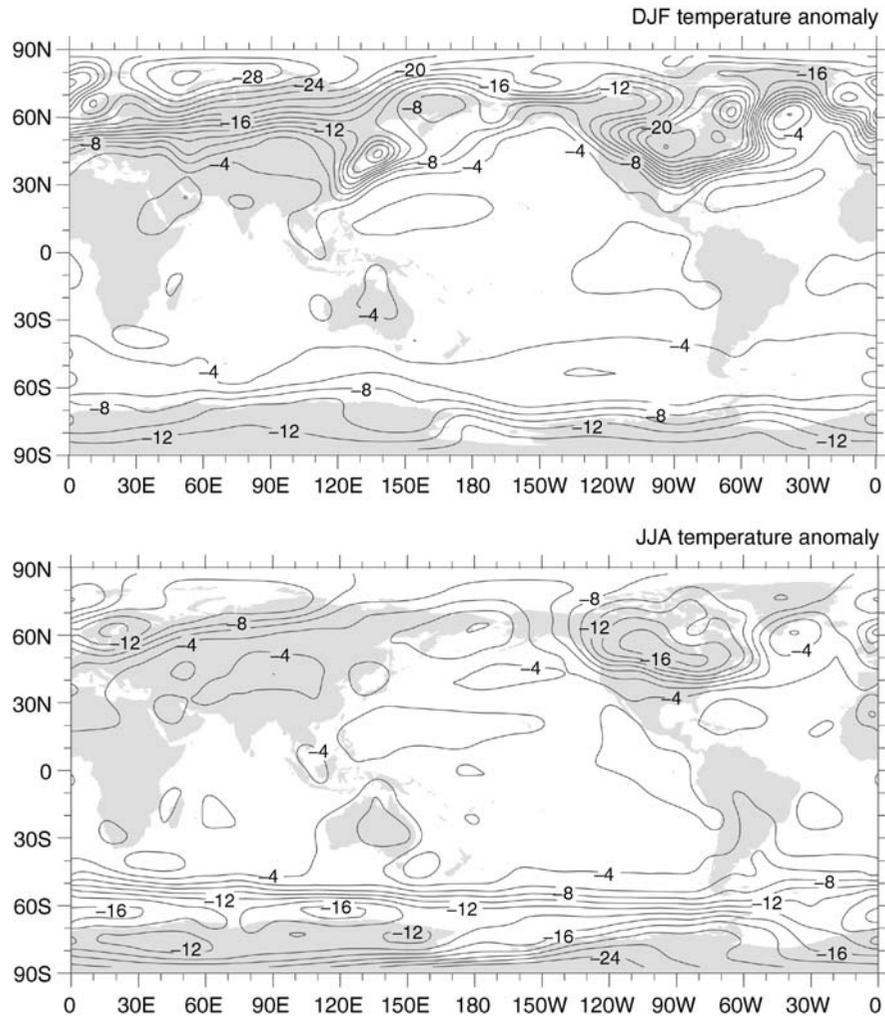

Figure P11 LGM minus present surface temperature anomaly from the NCAR CCSM GCM, averaged over December, January, and February (*top panel*) and averaged over June, July, and August (*bottom panel*). Units are in degrees Celsius (after Shin et al., 2003).

(Kutzbach and Guetter, 1986) were for 18 ka, 15 ka, 12 ka, 9 ka, 6 ka, and 3 ka, or every 3,000 years from what was then thought to be the time of the LGM (18 ka) until the present. Of course, as the difference between “radiocarbon years” and “calibrated years” became known, it was realized that the LGM actually occurred about 21 ka (especially important because it affects the particular configuration of orbital parameters). Thus, subsequent series of model runs had their timings adjusted accordingly. Taken individually, each run of the series can be compared to reconstructions of the Quaternary for that time period. Taken as a group, they can form a description of how climate changed from the LGM to the present, in effect accomplishing, albeit in a different way, a goal similar to that of low order dynamical modeling. These time slice runs have been repeated a number of times, with entirely different models, and with improved versions of the same model. This means that in addition to shedding light on the climate of each of these times, they are also used to describe inter-model differences, and track improvements to individual models.

Related to this time slice approach, the COHMAP (Cooperative Holocene Mapping Project) has focused on reconstructions

and modeling of the Holocene, loosely defined as the time after the ice sheets decayed to a point where they (presumably) had little impact (approximately 9–12 ka depending on research group and specific definitions) (COHMAP, 1988). Much of this attention has been focused on the mid-Holocene so-called “climatic optimum” at 6 ka, when, in the Northern Hemisphere at least, orbital parameters should dictate a relatively warm climate. Particular attention has been paid to changes in Asian, African, and North American monsoonal circulations and effects at 6 ka, as these presumably would have been enhanced. Prell and Kutzbach (1987) have also carefully studied monsoon response in simulations earlier in the Holocene as well as during glacial and interglacial times. Not surprisingly, they found that monsoon circulations tend to be stronger during interglacials than during glacials. In part, this is due to the absence of the ice sheets but it is also because interglacials tend to be times of enhanced orbital insolation.

The above modeling studies were primarily focused on model simulation of the overall climate of specific time periods, and comparison to climates of other times, especially the present-day climate. Quite a number of other studies have

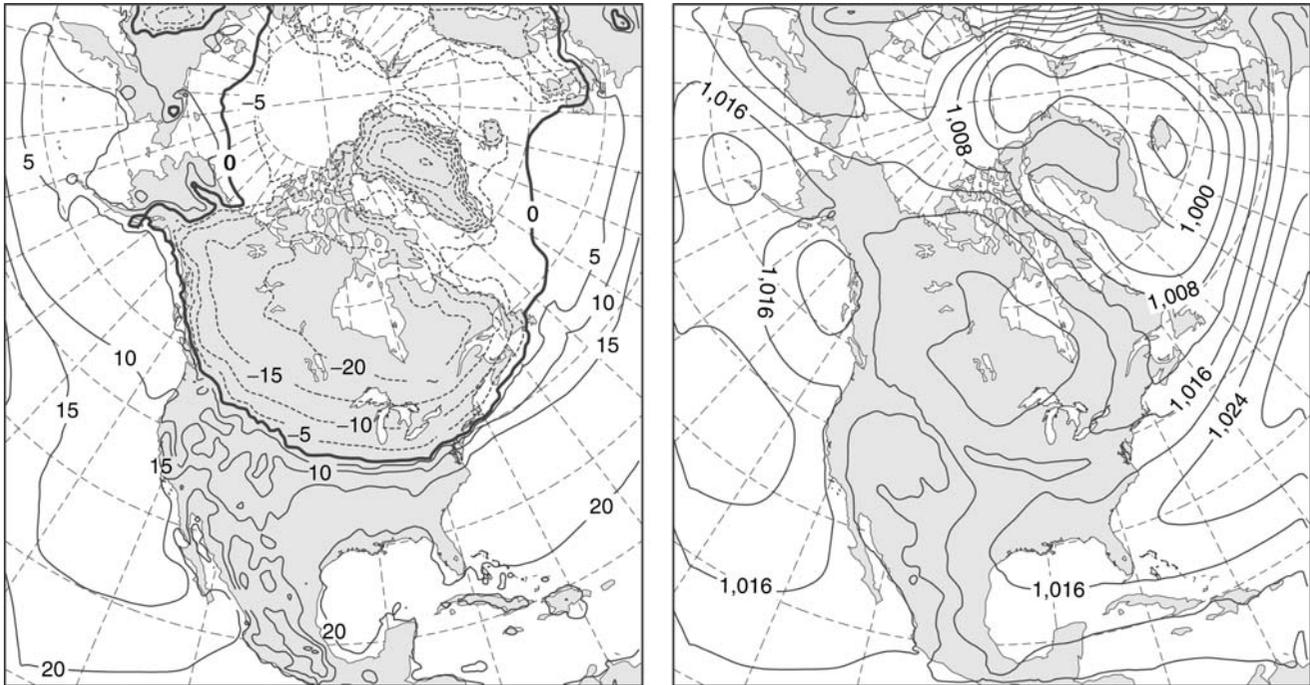

Figure P12 LGM surface temperatures and sea-level pressures as simulated by the PMM5 RCM. *Left panel* is surface temperature averaged over January in degrees Celsius and *right panel* is sea-level pressure averaged over January in hPa (after Bromwich et al., 2004).

addressed how these very different climates have been maintained. These studies fall into two broad categories, the first of which are process-oriented studies for a particular time period. Two key examples here include: (i) the dynamical effects of the ice sheets at the LGM on the circulation of the atmosphere, especially the way in which these very high elevation, white (due to the high albedo of snow and ice) ice sheets impact the circulation (Shinn and Barron, 1989), and (ii) the effect of tropical Pacific SST (especially so-called “permanent La Niña conditions”) on the hydrologic cycle and drought over central North America and northern Africa (Shin et al., 2006).

The second category includes sensitivity studies, in which a series of model simulations is made, spanning a range of values for a particular climate component, boundary condition, or forcing. These can be considered individually, or in concert. Key examples include evaluation of: (i) the sensitivity of climate to ice sheet areal extent, height, and “whiteness” (albedo) and (ii) the relative roles that such factors as atmospheric carbon dioxide (CO_2), orbital forcing, and the ice sheets themselves play in accounting for the cooler climate of the LGM. In the first case, Felzer et al. (1996), for example, demonstrated the importance of thresholds in ice sheet elevation – too low and the atmosphere flows over them, but above a certain height the atmosphere must flow around them instead, yielding a very different regional climate, whose effects in turn can be seen over a much larger portion of the Earth. In the second case, Felzer et al. (1999) showed that the ice sheets and lowered CO_2 played approximately equal roles in accounting for the colder LGM temperatures, with orbital forcing playing a much smaller role.

Recently, considerable attention has focused on extending modeling studies further back in the Quaternary. One particular interest has been 115 ka (sometimes taken as 116 ka), which is

when the last great Pleistocene ice sheet cycle is thought to have begun (Fig. P13). The primary focus of these studies has been on ice sheet inception, that is, how does the climate system change from little or no perennial snow cover to multi-year perennial snow cover and then to growth of ice of sufficient mass that it begins to flow and thereby leaves a trace in the geologic record (Vettoretti and Peltier, 2002)? This is a question yet to be satisfactorily resolved (Dong and Valdes, 1995). Cold temperatures will certainly help preserve snow/ice, but the colder the atmosphere the less moisture it can hold; the warmer the atmosphere the more moisture can precipitate out as snow (assuming surface temperatures not much above freezing). The other time period of interest has been the time around 125 ka, when the last major interglacial occurred. Evidence from the geologic record suggests this interglacial may have been even warmer than the mid-Holocene; orbital forcing was also somewhat larger at this time. Prell and Kutzbach (1987) indeed found in GCM studies that the monsoon at 125 ka was enhanced relative to 6 ka (and hence also to the present).

A few early attempts were made to use regional climate models (RCM) to address some of the above problems, but neither the RCMs nor the GCMs required for the lateral forcings were adequate. This has changed in recent years; regional model simulations of the Laurentide and Fennoscandian Ice Sheets at the LGM have been shown to yield much closer overall agreement with paleo proxy reconstructions than does the GCM used to drive the RCM (Bromwich et al., 2004). In particular, the much higher resolution RCM appears more capable of simulating the highly-variable spatial details of precipitation, and the nuances of topography, land surface type and state, and atmospheric circulation than the low resolution GCM, which all too often can only broad-brush these features. On the other hand, occasionally the RCM will provide surprising results that seem at odds with at least

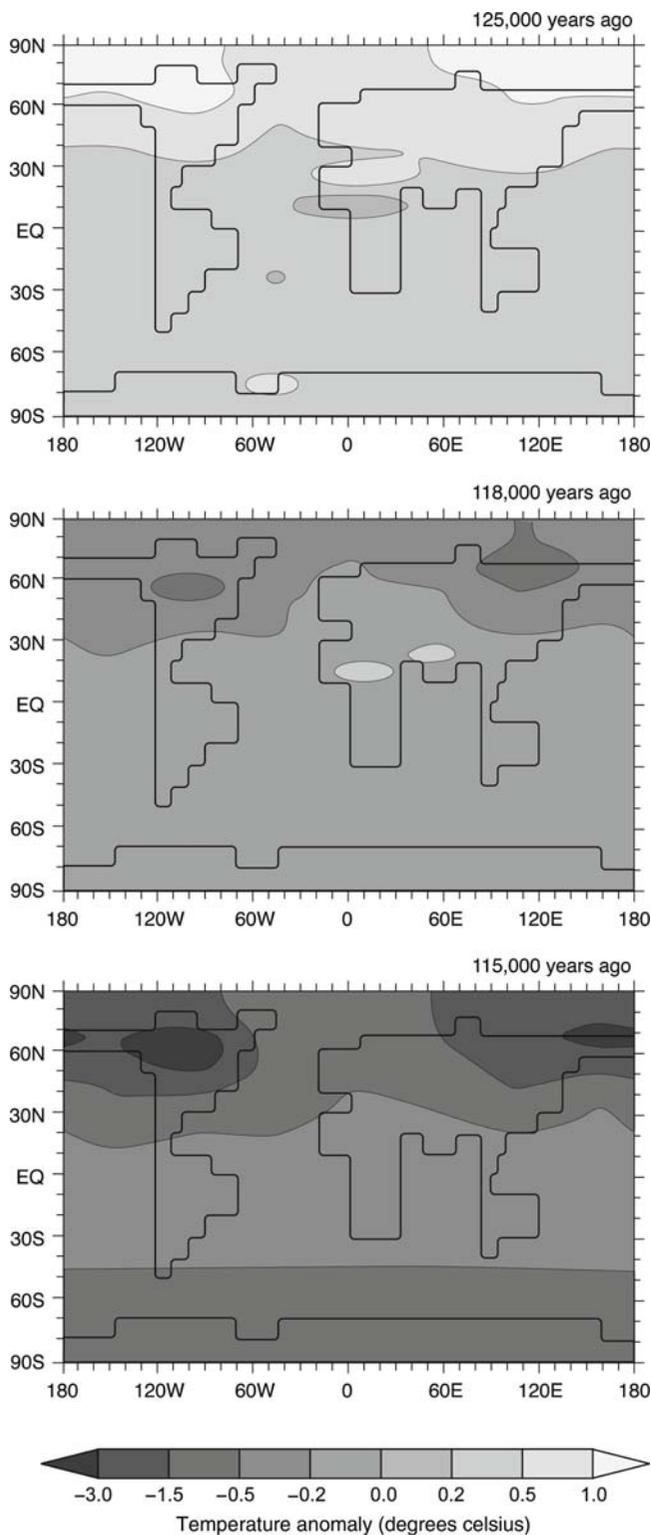

Figure P13 Annually-averaged temperature anomalies, relative to the present, at 125,000 years ago (*top panel*), 118,000 years ago (*middle panel*), and 115,000 years ago (*bottom panel*) from the CLIMBER-2 EMIC. Units are in degrees Celsius. The progression is from full interglacial conditions at 125,000 years ago, to the onset of the next glaciation at 115,000 years ago (after Calov et al., 2005).

the conventional paleo reconstructions. This is yet another example of how models and proxy data together can be used iteratively to provide a much deeper understanding than either one alone. It is likely that GCMs will continue to be used in future paleoclimate studies.

Most recently, the EMIC has been used to address climate problems of the Quaternary. The advantage to these models is that they can be easily integrated over long periods of time. EMICs have been used to simulate changing climate over the past few thousand years (although this is also beginning to be done with GCMs) (Crucifix et al., 2002; Calov et al., 2005). They have also been used to address problems earlier in the Quaternary, e.g., around 400,000 years ago, as well as at the Plio-Pleistocene transition. As described above, it is unclear how informative these models are, largely because of their low spatial resolution (how, for example, can monsoon effects be studied with a model that may only have a 57 degree resolution in longitude?). These models could possibly be considered as an attempt to combine the best of both worlds of low order dynamical models and GCMs; but instead they may actually only capture the worst of both worlds. Again, the jury is still out.

The current state-of-the-art

As climate models continue to evolve, together with our understanding of Quaternary climates, recent efforts have focused on addressing key Quaternary climatic issues with improved models. For GCM studies, this has meant explicitly including other climate components in addition to the atmosphere. Fully-coupled atmosphere-ocean GCMs have been used to simulate the climates of the LGM and the Holocene “climatic optimum” at 6 ka. While somewhat less mature and less well-developed, attention is also being paid to simulating these time periods with interactive vegetation, ice sheet, and biogeochemical cycle components embedded in the GCM (with the model now typically called an ESM). These new, enhanced modeling studies typically have broadly the same results as the more crude earlier models, but do highlight important regional differences and provide new understanding of the relevant physical processes. For example, fully coupled runs at 6 ka have shown the importance of tight atmosphere-ocean coupling in modulating the African and Asian monsoons. This same type of fully-coupled modeling for the LGM-Holocene transition (broadly 9–12 ka) has shown the importance of, and possible bimodality in, the ocean thermohaline circulation, especially the production of North Atlantic Deep Water (NADW). This type of bimodal “switch” or threshold, has profound implications for past climates, and is of potential importance concerning near-term future climate change.

Furthermore, many researchers are now starting to use GCMs not just to study “snapshots” of a particular past time, but instead are actually running the models for periods of thousands of years. A lot of this has already been done for the past 2,000 years, but runs are also underway using a GCM to simulate the past 6,000 years. In addition to the GCM, the EMIC has also been used to perform these simulations through geologic time. By coupling the GCM to high resolution RCMs, models can also commonly be run with local resolutions around 50 km, with as fine as 10–20 km possible. Finally, recovery of higher resolution paleoclimate proxy records in recent years has meant significant improvements in the iterative procedure by which the past reconstructions are used to evaluate the models and, in turn, the model results are used to help understand the implications of the geologic record and guide in the search

for more proxy data. Especially important has been the development of high temporal resolution, well-dated, multi-proxy records from ice cores and lake sediments, which have greatly complemented the more traditional deep-sea cores.

Future directions

One direction that has been discussed for years is the development of a super-model; that is, essentially a super-GCM that has very high spatial resolution, can be run for extended periods of time (at least thousands of years) and that incorporates all relevant climate phenomena, regardless of timescale. In other words, such a model would explicitly simulate the motions of the atmosphere on timescales of minutes, and would simulate the waxing and waning of ice sheets, with timescales of tens of thousands of years. Both the recent development of ESMs and of EMICs can be considered as steps towards the development of such a super-model; however, approaching from opposite ends of the spectrum. That is, the ESM attempts to include as many physical processes as possible at high spatial and temporal resolution (increasing the computer resources needed for long runs severely), while the EMIC, which also attempts to consider as many physical processes as feasible, explicitly uses low temporal and spatial resolution so that long runs can be made. The practical obstacles to developing a super-model are obvious – the need for considerably more computational resources than currently available as well as sharp limitations in our knowledge of the relevant physical processes. In addition, is it not even clear conceptually whether such a model is even possible given the huge range of timescales over which it must be run. Small errors in the short time-scale processes may cascade over longer times, making it impossible to get a satisfactory solution of the long timescale processes.

More use of coupled GCM-RCM studies is likely to be made so that climatic states and phenomena can be studied at much higher resolution. Also, the EMIC could mature as a class of models and continue to provide better ways of making fairly low-resolution but physically-plausible long simulations. Indeed, it may be expected that a “morphing” will continue to take place between the EMIC and low-order dynamical system models. Finally, there will be a continuing need for more and better geologic data to constrain the models, with the models in turn being used to help better understand paleoclimate reconstructions.

Summary and conclusions

The above is intended to provide a concise but necessarily brief and limited overview of how paleoclimate modeling of the Quaternary has developed from the early 1970s until the mid-2000s. Many important problems, concepts, and studies have either been given only a cursory treatment, or even not considered at all. As a glance at the bibliography quickly shows, full treatment of this topic would require at least one, if not several, entire lengthy volumes. All of the issues that have been raised above, as well as those beyond the scope of this discussion, are being actively investigated; none have been satisfactorily “proven,” nor, given the simple fact that we will never know precisely what happened in the past (unless someone eventually constructs a true time machine), will they ever be. Nonetheless, they have taught us many things about how the climate system works, which is perhaps the single most important issue to be addressed via climate modeling of any time period, be it the past, the present, or projected future climate states, as well as the climatic changes required to make them. The interested

reader is strongly encouraged to use this treatment, and especially the papers and books listed in the bibliography, as a starting point for a more in depth study and analysis of this very interesting and important theme.

PALEOCLIMATE PROXIES, AN INTRODUCTION

The Earth's climate has changed dramatically over the eons, as the atmosphere continuously interacts with oceans, lithosphere, and biosphere over a wide range of timescales. Efforts to place recent climate observations into a longer-term context have been stimulated by concern over whether the twentieth century global warming trend is part of natural climate variability or linked to increasing anthropogenic inputs of greenhouse gases into the atmosphere. The ability to decipher past climates has expanded in recent years with an improved understanding of present climatic processes and the development of more sophisticated analytical tools. Instrumental records go back only a century or two. To extend the record beyond the instrumental period, scientists turn to “proxies” or “indicators” that are indirect measures of past climates or environments preserved in natural archives, such as marine and terrestrial sediments, trees, and ice cores, among others. Paleoclimatic or paleoenvironmental proxies are materials that are sensitive to a variety of climatic or environmental parameters. These can be grouped into three major categories: (a) lithological/mineralogical, (b) geochemical, and (c) paleontological (Table P2). The types of information on past climates or environments that can be obtained from these proxies are briefly summarized in Table P2 and below. Additional information is provided in the individual entries listed under *Cross references*.

Lithological/mineralogical indicators

Lithological indicators consist of sedimentary deposits or fossil soils (paleosols) that have originated at or near the Earth's surface under conditions characteristic of a particular climatic regime or environmental setting. The paleoclimatic information yielded by terrestrial lithological indicators comes from interpreting the specific environments under which they formed and their spatiotemporal distribution on local to global scales (see Table P2; Parrish, 1998; *Sedimentary indicators of climate change*). Some lithological or sedimentary indicators point to specific climate conditions, such as glaciation (e.g., tills and tillites, moraines, eskers, kames, kettles), aridity (e.g., eolian dunes, evaporites), or warm, humid climates (e.g., laterites, bauxite) (see *Arid climates and indicators*; *Coal beds, origin and climate*; *Glacial geomorphology*; *Glaciofluvial sediments*; *Glaciomarine sediments*; *Laterites*). Others provide more indirect signs of climate change interpreted from the depositional environments of sediments, using classical geological techniques (see *Encyclopedia of Sedimentology*). Examples of depositional environments include fluvial, deltaic, lacustrine, eolian (wind-borne), near-shore, and deep sea settings (see *Coastal environments*; *Deltaic sediments, climate records*; *Eolian sediments and processes*; *Lacustrine sediments*; *Marine biogenic sediments*). Finely laminated sediments, such as varves, preserve seasonal variations in rainfall, streamflow, ice melt, or chemical precipitation in lakes (see *Varved sediments*). Lithological indicators are also closely linked to biogeochemical phenomena, which create additional paleoclimate proxies (see below).

Major shifts in the environment or climate over longer geologic time periods are marked by pronounced lithologic or compositional changes in the stratigraphic column. A beautiful example can be seen in the well-exposed Carboniferous-Permian strata of the upper half of the Grand Canyon, Arizona, where marine limestones of the Redwall Formation were overlain by intercalated reddish mudstones, sandstones, and calcareous sandstones of the Supai Group deposited in a complex coastal plain setting in which the sea repeatedly advanced and retreated. Eolian features within some sandstone units were likely formed by onshore winds (Beus and Morales, 2003). The Supai strata were succeeded by red beds of the Hermit Formation – siltstones, mudstones and fine-grained sandstones – deposited by rivers, showing cyclical alternations possibly related to climatic fluctuations. Desiccated mudcracks and ripples at the top of the Hermit Shale suggest a climatic aridification, which culminated in the vast accumulation of desert sands represented by the Coconino Sandstone. The seas returned toward the end of the Permian period, as exemplified by the thick marine limestone sequence (Toroweap Formation, Kaibab Limestone).

Minerals that form at or near the Earth's surface reflect ambient conditions at the earth-atmosphere interface and can therefore furnish important clues about former climates (see *Mineral indicators of past climates*). Climate-sensitive minerals can be used to infer past climates and changes over time, to deduce changes in atmospheric composition, to act as mineralogical “markers” in provenance studies, and to serve as “hosts” for stable isotopes and trace elements used in paleoclimate studies. The most direct mineral indicators or proxies are those that are generated under relatively narrow climatic ranges or within restricted environmental settings. Examples include chemical precipitates such as evaporites (e.g., halite, or rock salt), clays formed by intense chemical weathering (e.g., kaolinite, smectite), and chemically-resistant minerals concentrated into eolian

Table P2 Paleoclimatic and paleoenvironmental indicators

Major category	Indicator	Paleoclimate/paleoenvironment parameter(s)
Lithological/mineralogical	Banded iron formations	Atmospheric evolution; ocean paleochemistry
	Bauxite	Tropical, humid climates; paleogeographic reconstructions
	Beachrock	Sea level indicator
	Bedded chert (marine)	Ocean paleoproductivity
	Carbonates, cool water	Cool ocean paleotemperatures
	Chalk	Ocean paleoproductivity, carbonate compensation depth
	Clays (various)	Chemical weathering (humid vs. arid climates)
	Coal	Humid to perhumid climate
	Eolian dust (ice cores; ocean sed.)	Wind strength and direction
	Eolianite (carbonate-rich)	Arid, high wind and wave energy, low relief coasts; interglacial high sea-level stands
	Eskers	Glaciation
	Evaporites	Arid climate
	Dunes	Arid climate; wind direction and strength, atmospheric circulation
	Duricrusts	Warm, seasonally wet/dry climates, semi-arid climates (calcrete)
	Glendonite/ikaite	Cold climate
	Ice-rafted debris	Glaciation
	Kames and kettles	Glaciation
	Lacustrine sediments	Temperature, precipitation, salinity
	Laterite	Tropical, humid climates; paleogeographic reconstructions
	Loess deposits	Periglacial, desert environments, glacial-interglacial variations in wind direction and strength, atmospheric circulation
	Moraines	Glaciation
	Outwash plains	Glaciation
	Paleosols	Precipitation, (temperature–warm, cold), pCO ₂
	Patterned ground	Periglacial environment
	Pingo	Periglacial environment
	Phosphates	Ocean paleoproductivity, wind-driven upwelling zones
	Red beds	Warm, seasonally wet/dry climates
	Roche moutonnée	Glaciation
	Sapropels	Anoxic conditions and/or high paleocean productivity
	Speleothems	Paleotemperature ($\delta^{18}\text{O}$ ratios), vegetation change ($\delta^{13}\text{C}$ ratios), paleoprecipitation
	Tills, tillites	Glaciation
	Varved sediments	Seasonal variations in rainfall or streamflow, glacial or non-glacial sediments; annual dating
	Geochemical	<i>Isotopes</i>
¹⁰ Be		Solar variability, dating
$\delta^{11}\text{B}$		Paleo-ocean pH
¹³ C/ ¹² C		pCO ₂ , C ₃ versus C ₄ plant distributions, ocean paleoproductivity, global organic carbon burial/weathering
¹⁴ C/ ¹² C		Solar variability, dating
² H/ ¹ H		Paleohydrology, paleotemperature
¹⁸ O/ ¹⁶ O		Local atmospheric temperature (in ice), ice volume or sea level (air bubbles in polar ice; benthic foraminifera), paleoprecipitation
¹⁵ N/ ¹⁴ N		Rapid temperature fluctuations (air bubbles in polar ice), stratification in lakes, oceans
⁸⁷ Sr/ ⁸⁶ Sr		Continental weathering, river runoff
³⁴ S/ ³² S		Ocean paleochemistry—changes in sulfate precipitation (evaporites) or sedimentary sulfide burial
<i>Organic matter</i>		
Alkenones		Ocean paleotemperature
Carbon accumulation rates		Ocean paleoproductivity
<i>Trace elements</i>		
Barium (barite)		Ocean paleoproductivity
Boron (as B(OH) ₄ ⁻)		Paleo-ocean pH
Cadmium		Ocean nutrients (in planktonic forams, coccoliths), proxy for PO ₄ ³⁻
Magnesium		Ocean paleotemperature
Phosphorus		Ocean paleoproductivity
Iron		Ocean nutrient
Mn, Co, Ni, Zn, Cu	Ocean nutrients	
Strontium	Ocean paleotemperature	
Geophysical	Electrical conductivity	Variations in ice core acidity, volcanic activity, rapid climate oscillations
	Paleomagnetism	Paleolatitude, dating
Paleontological	Animals, invertebrates	Marine facies, cool versus warm climate, paleolatitude
	Animals, vertebrates	Paleotemperature, biogeography

Table P2 (Continued)

Major category	Indicator	Paleoclimate/paleoenvironment parameter(s)
	Beetles	Paleotemperature
	Coccoliths	Ocean paleoproductivity, biostratigraphy
	Corals, coral reefs	Tropical to subtropical shallow water temperatures
	Diatoms	Ocean paleoproductivity, temperature, salinity, pH
	Dinoflagellates	Ocean paleotemperature, salinity, productivity, sea-ice cover extent
	Foraminifera	
	Benthic	Ice volume, sea level ($\delta^{18}\text{O}$ ratios), ocean paleoproductivity
	Planktonic	Ocean paleotemperature, paleoproductivity
	Ostracodes	Ocean and lacustrine paleotemperature, salinity, precipitation
	Plants	
	Leaf morphology	Paleoaltitude, seasonal and mean annual temperature, precipitation
	Stomatal index	pCO ₂ , temperature, moisture availability
	Tree rings	Temperature, precipitation, interannual variability, annual dating
	Plant assemblages	Paleoecology, paleoclimate
	Pollen	Paleoecology, paleotemperature, paleoprecipitation
	Treeline fluctuations	Growing season temperature variations
	Radiolaria	Paleocean temperature, ocean paleoproductivity

sand (sandstone) deposits (e.g., quartz). Iron-bearing minerals sensitive to oxidation (e.g., pyrite, siderite) may provide information about past atmospheric composition. Hematite-stained quartz and feldspar grains help track the sources of ice-rafted debris in the North Atlantic during the late Pleistocene. Records of oscillations in late Quaternary East African rainfall and in eolian dust transport have been recorded by variations in tracer mineral composition. Minerals such as calcite or aragonite in speleothems, corals, or shells of foraminifera house vital paleoclimatic oxygen isotope data.

Although lithological and mineralogical indicators extend back to the oldest sedimentary rock record almost 4 billion years ago, they are generally qualitative and incomplete. Preservation may have been selective and affected by climate-influenced processes such as erosion, weathering, and deposition. While terrestrial sedimentary deposits or soils have developed in contact with the atmosphere and hydrosphere, their development can also be strongly controlled by other non-climatic processes, such as tectonics. Marine sediments are derived from a combination of terrestrial sources (fluvial, eolian, glacial), biogenic deposition (calcareous and siliceous oozes, bedded cherts, phosphorites, etc.), and authigenic mineralization (see *Carbonates, warm water; Carbonates, cool water; Marine biogenic sediments; Phosphorites*). Ocean sedimentation patterns are products of continental weathering, water temperatures, and ocean circulation, all of which are influenced by climate on regional to global scales. However, marine sediments contain a major archive of climate change, including evidence for rapid climate shifts. Mineralogical, geochemical, and paleontological signals enclosed in these sediments hold important keys to understanding the causes of climate change (see below).

Geochemical indicators

More detailed, quantitative information can be gleaned from geochemical markers contained in sediments. These proxies include isotopic ratios, trace elements, and organic molecules.

Isotope ratios. Most chemical elements have several isotopes, which differ only in atomic weight. Isotope ratios are reported in terms of the notation:

$$\delta^{\text{B}} = (R_{\text{sample}}/R_{\text{standard}} - 1) \times 1,000$$

where a is the atomic weight of the heavier isotope, B is the element, and R is the isotope ratio (heavy to light) in the sample and in a standard reference material, and values of δ are given in parts per thousand (‰). Positive δ values occur when $R_{\text{sample}} > R_{\text{standard}}$; conversely, negative δ values result when $R_{\text{sample}} < R_{\text{standard}}$. The most widely used isotope ratios in paleoclimatology are $^{18}\text{O}/^{16}\text{O}$, $^{13}\text{C}/^{12}\text{C}$, $^2\text{H}/^1\text{H}$, and to a lesser extent $^{15}\text{N}/^{14}\text{N}$ (see *Carbon isotopes, stable; Oxygen isotopes; Deuterium, deuterium excess; Nitrogen isotopes*). A broad array of geological and biological materials can be analyzed for their oxygen, carbon isotope, or hydrogen composition, including the shells of foraminifera, corals, speleothems, tree wood, and ice, to name just a few.

A number of geochemical and biogenic processes cause the ratios of stable (i.e., non-radiogenic) isotopes to vary in nature (see *Stable isotope analysis*). Several of these are related to climate variables, such as atmospheric and ocean temperatures, ice volume, and precipitation. Lighter isotopes of an element are usually more mobile and react faster chemically than heavier ones. The lighter isotopes of hydrogen and oxygen (^1H and ^{16}O) in water, for example, evaporate more rapidly and therefore are preferentially incorporated into water vapor. During condensation, the lighter isotopes remain in the cloud, while the heavier isotopes (^2H and ^{18}O) precipitate out in rainwater (see *Oxygen isotopes; Deuterium, deuterium excess*). Over successive cycles of evaporation and condensation, rainwater becomes progressively enriched in the lighter isotopes, as air masses travel landward and poleward. Thus, snow falling at the poles, which eventually turns to ice, is isotopically lighter. Conversely, ocean water becomes more depleted in the lighter isotopes. The partitioning (or fractionation) of isotopes is also temperature-dependent. The isotopic composition of a mineral, carbonate shell, or snow reflects that of the fluid from which it formed, which largely depends on temperature. In general, as temperature increases, the isotopic ratio of the resulting mineral, shell, or snow becomes progressively lighter. Thus, for example, variations in the oxygen and hydrogen isotope ratios in polar ice can be related to the local atmospheric temperatures from which the snow precipitated. The ice cores can therefore provide a record of temperature variations over glacial-interglacial cycles (see *Ice cores, Antarctica and Greenland*).

During glacial periods, large volumes of water were locked up in polar ice sheets, leaving the oceans relatively enriched in the heavier isotope, ^{18}O . Carbonate shells of benthic foraminifera (which are less influenced by local surface ocean temperature variations than planktonic forams) record deep sea isotope variations that correspond to major global climate changes. The $\delta^{18}\text{O}$ values of these shells were heavier during glacial periods than during interglacials, due in large part to the greater ice sheet volume and lower sea level. However, during globally warm climate periods (i.e., “greenhouse” climates) when polar ice sheets were small or even absent (e.g., the Cretaceous and Paleogene periods), variations in marine $\delta^{18}\text{O}$ values have been attributed mainly to water temperature variations. A number of other factors, however, influence the correlation between oxygen isotope ratios in ocean water and foraminifera, including the species and its preferred temperature range, mean annual and seasonal water temperature, and ocean salinity.

Biological processes also lead to isotopic fractionation that tends to enhance the lighter isotope. For example, $^{13}\text{C}/^{12}\text{C}$ ratios are lower in biologically-produced organic matter than in atmospheric CO_2 or in marine carbonates. Plants take up ^{12}C more readily than ^{13}C . Furthermore, plants utilizing the C_3 photosynthetic pathway show ever greater carbon isotope depletions than those following the C_4 photosynthetic pathway. Variations in $^{13}\text{C}/^{12}\text{C}$ ratios during the Phanerozoic Eon have been interpreted in terms of major changes in organic versus inorganic terrestrial carbon reservoirs (e.g., see *Carbon cycle*). In general, higher $\delta^{13}\text{C}$ values in carbonates imply a greater rate of storage of organic matter enriched in ^{12}C relative to ^{13}C (leaving the inorganic C reservoirs depleted in the lighter carbon isotope).

Trace elements. Trace metals in the hard parts of marine fossils also provide useful proxies of past temperatures and ocean biogeochemistry. Ratios of Mg/Ca , and to a lesser extent Sr/Ca , in foraminifera show temperature-dependent variations. Ba/Ca , Cd/Ca , and Si/Al ratios have been linked to nutrient concentrations and productivity, as have phosphorus and iron. The Mg/Ca paleotemperature proxy is based upon the observation that substitution of Mg for Ca in calcite of foraminifera and ostracodes increases with rising temperatures (see *Ocean paleotemperatures*). Mg/Ca temperature reconstructions can be paired with $\delta^{18}\text{O}$ measurements on the same sample, providing an independent estimate of temperature. However, Mg/Ca ratios are sensitive to differential solution effects as well as changes in ocean pH and salinity.

Organic biomarkers. A number of organic molecules produced through biological activity can serve as paleoclimate or paleoenvironmental proxies. In order to be useful, an organic biomarker should be geochemically stable and well-preserved in the sedimentary record. Furthermore, it should derive from a particular organism or group of organisms, within a restricted environment, and have modern analogs. It should also be fairly widespread in occurrence, over extended geological time periods. A number of organic biomarker molecules have been used as paleoclimate proxies, including hydrocarbons, fatty acids, alkenones, sterols, pigments (e.g., chlorophyll), and lignin derivatives (see *Organic geochemical proxies; Geochemical proxies (non-isotopic)*). Of these, alkenones are probably the most widely used (see *Alkenones*). Alkenones are long-chain ketones produced by marine coccolithophores (see *Coccoliths*), particularly the species *Emiliani huxleyi*. They extend as far back in time as the Cretaceous. The alkenone unsaturation

index, U_{37}^k , expresses the relation of alkenone composition to sea surface temperature. This index increases with increasing ocean temperatures.

Paleontological indicators

Fossils can serve as useful paleoclimate indicators, since plants and animals are often quite sensitive to their environment and to climate. A useful fossil species is one that responds rapidly to climate shifts, spans a range of time without significant evolutionary change, is relatively abundant and widespread in the geological record, and can be well-preserved without subsequent alteration. In some cases, important insights into paleoclimate can be gained if the morphology reflects the organism's adaptation to its environment. For example, plant leaf morphology has been used to interpret paleoclimate by comparing specific leaf characteristics, such as size, thickness, stomatal density, shape, and margin types in living plants to present-day climate (Parrish, 1998; see *CLAMP; Paleobotany*). Leaf physiognomy reflects annual and seasonal temperature and precipitation, whereas stomatal density is more closely related to CO_2 levels and water availability. These characteristics are responses to particular climate regimes and are often independent of taxonomic classification. The climate signal encoded in leaf morphology can be extracted using multivariate statistical methods, such as CLAMP. Leaf physiognomy is calibrated using a reference database with climatic information on modern vegetation. The CLAMP method has been applied to woody dicotyledons, spanning the late Tertiary and Quaternary periods.

Another widely-used approach is the nearest-living-relative (NLR) method. The NLR approach assumes that the fossil had the same environmental tolerances of its closest living relatives and that these tolerances have remained constant over time (for example, the presence of fossilized palm fronds might indicate mild or tropical climates; ancient mangroves would indicate intertidal zones or paleoshorelines). The NLR technique is limited to relatively young fossil assemblages (preferably Neogene and younger).

Statistical methods, such as transfer functions, are employed to quantify links between the modern distributions of species and specific climate parameters (see *Transfer functions*). The transfer function approach was used with certain species of planktonic foraminifera, radiolarians, and coccolithophorids to establish sea-surface temperatures during the Last Glacial Maximum, 18,000 years BP (e.g., CLIMAP Project Members, 1976). In the CLIMAP project, the geographic distributions of modern planktonic assemblages were sampled by collecting core-top material and living specimens from sediment traps. Correlations between the spatial distributions of the modern species and sea-surface temperatures were then established by multivariate regression analysis (e.g., Imbrie and Kipp, 1971). The abundance of the planktonic foram *Neogloboquadrina pachyderma*, for example, varies inversely with sea-surface temperature, making it an excellent high latitude, cold climate indicator. The geographic ranges of the modern species were then compared with their fossil counterparts and the resulting data used to construct boundary sea-surface temperatures for the last ice age (see *CLIMAP*).

The study of pollen and spores produced by plants and preserved in sediments reveals evidence of past ecological and climate changes (see *Pollen analysis*). The shape and texture of the outer layer of the pollen grain, when magnified, is characteristic of a given family, genus, and sometimes even species. Pollen is dispersed by wind, insects, or birds. The grains are

resistant to decay, especially under anaerobic conditions in lakes or peat bogs. Any shifts in pollen abundances over time observed in the sediment column represent changes in vegetation, caused by ecological or climatic factors. As with other biotic proxies, it is assumed that modern analogs exist, that the environmental factors affecting the plants have not changed over time, that their climatic tolerances are known, and that the pollen can be identified at some meaningful level. Biases can be introduced by dispersal mode or differential preservation. To overcome potential biases, palynologists may exclude certain local pollen types that tend to be over-represented. They may also count absolute numbers of grains per cm³ of sediment. Fossil pollen assemblages are interpreted in two principal ways: first by comparing the pollen assemblage at a given site with the surrounding vegetation (modern analog method), and second, by using an indicator species, whose habitat is narrowly defined by ecological or climatic factors that have remained constant. Although pollen analysis could, in principle, be extended much further back in geologic time, in practice this method has generally been applied to Quaternary and Recent vegetation, which have much closer living relatives.

Tree rings provide another important climate archive (e.g., Fritts, 1976; Cook, 1995; Stokes and Smiley, 1996). Trees that grow in seasonal climates, such as mid-latitude temperate or low-latitude monsoonal climates, generally produce discrete annual growth rings – wider during the growing season and narrower during the dormant period. Some useful characteristics include mean ring width, relative width of early to late wood, and ring density. The development of rings, however, depends on many environmental factors, among which are temperature and precipitation. The strongest climate signals come from trees living where sensitivity to some limiting factor, such as rainfall or temperature, is greatest, e.g., at the limits of their ranges. Because of the complex interactions among factors affecting tree growth, the climate response is inferred indirectly through semi-empirical relationships, using multivariate statistical analyses. Standardized tree ring indices are calibrated against long-term meteorological data from the nearest available stations. Additional information on the methodology of tree ring analysis, its application to paleoclimatology, and its limitations is summarized under *Dendroclimatology*.

Multiple proxies

The information provided by any single proxy is limited in its relation to a specific climate variable, or in its initial spatiotemporal distribution. Furthermore, the effects of preservation or subsequent alteration can lead to a certain ambiguity in interpretation. One way of increasing the reliability of paleoclimate reconstructions is by the use of multiple proxies. More confidence can be placed on consistent results obtained from several different proxies. Recent paleoclimate reconstructions often use multiple proxies. For example, a temperature curve of the last millennium has been derived from a combination of tree ring, coral, foraminiferal, δO^{18} , borehole, and ice core data (e.g., Mann et al., 1998; Moberg et al., 2005). A long-term record of global sea-level change has been pieced together, using stratigraphic data, oxygen isotope variations, and marine fossil assemblages (Miller et al., 2005).

Ice cores offer a multitude of paleoclimate proxies from a single source (see *Ice cores, Antarctica and Greenland*). These include concentrations of CO₂, CH₄, and N₂O in trapped gas bubbles, δO^{18} and δd in ice, and stable isotope composition of included gases, dust, and sulfate levels. These proxies

provide insights into glacial-interglacial changes in atmospheric composition and circulation, temperature, ice volume, volcanic activity, and global biogeochemical cycles, among others. The ice core record in Antarctica now extends to 8 glacial cycles (EPICA, 2004).

In summary, climate “proxies” or indicators preserved in sediments, ice sheets and glaciers, caves, corals, and trees provide indirect measures of former climates for geological periods when no instrumental data existed. Many different types of proxies exist (Table P2), which offer qualitative or quantitative information on a number of climatological or environmental parameters, such as paleotemperature, atmospheric composition, ocean and atmospheric circulation, glaciation, or paleoprecipitation. A more complete synthesis of paleoclimate is available through the integration of data from multiple proxies.

PALEO-EL NIÑO-SOUTHERN OSCILLATION (ENSO) RECORDS

Introduction

The El Niño-Southern Oscillation (ENSO) phenomenon involves two extreme states, El Niño and La Niña, and their connection with the atmosphere through the Southern Oscillation. The term El Niño (or “the boy child”) was originally used by Peruvian fisherman in the 19th century to refer to a Christmas-time warming of coastal sea surface temperature (SST), often associated with a decrease in the productivity of local fisheries. Today, El Niño refers to the well known, large-scale warming and deepening of the thermocline across the eastern equatorial Pacific affecting climate over much of the globe. In the mid to late 1980s, Philander (1990) coined the term La Niña (“the girl child”) for the opposite oceanic conditions to El Niño – large-scale cooling across the tropical Pacific. The Southern Oscillation (SO) portion of ENSO describes the global-scale surface pressure oscillation documented by workers around the turn of the century, and first studied by Sir Gilbert Walker. Subsequently, the normalized sea level pressure anomaly records from Tahiti and Darwin, Australia, have been widely used to index the atmospheric pressure gradient across the tropical Pacific basin.

The early physical explanations for ocean-atmosphere interactions at the heart of the ENSO phenomenon deduced by Jacob Bjerknes, and the subsequent oceanographic

contributions by Klaus Wyrtki, have formed the basis for much of what is known about ENSO. The term ENSO was first used by Rasmusson and Carpenter (1982) to describe the interaction of the oceanic El Niño with the negative phase of the Southern Oscillation phenomenon. Bjerknes (1969) popularized the word *teleconnections* to describe the complex of overturning cells consisting of the Hadley (north-south) and Walker (east-west) circulations that direct mass and energy from the equatorial Pacific to other regions of the globe. Thorough reviews of the historical development and our modern understanding of the ENSO climate system are presented by Philander (1990) and Allan et al. (1996).

On interannual time scales, ENSO and its teleconnections generate impacts in both marine and terrestrial environments over a large part of the globe (Rasmusson and Carpenter, 1982; Ropelewski and Halpert, 1987). During the El Niño phase, anomalous cloudiness and convection are generated over the band of unusually warm water that develops across the central to eastern equatorial Pacific. This coincides with lower than normal atmospheric pressure occurring in the eastern Pacific and higher than normal atmospheric pressure in the Australasian region. These patterns cause widespread drought across many parts of Australia, southern Africa, northern India, Sahelian Africa, Indonesia and Southeast Asia (Ropelewski and Halpert, 1987). During the La Niña phase, impacts are generally the opposite of those described above. ENSO also influences high-latitude processes, including North American air temperature, Antarctic sea ice extent and ice chemistry, as well as aspects of Atlantic hydrography relevant to thermohaline circulation (Philander, 1990; Allan et al., 1996).

One of the most significant contributions to the longer-term record of El Niño events was made during the 1970s–1980s by William Quinn, who compiled historical evidence of meteorological anomalies in Peru and adjacent countries back to A.D. 1525 (Quinn et al., 1987). According to this chronology, moderate to strong El Niño events occur at irregular intervals and may appear two years in succession and then not appear for another 3–12 years. An average period of 3.8 years between El Niños was arrived at by considering all events (moderate to very strong) over the period 1803 to 1987. However, these events were not always representative of the wider ENSO phenomenon across the Indo-Pacific basin. As a consequence, Quinn (1992) looked at evidence for responses to large-scale ENSO events, such as droughts in India, Australia and Indonesia, and weak Nile River floods.

Changes in the magnitude and frequency of ENSO events observed in instrumental records since the 1970s have generated considerable debate about recent ENSO behavior, and the possibility that it may be responding to global warming. There is also a growing body of evidence indicating that the near-global influence of ENSO teleconnections can wax and wane on decadal time scales. Decadal variations in ENSO frequency, strength and teleconnections are suggested by 20th century instrumental records. For example, the well-known link between ENSO and the Indian monsoon has virtually disappeared since 1976, in parallel with a recent shift in 1976 to warmer and wetter (El Niño-like) conditions in the tropical Pacific. Another style of decadal ENSO variability consists of modulating the frequency of extreme events; some decades have stronger interannual variability than others do. Fluctuations in ENSO and its teleconnection patterns are probably caused by changes in the frequency, magnitude and spatial characteristics of ENSO events between different climate epochs.

Paleo-ENSO reconstruction

Concerns about the future behavior of the ENSO, and its potential far-reaching effects on societies, have promoted research into its long-term history via proxy records. There is intense interest in documenting ENSO variability in the past, during times when Earth's climate was different from today. Documenting ENSO behavior during intervals when climate boundary conditions (e.g., orbitally determined seasonal insolation, global ice cover, sea level, aerosols) were markedly different from those of today is particularly important. Proxy records can be used to answer specific questions, such as how long has ENSO been operating in its present form and how robust is the ENSO phenomenon during the major climate changes accompanying glacial-interglacial cycles? Furthermore, is ENSO an unstable oscillation that can switch between being "El Niño-like," or permanently "La Niña-like"?

The paleoclimate record can be used to understand both high- and low-resolution changes in the ENSO phenomenon. The ideal situation would be to have a suite of paleo-ENSO records from the tropics that record both the oceanic and atmospheric components of the phenomenon at seasonal time scales. However, with the exception of records of SST and changes in surface-ocean salinity extracted from annually banded corals, no such records exist. High-resolution records, such as tree rings, fire scars, varved sediments and ice cores, register the effects of droughts, fires, floods and air temperature fluctuations that can be attributed to single ENSO events. Nevertheless, high-resolution records for long time periods are still rare.

On the other hand, low-resolution records can also be used, but these need to be interpreted with caution. Former impacts of the ENSO phenomenon can be recorded by riverine deposits, pollen assemblages in lake deposits, beach ridge sequences, marine sediments and geoarchaeological remains. Low-resolution studies of ENSO rely on networks of sites, especially from regions known for their sensitivity to ENSO. Multi-proxy analyses dramatically reduce the possibility that a non-ENSO environmental factor was responsible for ENSO-like changes in climatic patterns. Utilizing networks of sites and a multi-proxy approach is particularly useful when studying the distant past, when climate boundary conditions and ENSO teleconnection patterns may have been vastly different from those observed today.

Evidence for Plio-Pleistocene onset

How old is the ENSO? ENSO-like phenomena, both oceanic and atmospheric, have probably existed since the separation of the eastern Pacific Ocean from the western Atlantic Ocean. During the course of the mountain building process that produced the Andes and Central American chains, and the formation of the land bridge between North and South America, exchanges of seawater between the tropical Pacific and Atlantic Oceans ended. On paleogeographical grounds, the modern oceanic circulation of the Pacific basin has probably existed for about the last three million years (since the late Pliocene), following the final closure of the Isthmus of Panama (Keigwin, 1978). At this time, anticyclonic ocean circulation and high-pressure cells were established in the Pacific Ocean leading to the thermal gradients across the Pacific (cold in the east, warm in the west) that are essential for the development of ENSO events (Romine, 1982). However, the existence of Pliocene ENSO activity awaits confirmation with high-resolution sedimentary records.

Nicholls (1989) argued that ENSO must have persisted continuously throughout the Cenozoic because the fauna and flora of Australia are highly adapted to precipitation variability. Rainfall variability tends to be 30–50% greater in areas affected by the ENSO, such as Australia, compared with areas of similar mean rainfall. Therefore, marked adaptation of the fauna and flora to high precipitation variability in ENSO-affected areas may indicate that ENSO has been operating long enough for these characteristics to have evolved. The Australian red kangaroo, long-haired rat and several species of bird, for example, have all developed opportunistic life-history strategies tuned to erratic rainfall (Nicholls, 1989). These adaptations cannot be attributed to the arid or semi-arid Australian environment alone because they are absent in other arid regions. However, this theory of an ancient ENSO may underestimate the potential range of climatic conditions to which plants and animals can adapt. Comparative studies of adaptations to high rainfall variability in other ENSO-sensitive regions of the world are necessary in order to conclude that ENSO has helped shape the evolutionary paths of fauna and flora.

Pleistocene glacial-interglacial cycles

Low-resolution records

How did the ENSO respond to changes in background climate during glacial-interglacial cycles? One of the first discussions of the past expression of ENSO under an altered glacial climate state was presented by Quinn (1971). Quinn suggested that the paleoenvironmental evidence for enhanced upwelling in the east Pacific during the late Pleistocene, indicating permanently enhanced trade winds, would imply that ENSO was locked in the La Niña state. Anderson et al. (1990) came to a similar conclusion based on high-resolution analysis of late Quaternary marine varves indicating high biological productivity in response to enhanced upwelling along the coast of California. More recently, studies of the Mg/Ca paleothermometer in the surface-dwelling foraminifer, *Globigerinoides ruber*, from the equatorial Pacific Ocean showed that glacial intervals (marine oxygen isotope stages 2, 4, 6, 8, 10) were characterized by markedly stronger upwelling, suggesting enhanced Pacific trade winds and a La Niña-like state for the mean climate (Lea et al., 2000).

In contrast to marine proxies, terrestrial paleoclimate evidence for the last full glacial cycle from Australasia and South America does not show patterns that resemble modern La Niña teleconnection patterns (Markgraf and Diaz, 2000). Paleovegetation records from Java, Papua New Guinea, north-eastern Australia and South America invariably show colder and drier conditions during the last glacial. A high-altitude tropical ice core record from Huascarán, Peru, also shows cooler and drier conditions during the Last Glacial Maximum (LGM; Thompson et al., 1995). If, as suggested by the marine records, La Niña conditions had become a permanent mode, northern Australia and the western Pacific should have experienced high levels of precipitation, and only north-eastern South America should have become arid.

One explanation for this apparent discrepancy between marine and terrestrial records could be that a 3–4 °C reduction in SST in the warm equatorial western Pacific would result in weaker atmospheric convection and an overall reduction in precipitation over both the western Pacific and adjacent land areas. Furthermore, the most recent SST reconstructions, based on Mg/Ca paleothermometry using surface-dwelling foraminifera, suggest that the Pacific was in an El Niño-like state during the

LGM (Koutavas et al., 2002, Stott et al., 2002). An El Niño-like state for Pacific SSTs would help explain the precipitation patterns indicated by the circum-Pacific terrestrial paleoclimate records for the LGM. However, until we have high-resolution paleo-ENSO records from the equatorial Pacific “center of action,” ENSO reconstructions based on teleconnected precipitation patterns during glacial periods should be interpreted with caution because it is likely that ENSO teleconnections do not remain stationary as the background climate changes.

High-resolution records

The best high-resolution paleo-ENSO records for the Last Interglacial epoch (~128–118 kyr B.P.) come from massive corals from the tropical Pacific region. Spectral analysis of time-series of skeletal Sr/Ca and $^{18}\text{O}/^{16}\text{O}$ ratios extracted from annually banded fossil corals from Indonesia (Hughen et al., 1999) and

Papua New Guinea (Tudhope et al., 2001) reveals power at periods of 3–6 years during the Last Interglacial. Hughen et al. (1999) showed that the periodicity of the Last Interglacial ENSO was similar to that for the period 1856–1960, but different from that of 1960–1998. Thus it appears that interannual rainfall and SST variability in the western Pacific region was forced by ENSO during the Last Interglacial, when the background climate was similar to, or slightly warmer than, the modern climate.

The most complete study of past ENSO variability to date used a suite of coral records from Papua New Guinea to examine the behavior of ENSO over the last glacial-interglacial cycle (Tudhope et al., 2001). Multi-decadal sections of annually banded coral analyzed at near-monthly resolution showed that ENSO interannual variability is a common feature of the climate system over the past 130 kyr (Figure P14). While none

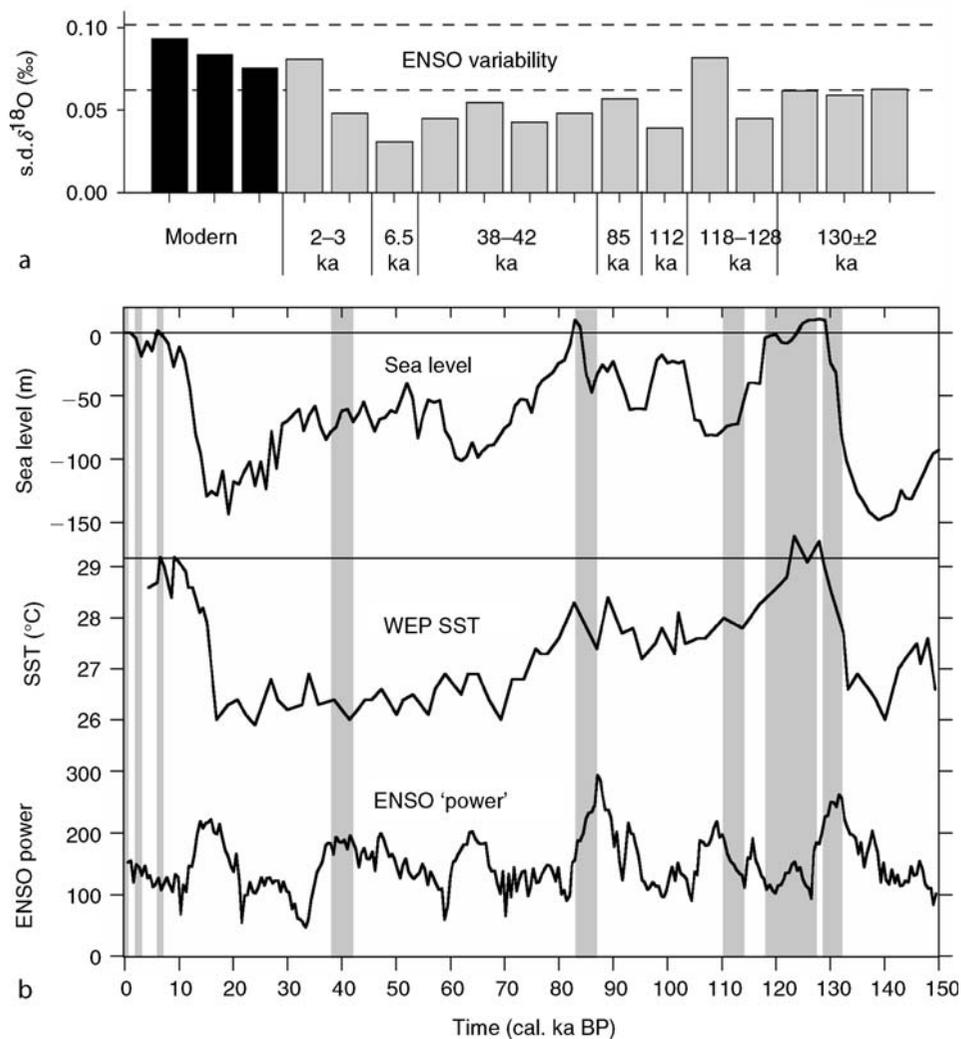

Figure P14 Comparison of paleo-ENSO variability in fossil coral oxygen isotope ($\delta^{18}\text{O}$) records from Papua New Guinea and climate parameters over the past 130 kyr (after Tudhope et al., 2001). **a** Standard deviation of the 2.5–7 year (ENSO) filtered $\delta^{18}\text{O}$ records for modern (black bars) and fossil (grey bars) corals. Dashed lines show the maximum and minimum standard deviations for sliding 30-year periods in the modern coral records. **b** Global sea level (Shackleton, 2000); sea surface temperature (SST) for the western equatorial Pacific (Lea et al., 2000); and changes in ENSO power forced by changing orbital parameters (Clement et al., 1999). Shading marks the eight time periods covered by the coral records.

of the coral specimens dated to the LGM, all the records showed ENSO variability in the characteristic 2.5–7 year band. However, the amplitude of ENSO variability was weaker, relative to modern ENSO variability, during the time intervals examined (130, 128–118, 112, 85, 40, 6.5, 2.5 kyr B.P.).

Paleo-ENSO forcing mechanisms

Three possible mechanisms could lead to weakening of ENSO activity during glacial periods. During glacial sea-level low stands and periods of cooler tropical SSTs, weaker ocean-atmosphere interactions may have dampened ENSO variability (Quinn, 1971). Secondly, shallow continental shelves exposed by lower sea level in the Indonesian Maritime Continent may also have stabilized ENSO variability by anchoring the Indonesian Low convection system. Finally, precessional forcing of the seasonal distribution of insolation in the tropics on ~21,000 year cycles may also contribute to suppressing ENSO variability. A numerical model of the equatorial Pacific Ocean and atmosphere shows that seasonal insolation changes associated with precession of the Earth's equinoxes influence the seasonal strength of the Pacific trade winds (Clement et al., 1999). When perihelion (the time that Earth is closest to the Sun) falls in the boreal summer/fall, stronger trade winds in that season inhibit the development of warm El Niño anomalies in the eastern-central equatorial Pacific. This response may be sufficient to have generated significant changes in ENSO frequency and recurrence over the late Quaternary (Clement et al., 1999).

LGM to early Holocene transition

Paleo-ENSO records

There have not been sufficient paleo-ENSO records to evaluate ENSO behavior during the postglacial to early Holocene transition until recently. Although late-glacial paleo-ENSO records are still scarce, the overall early Holocene trend exhibited in the records includes a low frequency and amplitude of events. Several studies have investigated the paleo-ENSO in north-western South America where torrential rain, floods and erosion occur along the normally arid coast of Peru during strong El Niño events. Based on the analysis of flood deposits from coastal Peru, Wells (1987) estimated that about 100 El Niño events had occurred over the last 40,000 years. Sediment profiles from archaeological sites along the coast of Peru indicate a lack of strong flood events (interpreted as El Niños) between 12–5.7 kyr B.P. at Quebrada Tacahuay (Keefer et al., 1998) and between 8.9–3.4 kyr B.P. at nearby Quebrada de los Burros (Fontugne et al., 1999). Nevertheless, a debris flow in northern Peru, dated at 7.5 kyr B.P. (Wells, 1990), has been interpreted to reflect a major El Niño event, suggesting that ENSO may have operated at that time. The most continuous, high-resolution record for the postglacial transition period comes from laminated clastic deposits in a high-altitude lake, Laguna Pallcacocha, in Ecuador (Rodbell et al., 1999). Today, such clastic laminae are associated with anomalously high rainfall during El Niño events. The sedimentary record shows a clear suppression of ENSO variability, with periodicities of ~15 years, between 12 kyr B.P. (the beginning of the record) and 7 kyr B.P.

Terrestrial paleo-ENSO records from outside the core ENSO impact area rely on the interpretation of teleconnection patterns. A late-glacial varve chronology from New England, USA, spanning 17.5 to 13.5 kyr B.P., shows a distinct

interannual band (3–5 years) of variability suggestive of ENSO teleconnections into North America (Rittenour et al., 2000). The interannual variability largely disappears by 13.5 kyr B.P., with only the highest frequency components persisting. Pollen records from South America, New Zealand and Australia indicate that early Holocene vegetation did not include types adapted to the periodic droughts associated with the ENSO (McGlone et al., 1992; Markgraf and Diaz, 2000). By comparing early Holocene vegetation, lake level and fire history records from these regions, McGlone et al. (1992) concluded that the circum-Pacific precipitation patterns, reduced environmental variability and absence of fire all suggest the suppression of ENSO between 10–8 kyr B.P.

Marine records of the paleo-ENSO during the postglacial transition are more sparse than terrestrial records. Nevertheless, the character and intensity of major El Niños has been traced back to 17 kyr B.P., based on evidence from the pollen of conifer and oak species in marine sediments from the Santa Barbara basin, California (Heusser and Sirocko, 1997). High-resolution marine records during postglacial sea-level low stands are also rare, but coral reconstructions of the paleo-ENSO exist for the end of the deglaciation, when sea levels reached near-modern positions. Coral records from Papua New Guinea indicate that ENSO variability was ~60% weaker at 6.5 kyr B.P. than during the 20th century (Tudhope et al., 2001). ENSO-related interannual variability was also weaker in a coral record from the Great Barrier Reef, Australia, for 6.2 kyr B.P. (Gagan et al., 1998). However, mid-Holocene reconstructions of SST variability in the tropical south-western Pacific suggest there is a significant mismatch between strong El Niño SST variability and weak precipitation variability, indicating some degree of decoupling of ENSO ocean-atmosphere interactions during this period (Gagan et al., 2004). These observations agree with results from a coupled climate system model (Otto-Bliesner, 1999), which indicate that ENSO teleconnections may have differed from modern patterns at 6 kyr B.P. because of the overriding influence of regional climate changes.

Models of insolation forcing of ENSO

A recent modeling study of orbitally-induced changes in insolation in the tropical Pacific reproduced the observed reduction in ENSO amplitude and frequency during the early Holocene (Clement et al., 1999). The authors attributed the reduced early Holocene ENSO to the peak in boreal summer/fall insolation brought about by precession of the Earth's equinoxes. According to the numerical model, the additional heating of equatorial Pacific surface waters in the early Holocene produced an easterly wind anomaly that suppressed the development of El Niño events. Ocean-atmosphere feedbacks drive the ENSO system towards a La Niña state by increasing SST and pressure gradients across the Pacific, in good agreement with the paleoclimate records. A similar effect has been observed in a global coupled ocean-atmosphere model, whereby the intensified Asian monsoon during the early Holocene further enhances Pacific trade winds, thus cooling the eastern equatorial Pacific and reducing ENSO interannual variability (Liu et al., 2000).

Mid-Holocene onset

Several lines of paleoclimate evidence suggest that the onset of modern ENSO variability occurred between 7 and 4 kyr B.P. Evidence for the demise of the period of weakened ENSO activity during the early Holocene is most clear in the tropical

eastern Pacific and northern South America. Spectral analysis of the 15,000-year high-resolution record of storm-derived clastic sedimentation in Laguna Pallcacocha, Ecuador (Rodbell et al., 1999; Moy et al., 2002) shows that the transition to modern ENSO periodicities (2–8 yr) began ~ 7 –5 kyr B.P. (Figure P15). A similar conclusion was reached by Sandweiss et al. (1996, 2001), based on their analysis of fossil mollusk assemblages and geochronological evidence from coastal Peru. There, the onset of El Niño events at 5.8 kyr B.P. is indicated by the demise of thermally anomalous molluscan assemblages. The beginning of monumental temple construction on the Peruvian coast at 5.8 kyr B.P. is thought to reflect the end of early Holocene hyperaridity brought about by the resurgence of El Niño activity (Sandweiss et al., 2001). More indirect evidence of Holocene ENSO variability is provided by titanium concentrations in sediment from ODP site 1002 in the Cariaco Basin, off northern Venezuela (Haug et al., 2001), which reflect variations in runoff associated with shifts in the position of the Intertropical Convergence Zone (ITCZ). Enhanced runoff variability beginning at 3.8 kyr B.P. indicates a mean southward shift in the position of the ITCZ, thought to be linked to the strengthening of El Niño events.

On the western side of the Pacific basin, pollen records from northern Australia yield a slightly later time for ENSO onset. The first occurrence of drought-adapted pollen taxa in lake sediment cores from tropical northern Australia indicates ENSO onset at ~ 4 kyr B.P. (Shulmeister and Lees, 1995). A composite charcoal abundance record derived from 10 lake and wetland records from eastern Indonesia and Papua New Guinea reflects changes in the pattern of regional burning from the LGM to the present (Haberle et al., 2001). Higher charcoal concentrations from the middle to late Holocene (5 kyr B.P. to the present) are interpreted to reflect higher precipitation variability associated with the onset of modern ENSO variability.

Late Holocene ENSO variability

The picture emerging for the most recent 5,000 years of ENSO history indicates that it began to operate as it does now, but

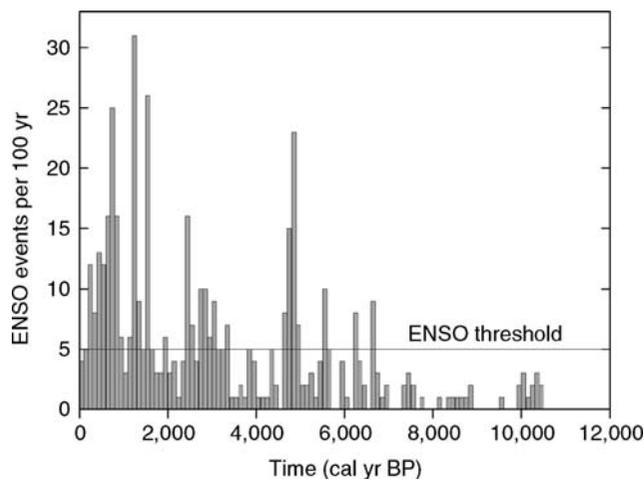

Figure P15 Number of El Niño events in 100 year intervals since 12,000 cal. yr B.P., based on the analysis of clastic laminae in Laguna Pallcacocha, Ecuador (after Moy et al., 2002). Line indicates the minimum number of events (~ 5) required to produce ENSO-band variance.

with variability on millennial timescales and a peak in ENSO frequency and magnitude at ~ 1.8 –1.2 kyr B.P. (Figure P15). The record of clastic sedimentation from Laguna Pallcacocha, Ecuador shows that El Niño events became more frequent over the Holocene until about 1.2 kyr B.P., and then declined towards the present (Moy et al., 2002). Superimposed on this long-term trend are periods of relatively high and low ENSO activity, alternating at a time scale of about 2,000 years. Geochronological evidence from the coast of Peru also indicates an increase in ENSO event frequency after 3.2–2.8 kyr B.P. (Sandweiss et al., 2001). Titanium concentrations in sediment from the Cariaco Basin (Haug et al., 2001) also show enhanced runoff variability after 3.8–2.8 kyr B.P., which is thought to be linked to a southward shift in the ITCZ related to warming of equatorial eastern Pacific SSTs in response to more frequent El Niño events.

Coral $^{18}\text{O}/^{16}\text{O}$ records from massive fossil *Porites* micro-atolls at Christmas Island in the central equatorial Pacific record the migration of warm SSTs and convective rainfall during El Niño events (Woodroffe et al., 2003). Three multi-decadal records from this locality indicate that ENSO amplitudes were 20–40% weaker than modern values during the period 3.6–2.9 kyr B.P., in good agreement with terrestrial paleo-ENSO records from tropical South America. The coral records from Christmas Island, like the Ecuadorian lake record, indicate that ENSO variability reached, or exceeded, modern values from 2.5–1.7 kyr B.P.

Coupled ocean-atmosphere model simulations forced by precessional changes in the seasonal cycle of insolation generally agree with paleo-ENSO records showing an increase in large El Niño events during the Holocene, with a peak ~ 3.1 –1.0 kyr B.P. However, according to the paleo-ENSO records, the abrupt onset of ENSO and millennial-scale variability was more complex than that predicted by the models, suggesting that factors other than insolation forcing may be at work. It has been suggested that the millennial variability in ENSO observed at Laguna Pallcacocha may be due to internal ENSO dynamics. Another possibility is that since ~ 3 kyr B.P., tighter coupling in the Pacific between the more southerly ITCZ and the Southern Oscillation (Haug et al., 2001) has served to amplify ENSO precipitation variability and associated teleconnections (Woodroffe et al., 2003). Such a scenario is consistent with terrestrial paleoclimate records indicating a marked increase in El Niño activity since ~ 3 kyr B.P.

The last millennium

Evidence for the behavior of ENSO over the last millennium comes from historical records, tropical ice cores, subtropical to mid-latitude tree rings, and corals from the Pacific basin. Historical records of Nile River flood level from as early as A.D. 622 (Quinn, 1992; Kondrashov et al., 2005) record the effects of summer monsoon (June–September) rainfall over the highlands of Ethiopia, the major source region for the Nile where El Niño events produce below-average flood levels at Cairo. At the start of the last millennium, during the Medieval Warm Period, the percentage of weak Nile floods from A.D. 1000–1290 was low (8% of years), suggesting that a La Niña-like climate mode operated when the climate of the Northern Hemisphere was warmer. In contrast, the period 1694–1899, spanning the latter part of the Little Ice Age, shows more frequent occurrences of weak Nile floods (35% of years), indicating that El Niño-induced droughts were common.

Analysis of drill cores from the Quelccaya ice cap in the high Andes of southern Peru has provided a record of ENSO variability back to about A.D. 1450 (Thompson et al., 1992). In contrast to the Nile River flood record, El Niño events were rare at Quelccaya during the Little Ice Age (~1550–1850), suggesting that the spatial signature of ENSO may have been different under the altered background climate at that time. Annually laminated ice cores from Dasuopu Glacier, on the southern Tibetan Plateau, allow examination of the teleconnections between El Niño events and the Asian monsoon (Figure P16). At Dasuopu, fluctuations in $\delta^{18}\text{O}$, dust and chloride concentrations are associated with major monsoon failures (e.g., 1790–1796, 1876–1877) during very strong El Niño events. The ~560-year record also shows rare, but large, monsoon failures associated with El Niño-induced drought in the region (Thompson et al., 2000). The full Dasuopu ice core record (not shown) reveals earlier moderate monsoon failures in the 1230s, 1280s, 1330s, 1530s, 1590s and 1640s.

Studies of tree rings have the potential to provide annual and even seasonal data from which the long-term behavior of ENSO may be derived (Cook et al., 2000). However, tree-ring analysis of tropical trees has been problematic due to a paucity of long-lived species and a lack of annual growth rings. Alternatively, Lough and Fritts (1985) developed a network of tree-ring width series back to A.D. 1660 based on the connection between precipitation anomalies and ENSO in western North America, particularly moisture limitation and its effect on tree growth during El Niño events. The result was a series of annual

maps of seasonal climate features such as temperature, precipitation and sea-level pressure indicative of ENSO variability in North America. Stahle et al. (1998) developed a 272-year (1706–1997) reconstruction of the Southern Oscillation Index based on drought-sensitive tree-ring chronologies (Figure P17). The proxy data set comprises 20 sub-tropical tree-ring chronologies from the southern United States and Mexico, and a single tropical teak chronology from Java. This index targets the Northern Hemisphere cool season (October–March), when El Niño and La Niña events typically mature in the equatorial Pacific. Their reconstruction indicates stronger interannual ENSO variance in the late 19th and 20th centuries as compared to earlier periods. However, a network of drought reconstructions over the continental USA shows that, although the ENSO-drought link in the southwest is relatively robust, drought in other regions (the Atlantic region) shows a more variable connection to tropical Pacific climate variability (Cole and Cook, 1998).

Coral records from the tropical Pacific clearly show that the characteristic timescale of ENSO variability has changed over the past four centuries (Dunbar et al., 1994; Urban et al., 2000). A 400-year long coral record from the Galapagos Islands, in the eastern equatorial Pacific, reveals that decadal SST variability and ENSO change in strength simultaneously (Dunbar et al., 1994). The Galapagos record indicates that the dominant oscillatory ENSO mode shifted from 6 years to 4.6 years by A.D. 1700, and to 3.4 years after A.D. 1850. Another coral record from Maiana Atoll, in the central equatorial Pacific, registers a long-term trend from cooler/drier to warmer/wetter conditions that is associated with changes in ENSO variance since A.D. 1840 (Urban et al., 2000). When the background climate was cooler/drier during the 19th century, ENSO variability occurred on a decadal time scale, in contrast to the shorter, dominantly interannual variance of the 20th century (Figure P18).

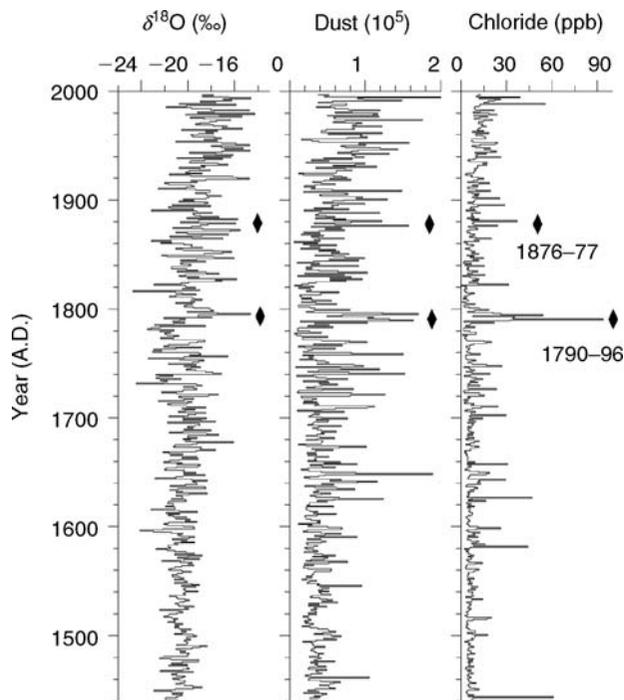

Figure P16 Annual averages of oxygen isotopes ($\delta^{18}\text{O}$), insoluble dust and chloride in ice from the high-altitude (7,200 m a.s.l.) Dasuopu Glacier in southern Tibet since A.D. 1440 (after Thompson et al., 2000). Dust concentrations are per milliliter of melted ice. El Niño events (low monsoon precipitation) are indicated by higher $\delta^{18}\text{O}$ values, dust and chloride concentrations in the ice. *Diamonds* mark very strong El Niño events (monsoon failures) in 1876–1877 and 1790–1796.

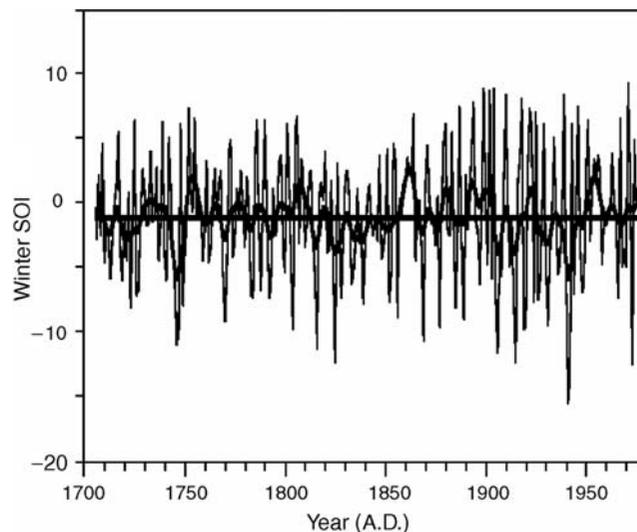

Figure P17 Boreal winter (October–March) Southern Oscillation Index (SOI) reconstructed using tree-ring data from Mexico, the southwestern USA and Indonesia (after Stahle et al., 1998). The tree-ring reconstruction indicates a significant increase in the interannual variability of the winter SOI, and more La Niña events, beginning in the mid-19th century.

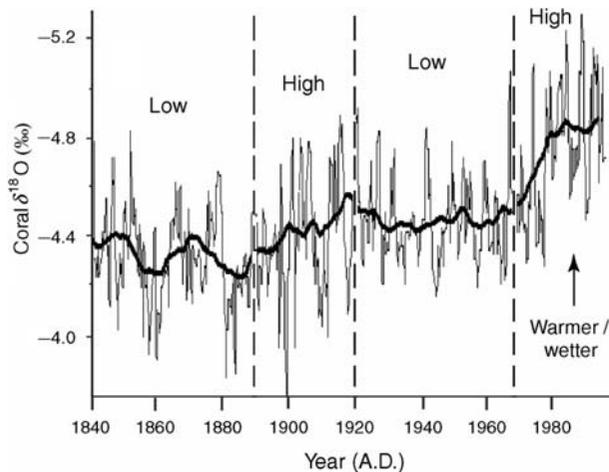

Figure P18 Bimonthly coral oxygen isotope ($\delta^{18}\text{O}$) record from Maiana Atoll, central equatorial Pacific (after Urban et al., 2000). The 21-yr running mean (thick line) shows a long-term trend towards warmer/wetter conditions. Decadal variance in ENSO (low frequency) prevailed during the cooler/drier conditions of the 19th century. Interannual ENSO variance (high frequency) dominated the transitions to warmer/wetter conditions at the beginning and end of the 20th century.

A composite record of ENSO-related rainfall and river runoff variability since A.D. 1615, compiled from eight multi-century coral cores from the Great Barrier Reef, Australia (Hendy et al., 2003), shows strong anti-correlations with SSTs in the equatorial eastern Pacific during the mid-17th to late 18th centuries. This suggests similar, strong ENSO-related teleconnections occurred then as in recent decades. However, disappearance of the anti-correlation between the eastern and western Pacific for most of the period from the 1800s to 1870s suggests that ENSO-related teleconnections with northeast Australian rainfall were not operating during much of the 19th century. During this period both interdecadal and interannual variability were suppressed, in good agreement with other coral and tree-ring records. The late 20th century increase in ENSO variability and the strength of ENSO teleconnections are, therefore, not solely recent phenomena.

Conclusions

In summary, significant progress has been made in our understanding of past ENSO behavior. However, well-calibrated records from the tropical Pacific region of strongest ENSO influence are still sparse. A full understanding of the paleo-ENSO will require the comparison of El Niño temperature forcing in the Pacific with rainfall perturbations that may be modulated under the influence of what is potentially an evolving ocean-atmosphere system.

PALEOGENE CLIMATES

Introduction

The Paleogene spans the first half of the Cenozoic era, from 65 to 23 million years ago. It includes the Paleocene epoch (65–55 million year ago), the Eocene epoch (55–34 million years ago), and the Oligocene epoch (34–23 million years ago). The Paleogene marked an important transformation in the climatic history of the Earth, from the “greenhouse” world of the Mesozoic (which persisted into the early Eocene), through the climatic deterioration to form the “doubthouse” world of the middle and late Eocene, to the Antarctic glaciation of the early Oligocene, producing the “icehouse” world that we are still experiencing today (Miller et al., 1987, 1991; Miller, 1992; Zachos et al., 1993, 1994; Prothero and Berggren, 1992; Prothero, 1994; Prothero et al., 2003).

The overall history of Paleogene climates is shown in [Figure P19](#). Our best proxy of global paleotemperature is the record of oxygen isotopes in the shells of microfossils from the deep oceans around the world (see *Oxygen isotopes*). Other indicators are used as well, such as the known paleoclimatic preferences of certain fossils, and the presence of certain sediments that are climatically informative. For example, in deep-sea cores, the presence of coarse sediments rafted by icebergs a long way from the continent and dropped into deep ocean muds is considered an excellent indicator of the growth of ice sheets and the calving of icebergs (see *Ice-rafted debris (IRD)*).

In addition to these important marine signals, there are many climatic indicators on land. Perhaps the most useful is the record of land plants, which are highly sensitive to climate and other changes in their growing conditions. The most

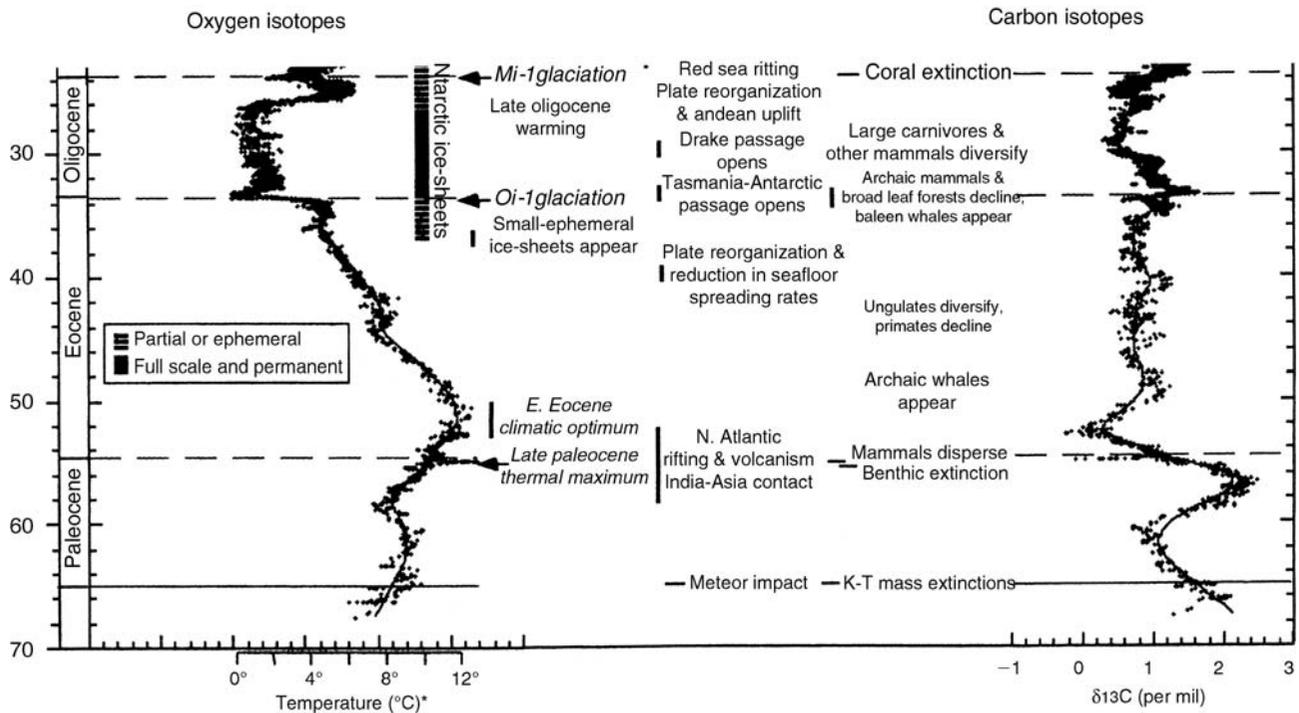

Figure P19 Climatic history, global deep-sea oxygen, and carbon isotope record correlated with major oceanographic and climatic events from 70 to 23 million years ago (modified from Zachos et al., 2001).

straightforward such index is the shape of leaves (Wolfe, 1978, 1994 see *Paleobotany*). Other terrestrial indicators, such as the presence of dune sands and evaporites indicating deserts, or thick coal deposits, indicating swampy conditions, are also used. Finally, certain types of terrestrial organisms, such as turtles and crocodylians (Markwick, 1994), and some kinds of land snails, are highly sensitive to climatic changes, and can also be used as constraints on the paleoclimate of a region (see *Animal proxies, invertebrates; Animal proxies, vertebrates*).

The Paleocene to early Eocene “greenhouse” world

The Paleocene epoch was the 11-million-year period of recovery from the great extinction at the end of the Cretaceous that wiped out the dinosaurs, ammonites, marine reptiles, and many other typically Mesozoic groups. Some groups that had been decimated by the extinction event, such as the foraminifera and mollusks, recovered and radiated in the Paleocene. Other groups, such as the mammals, had lived as tiny animals overshadowed by the dinosaurs during the entire Mesozoic. Once the dinosaurs were gone, mammals underwent an explosive adaptive radiation in the Paleocene, and evolved from a handful of rat-sized animals at the beginning of the Paleocene to over two dozen different orders by the early Eocene, including all the living orders of mammals. They soon occupied most of the terrestrial niches, from the tiny insectivore or seed eater, to the large and small carnivore, and even the huge herbivorous land animal niche as well. By the middle Eocene, there were also mammals in the seas (early whales) and the air (bats).

Although there were some perturbations of the oceans and atmospheres as a result of the end-Cretaceous extinctions, climate soon returned to the “greenhouse” state that had occurred through most of the later Mesozoic. Paleocene and early Eocene rocks

above the Arctic Circle and in Antarctica yield temperate-zone plants, and tropical plants, such as palms and cycads, occurred as far as 60°N latitude. Alligators and tortoises also lived above 77°N latitude in a region that today experiences 6 months of darkness and has only freezing climates and tundra vegetation. Calculations from oxygen isotopes suggest that tropical temperatures were much like those of today (Pearson et al., 2001), but polar waters (which are now at or below freezing) were as warm as 10–12°C in the late Paleocene, and 15°C in the early Eocene. To explain this puzzle, some scientists have suggested that the Arctic Circle would be much smaller if the Earth’s tilt on its rotational axis was much less than its present angle of 23.5°. However, such a major change in the Earth’s tilt creates all sorts of geophysical problems, and some climatic models of an Earth with a shallower tilt create colder, not warmer, polar regions. The consensus of scientists is that these polar animals and plants were capable of living for 6 months in a near-dark world as long as temperatures remained warm and mild even in the months of darkness.

Such conditions require that the entire Earth be much warmer than today on average, and that there was a lot of heat transport from the equators to the poles, so that the difference between their temperatures was much less than today. Most scientists agree that a higher level of greenhouse gases (such as carbon dioxide and methane) was largely responsible for the overall level of warmth in the early Cenozoic. Although some scientists point primarily to carbon dioxide (De Conto and Pollard, 2003), others have shown that the plant record does not support unusually high levels of this gas (Royer et al., 2001). Estimates from the geochemistry of carbonate (Pearson and Palmer, 1999) and climatic modeling (Sloan and Rea, 1995) also indicate that atmospheric carbon dioxide levels were

not much higher than present. Instead, Sloan et al. (1992) argue that methane might have been a more effective greenhouse gas, consistent with all the geochemical evidence.

However, plate tectonics and oceanic circulation must have been important factors as well. To explain the shallow gradient in temperature between poles and equator, there must be oceanic circulation that allows warm waters from the equator to mix with temperate and polar waters, transferring the heat to the poles. Oceanic circulation models with early Cenozoic continental positions show that a key factor is the connection of Antarctica to both Australia and South America. Today, Antarctica is isolated from these continents, producing the Circum-Antarctic Current, which circulates in a clockwise direction around the Antarctic. This shallow-water current is one of the most voluminous in the ocean, with a velocity of 25 cm s^{-1} , and a volume of 233 million cubic m s^{-1} , more than 1,000 times the flow of the Amazon River. The Circum-Antarctic Current acts as a “refrigerator door” that locks in the cold around the Antarctic continent, and promotes the growth of polar ice caps. It also promotes upwelling of deep waters from the Antarctic margin, which rise, chill, and then sink to generate the cold Antarctic bottom waters. These cold, oxygenated currents make up 59% of the world’s marine waters, and flow from the surface of the Southern Ocean to the bottoms of the deep oceans all the way to the Northern Hemisphere as far as 50° north latitude in the Atlantic.

For over 30 years now, geologists have known that this current and its effects could not have existed in the Paleocene and Eocene, as long as the connection between Antarctica and both South America and Australia blocked its path. Instead, models of Paleocene and Eocene oceanic circulation show that the tropical currents mixed with temperate and polar currents, warming the poles. In some models (Kennett and Stott, 1990a), the modern circulation pattern dominated by cold Antarctic bottom waters is replaced by a different kind of ocean, where warm saline waters are generated in the tropics by evaporation, and then sink (due to increased salinity) to form warm saline deep waters, which traveled along the ocean bottom all the way to the poles. These ideas are still controversial, but clearly warm tropical currents were reaching the poles and transferring heat to this region to keep it so balmy.

The late Paleocene thermal maximum

On top of the overall warm “greenhouse” climates of the Paleocene and Eocene, there are short-term events that cannot be explained by slow-moving causes such as changes in atmospheric gases or oceanic circulation. The most remarkable of these is the Late Paleocene Thermal Maximum (LPTM) at 55.6 million years ago, when deep-sea temperatures warmed 5°C , and sea surface temperatures warmed by $4\text{--}8^\circ\text{C}$ in less than 200,000 years (Röhl et al., 2000). Carbon isotope values show a dramatic negative excursion over the same short interval of time (Kennett and Stott, 1990b; Zachos et al., 1993), and this carbon isotope signal is even apparent in the teeth of land mammals and in ancient soil carbonates (Koch et al., 1992). In addition, there was a major mass extinction in the benthic foraminifera that live on the ocean bottom, and rapid diversification in the planktonic foraminifera and blooms of dinoflagellates. An evolutionary radiation in land mammals occurred and they freely migrated over the polar routes from Eurasia to North America in the early Eocene, and even lived above the Arctic Circle (papers in Aubry et al., 1998).

The extraordinary rapidity and the peculiarity of the warming of deep ocean waters led to another explanation of the LPTM (Dickens et al., 1995, 1997; Thomas et al., 2002).

The most striking evidence comes from the ratio of ^{12}C (the common isotope of carbon) to ^{13}C (a rare isotope of carbon). In two short pulses, each less than a thousand years in duration, the oceans became extremely rich in ^{12}C , suggesting that some source had released enormous amounts of biogenic carbon in a geologic instant. This rules out the slow oceanographic or plate tectonic changes discussed above. Instead, many scientists now think that methane (CH_4 , or natural gas) was trapped in a chemical form known as methane hydrate (methane combined with water in complex cage-like, icy compounds). These compounds can form huge volumes of trapped carbon, frozen on the ocean floor. According to the late Paleocene scenario, as much as $1.12 \times 10^{18} \text{ g}$ of CH_4 was locked up on the sea bottom. When the methane hydrates broke down and their methane was released, that flooded the deep ocean with excess methane and carbon dioxide (hypercapnia). This carbon-rich water nearly wiped out many of the bottom-dwelling organisms (especially the benthic foraminifera). Eventually this methane escaped to the atmosphere to produce a warm “super-greenhouse.” Although some of the carbon was eventually returned to the crust in the form of carbonates and coals, much remained throughout the early Eocene, and was responsible for the extraordinary global warming.

The Eocene climatic deterioration and the “doubthouse”

The warm, balmy world of the early Eocene began to deteriorate by the early part of the middle Eocene. Over the course of the 12 million years of the middle Eocene (49–37 million years ago), and the 3 million years of the late Eocene (37–34 million years ago), this climatic deterioration continued so that by the early Oligocene, glacial ice returned to Antarctica. From the beginning of the middle Eocene, mean global temperature declined by more than 10°C , more than during any ice age cycle (Figure P19). In North America, the land plants suggest $13\text{--}15^\circ\text{C}$ of cooling over the same interval. This climatic transformation was gradual during the entire middle Eocene, although there was an abrupt cooling episode (causing temperatures to drop 5°C globally) at the end of the middle Eocene (37 million years ago).

During the three million years of the late Eocene (37–33 million years ago), there was a slight warming and recovery from the long-term cooling trend. At least three major impacts struck the Earth in the middle of the late Eocene (35.5–36.0 million years ago), but they caused no significant changes in climate, nor any extinction of importance.

In addition to the isotopic and leaf-margin climatic signals, there are other indicators of cooling climate. Antarctic glacial deposits overlain by a lava flow dated at 49.4 million years old have been reported (Birkenmajer, 1987); although most scientists do not think that there was significant Antarctic glacial ice this early. Gradual changes in the oceanic circulation patterns are also seen during the middle Eocene (Boersma et al., 1987), although nothing as dramatic as the inception of Antarctic bottom waters in the early Oligocene. To many scientists, the middle-late Eocene is the “doubthouse” world (Miller et al., 1991): a time of transition between better known “greenhouse” and “icehouse” conditions, where there are few modern analogues and it is difficult to describe how the oceans and atmospheres worked during this time.

The causes of this middle-late Eocene climatic change are still unclear. As discussed above, some scientists argue that the climate was changed by addition or withdrawal of greenhouse gases, but it is not clear that carbon dioxide was the main

culprit. More importantly, it is difficult to say where all the carbon from those gases has gone if it has been locked up in the crustal reservoirs and withdrawn from the atmosphere. There are limited coal deposits of middle-late Eocene age, but none on the scale of the Carboniferous coals that locked up the greenhouse gases and shifted the late Carboniferous world from greenhouse to icehouse. The volume of carbonate precipitation in the middle Eocene is insufficient to serve as the chief reservoir, either. Some have suggested that these gases are locked up in methane hydrates on the seafloor (as discussed above), but so far there is no way to test this hypothesis.

The Oligocene

The Eocene-Oligocene boundary is formally recognized by the extinction of the hantkeninid foraminifera, although no other major climatic or extinction events occurred at this time. This invalidates the old idea from the 1970s and 1980s that a “Terminal Eocene Event,” comparable to the event that ended the Cretaceous, marked the end of the Eocene.

The most significant climatic event occurred in the earliest Oligocene (as currently defined, using the hantkeninid criterion), about 33 million years ago (now known as the “Oil event”). In the marine record from both benthic and planktonic foraminifera, the oxygen isotopes show about a 1.3‰ increase. Miller (1992) calculated that about 0.3–0.4‰ of the change was due to a major expansion of Antarctic ice sheets, which lowered global sea level by at least 30 m. The remaining 0.9–1.0‰ is explained by global cooling of about 5–6°C, which lowered global mean temperature from as high as 13°C in the early Eocene and 7°C in the latest Eocene to values just a few degrees above freezing (as a global average – the poles were well below freezing for the first time, while the tropics remained relatively unchanged).

Abundant evidence suggests that this global cooling event was largely due to the growth of the first major Antarctic ice sheet since the Permian, over 250 million years ago. Drilling on the margin of the Antarctic continent and in oceanic plateaus in the Southern Ocean (such as Maud Rise and the Kerguelen Plateau) has produced abundant evidence of the growth of the Antarctic ice sheet. Not only do the isotopic records show its effect, many of the sediments drilled from the Antarctic margin are glacial in origin, and even well out into the Southern Ocean where there are sediments dropped by melting icebergs.

What caused this global cooling and the extinctions in the early Oligocene? A few geologists have suggested that the late Eocene impact events or major volcanic eruptions in the Ethiopian Plateau might have had an effect, but these ideas are contradicted by the geological record. As noted above, the impacts occurred in the middle of the late Eocene, about 2 million years before the early Oligocene cooling, and 2 million years after the end-middle Eocene cooling. Likewise, the Ethiopian traps are now dated in the late Oligocene, when no significant extinctions are recorded. As discussed above, the primary culprit has been identified as the development of the Circum-Antarctic Current.

So what triggered the growth of this current? The most obvious factor is plate tectonics. In the late Cretaceous, Australia and South America were still attached to Antarctica as remnants of the ancient Gondwana supercontinent. As noted above, this caused the tropical currents to mix with polar currents and moderated global temperatures, since there were barriers

between the Atlantic, Pacific, and Indian Oceans, and there was not yet a global Southern Ocean. Geophysical evidence shows that these three southern continents began their separation in the latest Cretaceous, but they were not far apart enough to allow ocean currents to pass through until the latest Eocene or early Oligocene (Exon et al., 2002). By the early Oligocene, deep-sea cores south of New Zealand reveal that a blast of cold water was passing between Australia and East Antarctica. As the Oligocene progressed, the separation grew wider, and larger and more powerful cold-water currents developed. Originally, geologists thought that the separation between the tip of South America and the Antarctic Peninsula did not occur until the end of the Oligocene, but recent evidence (Diester-Haass and Zahn, 1996) has suggested that it was also occurring in the early Oligocene, so the entire Circum-Antarctic Current developed in a short period of time.

In addition to these important currents, it is also thought that another body of water, the North Atlantic Deep Water, which flows out of the Arctic Ocean past Greenland into the bottom of the North Atlantic, originated sometime in the Oligocene (Davies et al., 2001). Thus, the global “icehouse” conditions of the Oligocene can be largely attributed to the development of modern oceanic stratification and circulation patterns.

The effects of these global changes in oceanic temperatures are critical, not only to marine climates and organisms but also to land climates. The most complete record comes from the North American continent, where paleobotanical records (Wolfe, 1978, 1994) show that mean annual terrestrial temperatures dropped 7–11°C in the earliest Oligocene. This is true of floral records all the way from Alaska and the Pacific Northwest to the Gulf Coast. In addition to this rapid cooling, the record of ancient plants and soils also suggests that the continent underwent significant drying, with much more seasonal, drought-prone climates. In the Big Badlands of South Dakota, late Eocene paleosols suggest over a meter of annual rainfall, supporting a dense forest (Retallack, 1983). By contrast, in the early Oligocene, mean annual rainfall was less than half a meter and the vegetation was patchy scrubland with limited riparian forests. The land snails from the Badlands also change, from late Eocene forms like those found today in tropical Central America, to early Oligocene forms, which are smaller and more drought-tolerant, and found today in Baja California. In addition, the late Eocene reptilian fauna that was dominated by crocodylians and pond turtles was replaced by dry land tortoises in the early Oligocene.

Once the early Oligocene climatic deterioration was completed, the earth remained in this “icehouse” mode through the rest of the Oligocene. The other significant event was several pulses of glaciation during the middle part of the Oligocene, about 30 million years ago (the “Oi2” event). Thick, extensive mid-Oligocene glacial deposits are found throughout the Antarctic region, and benthic foraminiferal oxygen isotopes shifted by 1.6‰, suggesting another increase in ice volume and drop in global temperatures. As these ice sheets grew, they pulled water out of the oceans, resulting in the largest drop of sea level in the past 100 million years. Originally, it was suggested that sea level dropped almost 150 m, although more recent estimates suggest it was only about half that much. Whatever its magnitude, it had a major effect on the shallow marine realm, causing the continental shelves to be deeply incised once they were exposed to the aerial erosion, and producing huge mid-Oligocene unconformities in most marine rocks around the world.

The effect of the middle Oligocene cooling and regression on land climates was less obvious. The sensitive tropical floral elements were already gone by the mid-Oligocene, so the land plant record shows only minor cooling effects. The record of ancient soils from the Big Badlands of South Dakota shows that, as the climate became cooler and much drier, sand dune deposits became common in the mid-western United States in the late Oligocene (Retallack, 1983). These same soils suggest that vegetation was a mixture of scrublands and grasses, with few trees, by the late Oligocene.

As the climatic deterioration of the Eocene and Oligocene began, the total diversity of land mammals or marine organisms decreased significantly from Eocene levels, reaching an all-time low in the late Oligocene. The forests and jungles of the early Eocene were rapidly disappearing by the late Eocene, so that by the Oligocene most of the temperate latitudes were covered by a mixture of forest and scrubland vegetation. Along with the change in vegetation triggered by this cooling and drying was a major change in many of the land organisms. In this realm lived a land mammal fauna dominated by primitive members of mostly living families. These included three-toed horses (which began to radiate into multiple lineages by the late Oligocene), three different lineages of rhinos, early camels, deer, and peccaries, as well as a handful of archaic groups left over from the Eocene. Numerous modern carnivorous groups (especially early dogs, and the catlike nimravids, as well as primitive members of the bear, weasel, and raccoon families) became the dominant predators as the last of the archaic carnivorous mammals straggled on. On all the northern continents and Africa, rodents and rabbits both underwent a huge diversification as the niches for ground-dwelling seed-eaters increased, and the habitat for squirrel-like nut and fruit eaters diminished.

In Eurasia, many of the same trends were apparent. In the early Oligocene, the Turgai Strait across the Obik Sea between Europe and Asia opened up, allowing Asian mammals (such as rhinos and ruminants) to immigrate to Europe and drive many of the endemic natives to extinction. This early Oligocene event is known as the Grande Coupure. However, there was only limited migration between Asia and North America via the Bering Strait. In Eurasia, the Oligocene saw a similar diversification of rhinos (including one group, the giant indricotheres of Mongolia and Pakistan, which reached 6 m at the shoulder and weighed 20 tonnes), plus some of the earliest members of the deer, giraffe, pig, and cattle families. Tree-dwelling mammals became much less common and vanished from many continents. For example, primates once dominated all the northern continents during the early and middle Eocene, but became restricted to Africa and South America, where they evolved into Old World and New World monkeys, respectively. The rest of the African fauna was also endemic to this island continent, which was not connected to Eurasia at the Arabian Peninsula until the early Miocene. Instead, Africa had a fauna populated by archaic mastodonts, a wide diversity of hyraxes, and other peculiar endemic forms, such as the horned arsinotheres. South America and Australia were also island continents, unconnected to the rest of the world, and each developed their own endemic faunas.

In the marine realm, the early Oligocene extinctions triggered by global cooling were severe, causing major extinction in the planktonic and benthic foraminifera, and even in the planktonic algae such as diatoms and coccolithophores. In the Gulf Coast of the United States, 97% of the marine snail species and 89% of the clam species found in the late Eocene did not survive into

the late early Oligocene, and over 50% of the sea urchins and sand dollars went extinct as well. However, the overall taxonomic composition of the marine fauna remained essentially the same, with new species of clams, snails, and sea urchins replacing the extinct species (but at lower diversity), and making up the bulk of the fossilizable organisms in the Oligocene. By the end of the early Oligocene, diversity was at an all-time low. Marine faunas were dominated by groups tolerant of the cooler waters that began in the Oligocene. This is true especially in the mollusks of the Pacific Rim, which are mostly cold-water tolerant forms that migrated south to California from Alaska and Siberia during the Oligocene. Planktonic organisms were not only low in diversity, but occupied relatively few, simple biogeographic realms (since the area of the tropics had decreased), and evolved relatively slowly during the Oligocene.

Summary and conclusions

The Paleogene (from 65 to 23 million years ago) marked the global transition from "greenhouse" climates that had persisted from the Mesozoic to the modern "icehouse" world with glaciers on the poles. "Greenhouse" conditions persisted from 65 to 50 million years ago, with a "super-greenhouse" short-term warming event at 55.6 million years ago. The causes of this global warming are still controversial, although some combination of greenhouse gases, such as carbon dioxide and methane, are usually implicated. In addition, the circulation and mixing of polar waters with tropical waters prevented the poles from freezing, and allowed alligators and temperate plants to live above the Arctic Circle. This "greenhouse" world began a slow cooling from 49 to 33 million years ago, with the first signs of Antarctic ice appearing at 49 million years ago. At 33 million years ago, the Antarctic ice cap appeared, possibly due to the separation of Antarctica from Australia and South America to form the Circum-Antarctic Current, which generated cold bottom waters and began modern oceanic circulation patterns. Since that time, the Antarctic ice cap has waxed and waned, but the Earth continues in the "icehouse" state that began 33 million years ago.

PALEOHYDROLOGY

Introduction

Ecosystems, human life, economic activities, . . . , all life on the continents depends on the availability of liquid fresh water.

Today, the hydrosphere (about $1,400 \times 10^6 \text{ km}^3$) contains 2.5% of fresh water, of which 2/3 is stored as ice and permanent snow, 1/3 as groundwater, and only 0.3% is found in lake, wetland, soil, and river systems (Shiklomanov, 1998). The “global hydrological cycle” – the overturning of water from the Earth’s surface to the sky and back – recycles an amount of water equivalent to the world’s ocean in 3,000 years. With highly variable delays, precipitation falling on land surface (about $0.111 \times 10^6 \text{ km}^3 \text{ yr}^{-1}$) returns to the sea through overland, subterranean, and partly atmospheric paths.

Earth’s water distribution varies through space and time. The dramatic floods of August 2002 in central Europe and the 1970–1980s Sahel drought caused substantial damage but hydrological changes of much larger amplitude and duration have occurred in the past. From ~10 to 5 kyr ago, the Sahara was a verdant landscape with numerous lakes, supporting Neolithic populations; and 21 kyr ago, the sea level was ~120 m lower and the Northern Hemisphere continental ice volume was 20 times greater than today. Hydrological changes occur on all timescales (Figure P20).

Paleohydrology aims at reconstructing the timing, frequency, and magnitude of changes in water storage and quality, in moisture sources and trajectories, and understanding their causes and mechanisms. To represent the full range of natural variability, it has to go back in time far beyond the instrumental period, i.e., at most the past 200 years. Practically, paleohydrology studies the land-based portion of the hydrological cycle and focuses on its liquid phase; other components of the hydrosphere (atmosphere, vegetation, ocean, ice) are

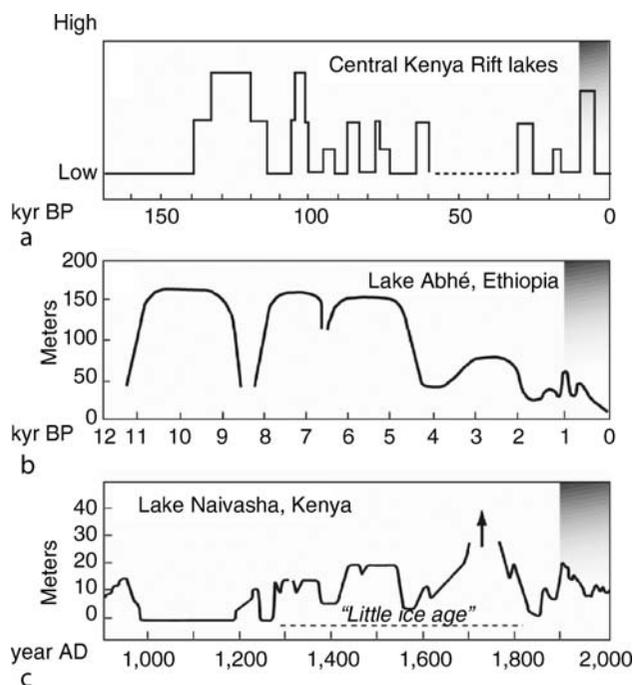

Figure P20 Hydrological variability on different timescales: lake-level changes in East Africa, reflecting changes in the Precipitation minus Evaporation balance in the lake catchment are; (a) after Trauth et al. (2003); (b) after Gasse (2000); (c) after Verschuren et al. (2000).

considered because of their relationships with liquid inland water bodies. The present dating techniques mainly allow coverage of the late Quaternary period.

Major concepts

Inland water systems

The irregular distribution of inland water bodies results from the global climate zonal belts, the regional climate, geological patterns, and topography. The latter provides a natural partitioning of land into drainage basins or catchment areas, also called “watersheds.” In an “exoreic” basin, water falling within its divides gathers to the same outlet toward the sea; an “endoreic” basin is a land-locked, inland drainage system.

Hydrological systems range from small ponds < 0.1 km² to the largest water bodies, e.g., the Caspian Sea (371,000 km²; 78,200 km²). They also differ in lifetime, from a few weeks for ephemeral floodplains to millions of years for subsident tectonic lake basins or deep aquifers.

The time of complete water renewal, or residence time, ranges in average from tens of days in rivers, to tens of years in lakes and 10³ years in groundwater reservoirs and mountain glaciers. It may reach up to 10⁶ years in deep groundwater systems, especially in endoreic basins of arid zones.

Hydrological variability

The major cause of hydrological fluctuations is climate variability. Human activities and geological events (e.g., landslides, lava flow dams) can also modify hydrological systems locally or regionally.

The variation of the amount of stored water in a time interval, ΔS , is the difference between total inflow and outflow, which can further break down as:

$$\Delta S = (P + R_i + G_i) - (E + R_o + G_o) \quad (1)$$

where P is precipitation, R_i and G_i are the surface and ground water inflows, respectively, E is evaporation + evapotranspiration, and R_o and G_o the surface and ground water outflows, respectively, during that interval. The terms P and E of this water-balance equation depend on climate, while R , G , and part of E are related to watershed specific factors, i.e., hydraulic properties, river bed geometry, soil and vegetation cover, and man-controlled water diversion.

Since Equation (1) expresses the conservation of matter, it is equally applicable to solutes, isotopes, dissolved substances, and solid particles.

Processes that relate hydrological variations to changes in climate and human activities need further research, e.g., how are the different surface and subsurface compartments physically and chemically interconnected? How do they respond to natural or human-induced disturbances? What is their individual response time? Although many paleohydrological records are still qualitative, emphasis is now placed on exchange processes and rates between water pools, on quantification of past hydrological conditions, and on periodicities and probability distributions of hydrological events. Crucial to any paleohydrology study is the establishment of a reliable and accurate chronology.

History

Paleohydrology sprang from several branches with their own techniques and methods, e.g., fluvial paleohydrology, paleolimnology. It emerged as an earth science of its own over the past decades (Schumm, 1965; Gregory et al., 1995). Integration of groundwaters as paleohydroclimatic archives is even more recent. This emergence was triggered by the urgent issue of predicting water resource evolution at global, regional, and local scales, in response to climatic and societal stress. It was favored by the development of new dating techniques, new methods for inferring past hydrological conditions, and computing facilities for data storage and modeling approaches.

Methods and techniques

Paleohydrological analysis of water systems usually begins at the watershed level, with a field observations and measurements, material collection and laboratory analyses (Stage 1). Dating is a major step (Stage 2). Then, primary data are converted into time series of hydrological parameters (Stage 3). The last stage analyzes the observed and inferred data through statistics and/or modeling (Stage 4), putting the findings into broader perspective, and eventually linking them with known geological, climatic, or human facts.

Archives and proxies (Stage 1)

Documentary records provide direct information over many centuries in Europe or China, for example on major floods or droughts, advance and retreat of mountain glaciers, or land-use changes.

Beyond instrumental and historical data, paleohydrology resorts to indirect indicators of past conditions, the proxies,

archived in the geomorphic features and sediments of ancient water bodies (Figure P21), and in fossil water trapped in aquifers and glaciers.

In river systems, the past stream regime and discharge are primarily inferred from geomorphic and hydraulic properties of the drainage network, the channel geometry (terraces, bankfull width, cross-sections, depth, slope, meander wavelength, . . .), the characteristics of channel sediments (particle sizes), botanic evidence, and indicators of past flood levels, e.g., slack-water or bouldery flood-bar deposits. Dead paleochannels can be detected through remote sensing and field observations.

Changes in lake and swamp water area, depth, and volume, as well as chemistry and biology, are reconstructed from geomorphology (ancient shorelines, ancient tributaries or outflow, spatial sediment distribution), and from the analysis of sediments collected from drillings and outcrops. The most widely used proxies derived from sediments are stratigraphic features, mineralogy and chemistry of the allochthonous (detrital) and endogenic fractions, stable isotopes of organic matter, primary carbonates, biogenic silica . . ., and biological remains (e.g., diatoms, ostracods, insects, pollen macrofossils . . .).

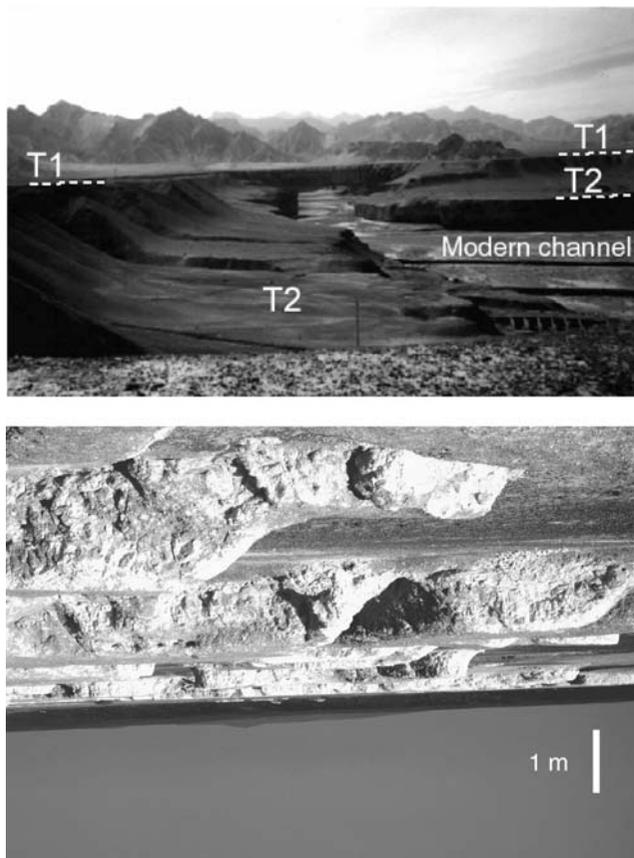

Figure P21 Examples of proxy sources. *Upper panel:* fluvial terraces (*T1*, *T2*) abandoned during phases of river entrenchment (Dang River, central China). *Lower panel:* early Holocene sediments of Paleolake Abhé (6,000 km², 160 m deep; see Figure P20), Afar desert (Ethiopia).

With speleothems (cave deposits), the annual growth layers and the carbonate stable isotope composition can inform on past precipitation and temperature.

The use of groundwater as a paleohydrological archive requires knowledge of the hydraulic conductivity, porosity, and geological structure of the system. Aquifer water is sampled from wells and boreholes, or springs in the discharge zones. The water isotopic composition, atmospheric noble gases, nitrates, chloride contents, and bromide/chloride ratio are the major indicators on input conditions (isotopic composition of paleoprecipitation, ground temperature, vegetation cover).

Dating (Stage 2)

Besides instrumental and historical records, a few archives deliver calendar ages intrinsically through annual layer counting: varved sediments, glacier ice, and tree rings. ¹⁴C dating is most widely used today when aerial plant remains are found; it is also applied to groundwater-dissolved carbon. It covers the last 40 kyr. Other radiometric methods are now available for different time-scales, which cover up to 10⁶ years: e.g., ²¹⁰Pb (0–200 yr) in lake sediments, ²³⁰Th/²³⁴U in carbonates and organic matter, ¹⁰Be to date geomorphic surfaces (fluvial terraces, lake shorelines) or sediments, and K-Ar and ³⁹Ar/⁴⁰Ar in volcanic interbedded materials. Dating methods also include luminescence, tephrochronology, and paleomagnetism for long continuous stratigraphic profiles.

The time resolution depends on the archive and on the dating method. Laminated deposits can provide annual resolution in best cases. Conversely, uncertainty on groundwater chronology can reach as much as thousands of years, due to the inherent characteristics of subsurface flow and the long residence time. However, groundwaters register the average magnitude of long-term climate change since the signal of local effects or short-term extremes is smoothed out.

Proxy calibration (Stage 3)

Data derived from the initial proxy analyses translate into hydro-climatic parameters, assuming that the relations between a proxy and its environment are similar to present. Calibration functions, also called transfer functions, can be established through statistical techniques, using a training set including modern observations on the proxies and measured parameters, e.g., diatom-inferred lake water salinity, or pollen-inferred rainfall amount and seasonality. They can also result from the study of the physical processes that control, retain, and modify the hydrological signal archiving, e.g., precipitation inferred from oxygen isotopes in speleothem calcite; these require quantitative adjustment against measured parameters. Because of uncertainties in all methods, multiple proxies and techniques are desirable for cross-checking. Calibrated data provide a record of hydrological variations through time at a particular location. Their synthesis can be conducted at a watershed-scale or wider, provided more local factors are identified.

Time-series analyses, hydrological modeling (Stage 4)

Spatial patterns of paleohydrological estimates through time can sometimes be transformed into statistical syntheses. Periodicities can be identified through spectral analyses. The distribution of discrete events, e.g., flood-frequency distribution, can be assessed through a variety of distribution functions.

Understanding the dynamics of hydrological changes often requires modeling of the investigated system, and calls for data beyond those derived from paleohydrological archives. For example, in a paleolake of known ΔS (Equation (1)), why and how have the water balance terms fluctuated? Evaporation and runoff rates are affected by solar radiation, wind speed, temperature, vegetation cover, etc. The evaluation of such factors comes from astronomical data, botanic evidence, or from outputs of Global Circulation Model (GCM) simulations, although the low GCM spatial resolution is usually inappropriate to the regional or local problem at hand. Models depend on the proxy source, the variable estimated, and the spatial scale under consideration. They greatly differ in complexity and accuracy. Once calibrated and validated on instrumental data, models can simulate past hydrological parameters, e.g., P , E or R (Equation (1)) using lake water, water-energy, water-isotope, or water-salt balance models. They also can predict hydrological changes in response to varying climate or land-use.

Time-series analyses and modeling represent the upper level of paleohydrological reconstruction and provide the greatest insight into the mechanisms and potential causes of hydrological changes.

Applications

Paleohydrology and paleoclimatology

Hydrological fluctuations are intrinsically linked to changes in climatic forcing factors; in turn, they have acted on climate through varying evaporative fluxes from the continental surfaces, and energy exchanges as water undergoes phase changes. While GCM simulations of past climatic conditions help understand the mechanisms of observed hydrological changes, conversely paleohydrological data are used to validate the climatic models: quantitative estimates of hydrological variables are then essential.

At the orbital time-scale, records primarily reflect the glacial/interglacial cycles and the smooth, long-term variations of the Earth's orbit. For example, over the past 70 kyr, changes in level of Lake Lisan (the precursor of the Dead Sea which extend along the Dead Sea-Jordan Valley Dead) correlates with temperature changes inferred from isotopic data in polar ice cores: high/low levels generally coincide with colder/warmer global climate intervals, respectively (Figure P22). Tropical hydrological changes are initially driven by the impact of the orbital precession cycle on monsoon strength; the spectacular early-mid Holocene wetting in the northern tropics (e.g., Figure P20b; Gasse and Roberts, 2004) is an example, although orbital forcing was modified by feedbacks from sea surface temperatures, vegetation, and moisture recycling from soils and large land waterbodies.

At shorter time-scales, subtle disturbances in the climate systems generate, abrupt hydrological changes. Sudden injections of large amounts of continental freshwater in the North Atlantic Ocean have generated remote rainfall anomalies, such as catastrophic droughts in the eastern Mediterranean region coeval with Heinrich events (Figure P22), as shown by abrupt decreases in the Lake Lisan level (Figure P22); the outbreak of Lake Agassiz in the Laurentide at 8.2 kyr BP may have had a widespread impact on rainfall. Holocene abrupt changes are commonly attributed to shift in total solar irradiance or injections of volcanic aerosols in the atmosphere. The Little Ice Age, a cold event in northern high-mid latitudes, is expressed as a wet episode in equatorial East African lakes

(Fig. P20C) but as a dry period in tropical East African and South American records, suggesting persistent El Niño-like conditions (Brown and Johnson, 2006). Despite significant progress in paleohydrological reconstructions during the past decades, further work is needed to quantify hydrological changes, to fill geographical gaps in data coverage, and to analyse changes in seasonality, in order to turn paleohydrology into a more accurate paleoclimatic tool.

Paleohydrology and landscape evolution

Changes in water routing induced by geological events or climate changes may drastically affect the regional geographic features. For instance, ~90 kyr ago, an ice sheet over northern Eurasia dammed the large rivers flowing north to the Arctic Ocean; and huge lakes developed between the sheet and the water divides to the South, and overflowed towards the Aral, Caspian, and Black Seas, and ultimately the Mediterranean, draining large, now endoreic, areas to the sea. The drainage direction of major catchments in Europe and western Siberia was reversed, with considerable impact on both continental and sea hydrology (Mangerud et al., 2001).

Paleohydrology allows quantification of such processes as erosion or river incision rate under varying climatic conditions. For instance, over the past 12,000 years, the northern alluvial piedmont of the Tian Shan in central Asia has been incised as much as 300 m by the rivers flowing from the mountain. Changes in hydrological regime were inferred from the geomorphic survey of one of them and from a model of alluvial stream erosion based on a transport-limit erosion law (Poisson and Avouac, 2004). The estimated incision rate increased markedly at the transition from the generally wet early Holocene conditions to a rather arid climate with enhanced seasonal contrasts around 6,000 years ago.

Paleohydrology and human societies in the past

Several studies suggest relationships between past natural hydrological variability and societal changes. A striking example is that of the Holocene occupation in the Sahara controlled by changes in water availability (Kuper and Kröpelin, 2006), as illustrated in Figure P23. The history of droughts evident in the 1,000-year hydrological reconstruction in Lake Naivasha, Kenya (Figure P20c, is in line with the cultural history of the region; prosperity during the wettest episode (the Little Ice Age).

Paleohydrology can also detect human impacts on hydrological systems. Increased erosion rate induced by forest clearance is fingerprinted in lake sediment magnetic properties. Atmospheric pollution (e.g., from lead in Roman times or acid rains in recent times) and eutrophication has been recorded in lake sediment chemistry and lake-water pH.

Water resource implications and hydrological risk-assessment

Groundwater is a crucial source of freshwater throughout the world. Paleohydrology shows that, in many areas, exploited groundwater is "fossil" and dates from periods of greater moisture availability thousands of years ago or more. Groundwater is often being mined at a rate vastly exceeding that of possible recharge under current climatic conditions, leading to a swift water resource decline.

Ice melting water is the prime water resource and hydroelectric power supply in several areas, e.g., the Andean countries of

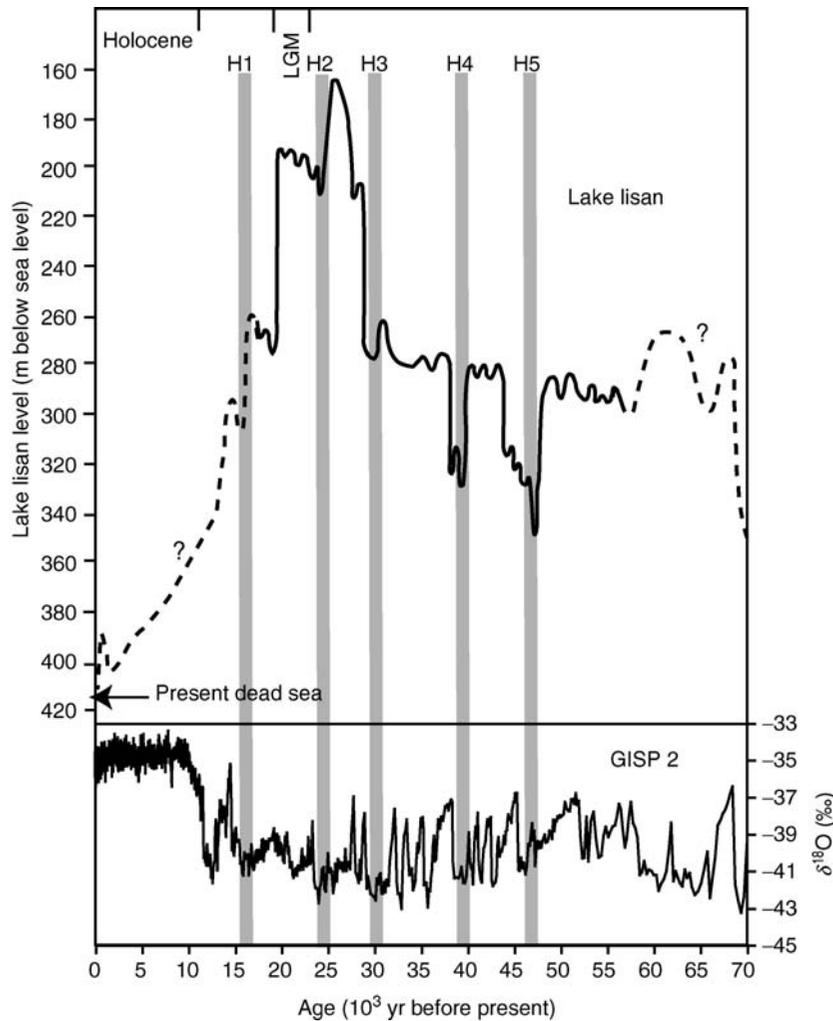

Figure P22 Correlations between levels of Lake Lisan and oxygen isotope records from GISP 2 (The Greenland Ice Sheet Project 2, 1997). After Bartov et al., 2003.

South America. The current global warming induced a rapid decay of mountain glaciers, especially in the tropics. Has such a decay an equivalent in the past? This question is approached through study of the glacier history and the dependent river and lake systems.

The risk of extreme floods and droughts is of critical concern for societies. It must be assessed for selecting the location of equipment, such as dams. Streamflow-gauging records are too short to provide realistic probabilities of the heavy flow magnitude and frequency distribution. Paleoflood data can be incorporated into flood-frequency analyses to extend the records, as exemplified by the regional Holocene paleoflood approach performed in northwestern Colorado (Jarrett and Thomlison, 2000). This study could estimate the peak discharge at recurrence intervals ranging from 10 yr to 10 kyr.

The suitability of potential repositories of chemical and radioactive waste also refers to paleohydrology. Estimating groundwater flow paths and fluxes through rocks of low permeability under past and current climates is necessary to assess future risk.

Conclusions

Paleohydrological research unveils an enormous natural variability in inland water quality and availability, primarily driven by climate change, at least over the Quaternary period. Superimposed on the natural variability, human activities affect the global climate and individual hydrological systems. Knowledge of hydrological changes in the absence of any significant human impact is key to disentangle natural and anthropogenic factors.

Paleohydrology is concerned with very practical applications, from changes in the hydrological cycle at a continental scale to local water resource management.

The anticipated global warming is expected to cause the hydrological cycle to churn more vigorously, putting more moisture into the atmosphere, generating a stormier climate in some regions and drier conditions elsewhere, and higher frequency and amplitude of extreme hydrological events (IPCC, 2007). However, even the most sophisticated numerical climate models do not yet provide a realistic representation of

Figure P23 Late Neolithic rock engraving in central Sahara (Temet, Aïr, Northern Niger).

precipitation patterns or amounts at regional scales. Better documenting and understanding of the full range of climate driven hydrological variability is a most urgent and significant tasks in paleoscience.

PALEOLIMNOLOGY

Paleolimnology is the multidisciplinary science that studies past environmental conditions from the evidence preserved in lake sediments. It addresses a very broad range of issues relating to former ecosystem composition and development, lake ontogeny, the variability of catchment and land use processes, climate change, water quality trends, pollution studies, and even the hydrocarbon potential of ancient lake sediments. Such diversity has led to the emergence of at least three major traditions within the subject. The first deals with trends in extant lakes, often investigating relatively short time scales (10–200 years) and allied to work by the limnological community. A second strand studies ancient lake basins, an area merging with the sub-discipline of limnogeology, and usually the realm of sedimentology. The third tradition considers the evidence of climate change preserved by lakes, usually with a recent or Quaternary perspective, using tools that bridge the aforementioned areas of paleolimnology. A convergence of methodologies, shared principles, and assumptions unifies paleolimnology as a discipline and these will form the initial part of this discussion. Given the focus of this encyclopedia, emphasis will then be placed on the application of paleolimnology to studies of past climates and climate change.

Principles, assumptions, and chronologies

Lakes are temporary stores of sediment in the drainage basin and have been described as an ecosystem’s memory (Smol, 2002). The length of the memory depends on the age of the lake and on the sedimentation rate. Since lakes accumulate

sediments faster than equivalent marine environments, they are often well-equipped to furnish high-resolution records. Some lakes are very young, for example those in recent volcanic craters or man-made reservoirs; others in formerly glaciated regions were formed after the retreat of the last ice sheet that covered the region and are typically less than $\sim 16,000$ years old. A further group of lakes, including the large rift lakes of East Africa and Lake Baikal, are extremely old and have been accumulating sediment for millions of years (Cohen, 2003).

The diversity of lakes matches the range of studies undertaken by paleolimnologists, but commonalities in approach and methods are evident. Paleolimnological studies exploit the fact that sediment accumulates in lake basins from different sources, sometimes arriving from great distances, as is the case in airborne deposition of fly ash, although more immediate and important sources are the lake catchment and materials produced within the lake itself (Figure P24). Allochthonous materials are those introduced from catchments including sediments derived from eroding soils, weathered materials, and vegetation. Some allochthonous components have origins outside the immediate catchment, for example long distance transport of pollen, volcanic ash, and airborne industrial pollutants. Identifying the source and flux of allochthonous materials is a major goal of many paleolimnological investigations as these can give clues about changing catchment conditions and regional processes. Autochthonous materials, or those living or produced within the lake, constitute the other major components of the sediments. The remains of algae, higher plants, fish, invertebrate animals, etc. that once lived within the lake, together

with chemical precipitates including salt deposits are all termed autochthonous. Diagenetic minerals that form *in situ* from previously deposited sediments would also contribute to this autochthonous group.

One key assumption of the paleolimnologist is the law of superposition. In collecting material from lakes it is usually reasonable to assume that more recent sediments overlie older materials, making them especially suited to temporal studies, and giving lakes an advantage in this respect over other sediment stores. However, there are instances when this assumption does not hold and the stratigraphy is disturbed or even inverted. All lakes experience some sediment focusing, a process that is a function of their bathymetry, catchment topography, river inputs, and internal water movements, creating uneven sedimentation patterns within a basin. Even in simple lakes some fining of deposits takes place, so that the representation of a particular indicator may be skewed, and therefore not all sampling sites are equally representative. Problems frequently occur in nearshore areas where the sedimentation may be erratic, leading to slumps or hiatuses, or in deltaic areas where variability in discharge may be important. Once deposited, sediments can be ruptured and faulted by tectonic movements, and localized slumps are common on slopes with even relatively shallow angles. In deep lakes, turbidity currents are common and these can intersperse the stratigraphy with homogeneous turbidite layers. To offset the problems posed by post-depositional deformation, a number of paleolimnologists have used seismic profiling to identify undisturbed coring sites. Excellent examples of this approach come from the large lakes

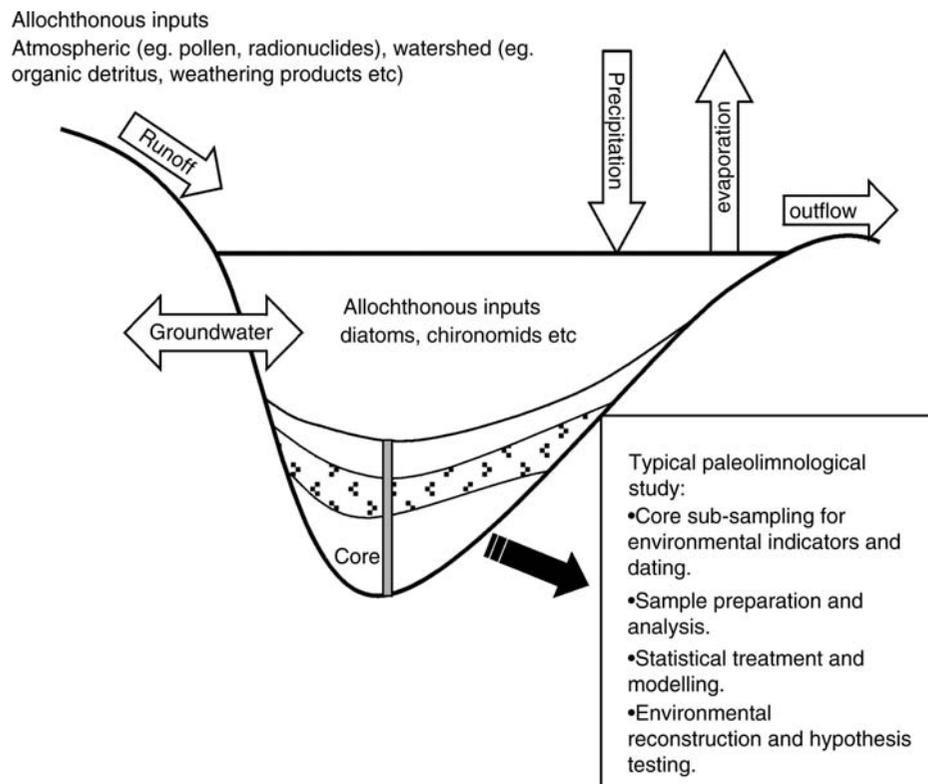

Figure P24 Principles of paleolimnology. The key sources of water and sediment to a typical lake are indicated. The core location is important to sample the most complete sequence of sediments. Major stages in a palaeolimnological investigation are listed.

of East Africa where deep-drilling operations need to be sure of collecting undisturbed sediment cores (Cohen, 2003).

In general, paleolimnology is more successful in small, deep lakes within sheltered catchments such as volcanic craters, rather than large shallow lakes that are more prone to wind stress and sediment mixing from wind-induced turbulence. Eddies can reach the sediment, causing remobilization of recently deposited sediment and smoothing of the stratigraphic record. A problem common to all paleolimnological studies is that of bioturbation. Burrowing benthic organisms tunnel into the sediments, once again smoothing the stratigraphy and limiting the temporal resolution possible. Extreme examples of bioturbation include fish mounds and even mixing by mammals using the lake as a watering hole. Bioturbation is less of a problem in anoxic deepwater sediments, out of the range of wading animals and often with a limited benthic fauna. The discussion above demonstrates the unique nature of lakes. While it is possible to generalize, each basin has to be treated differently. In extant lakes, the paleolimnologist can rigorously apply uniformitarian principles. By fully understanding present-day limnology, sedimentation, patterns, and responses of the lake to external forcing, interpretation of the sediment record becomes comprehensible.

Sampling the sediments of extant lakes usually requires the collection of sediment cores from a boat or other platform. The method selected depends on the length of core required and the nature of the study. If the aim is to investigate recent high-resolution changes, the collection of the mud-water interface is vital and sampling devices such as the Glue corer or Hongve sampler should be used to get short, <50 cm, gravity cores (see Smol, 2002). Both work by lowering a tube into the sediment and triggering a bung that seals the tube and enables it to be raised. A better, but more complicated system for taking high resolution short cores is freeze-coring, where dry ice or liquid nitrogen freezes the sediments and avoids deformation during the coring process. It has even been successfully deployed in warm tropical waters. Freeze-coring is particularly important in the recovery of sediment structures such as laminations.

Probably the most common coring system used by paleolimnologists is the 1 m Mackereth corer, which consists of a column of fixed height, containing a piston and a sampling tube, mounted on a large drum. During its operation, the Mackereth corer is lowered to the bottom of the lake, taking care to preserve verticality. The sampling tube is then forced into the sediments using compressed air, which when fully extended allows the air to fill a drum; this creates buoyancy to recover the corer. This system works well in many lakes, providing that sediments are sufficiently cohesive to remain within the tube, neither too sandy nor excessively consolidated. Mackereth corers are available in a range of fixed lengths up to 12 m.

A more flexible system is the Livingstone corer and its modified version, the Wright corer. These work by fixed rods that are used to collect 1–1.5 m of material at a time. The corer consists of a barrel, a piston, and sometimes a plastic inner tube that can be used to store the core. The corer is lowered in closed position and then the piston is raised using a cable before it is forced into the sediments. The operation is repeated for consecutive sections until an impenetrable barrier is reached or all the rods are deployed. Typical cores gathered using this method are 10–15 m long, but much longer (50–60 m) cores have also been taken. Locating the core hole after each drive is problematic in all but very shallow water and a core-hole

liner is often used both to facilitate relocating the hole and preventing materials falling into it. Good practice involves taking parallel cores with one offset to cover gaps between drives. The mud-water interface is rarely recovered intact with a Livingstone-type corer and has to be taken separately with a short coring system. Some recent work on large lakes has been undertaken using the GLAD800 coring rig, a system capable of reaching combined water-sediment depths of 800 m (Cohen, 2003). The technology involved here is broadly analogous to that used in the offshore oil and gas industries.

Not all paleolimnological work is from extant lakes. Some studies have used modified versions of the Wright and Livingstone corers to obtain cores from former lake beds or seasonally drained lakes without the need for a boat. While these cores will not be continuous, the extra stability gained by working in a relatively dry environment can be advantageous in ensuring precision. Other workers have sampled exposures of lake deposits, giving them the advantage of unlimited material to study, ready inspection of deformation features, and no distortion due to coring. Such exposed deposits are rarely as continuous in time as cored sediments and can be more prone to sub-aerial weathering. The study of fossil shorelines is frequently allied to core studies, as these give precise indications of former lake level and hence lake volume and surface area (important in paleoclimate climate modeling), but these only mark highstands and do not offer continuous sequences to investigate rates or directions of change, or information about lower lake stages.

All paleolimnological studies need to establish a chronology to understand the rate of change or the timing of an event. A precise method available in some lakes is the counting of annual varves (Lamoureux, 2001). A varve, in de Geers's original usage, is a couplet of sediments of contrasting size fractions caused by seasonal melting of glacier ice. Not all laminations are of glacial origin; in temperate regions, the regular seasonal cycle of diatom blooms in spring (and less strongly in autumn) can create a lightly colored layer contrasting with darker organic material deposited during the productive summer months. By counting the couplets, an absolute chronology can be established, as long as the mud-water interface is known or some other clearly identified dating horizon is present, such as the tephra from a known volcanic eruption. An exceptional series of varves has formed in Baldeggersee, an alpine lake showing evidence of recent eutrophication (Lotter, 1998). These have been used to tie trophic changes inferred using paleolimnological methods to a series of instrumental measurements. Sites like these help test the assumptions implicit in paleolimnology and the strength, or otherwise, of the methods. In areas of strong seasonality, such as parts of the tropics, the precipitation of salts during dry seasons often can create a distinct horizon, or a characteristic bloom of algae may occur on a seasonal basis. According to independent bracketing dates, it has been shown that laminations are not always annual, and a range of cyclical climate forcing mechanisms has been proposed to explain their origin. Some laminations are too fine to be easily visible and are difficult to enumerate without magnification or improved contrast. In these cases, x-ray images can help as they can be digitally counted using image analysis software. Similarly, gray-scale imaging can sometimes help decipher laminations, although difficulties can persist (Dean et al., 2002).

Unfortunately, annually laminated sediments are rare, and most paleolimnologists have to use either marker horizons of known date, or more often radiometric methods, to obtain a chronology. The most commonly used markers are volcanic

tephra layers, and tephrochronologies have become established for several volcanic regions (Turney and Lowe, 2001). Tephrochronology enables correlation between lakes, providing the tephra layers have distinctive chemical characteristics that enable them to be tied to a particular eruption. Paleomagnetic properties including field reversals and secular variations have been used in some localities to give chronologies, but the widespread use of paleomagnetism as an independent dating tool for recent lake sediments is not common. Magnetic measurements have been more extensively used to correlate cores from the same basin and to trace catchment erosion (Maher and Thompson, 1999). In recent studies, the use of spheroidal carbonaceous particles (SCPs) from high temperature combustion processes have been useful in giving a marker horizon, providing the history of industrialization in the region is known (Smol, 2002).

Virtually all published paleolimnological studies use a chronology derived from radiometric methods. Various radionuclides with different half-lives are routinely used, and choice is dependent on the temporal scale of the study and the materials present within the sediments. Recent paleolimnology relies heavily on ^{210}Pb that has a half life of ~ 22 years and is suitable for dating the last 150–200 years. It is usually partnered with ^{137}Cs , as this artificial radionuclide has distinctive peaks in the early 1960s and 1986, relating to the testing of atomic weapons and the Chernobyl nuclear accident, respectively. Studies of the last $\sim 40,000$ years make extensive use of ^{14}C measurements to produce a chronological framework. Radiocarbon measurements from lake sediments can be made on bulk organic material, charcoal, or plant macrofossils. The latter are preferred as terrestrial plants are more likely to be in equilibrium with the atmosphere and therefore give a more reliable date. Some lakes in karst terrains are difficult to date using ^{14}C because lake biota can incorporate old dissolved carbonate leading to ^{14}C dates that are too old. An alternative method is U/Th dating on carbonates or occasionally on silicates. U/Th has great potential in the dating of lake sediments up to 250,000 years old and is increasingly used by paleolimnologists.

Paleolimnology and climate change

Lakes have been referred to as “natural archives,” since like libraries they contain information that can be “read” if the “language” of the particular proxy indicator is known. To continue the literary analogy, the evidence contained in lake sediments is like an incomplete collection of books, with some pages missing, written in an unfamiliar language, and all with different perspectives on the question under consideration. Therefore, interpreting different environmental indicators is problematic, as they are rarely responsive to a single variable, they are frequently incomplete reflections of former ecosystems, and are often prone to diagenesis or other corruption. Moreover, few indicators can be used to directly reconstruct former climate variables such as precipitation or temperature, and a surrogate measure of climate such as lake water salinity is often used. With these caveats this discussion will now briefly consider the types of evidence used by paleolimnologists. It is not possible to review the full range of indicators used here, but some of the most common techniques will be introduced.

The water balance of a closed basin lake is determined by precipitation inputs, evaporation losses, and the net exchange with groundwater. Open systems also lose water through fluvial outflows. In theory then, it is possible to reconstruct precipitation minus evaporation (P-E) from the lake water volume, usually calculated from the lake level, providing groundwater

flux and any outflow component can be estimated. Fossil shorelines provide the only absolute method of reconstructing lake level, but paleolimnological indicators can at least show relative changes in P-E. An indirect measure of P-E is offered by salinity changes, since, as the volume contracts in a closed basin, the salt concentration should increase, assuming other variables are constant. This relationship is complicated by several factors, including changes in brine evolution since different salts precipitate at different stages of concentration, (see Cohen, 2003), and hysteresis as salt precipitates are redissolved during lake water dilution.

Diatoms, unicellular algae with silica shells (frustules), are one of the most ubiquitous autochthonous components preserved in lake sediments and have a great number of uses in paleolimnology (Stoermer and Smol, 1999). Diatoms are sensitive to changes in pH, nutrient levels, and salinity. The latter variable is especially useful in paleolimnological studies of climate change from closed basin lakes where salinity can approximate P-E providing local hydrological factors are understood. In the salt lakes of East Africa, diatoms have revealed long records of salinity change linked to climate fluctuations. One of the best comes from Lake Abhé, a closed basin lake in the Afar depression of Djibouti, where changes in the diatom community are indicative of monsoon strength and orbital forcing of palaeoclimate during the past 70,000 years (see Gasse et al., 1997). The interpretation of climate from diatom records is indirect and has to consider a range of taphonomic and diagenetic changes (Gasse et al., 1997). Similar data can be obtained using ostracods, millimeter-sized animals with carbonate shells or carapaces. Ostracods are often abundant in carbonate-rich lakes where statistical inference models can, as for diatoms, be used to predict past salinities from their assemblage composition (Holmes, 2001). Often, ostracods are found in sediments devoid of diatoms and vice versa. Ostracods also provide an alternative geochemical approach to salinity reconstruction, from the ratio of Ca/Sr and Mg/Sr in their carapaces.

Further insights into P-E can be obtained using oxygen isotopes. In closed basin lakes, oxygen isotope analysis, the ratio between ^{18}O and ^{16}O levels ($\delta^{18}\text{O}$), can be used to infer shifts in P-E (Cohen, 2003). In its simplest form, the lighter oxygen is preferentially evaporated under relatively dry climates, leaving waters enriched in the heavier isotope. Source area, water temperature, and precipitation amount all influence the $\delta^{18}\text{O}$ of lake waters, and a modeling approach is required to get quantitative climate estimates (Gat, 1995). The isotope ratios are derived from authigenic carbonates and the shells of organisms such as molluscs and ostracods. Until recently, this method was not applicable to the large number of lakes where carbonate was absent, but it is now possible to get reliable measurements from silica such as diatoms, and plant cellulose (see discussion in Cohen, 2003). More development work is necessary to establish fractionation processes and sources of error in oxygen isotope analysis from non-carbonate hosts but results do appear promising.

Distinguishing between the major climate variables of precipitation and temperature using paleolimnological indicators is difficult but can be achievable in some situations. Pollen analysis is one of the best known methods of environmental reconstruction, including quantitative estimates of climate variables, and it is usually abundant in anaerobic lake sediments (Bennett and Willis, 2001). In some cases it is possible to calibrate pollen records to reconstruct former precipitation and temperature values using transfer functions (Bonnefille et al., 1990). It is not always possible to confidently identify the contribution of

each of these variables, or to exclude the influence of edaphic conditions, ecological competition, and human agency on vegetation. Another widely used method of temperature reconstruction comes from chironomids (midges). These are extremely good indicators of temperatures, at least in high latitude regions. Fossil chironomid larvae in lake sediments can be used to reconstruct paleotemperatures providing temperature is the dominant variable in the region being investigated (Brooks and Birks, 2001). The greater abundance and ubiquity of chironomid remains in lake sediments gives them an advantage over coleoptera, although beetle remains have also yielded excellent temperature reconstruction.

Changing nutrient cycles in lakes can be reconstructed by paleolimnologists to better understand ecosystem changes and also to give insights into climate processes. Carbon isotope analysis ($^{13}\text{C}/^{12}\text{C}$, usually $\delta^{13}\text{C}_{\text{PDB}}$) of bulk lake sediments measures changes in lake productivity and shifts in the source of organic materials to the lakes. On Mt. Kenya, Street-Perrott et al. (1997), demonstrated how more positive $\delta^{13}\text{C}$ values occurred in the bulk organic matter of glacial age sediments because of materials derived from C_4 plants. Plants using the C_4 and CAM photosynthetic pathway are adapted to moisture and CO_2 stress, as would occur under relatively arid climates with low $p\text{CO}_2$. Conversely, in Holocene sediments, the $\delta^{13}\text{C}$ values became more negative as plants using the C_3 pathway increased, replacing the C_4 species; thereby indicating greater moisture and CO_2 availability. The analysis has been taken further by measuring compound specific isotope ratios, enabling the distinction of materials originating from algae, aquatic macrophytes, and terrestrial plants (Cohen, 2003). At the glacial-interglacial scale, paleolimnological research has shown that changes in the biogeochemical cycling of carbon is coupled with major climate shifts.

The cycling of nitrogen within lakes is also of interest to paleolimnologists given the importance of this element to aquatic productivity, where along with phosphorus it is often a limiting nutrient. Analysis of the ^{15}N to ^{14}N ratio ($\delta^{15}\text{N}_{\text{AIR}}$) helps determine the origin of organic materials (i.e., algae or higher plants), N-fixation and limitation, NH_3 volatilisation under high pH, flushing rates of soil N, dissolved inorganic N abundance, and the stratification regime (Talbot, 2001). Nitrogen isotopes have been successfully used by paleolimnologists, with one of the best examples being from Lake Bosumtwi, Ghana. Here a multidisciplinary study of bulk organic properties, $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ has shown limnological changes linked to regional climatic variability (Cohen, 2003).

Biological and geochemical indicators are most common in paleolimnological studies of climate change. Physical parameters can also be used as a proxy of catchment changes that may be indirectly linked to climate. Probably the most useful methods in this respect are a cluster of related magnetic techniques that can discriminate between particular minerals that are indicative of provenance. Some of these minerals are derived from topsoil, others from subsoil, and some from weathering of bedrock. It is possible to identify the nature and rate of the material being eroded and also the area supplying the major sources of sediment in catchments of mixed geology. These data are useful in a range of environmental management applications as well as for sediment tracing experiments (Maher and Thompson, 1999).

Conclusions and perspective

Paleolimnology has provided limnologists with time series data beyond the scope of ecological studies, and has answered questions about lake ontogeny and ecosystem response to climate that

would not have otherwise been possible. Furthermore, some of the longest, highest resolution sequences of environmental change are from the sediments of lakes. Paleolimnological investigations of climate change have been conducted worldwide, but a particular contribution has been made in low latitude regions where other hosts of paleoclimate data are either limited or have proven difficult to exploit.

Over the last decade, the number of publications in paleolimnology has risen enormously (i.e., in the *Journal of Paleolimnology*). Recent developments include high resolution automated techniques, greater accuracy, and more focused scientific questions. There is also a trend toward analysis of specific sedimentary components (e.g., biomarkers) rather than bulk samples, thereby achieving greater precision in reconstructions. Numerical modeling has further improved the importance and application of paleolimnology to climate change.

PALEO-OCEAN pH

Before discussing past variations in the pH of the oceans, it is first necessary to understand what controls the present distribution of pH in seawater. Along with alkalinity, total dissolved inorganic carbon (Σ_{DIC}) and the partial pressure of carbon dioxide ($p\text{CO}_2$), pH is one of the four key variables of the seawater dissolved carbonate system. If any two of these four variables are specified, then the values of the other two are fixed. For those areas of the modern oceans that are in equilibrium with the CO_2 content of the atmosphere, their pH is set at a value of ~ 8.2 (depending on the temperature of the surface ocean). An increase in atmospheric CO_2 (for a given value of alkalinity or Σ_{DIC}) will result in a decrease in the pH of surface waters. For example, increasing atmospheric $p\text{CO}_2$ from the pre-industrial value of 280 ppmv (parts per million by volume) to its present day value of ~ 370 ppmv would result in a decrease in pH from 8.18 to 8.08. Similarly, the rise in atmospheric CO_2 values from ~ 180 ppmv at the height of the last glacial interval to 280 ppmv would have resulted in a decrease in pH from 8.32 to 8.18.

Higher pH values are also seen in areas of the modern oceans where there is significant uptake of dissolved CO_2 by biological activity and downwelling of the surface waters before equilibrium with the atmosphere can be re-established. In the modern oceans, this process is mainly operating in the North Atlantic Ocean and in the southern oceans around Antarctica, and results in these areas acting as sinks for atmospheric CO_2 . Deeper waters have higher CO_2 concentrations and lower pH than surface waters (see below). Hence, areas of the oceans where there are strong upwelling currents (mainly the eastern equatorial Pacific and the Arabian Sea) have much lower pH values than would otherwise be expected. These areas of the oceans act as the Earth's largest natural source of CO_2 to the atmosphere.

The pH of the oceans also varies with depth. In the surface oceans, phytoplankton incorporate dissolved CO_2 to form

organic carbon and, in the case of coccoliths, they also form calcium carbonate shells. The former process acts to increase the pH of the surface water, while the latter acts to decrease it. In either case, the pH of the surface waters generally remains buffered at a constant value by exchange of CO_2 with the atmosphere. Once the phytoplankton and other organisms die, their remains sink through the water column. The organic matter is rapidly oxidized to CO_2 by microbiological activity, such that the pH of seawater decreases below the mixed layer, to reach a minimum value of between ~ 7.6 and 7.8 at depths of ~ 200 – 600 m. The precise depth and magnitude of the pH minimum depend on the rate of supply of organic matter from the surface (essentially a function of primary productivity) and the physical oceanography of the water column. At even greater depths, first aragonite shells and then calcite shells start to undergo dissolution, resulting in an increase in pH, such that the deepest waters of the ocean have similar pH to surface waters. The net result of all these processes is a water column pH profile similar to that shown in Figure P25.

It is apparent, therefore, that if we were able to generate a record of past variations in the pH of the oceans, we could glean much information about processes such as the history of atmospheric CO_2 , the spatial distribution of oceanic CO_2 sinks and sources, and the spatial and temporal history of oceanic primary production. Recent developments in boron isotope geochemistry have provided us with the first opportunity to address these problems.

In seawater, boron is a conservative element with an oceanic residence time of ~ 20 million years. Although the boron/salinity ratio is constant throughout the oceans, dissolved boron can exist as $\text{B}(\text{OH})_3$ or $\text{B}(\text{OH})_4^-$, with the former species being dominant at lower pH and vice versa. The boron isotope composition of seawater is also constant throughout the oceans at a $\delta^{11}\text{B}$ value of $+40\%$. However, the boron isotope systematics are such that the light isotope, ^{10}B , is preferentially partitioned into $\text{B}(\text{OH})_4^-$. The magnitude of this isotope fractionation is temperature dependent, but is of the order of 20% at 20°C . The relative proportions of $\text{B}(\text{OH})_3$ and $\text{B}(\text{OH})_4^-$ are pH dependent, but the boron isotope fractionation between them is constant, so the absolute $\delta^{11}\text{B}$ value of both species is also pH dependent (Figure P26).

Empirical studies and culture experiments have shown that when foraminifera form their calcite shells they incorporate

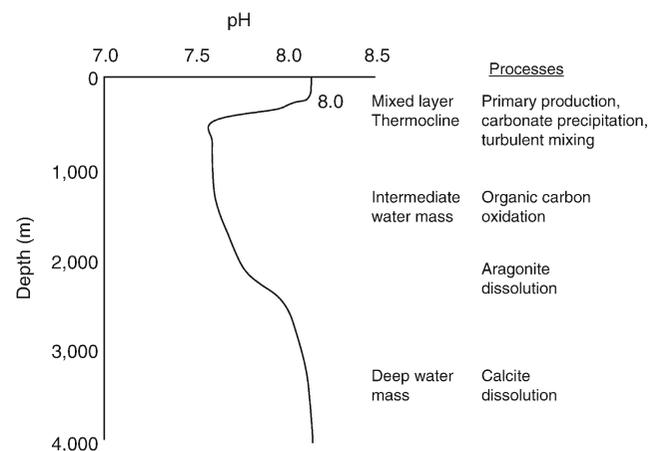

Figure P25 Schematic pH-depth profile in the ocean.

~10 ppm boron. This boron is exclusively derived from the dissolved $B(OH)_4^-$ in seawater and it is incorporated without significant fractionation of the $\delta^{11}B$ value of this species (Sanyal et al., 1996). Hence, measurements of the $\delta^{11}B$ of foraminiferal calcite can be used to reconstruct the pH of the waters from which they precipitated their shells. As with measurements of any other paleo-oceanographic proxy, care must be taken to ensure that the shells have not been altered (e.g., recrystallized or partially dissolved) since they were first

formed, and the foraminiferal calcite must be cleansed of any potential contaminant phases (such as clays and coccoliths) before it is analyzed. In addition, the analytical methods required for determining the $\delta^{11}B$ value of the small quantities of boron present (~1 ng) in the typical sample sizes available (20–50 shells) are not simple and much effort is required to obtain reliable data. Nevertheless, important results have emerged from this technique.

The utility of this approach in reconstructing the past pH of the oceans was provided by a study of the boron isotope composition of well-preserved foraminifera from sediments recovered from the Ontong-Java Plateau in the western equatorial Pacific by the Ocean Drilling Project (ODP) (Palmer et al., 1998). Samples of sediment deposited at five different times from 85 thousand years ago (ka) to 15.7 million years ago (Ma) were hand picked to separate individual species of foraminifera. This is important as different species of foraminifera precipitate their shells at different depths within the water column. For example, *Globigerinoides sacculifer* precipitates its shell within the mixed layer of the surface ocean that is in approximate equilibrium with atmospheric CO_2 , whereas *Globorotalia crassaformis* calcifies its test at depths of 200–400 m. Foraminifera from deeper waters would be expected to record $\delta^{11}B$ values indicating that they precipitated their shells in lower pH water than those that lived near the surface. Indeed, Figure P27 demonstrates that in the five time slices considered the foraminifera recorded pH values that yielded similar pH-depth profiles to that observed in the modern ocean at this site.

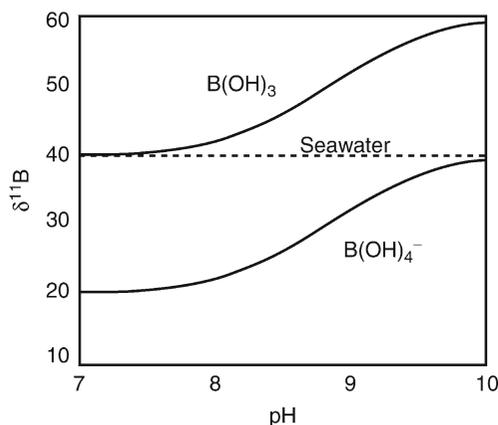

Figure P26 Boron isotope composition of dissolved boron species in seawater.

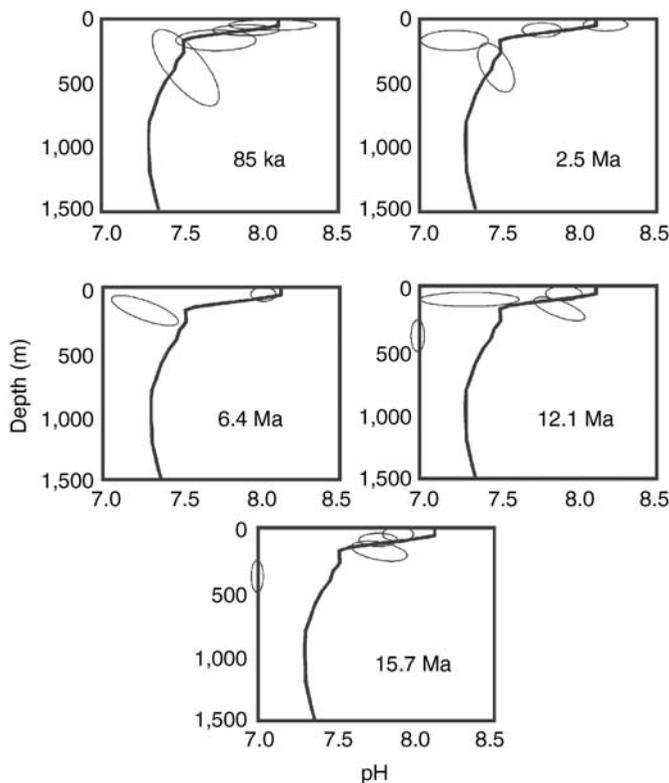

Figure P27 pH depth profiles for various time slices in the Neogene (ellipses define pH values calculated from the $\delta^{11}B$ of foraminifera; solid lines are present day pH-depth curve).

This technique of reconstructing pH-depth profiles was applied to foraminifera from the middle Eocene (~43 Ma) (Pearson and Palmer, 1999). At that time, the global climate was considerably warmer than today, such that polar ice caps were either absent entirely, or very much smaller than those of today. The warmer climate of the Eocene has been variously ascribed to higher atmospheric CO₂ levels or different ocean circulation patterns that resulted from the position of the continents at that time. Although boron has a very long oceanic residence time, which means that its isotopic composition will not change over periods of thousands of years, it is likely that there will have been changes in the $\delta^{11}\text{B}$ value of seawater over millions of years. Hence, any changes that are observed in the $\delta^{11}\text{B}$ of ancient foraminiferal calcite could arise from changes in the boron isotope ratio of seawater as well as changes in the pH of the seawater. Fortunately, this problem can be addressed by analyzing the $\delta^{11}\text{B}$ of foraminifera that precipitated their shells at different depths. As noted above, the decrease in pH from surface to intermediate depth waters is a result of the oxidation of organic carbon. This process utilizes dissolved oxygen in the water column and thus provides two constraints on the minimum pH that can be calculated for deeper waters. Firstly, the pH cannot have been so low as to inhibit

the calcification of the deepest dwelling foraminifera. Second, the change in pH from surface to deep waters cannot have been so great as to completely deplete the seawater of dissolved oxygen, as foraminifera cannot live in anoxic waters. Using these constraints Pearson and Palmer (1999) were able to calculate that the $\delta^{11}\text{B}$ of mid-Eocene waters lay between +41 and +38 (best estimate of +39.4) and that the pH of surface waters was between 7.91 and 8.33, with a best estimate of 8.05. This in turn implied that the CO₂ of the atmosphere at that time was similar to that of today or only slightly higher.

By using the boron isotope composition of surface dwelling foraminifera from the past 60 million years, Pearson and Palmer (2000) were able to provide a record of surface water pH over this time period (Figure P28a). This study showed that surface water pH values were roughly similar to present day values over the past 20 Ma, but that they were considerably lower during the late Paleocene thermal maximum (LPTM) and for much of the Eocene. By making certain assumptions concerning the past alkalinity of the oceans, it was also possible to reconstruct a record of atmospheric CO₂ levels since this time (Figure P28b). As might be expected, the uncertainties in the calculated pH and CO₂ values become greater further back in time. This uncertainty arises from some of the assumptions that have to be made concerning the past $\delta^{11}\text{B}$ -pH and alkalinity of the oceans, but the increased uncertainties in pH and CO₂ also arises from the fact that the $\delta^{11}\text{B}$ relationship illustrated in Figure P26 is not linear. Hence, at low pH values the same analytical error in measured $\delta^{11}\text{B}$ as was observed at higher pH results in a larger error in the calculated pH and

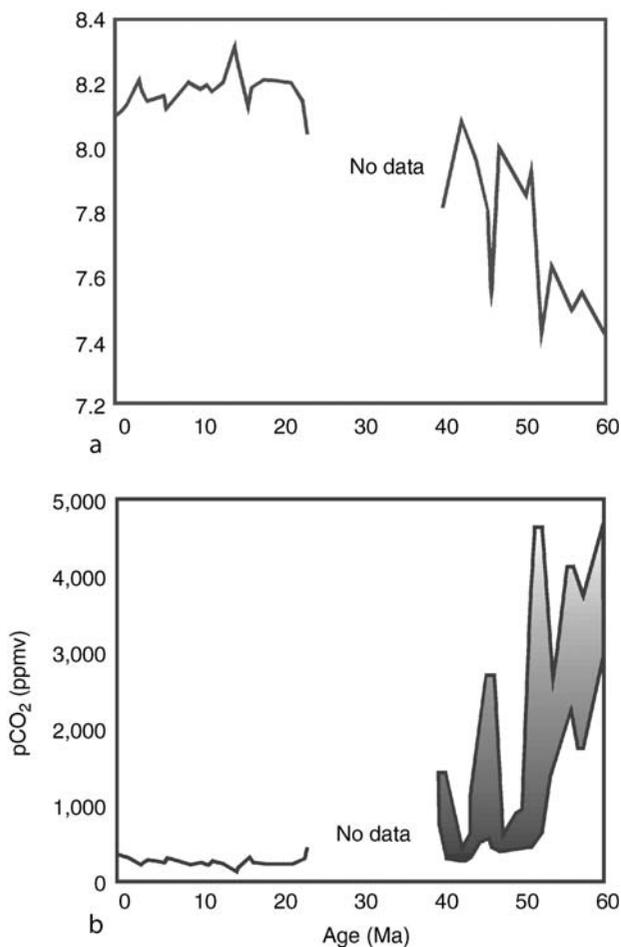

Figure P28 (a) Sea surface pH for the past 60 Ma; (b) Atmospheric CO₂ for the past 60 Ma.

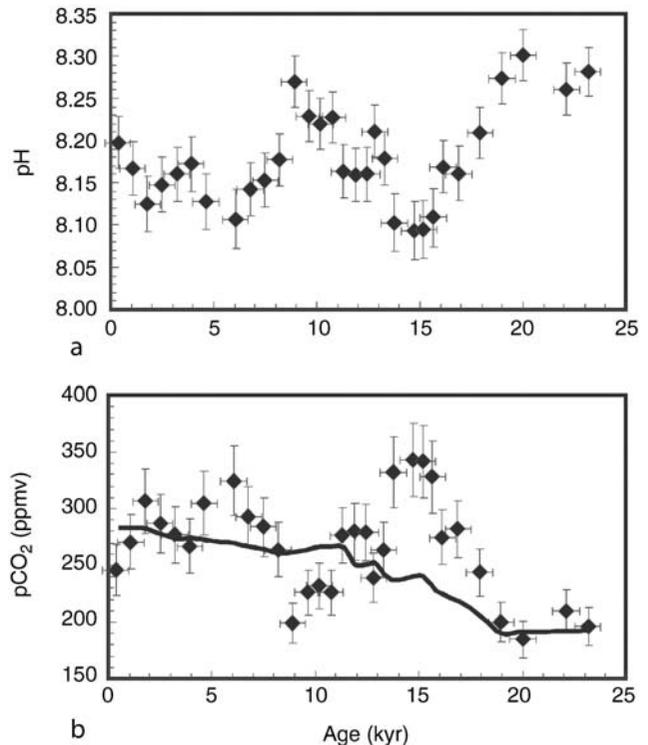

Figure P29 (a) pH of surface waters from the western equatorial Pacific Ocean; (b) pCO₂ of surface waters from the western equatorial Pacific Ocean – solid line gives contemporaneous atmospheric CO₂ levels.

CO₂ values. Despite these uncertainties, this study lends support to the theory that the very warm climate of the LPTM was due to high atmospheric CO₂ levels that also resulted in low surface water pH values.

More recently, Palmer and Pearson (2003) measured the $\delta^{11}\text{B}$ values of *G. sacculifer* to determine the change in pH and CO₂ of surface waters from the western equatorial Pacific (Figure P29a). By comparison with the record of atmospheric CO₂ preserved in ice cores, they were able to show that surface waters from this area were in equilibrium with the atmosphere during most of the Holocene and at the height of the last glaciation, but that they had much higher pCO₂ values during the transition from glacial to interglacial periods (Figure P29b). This study suggests that increased upwelling in the eastern equatorial Pacific may have played an important role in the increase in atmospheric CO₂ levels from glacial to interglacial times.

Although still very much in its infancy, it is apparent that the reconstruction of the paleo-pH of the oceans is a powerful tool with which to investigate some of the fundamental processes that have controlled the Earth's climate. With improvements in analytical techniques, it can be anticipated that we will be able to reconstruct increasingly detailed records of the spatial and temporal variation of seawater pH in the ancient oceans.

PALEO-PRECIPIATION INDICATORS

Introduction

Precipitation is one of the most important elements of the climate and the variability of precipitation affects much of life on Earth. Instrumental records of precipitation (and related measurements such as riverine discharge, lake-level change, outgoing longwave radiation, and others) exist for many parts of

the Earth, but rarely exceed one century in duration. In order to extend knowledge of precipitation variability further back in time, the use of paleo-precipitation indicators, also known as “proxies,” is required. There are no perfect proxies for past precipitation amount and Mann (2002) has argued persuasively that accurate paleoclimatic reconstructions are best achieved through application of multi-proxy approaches.

Natural archives of paleo-precipitation

The most important paleoclimatic archives are historical documentary records, lacustrine and marine sediments, mountain and continental glacial ice, tree rings, reef corals, speleothems (cave deposits), and loess (e.g., Bradley, 1999). Each archive has its own characteristic rate of formation and fidelity of preservation; both factors constrain the ultimate temporal resolution of sampling. For example, snow may accumulate on a mountaintop at a rate of centimeters to meters each year (a potential record of precipitation amount on a sub-annual timescale), but some of this snow may be subsequently lost by sublimation, melting, or wind erosion. The snow that remains is eventually buried, compacted, and recrystallized to ice; a portion of it may flow laterally under the force of gravity. All of these processes, which collectively may be called “diagenesis” (changes happening to materials after their initial formation), introduce complications for the interpretation of proxy measurements from glacial ice cores (for a thorough, but non-technical account of all aspects of ice cores see Alley, 2002). Similar diagenetic alteration may also impact proxy measurements made on sediments, corals, and speleothems.

Lacustrine indicators of paleo-precipitation

Lakes, especially lakes with no outlets, may effectively behave as very large rain gauges. Precipitation (plus runoff into the lake, minus any outflow from the lake) is recorded as changes in lake level, changes that are also dependent upon temperature-controlled evaporation, although several other climatic elements (e.g., humidity and wind speed) also influence evaporation rates. There are many published studies that attempt to quantitatively reconstruct precipitation history from a history of lake level (e.g., Blodgett et al., 1997; Cross et al., 2001). Lacustrine sediments contain many components that are useful in reconstructing lake level or related variables such as salinity. Pollen grains and spores commonly accumulate in lakes and wetlands. The analysis of pollen in sediments, the field of palynology, enables a regional reconstruction of the vegetation cover in the watershed of the lake (or beyond). Plant growth is dependent on precipitation as well as other variables such as temperature, light, and nutrients (atmospheric carbon dioxide). Because each may vary independently, multivariate statistical analysis is an important methodology that can sometimes permit the deduction of past precipitation. As a simple example, the ratio of non-arboreal pollen to arboreal pollen is sometimes utilized as a qualitative indicator of aridity (e.g., Maley, 1996). Diatoms are unicellular algae that inhabit rivers, lakes, and the ocean. Some diatom taxa are planktonic and some are benthic (shallow water). The ratio of benthic-to-planktonic diatoms in a sediment sample is often used as a qualitative measure of lake level (e.g., Gasse et al., 1997). Some diatom taxa are restricted to specific ranges of salinity, hence can also be useful indicators of lacustrine water balance (precipitation minus evaporation). The mineralogy, trace element composition, and especially the stable oxygen isotopic composition of calcium carbonate components of lacustrine sediments can all be useful measures of water balance. Most often, the carbonate components used in such studies are the shells of organisms such as ostracodes, gastropods, or

bivalves (e.g., Schwab, 2003). Less ideally, the isotopic analysis can be performed on the bulk carbonate fraction that may consist of shell fragments, carbonate precipitated by macrophytes or microorganisms, or apparently abiogenic carbonate precipitates. When calcium carbonate is absent, stable oxygen isotopic analysis of siliceous microfossils, such as diatoms, is also possible (e.g., Hu and Shemesh, 2003). Stable oxygen or hydrogen isotopic studies are increasingly being performed on specific organic compounds found in lacustrine sediments, such as cellulose, *n*-alkanes, or palmitic acid (Huang et al., 2004). The stable isotopic composition of all of these compounds is dependent not only upon the precipitation amount, but also upon the isotopic composition of the lake water (and in some cases the temperature of formation of the compound). This, in turn, is determined by the isotopic composition of the source precipitation and inflow as well as the amount of evaporative concentration of lake water. In many cases, variation of the isotopic composition of the source water (precipitation and inflow) is the dominant source of variation. The lack of knowledge of the temporal variability of the isotopic composition of precipitation and inflow is a common limit to quantitative application of this method, although in exceptional cases the isotopic composition of source precipitation may be known (e.g., Seltzer et al., 2000).

Marine sedimentary indicators of paleo-precipitation

Most open-marine (pelagic) sediments contain few indicators of paleo-precipitation. However, in marginal marine environments, sediments derived from adjacent land masses can be useful indicators of terrestrial runoff (precipitation minus evaporation). For example, color reflectance (Peterson et al., 2000) and Ti/Al ratios (Haug et al., 2001) of marine sediments from the Cariaco Basin just offshore of Venezuela were used to deduce the runoff from the adjacent continent. These studies demonstrated that northern South America was relatively dry during the Little Ice Age, the Younger Dryas, and the Last Glacial Maximum. DeMenocal et al. (2000) concluded that a rapid increase of wind-blown lacustrine diatoms and other terrestrial sediments in marine sediments off the coast of northwest Africa indicated an abrupt drying in the Sahara Desert at about 4,000 yBP. Pollen grains can also be transported by wind or runoff and deposited in marine sediments where they can provide important information about past precipitation amounts on the adjacent continent. In the marine sediments of the Amazon fan, analyses of pollen (Haberle and Maslin, 1999), iron-oxide minerals (Harris and Mix, 1999), oxygen isotopes in marine calcareous organisms (Maslin and Burns, 2000), and organic biomarkers of rain forest vegetation (Kastner and Goni, 2003) have all been related to past precipitation amount in the adjacent Amazon basin.

Ice cores as recorders of snow accumulation

Ice cores record many aspects of past climates. It is usually possible to detect annual layers in the upper portions of ice cores. These annual layers are due to summer melting and re-freezing (in high latitude ice cores) or to dry-season dust accumulation (in low-latitude ice cores). The annual precipitation amount can be calculated (as water equivalent) from the thickness of the annual layer and the snow/ice density. Unfortunately, wind erosion, melting, sublimation, and lateral flow are often significant and such direct deduction of past precipitation amount is limited to the upper portion of ice cores. In tropical ice cores, it is possible to reconstruct paleo-precipitation from the oxygen (or hydrogen) stable isotopic composition of the ice (Hoffmann et al., 2003). This

method of reconstruction (although not universally accepted) relies upon the observation that there is a significant correlation between precipitation amount and $\delta^{18}\text{O}$ (or δD) of the precipitation (e.g., Rozanski et al., 1993) in tropical latitudes and that this relationship has held through time.

Glacial mass balance (accumulation minus ablation), like the water balance of lakes, is dependent upon precipitation amount (as well as temperature). Reconstructions of snowline elevation in arid mountain regions can provide useful estimates of past levels of precipitation (Kull and Grosjean, 2000).

Speleothems as recorders of paleo-precipitation

Speleothems are calcium carbonate deposits, including stalagmites and stalactites, that are deposited from carbon dioxide dissolved in groundwater that seeps into caves. These deposits are increasingly being used for high-resolution reconstruction of precipitation. Rates of growth of the cave deposits may be related to precipitation amount, with more rapid deposition of calcium carbonate occurring in wetter periods. In rare cases, cave deposits may form annual layers, whose thickness can be related to annual precipitation amount. Oxygen isotopic composition of the speleothem calcite is determined by its temperature of formation and the isotopic composition of groundwater. If mean annual temperature changes are relatively small through time, then changes in $\delta^{18}\text{O}$ of the calcite are largely controlled by changes in the isotopic composition of groundwater, which is most often nearly the same as the isotopic composition of regional precipitation. As mentioned previously, in the tropics, $\delta^{18}\text{O}$ of rainwater is correlated with precipitation amount, thus, within accepted bounds, the isotopic composition of tropical cave deposits is a reliable indicator of past precipitation (e.g., Fleitmann et al., 2003). Because cave deposits can be precisely dated by the U/Th method, this method of precipitation reconstruction is of great utility for the past few hundred thousand years. Furthermore, if the hydrogen isotopic composition of fluid inclusions in the cave deposit is measured along with the oxygen isotopic composition of the host calcite, paleotemperatures can be directly calculated (e.g., Schwarcz and Yonge, 1983).

Other recorders of paleo-precipitation

Many other proxies have been used as recorders of paleo-precipitation. In semi-arid environments, tree growth is particularly dependent upon water availability and annual extension (tree-ring width) may be a reliable indicator of past precipitation amount (e.g., Villalba et al., 1998). The magnetic susceptibility of loess sequences in China has been utilized as a paleo-precipitation indicator (Maher and Thompson, 1995). The oxygen isotopic composition of the calcium carbonate precipitated by reef-building corals is controlled by both temperature and isotopic composition of surface seawater, itself partly dependent on precipitation amount, thus if temperature can be independently determined (for example, using the strontium/calcium ratio of the coral aragonite), then it may be possible to reconstruct paleo-precipitation (McCulloch et al., 1994).

PALEOSOLS, PRE-QUATERNARY

Introduction and definitions

Paleopedology is the study of the genesis, properties, climate, and landscape records of fossil soils, or paleosols. Pre-Quaternary paleosols are buried, “fossilized” soil horizons, which are older than 2 Ma; they are also commonly lithified, i.e., converted from soil into rock by the geological processes of burial diagenesis (Retallack, 1991). Unlike the more rigid definition used by soil scientists, who consider a soil to be a body of geologic material that supports plant life, geoscientists interpret pre-Quaternary paleosols as any former subaerially exposed surfaces or layers of earth material that have been affected by physical, chemical, and biological weathering processes. However, evidence for the presence of plants is not considered a prerequisite for identification of a fossil soil (Retallack, 2001). This broader geological definition allows for greater flexibility in examining parts of Earth history during which terrestrial plants were not present.

Paleosol features

Impetus for the study of pre-Quaternary paleosols largely originated with Dr. Gregory Retallack at the University of Oregon, who has published a widely used textbook on paleopedology (Retallack, 2001). In a 1985 Geological Society of America Penrose Conference on paleosols (organized by Dr. Retallack), geoscientists, for the first time, began to think about soils of the past set in the backdrop of “deep” geologic time. Recognition and interpretation of pre-Quaternary paleosols requires the use of multidisciplinary approaches that involve integration of field morphological, microscopic, and geochemical data, as well as an appreciation for evolutionary changes in terrestrial biota and flora that have occurred over time (Mora and Driese, 1999). Field morphological features such as plant root traces (in post-Silurian paleosols), soil horizons, and soil structures (especially peds or natural soil aggregates), are very diagnostic for pre-Quaternary paleosol identification (Figure P30a; Retallack, 1988). Micromorphological (thin section) features are commonly well preserved in

paleosols and include root and soil animal traces, peds, and concentrations (or evidence for removal) of soil constituents such as clays, carbonates, Fe-Mn oxides, etc. (Figure P30b; Driese and Foreman, 1992; Mora and Driese, 1999). Geochemical patterns related to weathering and element translocation, including molecular ratios of oxides or elements (e.g., Figure P30c; Retallack, 2001), concentration ratios (molecular ratios normalized to an assumed immobile element such as Ti; Driese and Foreman, 1992), and mass balance (residual enrichment, volume change during weathering, and mass transport, normalized to an immobile element such as Ti or Zr; Driese et al., 2000), provide supporting evidence for interpretations of paleosols. Stable isotopes, especially $\delta^{13}\text{C}$ values of paleosol organic matter and pedogenic carbonate, are useful in identifying terrestrial sources of organic matter and ecosystem types (Cerling, 1991). Most plant communities during the Paleozoic and Mesozoic eras were C3 (Calvin cycle), with $\delta^{13}\text{C}$ values of soil organic matter averaging -26‰ PDB and pedogenic carbonate values ranging from -5 to -12‰ PDB (Mora et al., 1996; Mora and Driese, 1999). The $\delta^{18}\text{O}$ values

of pedogenic carbonate, if not diagenetically altered, can be used as proxies for meteoric water compositions and paleotemperatures (Cerling, 1984), but most values measured for Paleozoic pedogenic carbonates have been apparently reset during burial diagenesis (Mora and Driese, 1999).

Problems in recognition and interpretation of paleoclimates from pre-Quaternary paleosols include extensive burial diagenetic alteration (Retallack, 1991). Common diagenetic alteration processes include physical compaction and consequent modifications of original soil thickness and morphology, oxidation of soil organic matter, burial gleization (Fe loss, largely through microbial reduction), color modifications (intensification) related to dehydration and recrystallization of hydrous mineral phases (such as FeOOH), recrystallization of soil smectites to illites (or even to metamorphic mineral assemblages; Table P3), and exchange of oxygen isotopes between burial fluids and pedogenic carbonates and clays (Mora and Driese, 1999). Mack et al. (1993) proposed an alternative paleosol classification, because of burial diagenetic alteration and associated lack of preservation of

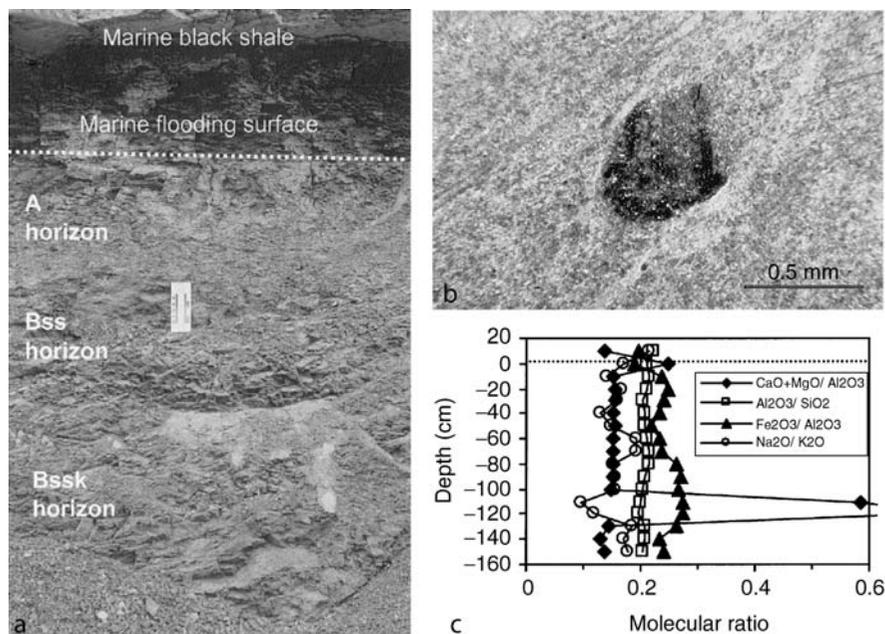

Figure P30 Pennington Formation (325 Ma, late Mississippian), Tennessee, USA paleosol. (a) Field photograph: A (surface), Bss (slickensided B) and Bks (slickensided B with pedogenic carbonate) refer to paleosol horizons. Note angular blocky ped structure in outcrop (scale card is 15 cm long). (b) Thin-section photomicrograph of paleosol shown in (a), which exhibits oriented bright clay microfabric related to seasonal cycles of wetting and drying and associated clay shrinking and swelling, as well as dark-colored Fe-Mn oxide nodule (cross-polarized light). (c) Molecular ratios for paleosol profile depicted in (a), including calcification ($\text{CaO} + \text{MgO}/\text{Al}_2\text{O}_3$), clay accumulation ($\text{Al}_2\text{O}_3/\text{SiO}_2$), Fe accumulation ($\text{Fe}_2\text{O}_3/\text{Al}_2\text{O}_3$), and salinization ($\text{Na}_2\text{O}/\text{K}_2\text{O}$). Note carbonate and Fe accumulation in deeper portion of paleosol, but relatively uniform clay content and salinization.

Table P3 Diagenetic alteration of paleo-Vertisols (high clay-content paleosols with extensive shrink-swell features such as slickensides) compared with a modern soil analog (Houston Black series), as a function of increasing burial depth, temperature, and time (Driese et al., 2000; Rye and Holland, 2000)

Name, Geologic age	Burial depth (km)	Burial temperature ($^{\circ}\text{C}$)	Clay mineral assemblage	wt% K_2O
Houston Black (modern)	Surface	22 (mean annual temperature).	Na-smectite	1.29
Pennington (325 Ma)	2–3	60–90	Illite (+ kaolinite + chlorite)	4.61
Hekpoort (2.25 Ga)	12–15	350	Sericite – muscovite – chlorite	9.50

features necessary for rigorous application of USDA Soil Taxonomy (Figure P31). Evolutionary changes in terrestrial plant and animal communities over time also create difficulties in paleosol interpretations because of attendant changes in morphological features such as root traces, which are: (a) not present in Ordovician paleosols; (b) rhizomatous and fine in Silurian paleosols; and (c) larger, deeper, and more “modern” in Devonian and post-Devonian paleosols (Driese and Mora, 2001).

Paleosols as paleoclimate proxies research

Current research on pre-Quaternary paleosols no longer concerns simple identification of paleosols in the geologic record, but instead focuses on the use of paleosols as proxies for reconstructions of paleoclimate, paleolandscape evolution, and paleoatmospheric chemistry. Paleoclimate reconstructions primarily emphasize the determination of estimates of mean annual precipitation (MAP) by using a variety of proxy measures, including: (a) the depth to pedogenic carbonate (Bkss) horizon used by Caudill et al. (1996) to estimate mean annual paleoprecipitation (MAP) of $648 \pm 141 \text{ mm yr}^{-1}$ (after Retallack, 2001;

Figure P30a), (b) Fe content of pedogenic Fe-Mn nodules and concretions (Figures P30b and P32a), which was used by Stiles et al. (2001) to estimate MAP of 989 mm based on wt% Fe content; (c) chemical indices of weathering based on bulk geochemistry (Figures P30c and P32b; e.g., Chemical Index of Alteration minus Potash or CIA-K, Sheldon et al., 2002); and (d) total element mass-flux and mass-balance calculations (Stiles et al., 2003). Paleolandscape reconstructions in which topography or hydrology are important variables (interpretation of paleocatenas) are commonly conducted at both local and more regional scales. Reconstructions of Phanerozoic $p\text{CO}_2$ employ the CO_2 -carbonate paleobarometer of Cerling (1991) to interpret Paleozoic (Mora et al., 1996; Mora and Driese, 1999) and Mesozoic paleoatmospheres. This technique utilizes the $\delta^{13}\text{C}$ values measured from pedogenic carbonates, measurements of $\delta^{13}\text{C}$ values of paleosol organic matter (or an estimate based on marine proxy records), and assumptions of soil productivity to infer paleoatmospheric $p\text{CO}_2$. These results are in good agreement with $p\text{CO}_2$ estimates based on long-term mass-balance carbon models (Figure P33). Studies of oxygen levels of Precambrian atmospheres focus on

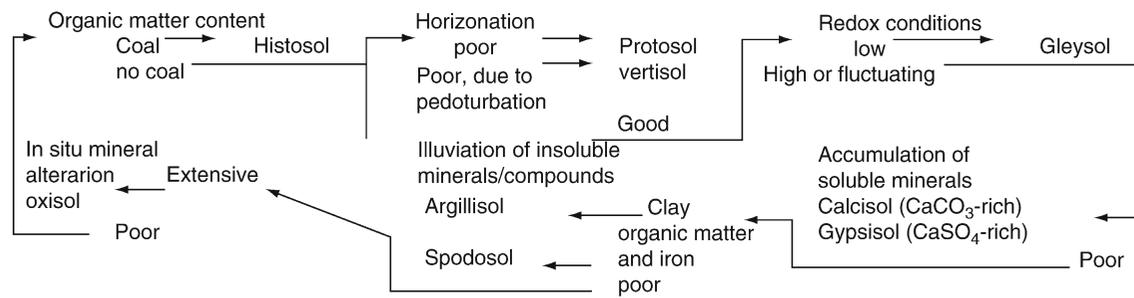

Figure P31 Classification for paleosols (Mack et al., 1993).

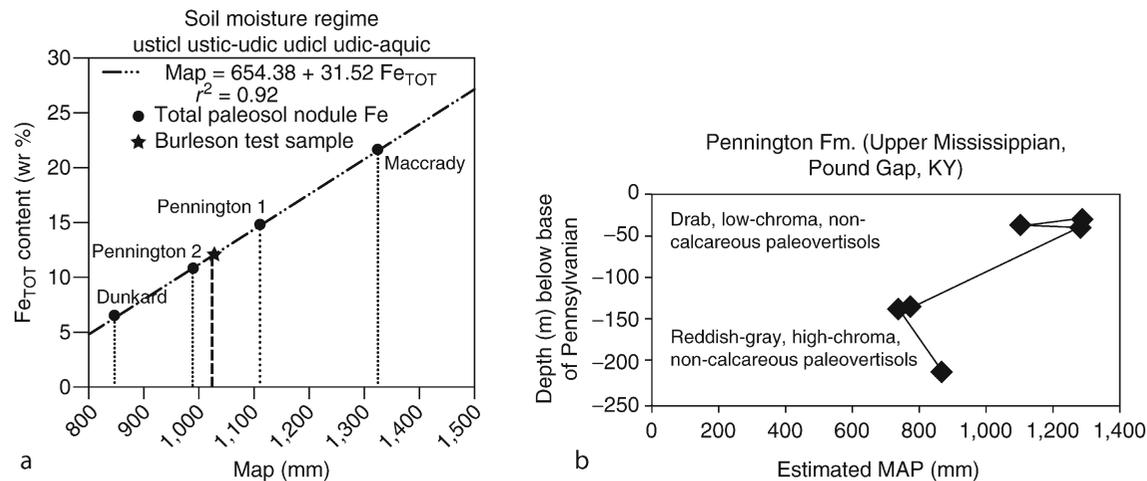

Figure P32 Geochemical climate proxies derived from pre-Quaternary paleosols. (a) Paleoprecipitation (MAP) for mid-Mississippian (Maccrady), late Mississippian (Pennington), and early Permian (Dunkard) Appalachian basin paleo-vertisols based on measured Fe content of paleosol Fe-Mn nodules and regression equation of Stiles et al. (2001) for total Fe content of Fe-Mn nodules in modern soil analogs in Texas, USA. Estimated MAP ranges from 850 to 1,310 mm yr^{-1} . (From Stiles et al., 2001, used with permission). (b) Mean annual precipitation (MAP) for six Appalachian basin paleo-Vertisols derived from bulk chemistry and regression equation of Sheldon et al. (2002) that relates MAP to Chemical Index of Alteration minus Potash (CIA-K = molar ratio of $\text{Al}_2\text{O}_3 / (\text{Al}_2\text{O}_3 + \text{Na}_2\text{O} + \text{CaO}) \times 100$, $P = 14.265(\text{CIA-K}) - 37.632$, where $P = \text{MAP}$ in mm yr^{-1} , $r^2 = 0.73$), which increases by 400–500 mm MAP during latest Mississippian time in southeastern Kentucky, USA.

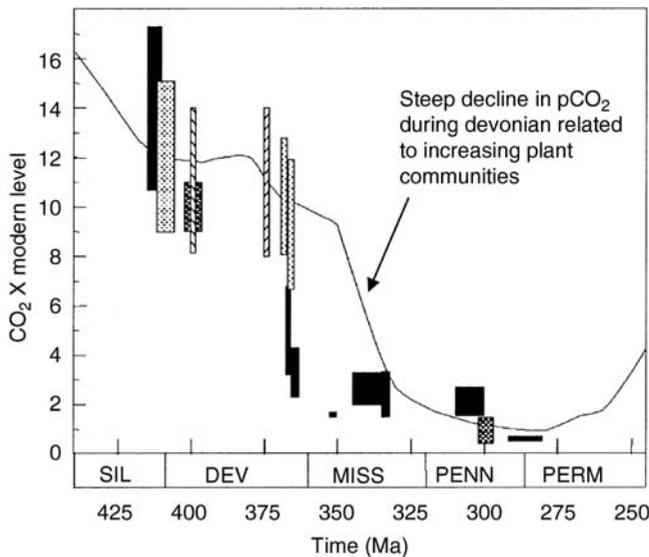

Figure P33 Estimates of middle to late Paleozoic atmospheric CO_2 levels (expressed as times present atmospheric level) derived from Appalachian basin paleosols (closed symbols from Mora et al., 1996; other sources (patterned symbols) of pedogenic carbonate-based estimates cited in Driese and Mora, 2001), calculated using the soil carbonate carbon isotope paleobarometer (Cerling, 1991). Other proxy-based estimates include stomatal density (open symbols) and carbon mass-balance model (line; see discussion in Driese and Mora (2001)).

measuring Fe contents and Fe losses during weathering of Precambrian paleosols. These investigations have been further expanded to include other redox-sensitive elements, as well as the ratio of oxygen demand to demand for CO_2 during weathering (Rye and Holland, 2000). Other research directions include systematic studies of root diameter, depth, and density in paleosols, using root traces, and relating these changes to development of soil morphology (Driese and Mora, 2001), widespread deposition of black shales, and carbon sequestration.

New research directions on pre-quaternary paleosols

Study of pre-Quaternary paleosols appears to be heading in many future directions. One important research area involves studies of soil chronosequences (a suite of related soils in which all soil-forming factors are held constant except for the time duration of pedogenesis) in order to interpret the time significance of paleosols in the geologic record (Stiles et al., 2003). Because paleosols represent unconformities within otherwise conformable stratigraphic successions, the ability to resolve time in paleosols is extremely important in terms of interpreting earth history. U-Pb age-dating of pedogenic carbonates offers a promise of improved chronology of pre-Quaternary paleosols, whose ages place them beyond the limits of ^{14}C or other dating methods commonly used for Quaternary paleosols. Applications of paleosol research to interpretations of sequence stratigraphy will help to connect time and sea level-base level relationships between marine and terrestrial stratigraphic sections. Careful documentation of continental traces of invertebrate animals (paleoichnological studies), especially those relating soil animals and their relationships to soil

forming-processes in the past, is yet another area that is currently developing.

PALEOSOLS, QUATERNARY

Introduction

Paleosols, the remains of former soil covers of the Earth now buried under younger deposits, are an important testimony of the environmental conditions of ancient epochs. Paleosols occur in sediment sequences of various origins, such as alluvial sediments of river terraces, and in shallow marine (lagoon), volcanic, and even glacial deposits. However, the most widespread and best-preserved paleosols occur in loess deposits. The buried soils are detected on all continents except for the Antarctic. The first half of the twentieth century was the period of upbuilding data about paleosols in loess sequences. It was established that paleosols contain very important information on chronostratigraphy and paleogeography.

Paleosols as a chronostratigraphic component of the Pleistocene

The horizons of paleosols are widely used as key horizons for the stratigraphic subdivision of continental sedimentary series. Frequently located in the periglacial zone and occupying an intermediate position between regions of moraine distribution on the one hand, and marine deposits on the other hand, horizons of buried soils represent an important link in a system of general correlation of events in glacial, periglacial, and maritime areas.

The reliability of usage of paleopedologic data has increased, especially with the development of methods of absolute and relative dating: radiocarbon, thermoluminescent, paleomagnetic, amino acid, and paleontological (palynological and paleofaunistic). The use of paleosols as components of the stratigraphic record has increased, especially after paleosols morphotypical features of different ages were studied (Figure P34).

Paleosols in various sediment sections were once compound units of soil covers of different ages. The possibility of their use as a reliable tool for chronostratigraphic subdivision and correlation is based upon the fact that each of the interglacial epochs of the Quaternary soil formation was characterized by intrinsic features of pedogenesis, combinations of paleosols in automorphic conditions, and specific features of their geographic distribution. These include, for example, soil complexes that belong to the late Pleistocene (Sangamon) interglacial in North America, to the Eemian interglacial in West Europe, to the Mikulino (East Europe), and to the Kazantsevo interglacial in Siberia. Such paleosols were named "soil stratigraphic units" or "pedostratigraphic units" (Catt, 1990). For these, R. Morrison (1967) has suggested the term "geosol." Not only interglacial soils can be used as stratigraphic markers. Interstadial Pleistocene soils having regional names (e.g., Kesselt, Gleina, Stilfrid B, and Mende F in West Europe; the Bryansk soil in East Europe; Farmdale in North America) with established genetic connections and age control based on radiocarbon dating (32–24 kyrBP) can also be used for distant correlations.

Diagnostic methods of paleosol genesis

The main aim of paleopedological studies is to reconstruct genetic paleosol profiles and to identify the soil formation factors. The structure of a soil profile can therefore be used for paleopedologic reconstructions.

Consequently, analysis of a paleosol in the field starts with a detailed description of its genetic profile on well-cleaned walls of natural exposures – those of open pits, ravines, river banks, marine coasts, and others.

Paleosols contain much more information on the relevant processes, which occurred at different times and affected not only the formation of the soil profiles, as such, but also their preservation. We can distinguish the following main processes responsible for the formation of the buried soils observed in loess-paleosol formations (where the best preserved paleosols are found):

1. Processes of soil formation, which took place during periods of intensive pedogenesis in warm semicycles of glacial-interglacial cycles. Their direction and intensity changed in response to different environmental-climatic conditions.
2. Processes specific to transitional stages to cold semicycles and to glacial ones. These specific processes, which took place at the end of or at the completion of soil formation during warm semicycles, greatly affected the preservation of soil of profiles, especially their upper parts that were marginal to the overlapping loess horizons. Cryogenic processes that contributed to distortion of soil horizons include processes of sedimentation

intensification, when intermediate deposits transitional from fossil soils to loess horizons were formed between loess and soil, and removal and re-deposition processes that affected materials in the upper parts of fossil soils located on slopes (formation of so-called pedosediments).

3. Pedometamorphic (after Gerasimov, 1971) or diagenetic processes that transformed the buried fossil soils. As a result of these processes, fossil soils lost their indices of low stability and acquired new secondary ones.

In studying the genesis of fossil soils, the greatest attention is naturally paid to indices of pedogenesis stages, which reflect conditions extant when the soils proper were formed. These processes lie at the base of paleopedologic reconstructions. However, study of the different forms of disturbances of the soil profile and of pedometamorphic changes in their properties is also very important.

The set of analytic methods that we use in our studies depends on the preservation of the most stable indices of soil formation. They include the following:

Analytical methods for studying the mineral components of soils

Data from chemical and physical-chemical analyses, including particle-size (granulometric) analysis, total chemical composition, clay minerals, and others can be used for diagnostic purposes (Figure P35a and P36a). In a number of cases, however, when fossil soils have been subjected to the impact of secondary

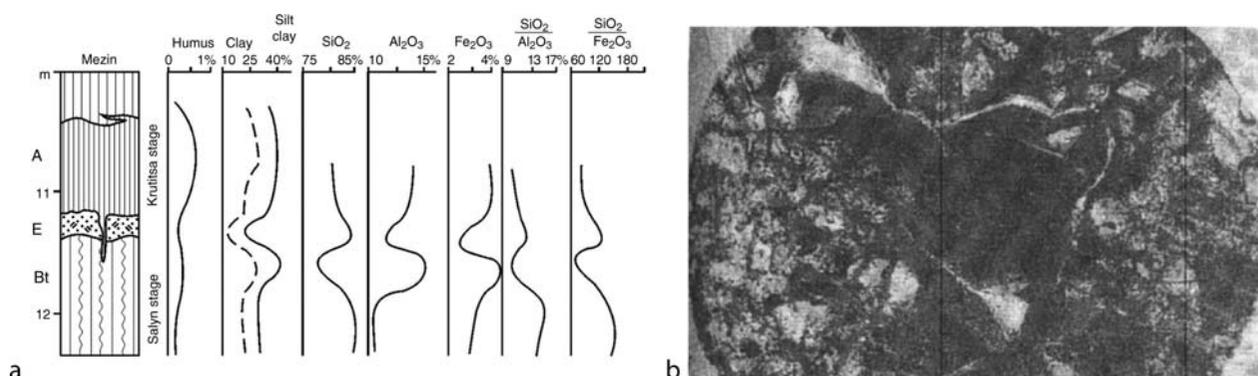

Figure P35 (a) Analytical data of Mezin paleosol complex, Mezin section, Dnieper basin; (b) Clay illuviation coating in Bt horizon.

cryogenesis and fracturing, their genetic horizons may appear to be mixed, and the data of the distribution of mineral components along their profiles may be greatly distorted.

Analytical methods for investigating organic matter

The composition and characteristics of organic matter in the soil are the most important diagnostic criteria of soil formation processes. Soils show differences in their humus content depending on natural climatic conditions. The fractional composition of soils, the properties of their humic acids, and the regularities of humus distribution along this profile all change as well.

When the soil is buried, the amount of organic matter it contains decreases noticeably in spite of the fact that the soil preserves its dark color. Analyses of radiocarbon data on the ages of different fractions of humus indicate that fractions of the humic acids proper and the humic acids of humins are the most of stable and the least subject to pedometamorphic transformation (Gerasimov and Chichagova, 1971). Numerous studies have confirmed the hypothesis, first advanced by I. P. Gerasimov, who suggested that the correlation of the main groups of humic matters (humic and fulvic acids, humins) in fossil soils generally reflects two main directions in the formation of paleosols: the forest and steppe types.

The data on some properties of humic acids (optical density, stability to electrolytes) are also used as diagnostic indicators of former pedogenesis. This was demonstrated for the first time in the study of humic acids in soils of the Bryansk interval and of the Mikulino interglacial (Morozova and Chichagova, 1979).

Micromorphological method

This method, developed by W. L. Kubiena (1970), is widely used for the study of fossil soils in different countries (Fedoroff, 1971; Bronger, 1972; Smolikova, 1972; Konecka-Betley, 1979; Morozova, 1981; Matviishina, 1982; Mucher and Morozova, 1983; Catt, 1990; and others). The micromorphological method permits us to study those details of the soil profile that contain the basic information both on processes of the old pedogenesis, and on those that resulted from soil fossilization and that disturbed its overall structure.

As micromorphological diagnostics of soils, the following are used: data about microstructure (aggregation and voids), grade of pedality (degree of aggregation; Bullock et al., 1985), ground-mass (b-fabric), pedofeatures, and other features (Figure P35b and P36b).

To define paleosols, the paleoactualistic principle is applied: paleosol properties are compared to the properties of modern soils, and their genesis is inferred on the basis of their commonality. Micromorphological research using these materials is presented in the works of Kubiena (1970) and Bullock et al. (1985). Genetic types of paleosols are named according to International (FAO) system and its correlation with the Russian system of soil classification (Gerasimova et al., 1996).

Evolution of soil formation in the Quaternary period

Quaternary types of soil formation epochs

The difference in heat and moisture supply between phases of the climatic macrocycles of the Pleistocene controlled succession of soil formation types, and various patterns of soil zonation, under changing conditions of sedimentation and lithogenesis through macrocycles.

Interglacial soil formation. This soil type developed during the thermal optimum of the climatic macrocycle. Interglacial paleosols either corresponded by their genesis to modern soils in

the considered territory or were formed against the background of a warmer and wetter climate. At temperate latitudes, over the vast spaces of large watersheds, a latitudinal soil zonation was developed. In the late and middle Pleistocene, cambisols, luvisols, luvisols, phaeozems, and chernozems were formed. During the early Pleistocene warm epoch (Cromer), paleosols with subtropical features of pedogenesis were formed.

Interstadial soil formation. During the cold semicycle, drastic landscape-climatic changes occurred. These were accompanied by climatic oscillations of heat and moisture supply, both of a stadial and interstadial nature, as reflected in the processes of soil formation and sedimentation.

Interstadial soil formation was characterized by two main types of paleosols. The first was typified by predominance of paleosols of the cryo-gley genesis (gelic gleysols). For example, in the Bryansk (Farndale) epoch, the gleyezems were widespread in west and middle Europe, on the southwestern margins of the East European Plain, and in some regions of North America. Gleyezems were characterized by the development of gleyization processes (i.e., water logged, anaerobic conditions), weakly developed pedality, and massive microstructures. Paleosols with aggregates of ooid type have been identified in the central regions of the East European Plain.

The second type differed from the interglacial paleosols by greater uniformity in the manifestation of soil-forming processes, with humus accumulation predominant among them. Pedality was moderately developed, with aggregation and plasma clay-humus. The latitudinal zonation was then essentially simplified, becoming nearly hyperzonal. Interstadial soils of early glacial stages (such as the Krutitsa soil of the Mezin complex) belong to that type.

Pleniglacial soil formation corresponded to the maximum of the cold phase of a semicycle. During this time, permafrost was widespread beyond the ice-sheet in the periglacial zone. Sedimentation was dominant over pedogenesis. Overall, the biogeochemical processes of rock breakdown were overwhelmed, and specific synlithogenic paleosols (loesses) were formed. These processes can be compared to those characteristic for the gray soils of semideserts, to some extent. Very low-intensity soil formation occurred during slightly wetter phases; it was manifested in the processes of gleyization, segregation of ferric hydroxides, and discrete humification.

General features of the pedogenesis in the Quaternary period

The nature of soil formation did not repeat itself, but changed consistently due to the overall trend of climatic changes. In general, interglacial soil formation within the middle latitudes of the Northern Hemisphere (the present-day temperate belt) changed from subtropical (Mediterranean) in the early stages of the Pleistocene up to subboreal (boreal) at its termination. These changes have been established based on genetic types of the interglacial paleosols known from the loess sections of North America, Europe, and Asia (West Siberia, and China).

Evolution of soil formation processes in the Quaternary and their climatic interpretation (based on the example of the central East European Plain)

At present, soddy podzols and gray forest soils in combination with leached chernozems of the meadow steppe occur in the central regions of the East European Plain. The main climatic parameters of this territory are: $t_1 = -10^\circ\text{C}$, $t_7 = +18^\circ\text{C}$,

$t_{yr} = +8^{\circ}\text{C}$, $P_{yr} = 550\text{--}600$ mm, where t_1 = average January temperature, t_7 = average July temperature, t_{yr} = annual mean temperature, and P_{yr} = annual mean precipitation.

The loess-soil series in this region are the most studied (Figure P37). Here, it is possible to observe changes in interglacial soil formation during the last million years. The earliest known interglacial soils are the paleosols of two climatic macrocycles prior to the Brunhes-Matuyama (780 kyBP) paleomagnetic boundary.

During the period when the oldest fossil soils studied were formed (the Balashovskaya paleosol, in the Matuyama zone), the type of pedogenesis with well-expressed subtropical features dominated. For this time, two types of paleosol profiles are established. One of them corresponded to wet subtropical conditions due to a texture-differentiated structure of the profile and presence of braunlehm plasma (containing fragments of illustrated coatings in finely dispersed clay; Kubiena, 1970) in the Bt horizon. In the second type, the features of rubefication

and ferruginization (reddening of soil due to iron oxide accumulation) of the soil plasma are established.

During the Okatovo interglacial, when the Rzhaksa soil formed, phaeozems appeared in this region (Figure P34). The Vorona (Muchkap) interglacial (the late Cromer) had set in after the Don glaciation. Polygenetic soils from less than two contiguous paleosols were detected in the soil cover. The soils of the main stage of soil formation were represented by phaeozems in combination with luvic cambisols. For this stage, the following climatic parameters (average values) have been reconstructed based on soil types: $t_1 = 0^{\circ}\text{C}$, $t_7 = +23^{\circ}\text{C}$, $t_{yr} = +12^{\circ}\text{C}$, $P_{yr} = 800\text{--}900$ mm.

During the main phase of the Inzhavino epoch of soil formation, corresponding to the Likhvin (Holstein) interglacial, pedogenesis occurred under conditions of the subboreal forest zone. The forest soils that had a genetically differentiated profile of eluvial-illuvial type, with traces of surface gleyization, were widespread (luvic cambisols, with participation of stagnic

Modern soil type analogs: I – gelic gleysols, gelic podzoluvisols; II – chernozem-like sols of cold steppe and forest steppe; III – luvisols; IV – luvisols with participation cambisols; V–VI – cambisols with participation of luvisols and stagnic podzoluvisols; VII – phaeozems with participation of cambisols. Area of distribution of modern soil type analogs: 1 – upstream basin of Lena river; 2, 5, 7, 9 – intermountain depressions of Central Altay; 3 – northern part of West and Central Europe; 4 – North of western Siberia; 6 – upstream basin of Visla river; 8 – upstream basins of Rhine and Danube rivers; 10 – intermountain depression of Danube midstream.

podzoluvisols). The modern analogs of these fossil soils are now widespread in West Europe, in the upper reaches of the Rhine and Danube rivers. The reconstructed climatic parameters for the Likhvin interglacial based on the paleopedologic data are: $t_1 = 0^\circ\text{C}$, $t_7 = +21^\circ\text{C}$, $t_{yr} = 10^\circ\text{C}$, $P_{yr} = -700$ to 750 mm.

During the main phase of the Kamenka (Demnitz) interglacial period of soil formation, the forest soils dominated. These soils can be attributed to luvisols and cambisols. Similar forest soils are now widespread in West Europe and in the south of central Europe, in particular, in the upper reaches of the Vistula River. For the Kamenka interglacial, the following climatic parameters are reconstructed: $t_1 = -1^\circ\text{C}$, $t_7 = +21^\circ\text{C}$, $t_{yr} = +9^\circ\text{C}$, $P_{yr} = 600$ – 700 mm.

Apparently, it is possible to consider the tundra-gley soil or gelic gleysols as a modern analog of soils of the Romny interval (Dnieper glaciation; Figure P32). The soils have a profile A1g-Cg. Near the upper contact of the Romny soil, the festoon-like cryogenic deformations are described. Their analogs can be found in similar formations of the modern active layer of permafrost in the western Yamal Peninsula. It is possible to assume that the modern analogs of the Romny interstadial paleosols lay within the limits of the West Siberian tundra. The climatic parameters of this interstadial based on paleopedologic data average: $t_1 = -26^\circ\text{C}$, $t_7 = +13^\circ\text{C}$, $t_{yr} = -6^\circ\text{C}$, $P_{yr} = 250$ – 350 mm.

At the base of the late Pleistocene loess-soil series, the polygenetic Mezin complex occurs. Its early phase (Salyn) corresponds to the Mikulino (Eemian, Sangamon) interglacial, the late phase to the Krutitsy (Brorup) interstadial. The soils of the Mikulino (Eemian) interglacial were formed in conditions corresponding to the forest zone of the subboreal belt.

They are represented by paleosols with the distinct texture-differentiated profile A-E-Bt-C. The Bt horizon is characterized by abundance of illuviation coatings, testifying to participation of inwashing processes (illuviation of clay) in the soil formation. As modern analogs of the Mikulino interglacial soils, one can consider luvisols, which comprise the present soil cover in the north of central and middle Europe. Climatic parameters of the Mikulino interglacial based on the paleopedological data are as follows: $t_1 = +1^\circ\text{C}$, $t_7 = +17^\circ\text{C}$, $t_{yr} = +9^\circ\text{C}$, $P_{yr} = 600$ – 650 mm. For this interglacial, small-scale maps of the soil cover of Europe and of the East European Plain were compiled (Figure P38).

Soils of the Krutitsy interstadial had a genetic profile A1-AB-C. The chernozem-like soils under the meadow-steppe vegetation or open larch woodlands in the intermountain depressions of Central Altai can be considered as their modern analogs. The reconstructed climatic parameters are: $t_1 = -7^\circ\text{C}$, $t_7 = +15^\circ\text{C}$, $t_{yr} = -0.5^\circ\text{C}$, $P_{yr} = 220$ – 450 mm.

It is necessary to note that the interglacial soil formation of the middle and, probably early Pleistocene, apparently included the concluding phases of interstadials of subsequent glaciations, when the soils, similar to those of the Krutitsy interstadial, were formed.

In the concluding phase of the Bryansk interstadial (correlated with the middle Valdai, Denekamp interstadial) soil formation took place under the conditions of the polar belt. The soils are identified as tundra-gley (gelic gleysols), with characteristic features of these paleosols being strong gleyzation of the entire profile (Ag-Bg-Cg), and a particular ooid aggregation. An area of modern analogs of these paleosols lies within the upper Lena River basin. The reconstructed climatic

parameters of the Bryansk interstadial (average values) are: $t_1 = -23^\circ\text{C}$, $t_7 = +13^\circ\text{C}$, $t_{yr} = -6^\circ\text{C}$, $P_{yr} = 150\text{--}250\text{ mm}$.

The peak of the late Valdai glaciation (20–18 kyBP), corresponding to the Last Glacial Maximum, was the main climatic minimum of the Cenozoic (Velichko, 1973). At this time, a vast periglacial zone stretched. Beyond the Scandinavian Ice Sheet, a considerable portion of this zone (up to 47–48%) was occupied by permafrost (Velichko, 1982). In this region, peculiar synlithogenic paleosols of pleniglacial type occurred. These were characterized by slow humus accumulation, microaggregation, and accumulation and re-distribution of secondary carbonates without their leaching. The reconstructed climatic parameters inferred from paleocryogenic structures of this time are: $t_1 = -25$ to 30°C , $t_7 = +12^\circ\text{C}$, $t_{yr} = -9^\circ\text{C}$, $P_{yr} = 250\text{--}300\text{ mm}$.

At the Pleistocene/Holocene transition, the permafrost boundary retreated to 54–55° N. Within the loess periglacial regions, thermokarst processes of the ground ice melting took place, along with formation of a specific complex of landforms – the relic cryogenic microrelief (RCM) (Velichko, 1973). RCM strongly influenced the structure of the Holocene soil cover. Within the range of the light-gray and soddy podzolic soils of the central Russian Plain, the small-contour differentiation of soils is represented by the combination of the eroded hummocky soils in place of polygonal blocks, and the meadow soils in the troughs and depressions in place of the melted out ice-veins of the Yaroslavl' cryogenic stage. The meadow soils were formed during the optimum phase of the Holocene and were preserved in the form of the relic second humus horizon in genetic profiles of modern soddy-podzolic and gray forest soils (Velichko et al., 1996).

Conclusion

During the Quaternary, abrupt changes took place in the direction and intensity of pedogenesis, corresponding to glacial-interglacial climate cycles and general trend. According to these changes, three main types of soil-formation epochs are distinguished: interglacial, interstadial, and pleniglacial (glacial). Within the macrocycles, all three types of pedogenesis occur. Due to the general trend of climate change, the soil formation process changed from subtropical type in the early phases of the Pleistocene to polar types in its final stages.

PALEOTEMPERATURES AND PROXY RECONSTRUCTIONS

Introduction

Earth's global temperature is mainly a function of energy derived from incoming solar radiation (insolation) of varying wavelengths, with a very minor energy input coming from geothermal processes. About 28% of the total incoming insolation is reflected back to space by clouds, particles and molecules in the atmosphere, about 25% is absorbed in the atmosphere by ozone, clouds and water vapor, and about 47% is absorbed at the Earth's surface. Of this 47%, about 18% is reflected to back to space, while the remainder heats the atmosphere through latent heating (conversion of water to water vapor), convection, and absorption of infrared radiation by greenhouse gases. This trapping of solar energy by the atmosphere is why the Earth's mean annual temperature is ~33°C warmer than it would be otherwise and the main reason there is concern about future global warming caused by anthropogenic greenhouse gas emissions.

Earth's temperature, however, is not stable. It is governed by many external and internal processes operating over different spatial and temporal scales. Changes in the output of energy by the Sun, in the seasonal and geographic distribution of insolation due to changes in Earth's orbital configuration (axial tilt, precession and the eccentricity of its orbit), and in physical (wind-blown dust, volcanic emissions) and chemical (radiatively-active gas concentrations) characteristics of the atmosphere, as well as tectonic processes altering the continental distribution and oceanic circulation, all serve to influence temperature. For example, the oxygen isotopic record of ocean foraminifera (Figure P39) provides a vivid picture of the progressive cooling

in climate over the past 100 million years, due mainly to the influence of long-term changes in ocean basin and continental configurations, atmospheric composition and other factors (Miller et al., 1987).

Historical and instrumental temperature records are far too short to understand these and other complex patterns of Earth's temperature variability over different timescales, or to serve as a baseline against which to evaluate current global temperature trends and human influence on climate. Therefore, one of the most actively researched topics in paleoclimatology is the reconstruction and interpretation of past atmospheric and ocean temperatures. This entry deals with general aspects of Earth's temperature history, mainly atmospheric temperature; see also *Ocean paleotemperatures* for methods of estimating oceanic temperatures.

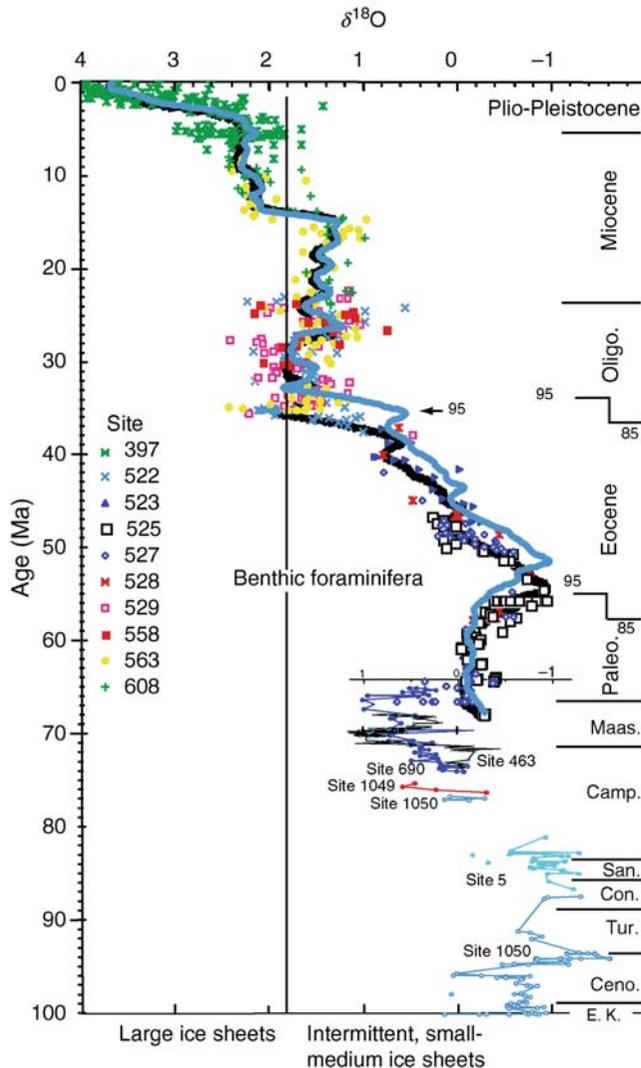

Figure P39 Progressive cooling of global climate is illustrated by changes in the isotopic composition of foraminifera from deep-sea cores. More negative $\delta^{18}\text{O}$ values characterize the Cretaceous and Eocene periods of global warmth and minimal polar ice volume; more positive values during the Oligocene through Quaternary signify gradual cooling and the build-up of polar ice caps. Modified from Miller et al. (1987); Cretaceous data from Huber et al. (2002). Courtesy of Kenneth G. Miller, Rutgers University, Brian Huber, Smithsonian Institution.

Methods of paleotemperature reconstruction

Paleoclimatologists use a wide variety of temperature “proxies” preserved in natural archives such as tree rings, ocean and lake sediments, glaciers and ice sheets (ice cores), speleothems (precipitated calcite), ancient soils (paleosols), corals and other mineralized organisms, and geological and geomorphological features to estimate past changes in temperature (Table P4). Paleotemperature reconstructions can be qualitative or quantitative, depending on the proxy method used; however, all methods carry a certain error bar due to analytical uncertainty, incomplete knowledge of processes governing organic and biogeochemical systems, and the influence of factors other than temperature. Uncertainties notwithstanding, paleotemperature estimates have improved markedly in their accuracy and reliability over the past few decades, and some of the more important applications to reconstruct past atmospheric temperatures are discussed here.

Tree rings

The study of tree rings, or dendroclimatology (Fritts, 1976; Schweingruber, 1988), relies on the influence that temperature and precipitation have on the growth of trees and is most useful in the study of climate variability over the past millennium. Tree rings consist of couplets of alternating light and dark layers of earlywood and latewood growth, respectively, forming seasonal growth patterns that vary year-to-year depending on environmental conditions, soil, the age of the tree, and other factors. Tree ring width, density (a function of several aspects of cell and wood morphology), and the isotopic (carbon, oxygen and hydrogen) composition of the wood are commonly used to reconstruct climate history especially in middle to high latitudes. Summer temperature is a particularly important influence on latewood density in boreal trees. The success of dendroclimatology hinges on careful selection of sites and trees, sophisticated statistical analyses to calibrate tree ring characteristics to climatic parameters, extensive cross-calibration of multiple trees for chronological control, and an understanding of the ecology and growth of various tree genera. For example, ring widths have been used to produce annual temperatures in northern parts of North America for the past few centuries (D'Arrigo and Jacoby, 1992). Longer temperature records are available from carbon isotopes in the case of a 2,000-year record of temperature developed from conifer trees from the western United States (Stuiver and Braziunas, 1987).

In recent years, researchers have produced extensive networks of tree ring records of temperature and other climate parameters such as sea level pressure in North America, Europe, and Asia (Briffa and Matthews, 2002; Cook et al., 2002), with more

Table P4 Summary of methods used to reconstruct atmospheric temperatures

Paleoclimate archive ^a	Proxy method for temperature	Comments and complications	Reference ^b
Ice Sheets & Glaciers (ice cores)	Oxygen and hydrogen isotopes	Changes in moisture source and seasonal precipitation	Jouzel et al. (1997); Grootes et al. (1993)
	Deuterium excess Melt layers	Summer only	Bradley (1999)
Lake Sediments and Peats	Insects (mainly beetles)		Elias and Coope (1994)
	Fossil pollen		Prentice et al. (1991), Guiot et al. (1989)
	Ostracode shell isotopic composition		Von Grafenstein et al. (1999)
	Ostracode shell trace element composition		Holmes and Chivas (2002)
Speleothems (stalagmites, stalagmites, vein calcite)	Oxygen isotopes	Temperature effects during calcite (aragonite) deposition; composition of regional precipitation	McDermott et al. (2001), Winograd et al. (1992), see text
	Tree rings (dendroclimatology)	Ring density and ring width	Usually <1,000 years; standardization due to growth (1988)
Geological & Geomorphological features	Carbon, oxygen, hydrogen isotopic composition	Precipitation and other factors important; complex hydrological and biological processes during wood growth	Briffa and Matthews (2002), Mann et al. (1999), Mann and Jones (2003)
	Paleosols (fossil soils)	Rainfall has strong influence	Retallak (1990)
<i>Other</i>	Glacial sediments	High latitudes, elevations	Washburn (1979)
	Periglacial sediments	Only near glacial margins	
Tree lines, elevation changes	Lithology & mineralogical associations	Qualitative	Parrish (1998)
	Tree lines, elevation changes	Pollen, macroflora from packrat middens	Discontinuous, mainly glacial-interglacial timescales
Tree lines, geographic changes	Pollen	Mainly used in Arctic region	Betancourt et al. (1990)
Plant macrofossils	Plant associations, leaf morphology

^bThese are either comprehensive texts on the proxy method or important applications.

limited data from the Southern Hemisphere. By combining tree ring data with other temperature proxy records (i.e., ice cores, lakes) and splicing the proxy records with instrumental records dating back to the nineteenth century, mean annual hemispheric and global temperature anomalies and climate variability can be estimated for the past 2,000 years (Mann and Jones, 2003, Figure P40). These studies provide convincing evidence that Northern Hemisphere twentieth century temperatures are among the warmest in the last 1,000 years, although the density of Southern Hemisphere sites is too sparse to make conclusions about that region. These and other studies also suggest that the interannual and decadal climate variability during the twentieth century exhibits patterns consistent with the hypothesis that anthropogenic greenhouse gases have influenced global climate. They also demonstrate the importance of integrating temperature records derived from multiple proxy indicators to achieve hemispheric and global scale atmospheric temperature reconstructions.

Ice core studies of ice sheets and glaciers

Water trapped as ice in glaciers and continental ice sheets provides a wealth of information on temperature history of high latitudes and high elevation regions because the isotopic composition of the water is heavily dependent on the atmospheric temperature at time of precipitation. Ice cores from Greenland

and Antarctica recovered paleotemperature records dating back about 110,000 and 700,000 years, respectively. Of the dozens of paleoclimate proxies recovered from ice cores, the most widely used to reconstruct past atmospheric temperatures are the oxygen ($^{18}\text{O}/^{16}\text{O}$ ratio) and hydrogen (deuterium = ^2H) isotopic composition of the ice. Due to the lower vapor pressures of water molecules containing heavy isotopes of H (D) and O (^{18}O), water condensed from vapor is preferentially enriched in heavier isotopes. At cooler temperatures, there is progressively less enrichment in condensation. The relationship between $\delta^{18}\text{O}$ of precipitation and atmospheric temperature has been expressed in a number of equations depending on geographic location and other climatic factors (Jouzel et al., 1987; Rozanski et al., 1993; Bradley, 1999).

Complications with the ^{18}O -temperature relationship arise due to changing moisture source and seasonal variability in precipitation, which can also influence the oxygen isotopic composition of the water. These processes are particularly important over longer timescales and researchers must devise means to sort them out to obtain paleotemperature curves. One approach is to exploit the relationship between differential fractionation of hydrogen and oxygen during precipitation, known as the deuterium excess, or d. During precipitation, a global relationship exists between hydrogen and oxygen expressed as $\delta\text{D} = 8 \delta^{18}\text{O} + 10$. The value + 10 represents an offset between the hydrogen and oxygen

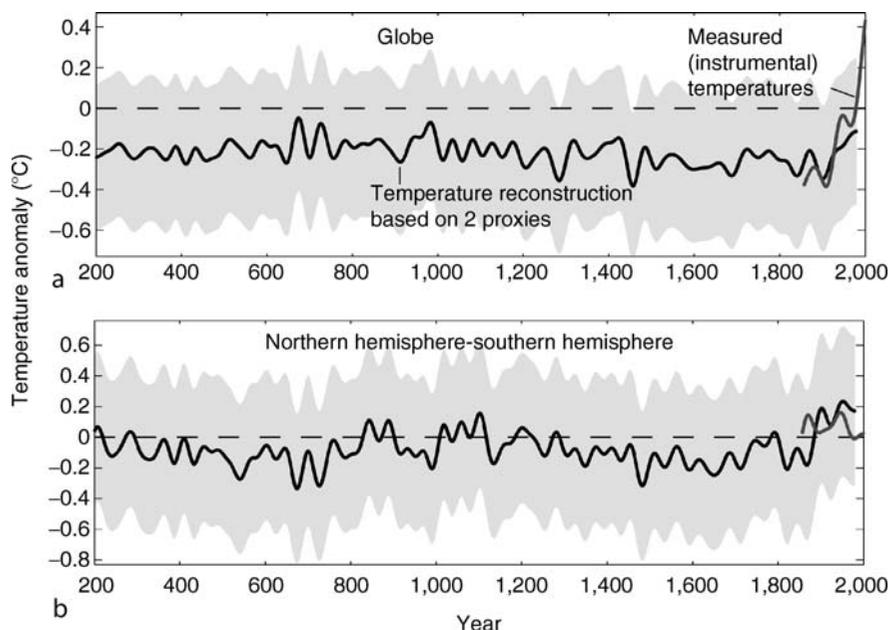

Figure P40 Reconstructed and measured global mean temperatures averaged from tree rings, polar and alpine ice cores, and lake and estuarine sediments for the last 1,800 years. (a) Reconstructed temperatures combining Northern and Southern Hemisphere records. Alternative temperature reconstructions based on different weighting methods given in Mann and Jones (2003) and references therein. (b) Hemispheric temperature difference based on same reconstructed and instrumental temperature curves. From Mann and Jones (2003); Courtesy of Michael E. Mann, Pennsylvania State University.

isotopes and is known as d . As atmospheric conditions vary over time, the value for d also changes and by measuring both $\delta^{18}\text{O}$ and δD in ice cores, a measure of d through time is obtained. The influence of kinetic processes during both evaporation and condensation, changing moisture sources and temperature of the water are complex and need to be sorted out for application of d to the study of paleotemperature.

Despite these and other complexities, some of the most important discoveries about Earth's climate history have come from oxygen and hydrogen isotopic records from Greenland, Antarctica, and low latitude alpine glaciers. At the Summit region of Greenland (mean annual temperature = -31°C), two large research projects carried out under the auspices of the European research program called GRIP (Greenland Ice Core Project), and its American counterpart, GISP II (Greenland Ice Sheet Project II), have provided excellent isotopic records of past temperature variability (Dansgaard et al., 1993; Grootes et al., 1993) that have become a standard against which all late Quaternary climate records are compared. Figure P41 depicts the GRIP oxygen isotopic record for the past 100,000 years, indicating extreme temperature-related isotopic stability during the Holocene (10,000 years to present) and the existence of more than 20 millennial-scale climatic oscillations between $\sim 100,000$ and 15,000 years ago. These events, known as Dansgaard-Oeschger events, reflect extreme climate instability during the last glacial period, and they are also recognized in the GISP II core and many paleoclimate records from around the world. Since the Greenland ice core isotopic fluctuations were first described, the interpretation of the temporal variability of the Greenland $\delta^{18}\text{O}$ -temperature relationship has been improved based on borehole calibration and other means (Cuffey et al.,

1995; Johnsen et al., 1995; Jouzel et al., 1997) and suggest a glacial to interglacial temperature difference of as much as 15°C .

Speleothems and precipitated calcite

Speleothems are rocks deposited when calcite or aragonite precipitate from groundwater, often forming stalactites and stalagmites. Vein calcite is a type of low temperature ($\sim 34^\circ\text{C}$) hydrothermal deposit precipitated from groundwater. Speleothems and vein calcite, when sampled at fine sub-millimeter-scale intervals, can yield important paleoclimate information because oxygen fractionation that occurs during deposition of the calcitic rock is dependent on surface temperature. However, precipitation of source water is itself temperature dependent and also varies due to kinetic processes, such that the interpretation of speleothem oxygen isotope records must be carried out carefully, on a case-by-case basis. For example, in an excellent centennial-scale speleothem record from Ireland, McDermott et al. (2001) were able to detect rapid climate shifts in the regional climate, which they attributed to both the effects of temperature and changes in water vapor sources.

In a series of studies of vein calcite at Devils Hole (DH), Nevada, Winograd, Landwehr and colleagues (Winograd et al., 1992, 1997; Landwehr et al., 1997; Landwehr and Winograd, 2001) provided an important, but controversial late Quaternary paleotemperature record reflecting mainly eastern Pacific sea surface and western United States atmospheric temperatures (Figure P42). The DH record is unique because, in contrast to marine records covering the past 400,000 years, DH is directly dated by the uranium-series methods, and thus yielded a test of the Milankovitch theory of climate (see *Astronomical theory of climate change*). The DH temperature record shows remarkable

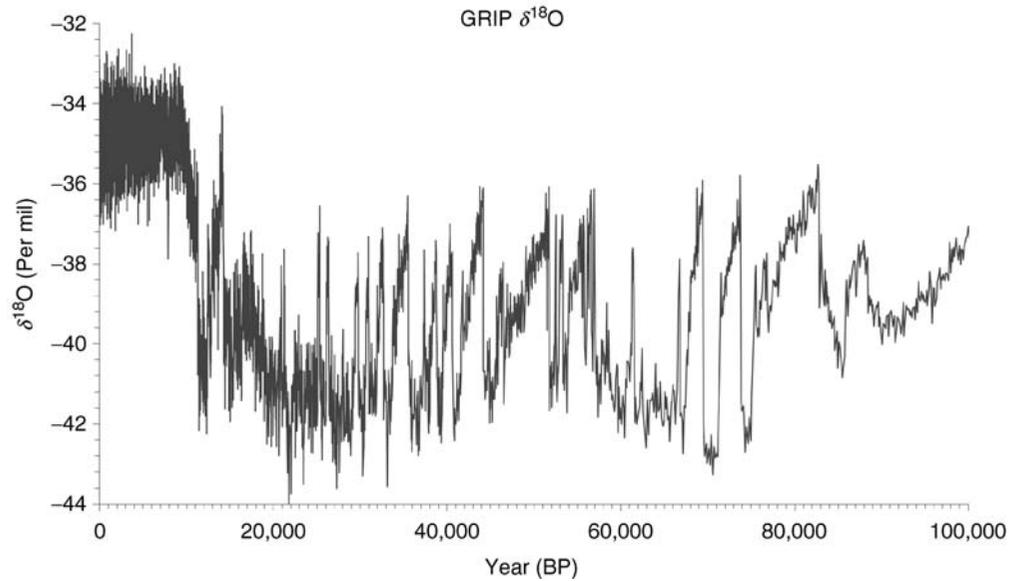

Figure P41 Isotopic record from the GRIP ice core, Summit, Greenland for the past 100,000 years. Oxygen isotopes are 55 cm averages in parts per mil. Isotopic excursions between 90,000 and 15,000 yBP represent Dansgaard-Oeschger millennial climate events when rapid atmospheric warming and cooling occurred over Greenland and many other parts of the world. Isotopic data from Dansgaard et al. (1993), GRIP Project members (1993), obtained from World Data Center for Paleoclimatology.

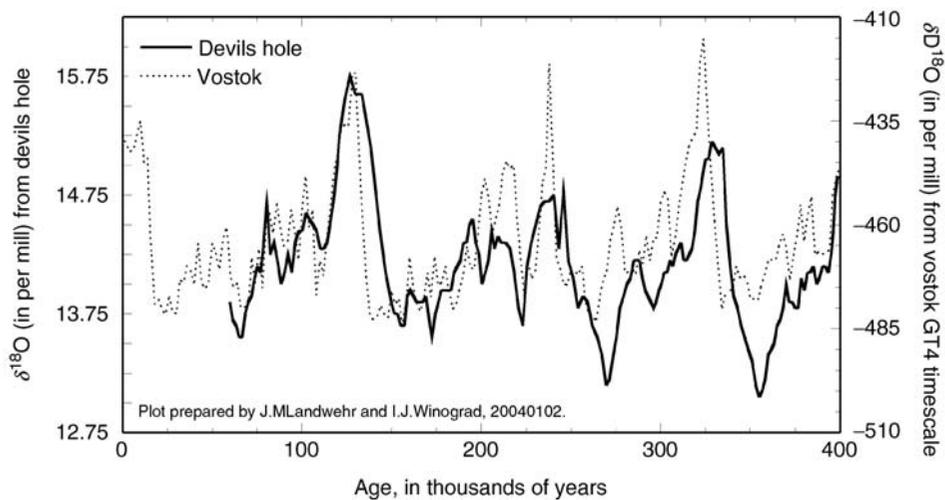

Figure P42 The Devils Hole, Nevada, core DH-11 vein calcite oxygen-18 and the Vostok, Antarctica, ice core deuterium time series for the past 400,000 years. These sites are separated by 114 degrees of latitude: the Devils Hole record reflects northeast Pacific sea surface temperatures and the Vostok deuterium record reflects East Antarctic regional temperatures. The Devils Hole data are from Landwehr et al. (1997); detailed discussions of these time series appears in Landwehr and Winograd (2001), Winograd et al. (1992, 1997) and Petit et al. (1999).

similarities to many other climate records in its clear pattern of 100,000-year eccentricity cycles. For example, Figure P42 compares the DH isotope record to the deuterium records from the Vostok, Antarctica, ice core (Petit et al., 1999). Controversy has arisen, however, because the Devils Hole record indicates that climate warming at the inception of the last interglacial period began about 135,000 years ago, about 8,000–10,000 years earlier than predicted by the Milankovitch theory of climate. This early age for the penultimate interglacial remains an unresolved challenge to the Milankovitch theory.

Lake records of temperature

Several floral, faunal and geochemical proxies have been used to reconstruct atmospheric temperatures from lake sediment cores. Fossil pollen assemblages are commonly used to infer past temperatures (and precipitation) using a variety of quantitative statistical techniques. The modern analog technique (MAT) compares fossil assemblages to a large modern pollen database linked to winter and summer climate parameters. Except during time of rapid climate change, when forest and pollen assemblages

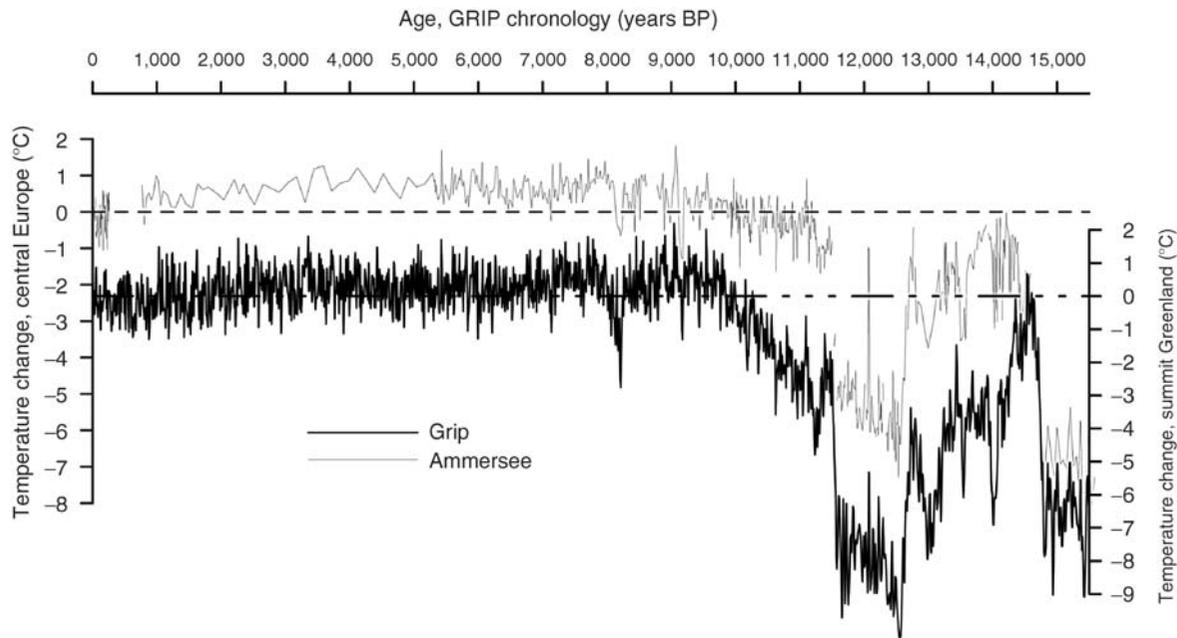

Figure P43 Comparison of temperature changes at Summit, Greenland GRIP ice core reconstructed from oxygen isotopes (*thick line, bottom*) and central European temperatures reconstructed from ostracode oxygen isotopes from Ammersee (*thin line, top*). Modified from Von Grafenstein et al. (1999), GRIP record of Dansgaard et al. (1993); Courtesy of U. Von Grafenstein, Laboratoire des Sciences du Climat et de l'Environnement, Commissariat à l'Énergie Atomique and Centre National de Recherche Scientifique, Gif-sur-Yvette, France.

sometimes had no modern analogs, the MAT method has provided excellent temperature history for North America during the past 15,000 years (Prentice et al., 1991). In Europe, using a slightly different statistical approach to fossil pollen, Guiot et al. (1989) reconstructed a 140,000-year long temperature record from La Grande Pile and Les Echets in France. These studies show that mean annual temperature in France varied from as low as -12 to -13°C during peak glacial conditions, to $+2$ to 4°C during the Eemian interglacial compared to today.

Geochemical methods applied to fossil lacustrine ostracodes recovered from lake cores also provide quantitative estimates of aquatic and atmospheric temperatures (Curtis and Hodell, 1993; Holmes and Chivas, 2002). Von Grafenstein et al. (1999) applied the relationship between mid-European oxygen isotopic composition of precipitation and atmospheric temperatures to reconstruct a 15,500-year temperature record from the $\delta^{18}\text{O}$ of fossil ostracodes from Lake Ammersee, Germany (Figure P43). This decadal resolution achieved at Ammersee allowed the researchers to correlate fine-scale European temperature changes during the deglacial period with the record from Greenland.

Other methods

A wide variety of methods have used qualitative (i.e., relatively warm, cool) and semi-quantitative (i.e., $< 4^{\circ}\text{C}$, between 15 and 20°C) interpretations of paleotemperature from the geological record (Table P4; see Frakes et al., 1992; Parrish, 1998; Bradley, 1999). These approaches rely on expert interpretation of glacial and periglacial sediments and geomorphological features, lithologic types (i.e., gypsum, peat) and paleogeographic distribution, fossil plant associations and morphologies (leaf shape), ancient soils (paleosols), ancient snowline and treeline positions, among others. As is the case with more quantitative

methods, some of these indicators are influenced as much by precipitation and other climatic factors as they are by temperature. Even when firm estimates of temperature can be obtained, for example, in the case of fossil insects (Coope, 1994; Elias and Coope, 1994), many of these records are temporally and spatially discontinuous, making it difficult to achieve interregional paleotemperature correlations and to infer causal factors. Nonetheless, for many regions of the world, these methods provide a rich and valuable literature providing local and regional information on mean annual or seasonal temperature conditions for many periods in the geological past.

PALEOTEMPESTOLOGY, THE SEDIMENTARY RECORD OF INTENSE HURRICANES

Introduction

Intense storms can modify landforms, and in appropriate depositional settings a geologic record can be preserved (e.g., Liu and Fearn, 2000; Donnelly et al., 2001a, b). Due to the relatively short period of reliable instrumental and historic records, little is known about past intense hurricane landfalls and tropical cyclone activity in general, and the processes that govern the formation, intensity, and track of tropical cyclones are poorly understood (Goldenberg et al., 2001). Reliable records of Atlantic tropical cyclones maintained by the National Oceanic and Atmospheric Administration (NOAA) only extend back to the mid-nineteenth century. An often incomplete historical record of North Atlantic hurricanes dates back several hundred years.

Given the potential for changes in the intensity and frequency of storms due to anthropogenic warming of the global

climate system, decision makers, scientists and the general public have become increasingly concerned about potential risks to coastal populations. Gaining an understanding of how changes in hurricane activity may link to changes in climate is important in order to forecast future changes and possibly mitigate socio-economic impacts. Potential connections between the frequency and intensity of hurricanes and changes in the Earth's climate system can be examined if long-term records of hurricane activity can be developed.

Hurricanes and climate

Some studies have suggested that the intensity and frequency of hurricanes may increase in a warmer climate. In a case study from the western Pacific, model results suggest a 5–12% increase in hurricane intensity with a 2.2 °C increase in sea-surface temperatures (SSTs) (Knutson et al., 1998). Globally SSTs increased by 0.31 °C in the last half of the twentieth century, possibly as a result of anthropogenic greenhouse gas emissions (Levitus et al., 2001). Goldenberg et al. (2001) attribute the recent increase in North Atlantic hurricane activity to increasing SSTs and lower amounts of vertical wind shear. Long-term records of SSTs derived from oxygen isotope data (e.g., Keigwin, 1996) and faunal data (deMenocal et al., 2000) document centennial- to millennial-scale fluctuations in SST in the North Atlantic. These records indicate that SSTs were as much as 1 °C greater than present during the Medieval Warm Period about 1,500–900 years ago and again for a brief interval, interrupting the Little Ice Age, about 500–600 years ago.

Recently numerous researchers have postulated links between changing modes of interannual climate variability, like El Niño-Southern Oscillation (ENSO) and the North Atlantic Oscillation (NAO), and patterns of tropical cyclone activity. Studies relying on recent climatology indicate that North Atlantic hurricane activity is greater during strong La Niña years and suppressed during strong El Niño years (Bove et al., 1998). In strong El Niño years, increased vertical wind shear associated with a strengthening of the subtropical jet over the tropical North Atlantic hinders tropical cyclone development. Several reconstructions of past ENSO variability have been published in recent years. For example, Moy et al. (2002) reconstructed a 12,000-year sedimentary record of ENSO variability from southern Ecuador. Significant millennial and sub-millennial scale ENSO variability is evident in this record. Warm ENSO (El Niño) events became more frequent in the Holocene. Approximately 1,200 years ago, a trend of decreasing frequency of warm ENSO events began. Several intervals in the last 2,000 years had notably few warm ENSO events. Given that warm ENSO phases are thought to diminish North Atlantic tropical cyclone activity, including intense hurricanes, more North Atlantic hurricanes may have occurred in intervals with relatively few warm ENSO events.

Elsner et al. (2000a) propose a possible link between a weak NAO and increased intense hurricanes in the North Atlantic, possibly related to the strength of the trade winds. Using sandy washovers preserved in a coastal lake from the Florida Panhandle, Liu and Fearn (2000) inferred two intervals of intense hurricane activity in the Gulf of Mexico from present day to 1,000 and 3,400–5,000 years ago. They suggest that this millennial-scale variability may be associated with changes in the position of the Bermuda High that may alternately focus hurricanes into the Gulf Coast and East Coast of the USA. Elsner et al. (2000b) document this kind of see-saw pattern in Atlantic hurricane tracks associated with the position of the Bermuda High and NAO intensity over the last

two centuries, where the Gulf Coast experiences more hurricane activity during a weak NAO and the U.S. East Coast experiences more activity during a strong NAO.

Storm-induced deposits

Washovers (overwash deposits) occur when wave energy combined with high water levels (storm surge) overtop or breach barrier beaches and transport nearshore and barrier sediments into the backbarrier environment. If the barrier is breached, a lobate fan will form at the terminus of the breach. If multiple breaches occur close together, these lobes may coalesce. When the entire barrier is overtopped by storm surge, sheet washovers that extend the length of the barrier are deposited. In a regime of rising sea level, low-energy estuarine deposits are typically deposited over washovers between overwash events. If these deposits are not reworked during subsequent storms, the overwash fans will be preserved as laterally continuous horizons of sand within backbarrier sediments and provide a record of past storm surge (Figure P44).

Washovers are composed of locally-derived material from the foredune, beach and nearshore environments and are typically well- to poorly-sorted, fine- to coarse sand. The mean grain-size within overwash deposits generally decreases as a function of distance from the barrier (Hennessy and Zarillo, 1987). Washovers often exhibit horizontal stratification, and if the deposit terminates in a coastal pond or lagoon they can exhibit medium- to small-scale delta foreset stratification (Schwartz, 1975). However some washovers can also lack stratification. Cores from backbarrier environments in southern Rhode Island contain washovers with little or no horizontal stratification (Donnelly et al., 2001a). In some cases post-depositional processes like ice scour and bioturbation may eradicate laminations.

Another characteristic of washovers preserved in backbarrier environments is the abrupt nature of the contact with the underlying peat or estuarine mud (Donnelly et al., 2001a, b). Evidence of soft-sediment deformation is common where a washover is deposited over saturated, fine-grained sediments (Klein, 1986). In addition, rip-up clasts are frequently encountered at the basal contact of washovers and are indicative of high-velocity currents associated with overwash deposition.

Washovers preserved in coastal sediments have provided the basis for constructing prehistoric records of intense-hurricane strikes in Alabama, Florida, Rhode Island, and New Jersey (Liu and Fearn, 2000; Donnelly et al., 2001a,b). In Alabama and Florida, sand deposited in coastal lakes provided evidence of apparent intense-hurricane strikes dating back several

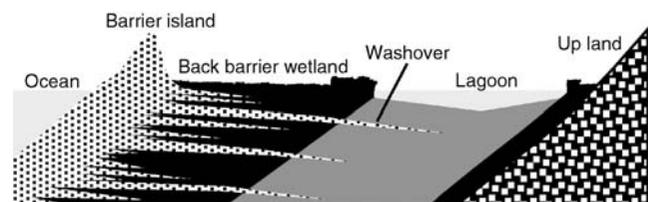

Figure P44 Cross-section of conceptual model of overwash deposition and the landward translocation of the barrier-marsh system in a regime of rising sea level. Overtopping of the barrier beach by storm surge results in washover deposition across backbarrier marshes. Washover fans are preserved as sea level increases and they are covered with marsh deposits. Vertical exaggeration = approximately 100 to 500×.

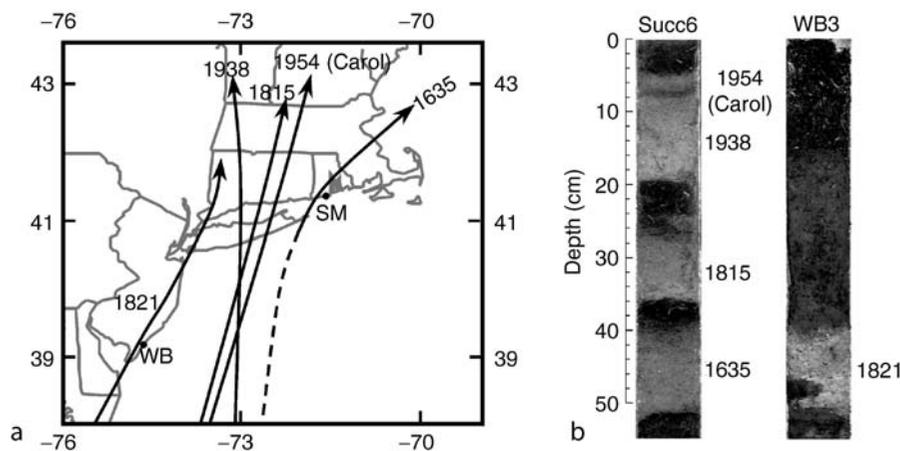

Figure P45 (a) Tracks of historic hurricanes resulting in over 3 meters of storm surge in the northeastern U.S. and the location of Succotash Marsh, RI (SM) and Whale Beach, NJ (WB). (b) Photographs of sandy washovers (light layers) interbedded with backbarrier marsh sediments (dark layers) at Succotash Marsh, RI (Succ6; Donnelly et al., 2001a) and Whale Beach, NJ (WB3; Donnelly et al., 2001b). (Note: the rip-up clast 46–50 cm in WB3).

thousand years (Liu and Fearn, 2000). Higher-resolution records obtained from backbarrier marshes in Rhode Island (Donnelly et al., 2001a) and New Jersey (Donnelly et al., 2001b) contain evidence of intense-hurricane strikes dating back approximately 700 years.

Succotash Marsh in Rhode Island contains six distinct washovers dating back to A.D. 1300 (Donnelly et al., 2001a). Four of these deposits (Figure P45) date to the historic period and the ages are consistent with known hurricane strikes (A.D. 1954, 1938, 1815, and 1635) that resulted in significant levels of storm surge (>3 m). Two additional washovers at Succotash Marsh date to A.D. 1411–1446 and A.D. 1295–1446 and were probably deposited during prehistoric hurricane strikes. At Whale Beach, NJ, a large-scale washover is attributed to an intense-hurricane strike in A.D. 1821 (Donnelly et al., 2001b). An earlier land-falling hurricane probably deposited an older, larger-scale washover at Whale Beach dated to between A.D. 1278 and 1434.

Conclusions

Faced with expectations of a potentially rapidly changing global climate system, concern has increased about potential risks to coastal communities and ecosystems from possible increased tropical cyclone activity. An improved understanding of the relationship between changes in tropical cyclone activity and changes in climate will help to anticipate future changes and possibly mitigate socio-economic impacts. Long-term records of these events can show how hurricane activity has varied in the past as the Earth's climate has changed. The relatively new field of paleotempestology is focused on extending the limited instrumental and historic records of intense storms by recovering and quantifying natural archives of storm occurrence.

Backbarrier wetlands, lagoons, and coastal ponds are often well situated to receive allocthonous sediments during intense hurricane landfalls. These normally low-energy environments are dominated by fine-grained highly organic sediments, with the exception of episodic deposition of coarser-grained mineral sediments from the beach and near-shore environment during extreme storms. Results from the northeast and Gulf coasts of the United States indicate that intense hurricane strikes produce

a distinctive sedimentary signature that can be used to reconstruct long-term records of these events.

PALYNOLOGY

Palynology is the study of microorganisms, and microscopic fragments of mega-organisms, that occur in sediments. “Palynomorph” is a broad term for a variety of acid-resistant microfossils produced by plants, animals, or Protista that have existed since the late Proterozoic (approximately one billion years ago). The oldest known palynomorphs are arcritarchs (Figure P46), which are likely marine algal bodies that appeared in the Proterozoic eon. Other palynomorphs that appeared in the Paleozoic and are frequently studied are chitinozoans (marine fossils of uncertain origin); scolecodonts (annelid worm jaws); microscopic colonial algae; embryophyte spores; megaspores; pollen (Figures P47–P51); and dinoflagellates. All of these are still present except the chitinozoans. Chitinous fungal spores are first found in Jurassic rocks, and microforaminiferal inner tests can be dated to the Lower Cretaceous (Traverse, 1988). Fragments of wood and cuticle are additional acid-resistant plant materials that may be present in palynological preparations and are frequently studied in

conjunction with palynomorphs. Palynomorphs range in size from 5 to 500 microns. Identification to the specific, generic, or higher taxonomic rank requires study with a light microscope. With few exceptions, palynomorphs are at least partly composed of sporopollenin, chitin, or pseudochitin; resistant organic molecules that survive the standard laboratory treatments with hydrofluoric and hydrochloric acids (Traverse, 1988). Thus neither siliceous microorganisms (e.g., diatoms and radiolarians), nor

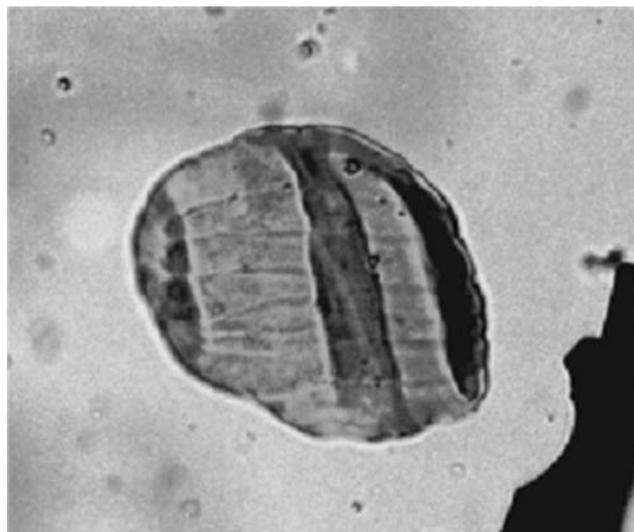

Figure P47 The pollen grain *Vittatina costabilis* Wilson, 1962, identified from 7.1 meters below the Carboniferous-Permian boundary stratotype section at Aidaralash Creek, Ural Mountains, Kazakhstan (Dunn, 2001). This grain is striate (deep parallel grooves) and slightly saccate. The palynomorph was well-established in the late Carboniferous and early Permian and has been referred to the Gnetales order by some authors, and conifers by others (Traverse, 1988). Photo courtesy of M. Dunn.

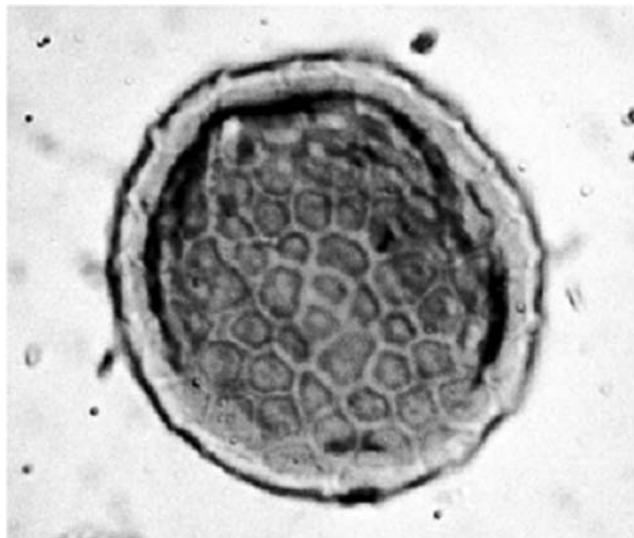

Figure P46 The arcritarchs *Inderites* spp. This example occurs 5.8 meters above the Carboniferous-Permian boundary stratotype section at Aidaralash Creek, Ural Mountains, Kazakhstan (Dunn, 2001). Photo courtesy of M. Dunn.

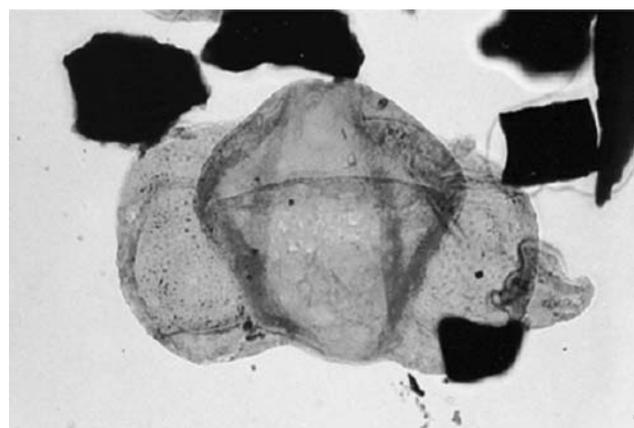

Figure P48 The pollen grain *Limitisporites monstruosus* Lyuber and Val'ts, from 7.4 meters above the Carboniferous-Permian boundary stratotype section at Aidaralash Creek, Ural Mountains, Kazakhstan (Dunn, 2001). This pollen grain has a bisaccate form. Bisaccate pollen with residual three-rayed slits (called trilete) may be intermediate forms between ancestral trilete spores and the modern bisaccate conifer pollen, which have no slits. Photo courtesy of M. Dunn.

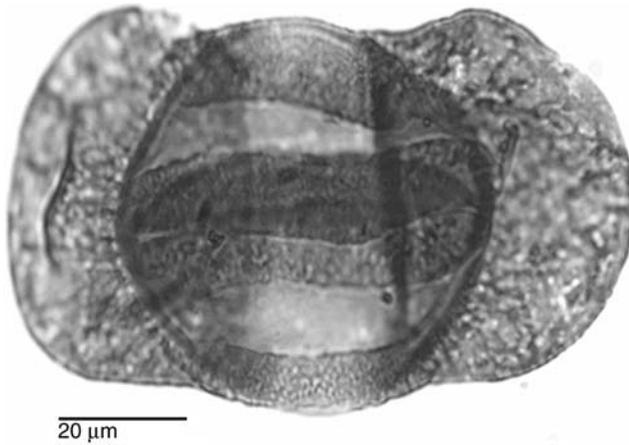

Figure P49 *Lunatisporites* sp. (Upper Permian, UK) pollen. This is a pollen grain that is bisaccate in form, with a striate sculpture consisting of parallel grooves and/or thickenings on the main body (corpus). Striate bisaccates, which appeared during the Carboniferous and flourished during the late Permian and early Triassic, were produced by coniferous and glossopterid gymnosperms, which have since vanished from the paleobotanical record. However, striate, non-saccate pollen is known from the extant gnetalean gymnosperms *Ephedra* and *Welwitschia* (Traverse, 1988). Photo courtesy of S. Fowell.

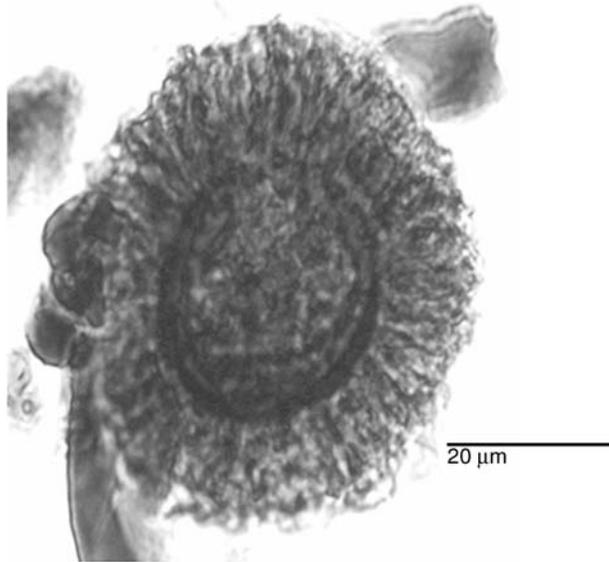

Figure P50 An example of a pollen grain, *Patinasporites densus*, Leschik, 1955 (Upper Triassic, North America), which is monosaccate in form. Monosaccate pollen appeared during the Carboniferous and proliferated during the Lower Permian. Transitional forms between monosaccate and bisaccate grains suggest that at least some bisaccate pollen types originate by modification of the monosaccate condition. *P. densus* has been recovered from Triassic conifer cones (Cornet, 1977). Abundant in Upper Triassic rocks, *P. densus* disappears at the Triassic-Jurassic boundary. Monosaccate pollen is still produced by modern conifers such as *Tsuga* (hemlock). Photo courtesy of S. Fowell.

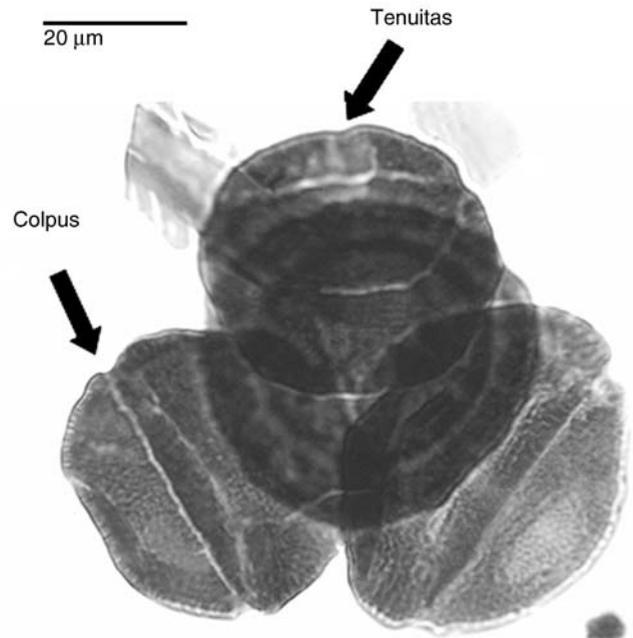

Figure P51 *Corollina torosa* (Reissinger, 1950) Klaus, 1960 emend. Cornet and Traverse, 1975 (Lower Jurassic, North America) pollen. The palynomorph is found as a tetrahedral tetrad, as shown here, or as a single grain, monad. The pore-like thinning, or tenuitas, and the encircling colpus of the *Corollina* genus are features generally associated with angiosperms. However, pollen grains of *Corollina* have been extracted from Mesozoic conifer cones of the family Cheirolepidaceae. *C. torosa* appears in the late Triassic and becomes extremely abundant in early Jurassic assemblages. In North America, the acme zone of *Corollina* spp. can be used to distinguish basal Jurassic palynofloras from those of latest Triassic age. Photos courtesy of S. Fowell.

calcareous microorganisms (e.g., foraminifera and coccolithophores) are palynomorphs.

Modern palynology addresses the morphology and biochemistry of the microorganisms, and their production and distribution within the present environment. Palynological studies are used in plant taxonomy, plant pathology, phytogeography, ecology, forensics, medicine (allergies), entomology, melissopalynology (study of honey), and archeology. An extant palynomorph's environmental preferences can help define the ecological preferences of the same (or possibly similar) palynomorph in the geological record; this is the "modern analogue" interpretive technique, which is applied to paleopalynology. Recently, some palynomorphs have been increasingly utilized for environmental monitoring (e.g., algal blooms, including the "red tide" phenomena).

Palynomorphs may be found in consolidated or unconsolidated marine and terrestrial sediments of siliclastic or carbonate composition. Fossil palynomorphs are typically studied from small samples (even 10 grams) of fine-grained sediments or sedimentary rock, such as siltstone retrieved from sediment cores, drill cores, or rock outcrops. The age of the sedimentary matrix will determine the geological age of the constituent palynomorphs.

Paleopalynology is utilized in biostratigraphy, geochronology, and in paleoenvironmental studies (Traverse, 1988). Biostratigraphy involves dating and correlation of spatially distant rock strata, based upon assemblages of palynomorphs found within the sedimentary matrix. Geochronology, or relative age dating, is based

on correlation of palynomorph taxa from a sedimentary rock of unknown age with established palynomorph reference sequences. Paleopalynology is also utilized in paleoecological studies, since many palynomorphs are indicative of specific environments. Pollen and spores in particular are sensitive indicators of terrestrial environments and thus have been used in terrestrial paleoenvironmental studies (Traverse, 1988). Palynomorphs have been used extensively in exploration geology and hydrocarbon studies, because the color of constituent pollen and spores reflects the thermal maturity of the rock. Regional studies can elucidate paleogeographic patterns, biodiversity, phylogeny, taxonomy, and ecology of the plant or animal group under examination.

The scientific issues addressed by palynological studies vary considerably, dependent on the organism and time period analyzed. In Pliocene to Holocene studies, the ecological and climatic range of the vascular plant taxa that produced the fossil pollen (or spore) is almost always considered relevant to the scientific interpretation. Thus, studies of Pliocene to Holocene fossil pollen will often have a strong ecological component. Similarly, marine dinoflagellate species are distributed according to distinct environments (e.g., temperature, salinity, nutrients). Thus a paleoenvironment may be interpreted based upon the present-day environmental affinity of a taxon. Palynological studies of Proterozoic to middle Miocene strata are generally conducted in order to resolve biostratigraphic and geochronologic questions, to provide information regarding the past distribution of organisms, or to place broad constraints on past climatic conditions.

The application of palynomorphs to biostratigraphy is exemplified by a study of the Carboniferous-Permian boundary stratotype section at Aidaralash Creek, in the southern Ural Mountains of Kazakhstan (Dunn, 2001). The Lower Permian boundary has already been established based upon conodont biostratigraphy. Palynomorphs found in this stratotype section include abundant and diverse species of the pollen genus *Vittatina*, *Limitisporites monstruosus* pollen, and the acritarch *Inderites* (Figures P46–P48). Documentation of the palynomorph assemblages may help determine which microfossils can be correlated from the stratotype section to other palynomorph-bearing Permian sections and permits correlation with stratigraphic sections where the conodonts (other marine invertebrates) are rare or absent (Dunn, 2001). In North America, identification of *Corollina* spp. pollen grains (Figure P51) has biostratigraphic and evolutionary plant taxonomy implications. The *Corollina* pollen grains were apparently produced by conifers, yet show morphology characteristics usually unique to angiosperms (Cornet, 1977). The acme zone of *Corollina* spp. can be used to distinguish basal Jurassic palynofloras from those of latest Triassic age.

PATTERNED GROUND

Patterned ground occurs in a variety of different geographical environments, but is perhaps best developed within soils subject to regular freeze-thaw cycles. It provides a good example of self-organization within a geomorphological system (Hallet, 1990a). The term-patterned ground is used to describe a plethora of different phenomena with a variety of characteristics and sizes. On horizontal surfaces, patterned ground usually consists of isolated circles, polygonal nets, or closely spaced mounds, while on slopes it commonly occurs as either transverse steps or down-slope stripes. The most spectacular forms of pattern ground involve size sorting (Figure P52a, b). The formation of patterned ground has been the subject of considerable debate ever since earlier explorers of Arctic regions marveled at its regularity. It is now clear that there is no single mechanism to explain all examples of patterned ground, most types are polygenetic, and several different processes may result in very similar forms (Washburn, 1979). Three suites of processes are required to give the range of forms observed (Figure P53). Firstly, a sorting process (or processes) is required that can separate and concentrate particles of different sizes. Secondly, a process (or processes) is needed that can give rise to the regular patterns and spacing observed. Finally, it is clear, as one would expect, that gravity must play an important role in modifying the patterning and sorting processes on slopes. Of these three process suites, it is sorting and patterning that provides the greatest challenge and remains controversial despite considerable research (French, 1996).

It is possible to provide a size sorting mechanism by examining the behavior of a soil of mixed grain size subject to repeated freeze-thaw cycles (Mackay, 1984; French, 1996). As a soil freezes, it expands as the water within it changes phase. As the freezing front (0 °C isotherm) descends through the soil, the upper part of a large stone is likely to freeze firmly to the adjacent soil before the lower part. Subsequent ice growth and expansion will tend to raise each stone relative to the surrounding unfrozen soil beneath it. Most of this relative motion will be lost during a thaw, as the stone settles. However, the reversal is unlikely to be complete as finer particles will tend settle and work beneath the larger ones. The net result of this process after successive freeze-thaw events is the upward movement of larger stones with respect to the finer matrix. The movement of these stones will parallel the direction of maximum heat flow (Hallet, 1990b). If the freezing front descends parallel to the surface, movement will occur perpendicular to it. However, given slight heterogeneities in natural terrain due to local relief, cracks, varying soil texture, or vegetation cover, the freezing front may not be a planar surface. The consequence of this is that stones will be drawn towards certain areas on the ground surface. For example, freezing is likely to be slowest in finer grained soils, in part because they retain more moisture and hence release more latent heat upon freezing than coarser soils (Hallet, 1990b). The freezing front will therefore propagate faster in areas of coarser texture and will be lowered in these regions with respect to areas of finer texture. The heat flow vectors will therefore be directed towards areas of coarser soil, and consequently coarser particles within the soil will tend to move towards these areas during repeated freeze-thaw cycles, thereby reinforcing the textural inhomogeneities present. This provides not only a vertical but also a lateral sorting mechanism.

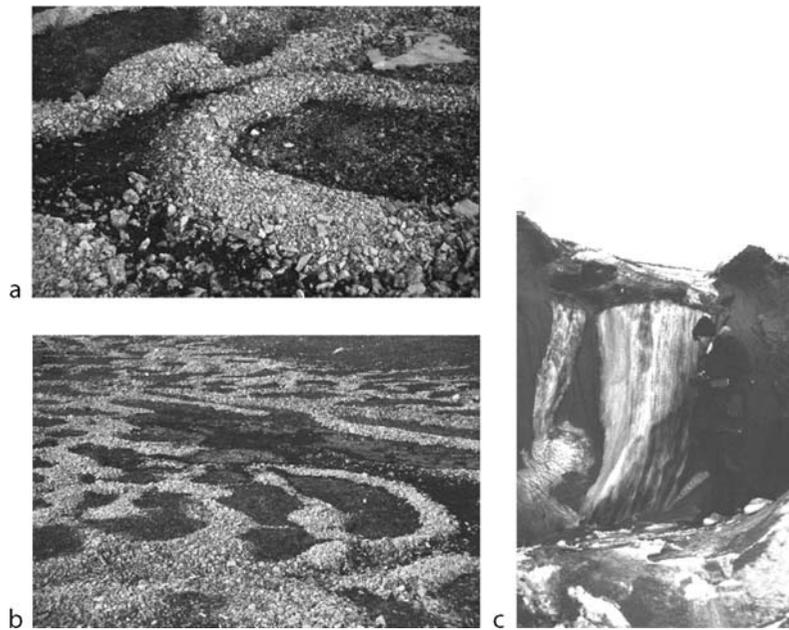

Figure P52 (a, b) Sorted circles and nets, Brøggerhalvoya (Photo: M. R. Bennett); (c) ice wedge below polygonal patterned ground, Tuktoyaktut, MWT Canada (Photo: R. I. Waller).

The next issue to consider is the range of possible patterning processes. The simplest of these processes is contraction cracking of frozen ground and the formation of polygonal nets (Washburn, 1979). These result from horizontal tension within the soil associated with a decrease in volume caused by thermal contraction, and resemble patterned ground produced in arid regions by the desiccation of surface soils. The size and configuration of the polygons depends on the rheological behavior of the soil and the nature of the volume change, which is in part determined by the climatic regime. In permafrost areas, the cracks become ice-filled and demarcated by ice wedges (Figure P52c; French, 1996). Thermal contraction does not explain all patterned ground and additional patterning processes are required. Research in recent years has concentrated on the presence of convective systems within soils subject to regular freeze-thaw cycles (Hallet, 1990b). There are two main types of convective systems. The first of these involves the movement of water through porous soils (Gleason et al., 1986; Krantz, 1990). This process operates during summer months when the temperature near the ground surface is a few degrees above 0°C , while at depth it remains at 0°C along the thaw surface. In the case of permafrozen soils, this corresponds to the top of the permafrost table. Water reaches its maximum density at 4°C and consequently the warmer surface waters are denser than the water at the thaw front, leading to a density-driven water circulation through the soil pore network. This circulation will result in the movement of heat, and therefore variations in the rate of thawing at different depths within the soil. Irregularities in the downward propagation of the thaw front may develop, producing patterns that are dictated by the size and geometry of the circulation cells. Although water movements have been observed and the theoretical geometry of the cells corresponds well with the scale of observed patterning, problems remain in understanding how this process controls the long-term formation and maintenance of patterned ground (Hallet, 1990b; French, 1996). The alternative

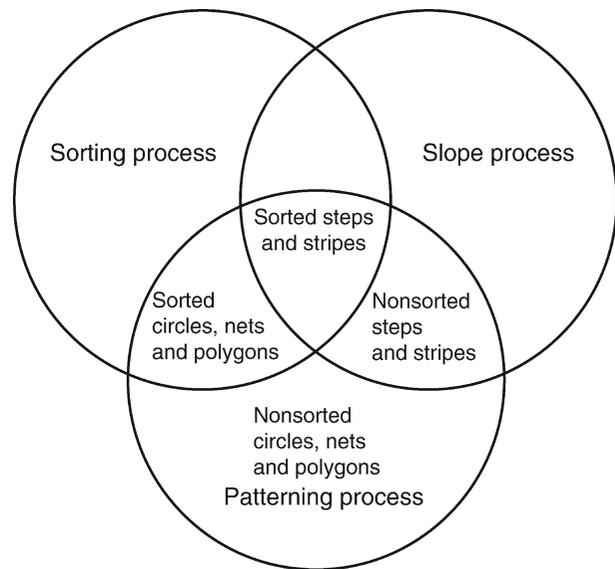

Figure P53 Processes involved in the formation of patterned ground (after Washburn, 1979, fig. 5.41, p. 160).

view involves the convective movement of soil. Again, theoretical considerations suggest that potential cell dimensions correspond well with the scale of patterned ground, and soil movement has been observed at rates of 1 cm per year, but the mechanism that drives this circulation remains elusive (Hallet et al., 1988; Washburn, 1989). Research is underway to observe and model potential convective movement of soil and water and to relate this movement to the formation and maintenance of patterned ground.

Irrespective of the lack of consensus about the formation of patterned ground, it remains one of the most spectacular examples of self-organization within a geomorphological system.

Periglacial Geomorphology

PERIGLACIAL GEOMORPHOLOGY

Definition

The periglacial system is characteristic of cold morphogenetic regions at both high latitudes and high altitudes. It is specific to cold regions, both in the vicinity of glaciers and not. In periglacial areas, ice can modify the landscape by two ways. The dominant process is through landforms associated with freezing and thawing on an annual or shorter-term basis, the *seasonal frost*. The second is through landforms associated with *permafrost* or permanently frozen ground that melts only superficially in summer. As cold climates imply cold temperatures, at least in winter, water is present during part of the year in the form of snow or of ice. As ice is needed for most of the specific mechanisms, water is the sine qua non condition of frost activity (Washburn, 1979). Frost also implies desiccation, as the vapor tension is low at temperatures below freezing. Other processes such as alluvial and eolian also act specifically in this environment. For these reasons, the present-day periglacial landscape preserves morphologies surviving from Tertiary climates. The periglacial transformation of the landscape is limited at depth.

History

The term “peri-glacial” was introduced in 1909 by W. Lozinski and has been used since the beginning of the twentieth century to describe cold Pleistocene landscapes of non-glacial origin.

Permafrost

Permafrost is a part of the subsoil that remains frozen ($T < 0^{\circ}\text{C}$) during at least two successive years. The upper part of the soil melts each summer; it is the *active layer*. The depth of the active layer is controlled by climate and moisture content, being deeper in drained terrains and shallower in poorly drained soils. The upper part of the permanently frozen ground is called the *permafrost table*. It is often rich in ice accumulation for the first 10 m of the soil in interglacial conditions, with much poorer ice accumulation during glacial events. Permafrost records the thermal deficit induced by climate, especially in summer on a long time span (10^3 years). We can distinguish:

- *Continuous permafrost*. It covers more than 80% of the topography. Mean Annual Air Temperature (MAAT) is $< -7^{\circ}\text{C}$, Mean Annual Soil Temperature (MAST) is $< -3^{\circ}\text{C}$, varying with the dynamic of the snow cover.
- *Discontinuous permafrost*. It covers less than 80% of the landscape. MAAT mostly ranges from -3 to -7°C , MAST from 0 to -3°C , controlled by the snow cover. The depth of the lower boundary of the permafrost ranges from 20 m to about 60 m.
- *Sporadic permafrost*. Patchy permafrost located only in peat bogs or on north-facing slopes. It covers less than 30% of the landscape. MAAT is $> -3^{\circ}\text{C}$, MAST is close to 0°C . The permafrost reaches a thickness of about 20–30 m.

Thermal and hydrological impacts of permafrost on the substratum

The permafrost table creates a summer barrier for surface waters. Its lower boundary is in equilibrium with the long-term climate (10^3 years) and the local geothermal gradient. The occurrence of permafrost has an impact on the hydraulic functioning of the subsoil. Fluids migrate from the subsoil to the coldest part of this horizon, at a depth of about 10–20 m, which corresponds to that of penetration of the annual thermal fluctuations (Williams & Smith, 1989).

Present extent

At low altitudes, permafrost extends today between 57°N on the eastern sides of continents and 70°N on the western sides. Its thickness varies from 20 m in the south, reaching about 300 m in the deglaciated regions, and more than 600 m in the continental never-glaciated regions such as Siberia. The deepest record is more than 1,000 m in the Verkoyansk Mountains, in eastern Siberia.

Permafrost in polar and middle latitude regions

Antarctic permafrost is very old; it probably occurred prior to the onset of the Cenozoic glaciations (38 Ma). Arctic permafrost is a little younger, but still as old as the late Miocene (7–5 Ma). It has probably spread since 20 Ma. Its thermal inertia allowed its preservation at depth, as well as during the lower Pliocene warming, and during the warmest interglacials of the Quaternary. Its extent over geological time has been controlled at polar latitudes by the same parameters as glaciations: the massiveness of continents, orbital parameters (obliquity and precession), and eustatic lows. At middle latitudes, permafrost developed during periods with a depleted summer input in solar energy without being necessarily linked to large ice sheets. Its occurrence is a recent feature in Western Europe and temperate North America (<1 Ma) (Van Vliet and Hallégouët, 2001).

Interglacial-glacial extent of permafrost

The extent of permafrost reached an average 44° N latitude at low altitude during the Late Glacial Maximum (LGM). Its extent during the Holocene Optimum is restricted to 50° N along the east side of continents (Bering Strait) and to 65–70° N on the western sides. Its maximal extent, during the coldest episodes of the Quaternary, was not more significant than those of the LGM, due to the landmass configuration. During the Holocene Optimum, permafrost extent was restricted within the polar circle in the North. As a result of the lowering of the solar summer energy input during the second half of the Holocene, the southern re-expansion of permafrost today reaches about one-third of its LGM extent.

Thermal cracking

Thermal cracking occurs when temperature drops around 15 °C in a dozen hours, such as from 0 to –15 °C and from –15 to –30 °C (Mackay, 1990). The efficiency of the thermal contraction is controlled directly by the ice content of the ground, even in peat, because the ice retraction coefficient is much larger than that of most of the rocks or sediments. This is not specific to the permafrost environment. The crack may be shallow or many meters deep. It develops either as an isolated event or in polygonal nets with a 1–40 m mesh, even on rather steep slopes (up to 22°) (Figure P54). The net is usually pentagonal

or hexagonal in poorly-stratified material. In alluvial plains, it is often square. When weaknesses such as tension faults pre-exist, they control the development of the net. In the High Arctic today or in pleniglacial deposits, thermal cracking is located only in waterlogged sites (oasis in the cold desert).

When thermal cracking occurs in frost-susceptible grounds, *soil wedges* form by percolating soil suspension into the open fissure in spring. In gravel, when the crack opens, gravel and stones may fall into the furrow.

When permafrost exists, the crack that opens in winter is filled up by impure melt water (from snow and active layer), which is preserved in the form of refrozen ice, forming an *ice vein*. Year by year, as the thermal contraction follows pre-existing weaknesses, the accumulation of successive ice veins leads to the development of *ice wedges* from about 20 cm wide for recent forms up to 30 m for very old forms. The ice wedge develops exclusively in the upper permafrost horizons and the ice is vertically foliated.

In a very dry climatic context, eolian sand replaces most of the ice, leading to *sand wedges* with vertically laminated infill. Usually, lateral stresses deform the permafrost horizon with upturning of the adjacent strata. In the active layer, deformations are linked with the width of the ice wedge, and the rheology of the unfrozen material and its climatological history. Cryoturbation and thermal cracking may be synchronous.

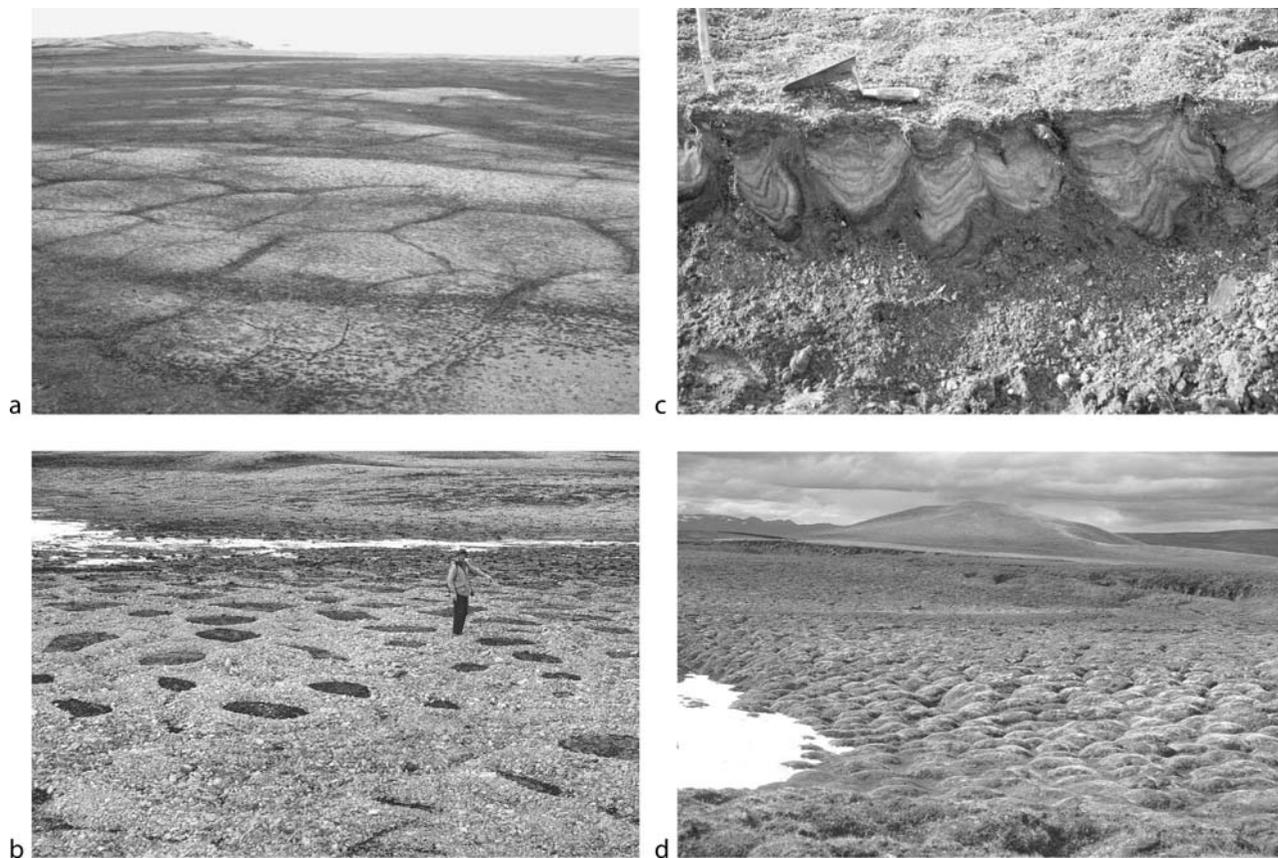

Figure P54 Examples of periglacial land forms; (a) thermal cracking, NW Svalbard, average width of polygons ~30 m; (b) patterned ground (sorted circles), NW Svalbard; (c) cryoturbation (Gåsebu, Svalbard); (d) thufur or hummocks, Northern Iceland.

These forms are further deformed by thermokarst and differential frost heave, according to the lithology and ice content of the infill when thaw occurs.

The significance of thermal cracking is limited; ice wedges reveal very short but abrupt cooling events in a continuous permafrost context. Fully vertically stratified sand wedges trace thermal cracking in dry climate with continuous permafrost (Romanovskii, 1985).

Patterned ground

These forms are the most spectacular and beautiful of the periglacial landscape (Figure P54).

Ground ice and differential frost heave

Frost may be considered as a peculiar type of thermally induced desiccation. This means that most of the cryogenic (micro) fabrics may be linked to shrinkage related to desiccation induced by low vapor tension and crystallization, *frost heave* pressure or frost induced swelling, and gravitational movements during thaw consolidation (sliding or setting). This heave is due to ice segregating in the soil as lenses and reticulated crystallizations.

Ice can nucleate at the surface of a wet soil during quick cooling and form pipekrake or *needle ice*, which lifts stones, or at depth in desiccation fissures or nets, segregating *ice lenses* or *reticulate ice*. Ice segregations cut the sediment in aggregates and generate the *cryogenic fabric*.

Frost heave is controlled by: (a) a moisture content that is optimal at the field capacity and the maximal water retention in drained conditions, (b) a thermal gradient leading to a coldward water suction, and (c) the particle size distribution (hydraulic conductivity) of the sediments. Local differences in temperature, porosity, specific surface of the mineral/organic matter fraction in connection with the particle size, and vegetation cover lead to *differential frost heaving*. Soil horizons with low water retention freeze first and those richer in fine particles freeze later because of their higher water retention. They heave more intensely because of a longer and a more efficient suction driving migration of capillary water to the growing ice segregation. Soils that easily develop a high content in segregated ice are called *frost susceptible*. Very small differences in water retention or permeability can lead to differential frost heave and *frost susceptibility gradients* (Van Vliet, 1998). Deformations known as *cryoturbations* develop by differential heave where sediments are stratified or translocated. An upward or downward *gradient of frost susceptibility* controls the geometry of the deformations. A regular network of fissures (thermal or desiccation net) assists the cryoturbation. Deformations develop both in waterlogged and drained sites. These are noticeable on flat land surfaces as well as on slopes, irrespective of density gradients. Deformations evolve in morphology along a topographic catena; the deformation morphology and its evolution with ageing will be ruled by the drainage quality and its evolution with time.

Desiccation cracking, pattern ground and hummocks

Because of the ice segregation process, all the soils are wetter on the surface from the onset of thaw. Every year, by late fall, the active layer or the seasonally frozen ground starts freezing both from the soil surface and from the permafrost table. The following spring, the soil drains progressively from the onset of thaw, leading to shrinkage pattern expression. In more

or less frost-susceptible material, desiccation cracks develop further with drainage, creating small polygonal forms up to 1 m in diameter. Frost fissures or desiccation fissures are the most common features associated with downward bending of the stratification. These fissures are at the starting point for most periglacial deformations.

Polygonal forms evolve from flat microtopography in waterlogged sites to hummocky or raised small mounds in drained conditions (Tedrow, 1977). Mounds vary from purely mineral to holorganic. They can be associated with cryoturbation, with stone jacking, and with solifluction. In this case, the material is stretched and forms sorted stripes.

Polygonal forms do not necessarily imply permafrost. Nevertheless, permafrost induces a high water table and enhances frost heave and frost jacking of stones. Polygons and hummocks develop during a cooling event such as a Heinrich event. Further warming, by enhancing the drainage, favors raised hummocky forms, leading sometimes to pseudo-convective forms.

Cryoturbation induces deformation similar to gilgai, produced by differential swelling by hydration. Cryoturbations are often confused with loading or explained by "thermal convection" not compatible with the hydrothermal regime of permafrost soils. This is related to the high frequency of cryoturbations in the same regions as tremors during the onset of deglaciations.

Stone jacking

Frost jacking is the traction of stone towards the soil surface by frost heave. This process is very fast and leads to vertically oriented stones and to loose gravel accumulation at the soil surface. This process is assisted by *needle ice*, which allows displacement of the lifted stones downslope. When the soil develops a polygonal pattern of various sizes, stones are accumulated in the furrow at the top of the fissure: the form becomes *sorted*. Similarly, if the fissure reaches a level of frost-shattered rocks at depth, differential frost heave leads to an upward migration of stones. Both processes generate *sorted polygons*. When frost susceptible material rises to the surface and pushes the superficial gravel laterally, it forms *sorted circles*. The morphological shaping induced by drainage is also valid in this case, with low and raised forms. When the stone circles are deformed by frost creep on slopes, they evolve into sorted stripes. These forms do not necessarily imply permafrost. Their climatic signature is similar to that of the normal patterned grounds.

Slope deformation

Periglacial solifluction is mass movement controlled by soil creep, which results from a combination of thaw settlement and sliding on slopes under gravity; it is directly related to the content of ice and to the water supply during thaw. It is at least ten times more efficient than common soil creep (thermo-hydric creep) (Figure P55).

Permafrost creep and rock glacier

Soils rich in segregated ice, or regolith rich in ice, flow down at a very low annual rate in relation to the ice plasticity, just as in glaciers. The origin of the ice may be segregated, refrozen meteoric water, or buried snow or ice. Scree and rock falls present a glacier-like mobility when ice-saturated. The rock glacier is a peculiar type, intermediate between a mobile scree and a decaying glacier.

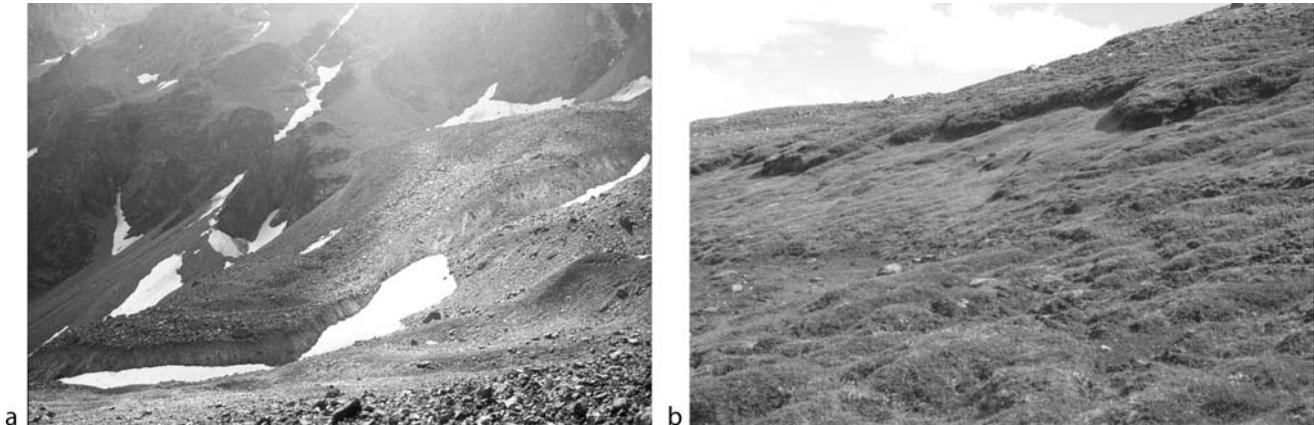

Figure P55 Examples of slope deformation in a periglacial environment; (a) rock glacier (Chambeyron, French Alps); (b) solifluction lobes (Northeast Iceland).

Mobile screes and rock glaciers are representative of dry, precipitation-starved environments, usually in discontinuous to continuous permafrost zones. They usually develop during cooling events, following a deglaciation.

Frost creep, gelifluction, and mud flow

Specific versions of solifluction in periglacial system are enhanced by soil freezing. *Frost creep* is a slow laminar flow of about 1cm per freezing cycle. In soil that is frost heaved orthogonally to the slope, frost creep develops from the onset of thaw, starting on very low angle slopes ($2-22^\circ$). The displacement is the summation of a gravity collapse by thaw consolidation, of a lateral sliding on the roof of the successive sheets of ice lenses, and of shrinking that results from drainage. The more abundant that water is during thaw, the more important the sliding component is. Below a snow patch or in a down slope position, this is fulfilled by oblique seepage. This process is common in deep seasonal frozen soils as well as in the active layer of permafrost (Harris, 1988). Frost creep is syngenetic with frost jacking, cryoturbation, and particle translocation.

Gelifluction is an accelerated form, characterized by a turbulent flow on a centimeter scale even if the total mass flows in a laminar mode. It is linked with more abundant seepage, and is more frequent on permafrost. The permafrost table restricts the water flow to the active layer only. In that case, the cryogenic fabric is stable and the form is drained when thaw proceeds: oversaturation is never reached.

When the cryogenic fabric is unstable, it collapses at thaw and the excess water cannot be evacuated: oversaturation is raised, leading to hydrostatic instability and *mud flow*. This is also common in *thermokarst* conditions.

Common deformations are terminal curvature of beds and solifluction deforming by buckling and stretching the strata, sometimes with syngenetic cryoturbation (permafrost). They are usually shallow (<1 m max) and tend to diminish and vanish with depth. Deformations and clast alignments are related to ice content and moisture supplied during thaw: flat lying clasts with their long axes oriented down slope indicate excess moisture from snow melt; vertical clasts indicate dominant frost heave. The morphology is commonly lobbed or elongated parallel to the slope. It occurs in pure mineral soils as well as in organic material. Vegetation, as shrubs or grassy mats, and

frost-jacked gravel accumulations may support the fronts of some features, leading to terraces or lobate morphology.

Frost creep has no specific climatic association as only frost is needed. It occurs from subtropical to high latitude or altitude, and on permafrost as well as in seasonally frozen ground. The presence of permafrost is indicated by a regionally higher frequency of gelifluction.

Frost shattering

Frost shattering is controlled by the porosity of the rock, especially the closed porosity and the pre-existing fissility. It can result from three mechanisms: the change of the pore water volume by freezing, acting like a wedge; induced hydrofracturation of the rock or water expulsion; and ice growth by segregation in fissures when some accumulated debris or organic matter (in situ or by translocation) induces water retention – mechanisms are similar to those in soil. The efficiency of the shattering is linked with the rapidity of frost, allowing trapping of water into the porosity and a sudden rise in pressure.

In the field, paleo-weathering or hydrothermal activity, tectonism, and previous thermal and hydric (dilation) shattering commonly enhance frost shattering. Frost shattering fragments the rock into blocks, flakes, shards, and particles, down to sandy or loamy size following the lithology. The sorting is normally poor except for some isograined lithologies (Lautridou and Ozouf, 1982). In situ frost shattering and cliff frost shattering produce screes, stratified slope deposits (“grèzes litées,” “heads”), and debris flows. Snow patches may locally enhance the frost shattering and permit the formation of nivation *benches* or *terraces*. Salt can emphasize the process, by lowering the freezing point. This is common on the coast. Along lakes or seashore, frost shattering, associated with the action of drift ice, facilitates the formation of *abrasion surfaces* and *littoral notches*. Normally, frost shattering is associated with moisture and the speed of frost penetration. It is inactivated within permafrost as in frozen caves. Climatic significance is thus limited.

Thermokarst

When the ground contains an excess of ice (ground ice, injected ice, or buried ice of various origins), thawing leads to subsidence, which results in sink-holes or retrogressive sliding. Simple subsidence of 8–25 m of an important portion of

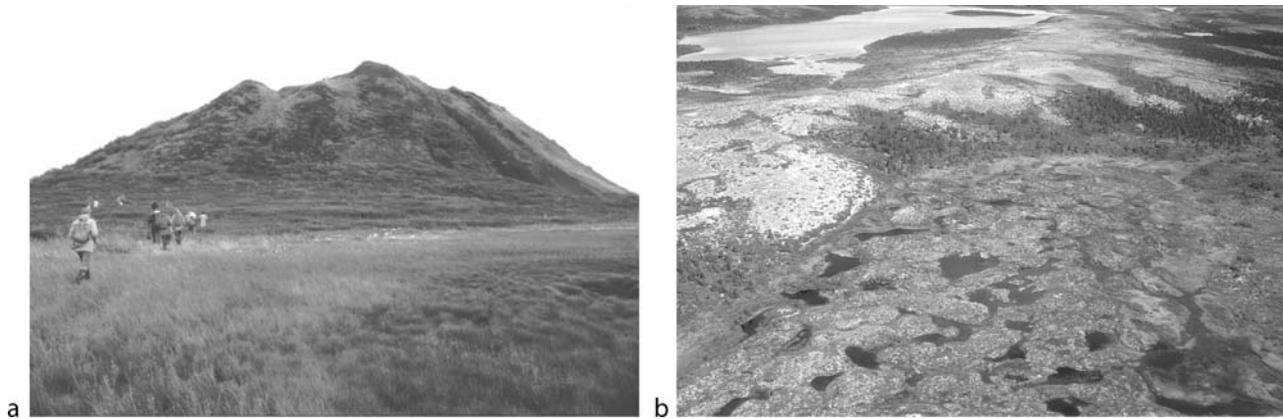

Figure P56 Examples of periglacial mounds; (a) Pingo (Mackenzie delta, Canada); (b) Palsa field (Ungava, Canada).

the ground allows the formation of *sink-holes*, often associated with *normal faulting*. The hollows are commonly occupied by a circular lake, which is further extended by the undercutting of waves. It results in a landscape of *oriented lakes*. In the presence of a polygonal network of ice wedges, thermokarst activity develops firstly polygonal furrows occupied by water and later, when drained, a specific hilly morphology called “*bad-jarak*” by the Russian authors (Solovyev, 1973). As the drainage is modified, melting progresses retrogressively upwards. On a slope, a modification of the thaw depth and drainage may induce the thawing of the ice-rich upper horizon of the permafrost, allowing downward collapse and slumping of water-saturated sediments. Mud flows can be generated. As the drainage is modified, melting progresses *retrogressively upwards* with *slumps* (MacRoberts, 1978). This process may lead to a cyclic landscape rejuvenation, as in the high Arctic.

Thermokarst is generated by various disturbances: (a) by warming, such as during the late glacial and the early Holocene; (b) by fire modifying the local energy budget, by destroying the vegetation cover; (c) by river incision, which alters the drainage and allows a deeper thaw; and (d) by anthropogenic perturbations or global warming, which like fire can modify the energy budget (Burn, 1997).

Periglacial mounds

Two main types exist: the pingo and the palsa. The fossil traces are similar except for size and some specific details (Figure P56).

Pingo

These are the largest forms, often more than 50 m in diameter (they can be several hundred meters in diameter) and up to 60 m high. They generally occur isolated. They are specifically linked to the growth of a hydrolaccolith (injected massive ice), to permafrost aggradation squeezing a water table in a former lacustrine depression, or to lateral seepage from a slope talik or unfrozen volume in the permafrost. This form lifts up sediments until the pressure of the water balances the overburden pressure. Tension fissures may open at its top. The basal layer is porous or fractured, allowing water circulation.

During the growth and the decay phases, solifluction develops on the sides. After the melting, a circular lake remains in a sink-hole surrounded by a rather high, residual circular rim. Upturned layers dipping towards the outer part of the structure exist in the rim and at depth, with a “cone-in-cone”

collapsed structure (thermokarst) (De Gans, 1988). Lacustrine deposition and peat formation occur in the lake. These mounds are specific to a continuous permafrost environment and indicative of a cooling trend during the end of an interstadial or an interglacial.

Palsa

These forms range from rather small sizes (1–5 m high) up to rather large forms, reaching up to 15 m high and 50 m wide. They develop in waterlogged depressions (mire) by segregation of ice in peat or sediments, usually when the wind drift in winter reduces the thermal insulation by the snow cover (Seppälä, 1988). The surficial layer is desiccated when uplifted, and acts as a thermal insulation in summer. Some palsas are purely mineral soils. The mounds occur in clusters, often forming oriented plateaus, sometimes affected by thermal cracking. The ice segregation is reticulated in lacustrine or glacio-marine deposits, or forms ice lenses in sectors affected by impeded drainage connected with climate cooling.

During the growth and decay phase, solifluction develops on the sides. The decay is not necessarily linked to a warming: the drainage of the peat allows its fracturing and warmth penetration, and solifluction develops on the sides, stretching the peat layer; wind abrasion may also destroy the peat cover and favor the thermokarst collapse. After the melting, a circular lake subsists in a sink-hole surrounded by a residual, circular rim. Upturned (peat) layers dipping towards the outer part of the structure exist in the rim (Pissart, 1983) with no peculiar organization at depth (thermokarst). Lacustrine deposition and peat formation occur in the thaw lake.

These mounds are specific to sporadic to discontinuous permafrost zones. Their development is specifically epigenetic during a cooling trend that follows a long, humid period such as an interstadial or an interglacial. Syngenetic forms develop in a rather stabilized climate.

PHOSPHORITE

Phosphorite (often referred to as phosphate rock) is a sedimentary rock of which the main mineralogical constituent is francolite (carbonate-fluor-apatite, CFA). The above definition excludes igneous phosphate-rich rocks as well as continental deposits (e.g., guano; a few lacustrine deposits) Whereas most sedimentary rocks contain less than 1% of P₂O₅, its content in phosphorites is above 18%, (>50% in francolite) and may reach values as high as 37%. Usually phosphorus content is expressed as P₂O₅ percentage. An alternative unit is BPL (bone phosphate of lime or tricalcium phosphate), where BPL = 2.185 × %P₂O₅.

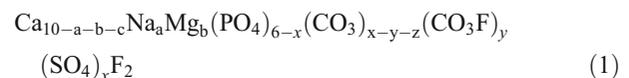

Since antiquity have farmers applied lime-treated bones to soil as a means of improving soil fertility. However it was only in the mid 19th century that J. von Liebig suggested the use of phosphorite as a fertilizer, and J. Lawes (1842) invented the dissolution of phosphorite in sulfuric acid to produce a more soluble and efficient fertilizer. The study of phosphorites received much attention beginning with the late thirties of the 20th century, when the demand for fertilizers increased dramatically. Research boomed after WW II, and the last decades of the previous century saw several comprehensive reviews of the subject in the literature (Cook, 1976; Bentor, 1980; Kolodny, 1981; Sheldon, 1980; Notholt and Jarvis, 1990; Föllmi, 1996, Burnett and Froehlich, 1988). The three volumes of “Phosphate Deposits of the World” were the fruits of a concentrated effort of an international research program (IGCP156) between 1977 and 1984 (Cook and Shergold, 1986; Notholt et al. 1989; Burnett and Riggs, 1990). The three multi-authored volumes are a comprehensive summary of all important phosphorite deposits of the world.

Distribution

Phosphorites are found in marine deposits of all ages, from the Proterozoic to the Recent seafloor (Burnett and Riggs, 1990, Cook and Shergold., 1986, Notholt et al., 1989, [Figures P57, P57](#)). Phosphorites have been found on all continents except Antarctica. Cook and McElhinny (1979) ([Figure P57](#)) have shown that the distribution of phosphorites in the record is uneven: “phosphate giants” dominate geological history with peaks in the Cambrian, Permian, and Mio-Pliocene. The young and Recent phosphorites on the shelves around America, the western coast of Africa, and surrounding Australia ([Figure P58](#)) were the object of intensive study since their discovery by Murray and Renard in 1891, especially since the identification of localities of present phosphogenesis by Baturin in 1971 (Baturin, 1981). The most common lithological association is that of phosphorites with cherts and black shales (reflecting the geochemical nutrient trinity of P-Si-C). This is the association typical of many phosphorite “giants” such as the Permian Phosphoria Formation of the western United States, the Cretaceous-Eocene phosphorites of the southern Tethys, and the Karatau (Kazakhstan) and Khubsugul (Mongolia) Cambrian deposits. In contrast to this “West Coast” type association, an assemblage of phosphorites with carbonates and siliciclastic rocks has been described from the Neogene of the East Coast of the US. Surface weathering of primary marine phosphates may result in residual type deposits such as the Holocene brown-rock weathering products of Ordovician phosphatic limestones in Tennessee. Various authors (e.g., Bentor, 1980) have mentioned evaporites, dolomite, Mg-rich clays (e.g., palygorskite), and glauconite as being paragenetically related to phosphorites.

Mineralogy and petrology

The chemical formula of francolite, the major phase in phosphorite, can be approximated by

where $x = y + a + 2c$, x varies from near zero to 1.5, $y = 0.4x$ on average, and $b = 0.4a$. c is the number of Ca vacancies (Nathan, 1984). The key substitution seems to be that of a planar $(\text{CO}_3)^{2-}$ triangle replacing a tetrahedral $(\text{PO}_4)^{3-}$ ion.

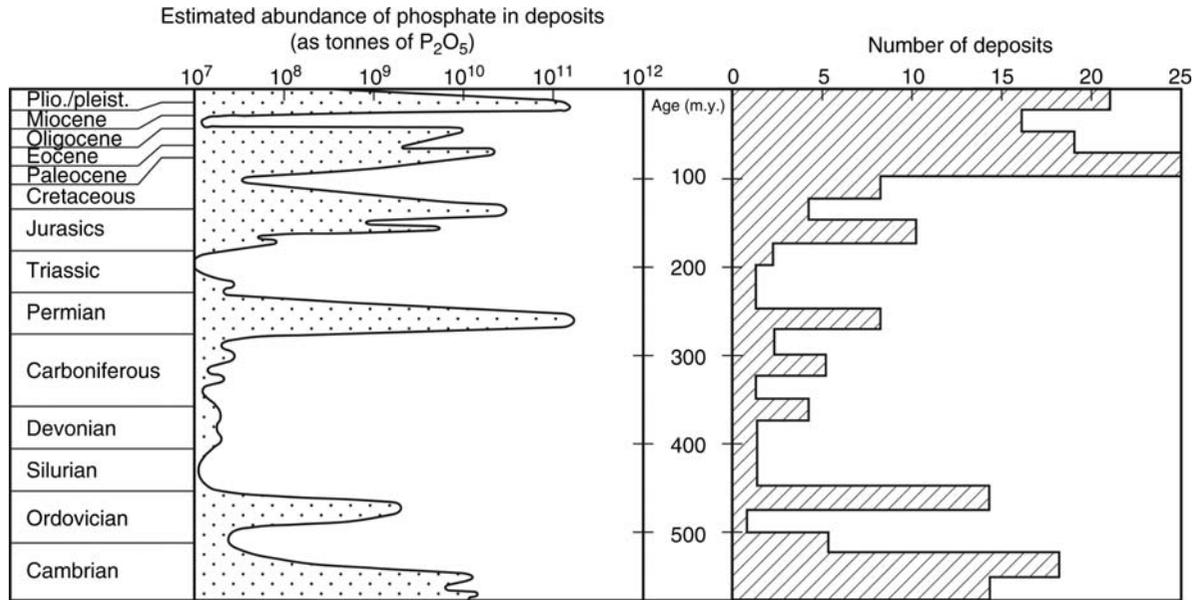

Figure P57 Estimated abundance of phosphorite deposits and P₂O₅ tonnage in Phanerozoic sediments (from Cook and McElhinny, 1979).

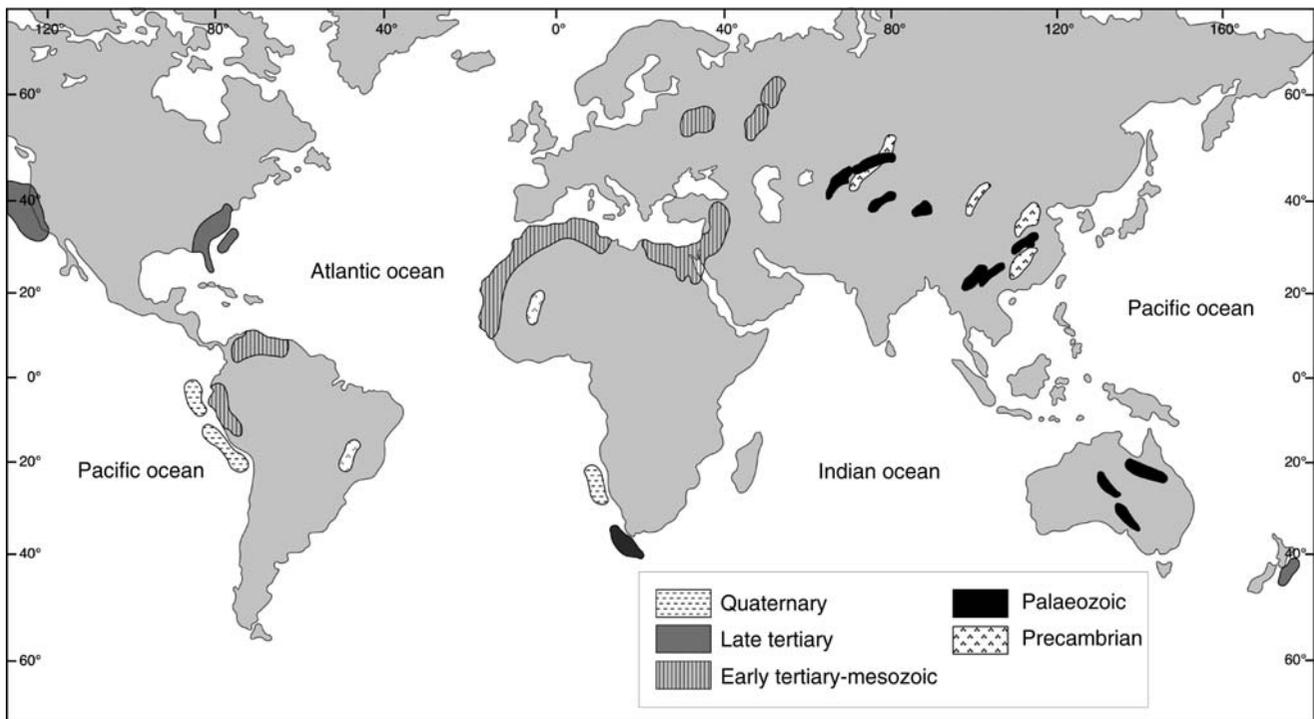

Figure P58 Distribution of major and important sedimentary phosphorite deposits. The symbols mark the age of the deposit. Note the South-Tethyan Mesozoic belt that extends from Turkey via Morocco to Mauritania and Senegal; it extends across the Atlantic to Venezuela and Colombia (after Cook, 1976).

Figure P59 summarizes only the most important substitutions in the very “open” apatite structure.

Phosphorites may be texturally classified into: (a) bedded phosphorites, (b) bioclastic phosphorites, (c) nodular phosphorites, and (d) pebble-bed phosphorites. Francolite occurs in

phosphorites as laminae, pellets, ooids, crusts, nodules of various irregular shapes, skeletal shell and bone fragments, and cements. Phosphorite types may range from predominantly pelletal to purely bioclastic – or “bone beds.” Glenn et al. (1994), distinguished between *pristine* phosphate-bearing deposits,

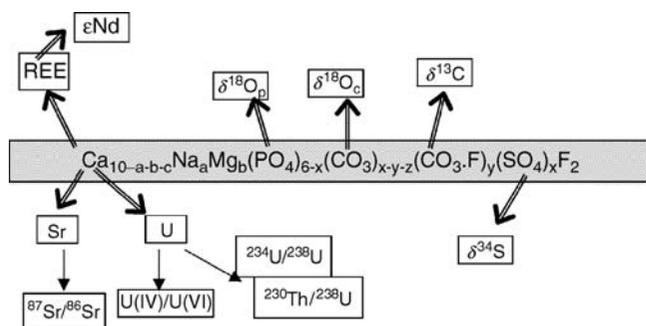

Figure P59 Scheme of possible substitutions and of the isotopic tracers that are commonly analyzed in francolite. Note that whereas the light stable isotopes (of C, O, S) are major anions in CFA, the heavy isotopes (of Sr, Nd and U) substitute for Ca in the lattice (after Kolodny and Luz, 1992).

which lack any sign of reworking, *condensed* phosphatic laminae in which particles were concentrated by winnowing, and *allochthonous* redeposited particles.

The weathering zone of phosphorites often includes several Al- and Fe-phosphates such as wavellite and millisite.

Geochemistry

The large amount of substitutions in francolite makes it a most sensitive recorder of the environments in which it forms.

Major elements

Most unweathered seafloor francolites contain about 6.3% CO₂ and between 3 and 4% F. Carbonate and fluorine concentrations are correlated, probably reflecting the coupled substitution of (CO₃F)³⁻ for phosphate. Several interpretations have been offered for this variability: (a) temperature variation of the depositional basin, causing variable degrees of CO₂ saturation; (b) late diagenetic burial effects, metamorphism and weathering; and (c) CO₃²⁻ content of the interstitial water, i.e., carbonate alkalinity.

Trace elements

Phosphorites are enriched in a large number of trace elements. Many of these enrichment factors can actually be attributed to the organic matter associated with the phosphorites rather than to the francolite itself. Still, after accounting for the organic matter, a strong enrichment in Cd, Ag, Mo, Se, U, Y, Zn, REE, and V is probably related to apatite. Some of these have been studied for their importance as valuable by-products (U, REE), others because of their toxicity, which requires their removal from the marketable product (Cd and U in production of phosphogypsum). We shall consider here only those from which paleo-environmental information has been retrieved.

REE. The rare-earth elements (La–Lu) and Y apparently substitute for Ca²⁺ in the francolite lattice. Both total REE concentration and the relative abundance of the different REE in phosphorites vary. It is customary to consider such abundances on a shale- (or chondrite-) normalized distribution graph, with atomic number as the abscissa and log (normalized abundance) as the ordinate. In such space, “anomalies” can be conveniently expressed. Thus a Ce anomaly (Ce*) in a rock is defined as

$$Ce^* = \log(3Ce_{SN}/(2La_{SN} + Nd_{SN})) \quad (2)$$

where the subscript SN denotes a shale-normalized concentration. Many phosphorites display a typical “seawater pattern”:

they are strongly depleted in Ce and enriched in the heavy REE (HREE; Ho–Lu). These include the western US Permian Phosphoria Formation, as well as many of the Mesozoic Tethys belt deposits: Morocco, Egypt, Jordan (Jarvis et al., 1994). On the other hand, numerous deposits (offshore Namibia, Agulhas Bank, off Peru, Karatau, Kazakhstan) have shale-like (flat) patterns with no Ce anomaly. The Ce anomaly has been attributed to the oxidation of Ce³⁺ in the deep sea to Ce⁴⁺, which is then sequestered from seawater by ferromanganese oxides. Indeed modern coastal and surface seawater display little or no Ce* and little HREE enrichment. Numerous attempts have been made to interpret REE patterns in phosphorites as reflecting depositional environment, specifically depositional oxygenation levels. The very low content of REE in apatitic skeletal elements of living organisms (e.g., fish bones) compared to their higher concentration in fossils suggests, however, that at least a large part of the REE is introduced into francolite during early diagenesis.

Uranium. Phosphorite typically contains between 50 and 200 ppm U, though numerous deposits (Proterozoic-Cambrian of Karatau and Khubsugul) contain as little as 2 ppm whereas others (Eocene of the Central African Republic) may reach levels of 5,600 ppm. Uranium in phosphorites occurs both as U(IV) and U(VI), both apparently substituting for Ca in francolite. U(IV) content varies between zero and almost 90%. That variation in conjunction with petrography and other geochemical parameters has been successfully used for the reconstruction of marine paleo-redox conditions.

Uranium and uranium series daughter isotopes (specifically ²³⁴U/²³⁸U, ²³⁰Th/²³⁴U, ²³¹Pa/²³⁵U) have been successfully used as dating clocks of young phosphogenesis in the ocean (Baturin, 1981; Jarvis et al., 1994; Kolodny and Kaplan, 1971; see also summary in Kolodny and Luz, 1992). Dating was instrumental in demonstrating that: (a) most sites of seafloor phosphorite nodule occurrence are *not* sites of present-day phosphogenesis, and (b) phosphorites *have* formed recently off the coasts of Peru-Chile, Namibia, western South Africa, and East Australia. Applying these techniques, the episodic nature of phosphogenesis – confined to periods of high eustatic sea level – has been demonstrated for the region off Peru-Chile and western South Africa.

Sr and Nd isotopes (Jarvis et al., 1994; Kolodny and Luz, 1992). Since the 1970s, it has been demonstrated that the ratio of ⁸⁷Sr/⁸⁶Sr in the world ocean can be described by the ⁸⁷Sr/⁸⁶Sr reference curve (see *Strontium isotopes*). The high Sr content of francolite makes it potentially possible (within reasonable assumptions) to date phosphorite formation by measuring this ratio and comparing it to the reference curve. Thus, episodes of Neogene phosphogenesis, grain concentration, and reworking of phosphatic sediments have been established for the phosphorites of Florida and the North Carolina shelf by Glenn et al. (1994), as well as by P. Stille and his coworkers.

Unlike Sr, the much shorter residence time of Nd (*see Dating, radiometric methods*) in the ocean (about 2 kyr) results in a heterogeneity of the ¹⁴³Nd/¹⁴⁴Nd ratio in seawater: each major ocean yields a different Nd-isotope evolution curve. Measurements of εNd in sedimentary apatites showed that the present day Pacific-Atlantic provincialism is about 50 Ma old. Prior to that, a single Panthalassa Ocean seems to have existed for about 400 Ma. Prior to 450 Ma, two separate water masses can again be distinguished – the South and North Iapetus Oceans.

Stable isotopes (Jarvis et al., 1994; Kolodny and Luz, 1992)

Significant information on the nature of phosphogenesis has been acquired from the study of the stable isotopes of oxygen, carbon, and sulfur.

Oxygen. Francolite has the unique property of containing oxygen in two distinct sites, which are rather simply analytically separated. These are oxygen in the carbonate – $\delta^{18}\text{O}_c$ and oxygen in phosphate – $\delta^{18}\text{O}_p$ (Figure P59; see *Stable isotope analysis* for definitions of the δ notation used here). It is assumed that oxygen (and carbon) isotope fractionation in the carbonate follows the carbonate paleotemperature equation (Epstein et al., 1953, see *Paleotemperatures, proxy reconstructions*)

$$T(^{\circ}\text{C}) = 16.5 - 4.3(\delta^{18}\text{O}_c - \delta^{18}\text{O}_w) + 0.14(\delta^{18}\text{O}_c - \delta^{18}\text{O}_w)^2 \quad (3)$$

and $\delta^{18}\text{O}_p$ is governed by (Kolodny and Luz, 1992; Longinelli and Nuti, 1973)

$$T(^{\circ}\text{C}) = 111.4 - 4.3(\delta^{18}\text{O}_p - \delta^{18}\text{O}_w) \quad (4)$$

In Equation (3), $\delta^{18}\text{O}_c$ is for all practical purposes equal to $\delta^{18}\text{O}$ of the CO_2 extracted with phosphoric acid and measured vs. PDB, $\delta^{18}\text{O}_p$ in Equation (4) is the $\delta^{18}\text{O}$ value (vs. SMOW) of the oxygen of the francolite phosphate, and $\delta^{18}\text{O}_w$ in both equations is the $\delta^{18}\text{O}$ value of the water with which the francolite equilibrated. T is the temperature of formation of the francolite. It was initially hoped that $\delta^{18}\text{O}_p$ might be a sensitive recorder of environmental temperature and water composition, and a robust preserver of such records. It turned out, however, that although $\delta^{18}\text{O}_c$ is more susceptible to alteration than $\delta^{18}\text{O}_p$, both oxygen sites are prone to post depositional exchange. Indeed $\delta^{18}\text{O}_p$ and $\delta^{18}\text{O}_c$ in phosphorites that span the time range of the last 10^9 years are very well correlated. $\delta^{18}\text{O}_p$ and $\delta^{18}\text{O}_c$ in phosphorites vary with time in a roughly parallel pattern, both decreasing with increasing age, the greatest changes occurring within samples of the last 100 Myr. A similar trend has been observed before for several other sedimentary phases: carbonates, cherts, and glauconites. The question whether these trends record changing temperature, change in $\delta^{18}\text{O}$ of seawater, or increasing alteration has not yet been resolved. Several attempts were made to use $\delta^{18}\text{O}$ in phosphorites for paleotemperature reconstruction: Karhu and Epstein, 1986 (see also Kolodny and Luz, 1992) deduced high pre-Cambrian temperatures from the phosphate-chert oxygen isotopic fractionation. Shemesh and Kolodny (1988) concluded from the stratigraphic variation in $\delta^{18}\text{O}_p$ of Tethyan phosphorites that the phosphogenic event was associated with a cool-water upwelling. In many phosphorites (e.g., Miocene Monterey Formation of California, Cambrian Georgina basin in Australia), $\delta^{18}\text{O}_p$ values are much too low to represent marine temperatures. Thus, the interpretation of such results is still problematic.

Carbon. The carbonate ion in francolite (CFA) can also be analyzed for $\delta^{13}\text{C}$. Such measurements lead to the conclusion that not all carbonate enters the CFA lattice at the time of precipitation; usually such carbonate is in equilibrium with interstitial water rather than with seawater. McArthur et al. (1986) have demonstrated that organic matter-derived (low $\delta^{13}\text{C}$) carbon was to some degree involved in the diagenesis of francolites. $\delta^{13}\text{C}$ is negatively correlated with the CO_2

content of CFA. These studies led to the realization that most phosphorites formed in dominantly suboxic conditions; some (e.g., the Blake Plateau) were formed in a clearly oxic environment, others (Morocco) have been in contact with anoxic pore waters.

Sulfur. The sulfate ion substitutes for phosphate in CFA. $\delta^{34}\text{S}$ varies in phosphorites between values equal to those of coeval seawater sulfate and much higher values (by as much as 10‰). The former apparently reflects seawater sulfate incorporation, whereas the heavier sulfur reflects the residual sulfate after partial reduction. Such “Rayleigh distillation” in a closed system results in a negative correlation between SO_4^{2-} and $\delta^{34}\text{S}$, as observed in francolites of the Phosphoria Formation (Piper and Kolodny, 1987).

Origin and paleoclimatology

Three closely related observations influence strongly all thinking on the genesis of phosphorites: (a) Though phosphorites were deposited in a variety of settings, on seamounts, continental margins, and epeiric seas, all were related to high organic productivity and nearly all to upwelling. This is evidenced by the very nature of phosphorus as a biolimiting element and by the ocean being the major phosphorus reservoir, as well as by the abundance of phosphatic skeletal fragments in phosphorite deposits. (b) Though most phosphorites on the seafloor were proven to be relict (see Kolodny and Luz, 1992), all modern phosphorites are found in areas of oceanic upwelling. (c) The strong association of phosphorites with chert and black shales (P-Si-C) in the geological record further points to such an association. In a series of studies, J. Parrish and coworkers (see Parrish, 1998 for summary and references) concluded that “the distribution of phosphorites is mostly simply dependent on the distribution of upwelling zones over continental shelves for much of the Phanerozoic.” She then used phosphorite distribution as a tool for mapping upwelling zones of the past. Cook and McElhinny (1979) stressed the low paleolatitude distribution of ancient phosphorites and their association with evaporates.

Thus, the explanation of the formation of phosphorite deposits amounts to pointing to a suggested break (sink) in the chain: river input \rightarrow dissolved phosphate \rightarrow organic matter formation \rightarrow dissolved phosphate. In about two centuries of research, almost all possible breaks in the chain were offered in addition to suggestions of additional sources such as volcanism (see Bentor, 1980; Cook et al., 1990; Glenn et al., 1994; Kolodny, 1981). Of seminal importance was the publication of Kazakov’s paper in 1937, in which he linked phosphogenesis to oceanic upwelling, warming of the rising cold water, CO_2 release, and francolite precipitation. Kazakov’s idea, though ultimately rejected in its original form, became the basis of most variants of modern theories of phosphogenesis. Most researchers today agree that francolite is primarily precipitated interstitially in sediments, either chemically or biochemically. In many cases, an association between microbial activity with both mobilization and precipitation of CFA has been documented. Apatitic microbial structures were identified in phosphorite deposits (e.g., Krajewski et al., 1994; Soudry and Champetier, 1983). It is not clear whether the role of microbial mats in phosphogenesis was active, passive, or in-between these extremes. Apatite was also formed bacterially in the laboratory by J. Lucas and L. Prevot (see also Krajewski et al., 1994).

Although seawater is oversaturated with respect to CFA, the slow kinetics of its nucleation and crystallization at the sediment water interface cause the principal formation site to be a

few centimeters inside the sediment, and associated with surfaces of non-deposition or slow sedimentation rates. Whatever the process of primary francolite formation is, the achievement of a high-grade phosphorite requires an additional step of concentration, most likely by mechanical re-working and winnowing (Baturin, 1981). It has been stressed by Föllmi (1994) that no exceptionally long times were required to form even the very large phosphorite deposits. Thus, he estimates that assuming an efficient P supply, only about 12 kyr were required to form the southern Tethyan Paleocene-Eocene province, and only 240 kyr of similar conditions for the formation of the Permian Phosphoria deposit in the Western US. Filippelli and Delaney (1992) showed that phosphorus accumulation and burial rates of major phosphorite deposits are comparable to those of the modern Peru margin.

Following the different models of phosphogenesis, various authors chose to interpret the occurrence of “phosphate giants” in the sedimentary record. These were cited as evidence for times of warm climate (Fisher and Arthur, 1977), as well as times of glaciation (Sheldon, 1980), times when continents drifted into low latitudes (Cook and McElhinny, 1979), major transgressions leading to major anoxia (Arthur and Jenkyns, 1981), or increased continental weathering. The broad spectrum of causes cited above probably shows that no single cause could be regarded as *the* cause for phosphogenesis. Upwelling may be an exception, it seemingly being related to most large phosphorite deposits.

Economics

Phosphorites account for about 85% of the world's phosphate consumption (the rest is supplied from igneous and guano ores). Mineral fertilizers account for approximately 80% of phosphate use, with the balance divided between detergents (12%), animal feeds (5%) and specialty applications (3%), e.g. food grade, metal treatment etc. The production of phosphate rock peaked in 1988 at a level of 166 million tons product, falling to 125 million tons in 2001, and rebounding to 147 million tons in 2007. Over 30 countries are currently producing phosphate rock for use in domestic markets and/or international trade. However, the world's top 12 producing countries account for nearly 95% of the world's total phosphate production. The main producers are the USA, China, Morocco, Russia and the Middle East.

In 2002 the US Geological Survey estimated that world phosphate rock reserves amounted to about 12 billion tons, with a larger reserve base of about 47 billion tons. Of these reserves the lion's share is concentrated in Morocco. The last two decades of the twentieth century have seen a sharp decrease in the demand for phosphate, primarily due to an economic slowdown in developing countries. In 2008 the price of phosphate rock reached \$200/ton after several years of a stable price of \$50/ton. The expected growth is based on the demand for more food by a growing and more affluent population, especially in the developing countries. It also is a reflection of the fact that there is no substitute for phosphorus in agriculture.

PHOSPHORUS CYCLE

Introduction

Phosphorus (P) is a limiting nutrient for terrestrial biological productivity, and thus it commonly plays a key role in net carbon uptake in terrestrial ecosystems. Unlike nitrogen (another limiting nutrient but one with an abundant atmospheric pool), the availability of “new” P in ecosystems is restricted by its rate of release during soil weathering. The release of P places a limit on ecosystem productivity (Schlesinger, 1997), which in turn is critical to terrestrial carbon balances. Furthermore, the weathering of P and transport by rivers is the only appreciable source of P to the oceans. On longer time scales, this supply of P limits total primary production in the ocean (Smith, 1984). Thus, understanding the controls on P cycling is one key element of elucidating biogeochemical responses to and forcing of paleoclimate.

Natural Phosphorus Cycle

The human impact on the global P cycle has been substantial over the last 150 years. Because this anthropogenic modification began well before scientific efforts to quantify the cycle of P, we can only guess at the “pre-anthropogenic” mass balance of P. Several aspects of the P cycle are well-constrained (Figure P60). Phosphorus is initially solubilized, mainly from apatite minerals, by chemical weathering during soil development. Physical weathering also plays a role by producing fine materials with extremely high surface area/mass ratios, which enhances chemical weathering in continental environments (i.e., floodplains, delta systems).

Phosphorus cycling in soils

The cycling of P in soils has received much attention, in terms of both fertilization and the natural development of ecosystems. Of the approximately 122,600 Tg P within the soil/biota system on the continents, nearly 98% is held in soils in a variety of forms. The exchange of P between biota and soils is relatively rapid, with an average residence time of 13 years, whereas the average residence time of P in soils is 600 years (Figure P60). The most significant weathering source for phosphorus in soils are apatite minerals. These minerals can be congruently weathered as a result of reaction with dissolved carbon dioxide:

In soils, P is released from mineral grains by several processes. First, the reduced pH produced from respiration-related CO_2 in the vicinity of both degrading organic matter and root hairs dissolves P-bearing minerals (mainly apatites) and releases P to root pore spaces. Second, organic acids released by plant roots also can dissolve apatite minerals and release P to soil pore spaces (Jurinak et al., 1986). Phosphorus is very immobile in most soils, and its slow rate of diffusion from dissolved form in pore spaces strongly limits its supply to rootlet surfaces. Furthermore, much of the available P in soils is in organic matter, which is not directly accessible for plant nutrition. Plants have developed two specific tactics to increase the supply of P to roots. Phosphatase, an enzyme that can release bioavailable inorganic P from organic matter, is often excreted

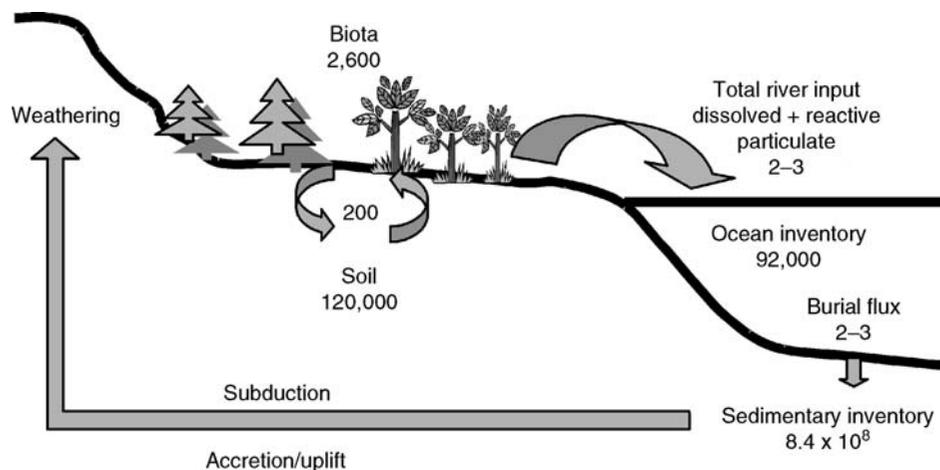

Figure P60 The natural (pre-human) phosphorus cycle, showing reservoirs (in Tg P, where Tg = 10^{12} g) and fluxes (denoted by arrows, in Tg P yr⁻¹) in the P mass balance (after Filippelli, 2002).

by plants and soil microbes, and the symbiotic fungi *Mycorrhizae* can coat plant rootlets, excreting phosphatase and organic acids to release P and providing an active uptake site for rapid diffusion of P from soil pore spaces to root surfaces (e.g., Schlesinger, 1997).

Phosphorus in soils is present in a variety of forms, and the distribution of P between these forms changes dramatically with time and soil development. The forms of soil P can be grouped into refractory (not readily bioavailable) and labile (readily bioavailable). The refractory forms include P in apatite minerals and P co-precipitated with and/or adsorbed onto iron and manganese oxyhydroxides (termed “occluded” P). The reducible oxyhydroxides have large binding capacities for phosphate, due to their immense surface area and numerous delocalized positively charged sites (e.g., Froelich, 1988). The labile forms include P in soil pore spaces (as dissolved phosphate ion) and adsorbed onto soil particle surfaces (these forms are termed “nonoccluded” P), as well as P incorporated in soil organic matter. On a newly-exposed lithic surface, nearly all of the P is present as P in apatite. With time and soil development, however, P is increasingly released from this form and incorporated in the others (Figure P61). Over time, the total amount of P available in the soil profile decreases, as soil P is lost through surface and subsurface runoff. Eventually, the soil reaches a terminal steady state, when soil P is heavily recycled and any P lost through runoff is slowly replaced by new P weathered from apatite minerals at the base of the soil column.

Riverine transport of particulate and dissolved phosphorus

The eventual erosion of soil material and transport by rivers delivers P to the oceans. Riverine P occurs in two main forms: particulate and dissolved. Most of the P contained in the particulate load of rivers is held within mineral lattices and never participated in the active biogenic cycle of P. This will also be its fate once it is delivered to the oceans, because dissolution rates in the high pH and heavily buffered waters of the sea are exceedingly low. Thus, much of the net

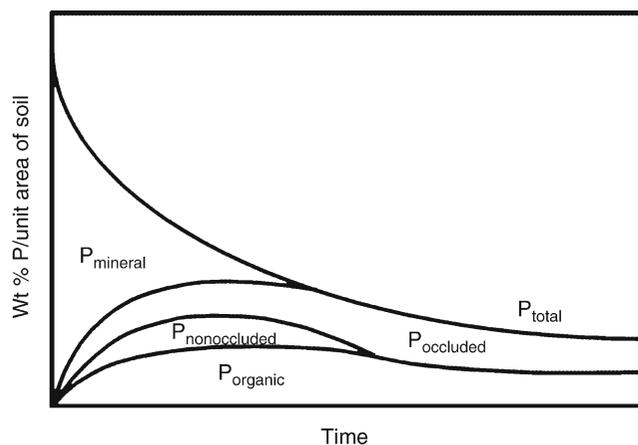

Figure P61 Modeled changes in soil phosphorus geochemistry over time (based on Walker and Syers, 1976), showing transformation of mineral phosphorus into non-occluded and organic forms before eventual dominance of occluded (oxide-bound) and organic forms. The relative bio-reactivity of phosphorus increases from mineral to occluded to organic forms of phosphorus. Note the continual loss of total phosphorus from system.

P physically eroded from continents is delivered relatively unaltered to the oceans, where it is sedimented on continental margins and in the deep sea, until subduction or accretion eventually returns P to be exposed on land again. Some of the particulate P is adsorbed onto soil surfaces, held within soil oxide, and incorporated into particulate organic matter. This P likely interacted with the biotic P cycle on land, and its fate upon transfer to the ocean is poorly understood. For example, P adsorbed onto soil surfaces may be effectively displaced by the high ionic strength of ocean water, providing an additional source of P into the ocean. Furthermore, a small amount of the P incorporated into terrestrial organic matter may be released in certain environments during bacterial oxidation after sediment burial. Finally, some sedimentary environments along continental margins are suboxic or even anoxic, conditions favorable for oxide dissolution and release of the incorporated P. The net pre-human flux of dissolved P to the oceans is $\sim 1 \text{ Tg P yr}^{-1}$, with an additional $1\text{--}2 \text{ Tg P yr}^{-1}$ of potentially soluble P, bringing the total to about $2\text{--}3 \text{ Tg P yr}^{-1}$. Thus, the residence time of biologically available P on land is about 40–60 kyr with respect to export to the oceans. That this residence time is of a glacial time-scale may be no coincidence, and is likely tied to variable inputs from continental weathering and output sinks driven by sea level variations. However, the interaction between biologically available P on land and loss of this P to the oceans is clearly relatively dynamic and suggests the relatively rapid cycling of P on land.

Marine sedimentation

Once in the marine system, dissolved P acts as the critical long-term nutrient limiting biological productivity. Phosphate concentrations are near zero in most surface waters, as this element is taken up by phytoplankton as a vital component of their photosystems (phosphate forms the base for ATP and ADP, required for photosynthetic energy transfer) and their cells (cell walls are comprised of phospholipids). Dissolved P has a nutrient profile in the ocean, with a surface depletion and a deep enrichment. Furthermore, deep phosphate concentrations increase with the age of deep water, and thus values in young deep waters of the Atlantic are typically $\sim 1.5 \mu\text{M}$ whereas those in the older Pacific are $\sim 2.5 \mu\text{M}$. Once incorporated into plant material, P roughly follows the organic matter loop, undergoing active recycling in the water column and at the sediment/water interface.

Phosphorus input and output are driven to steady state mass balance in the ocean by biological productivity. As mentioned previously, one of the difficulties with accurately determining the pre-anthropogenic residence time of P in the ocean is that input has been nearly doubled due to anthropogenic activities, and thus we must resort to estimating the burial output of P, a technique plagued by site-to-site variability in deposition rates and poor age control. Estimates of P burial rates have been performed by a variety of methods, including determination via P sedimentary sinks and riverine suspended matter fluxes calibrated to the P geochemistry of those fluxes. An areal approach is a more direct route to quantifying the burial terms in the P mass balance, and indicates that reactive P burial in continental margin sediments accounts for about 60% of the oceanic output, with deep sea sediments nearly equivalent as a sink (Filippelli and Delaney, 1996). Although continental margins comprise less than 10% of ocean surface area, high burial rates in these settings are linked to high bulk sedimentation rates, which ultimately drive P accumulation rates in marine sediments (Filippelli, 1997).

Impact of climate change on the terrestrial phosphorus cycle

The effect of climate and soil development on P availability has been a focus of several excellent papers (e.g., Chadwick et al., 1999). For the most part, these studies have used P extraction techniques to determine the biogeochemical forms of P within soils (e.g., Figure P61). The extraction techniques have been applied to depth and age profiles in soils, and to assessment of the rate of soil P transformations, the role of climate on these processes, the bioavailability of P in these systems, and the limiting controls on plant productivity. As the current geochemical state of a given soil is an integration of all conditions acting since soil development, most efforts have focused on settings in which climate is likely to have been constant (i.e., tropical settings), and the beginning state of the system and its age are very well known (i.e., soil developing on lava flows). These studies have thus made the classic substitution of space for time, with all the inherent assumptions of constancy in climate and landscape history.

Another approach to assessing terrestrial P cycling is to examine P geochemistry in lake sediments, using the same extraction techniques as the soil studies. This technique adds several dimensions to the soil work outlined above. First, lake sediment records allow us to examine an integrated record of watershed-scale processes associated with P cycling on the landscape. Second, it allows discrete temporal resolution at a given site, providing an actual record of local processes including landscape stability, soil development, and ecosystem development. Third, it extends our understanding of terrestrial P cycling to alpine and glaciated systems. The soil chronosequence approach is not likely to be successful here because of the climatic and slope variability between various sites (i.e., no substitution of space for time is possible). This third dimension is perhaps the most critical in terms of

the P mass balance, as the greatest degree of variations in climate has occurred in these settings, and thus they hold the key to understanding the terrestrial P cycle on glacial/interglacial timescales.

Example of the lake history approach to terrestrial P cycling

The lake sediment approach described above has been applied to several settings, revealing the impact of paleoclimatic variations on the terrestrial P cycle (Filippelli and Souch, 1999). One example of this application is a ~20,000 year record from two small lakes (Jackson and Anderson Ponds) in the western Appalachian Plateau. Paleoclimatic variations have strongly affected the ecological development of this region (Wilkins et al., 1991), although neither lake was directly glaciated. The geochemical profile for Jackson Pond reveals extreme changes in P cycling through time (Figure P62). In the early part of the record, marked by full glacial conditions, mineralized P was the dominant form entering the lake, with occluded and organic forms of lesser importance. During this interval, the landscape was marked by thin soils, high surface runoff, and closed boreal forests (Wilkins et al., 1991). With landscape stabilization and the onset of soil development (17–10 ka), the dominant forms of P entering the lake changed significantly, marked by a decline in the proportion of mineralized P and an increase in organic P (occluded P varied but exhibited no clear trend with age during this interval). In this interval, the closed boreal forests gave way to more open boreal woodland and a rapidly thickening soil cover. From the early mid-Holocene to the present, the concentration of mineral P shows little variation, while that of organic P and occluded P increased. Meanwhile, the ecosystem became dominated by deciduous hardwood forests and grasses, and a thick, stable soil existed. In terms of the percent of total P reflected by each fraction, the

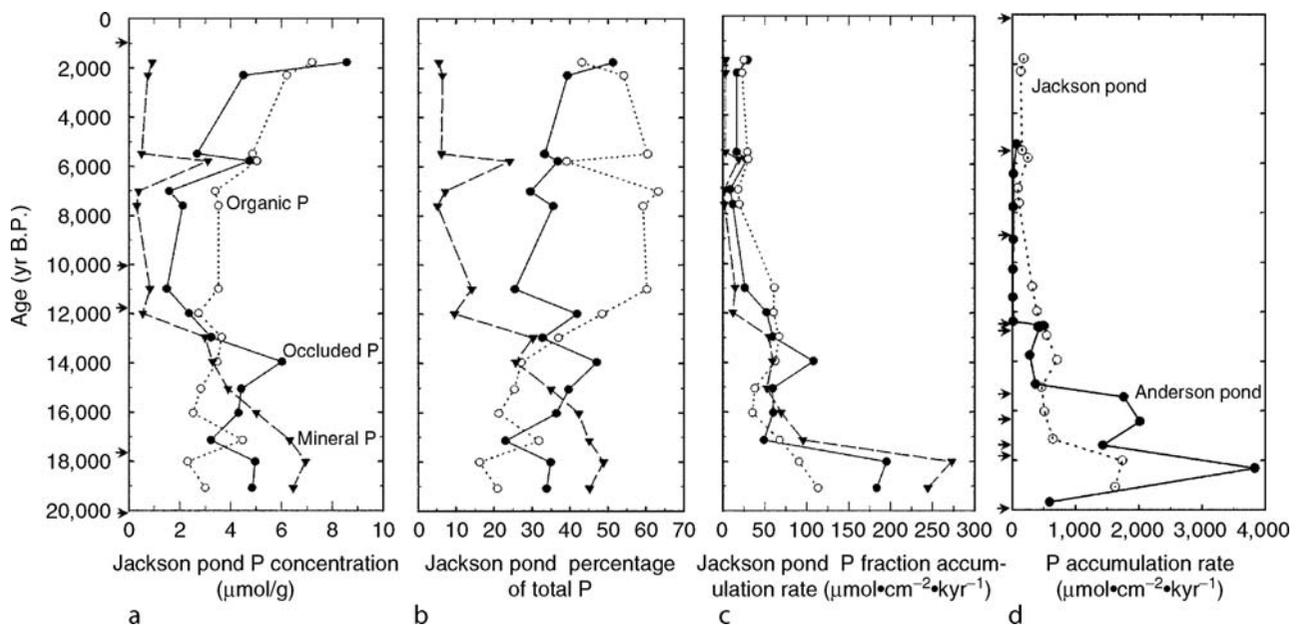

Figure P62 (a) P concentration, (b) percent of total P for each P-bearing fraction in sediments, and (c) accumulation rate of P fractions at Jackson Pond, (d) Total P accumulation rate at Anderson and Jackson Ponds. ¹⁴C age-control points for Jackson Pond (Wilkins et al., 1991) are shown as arrows on age axis in a. Lowermost point is 20,330 yr. ¹⁴C age-control points are also shown for Anderson Pond as arrows in d (after Filippelli and Souch, 1999).

early Holocene marks a stabilization of the system to one dominated by organic and occluded P.

Large changes in the accumulation rate of P over time are reflected in the lake records. These accumulation rate changes are driven partly by changes in bulk sedimentation rate, but several of the rapid shifts in P accumulation occur between age control points and are thus not just driven by rates of sedimentation. The two western Appalachian sites reveal a rapid pulse of P input during the glacial and initial deglacial interval (Figure P62), a period of enhanced colluvial activity when soil development was just commencing. Upon landscape and soil stability (by 10 ka), P inputs had decreased 10–40 fold, and remained low and constant to the top of the record (2 ka). In the case of dissolved phosphate, we can infer that the initial stage of soil development, marked by high solid-phase loss (reflected by the accumulation rate record) also likely leads to a relatively poor recycling of the dissolved phase (from a lack of oxide-bound occluded pools), a so-called ‘leaky ecosystem.’

The lake sediment records presented here indicate a terrestrial P mass balance that is not near steady state on glacial/interglacial time-scales, with important implications for the functioning of terrestrial and oceanic systems. Coupling these records of solid-phase P changes over time with oceanic records of dissolved inputs from rivers will eventually provide important constraints for the influence of climate on chemical weathering and the global P cycle.

PINGOS

Pingos are ice-cored hills (Figure P63), typically conical in shape, covered by soil and vegetation with a core of massive ice produced primarily by the injection of water to the base of aggrading permafrost. They grow and persist only in a permafrost environment. Porsild (1938) first proposed the term pingo, which is a local Inuit word for an ice-cored conical hill in the Mackenzie Delta. In Siberia, similar forms are referred to as bulgannyakh. Pingos vary considerably in size (anywhere from 2 to 50 m high) and active examples show steady increases in height during their lifetime.

Perhaps the greatest concentration of pingos occurs in the Tuktoyaktuk Peninsula to the west of the Mackenzie Delta in the North West Territories of Canada, where over 1,350 examples have been identified. This is a significant concentration given that the number of active pingos world-wide is estimated at around 5,000, with examples occurring in the Yukon, Alaska, Svalbard, Greenland, Siberia, Mongolia and at altitude on the Tibetan Plateau (Mackay, 1998). There are two basic types of pingos, they are:

1. *Open (hydraulic) system pingos*. These occur in hydraulic systems where intra- or sub-permafrost groundwater flows under a hydraulic gradient to the pingo site and maintains a sub-pingo water lens that freezes to form a body of injection ice (hydrolaccolith) that uplifts the surface permafrost to form a conical hill (Figure P64). The key element in this process is the presence of artesian water pressures, which maintain a steady but slow supply of groundwater to the growing ice mound. Open system pingos tend therefore to be concentrated in high relief areas, such as on lower hill-slopes, at the base of alluvial fans, in alluvial valley bottoms or in front of glaciers where subglacial groundwater rise beneath proglacial permafrost. The hydrology of these systems is poorly understood, and other growth mechanism may be involved. In particular, their formation appears to require a delicate balance between three variables all of which may be subject to seasonal or annual oscillations (French, 1996), namely water pressure, overburden or permafrost strength, and the rate of freezing. If water is injected

Figure P63 Closed system pingo from the Tuktoyaktuk, NWT Canada (photo: R.I. Waller).

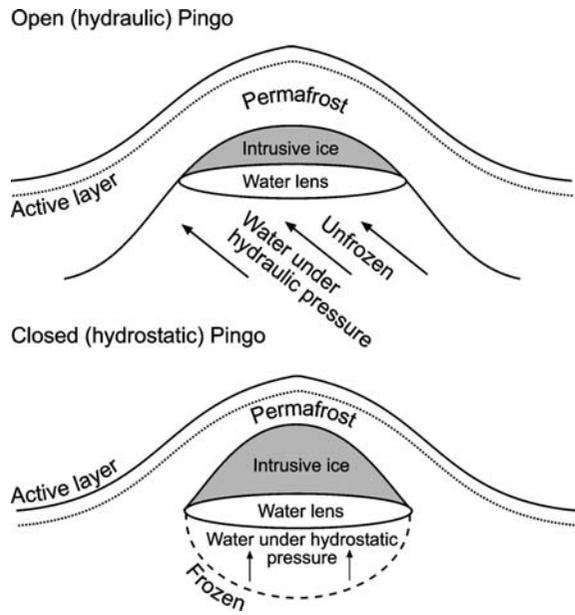

Figure P64 Two main types of pingo.

toward the base of the growing pingo too fast, water pressure will rise until the pingo ruptures and a surface spring is formed. Alternatively, if the water is injected too slowly then the sub-pingo water lens will freeze and the pingo will cease to grow. These variables are unlikely to remain in perfect balance for long and consequently other mechanisms may be involved in sustaining the growth of the ice-core, such as the formation of segregation ice.

2. *Closed (hydrostatic) system pingos.* In this case, the groundwater flow necessary to maintain the growth of the ice core results from pore water exclusion caused by permafrost aggradation within saturated sands found beneath drained lakes or in areas of permafrost talik (Figure P64). Hydrostatic pingos tend to occur in regions where thaw lakes, in areas of permafrost, are drained catastrophically via either coastal retreat or the headward erosion of rivers. Closed system pingos have been widely studied and perhaps the most comprehensive data set exists for those examples on Tuktoyaktuk Peninsula (Mackay, 1998).

Relict pingos occur extensively within areas of former permafrost, and consist of a circular rampart surrounding a shallow depression. Relict examples are considered by many to provide good evidence of former extent of permafrost in the past and Pleistocene examples have been described from across Northwest Europe (Watson, 1977; De Gans, 1988), and North America (Bik, 1969). In addition, fossil examples have been recorded from glacial deposits of late Ordovician age in Jordan (Abed et al., 1993).

Periglacial Geomorphology

PLATE TECTONICS AND CLIMATE CHANGE

The horizontal and vertical displacements associated with plate tectonics play a fundamental role in climate change over a wide range of timescales. The solid-earth surface is in direct contact with the atmosphere and oceans and its evolving character affects balances of incoming and outgoing radiation, atmospheric circulation, ocean currents, and the location of elevated terrain suitable for glaciers and ice sheets. Tectonic processes also have important indirect climatic effects through their control on geochemical cycling and the composition of the atmosphere and ocean. This entry provides an introduction to the more direct, physical effects of tectonics on the climate system. While touched on briefly, the less direct climatic effects of volcanism and chemical processes are left to other entries in this volume. For a historical perspective on many of the ideas presented here, the interested reader should refer to the comprehensive survey by Hay (1996). Other excellent resources include an in-depth discussion of climate forcing mechanisms and climate modeling strategies relevant to tectonic timescales (Crowley and North, 1996), and edited volumes focusing on the climatic and geochemical effects of mountain uplift (Ruddiman, 1997) and uncertainties related to tectonic reconstructions and climate forcing (Crowley and Burke, 1998).

Shifting continents

While the German astronomer and climatologist Alfred Wegener (1880–1930) is usually credited with founding the modern theory of plate tectonics, the concept of a fundamental link between climate and the changing distribution of continents and oceans dates back at least to Lyell (Hay, 1996). He speculated that a concentration of polar land area should cool the Earth and that changing land distributions were somehow responsible for the deposition of Carboniferous coal beds and the obvious differences between Mesozoic and Cenozoic fossil assemblages (Lyell, 1830). Today, we acknowledge that tectonic processes can indeed have local to global-scale climatic impacts. Those impacts can be direct or indirect, and can be the result of horizontal displacements, vertical displacements, or both.

Perhaps the most fundamental, direct link between plate tectonics and climate comes from the slowly evolving global distribution of continental blocks and fragments (Figure P65). As tectonic plates move, so do the subaerial continents and

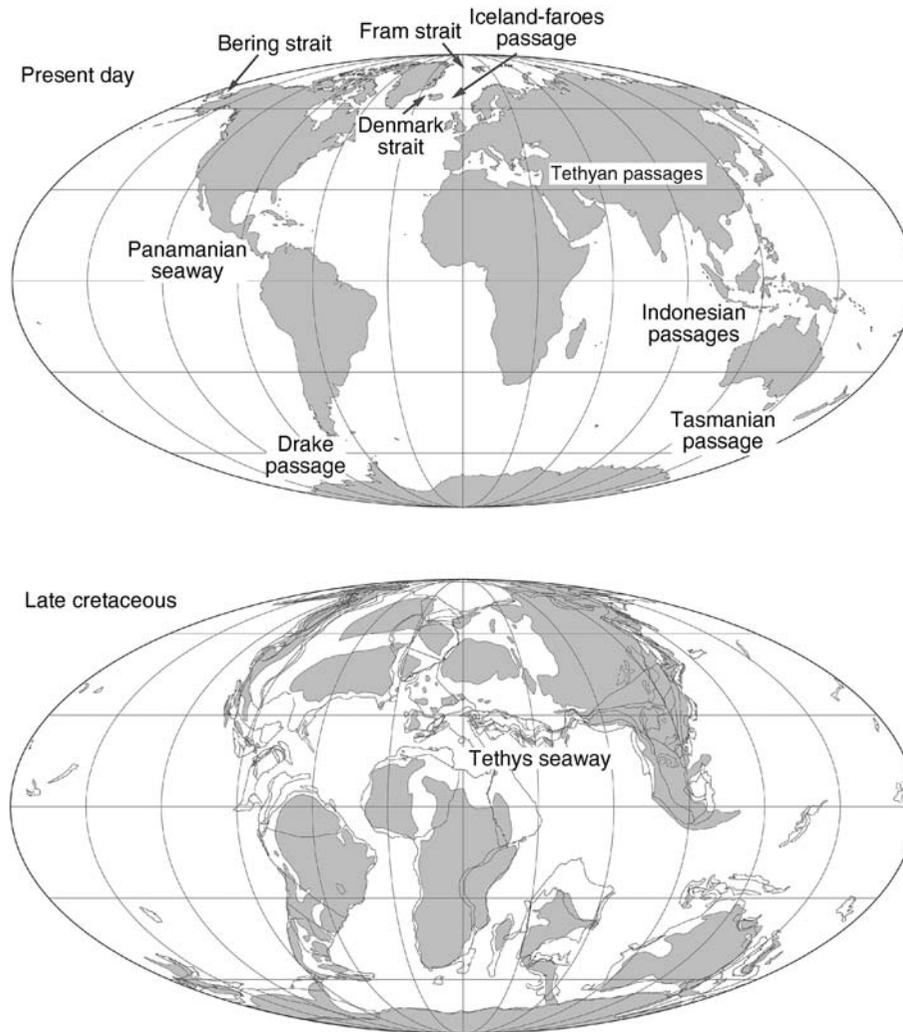

Figure P65 A comparison of modern and late Cretaceous (80 Ma) geography (after Hay, 1996; DeConto et al., 1999; Hay et al., 1999). The approximate locations of Cenozoic gateways discussed in the text are shown on the present day map (*top*). The outlines of tectonic blocks and subaerial land areas (*shaded*) are shown on the Late Cretaceous map (*bottom*). Note the low latitude, circum-global ocean passage (Tethys Seaway), closed Southern Ocean gateways, narrow Atlantic Basin, and flooded continental interiors characteristic of the mostly ice-free Cretaceous and early Cenozoic.

this redistribution of landmass has an important effect on the spatial heterogeneity of the Earth's energy balance via differences in the albedos (reflectivities) and thermal properties of land versus ocean.

Albedo and thermal properties of land and sea

As a whole, the albedo of today's Earth is ~ 0.31 , with the atmosphere and clouds responsible for most (about 85%) of the energy reflected back to space. While the atmosphere and clouds dominate planetary albedo (see entry on *Albedo feedback*), the surface is the dominant absorber of solar energy, responsible for $\sim 65\%$ of the total absorbed solar radiation and for transferring energy to the atmosphere through long-wave radiation, and fluxes of sensible and latent heat. Consequently, variations in surface albedo have important effects on atmospheric dynamics and climate. This is particularly true in mostly cloud-free regions and polar latitudes, which on today's

Earth are covered by highly reflective snow and ice. Surface albedos over open, ice-free ocean are generally much lower than those over land (Table P5). Thus, at the global scale, changes in the latitudinal distribution of land can have a significant effect on zonally-averaged net radiation balance. For example, an Earth with polar continents covered by perennial snow and ice will have higher surface albedo than an Earth with a polar geography dominated by open water. Because the need for poleward heat transport (the ultimate driver of winds and ocean currents) is determined by the latitudinal net radiation gradient, major changes in the distribution of continents are likely to have significant climatic consequences.

Like albedo, the thermal properties of open water are also very different from those of land. Water has very high specific heat (about five times greater than soil and rock) and the upper $\sim 10\text{--}150$ m of the oceans are well mixed by winds and convection. This allows seasonal temperature changes to

Table P5 Albedos of different cloud and surface types

Cloud/surface type	Range of values	Typical values
Cumulonimbus clouds		0.9
Stratocumulus clouds		0.6
Cirrus clouds	0.4–0.5	0.45
*Water (low wind)	0.02–0.12	0.07
Water (high wind)	0.10–0.20	0.12
<i>Bare land surfaces</i>		
Moist dark soil	0.05–0.15	0.10
Moist gray soil	0.10	0.15

*At the low solar zenith angles typical of tropical latitudes, the albedo of calm water can be as low as ~ 0.02 , much lower than typical land-surface albedos. Albedos over open water increase sharply as solar zenith angles approach 90° .

penetrate much deeper into the ocean (tens to hundreds of meters) than into immobile soil and rock on land (~ 1 m, by conduction). Consequently, sea surface temperatures (SSTs) are relatively slow to respond to seasonal changes in insolation. In the hemisphere experiencing winter, relatively warm surface waters suppress extreme temperature swings and provide the atmosphere with a source of moisture and diabatic heating. In contrast, the smaller heat capacity of land combined with relatively high albedo allows much greater seasonality, particularly in the interiors of the larger continents (Figure P66).

Monsoons and the intertropical convergence zone (ITCZ)

The seasonal thermal contrast between land and ocean mentioned above is generally considered to be responsible for the well-known monsoonal circulation systems driven by seasonally alternating low-level pressure patterns over land and sea. The best example on today's Earth is the Asian monsoon system (Figure P66). Over central Asia, seasonal mean temperature differences can exceed 50°C . During boreal winter, cold (dense), sinking air contributes to high atmospheric surface pressure (the Siberian High). Lower atmospheric pressure over the warmer Indian Ocean produces a meridional pressure gradient and northeasterly flow over southeastern Asia, Indonesia and the northern Indian Ocean. During the summer months, continental heating reverses the pressure gradient and the regional wind field. The resulting southwesterly winds (Southwest Monsoon) bring moisture-laden air and rain northward across India, the foothills of the Himalaya, and parts of China and Indonesia. This seasonal reversal of the wind field also produces dramatic changes in the dominant Indian Ocean currents. For example, during boreal summer, a strong low-level atmospheric jet, in part deflected northeastward by east African highlands, drives the northeastward flowing Somali Current, vigorous coastal upwelling, and high

ocean productivity along the coasts of Somalia and Oman. During the Northeast Monsoon, the Somali Current reverses, primary productivity in the Arabian Sea slows, and the entire Indian Ocean equatorial current system reorganizes.

While definitions of the monsoons and the ITCZ are somewhat intertwined, the ITCZ is traditionally considered to be the region of low-level convergence and convective precipitation near the equator, where the trade winds meet. As the seasons progress, uneven interhemispheric heating moves the mean latitudinal position of the ITCZ into the hemisphere experiencing summer (Figure P66). This seasonal shift in the ITCZ is exaggerated over the continents. On today's Earth, the Northern Hemisphere contains a greater fraction of total land area, which contributes to the average position of the ITCZ being several degrees north of the equator, as does the orientation of the coastlines of western tropical Africa and South America (Philander et al., 1996). Because the northeast and southeast trade winds generally converge north of the equator, the Southeast Trades can cross the equator where the effects of the Earth's rotation are minimal. This has important consequences for the latitudinal position of the major zonal equatorial ocean currents and zones of oceanic convergence, divergence, and upwelling, which, like the winds, are also asymmetric with respect to the equator (Gill, 1982).

Alternatively, monsoons have been described as convergence zones more than 10° away from the equator that do not necessarily require a strong land-sea thermal contrast (Chao and Chen, 2001). In this interpretation, the Earth's rotation is considered the primary cause of the monsoons, with land-sea contrast playing a lesser, modifying role. This notion is supported by numerical climate modeling studies showing the existence of monsoons even in the absence of continents. In simulations with the Asian and Australian continents, which are replaced by open ocean, monsoonal circulation patterns still develop over roughly the same regions as today's Asian, Indian and Australian monsoons occur. Land-sea contrast appears to play a more fundamental role in monsoons over Africa, South America and Mexico, however (Chao and Chen, 2001).

Continentality

At times in the geologic past, episodic convergence of major continental plates formed giant supercontinents (e.g., Rodinia, Pangea, Gondwana, and Laurasia). Enhanced *continentality* likely produced extreme seasonal temperature swings and aridity in the continental interiors, and invigorated monsoonal circulation patterns in many coastal locations (Crowley et al., 1989; Kutzbach and Gallimore, 1989). The Permo-Triassic convergence of Laurasia and Gondwana provides a well-known example of a single supercontinent, *Pangea*, and a giant *Panthalasia Ocean*. In central *Pangea*, mean summer temperatures were at least $6\text{--}10^\circ\text{C}$ warmer than today's continental interiors, with daytime high temperatures reaching 50°C in some locations (Crowley and North, 1996). Extreme aridity dominated the continental interiors because most atmospheric water vapor would have been lost to precipitation near the continental margins and because high summer temperatures would have increased evaporation. This continental aridity effect would have been exacerbated downwind of mountain ranges (see *Rain shadows* below). Estimates of net precipitation minus evaporation over *Pangea* are only about half that of modern land areas and these conditions must have played an important role in the distribution of terrestrial ecosystems (Crowley and North, 1996).

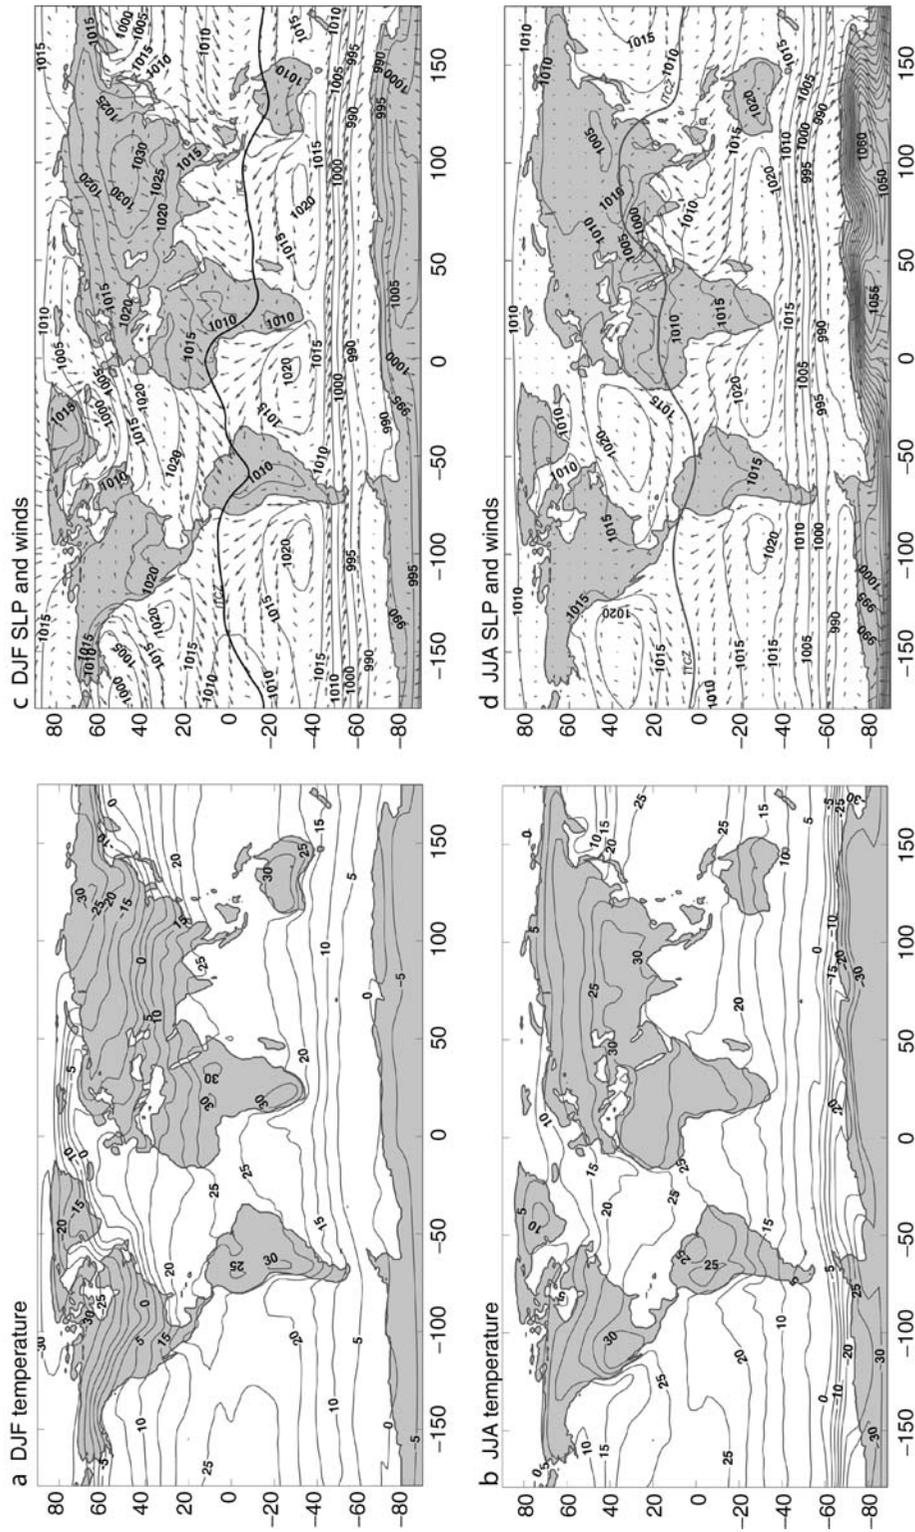

Figure P66 Seasonal surface air temperature (a and b), sea level pressure, and winds (c, d). Modern DJF (December, January, February) and JJA (June, July, August) averages are calculated from 1971–2000 NCEP/NCAR reanalysis data. Seasonal temperatures (a, b) are shown in °C with 5 °C contours. Sea level pressure (c, d) is shown in hPa with 5 hPa contours. The *thick black line* (c, d) shows the approximate seasonal location of the ITCZ (see text for discussion). Vectors show wind velocity, with the longest vectors representing winds of $\sim 13 \text{ m s}^{-1}$.

Pangean climate simulations using global climate models (GCMs) exhibit enhanced land-ocean pressure gradients, resulting in “mega-monsoons” (Kutzbach and Gallimore, 1989) analogous to today’s Asian monsoon system described above, albeit more severe. Such mega-monsoons were likely strongest in the hemisphere with more land area in the subtropics (Gibbs and Kump, 1994) and would have been highly sensitive to the location of mountains and high plateaus (Hay and Wold, 1998). Monsoonal circulation systems have also been shown to be sensitive to orbital forcing (see *Astronomical theory of climate change*), with the summer monsoon becoming invigorated in the hemisphere experiencing increased insolation (Kutzbach and Liu, 1997). This sensitivity was likely enhanced over the largest continents and may account for some of the rhythmic sedimentary sequences (cyclothem) seen in the late Paleozoic and early Mesozoic sedimentary record.

Extreme seasonality associated with large continents also affects the potential for widespread glaciation. While extreme cold winters provide many opportunities for winter snow accumulation, summer ablation is the critical factor in maintaining perennial snow cover leading to the growth of ice sheets. Increased seasonality and a lack of precipitation in the interior of ancient supercontinents would have been generally unfavorable for the growth of continental-scale ice sheets in mid-high latitudes (Crowley et al., 1989), unless accompanied by global cooling and/or uplift. For example, the Carboniferous glaciation of the Gondwanan supercontinent is thought to coincide with a time of broad epeirogenic uplift (Gonzalez-Bonorino and Eyles, 1995) combined with relatively low levels of atmospheric CO₂ (Berner and Kothavala, 2001), an important contributor to the heat-trapping greenhouse effect. In more recent times, the Cenozoic separation of Southern Hemisphere continents and associated reductions in continentality and seasonality, along with declining CO₂, may have contributed to the summer cooling requisite for the first extensive glaciation of Antarctica in the Paleogene (DeConto and Pollard, 2003a,b; Oglesby, 1991).

The polar latitudes’ sensitivity to geography is clearly illustrated by the very different climatic regimes of today’s north versus south polar regions. Increasing concentration of land area in high northern latitudes has long been considered a

contributor to the overall global cooling trend through the Cenozoic, eventually culminating in Northern Hemisphere glaciation (Crowell and Frakes, 1970; Donn and Shaw, 1977). A number of early paleoclimate modeling studies using GCMs explored the potential global impacts of latitudinal shifts in land area (Barron et al., 1984; Hay et al., 1990a). Like the simulations shown in Figure P67, these studies showed that an Earth with a concentration of equatorial continents and open polar oceans is indeed warmer and has lower equator-to-pole temperature gradients than an Earth with a concentration of polar continents and an equatorial ocean (Figure P67). Subsequent modeling studies focusing on the extreme warmth of the Cretaceous period (Barron et al., 1993) showed that the effect of paleogeography alone does not account for all of the warmth characteristic of much of the Mesozoic and early Cenozoic. This work concluded that some other climate forcing factor in addition to paleogeography (probably elevated concentrations of atmospheric CO₂) must have contributed to the warmth of the Cretaceous and other warm periods in Earth history, as speculated a century earlier (Arrhenius, 1896). While the models used in these studies were crude by current standards, they showed that changes in continental configuration could produce significant climate change, albeit smaller than the full range of climate variability recognized in the geologic record. They also showed that small tectonic changes associated with the movement of individual continental blocks and fragments have only limited, local effects (Hay, 1996) and could only produce major climatic change if combined with amplifying feedbacks.

In addition to latitudinal displacements, the evolving zonal (east-west) distribution of land can also have important climatic consequences. In tropical latitudes, the modern pan-Pacific atmospheric pressure pattern is dominated by the *Walker Circulation*. The Walker Circulation is driven by the longitudinal distribution of diabatic heating over land and sea, with Africa, South America, and the warm waters surrounding Indonesia providing sources of heating. On today’s Earth, easterly trade winds drive warm surface waters westward, forming the Western Pacific Warm Pool, where surface waters “pile-up” against the Indonesian archipelago. Consequently, the equatorial thermocline (the layer in the ocean below the surface mixed

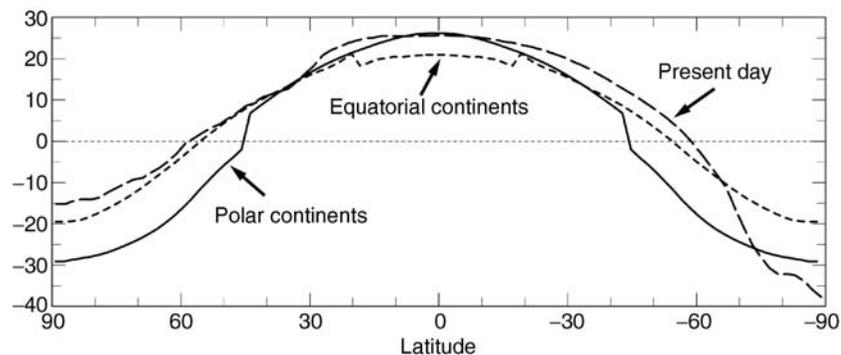

Figure P67 Zonally-averaged, mean annual surface air temperature over the modern Earth (*long dashes*) compared with GCM simulations of a planet with two polar continents (*solid line*) and a planet with a single equatorial supercontinent (*short dashes*). The climate simulations used the current (2008) version of the GENESIS V.3 GCM (Thompson and Pollard, 1997), preindustrial CO₂ (280 ppmv), and a mean orbital configuration (zero eccentricity and an obliquity of 23.5°). Total land areas in the polar and equatorial geographies are equal and close to modern. All land points were assigned an elevation of 800 m and a generic (mixed deciduous and evergreen) vegetation. Note the similarity of north polar temperatures in the modern versus equatorial continent (polar ocean) scenarios, and south polar temperatures in the modern versus polar continents scenarios.

layer where temperature decreases rapidly with depth) slopes down toward the west and shoals on the eastern margin of the basin to produce the $\sim 5^{\circ}\text{C}$ zonal SST difference across the Pacific. On the warmer, Indonesian side of the Pacific, latent and diabatic heating contributes to convection, low surface pressure, low-level convergence, and high pressure aloft. The upper-level, westerly pressure gradient is balanced by a sinking branch of the *Walker Circulation* and corresponding high surface pressure near the west coast of South America – a region typically dominated by upwelling and relatively cool sea surface temperatures.

Thus, the distribution of landmasses and restriction between the Pacific and Indian Oceans provided the basic framework for the *Walker Circulation* and related atmosphere-ocean dynamics like ENSO (El Niño Southern Oscillation – the dominant mode of modern Pacific climate variability). During an El Niño event, the western tropical Pacific cools and the core of warmest surface waters moves eastward, inhibiting upwelling along the west coast of South America. This zonal redistribution of SSTs perturbs the *Walker Circulation* and this is reinforced by atmosphere-ocean feedbacks involving the trade winds (Bjerknes, 1969). The 2–7-year quasi-periodicity of the modern ENSO cycle is, in part, modulated by equatorially-bound Kelvin waves in the ocean's interior, propagating from west to east in the upper thermocline, and westward traveling Rossby waves. On the eastern side of the basin, where the thermocline is already near the surface, these long waves can have a significant impact on SSTs and hence the atmosphere (Battisti and Hirst, 1989).

The long-term evolution of the Warm Pool has likely been influenced by the progressive closure of the eastern Tethys Sea (Figure P65) and restriction of the Indonesian Seaway through the Neogene (Cane and Molnar, 2001). While the character and timing of long wave-modulated atmosphere-ocean dynamics are expected to be different in a world with a wider Pacific basin, climate model simulations and geological evidence show the presence of ENSO-like variability as early as the Eocene (Huber and Caballero, 2003). This would suggest atmosphere-ocean oscillations like ENSO are robust features of the climate system that operate over a wide range of paleogeographic boundary conditions.

Eustasy

Tectonically-driven changes in global mean sea level (eustasy) and the associated flooding or exposure of low-lying continental areas also have important climatic consequences. The effects mainly stem from the changes in albedo and surface-atmospheric heat and moisture exchange associated with sub-aerial versus water-covered surfaces, although indirect effects on the marine carbon cycle and atmospheric CO_2 may also be important (Gibbs and Kump, 1994). Over 10^6 -year and longer time scales, eustasy is thought to be dominated by tectonic influences on the volume of the ocean basins (Hays and Pitman, 1973). Increases in the total length of mid-ocean ridges, high sea floor spreading rates producing warm, lower-density ocean crust, and the emplacement of Large Igneous Provinces (LIPs) can all displace ocean water and raise sea level (Kominz, 1984). Increased spreading rates have also been associated with increased volcanic outgassing and high levels of atmospheric CO_2 (Larson and Erba, 1999), although the linkages between sea floor spreading and atmospheric composition remain equivocal (Conrad and Lithgow-Bertelloni, 2007; Rowley, 2002).

The Cretaceous period offers one of the best examples of a warm “greenhouse” climate during a time of high sea level, when a combination of mostly ice-free poles and high sea floor spreading rates produced sea levels ~ 100 m higher than today (Haq et al., 1987; Larson, 1991). More than 20% of the continents were flooded (Figure P65), forming vast epicontinental seas (Hay et al., 1999). Climate modeling studies (Barron et al., 1993; DeConto et al., 1999; Otto-Bliesner et al., 2002) have shown that the combination of high greenhouse gas concentrations, continental positions, and high sea levels all contributed to the overall warmth of the Cretaceous. The ameliorating effects of open water in epicontinental seas and inland lakes likely reduced seasonality and contributed to the apparent winter-warmth of many continental locations (Sloan, 1994; Valdes et al., 1996). As discussed below, however, a satisfactory explanation for the extreme warmth of the polar regions during the Cretaceous and other warm climate intervals remains elusive.

Ocean gateways

The oceans transport vast amounts of water, heat, and salt across entire ocean basins and from low to high latitudes. As the ocean basins and the *gateways* between them evolve over tectonic timescales, so does ocean circulation. These tectonically-forced changes in ocean circulation have long been thought to play a key role in some of the major climatic events and transitions recognized in the geological record. While the timing of some tectonic gateway events broadly correspond with major paleoenvironmental changes (e.g., the ocean anoxic events (OAEs) of the Cretaceous (Leckie et al., 2002), the onset of Antarctic glaciation in the earliest Oligocene (Kennett, 1977; Livermore et al., 2004), and the onset of Northern Hemisphere glacial cycles in the Pliocene (Haug and Tiedemann, 1998)), the actual role of the ocean in these changes remains equivocal and likely involves a complex web of both direct and indirect effects.

Ocean heat transport

The link between tectonically forced changes in ocean circulation and global climate is usually attributed to changes in the ocean's contribution to poleward heat transport (Covey and Barron, 1988; Rind and Chandler, 1991). While modern estimates of atmospheric and oceanic heat transport remain poorly constrained, it is generally believed the oceans contribute about half of the total heat transport required to maintain the Earth's meridional energy balance. Because of the large equatorward latent heat flux associated with the lower limb of the Hadley circulation, the atmosphere contributes little heat transport out of the tropics, where the oceans do most of the work (maximum poleward ocean heat transport of about 2×10^{15} watts occurs at about $20\text{--}25^{\circ}$ North and South (Peixoto and Oort, 1992; Trenberth and Solomon, 1994)). While ocean circulation contributes little direct poleward heat transport in high latitudes, it plays an important role in polar climate via its influence on atmospheric teleconnections to the tropics (Cane and Evans, 2000) and its control on seasonal distributions of sea ice, which affects albedo and energy transfer between the ocean and atmosphere (Rind et al., 1995).

Because changes in the physiognomy of ocean basins and/or the opening or closure of gateways alters both the wind-driven (surface) and density-driven (deep) components of the ocean's meridional overturning (Bice et al., 1998; Poulsen et al., 2001), it may be reasonable to assume that tectonically-forced changes in ocean circulation can have profound climatic consequences (Covey and Barron, 1988). Conversely, theoretical

arguments suggest the potential effects of ocean circulation on total poleward heat transport are inherently limited. It has been hypothesized that the total energy transport by the atmosphere-ocean system remains roughly unchanged, so if the efficiency of either the atmosphere or ocean is reduced, the other compensates (Stone, 1978). Furthermore, ocean heat transport is proportional to the product of the temperature change and mass transport of water advected into a given region. Thus, the ocean's potential to transport heat would have been limited during times in the past when the temperature difference between low and high latitudes (and surface and deep waters) was much smaller than today, such as during the Cretaceous and early Eocene (Hay and DeConto, 1999; Sloan et al., 1995).

The limited potential of the oceans to maintain the warm, ice free polar conditions characteristic of most of the Phanerozoic is generally supported by numerical climate model simulations of paleoclimates using Mesozoic and early Cenozoic paleogeographies and high greenhouse gas concentrations (Brady et al., 1998; Huber and Sloan, 2001; Otto-Bliesner et al., 2002). While these simulations do produce relatively warm climates with somewhat reduced equator-to-pole temperature gradients relative to today, they fail to produce the dramatic increases in ocean heat transport required to explain all of the polar warmth of these intervals, provided the oceans were the primary mechanism for polar warming (Lyle, 1997). Several alternative mechanisms have been proposed to account for extreme polar warmth during these periods, including increased atmospheric latent heat transport (Hay and DeConto, 1999), increased tropical cyclone activity (Emanuel, 2001) and polar stratospheric clouds (Sloan and Pollard, 1998), although the potential climatic effects of these mechanisms are speculative. The underestimation of polar warmth in model simulations of these ancient climates remains an important problem, because it implies that climate model simulations of future climates may be underestimating future polar warming in response to anthropogenic increases in greenhouse gas concentrations.

While the global-scale impact of tectonically forced changes in ocean circulation is debatable, the breakup of Pangea certainly had profound effects on both the wind-driven current system and location(s) of deepwater formation. Such changes likely had important regional climatic effects that could have triggered indirect forcing mechanisms with global consequences. For example, tectonically forced changes in ocean circulation can impact atmospheric CO₂ via changes in ocean overturning, primary productivity, and the biological pump. Furthermore, changes in ocean circulation contributing to deep sea warming have the potential to trigger the release of methane (another important greenhouse gas that oxidizes to form CO₂) from frozen, temperature-sensitive gas hydrates (clathrates) stored in deep sea sediments. Such a feedback mechanism has been proposed to have contributed to the dramatic global warming event known as the Paleocene-Eocene Thermal Maximum (Dickens et al., 1997).

The oldest surviving ocean crust is less than 200 million years old and detailed paleogeographic reconstructions become increasingly difficult to assemble with increasing age (Crowley and Burke, 1998). Despite the inherent limitations, the timing of major late Mesozoic and Cenozoic gateway events are becoming better constrained, including the opening of the North and South Atlantic basins, the closure of the ancient Tethys Ocean, the opening of the Southern Ocean gateways, the restriction of the Indonesian Seaway, and the closure of the Panamanian Isthmus (Figure P65). Among these, the closure of the Tethys and the

opening of the Southern Ocean may be the most profound because they produced the late Cenozoic world as we know it today – with a single high-latitude circum-global passage (Southern Ocean) rather than a tropical circum-global passage (Tethys Ocean) as existed during the relative global warmth of the late Mesozoic and early Cenozoic.

Tethys Ocean

The Tethys (Figure P65) formed sometime in the late Jurassic, reached its zenith during the Cretaceous, and remained at least partially open until the Miocene (Hay et al., 1999). The modern Mediterranean Basin is the last remaining expression of the ancient Tethys, which both reduced Eurasian continentality and provided a low latitude ocean passage between the Indian and Atlantic Ocean basins. The Cenozoic retreat of the Tethys and Paratethys Seas, and the associated increase in Eurasian continentality and aridity, may have had climatic effects comparable in magnitude to the uplift of the Himalaya and Tibetan Plateau (Ramstein et al., 1997).

Like the modern Mediterranean, Tethyan (sub-tropical) latitudes were likely dry and dominated by strong net evaporation. Relatively warm and saline (high density) deep-water masses could have formed there. Given the size of the ancient Tethys, such water masses have been proposed to have driven a thermohaline circulation system essentially the opposite of today's, with warm, but dense (high salinity) deep waters sinking in low latitudes and flowing polewards (Brass et al., 1982; Chamberlin, 1906). The potential climatic impacts of warm saline deep and bottom water formation remains equivocal, however. Numerical ocean models have not been able to maintain a stable mode of circulation with deep convection in low latitudes (Bice, 1997; Brady et al., 1998). Furthermore, even if such a mode of circulation did persist, it is unlikely that a reversal of the thermohaline component of the meridional overturning circulation would significantly increase ocean heat transport on an Earth with warm polar temperatures already in place.

While the global importance of Tethyan deepwater formation is debatable, closure of the Tethys likely did have a number of important impacts on the evolution of Cenozoic oceans and climate. For example, a recent modeling study of Cenozoic ocean circulation (von der Heydt and Dijkstra, 2006) showed that the opening of Southern Ocean gateways combined with progressive closure of the Tethys could have induced a flow reversal (from westward to eastward) between the Atlantic and Pacific oceans through the Central American Seaway. Today, net fresh water flux out of the Atlantic basin maintains a relatively saline Atlantic and fresh Pacific. In turn, dominant sources of deepwater formation are limited to the Atlantic. Prior to the closure of the Tethyan and Panamanian seaways, inter-basin connectivity would have reduced this salinity contrast, possibly allowing locations of major deepwater formation in both the North Atlantic and North Pacific. Another ocean modeling study of an open versus closed circum-equatorial passage suggest an open Tethys would have increased upwelling of cold deepwaters in low latitudes, possibly helping to moderate tropical temperatures during warmer Mesozoic and early Cenozoic climate intervals (Hotinski and Toggweiler, 2003).

While the actual global climatic effects of these changes in the ocean remain unconstrained, the final closure of the eastern Tethys, ongoing Cenozoic restriction of Indonesia throughflow, and final closure of the Panamanian Isthmus in the Pliocene all contributed to forming the thermal structure of the oceans

as we know them today. This includes a trade wind-driven Western Pacific Warm Pool (WPWP), westward dipping thermoclines in the major ocean basins, and cool eastern Pacific tropical SSTs – the essential components of the modern ENSO system (Philander, 1999). Differentiation of the ocean basins during the Cenozoic also influenced the partitioning of salt in the oceans, with fundamental consequences for the location of deepwater formation and ocean circulation in general.

Southern Ocean gateways

The opening of the Southern Ocean passages between Antarctica and Australia (Tasmanian Passage) and Antarctica and South America (Drake Passage) and Antarctic glaciation in the earliest Oligocene is an often-cited example of ocean gateways causing a specific climatic event. As these passages widened and deepened and the Antarctic Circumpolar Current and Polar Frontal Zone developed, reduced poleward ocean heat transport and cooler Southern Ocean temperatures are thought to have cooled Antarctica enough to allow continental glaciation (Kennett, 1977; Robert et al., 2001). While the earliest Oligocene glaciation of East Antarctica broadly coincides with the timing of Tasmanian gateway development (Stickley et al., 2004), estimates of the opening of Drake Passage range between about 45 and 22 Ma (Barker and Burrell, 1977; Lawver and Gahagan, 1998; Scher and Martin, 2006), clouding the direct cause and effect relationship between the gateways, cooling, and glaciation.

Several ocean modeling studies (Mikolajewicz et al., 1993; Toggweiler and Bjornsson, 2000) have reported reductions in Southern Ocean heat transport and cooler SSTs ($\sim 1\text{--}4^\circ\text{C}$) in response to opening Southern Ocean gateways. In contrast, a recent study using a fully coupled atmosphere-ocean GCM showed little change in ocean heat transport or the climate of the Antarctic interior associated with the opening of the Tasmanian gateway (Huber et al., 2004). Even when forced with an unrealistically large (25%) change in southward ocean heat transport, a coupled GCM-ice sheet model showed that the effect on the timing of Antarctic glaciation caused by the gateways is small (DeConto and Pollard, 2003b) relative to the effects of declining Cenozoic CO_2 (Pagani et al., 2005). When considered together, these results suggest some other forcing mechanisms and/or feedbacks, perhaps related to the carbon cycle, may bear greater responsibility for Antarctic cooling and glaciation than the direct physical effects of the gateways on the oceans (Zachos and Kump, 2005).

The importance of atmospheric CO_2 concentrations relative to ocean gateways has also been recognized in modeling studies of other periods. For example, in ocean simulations testing the effects of the mid-Cretaceous opening of the gateway between the North and South Atlantic (Poulsen et al., 2001), very warm, saline conditions dominate the North Atlantic prior to the opening. While connecting these basins produces significant changes in regional ocean circulation, no fundamental change in the mode of thermohaline circulation occurs, and globally averaged SSTs change only by $\sim 0.2^\circ\text{C}$, which is insignificant relative to the warming caused by the levels of greenhouse concentrations presumed to have existed at that time.

Central American passage and Indonesian Seaway

The Neogene closure of the Central American passage and ongoing restriction of the Indonesian Seaway have also been implicated in climate change, including the onset of Northern Hemisphere glaciation and African aridification (Cane and

Molnar, 2001; Mikolajewicz et al., 1993). In the case of the Panamanian Seaway, restricted inter-basin water mass exchange was thought to have invigorated the Gulf Stream component of the North Atlantic subtropical gyre, increasing the moisture available for advection to high latitudes and growing ice sheets (Keigwin, 1982). More recent studies, however, have shown that closure of the Isthmus of Panama likely predates the onset of Northern Hemisphere glaciation, pointing to other possible forcing mechanisms (Haug et al., 2005).

Between the Pacific and Indian Oceans, the northward movement of Australia and New Guinea through the Cenozoic, combined with the emergence of individual volcanic islands, has led to the progressive restriction of Indonesian throughflow and a change in the source of surface waters entering the Indian Ocean from predominantly warm South Pacific waters to cooler North Pacific waters. The resulting cooling of the Indian Ocean has been implicated in African aridification $\sim 3\text{--}5$ Ma, with possible impacts on Hominid evolution. Furthermore, the restriction would have increased the zonal temperature gradient across the Pacific, with potentially important teleconnections to high northern latitudes (Cane and Molnar, 2001).

Other significant gateway events during the Cenozoic include the opening of Fram Strait, which has allowed a deep water passage between the Arctic and North Atlantic basins since sometime in the late Miocene (Kristoffersen, 1990), and the Oligocene-Miocene deepening of the Denmark Strait and Iceland-Faeroes passages (Wold et al., 1993). The Denmark Strait and Iceland-Faeroes passages are of particular importance because they allow the outflow of deep waters formed in the Greenland and Norwegian Seas to flow into the North Atlantic, then becoming North Atlantic Deep Water – an important component of the so-called “global ocean conveyor” (Broecker, 1991).

The relatively narrow and shallow (< 50 m) Bering Strait provides the only modern connection between the Arctic and the Pacific. While the gateway lies on continental crust, the low elevation of the area is attributed to regional extension and faulting associated with subduction of the Pacific Plate and rotation of the Bering Block (Mackey et al., 1997). The Bering Strait has allowed an intermittent shallow-water connection between the Arctic and Pacific basins since the late Miocene, with the Strait and surrounding area becoming subaerial during glacial periods. Today, only about 1 Sv ($10^6\text{ m}^3\text{ s}^{-1}$) of water passes through the strait into the Arctic basin; however, it has had an important impact on Plio-Pleistocene climate via its influence on North Pacific and Arctic salinity, sea ice, and the effect of repeated flooding/exposure of the Bering and Chukchi shelves on regional albedo and moisture availability for Beringian ice sheets (Brigham-Grette, 2001).

While the global effects of tectonically forced changes in ocean circulation remain equivocal, numerous ocean modeling studies have indeed shown that changes in ocean circulation in response to evolving basin configuration do have important regional impacts. Indeed, ocean currents are often attributed to the maintenance of specific terrestrial climate patterns, especially in maritime locations. Perhaps the most obvious example is the transport of warm subtropical surface waters in the North Atlantic Subtropical Gyre (via the Gulf Stream and North Atlantic Current), which warms the waters adjacent to northwestern Europe. The advection of warm waters into this region, in part driven by the North Atlantic Deep Water formation noted above, has long been presumed to be the primary reason for Northern Europe's equability relative to North

American climates at the same latitude. This paradigm has recently been challenged, however, with the role of topographically-forced atmospheric planetary waves (see below) and prevailing North Atlantic wind patterns possibly being more important in the transport of heat to Northern Europe (via the atmospheric transport of heat stored seasonally in North Atlantic surface waters) than previously considered (Seager et al., 2002).

Mountain uplift

Tectonic uplift is often cited as an important contributor to long-term climatic change (Birchfield et al., 1982; Raymo and Ruddiman, 1992; Ruddiman and Kutzbach, 1991). Because modern orography appears to be anomalously high relative to the warmer climatic intervals that dominated the Mesozoic and early Cenozoic, relatively recent mountain building events, like the collision of India with Asia that formed the Himalayas beginning ~ 40 Ma, are often implicated as primary contributors to Cenozoic cooling and Northern Hemispheric glaciation. In fact, a number of the world's mountainous regions have been described as having undergone significant uplift during the late Cenozoic (see Hay et al., 2002 and references therein) and speculated linkages between those uplifts and Cenozoic cooling date as far back as the nineteenth century (Dana, 1856).

With the exception of the ice sheets covering Greenland and Antarctica, the most prominent topographic feature on today's Earth is the Himalayan-Tibetan plateau, covering a vast area (4×10^6 km²) at an elevation averaging ~ 5 km. The only geological intervals known to have had comparable orographic features occurred as a result of the continental collisions that formed Pangea about 320 and 240 Ma (see Ruddiman, 1997). The climatic effects of such features are multifaceted and complex. In addition to providing a barrier to atmospheric flow, mountains and high plateaus produce rain shadows on their leeward slopes and can have important effects on albedo and energy balance. Tectonic setting, including the orientation of land surface slope and the presence of bare soil and/or rock can influence albedo directly and through its control on vegetation. Vegetation is of particular importance because it affects land surface roughness, atmospheric moisture, and the partitioning of sensible and latent heat fluxes between the surface and atmosphere (Dickinson and Henderson-Sellers, 1988). Areas dominated by evergreen vegetation are also likely to maintain much lower albedo and warmer temperatures than bare soil or tundra, which are easily covered by winter snow (Bonan et al., 1992). Because tropospheric temperatures generally decrease with increasing altitude (the globally averaged tropospheric lapse rate is about $6.5^\circ\text{C km}^{-1}$), high terrain is more likely to maintain perennial snow cover and glacial ice with high albedos (0.6–0.8).

Uplift and glaciation

In addition to the latitudinal position of continents, epeirogenic uplift is a critical factor in glaciation (Birchfield et al., 1982). This is mainly due to the dependence of both temperature and orographic effects on snowfall. On local to regional scales, glaciers are found where winter snowfall is high and summer temperatures remain cold enough to limit ablation. Conversely, the termination zones of glaciers often occur in low-lying valleys, where temperatures are warmer and summer ablation outpaces winter accumulation. The slope of the land surface also has a mechanical effect on ice flow, although the relative importance of snowline elevation versus flow

effects is likely to depend on the amplitude and spacing of individual mountain peaks and troughs (Marshall and Clarke, 2000; Oerlemans, 2002).

Theoretical and numerical modeling studies have shown that tectonic uplift of widespread land areas above the equilibrium snowline can lead to the sudden, non-linear growth of glaciers and ice sheets, possibly leading to continental-scale glaciation. The rapid non-linear response is caused by albedo and height-mass balance feedbacks (North et al., 1983; Weertman, 1961) associated with the high reflectivity of snow and ice and the geometrical effect of a growing ice cap and its rapidly expanding net accumulation zone. The spatial scale of uplift appears to be a key factor in the potential response. For example, climate-ice sheet modeling studies have shown that broad uplift of an initially ice-free Antarctic interior can trigger sudden glaciation, provided the continent is already near a glaciation threshold (DeConto and Pollard, 2003b). In contrast, ice modeling studies of the effects of the Transantarctic Mountains on the East Antarctic Ice Sheet have shown that the uplift of individual mountains or the development of mountain troughs has limited influence (Kerr and Huybrechts, 1999).

Mountains, high plateaus, and atmospheric planetary waves

In mid-latitudes, zonal distributions of major landmasses and sea surface temperatures contribute to the position of standing atmospheric planetary waves via their influence on dominant low-level pressure patterns. Large mountains belts (Himalaya and Rocky Mountains) and high plateaus also provide direct physical barriers to atmospheric flow, which induce these long planetary Rossby waves in the upper-level westerlies, recognizable by the well-known meridional meanders in the polar and sub-tropical jet streams. Rossby waves form as a consequence of the conservation of absolute vorticity. When a parcel of air (or water) is displaced from its original latitude or changes its thickness as it passes over a mountain range, it responds by changing its latitude (planetary vorticity) and/or its relative vorticity (tendency to rotate). The resulting oscillations in the mean flow about a given latitude produce long planetary waves which move westward relative to the flow. In the fast flow of the upper troposphere, the waves appear to move slowly eastward relative to the Earth's surface. In the Northern Hemisphere, the longest of these waves tend to become stationary or *locked* relative to major orographic features. Wave crests (ridges) form over the Rocky Mountains and Tibet where the westerlies are displaced poleward before turning equatorward in the lee of the mountains, forming atmospheric troughs at $\sim 70^\circ\text{W}$ and $\sim 150^\circ\text{E}$ (Figure P68). While the amplitude of the long waves is highly variable, higher elevations tend to increase the meridional component of flow (Nigam et al., 1988). Thus, atmospheric planetary waves in the Northern Hemisphere tend to exhibit higher amplitudes than those in the ocean-dominated Southern Hemisphere, where the upper-level flow is more zonal.

Because vorticity associated with curvature in the waveform produces convergence downwind of the wave's crest (ridge) and divergence downwind of the trough, high pressure and generally fair conditions tend to be maintained eastward of the ridge. Conversely, cyclonic flow, low pressure, and storminess are found east of the trough. Thus, the time-averaged position of the waves has a fundamental effect on regional climates, storm tracks, and precipitation patterns. For example, the general aridity of the American interior and storminess of the

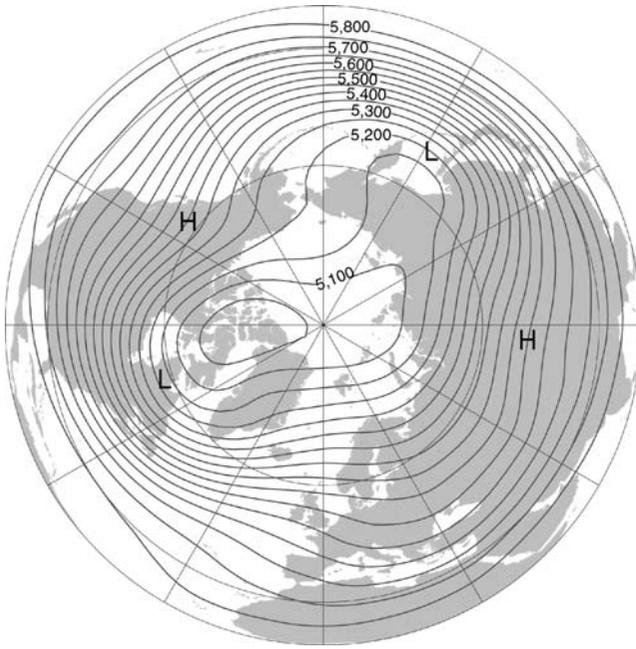

Figure P68 Seasonally averaged (DJF) 500 hPa geopotential heights over the Northern Hemisphere. Heights (shown in meters with 100 m contours) are calculated from 1971–2000 NCEP/NCAR reanalysis data, showing the time-averaged position of the dominant planetary wave pattern (see text for discussion).

U.S. East Coast can, at least in part, be attributed to the effect of the Rocky Mountains on the planetary wave pattern (Manabe and Broccoli, 1990). Further downstream, some of Western Europe's winter warmth can be attributed to the generally southwesterly flow over the relatively warm eastern North Atlantic, which is ultimately controlled by the standing wave pattern fixed by the Rockies (Seager et al., 2002). The standing wave pattern forced by the Rockies and Himalayas has also been implicated in establishing the conditions necessary for the onset of Northern Hemisphere glacial cycles in the Pliocene by allowing increased moisture advection from the warmth of the Gulf of Mexico and the western Atlantic to sites of Laurentide and Scandinavian Ice Sheet nucleation (Ruddiman and Kutzbach, 1989).

Uplift and monsoons

In addition to their effect on zonal airflow, the lower air densities associated with high elevations amplify seasonal temperature changes and vertical motions associated with monsoonal systems (rising and sinking air in summer and winter, respectively). This effect is thought to be largely responsible for the strength of the modern Asian-Indian monsoon system (Prell and Kutzbach, 1992) and modeling studies have shown that elevations roughly equal to half those of the modern Himalayan-Tibetan elevation are required to produce the strength of the southeast summer monsoon over India (Kutzbach et al., 1993). The Himalayan and Tibetan plateaus have also been implicated as an amplifier of orbital (Milankovitch) variability, whereby a combination of enhanced condensational heating over South Asia and dynamical effects associated with planetary waves significantly increases the monsoon's sensitivity to orbital forcing (Liu et al., 2003).

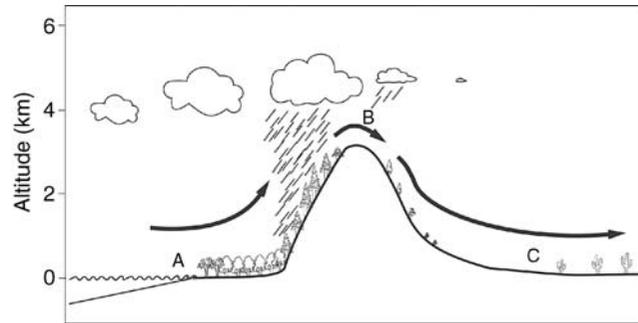

Figure P69 A schematic diagram showing the orographic precipitation and rain shadow effects of a mountain range. The *black arrow* represents air flow. Relationships between altitude, pressure, temperature, and absolute humidity control the distribution of precipitation, temperature and humidity on the windward and leeward side of the mountains. Typical temperatures and relative humidities of air at locations A, B, and C are $\sim 28^\circ\text{C}$ and 70%, 8°C and 100%, and 38°C and 25%, respectively (redrawn from Hay, 1996).

Rain shadows

In addition to their widespread radiative and dynamical effects, mountains can have important regional impacts – especially on precipitation. When air is forced upward as it passes over a mountain range, adiabatic cooling induces condensation of available water vapor, resulting in clouds and precipitation (Figure P69). Having lost some of its available water, sinking, dry air on the leeward flanks of a mountain range is adiabatically warmed, which is why arid and warm conditions tend to prevail downwind of mountain ranges. This *rain shadow* effect can extend hundreds of kilometers, with obvious implications for the distribution of vegetation and the formation of climate sensitive sediments, such as evaporites. This drying effect is strongest where air can descend back to (or below) its initial altitude after passing over a mountain range, as can occur in rift valleys. Due to the non-linear relationships between temperature, saturation vapor pressure, and air pressure, an air mass passing over a second mountain range (out of a rift valley, for example) will be warmer and capable of carrying more water vapor than it was before it entered the basin. The resulting net export of fresh water out of rift valleys may account for the wide latitudinal distribution of Phanerozoic evaporite deposits, which extends far outside the subtropical arid zones (see Hay, 1996).

The modern Andes provide an excellent example of the importance of orographic effects on regional precipitation. In mid latitudes dominated by the westerlies, precipitation is enhanced on the western side of the mountain range, while the Patagonian Desert lies to the east. In tropical South America, where the winds are generally easterly, the opposite pattern is found, with enhanced precipitation over the rainforests of the Amazon Basin and dry conditions along the coastal margin of the Andes. For example, the high altitude Atacama Desert in northern Chile, one of the driest places on Earth, lies between the Pacific Ocean and the foothills of the Andes at a latitude of about 20°S and within the influence of the easterlies.

Similar rain shadow effects may have been even more profound on ancient supercontinents, with large seasonal cycles and arid interiors already in place. In GCM simulations using a single, idealized supercontinent extending from the north to south poles and with meridionally-oriented coastal mountain

ranges running along the eastern continental margin, tropical precipitation associated with the trade winds and the ITCZ is intercepted on the seaward (eastern) flanks of the mountains (Figure P70). In a simulation with mountains running along the west coast of the supercontinent, continental precipitation is increased in tropical latitudes, while precipitation associated with cyclonic systems embedded in the westerlies falls mainly on the western slopes of the mountains (Hay et al., 1990b).

Mountain uplift or climate change?

In addition to tectonic, geomorphological, and structural studies, evidence of mountain uplift comes from records of continental denudation found in sediment accumulation rates (Hay, 1988) and marine records of $^{87}\text{Sr}/^{86}\text{Sr}$ (an indicator of chemical weathering (Richter et al., 1992)). Other techniques rely on the physiognomy of fossil vegetation (Royer, 2001), and oxygen isotopes in carbonate rocks (Garzzone et al., 2004) to constrain the ancient elevations of specific locations. It should be noted that the term “uplift” can be used to describe the uplift of a region of the Earth’s surface (with respect to the geoid) or the uplift of rocks (with respect to the surface). Depending on erosion rates, the uplift of rocks relative to the local surface, sometimes referred to as “exhumation” (England and Molnar, 1990), can be much greater than the uplift relative to the geoid. Erosion and the removal of mass from mountain valleys can actually raise the surrounding peaks through isostasy (Molnar and England, 1990). In the Alps and Himalayas, loss of mass in deep fluvial and glacial valleys has been estimated to account for up to 25% of the elevation of the highest mountains (Hay et al., 2002; Montgomery, 1994). Because chemical and

physical erosion rates are ultimately controlled by the combined effects of surface relief and climatic parameters such as seasonality, precipitation, and glaciation, observed increases in the delivery of sediment to basins and continental margins can be attributed to climate change, mountain uplift, or both. The paradigm of Cenozoic uplift causing global cooling and Northern Hemisphere glaciation was challenged by Molnar and England (1990), who argued that the appearance of recent uplift in a number of disparate mountain ranges may be an artifact of Cenozoic climate change rather than the cause of the cooling (see also *Mountain uplift and climate change*).

Can the atmosphere drive tectonic processes?

The potential for the atmosphere to be a driver of tectonic processes has only recently begun to be appreciated. In addition to the processes mentioned above, whereby erosion in mountain valleys can raise mountain peaks, differential erosion rates on the windward (wet) versus leeward (dry) flanks of mountains and latitudinal climate gradients can cause structural asymmetries that influence the morphological evolution of entire mountain ranges. This effect has been proposed for the Andes (Montgomery et al., 2001), where structural asymmetries and latitudinal changes in crustal thickness correlate with climatically-controlled erosion patterns. Furthermore, progressive Cenozoic cooling and associated increases in wind stress, upwelling intensity, and cooler sea surface temperatures along the South American margin may be enhancing rain shadow aridity along the Chilean and Peruvian margin. The resulting decrease in precipitation and runoff is thought to be starving the adjacent convergent plate boundary (subduction zone) of lubricating sediment, thus contributing to the stresses supporting the high Andes (Lamb and Davis, 2003).

Plate tectonics and the global carbon cycle

While not the focus of this entry, the effects of tectonic processes on geochemical cycling and atmospheric greenhouse gas concentrations should be considered in any discussion of plate tectonics and climate change. Primary inputs of CO_2 include mantle outgassing at sea floor spreading centers and volcanoes, metamorphism of carbonate rocks along subduction zones, and respiration and burning of organic matter. Long-term sinks for CO_2 are controlled by the burial of organic matter and by the weathering of silicate rocks to form carbonates (Berner and Kothavala, 2001). Cenozoic mountain building, particularly the uplift of the Himalayan-Tibetan Plateau, has been related to CO_2 drawdown, cooling, and glaciation via increased weathering rates and the effects of increased nutrient delivery on ocean productivity and organic carbon burial (Chamberlin, 1899; Filipelli, 1997; Raymo et al., 1988). While the actual mechanisms responsible for CO_2 drawdown on tectonic timescales are complex and continue to be debated, geochemical reconstructions of Cenozoic CO_2 levels do show a dramatic decrease in atmospheric mixing ratios from more than three times present day levels during the warmth of the Eocene, to near modern levels by the early Miocene (Pagani et al., 2005).

Volcanism and large igneous provinces

Volcanism, often associated with tectonic processes, can also play an important role in climatic change. In addition to outgassing CO_2 , an important greenhouse gas with the potential to raise global temperatures, magma can be rich in SO_2 , which can lead to the production of sulfuric acid (H_2SO_4) aerosols in the atmosphere. When injected into the stratosphere via

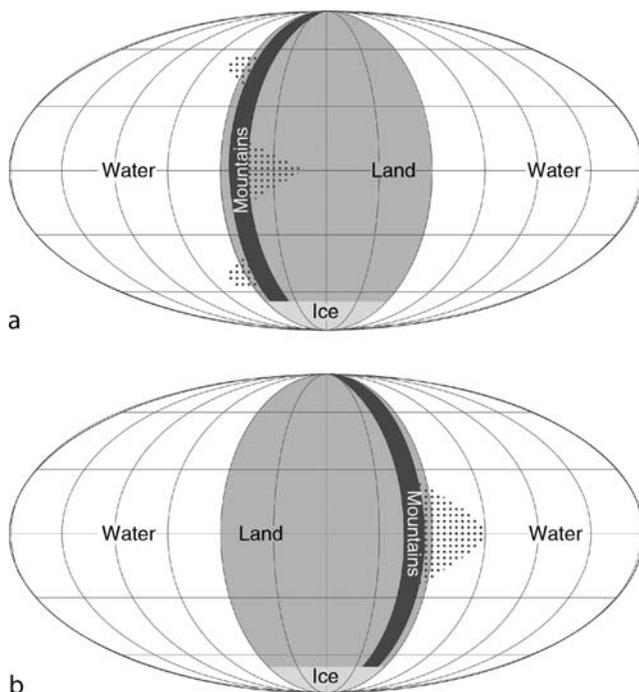

Figure P70 The distribution of maximum precipitation rate (stippling) in GCM simulations of a planet with a single supercontinent and a meridional mountain range oriented on either the western (a) or eastern (b) continental margin (redrawn from Hay, 1996 and based on GCM simulations described in Hay et al., 1990a).

energetic volcanism, sulfur aerosols are highly reflective to incoming short wave radiation from the Sun, providing a cooling effect on the troposphere and Earth's surface. In 1991, the SO₂-rich eruption of Mt. Pinutubo in the Philippines cooled the Northern Hemisphere by 0.5–0.6 °C (Hansen et al., 1996) and the recent frequency of volcanic events may account for some of the variability recognized in highly resolved climate reconstructions of the Holocene (Mann et al., 1999). Global cooling associated with each injection of stratospheric aerosols is generally limited to a few years. On longer timescales, the atmospheric CO₂ loading associated with pervasive volcanism could have a net warming effect, complicating estimates of the net global environmental impacts of the larger and most long-lived volcanic events in Earth history.

The prolonged, effusive emplacement of mafic magmas to form large igneous provinces (LIPs) is usually associated with plate tectonic processes including uplift and continental rifting. LIPs can be continental or oceanic, and large oceanic LIPs, such as the Ontong Java Plateau in the western Pacific, can contain more than 50 million km³ of volcanic and plutonic rocks. The episodic emplacement of LIPs has occurred throughout Earth history; although most surviving examples of continental and oceanic flood basalts are Mesozoic and Cenozoic in age (see *Flood basalts, climatic implications*). While the timing of some emplacement events has been directly associated with climate change (Mahoney and Coffin, 1997), LIP-climate connections are highly complex. In addition to their effect on sea level, LIP and mid-ocean ridge volcanism can release CO₂, SO₂, Cl, F, and H₂O into the atmosphere with significant climatic consequences. For example, the overall warmth of the Cretaceous period has been attributed, at least in part, to a combination of high atmospheric CO₂ and high sea level, with times of peak warmth and ocean anoxia associated with LIP emplacement (Larson and Erba, 1999; Leckie et al., 2002). While a number of studies have related LIP emplacement to extinction events (Rampino and Caldeira, 1993), the specific mechanisms causing environmental stress are difficult to tease apart and may be due to the direct effects of LIPs on climate, the biotic effects of toxic atmospheric fallout (i.e., acid rain), or some combination of the two.

The Neoproterozoic *Snowball Earth* provides another example of indirect tectonic-climate linkages through volcanism. Between ~750 and 580 Ma, the Earth is thought to have been episodically completely covered by ice, with some glaciations lasting for millions to tens of millions of years (Hoffman et al., 1998). While the evidence of significant ice at the equator remains controversial, tectonic processes (largely through volcanism's contribution to atmospheric CO₂) play a central role in most theoretical models of both the onset and demise of the snowball. First, a prolonged period of tectonic quiescence and minimal outgassing is thought to have allowed CO₂ concentrations to drop below some critical threshold, initiating a powerful ice-albedo cooling feedback (Schrage et al., 2002). The continental breakup of Rodinia (a Proterozoic supercontinent), and associated changes in runoff and weathering have also been linked with a decline in CO₂ around this time (Donnadieu et al., 2004). As the Earth cooled, expanding ice sheets and sea ice would have increased planetary albedo. As shown in simple energy balance model (EBM) experiments, the ice-albedo feedback becomes unstable once snow and ice reach ~30° North and South, resulting in the sudden expansion of ice to the equator (Budyko, 1968). Once the Earth was completely covered by ice, continental weathering of silicate rocks,

a long-term sink for CO₂, would have been greatly reduced. This would have allowed atmospheric CO₂ to accumulate to levels sufficient to cause significant warming, although additional warming mechanisms including the presence of other greenhouse gases and/or other feedbacks may have been necessary to trigger deglaciation (Pierrehumbert, 2004).

Summary

A number of tectonic processes are linked both directly and indirectly to a wide range of climate forcings, so the direct role of plate tectonics in specific ancient climate events is often difficult to decipher. In addition to the direct climatic effects of horizontal and vertical tectonics discussed here, paleogeography strongly influences the climate system's sensitivity to external forcing and provides the basic framework for studying ancient climate change over geological timescales.

While the relative contributions of greenhouse gas concentrations and plate tectonics in the evolution of the Earth's climate continues to be debated, tectonic processes influence the composition of the atmosphere, so the two cannot be entirely separated. Tectonically forced changes in ocean and atmospheric circulation have greatly influenced the evolution of specific regional climates; however, their potential to produce the full range of global climatic variability recognized in the geological record may not be as great as once suspected.

Lastly, while tectonic processes are usually associated with slowly evolving environmental change, there are important exceptions. Volcanism's essentially instantaneous effect on the atmosphere provides one example. Less obvious is the climate system's potential to respond non-linearly to the most gradual tectonic forcing, with sometimes sudden and extreme consequences. Thus, plate tectonic processes should be considered a potential climate forcing mechanism on all timescales.

PLEISTOCENE CLIMATES

Introduction

In the search to understand Pleistocene climates, it is necessary to reconstruct “horizontal” time slices representing the surface of the Earth from which the prevailing climate may be inferred, and to mesh them with “vertical” time-series data, primarily from ocean, ice and lake cores, to understand processes involved. These include forcing functions and their consequential fluxes of heat and moisture as they are propagated through the complex systems of the atmosphere, oceans and biosphere. Ultimately, it will be a meshing together of these two thrusts that may bring about a more comprehensive understanding. The past decade has witnessed major advances in the field, especially in greater understanding of lateral connections and phase relationships. However, modeling of climates has lagged behind other advances and no model has yet simulated the millennial variability of Pleistocene climates as inferred from high-resolution records.

Pleistocene climates have varied in time and space and are inferred from a wide range of evidence on the continents and in the oceans. They reflect the evolution of the climate system over the last 2.4–2.5 Ma, more or less under the same boundary conditions as today with regard to the present configuration of continents and oceans, location of mountain ranges, high plateaus, and ocean seaways. The major prelude to the Pleistocene epoch, around 3 million years ago, was a transition from relatively milder Pliocene climates to cooler ones, strongly affected by the closure of the Straits of Panama (Figure P71). This changed a zonal circulation of ocean surface water into a meridional one, thus providing precipitation to nourish the high latitude ice growth that duly followed (Figure P71). The earlier part of the Pleistocene, until about a million years ago, was dominated by ice age cycles of low amplitude but relatively high frequency at 41,000 years (obliquity – see below), whereas since that time the climate has been dominated by high amplitude cycles of longer, 100,000 year, frequency (eccentricity – see below). The cause of the change in climate pacing is still uncertain: the role of large mid-latitude ice sheets, such as the Laurentide, may have had a role in affecting the circulation of the atmosphere; or there may have been a long term trend in decreasing atmospheric carbon dioxide.

The latest findings show that in order to understand Pleistocene climates it is necessary to examine them in relation to the forcing associated with several interacting timescales, from orbital to millennial to interannual (Cronin, 1999).

No significant speciation occurred during the Pleistocene because of the rapid reversals in climate, although a major exception was hominid speciation in Africa that may have been a response to intensified Northern Hemisphere glaciation and the rigors of repeated and enhanced aridity in tropical Africa (deMenocal, 1995) (Figure P71).

History

Traditional appreciation of Pleistocene climates involved a concept of four major ice ages (glacials) when ice sheets grew at middle latitudes of the Northern Hemisphere. “Interglacial” climates in between them were similar to that of the present. During the ice ages, the snowline dropped spectacularly (Figure P72),

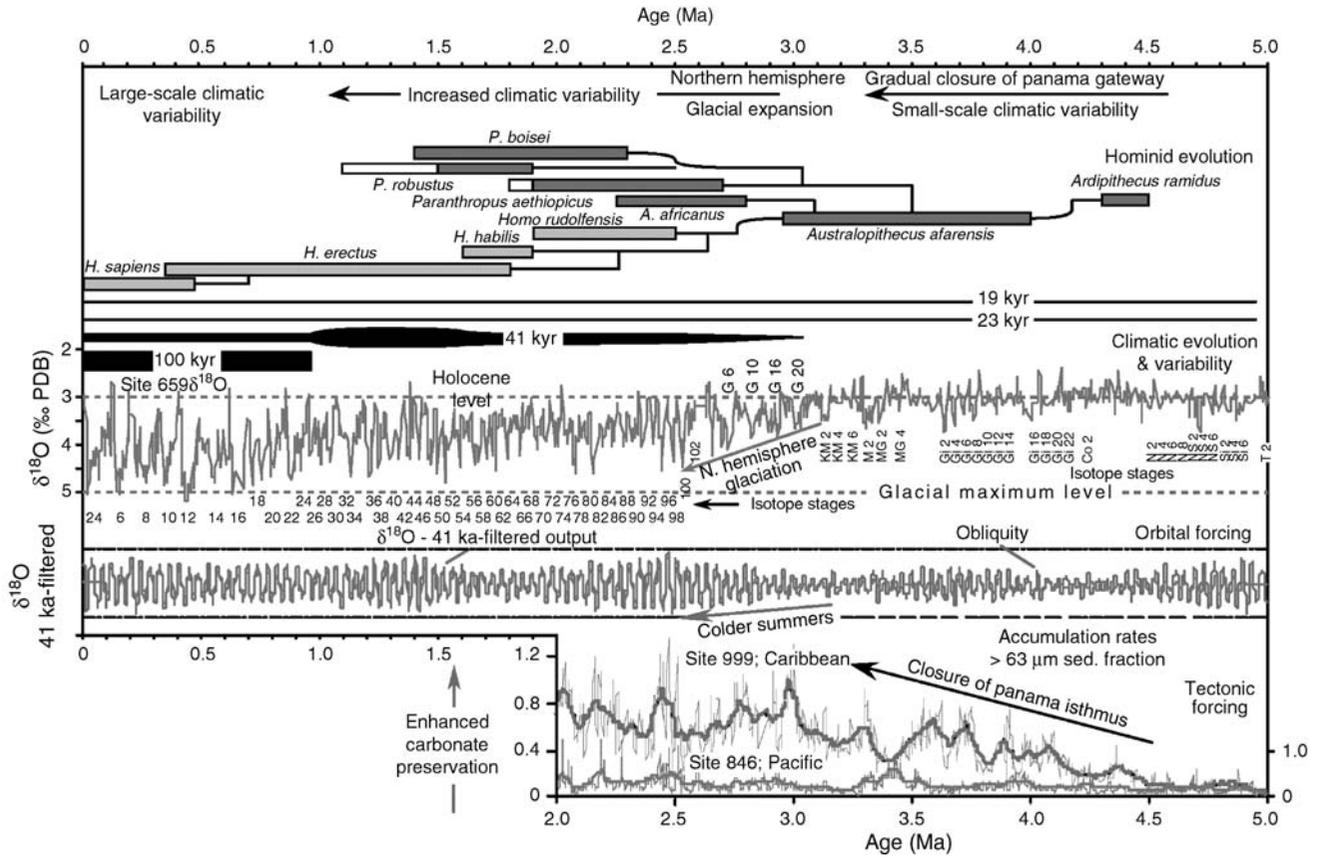

Figure P71 Evolution of climate over the past 5 million years. *Top panel* shows hominid speciation in Africa and its possible relationship to major climate events. *Middle panel* shows the detailed climate record from deep ocean core ODP 659 (offshore from northwest Africa) inferred from oxygen isotope measurements on benthic foraminifera, which shows coherence with orbital forcing frequencies of axial tilt (41,000 years), precession (23,000 years) and eccentricity of the orbit (100,000 years). Stages are oxygen isotope stages numbered backwards in time: even numbers are glacials and odd numbers interglacials. *Bottom panel* shows the effect of the closure of the Straits of Panama on calcium carbonate preservation (Zahn, 2002).

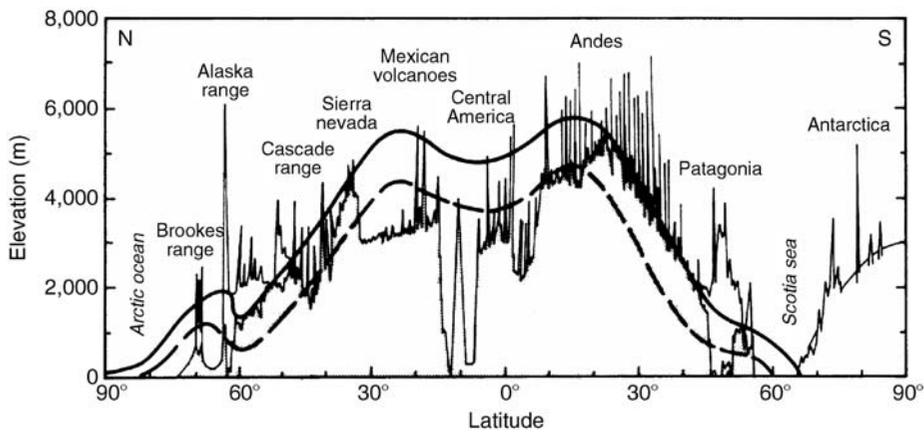

Figure P72 Meridional transect along the cordillera of the Americas (Broecker and Denton, 1989). The present snowline is shown by the *heavy line* above which are present glaciers. During the Last Glacial Maximum the snowline was depressed (*dashed line*) and the area occupied by ice correspondingly increased.

the albedo of the Earth increased strongly, and vegetation and climatic zones were telescoped between continental ice sheets in the north and wetter ("pluvial") conditions in the near tropics and tropics.

Conceptual reconstructions or climate schema were zonal in character: southward of the ice sheets in Europe were climate zones corresponding to tundra, loess steppe and evergreen forest. Some mixed oak deciduous forest occurred in the Mediterranean area or in favorable areas called "refugia." At lower latitudes, wetter, "pluvial" climates appeared as the tropics contracted. However, in North America, where moist tropical maritime air from the Gulf of Mexico was channeled northwards between the Appalachians and the western Cordilleran mountain system, a more complicated mosaic pattern of vegetation prevailed. Thus, the existence of large, high domed ice sheets not only influenced the Earth's albedo, but maintained quasi-permanent anticyclones, which influenced the circulation of the atmosphere and contracted the zonal climatic belts.

Interglacials, when ice sheets melted and sea level rose, witnessed a return to climates not greatly unlike that of the present (Holocene) interglacial. Although the characteristics of successive interglacials have yet to be established definitively, it is assumed that vegetation zones were similar to the present.

The four-fold ice ages concept, together with some indications of earlier Pleistocene complexity, was based on geologic evidence in Europe and North America for major expansions of continental ice sheets marked by moraines and outwash terraces. Interglacials were inferred from temperate vegetation provided by pollen analysis in Europe or from paleosols in America that evolved under deep chemical weathering. These ideas dominated thinking during the twentieth century up until the 1970s. All evidence for climate and climate change was pigeonholed into what came to be seen as a straitjacketed classification of Pleistocene climates. Even contrary indications from back-calculated variations in the orbital configuration of the Earth, and evidence from the earliest ocean cores, was forced into the prevailing classification.

Techniques

Technological advances in obtaining long cores through oceans sediments, ice sheets and lake basins, together with new analytical techniques, have revolutionized the field since the early 1970s (Cronin, 1999). Geochemical measurements have elucidated the record preserved in deep ocean sediments: oxygen isotope measurements ($^{18}\text{O}/^{16}\text{O}$) on benthic and planktic microfossils (mostly foraminifera) have allowed inferences to be drawn about the isotopic composition of the ocean that is directly related to the volume of isotopically lighter ice on the continents, and indirectly to sea level fluctuations. Carbon isotopes in fossil shells (^{13}C) reveal patterns of productivity in the oceans and the strength and direction of intermediate and bottom ocean circulation. Nitrogen isotopes indicate nutrient inventories. Surface or near-surface dwelling plankton provide estimates of former sea surface temperatures (SSTs) using transfer functions that compare the fossil record with core top faunas assumed to represent the present day. This, however, is being superseded by the use of SST temperature-dependent Mg/Ca ratios fixed in the shell during life. A further developing tool is alkenone thermometry derived from fossil phytoplankton from sediment cores. This provides not only information about sea surface temperatures, but also regarding primary productivity and atmospheric carbon dioxide levels in the past. Finally, sedimentological techniques indicate current

speeds as well as the provenance of ice-rafted debris and other sediment derived from the continents.

Oxygen isotope ($\delta^{18}\text{O}$) measurements on layers of ice from ice cores reveal the temperature of snow deposition; greenhouse gas concentrations are measured from bubbles of air within the ice, and the nature and derivation of various aerosols provide insight into wind direction and intensity (Alley, 2000).

Continental data are obtained from the fossil record of flora and fauna preserved in different environments such as peat, lake, and cave sediments. Because of the relative lack of speciation, most of the fossil record is used for paleoecologic reconstruction. Such reconstructions of Pleistocene environments as time slices across major areas provide a broad-brush reflection of the prevailing climate.

Common to all evidence is the need for a precise geochronology to determine the age of isolated pieces of evidence as well as for dating continuous sequences of change. Most methods, however, have inherent uncertainties, limited age ranges and, sometimes, spatial limitations (Cronin, 1999).

Orbital cycles

The most fundamental change in understanding of the last thirty years or so has been the result of $\delta^{18}\text{O}$ measurements on benthic and planktonic fossils from ocean cores, interpreted as showing major changes in ice volume on the continents, and a more complex evolution of the climate system than was suggested by classical concepts of the Pleistocene.

Essentially, such measurements in all ocean basins showed that some 50 ice ages and interglacials had occurred over the last 2.5 Ma or so (Figure P71). This alone shows that rates of climate change were much more rapid than previously thought. This has compelled a re-thinking of the climate system and what forced it, and in 1976 it was shown that back-calculations of variations in the Earth's orbit matched the deep-sea evidence for ice ages (Imbrie and Imbrie, 1979). This study marked a turning point and evidence of all kinds became interpreted in terms of the 100,000 eccentricity, the 41,000 obliquity and the 23,000 and 19,000 precessional paces of the Earth's orbital parameters (Figure P71). Precise dating of the marine isotopic record is still hindered by an insufficient number of age markers. Those provided by paleomagnetic reversals serve to subdivide the record but on a relatively crude scale: for example, the Matuyama-Brunhes reversal at 790,000 years B.P. occurs in oxygen isotope stage 19, but ages for subsequent ice ages and interglacials are provided only by assuming constant sedimentation and/or the "tuning" of the sedimentary record with orbital parameters using theoretical phase relationships between the timing of insolation changes and oxygen isotope (ice volume) response (e.g., see *SPECMAP*). In the absence of adequate dating controls, debate continues, for example, on the age of the last interglacial, despite its high sea level on global coastlines, especially in the low latitude coral belt where orbitally-tuned ages suggest an age between 128,000 and 118,000 years. On the other hand, many uranium series ages suggest it occurred between 135,000 and 116,000 or even 113,000 years. The latter corresponds with a chronology for the last interglacial from earlier ice flow models from the Vostok ice core, but also from the Devil's Hole calcite vein in Nevada.

The stratigraphic framework provided by oxygen isotope stratigraphy led to attempts to map the surface of the ice age Earth at the Last Glacial Maximum (LGM) by the CLIMAP group

(Imbrie and Imbrie, 1979). One of the findings of the CLIMAP ocean reconstructions was that ice age tropical SSTs did not fall greatly relative to the present. However, since then it has been shown that tropical SSTs were considerably cooler than at present. Continental reconstructions, however, lagged behind because of the fragmental nature of the record, often of insufficiently high quality. Indeed, land-sea correlations remain as one of the greatest challenges.

Some of the earliest land-sea correlations were between marine oxygen isotope stratigraphy and the loess sequences of Central Europe and China. Ice ages were indicated by loess deposition in arid environments and interglacials were indicated by soil development. The long loess sequences in China, as well as those offshore in the North Pacific, show that atmospheric dust was an important component of the changing climate system.

Better and longer pollen sequences on the continents questioned earlier precepts: for example, it was shown that temperate forest did not exist during the last ice age in the Mediterranean but instead steppic plant communities were extensive, with temperate forest survival in Balkan and Greek plant refugia. More significantly, much of the tropics and sub-tropical regions were shown to be arid rather than, as previously thought, wetter places. This compelled a review of the climate system and the role of the Hadley-Walker cells, the trade winds and Intertropical Convergence Zone (ITCZ) in a drier and cooler ice age world. The pollen record from some long lake sequences, for example in Greece, Colombia and Lake Baikal in Asia, matched the deep sea record and confirmed that Pleistocene vegetation patterns pulsed primarily to the orbital beat as the result of changing seasonality and insolation. The 41,000-year obliquity forcing was dominant at mid to

high latitudes, especially in influencing ice sheet growth and decay, whereas precession (23,000 and 19,000 years) was dominant at lower latitudes.

Although much is now known about the last glacial cycle, aided to a large extent by the availability of ^{14}C ages for the past $\sim 40,000$ years, relatively little is known in detail before the last interglacial (oxygen isotope sub-stage 5e or event 5.5 of the marine record). Currently some emphasis is placed on oxygen isotope stage 11, the interglacial some 400,000 years ago, because of its orbitally similar configuration to the current (Holocene) interglacial (Droxler et al., 2003). However, relatively little is known about major continental areas during other ice ages and interglacials.

Millennial cycles

Although the evidence for sub-orbital pacings had been long available from the Camp Century drill hole in Greenland (Dansgaard et al., 1969), it was not until additional ice cores were recovered that their millennial time scale records were appreciated, especially the 1,450 or 1,500 year pacing (Alley, 2000; Bond et al., 2001). These Dansgaard-Oeschger (D-O) cycles, with the warmer events called interstadials and colder ones stadials, are grouped into saw-toothed packages of increasing cold that are terminated by rapid warming events. Rapid changes in temperatures at the surface of the ice sheets occurred in less than a decade. The pattern of square-wave climate changes shown by the ice core records is matched by evidence from high sedimentation cores in the North Atlantic of SSTs inferred from the polar-dwelling foraminifer *Neogloboquadrina pachyderma* (s.) and oxygen isotope variability (Bond and Lotti, 1995). The evolution of these cycles has been

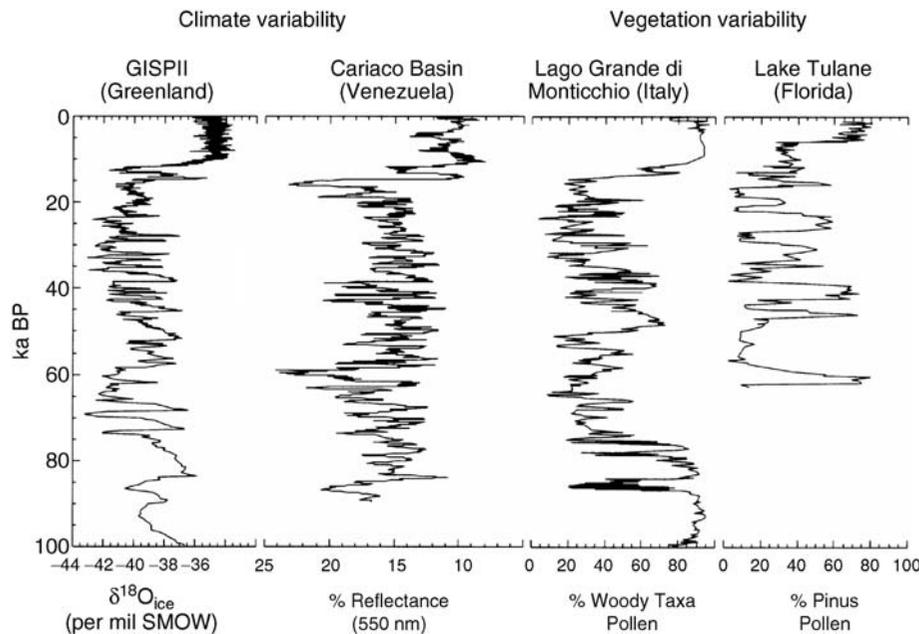

Figure P73 Four records showing millennial time scale variability over the last glacial cycle. The Greenland record of oxygen isotope variability shows the last 10,000 years of the present (Holocene) interglacial with which the warmer climates of the last glacial cycle (interstadials) alternate with colder ones (stadials). The offshore Cariaco Basin records influxes of minerals (high reflectance) from South America during stadials. In Italy and Florida, the changing vegetation, inferred from the fossil pollen record, shows similar variability, including cooler climates during Heinrich events (Overpeck et al., 2003).

attributed to oscillations in the strength of heat delivery by the Atlantic thermohaline circulation that caused changing temperatures at the ice sheet surface (Alley, 2000). Others have pointed to a solar connection because oxygen isotope variability in ice cores corresponds with similar variability in the concentration of the cosmogenic isotope ^{10}Be , which indicates changes in solar irradiance (Rind, 2002). Corresponding with the rapid warming at the end of Bond Cycles (Bond and Lotti, 1995), layers of ice-rafted debris (IRD), representing “Heinrich events” occur in marine cores. Deposited from “armadas” of icebergs discharged into the North Atlantic (Broecker, 1994; Bond and Lotti, 1995), IRDs indicate collapse and surging of ice sheets into the tidewater zone. Because they do not correspond with every D-O package of events, it is likely they were partly forced by climate, but only occurred when appropriate glaciological conditions for collapse and surging existed.

Greenland and Antarctic ice cores contain bubbles of air from which the near-contemporary concentrations of atmospheric greenhouse gases (CO_2 and CH_4) can be measured (Alley, 2000). Spikes of CH_4 provide a means of correlation of the oxygen isotope temperature record between Greenland and Antarctica and allow phase relationships between the

Northern and Southern Hemisphere polar regions to be explored. The pattern of greenhouse gas variability pulsed on both orbital and millennial time scales. When correlated with other evidence, they confirm previous inferences of a cooler and more arid Earth during the ice ages, with relatively lower atmospheric concentrations (~ 180 ppm) of carbon dioxide, and warmer interglacial conditions with relatively higher (~ 280 ppm) concentrations.

Further evidence that all the Earth’s systems pulsed at millennial timescales is available from a wide range of environments that show that atmospheric patterns changed rapidly: for example, in the lake systems of western North America, and monsoonal climates in India, Asia and South America (Clark et al., 2001). Figure P73 (Overpeck et al., 2003) shows the GISP2 (Greenland Ice Sheet Project 2) $\delta^{18}\text{O}$ temperature signal with packages of D-O pacings that end with a rapid warming. These pacings at 1,450 years continue, with reduced amplitude, into the present (Holocene) interglacial (Bond et al., 2001). The reflectance characteristics of sediments from the Cariaco Basin, offshore of Venezuela, record major changes in the hydrologic systems of the tropical Atlantic. Increased precipitation and river discharge from northern South America

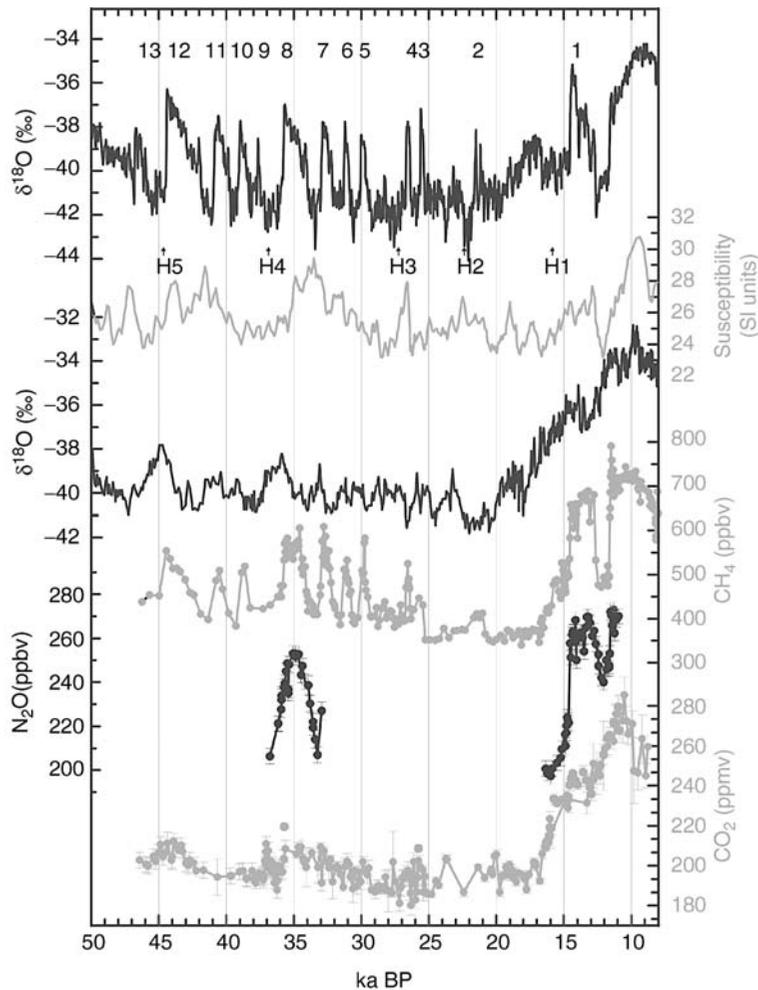

Figure P74 Greenland and Antarctic ice core records and Loess in China show millennial pacing for variability in temperature, carbon dioxide, methane, nitrous oxide and the East Asian monsoonal over the past 50,000 years (from Raynaud et al., 2003).

correspond with interstadial (warmer) events, which suggests higher moisture fluxes from the Atlantic to the Pacific, interspersed with lower precipitation (light colored sediments) as the Intertropical Convergence Zone migrates south during colder stadials. Note the rapid changes in vegetational stability in Italy and Florida that are correlated with D-O events.

Figure P74 shows millennial scale changes from different sources (Raynaud et al., 2003). From top to bottom: temperature variability as shown by the Greenland (GRIP) oxygen isotopic record; record of the Asian summer monsoon from magnetic susceptibility of Chinese loess, peaks indicate times of strong monsoons; temperature variability as shown by the Antarctic (Byrd station) oxygen isotope record; the methane record from Greenland; the N₂O record from Greenland; and the CO₂ record from Antarctica (Byrd station). Note that the Greenland and Antarctic records have been correlated by global methane spikes. Numbers 1–13 indicate Dansgaard-Oeschger (D-O) events in the Greenland record, while H1–H5 indicate Heinrich events.

Clearly, different sub-systems that were widely separated pulsed at the 1,450 pacing. Millennial variability at a global scale shows that climate signals are transmitted rapidly throughout the entire system. However, is this compatible with heat distribution by ocean thermohaline circulation? To what extent does the atmosphere play a role in the advection of heat and moisture from low latitude tropical oceans, notably the Pacific Ocean (Cane and Clement, 1999)?

Sub-millennial changes

Some of the answers to the questions raised above may come from records of sub-millennial changes in climate on inter-decadal or inter-annual timescales of physical annular modes of variability. These include records of the transfer of heat and moisture by Indian, African and Asian monsoons, El Niño (ENSO), North Atlantic Oscillations (NAO), Arctic Oscillation and Antarctic Oscillation. These are all interconnected in transporting heat from tropical oceans to higher latitudes. Their teleconnections are complex and may be driven in part by variability in solar irradiance as well as eccentricity-modulated precession. Cane and Clement (1999) have suggested that scaling El Niño (ENSO) events may well provide explanations for variability in large-scale Pleistocene climates. This may also account for the “stage 11 problem,” the apparently disproportionate response of the climate system to weak eccentricity forcing. Perhaps low eccentricity may dampen precessional variability and concentrates heat in the low latitude tropical belt from where it is advected polewards.

Although there seems little doubt that discharges of freshwater from the Laurentide Ice Sheet influenced thermohaline activity in the North Atlantic Ocean during ice ages (Clark et al., 2001), it is otherwise undeniable that the concept of the North Atlantic, Greenland and Norwegian Seas’ thermohaline influence in redistributing heat is under challenge from the tropical Pacific as the main source of heat and moisture. Thus, 65° N, the “critical latitude” of Milutin Milankovitch, and the ocean thermohaline circulation climate signal carrier is challenged by data from the tropical Pacific Ocean.

This debate has rejuvenated the climatologic-paleoclimate link in the search for mechanisms of abrupt and rapid change for Pleistocene climates. Increasing interest in solar irradiance variability is the result of ongoing physical measurements as well as the record of variability inferred from cosmogenic isotope abundances in ice cores. The not-unrelated role of cosmic

particles may also have a bearing on the elusive role of cloud and water vapor in climate variability on different timescales. Concepts of Pleistocene climates have been revolutionized in less than half a century and, while the Pleistocene past may hold a key to the present and future, its reciprocal, of the present being the key to the past, remains undiminished.

PLIOCENE CLIMATES

Introduction

The Pliocene (*Plio More – Cene Recent*) epoch represents the uppermost sub-division of the Tertiary period. It spans a time-frame from 5.3 to 1.8 million years before present, according to the geological timescale of Berggren et al. (1995). The epoch incorporates the time interval in which Earth experienced a transition from relatively warm climates to the prevailing cooler climates of the Quaternary period.

Climatically, the Pliocene can be crudely divided into three phases, (a) an Early Pliocene warm period, (b) a relatively short-lived ‘warm blip’ during the middle part of the Pliocene (centered around 3 million years before present), and (c) a climatic deterioration during the late Pliocene. It is important to realize that available higher resolution climate records for this time (e.g., Leroy and Dupont, 1994) suggest that even relatively short subdivisions of the epoch were characterized by almost continuous changes in precipitation and temperature, occurring on the timescale of several thousand years. This climatic variability is poorly resolved in terms of magnitude (Haywood et al., 2002a) but often occurred with detectable periodicities of 41,000 and 19,000, 21,000 and 23,000 years, linked to obliquity and precessional Milankovitch cycles (cyclic variations of the Earth’s orbital position; obliquity is the angle of Earth’s axial tilt as measured against the plane of the

ecliptic; precession is the degree of wobble of the Earth on its axis, which is caused by the gravitational pull of the Sun and the Moon). It is likely that many abrupt, short timescale climate events currently remain undetected due to the lack of high resolution and long paleoclimatic records, thus making the process of generalization regarding the climate of the Pliocene extremely hazardous.

Even though a progressive cooling was occurring during the Tertiary, the Pliocene world appears to have been, for the most part, warmer than at present. The ancient distribution of planktonic (free-floating marine organisms) and benthic (bottom-dwellers) foraminifer (minute aquatic organisms that consist of a single cell or a colonial aggregate of cells without differentiation of function) along with terrestrial fossil fauna and flora, indicates that mean annual temperatures in the mid-latitudes were often several degrees higher (3 °C to 5 °C) than at present (e.g., Thompson, 1991; Dowsett et al., 1996). The greatest warming appears to have been in the high latitudes and polar regions, where temperatures were often warm enough to allow species of animals and plants to exist at higher latitudes than their nearest modern relatives (Adam, 1994).

The recognition that significant warming took place at high latitudes and at the poles has interesting implications for the behavior and extent of sea ice, the major terrestrial ice sheets of Greenland and Antarctica, and for Pliocene sea levels.

Sea ice

Diatom (see *Diatoms*) data from the Southern Ocean (Barron, 1996), and foraminifer, ostracod (see *Ostracodes*) and mollusk (invertebrate of the phylum Mollusca) data (Cronin et al., 1993) suggest that sea ice extents were greatly reduced at approximately 3 million years before present, with modern summer sea-ice limits similar to Pliocene winter sea-ice cover and the possibility that the Arctic Ocean was seasonally sea-ice free (Cronin et al., 1993).

Ice sheets

Significant debate has centered on the nature of the terrestrial ice sheets of Greenland and Antarctica during the Pliocene. The consensus view, through examination of ice-rafted detritus (IRD) in marine sediment cores (e.g., Kleiven et al., 2002), is that the initiation of significant Northern Hemisphere glaciation began during the middle to late Pliocene. However, there may have been many false starts to this glaciation, with evidence existing for glacial activity on Greenland as far back as the late Miocene. Total ice volume on Greenland may have remained significantly less than at present even during the latter parts of the Pliocene epoch.

With regard to Antarctica, two contrasting viewpoints exist. The first, based on evidence derived from Pliocene marine diatoms (Harwood and Webb, 1986) and the remains of *Nothofagus* (Southern Beech) in the Sirius Group glacial sediments along the Transantarctic Mountain Range (Francis and Hill, 1996), suggests that the East Antarctic Ice Sheet (EAIS) may have been significantly reduced in size (by a maximum of one-third). The second, based on geomorphic investigations of the landscape in the Dry Valleys region, suggests that stable polar conditions have persisted for at least the last 14 million years (Denton et al., 1993). The dating of a variety of landforms including superficial till sheets, old desert pavements, avalanche deposits and volcanic ash layers that span the Miocene and Pliocene apparently testify to remarkably slow

rates of weathering and erosion in the Dry Valleys (Marchant et al., 1993). If the EAIS did behave in a dynamic manner, it is unlikely that such geomorphic features, if truly Miocene or Pliocene in age, would have survived.

Sea level

If terrestrial ice cover was reduced during the Pliocene, then global sea levels should also have been higher than at present. Evidence exists which indicates that sea levels were higher, although the potential errors in the data make it difficult to assess the true magnitude of sea-level change. Based on sequence stratigraphic techniques, sea-level highstands of up to 60 m were reported by Haq et al. (1987). Dowsett and Cronin (1990) used the presence of the Orangeburg Scarp (an extensive paleoshoreline from the southeastern U.S. Atlantic Coastal Plain) combined with micropaleontological evidence to suggest that a sea-level highstand of approximately 35 ± 18 m higher than present existed between 3.5 and 3.0 million years before present. The stratigraphic distribution of disconformities (type of unconformity where the buried erosion surface lies between two series of strata that are parallel on a large scale) at Enewetak Atoll suggests a Pliocene sea level 36 m higher than today's (Wardlaw and Quinn, 1991). Through the analysis and correlation of Atlantic Coastal Plain sediments with $\delta^{18}\text{O}$ (see *Oxygen isotopes*) isotopic records from deep-sea cores, sea levels between 4.0 to 3.5 million years ago and 3.0 million years ago have been estimated as 30–35 and 25 m higher than modern, respectively (Krantz, 1991). These sea-level changes appear to have been driven by glacio-eustatic events (see *Glacial eustasy*), but their precise correlation to changes in the polar regions remains unclear (Dowsett et al., 1996).

Climate dynamics and climate modeling

The use of numerical climate models, or General Circulation Models (GCMs), is one of the most powerful tools at our

disposal for the investigation of past climate dynamics. Numerous climate modeling studies have been conducted for the Pliocene using a host of different models of varying sophistication (see *Mid-Pliocene warming* this volume; Chandler et al., 1994; Sloan et al., 1996; Haywood et al., 2000a,b; Kim and Crowley, 2000; Haywood, 2001; Haywood et al., 2001; Haywood et al., 2002a,b,c; Haywood and Valdes, 2004). The focus of these modeling studies has been on the period of warming which occurred around 3 million years before present. This is primarily due to the wealth of geological and boundary condition data sets (necessary for the initiation of the climate model experiments) that exist for this period (see Dowsett et al., 1999).

Climate modeling – surface temperature ($^{\circ}\text{C}$)

Atmosphere-only climate model studies (experiments that do not include an interactive ocean model in any form) suggest that the climate of 3 million years before present was, as a global annual average, 2 to 5 $^{\circ}\text{C}$ warmer than at present (Sloan et al., 1996; Haywood et al., 2000a; see Figure P75). Three zones of temperature change were predicted in the climate modeling study of Haywood et al. (2000a). Between 10 $^{\circ}$ and 30 $^{\circ}$ North and South of the equator, the predicted warming was a modest 1 to 4 $^{\circ}\text{C}$. Between 30 $^{\circ}$ and 50 $^{\circ}$ in the Northern Hemisphere, temperatures warmed by 4–8 $^{\circ}\text{C}$. This pattern was not duplicated in the Southern Hemisphere, where the temperature rise was 0–4 $^{\circ}\text{C}$. By far the greatest relative warming was indicated at latitudes above 70 $^{\circ}$ in both hemispheres (Figure P76). Temperature changes relative to present in high latitude areas of the Northern Hemisphere during the winter period (December, January and February; DJF) ranged from 16–20 $^{\circ}\text{C}$ in Greenland to 20–28 $^{\circ}\text{C}$ in the Arctic. During DJF (Southern Hemisphere summer), dramatic warming in parts of west and east Antarctica (~32–36 $^{\circ}\text{C}$) was predicted. During June, July and August (JJA), Antarctica warmed in a

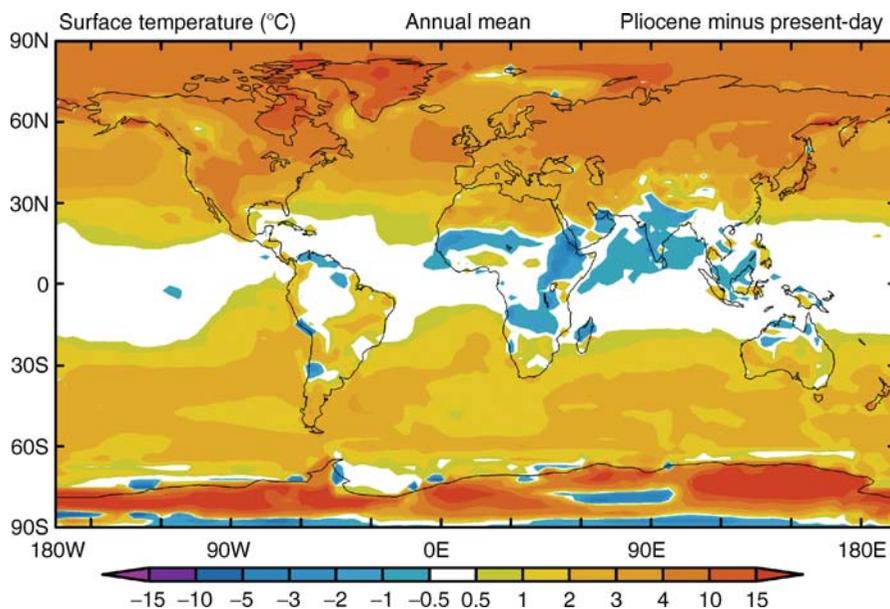

Figure P75 Climate model prediction: difference between simulated Pliocene (3 million years before present) and present-day surface temperature ($^{\circ}\text{C}$) as an annual mean (redrawn from Haywood et al., 2000a; Haywood, 2001). Model used was the Hadley Center Atmospheric Climate Model Version 3 (HadAM3), boundary conditions specified from the PRISM2 data set (Dowsett et al., 1999).

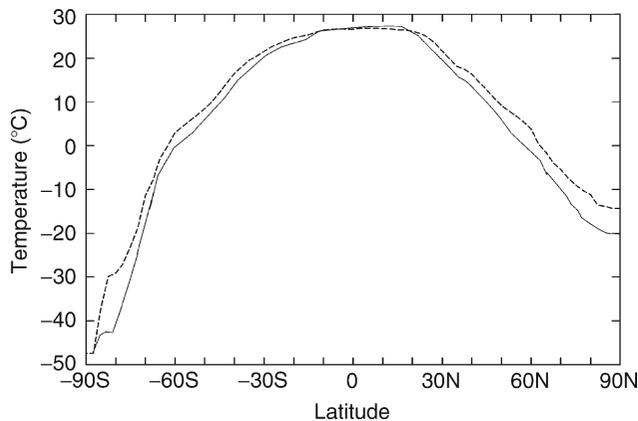

Figure P76 Model-predicted Pliocene (*dashed line*) and present-day (*solid line*) mean annual surface temperatures ($^{\circ}\text{C}$) plotted as a function of latitude. This plot indicates a surface temperature regime with reduced seasonality and greater equability during the Pliocene compared to present-day (Haywood, 2001).

comparable fashion to the DJF period ($20\text{--}32^{\circ}\text{C}$). However, the warming occurred over a significantly wider area of the continent.

The pattern of temperature change was not spatially uniform. During DJF, a zone of discontinuous cooling (maximum of 4°C) was predicted from 10° North to 10° South of the equator; this extended over parts of northern Australia and South America. During JJA, the equatorial/low latitude belt of cooling became more continuous, especially over parts of Africa and southern Asia. Temperatures in parts of Africa at 10° North of the equator cooled by 4 and 8°C as compared to the present.

The predicted high latitude warming ($>70^{\circ}$ North and South) can be attributed to a reduction of ice cover in both oceanic and terrestrial settings during the Pliocene and to the prescribed warmer high latitude sea surface temperatures (SSTs). Furthermore, the significance of a higher Pliocene sea level should not be underestimated. Oceans cool less than land when exposed to cold conditions, so higher sea levels act as a positive feedback mechanism for temperature, especially in the high latitudes (Sloan et al., 1996). The equatorial and low latitude cooling is due to more than one contributing factor. SST values for the oceans in equatorial and low latitudes are likely to have an effect, as are variations in cloud cover and vegetation in these areas. Increased precipitation promoting greater evaporation in this region acts as a cooling feedback. This is probably the main cause of the tropical cooling observed over Africa.

The GCM indicated that the greatest degree of warming occurred in the Northern and Southern Hemisphere during their respective winter seasons. This is attributable to the warmer SSTs in the mid to high latitudes, with associated changes in snow and ice cover.

Climate modeling – total precipitation rate (mm day^{-1})

The distribution of total precipitation during the Pliocene was simulated in Haywood et al. (2000a) and Haywood (2001) to be broadly similar to present (Figure P77). A general but modest increase, of between 0 and 2 mm day^{-1} , was predicted in both hemispheres during DJF and JJA. Although sporadic pockets of less rainfall (-2 mm day^{-1}) were common, especially during JJA, they were frequently not statistically significant. Annual mean precipitation during the Pliocene was $34.65\text{ cm year}^{-1}$,

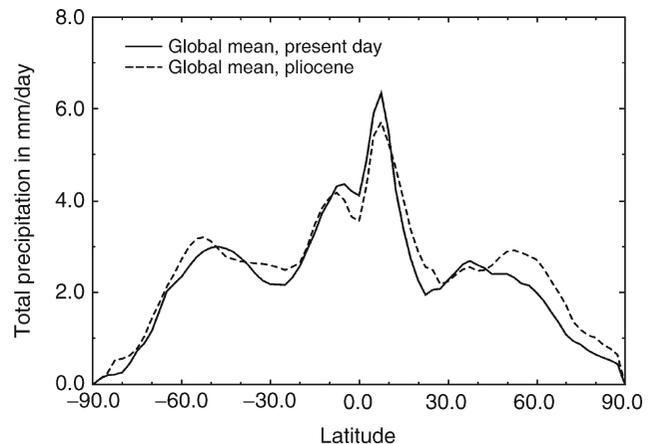

Figure P77 Annual mean total precipitation rate as a function of latitude for present-day and the Pliocene in mm day^{-1} (redrawn from Haywood et al., 2000a; Haywood, 2001).

2 cm higher than at present ($32.84\text{ cm year}^{-1}$), representing a 6% increase relative to modern values (Figure P77). During DJF in the Northern Hemisphere ($10^{\circ}\text{--}70^{\circ}$ North), areas of enhanced precipitation were noted (Figure P78). These areas include the Indian Ocean, the Caribbean, the North Atlantic and northwestern North America, where precipitation was enhanced by $2\text{--}8\text{ mm day}^{-1}$. The increase in mid-latitude precipitation in the Northern Hemisphere was associated with the warmer surface temperatures.

Increases in precipitation during JJA were seen to occur in a narrow belt at equatorial and low latitudes. India, Arabia, Central and West Africa, the Caribbean and the West Coast of Central and Latin America all showed an increase in precipitation of between 2 and 10 mm day^{-1} (Figure P78). The model indicated that the southern limit of the Hadley Cell (atmospheric cell which transports heat and momentum in the atmosphere at low-latitudes) was in approximately the same position as at present. However, the northern limit was shifted further to the North by 5° of latitude. The result was a net ‘broadening’ of the Hadley Cell in the Pliocene, which allowed more precipitation to fall over a larger geographical area. This change in the Hadley Cell was caused by the simulated reduction in the equator-to-pole temperature gradient (by 6°C). Broadening of the Hadley Cell explained several of the model’s responses observed at equatorial and low latitudes, such as increased precipitation, evaporation and subsequent reduction of surface temperatures.

Over Greenland, a statistically significant increase in precipitation was predicted, except over the southern tip of Greenland where precipitation decreased. This decrease was related to a shift in the position of the Atlantic storm track.

Climate modeling – wind (m s^{-1}) and surface pressure (hPa)

As a global annual average, surface wind strength decreased in the Pliocene experiment compared to the present. This response was consistent with the model-predicted reduction in the equator-to-pole temperature gradient of 6°C , which diminished the general circulation of the atmosphere. Most variations in wind dynamics were observed in the westerly component.

In the simulation, Pliocene wind directions were broadly similar to the present. Increases in wind speed were observed

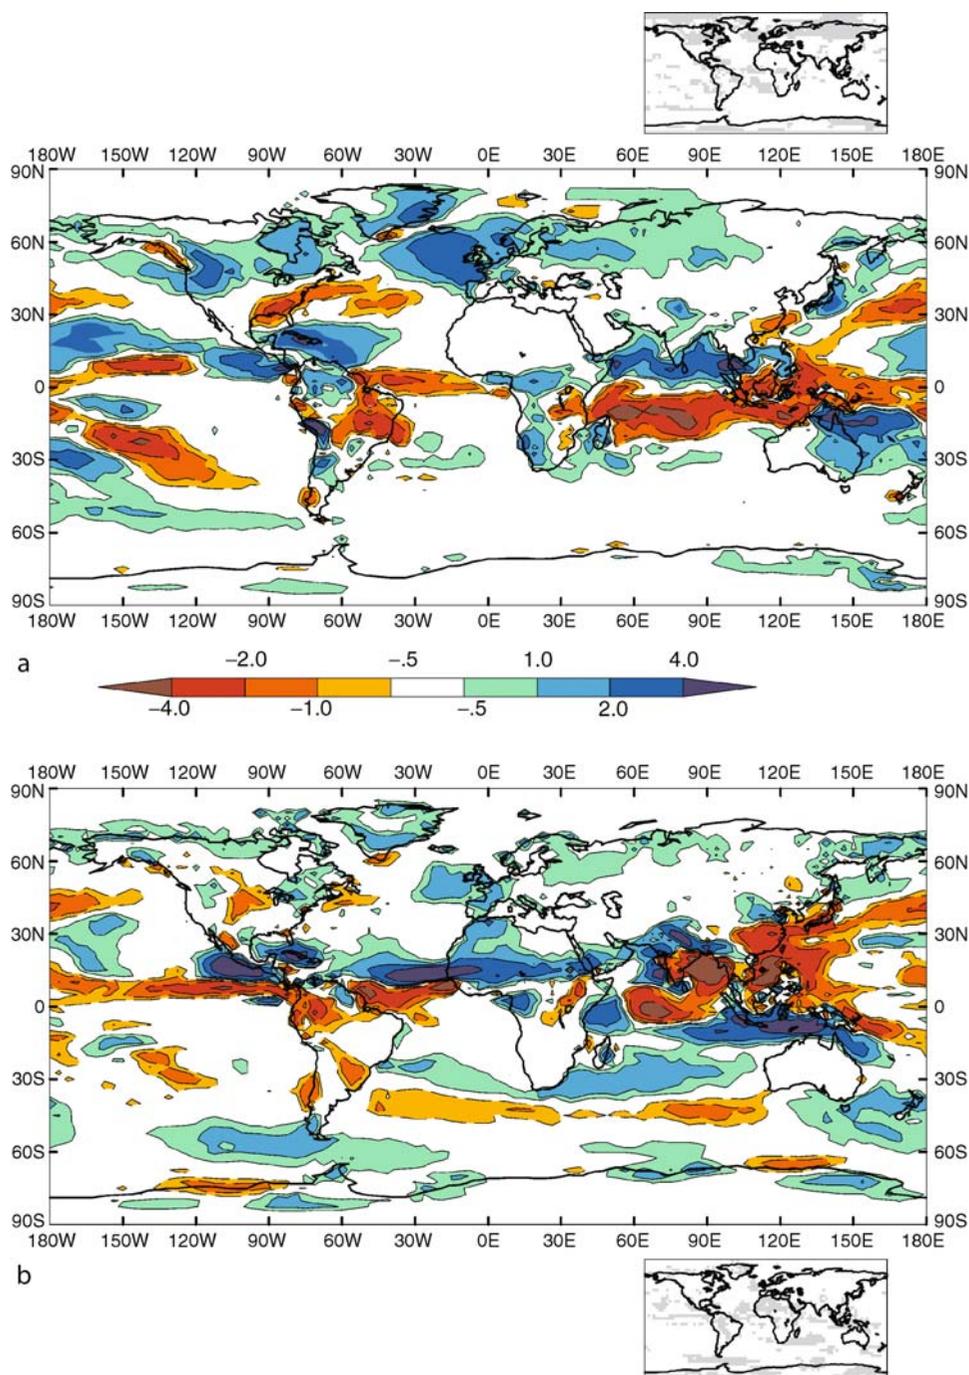

Figure P78 Model-predicted difference in mean total precipitation rate (mm day^{-1}) between the Pliocene and present-day for (a) DJF and (b) JJA. Note that the contour interval is not equally spaced and regions where precipitation change is less than 0.5 mm day^{-1} are unshaded. The grey shading in accompanying mini-boxes shows the geographical areas in which the difference in precipitation rate is significant to a 95% statistical significance level (redrawn from Haywood et al., 2000a; Haywood, 2001).

over areas of North America, Siberia and the Tibetan Plateau. This was a function of the altered land cover and surface heating characteristics of the Pliocene simulation as compared to the modern one. Wind strengths over the oceans exhibited a more dramatic change in the Pliocene scenario. Wind speeds increased by a maximum of 6 m s^{-1} during DJF in areas

affected by the Icelandic and Aleutian low-pressure systems. These pressure systems deepened in the Pliocene simulation as compared to the present (Figure P79).

Analysis of wind strength fields at 200 mbs indicated that the strength of the mid-latitude jet streams was enhanced in the Pliocene experiment. Increases in wind speeds in other locations

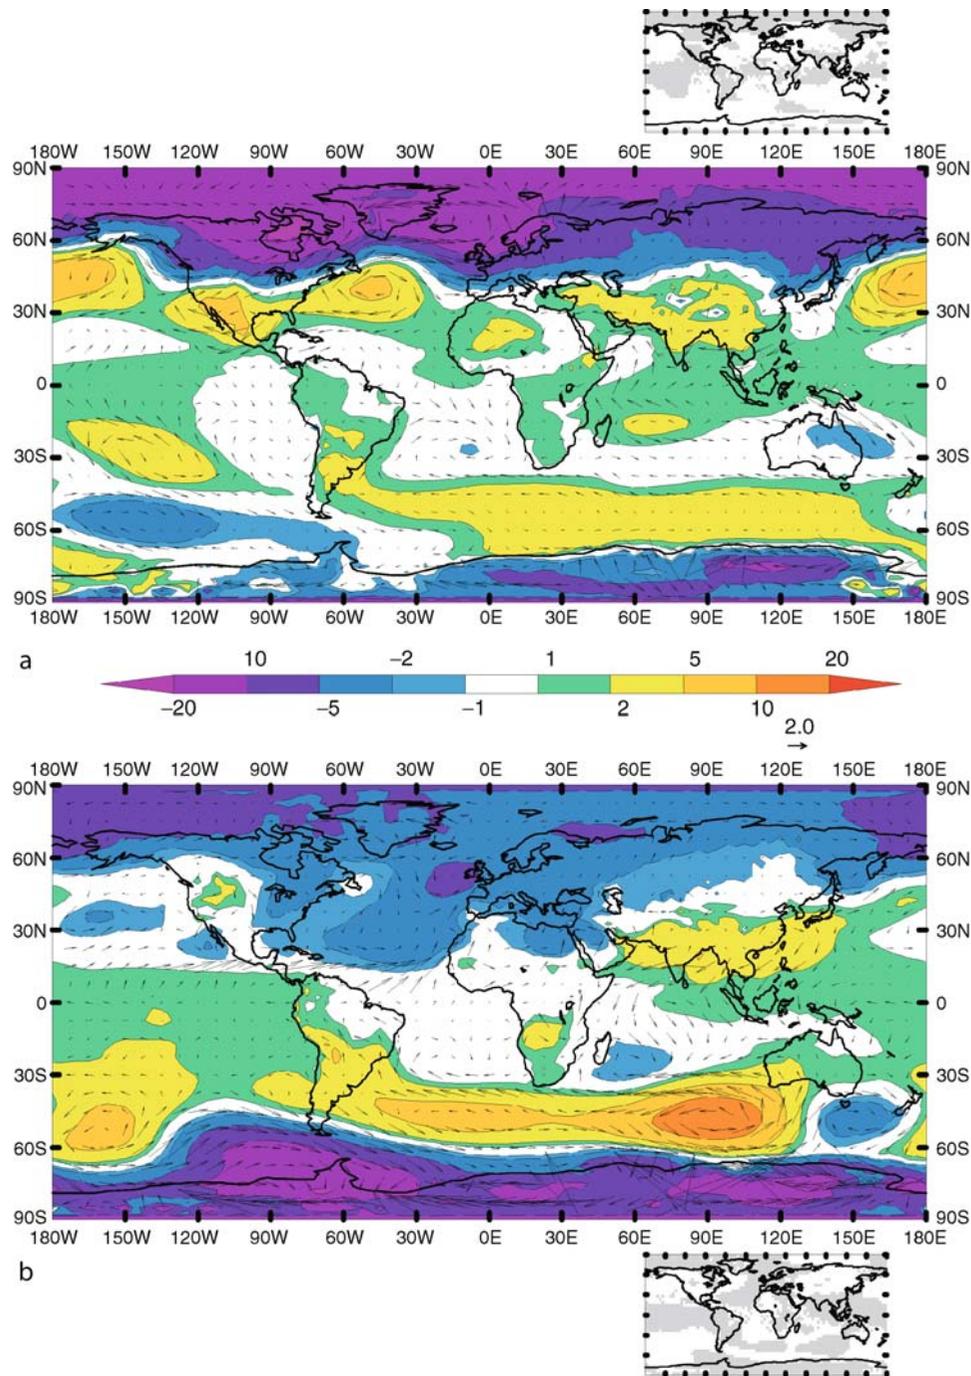

Figure P79 Model-predicted difference in surface pressure (hPa) between the Pliocene and present-day for (a) DJF and (b) JJA: Vector surface mean winds are also shown. The *grey shading* in accompanying mini-boxes shows the geographical areas in which the difference in precipitation rate is significant to a 95% statistical significance level (redrawn from Haywood et al., 2000a; Haywood, 2001).

were accounted for by the enhancement of high-pressure zones over subtropical ocean regions. A strong high-pressure anomaly was observed in the Southern Ocean west of Australia during DJF and JJA (Figure P79). This was related to alterations in Rossby wave (planetary wave) propagation caused by changes in the Antarctic orography in the Pliocene simulation. The

strength of JJA monsoon circulation in the Indian Ocean was weakened in the Pliocene experiment.

Climate modeling summary

The results of the modeling study by Haywood et al. (2000a) and Haywood (2001) are closely linked to, and dependent

on, the specified model boundary conditions. From analysis of the model simulation and from sensitivity experiments (Haywood, 2001), it is clear that alterations in SSTs combined with sea and land ice volumes within the model boundary conditions are primarily responsible for the observed variations between Pliocene and present-day climates. The variations in climate are caused by the alteration of processes, including the release of sensible and latent heat (SST driven) and by variations in heat exchange between the ocean and atmosphere that are also caused by differences in sea ice.

The warmer SSTs are responsible for the majority of model-predicted annual mean increase in surface temperatures and precipitation for the Pliocene. However, changes in high latitude surface temperatures and precipitation rate are also closely linked to the altered configuration of terrestrial ice sheets and sea-ice extents specified within the model boundary conditions. The enhancements of the mid-latitude jet streams and surface westerly winds predicted in the Pliocene experiment are primarily linked with changes in atmospheric pressure systems, which are themselves generated by reduced high latitude terrestrial and sea-ice cover. The role of altered jet stream flow, in response to the altered orography of the western cordillera of North America, may also be important in generating the enhancements in westerly wind strength observed in the Pliocene simulation.

Causes of pliocene climate change

Climatic warmth

The causes of Pliocene climate change have been widely discussed (e.g., Raymo et al., 1996). The applicability and scientific usefulness of the question “what was the cause of Pliocene warmth?” is arguable. This is because of (a) the multiple interactions of different components of the Earth’s climate system, (b) equifinality (different climate forcing mechanisms leading to the production of a similar response in climate), and (c) climatic memory effects (the existence of a global climate regime at any one time depends not only on forcing mechanisms in operation during the said regime but also those which occurred previously). A more scientifically useful question to pose might be “what were the processes that helped promote, sustain and ultimately terminate the climates of the Pliocene?”. Such an approach has the advantage of being process rather than causation driven, which increases the usefulness of studying past warm periods in our quest to better understand future climate change.

Atmospheric CO₂

Estimates of atmospheric CO₂ levels have been derived from analyses of the stomatal density of fossil leaves (stomata are small pores on a leaf surface that allow carbon dioxide to enter the leaf and oxygen to escape, thereby facilitating photosynthesis; Kürschner et al., 1996), through analyses of $\delta^{13}\text{C}$ ratios of marine organic carbon (Raymo and Rau, 1992) and through measurement of the differences between the carbon isotope composition of surface and deep waters (Shackleton et al., 1992). Use of all of these proxy methods suggests that absolute CO₂ levels during the epoch ranged from 360 to 400 ppmv, compared to mid-nineteenth century levels of approximately 280 ppmv and modern concentrations of 375 ppmv. The cause for this higher Pliocene concentration is not well understood and may be attributable to the long-term trend of CO₂ change throughout the Tertiary (Berner, 1990). Alternatively, feedbacks between climate and the carbon cycle (the cycling of

carbon in the form of carbon dioxide, carbonates, organic compounds, etc. between various reservoirs, e.g., the atmosphere, the oceans, land and marine biota and, on geological time scales, sediments and rocks) may also have been important.

The modest CO₂ increase reconstructed for the Pliocene would produce a radiative forcing of approximately 2 W m^{-2} . This may be sufficient to explain the warmth of the Pliocene globally, depending on the chosen climate sensitivity parameter, and whether there are any significant changes in other aspects of the radiative forcing. It cannot explain the regional changes in reconstructed SSTs, which apparently display no warming trend relative to present day in the tropics (Dowsett et al., 1996). Therefore, an additional mechanism (or mechanisms) working independently or combined with variations in CO₂ concentrations in the atmosphere would have been required to drive and maintain the warmer climates reconstructed for the Pliocene.

Ocean heat transport

A likely additional factor is a change in the heat transport of the oceans. This could be achieved through an increase in thermohaline or surface gyre circulation. This possibility was highlighted in early modeling studies (e.g., Rind and Chandler, 1991), but many difficulties and unexplained issues remain. Paradoxically, a reduced latitudinal SST gradient implies weaker atmospheric forcing of surface oceanic circulation, and hence weaker oceanic heat transport from equator to higher latitudes. This is a common problem associated with past warm climate dynamics. Problems exist in any explanation of Pliocene warmth that is based solely upon strengthening of the thermohaline circulation as it is, (a) difficult to ascribe a thermohaline coupling argument to all ocean basins and, (b) difficult to generate the correct reconstructed hemispheric temperature distribution (Crowley, 1996).

The arguments above are largely based on a consideration of global scale energetics. The importance of specific regional aspects, such as changes in surface wind strength and wind stress over different ocean basins, has only recently been considered in detail. Climate modeling results presented in Figure P79 indicate an increase in westerly component winds at mid to high latitudes in both hemispheres. This is a direct response to less ice cover and warmer surface temperatures over Greenland, the Arctic, Southern Ocean and Antarctica and to warmer sea-surface temperatures in the North and South Atlantic Oceans during the Pliocene. Conversely, sub-tropical high-pressure systems in both hemispheres are also enhanced. Therefore, regional pressure gradients in the mid to high latitudes of both hemispheres may have been intensified during the Pliocene. This has the potential, when combined with warmer SSTs, to increase the atmospheric transport of heat and moisture to the high latitudes (Figure P80). Increasing westerly wind strength applies greater wind stress (maximum 20 N m^{-2} on the basis of modeling experiments) to the surface of the oceans, thus potentially strengthening the flow of heat-transporting surface ocean currents such as the Gulf Stream (Figure P81).

These interpretations, based upon modeling studies (e.g., Haywood et al., 2000b), support paleoceanographical evidence for enhanced oceanic heat transports (e.g., Dowsett et al., 1996). Enhanced carbonate accumulation and upwelling from the California margin during the Pliocene relates to increased wind stress (Ravelo et al., 1997). Results from a study of marine ostracodes (Cronin, 1991) suggest that: (a) North Atlantic circulation may have been intensified, and (b) reconstructed

cooler ocean temperatures off the southeastern and mid-Atlantic coast of the USA during the Pliocene were a result of enhanced upwelling driven by the Gulf Stream. Billups et al. (1998) speculated that positive feedbacks involving Southern Hemisphere atmospheric circulation and Northern Hemisphere poleward heat transport, together with sea-ice feedbacks, might have played an important role in maintaining the climatic warmth of the Pliocene.

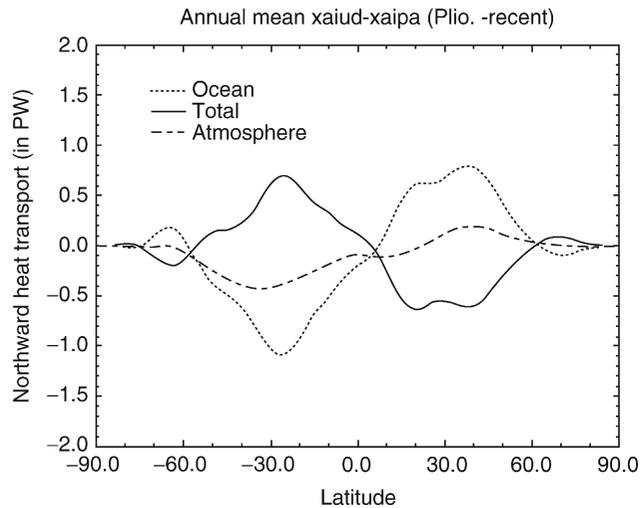

Figure P80 Model prediction of the difference in total poleward heat transport (in PW), by atmosphere and oceans between the Pliocene climate modeling experiment of Haywood et al. (2000a) and the present-day (*xaiud* = mid-Pliocene simulation; *xajpa* = present-day simulation).

Ocean heat transport – difficulties

The mechanism of enhanced ocean heat transport may have been important in helping to maintain greater mid to high latitude warmth during the Pliocene. However, the oceans act, to a first approximation, as a feedback mechanism rather than a direct forcing on climate. In other words, if we invoke greater oceanic transport of heat to help explain the warmth of the Pliocene then we must deal with the following question “what were the factors responsible for forcing a change in oceanic circulation and heat transports?”. Rind and Chandler (1991) postulated that changes in poleward ocean heat transport might be related to changes in orography, which would affect the planetary wind-driven circulation. However, it is unknown whether changes in orography are capable of affecting wind-driven circulation on anything more than a regional scale (Crowley, 1991). Climate modeling sensitivity experiments conducted by Haywood (2001) indicate that lowering the elevation of the western cordillera of North America, for example, does have an impact on the surface circulation across North America and into the Atlantic sector. However, alterations in high latitude low-pressure and sub-tropical high-pressure cells, as a result of reduced ice cover and altered SST gradients, are required to sustain the changes in circulation over the European and other sectors. Hence, whilst changes in orography may have been an important contributing factor in forcing changes in the wind-driven circulation, other mechanisms must have been in operation to drive larger-scale alterations in oceanic circulation, for the Pliocene at least.

The potential influence of changing terrestrial ice cover on oceanic circulation should not be forgotten. Although the direct effect of reduced high latitude ice cover on surface temperatures may only be observed over a couple of thousand kilometers away from the ice edge, it can have a significant impact on atmospheric pressure systems in the mid to high

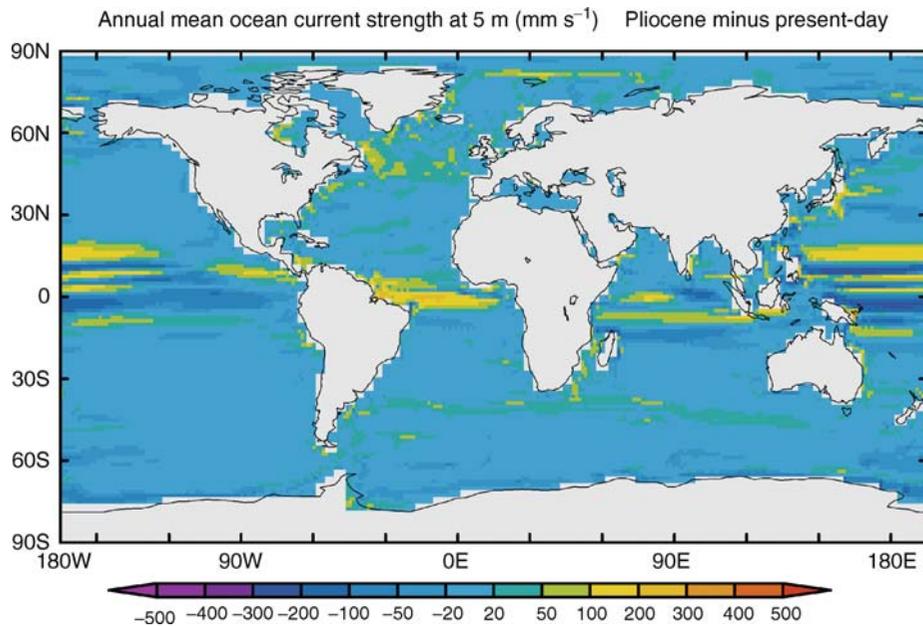

Figure P81 Coupled ocean-atmosphere model prediction of the difference in ocean current strength (mm s^{-1}) at 5 m between the Pliocene and present-day. Note the increase in the strength of the Gulf Stream and North Atlantic Drift currents in the North Atlantic (redrawn from Haywood and Valdes, 2004).

latitudes. This can affect atmospheric circulation and hence the wind-driven circulation of the ocean surface (Haywood et al., 2000b), thus providing a mechanism for forcing changes in oceanic heat transport. The key to understanding Pliocene warmth may therefore be as simple as knowing why the global coverage of ice was reduced compared to the present. This of course assumes that ice sheets of greater size than those of the Pliocene existed before that epoch.

One tectonically-driven process that may have had a significant impact on oceanic circulation during the Pliocene is the closing of ocean gateways and changes in the character of ocean sills. The sill depth of the Central American Seaway (CAS) decreased from approximately 1,000 m during the Miocene to near breaching of the sea surface during the early Pliocene. This may have had the effect of redirecting the flow of warm and salty water to the North within the Atlantic (e.g., Haug and Tiedemann, 1998). The sill depth between the North Atlantic and Norwegian-Greenland seas may have been lower during the Pliocene. This would have allowed the overflow of Arctic waters into the North Atlantic, thereby stimulating North Atlantic Deep Water (NADW) Formation (Wright and Miller, 1996). Changes in the depth of the Indonesian throughflow between 5 and 3 million years before present may have enhanced oceanic heat transports away from the tropics (Cane and Molnar, 2001). Finally, the first opening of the Bering Strait was an oceanographic event of global importance. Stratigraphic information suggests that the minimum age range for the strait's first opening was between 4.8 and 7.3–7.4 million years before present (Marincovich and Gladenkov, 1999). The fact that many more Pacific invertebrates invaded the Arctic Ocean than the reverse (Fyles et al., 1991) suggests that the main current flow was to the North. Heat transfer through the strait represents only a small part of the Arctic energy budget but the event may have warmed and moderated the Pliocene climate of the Arctic (White et al., 1997).

Climatic deterioration

Explanations for the climatic deterioration that occurred during the late Pliocene have centered on the effects of tectonics, alterations in atmospheric composition and the effect of changing orbital forcing on ice-sheet growth. The onset of Northern Hemisphere glaciation may be related to the progressive uplift of the Tibetan-Himalayan and Sierran/Coloradan regions (e.g., Ruddiman and Raymo, 1988). It is possible that the uplift in these two regions altered the circulation of atmospheric planetary waves so that summer ablation was decreased, allowing for the progressive build up of snow and ice in the Northern Hemisphere. The coincidence of Tibetan-Himalayan uplift and the sudden climatic deterioration during the late Pliocene remains to be confirmed; Copeland et al. (1987) and Spicer et al. (2003) have suggested that the majority of Himalayan uplift was completed between 20 and 15 million years before present and not during the mid-Pliocene as suggested by paleobotanical studies (Mercier et al., 1987). Until the dating of Tibetan-Himalayan uplift has been established it will be difficult to assess the true significance of this mechanism in forcing the climatic deterioration of the late Pliocene.

The Tibetan-Himalayan debate has broadened to include the impact that such uplift could have on atmospheric concentration of CO₂. Raymo (1991) discussed how Himalayan uplift might have increased chemical weathering rates during the late Cenozoic (see *Weathering and climate*). Weak carbonic acid

(rainwater) weathers rocks via hydrolysis. The chemical weathering of carbonate rocks returns CO₂ to the atmosphere. However, the weathering of silicate rocks has the potential to reduce atmospheric concentrations of CO₂. During chemical weathering of silicate rocks, bicarbonate (HCO₃⁻) is produced as a bi-product. The bicarbonate is metabolized by marine plankton upon reaching the oceans and converted into calcium carbonate (CaCO₃). The calcite skeletons of the marine plankton are ultimately deposited as deep-sea sediments which lock up the stored CO₂ in the calcium carbonate for the lifespan of the oceanic crust on which they were deposited. This process continually removes CO₂ from the atmosphere, cools global climate and hence could have initiated Northern Hemisphere glaciation. If left unchecked, this mechanism would very quickly deplete the entire atmospheric CO₂ reservoir (Berner, 1994). However, subduction-related volcanism would release CO₂ back into the atmosphere. Resolution of this problem awaits our improved understanding of the global carbon cycle for the Cenozoic.

The closing of the CAS is also considered to be a potentially important event in forcing the build up of substantial ice sheets in the Northern Hemisphere. At present, it is not known if the closing of the CAS and the abrupt shift in climate of the late Pliocene are coincident. Furthermore, the current scientific understanding of whether the closing of the CAS would have helped or hindered the intensification of Northern Hemisphere glaciation is incomplete. One theory is that the closing of the CAS would have increased the salinity of the Caribbean, which would have increased the salinity and strength of the Gulf Stream and ultimately NADW formation. Mikolajewicz et al. (1993) argued that an increase in the Gulf Stream and NADW formation brought about through the closure of the CAS would have worked against the progress of Northern Hemisphere glaciation since the oceanic heat transport to the high latitudes would be enhanced. In contrast Haug and Tiedemann (1998) argued that enhanced Gulf Stream flow would have brought more moisture as well as heat to the higher latitudes. The increased flux of moisture may have promoted the growth of the Greenland Ice Sheet.

Changes in orbital forcing have been suggested as an important mechanism contributing towards the global cooling of the late Pliocene. Maslin et al. (1995) suggested that the observed increase in the amplitude of the orbital obliquity cycles from 3.2 million years before present increased the seasonality of the Northern Hemisphere, thus initiating the long-term global cooling trend. Furthermore, the rise in amplitude of precession and variation of insolation between 2.8 and 2.55 million years before present may have forced the rapid glaciation of the Northern Hemisphere. Inevitably, like the warmth that preceded it, the climatic deterioration that characterizes the late Pliocene is likely to have more than one origin. Tectonic changes might have brought the global climate to a critical threshold with relatively rapid variations in the Earth's orbital parameters triggering the intensification of Northern Hemisphere glaciation.

Summary

The 3.5 million year long Pliocene epoch appears to have been generally warmer than at present, particularly at mid to high latitudes. This greater warmth may have been generated and/or sustained by a number of forcing mechanisms working concurrently. These include enhanced levels of atmospheric CO₂, enhanced

oceanic heat transports, and ice-albedo feedbacks. Climatic variability occurred during the epoch on Milankovitch periodicities. A climatic deterioration occurred during the late Pliocene which saw the initiation of significant Northern Hemisphere glaciation. This downturn, like the warm period that preceded it, is likely to have a complex origin. Current hypotheses include the effect of tectonic uplift, drawdown of atmospheric CO₂, and changes in oceanic circulation, heat transports and orbital forcing.

PMIP

Objectives and project design

The Paleoclimate Modeling Intercomparison Project (PMIP), initiated in 1992, is an international undertaking designed to evaluate the performance and reliability of global atmospheric general circulation models by comparing past climates for periods that had significantly different external forcings from the modern climate. This initiative has been endorsed by the World Climate Research Programme (WCRP) and the International Geosphere-Biosphere Programme (IGBP). The first phase of this project (PMIP 1) initially focused on simulations of the Last Glacial Maximum (LGM, 21,000 yBP) and the mid-Holocene (6,000 yBP). The LGM was selected to assess the models' ability to simulate conditions characterized by extensive ice sheets, cold oceans, and reduced atmospheric CO₂ levels. Boundary conditions for the LGM experiment included specification of the ice sheet extent and height with lower ice elevations (Peltier, 1994) than those used in CLIMAP (1981) and an atmospheric CO₂ concentration of 200 ppm (as compared to a modern pre-industrial level of 280 ppm). Two different ocean scenarios were specified: the first employing fixed sea surface temperatures (SSTs) based on CLIMAP (1981), and the second computing SSTs from coupled atmosphere-mixed layer ocean models, assuming the same ocean heat transports as today (Joussau and Taylor, 2000). Earth's orbital parameters were also adjusted to correspond to their values 21,000 years ago (see *Eccentricity, Obliquity, and Precession, climatic*, this volume). For the mid-Holocene experiment, only two factors differed from those of the control run: the atmospheric CO₂ concentration was reduced to a pre-industrial level of 280 ppm and orbital parameters were adjusted to their 6,000 yBP values. The difference in obliquity 6,000 years ago induces only minor changes in low- to mid-latitude annual mean insolation from that of the present, but the change in precession causes an intensified Northern (and lessened Southern) Hemisphere seasonal cycle (see *Astronomical theory of climate change; Precession, climatic*, this volume). SSTs were assumed to be the same as at present; land-surface characteristics were also assumed to remain unaltered.

Simulations were compared with observations using inverse and forward-modeling techniques (Harrison, 2000). The inverse technique derives climate-related parameters by means of statistical techniques such as transfer functions, modern analog analyses, or response surfaces (see *Transfer functions, Paleobotany, Nearest living relative method*, this volume). Correlations are established between modern distributions of species and specific climate parameters, from which past climates are inferred, based on the paleodata. The forward modeling approach predicts the response of the paleoclimate proxy to the simulated climate change by means of process-based models. The predicted response is then compared with the original paleoclimate record. In PMIP, this approach has enabled closer comparisons between terrestrial vegetation and lacustrine data sets.

Model performance was evaluated using paleoenvironmental data bases (Harrison, 2000), including: (a) the Global Lake Status Data Base – a compilation of geomorphological and biostratigraphic data relating to changes in lake level, area, or volume; (b) BIOME 6000 – global paleovegetation data sets

for the LGM and mid-Holocene (Prentice and Webb, 1998; Prentice et al., 2000); and (c) the 21 ka Tropical Terrestrial Data Synthesis – a compilation of data for sites between 32°N and 33°S from diverse land-based paleoclimate proxies (e.g., pollen, lake level records, speleothems, etc.). These enable derivation of several climate-related parameters (e.g., mean temperature of the coldest month (MTCO), mean annual ground temperature (MAT), plant-available moisture (PAM), and stream runoff (precipitation minus evapotranspiration, P-E)).

More recent experiments initiated under PMIP 2, and which started in 2002, were designed to address several shortcomings identified in the initial simulations, such as a need for improved representation of ocean and vegetation feedbacks and the role of freshwater fluxes, using fully coupled ocean-atmosphere (OAGCM) and ocean-atmosphere-vegetation (OAVGCM) models. A more realistic recreation of ocean-vegetation interactions is necessary in order to account for discrepancies between climate models and land surface proxies identified in earlier experiments (e.g., in mid-Holocene monsoon intensity, Joussaume et al., 1999). Several more time periods have been added (Harrison et al., 2002; Crucifix et al., 2005). Time slices investigated in PMIP 2 now include the “glacial inception” (115,000 yBP), the early Holocene (10,000–9,000 yBP), the Younger Dryas (12,700–11,700 yBP) and the abrupt cooling event (8,200 yBP), in addition to the LGM and mid-Holocene, which were examined previously (Crucifix et al., 2005). The glacial inception experiment examines the role of vegetation and ocean feedbacks on interannual snow accumulation in northeastern North America at the end of the last interglacial period in order to better understand how an ice age is initiated. The early Holocene experiment explores the way in which climate reacts to changes in insolation and ice sheet coverage. The Younger Dryas and 8,200 year experiments examine the effects of meltwater additions on thermohaline circulation and their role in abrupt climate change.

Revised boundary conditions for the LGM under PMIP 2 include new estimates of ice sheet extent and height. In the latest reconstruction (ICE-5G), the thickness of the central Greenland ice sheet at the LGM has been reduced from that used in PMIP 1, but is still ~100–300 m thicker than at present (Peltier, 2004). Antarctica remains approximately the same, whereas the Laurentide Ice Sheet has increased in thickness relative to the earlier reconstruction. Paleoclimate databases used to define and constrain initial boundary conditions have been updated, including additional pollen and macrofossil data, revised ice sheet extent, and a river routing scheme that provides a more naturalistic representation of the hydrological cycle (Crucifix et al., 2005). A series of experiments probe the role of major feedback loops, by successively shutting off the contribution of oceans or vegetation singly, and ocean/vegetation in combination (Harrison et al., 2002). Another set of experiments simulate climate responses to 6,000 kyr BP changes in solar insolation and removal of ice sheets.

Results

The PMIP 1 LGM model runs forced by CLIMAP SSTs produced a global mean cooling of 4 °C, which was stronger over Northern Hemisphere ice sheets and landmasses, especially around the North Atlantic (Joussaume and Taylor, 2000). Computed SSTs yielded a wider range of cooling, from 2 to 6 °C below present, as well as a sharper hemispheric temperature gradient. Both types of simulations found greater LGM aridity over most northern continents and tropics. The relatively warm

CLIMAP-specified tropical SSTs led to higher land temperatures than suggested by paleotemperature proxies, except for equatorial Africa. Slab ocean models, on the other hand, generated a range of land cooling, related to the intensity of tropical ocean cooling, which in some cases was much too high. Regionally, the Afro-Asian monsoon was reduced in strength and intertropical aridity increased. The presence of ice sheets modified mid-latitude atmospheric circulation by inducing anticyclonic circulation over the ice and intensifying planetary waves. However, splitting of the jet stream (e.g., COHMAP, 1988) was not clearly seen in PMIP 1. Increased meridional temperature gradients due to the presence of ice sheets enhanced baroclinicity and shifted storm tracks eastward, particularly over the North Atlantic. While all models displayed an increase in the summer monsoon over Africa during the mid-Holocene, they tended to underestimate its intensity relative to that suggested by pollen data and lake models (Joussaume et al., 1999). The models also missed some important features, such as a colder/wetter Mediterranean growing season than at present, as implied by lake level data.

Initial PMIP 2 results show that global mean temperatures at the LGM are 3–6 °C below present, with a median value of –4 °C (Masson-Delmotte et al., 2006). Polar amplification (ratio of polar to global annual mean temperature change) at the LGM ranges between 2.1 and 2.6 for Greenland, but only 1.2–1.9 for central Antarctica. However, the models underestimate the extent of glacial cooling for Greenland, whereas the polar amplification is realistically simulated for Antarctica. PMIP 2 simulations find mid-Holocene global mean temperatures close to present values (Masson-Delmotte et al., 2006). Temperatures are 0.35°–0.9° C higher in central Greenland during the mid-Holocene, and 0.1°–0.7° C warmer in Antarctica. The OAGCMs reproduce mid-Holocene seasonal cycle and regional changes, such as higher mid-latitude summer temperatures in many regions, which stem from the altered precessional parameters (Zhao et al., 2005). They produce consistent changes in summer monsoon behavior, such as increased precipitation over northern India and Sahelian Africa, and strengthened monsoon flow from the western Pacific warm pool to the Indian Ocean, although the areal extent and magnitude of the monsoons appears model-dependent. The changes in monsoonal flow appear to be associated with a reduction in Hadley-style circulation and a westward shift in Walker-type circulation from the Pacific to Indian Oceans (Zhao et al., 2005).

Illuminating insights have emerged from new paleodata used to validate the PMIP 2 climate models. For example, pollen and macrofossil data reveal that the warmest period during the Holocene (see *Hypsithermal*, this volume) varied sharply over time in different regions, beginning as early as 10,000 years ago in Alaska-eastern Siberia, and ending less than 6,000 years ago in northeastern North America. This was in part related to lingering remnants of the Laurentide Ice Sheet (Crucifix et al., 2005). New information about ice sheet history also contributes to the climate modeling efforts. For example, catastrophic outflow from Glacial Lake Agassiz had long been considered to be the main source of freshwater outflow that led to a decrease in rate of North Atlantic Deep Water Formation, presumably triggering the Younger Dryas cooling. Recent dating of glacial landforms suggests, instead, that ice retreat around southern and western Hudson Bay occurred approximately 1,000 years after the start of the Younger Dryas (Lowell et al., 2005), casting doubt on the role played by Lake Agassiz. Moreover, detailed geophysical models of the Laurentide Ice

Sheet retreat, constrained by ^{14}C -dated geomorphological features, relative sea level data, and geodetic measurements point to large meltwater influxes via the Arctic Ocean, Fram Strait, into the North Atlantic Ocean during the Younger Dryas (12,700–11,700 yBP) (Tarasov and Peltier, 2005). Freshwater input via this route rather than outflow from Lake Agassiz may have led to the abrupt Younger Dryas cooling.

Conclusions

PMIP, by comparing and contrasting results from a number of general circulation models under climate regimes that differ significantly from the present, enables one to test the ability of these models to reproduce key elements of climate, such as temperature, precipitation, atmospheric dynamics, and seasonal and regional variations. Results to date point to the importance of using fully coupled ocean-atmosphere models and the role played by vegetation. The sensitivity of various climate features, such as changes in the North Atlantic Oscillation or the role of tropical SSTs, to altered global conditions is also best evaluated with a “super-ensemble” of models. Concomitant with the PMIP modeling program is the growth and expansion of supporting paleoclimate databases that are used to validate these models.

POLLEN ANALYSIS

Introduction

Pollen analysis is a scientific method that can reveal evidence of past ecological and climate changes: it combines the principles of stratigraphy with observations of actual (modern) pollen-vegetation relationships in order to reconstruct the terrestrial vegetation of the past.

Early history

Pollen analysis plays a critical role in climate change studies during the Quaternary (Fægri and Iversen, 1975) and is the single most important branch of paleoecology for the late Pleistocene and Holocene (Roberts, 1998). Its scientific scope is broad since it encompasses knowledge from many disciplines including botany, geology, ecology, climatology and archeology. The extent to which a pollen analysis study may be slanted toward botanical, ecological or geological questions will depend on the sedimentary deposits analyzed and the researcher's background. Pollen analysis may be utilized for the evaluation of vegetation changes occurring as recently as the Holocene. It may also be applied as far back as the late Devonian, when the first seed plants evolved, although presumably not until the Pennsylvanian or later did distal germination of the pollen evolve in the early gymnosperms (Traverse, 1988, p. 163).

A brief summary of key historical developments shows how pollen analysis evolved as a methodology, and how distinct disciplinary characteristics have been imprinted upon it. An early history of pollen analysis is found in the book entitled “An Introduction to Pollen Analysis,” written by G. Erdtman (1943). Erdtman recounts how European scientists had laid the groundwork for pollen analytical studies in the late nineteenth and early twentieth centuries. The Swiss geologist, J. Früh had identified many of the common tree and herb pollen types, and spores from ferns and mosses, found in the regional environment, in an 1885 paper. The Swedish geologist F. Trybom, in 1888 showed that pine and spruce pollen grains were found in sediment samples from the bottoms of Swedish lakes. The microscopist G. Lagerheim introduced a quantitative aspect: he and N. O. Holst published a paper in the Geological

Survey of Sweden, in 1909, entitled, “*Postglaciala tidsbestämningar*.” In this paper, common northern European tree genera pollen had been identified (i.e., *Pinus* (pine), *Betula* (birch), *Alnus* (alder), *Ulmus* (elm), *Corylus* (hazel), *Fraxinus* (ash), *Quercus* (oak), and *Tilia* (basswood)) from different levels of lacustrine sediment layers within Kallsjö bog in southern Sweden. Lagerheim identified pollen within the layers, and presented the quantity of each genus as a percentage of all pollen; furthermore, he examined the shifts in these pollen percentages from layer to layer. Lagerheim (as translated by Erdtman, 1943, p. 4) concluded that the varying pollen frequencies are “a reliable method with which to follow, step by step, from one layer to another, the immigration of all plants whose pollen or spores are preserved as fossils as well as the relative frequency of these species.” A decrease in the percentage of pine pollen from the lower to the upper layers caused Holst to speculate that, “the pine disappeared from southernmost Sweden in historical times, exterminated probably by the activity of man.”

Lennart von Post (a pupil of Lagerheim at the University College of Stockholm) transformed pollen analysis into a refined method in Quaternary geology, he “indicated how pollen analysis should be applied in order to give information on problems related to Quaternary geology and paleontology (Erdtman, 1943).” Von Post drew the first pollen diagrams and defined distinctive tree pollen “horizons” and “limits” in 1909. A “spruce pollen limit” or “spruce horizon” could be used as a datum line to trace time synchronous horizons in different bogs within a small area. In 1916, von Post presented a paper with many pollen diagrams at the Sixteenth Meeting of Scandinavian Naturalists in Oslo, examining the pollen of forest trees in bogs in southern Sweden (von Post, 1967 [1916]). His presentation is considered the realization of pollen analysis as a science.

Thus by the early 1900s, the basic principles underlying pollen analysis were already in place. Plants produce pollen grains, which are dispersed and then preserved in sediments for thousands and exceptionally even millions of years. Then, samples taken from a column of sediment will show shifts in pollen occurring over time, assuming that the original stratigraphy has been maintained. Any apparent shifts may be interpreted as due to changes in vegetation, perhaps forced by climatic, geological, or ecological factors.

Subsequently, the number of pollen studies vastly expanded to include other geographical regions and other geological time periods. The advent of radiocarbon dating and its extensive application in the late 1900s allowed relatively firmer chronologies to be developed from the late Quaternary. Extensive research of pre-Pleistocene deposits is also carried out by geologists (Traverse, 1988). Pollen analysis has also evolved with the increasingly interdisciplinary aspect of many sciences (including geology and ecology), as results from pollen analysis are now interpreted with respect to site data of a limnological, isotopic, or microfaunal nature, to name just a few.

Theory of pollen analysis: the pollen-vegetation relationship

The basic theory of pollen analysis is that pollen is released by plants, transported through the air, and then deposited uniformly upon the Earth’s surface. In fact, the pollen represents the actual surface vegetation growing over an area (the area to be defined by the researcher). The pollen that is transported in the air is called *pollen rain*. The pollen rain may be deposited over land or any water body. The pollen that is deposited

in lakes or other water bodies (such as bogs and marshes) sinks to the bottom of the basin and becomes part of the accumulating lacustrine or peat sediment. When pollen is deposited in water, the pollen’s outer layer may remain practically intact for thousands and perhaps even millions of years. Thus, the pollen becomes part of the fossil record. This fossilized representation of the terrestrial vegetation may then be used to interpret the vegetation, or plant geography, which existed in the past. Furthermore, since climate is one of the key determinants of the plant taxa growing at any place on the Earth’s surface, the fossil pollen may be used to interpret past climates. This is highly useful when attempting to reconstruct the Earth’s climate and ecology, as it existed before any instrumental records or observations made by humans.

A fundamental operating assumption is that the pollen-vegetation and vegetation-climate relationships that can be observed now also operated in the past (Roberts, 1998). This is the principle of *uniformitarianism*, which is applied in many disciplines related to Earth history. Paraphrasing from Roberts (1998, p. 29) and applying to the field of pollen analysis, the uniformitarian assumptions are: (a) the environmental factors affecting present-day vegetation are understood, (b) a species’ natural history has not changed over time, (c) the vegetation was in equilibrium with its environment (this means that the environment remained unchanged during the plant’s lifespan), (d) modern analogs exist, (e) the origin (taphonomy) of the fossil pollen assemblage can be established, (f) the pollen assemblage has not been biased by contamination (from outside the sample) or differential preservation, and (g) the pollen can be identified to a meaningful taxonomic level.

In practice, all these assumptions are never perfectly met. In fact, pollen analysis as applied to the fields of paleoclimatology and paleoecology exemplifies the concept succinctly phrased by the ecologist Edward Deevey (1969), “coaxing history to conduct experiments.” Essentially, the sciences of paleoecology and paleoclimatology do not utilize data from controlled experiments conducted in an artificial laboratory. Instead, the experiment has been conducted by nature, in the natural environment, in the geological past. The data, or evidence, from these experiments remains within the natural environment, waiting to be retrieved and interpreted by the discerning researcher via a variety of tools.

Pollen production and dispersal

Pollen and spores are produced by green plants (Viridophytae) (taxonomy according to Pennisi, 2003). What is commonly called “pollen” comes from the conifers (sometimes referred to as gymnosperms) and angiosperms. Green plants that are neither angiosperms nor conifers produce what are commonly called “spores.” Mosses, lycophytes, and ferns are green plants that produce spores. Both pollen and spores are typically identified by the researcher conducting the pollen analysis.

Pollen is produced in a flower’s anthers (microsporangia or pollen sacs). It is the haploid microgametophyte, male partner, in sexual reproduction. Pollen grains germinate on the female (stigma) surface by forming a pollen tube, which emerges through one of the apertures in the pollen grain wall (Twell, 2000). In pollen analysis, the scientist studies those pollen grains that have been dispersed, but rather than germinating, have accumulated as sediment. This is because the pollen shape and surface texture, which is called morphology, is highly distinctive when magnified.

The most striking structural feature of the pollen or spore grain is the tough, resistant outer coat, called the exine, which protects the reproductive cells from environmental injury. Beneath the exine is a second major layer surrounding the pollen grain protoplasm, called the intine. The exine is composed of a material called sporopollenin, which is a very inert C–H–O compound (Traverse, 1988). Sporopollenin has been identified in acritarchs in Precambrian rocks, and is a component of many higher green plants. What is unique about sporopollenin is its ability to withstand desiccation and oxidation. Sporopollenin within a sediment matrix is able to survive for extended time periods, even as the other components of the pollen or spore degrade. Oxidizing, highly alkaline, and high temperatures environments are likely to accelerate sporopollenin's degradation. In short, the accumulating sediment within a water body is an ideal place to store the exine of pollen and spores. This exine may survive for thousands to even millions of years in a non-oxidizing environment, and thus becomes the fossil utilized in pollen analysis.

The pollen of different plant taxa manifest considerable variation in size, shape and surface characteristics. To the naked eye, it is a fine granular or powdery substance. Pollen grains may vary in length from 5 µm in *Myosotis* to more than 200 µm in the *Curcubitaceae*; the shape varies from spherical to elliptical to more unusually and irregularly shaped objects. The exine has a three-dimensional patterned surface, several microns deep, called sculpturing, which helps the grain adhere to insect pollinators and the stigma. The exine does not develop over certain regions; these define the positions of the germination apertures. Apertures also show wide variation in shape, ranging from elongated furrows to circular pores, and combinations of furrows and pores. The pollen's shape, aperture number and position, and exine sculpturing are unique taxonomic features that allow the identification of species, genus, or family (Twell, 2000).

The dispersal of the pollen strongly conditions the pollen-analytical studies. Fægri and Iverson (1975) describe the different means of pollen production and dispersal. Those plants that are pollinated by wind-carried pollen, called anemophilous, produce the greatest quantities of pollen. In zoophilous plants, the pollen is carried from the anther of one flower to the stigma of another by an animal vector such as insects, birds or bats; these plants produce relatively less pollen. Hyp-hydrogamous (pollination under water) and obligate autogamous plants produce very little pollen and are rarely analyzed. The earliest pollen studies involved the anemophilous species and even now, wind pollinated species are those most commonly addressed. Because of the larger quantities of pollen dispersed, the anemophilous species are more likely to leave pollen deposited within the sediment. Typical quantities of pollen produced by mid-latitude forest tree species are: 10,000 pollen grains in a single *Betula* anther, 28 million pollen grains produced by 10-year old *Betula* branch system, up to 350 million pollen grains produced by a 10-year old *Pinus* branch system (Fægri and Iverson, 1975). A common mid-latitude zoophilous tree, *Acer* (maple), may have only 1,000 pollen grains per anther. Generally, those trees reaching the upper canopy will produce the most pollen, while the shrub and herb plants under the canopy will produce less. Zoophilous species are usually more frequent in the lower strata. Pollen production will also vary seasonally and even annually.

Pollen analysis is based upon the assumption of uniform dispersal of this great quantity of pollen grains (Fægri and

Iverson, 1975). The pollen of wind-pollinated species should be dispersed by the wind, then settle out and be deposited over a region, including any lakes and bogs, in which strata they will remain, until finally being retrieved by the researcher.

All aspects of pollen production and dispersal continue to be studied by botanists and ecologists, more detailed information may be found in the specialist literature. Since the earliest pollen studies were based in the temperate northern European forests, the earlier methodologies were constructed around the life history of the local, predominantly anemophilous species. Newer studies also address the tropical and even high-latitude habitats. Understanding key species in pollen production in tropical habitats is especially challenging as the number of species composing the local vegetation formations is high, and many are zoophilous.

Pleistocene palynology

Living organisms evolve over time. The assumption that the ecological and climatological affinities of extant vegetation have the same paleoecological and paleoclimatological affinities as paleovegetation (interpreted via pollen), is accepted as generally holding true for the Pleistocene, that is the most recent 1.8 million years. This conclusion is based on the studies of Neogene fossil flora remains, both megafossils and microfossils. Fossil pollen are usually identified by genus, although sometimes a species identification is possible. Some pollen can only be identified to its taxonomic family, a good example being the grasses (*Poaceae*) and sedges (*Cyperaceae*). By the beginning of the Pleistocene, nearly 100% of flora species recognized are still extant. Nearly 100% of extant plant genera are present by 10 million years ago; by 20 million years ago, practically all angiosperm remains are referable to extant families (Traverse, 1988). Thus, as one moves from the distant geological past to the present, the precision with which a researcher can link the pollen fossil to an extant plant, and hence that plant's natural history, improves. Thus returning to the uniformitarian assumptions given by Roberts (1998), we see that at least the first two assumptions (the environmental factors are understood, a species natural history has not changed over time) can be applied with greater certainty to the most recent geological time – the Pleistocene and the Holocene. Hence, pollen analysis applied to Pleistocene and Holocene sediments may aim for relatively precise determinations of climate and environment. Pollen analysis applied to fossils of the last 10 million years may still yield information relevant to climate and ecology, since most of the plant genera were extant, but the questions will have more of a geological flavor (Traverse, 1988).

The sample site and laboratory technique

Field sites

Determining which site was a suitable pollen collection basin will have a decisive impact upon the relevance of the final results. Equipment and the natural landscape are major limiting factors. Ideally the basin should have accumulated sediment continuously over time, thus its geological origins should be clear. From an ecological perspective, one wishes to know the distance of the pollen from the source vegetation.

The aim of the field work is to collect uncontaminated samples, to define as precisely as possible the conditions under which the samples were taken, and to characterize the sediments and stratigraphy (Fægri and Iverson, 1975). The investigator must evaluate and balance two (sometimes competing)

factors: the field sites actually available, and the spatial scale which the pollen analysis will address. Most frequently, the investigator is seeking to reconstruct changes in the natural undisturbed vegetation – present day vegetation is frequently altered by human activity and undisturbed sites are usually kilometers to hundred of kilometers from roads. In addition, pollen is best preserved under anaerobic conditions – those at the bottom of a peat bog or lake.

Given the historical roots of pollen analyses in the northern temperate latitudes, the ideal sedimentary basin is a lake or bog of roughly 5,000 m² which collects windblown pollen (Fægri and Iverson, 1975). The pollen sources are defined as local, regional, and extra-regional (Fægri et al., 1989) – these divisions are usually only qualitative (Figure P82). The researcher usually wishes to describe the “regional” vegetation; very approximately, the vegetation within one kilometer of the basin’s center. The relatively small basins allow this interpretation of a “regional pollen signal.” Since the pollen deposited should be transported by wind, input to the basin from streams must be avoided – this would bring in pollen from outside the “region,” and also pollen eroded from older sediments.

In the first pollen studies conducted in northern Europe and Scandinavia, a single person might have cut samples from exposed peat deposits. Peat sediments were easy to examine, pollen was frequently well preserved within the peat and mud matrix, and continuous sedimentation was possible for approximately 10,000 years; that is, since the last deglaciation.

Pollen analyses have expanded in their scientific and geographic scope. The ideal 5,000 m² size catchment basin is simply unavailable in the lower latitudes and tropics, thus other catchments may be utilized. Small basins also effectively limit the geological time span of the sediment, since they are almost always the by-product of a geomorphological regime occurring after the last glaciation. Hence, large basins are studied: wind-blown pollen is collected from a much larger “region,” yet sediment cores may be longer and hence encompass more time. Pollen accumulated in marine sediments may be very useful in paleoclimatological studies. Rat middens and cave deposits have been frequently utilized in the arid southwest of North America. Archeological sites also contain pollen. These

sedimentary accumulations have the disadvantage of being relatively stratigraphically discontinuous; however, in more arid regions they still provide valuable information.

Sampling methods have also advanced. Piston corers of varying degrees of sophistication are now often utilized: they consist of drill bit that can bore into the ground, a sampling tube into which the sediment slides, a piston which maintains a vacuum inside the tube, and extension rods connecting the sampling tube to the piston, allowing the entire apparatus to be taken in and out of the ground. A typical sediment core is 5–10 cm in diameter and from 1 to more than 10 meters in length, the core is retrieved in sections of usually a meter’s length or less. The coring operation may be conducted on dry land or on water. In the latter case, the machinery and people operating the coring equipment must utilize a dry and level platform: the platform may range from portable wooden planks, to the drilling rigs aboard modern research sea vessels, even to the ice covering a lake. The goal is always to reach the deepest depths, while retrieving the most continuous sections of sediment to the surface. The depths achieved, and the continuity of the core, depend mostly on the types of sediment cored and the equipment being used. Marine sediments, usually composed of clays and silts, are easier to penetrate and may yield cores in the range of tens to hundreds of meters. Lacustrine cores may exceptionally exceed ten meters in depth, peat and lake sediments are relatively soft and easy to penetrate. However, changes in the climatic or geomorphological regime must be expected as one proceeds deeper into any sediment, essentially going back in time, and thus coarser sediments such as sands, gravels, and even bedrock may be encountered at the bottoms of the collecting basins. Indurated or coarse sediments, or bedrock, effectively stop the drilling equipment.

Laboratory techniques

The laboratory work comprises the separation of pollen grains from their sediment matrix, and then identification of the pollen grains. Work in the laboratory is the most time consuming aspect of pollen analyses, and the identification of the pollen is the most beautiful aspect of the study. The sediment (in cores, blocks, or even sub-samples taken from other studies) retrieved during field work must be described, evaluated for any possible lack of stratigraphic continuity, and then sub-sampled. Sub-samples are taken from the cores or sediment blocks, the researcher must decide at what distance interval to sample. A closer sampling interval usually increases the time resolution of the study.

The description of the sediment combined with any geological study of the sampling site should allow a geological reconstruction of the site’s genesis over time. Furthermore, a correct interpretation of the changing vegetation or climate based upon the pollen data requires knowledge of the depositional environment. The description of sediment may follow geological or soil classification schemes. Two commonly utilized classification schemes are the “Fægri and Gams” and the “Troels-Smith” descriptions. “Fægri and Gams” is a synthetic-interpretive approach in which the sediment’s description implies its genesis. The “Troels-Smith” scheme is an analytic-descriptive approach. A referenced system of notation and graphic symbols (called *signatures*) exists for each system, the signatures are usually presented in the final pollen diagram. Fægri et al. (1989) emphasized that classification should include the identification of deposit-forming vegetation (e.g., sedges, mosses, wood), degree of humification, mineral content and grain size. Basins formed by glacial action in the temperate

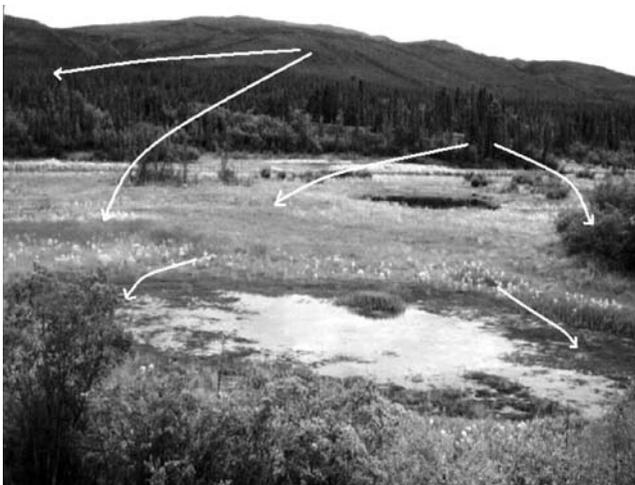

Figure P82 Schematic representation of wind deposition of pollen from local, regional, and extra-regional sources.

mid-latitudes, used in early pollen studies, typically show a change (over several thousand years) from minerogenic sediment to organic muds or gyttja – this change is a response to the gradual development of soil and vegetative cover. In the tropical basins, the more dramatic changes in the sedimentary matrix are usually linked to fluctuations in water level.

Fossil pollen is separated from the sediment matrix in a laboratory. Essentially, the extraneous, non-pollen material must be removed from the sediment samples so that the final preparation contains only the pollen, which will be easily visible and unobscured when viewed under magnification. The laboratory and all air, water and supplies that enter the room must be pollen-free, only the samples themselves should contain pollen. A typical pollen laboratory is furnished with a fume hood, centrifuge and water baths.

The quantity of sediment needed for a single sample is usually small, approximately 1 cubic centimeter for lacustrine sediments, and 10 cubic centimeters or more for marine sediments – hundreds to thousands of pollen grains may be hidden within. To allow the absolute pollen frequency count or the density of the individual pollen taxa in the sediment to be determined, a known quantity of a *marker* is commonly added to the sample. Common markers are polystyrene spheres or a pollen taxon that is clearly foreign to the native vegetation.

Filters and chemicals are used to remove the extraneous material. The large majority of pollen grains have a minimum diameter between 7 and 125 microns, while the supporting sediment matrix ranges from finer-grained clays to coarser-grained sands. Filters or sieves can be used to separate these fine and coarse materials from the pollen containing sediment; the researcher decides which filter sizes to utilize. The basic chemical processing steps applied to a measured quantity of sediment are the addition of alkalis (KOH or NaOH solution) to remove and deflocculate humic acids (associated with peat and organic matter), and acid baths to chemically remove the silt and fine sand. Hydrochloric acid removes the calcium carbonate components. Siliceous sediments are dissolved by hydrofluoric acid. Gravity separation, utilizing what are known as “heavy liquids” (e.g., bromoform, stannic chloride, or zinc chloride) may be used as alternatives to the hydrofluoric acid treatments. Both the acids and heavy liquids are noxious and must be carefully handled. Excessive use of acids may degrade the pollen exine. Different samples will react quite differently to the same treatments; the researcher must adjust methods to fit the nature of the sediment. It is important that no pollen should be lost during this processing, and the pollen types must not respond differentially to the physical and chemical treatments (Traverse, 1988; Fægri et al., 1989).

The prepared samples containing only pollen may be stained in order to increase contrast in the exine’s features. The sample is mounted on a microscope slide; common mounts are glycerol and silicone oil. It is crucial that the grains can be turned within a liquid medium so that all sides are visible.

The next step is to make a taxonomic identification of each pollen grain, and an absolute count of frequency. The researcher is aiming to define two quantities: *percentage* of total pollen for each pollen type found; and *pollen concentration*, which is expressed as the number of pollen grains per unit volume of the sediment. These two quantities, combined with the eventual determination of the rate of sedimentation, allow the calculation of two additional variables: the *sediment matrix accumulation rate*, expressed as thickness of sediment accumulated per unit of time; and *pollen deposition rate* (also called

pollen accumulation rate, or *pollen influx*), which is expressed as number of grains accumulated per unit area of sediment per unit time (Davis, 1969). It is the *pollen percentages* of the taxa of interest, usually graphically presented on a single page, that are considered the main result of the field work and laboratory analysis.

The brief description here cannot do justice to the time intensive aspect of the pollen analyses. Most identification is done with an optical microscope; the magnification necessary ranges from 250× to 1,000×. This is the resolution needed to evaluate the three-dimensional shape of the pollen grain, the number and shape of the apertures, and exine structure and sculpturing (examples in Figure P83). Identification is based upon a combination of modern samples in a pollen herbarium, and pollen and spore identification keys. A “pollen herbarium” is essential for learning to identify a plant taxon by its pollen. Herbariums are usually created by individual researchers, or members of a research institution: at their smallest, they may be composed of only the key vegetation relevant to the studied region, while at their largest they may contain multiple exemplars of pollen collected from different individuals, and include both common wind-pollinated and rare insect-pollinated species. Identification keys are usually composed for the native flora of a specified geographic region: the “Identification Key for Northwest European Pollen Flora” compiled primarily by Fægri and Iversen (1975), and the “Key to the Quaternary Pollen and Spore of the Great Lakes Region,” by McAndrews et al. (1973) are examples of pollen keys that are utilized extensively for research in the appropriate geographic regions. In these keys, most grains are identified to the taxonomic level of genus, others to species, and a few only to family. There have been many recent efforts to compile pollen keys for other geographic regions including tropical, Southern Hemisphere, African and Asian flora.

The shape of the pollen or grain, and the arrangement of the apertures, can be classified into “morphological types (Traverse, 1988)” or “pollen classes (Fægri and Iversen, 1975).” The exine morphology also has its own vocabulary. However, morphology terminology has been, and still to a great extent is, a controversial and even chaotic subject (Fægri et al., 1989). The morphological reference the researcher utilizes will depend on the area and geologic age of the samples being studied. It can be difficult to discern the features of a fossil pollen grain even at high magnification. The identification and counting of pollen grains has still not been successfully automated. A sample that contains only pollen grains, all of which are in perfect form, may lend itself to computerized image recognition. In reality, most samples still contain extraneous material (ranging from charcoal to mineral dust) and pollen grains that have been folded and broken – the trained human eye still making the more definitive identification.

The pollen record

Typically, the researcher takes a few hours to examine the pollen from a single sediment sample. A minimum number of pollen grains, the *pollen sum*, must be counted in order to ensure the statistical robustness of the pollen percentages; this number varies from approximately 300 to 1,000 grains. The number counted will depend on the pollination characteristics of the vegetation; for example, pine trees produce greater quantities of pollen than other typical North American deciduous genera (such as beech and elm) and therefore pine pollen is said to “swamp” the pollen counts. A large pollen sum may

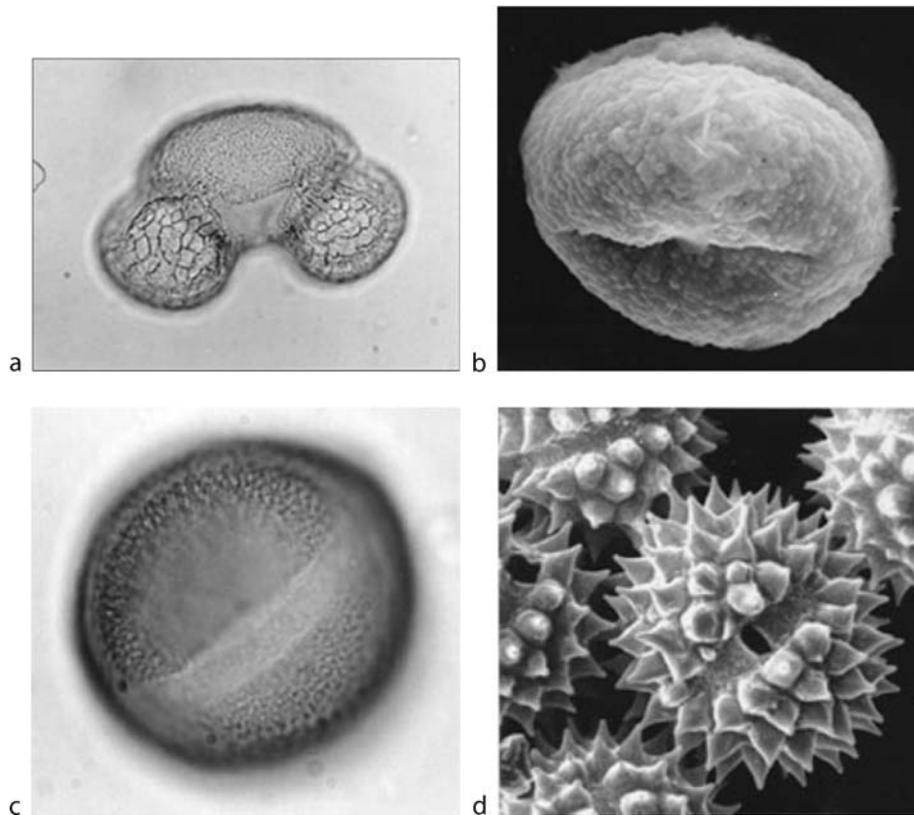

Figure P83 (a) Light micrograph of *Pinus palustris* P. Miller. *Pinus* is a vesiculate pollen grain, the two hemispheric bladders show reticulate sculpturing; the cap of the body (proximal surface) shows verrucate sculpturing (terminology follows Faegri and Iversen, 1975). Courtesy of Gretchen D. Jones, USDA-ARS, APMRU. (b) Scanning electron micrograph of *Quercus alba* L. *Quercus* pollen often has three furrowed apertures called colpi, this grain is tricolpate, the sculpturing is verrucate (terminology follows Faegri and Iversen, 1975). Marshall var. *saccharum*. *Acer* pollen is tricolpate, the exine is relatively thick with spines, echinate sculpturing (terminology follows Faegri and Iversen, 1975). Courtesy of Gretchen D. Jones, USDA-ARS, APMRU. (d) Scanning electron micrograph of *Aster sericeus*. *Aster* pollen, and many genera in the Asteraceae family, have three colpi, each with a pore; this grain is tricolporate, the sculpturing is reticulate (terminology follows Faegri and Iversen, 1975). Courtesy of Gretchen D. Jones, USDA-ARS, APMRU.

be used in order to discern abundance patterns of less-prolific pollen producers. It is also common to exclude some pollen taxa from the pollen sum: grains commonly excluded are those from aquatic plants, ferns, or all non-arboreal plants. The end result of the pollen analysis is a *pollen record* (Faegri et al., 1989), or a numerical matrix of pollen taxa identified per depth sample.

Commonly, after the pollen record has been compiled, the various types of pollen and spores encountered are calculated as percentages of the pollen sum. Admittedly, “percentage data have a built in bias, because the percentages must total 100%, and the percentage of pollen ‘A’ therefore influences the percentage of pollen ‘B’” (Traverse, 1988). Nevertheless, a *pollen diagram*, which presents the percentages in a simple graphic form, continues to provide easily readable information, relevant to further ecological or climatological interpretation. If the researcher has sufficient chronological control to calculate sedimentation rates, then pollen deposition rates may also be calculated and graphed. The graphical format of pollen deposition rates is similar to the pollen percentage diagrams graphs, although usually only a few key taxa are presented.

Ideally, the pollen percentage diagram should contain chronostratigraphic, lithostratigraphic, and biostratigraphic data

(Faegri et al., 1989). The chronostratigraphic element, on the ordinate axis, is composed of the depth scale, radiometric or relative dates, and any geological age assignments. The lithostratigraphy is usually a single column utilizing symbols, with accompanying legend, which conveys sediment information. The biostratigraphy is the heart of the pollen diagram: the *pollen spectrum*, which are the relative frequencies (percentages) of the various types of pollen per single sample, on the abscissa. Graphically the spectrum are shown as histograms, or as points which connect from depth to depth forming a “sawblade.” A variety of diagram types is found (see Figures P84 and P85). The most common diagram type presently constructed is termed the *resolved diagram* (Faegri et al., 1989); the varying percentages of many taxa are displayed, side by side.

The pollen percentage diagrams may contain any number of depth points, and their respective pollen spectra. The more spectra a diagram contains, the more it becomes practical to sub-divide the biostratigraphic portion of the diagram into pollen zones. A “zone is a common, usually informal, term for a minor stratigraphic interval in any category of stratigraphic classification (Hedberg, 1972 in Faegri et al., 1989).” Zones may be defined by presence/absence relations or by percentage variations of key pollen taxa. Pollen assemblage zones have

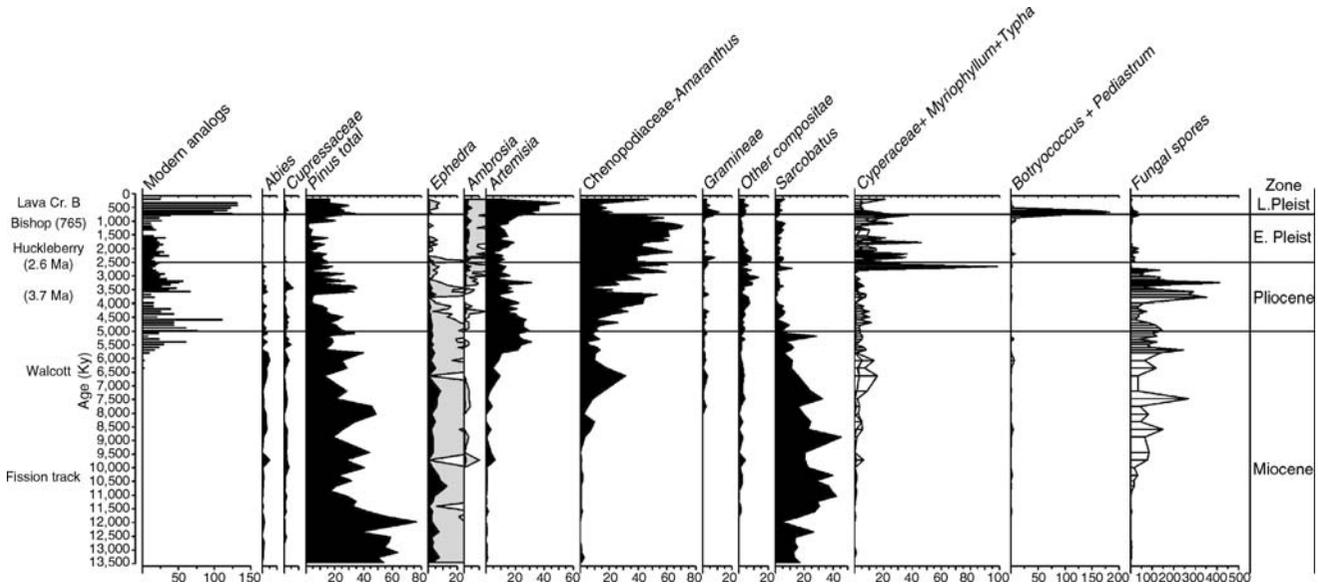

Figure P84 Percentage pollen diagram from Amoco Production Company's Bridge well, Great Salt Lake. The volcanic ashes utilized for age control are at the far left, along with a chronostratigraphic ordinate axis. The modern analog index has been plotted, along with ten common pollen taxa utilized in the pollen sum. The shaded sawtooth curve for "Ephedra and Artemisia" represents a 10× exaggeration of the percentages. "Cyperaceae + Myriophyllum + Typha" are wetland plants. "Botryococcus + Pediastrum" are algae. Geological time periods appear to the far right (from Davis and Moutoux, 1998). Reproduced with permission from the author.

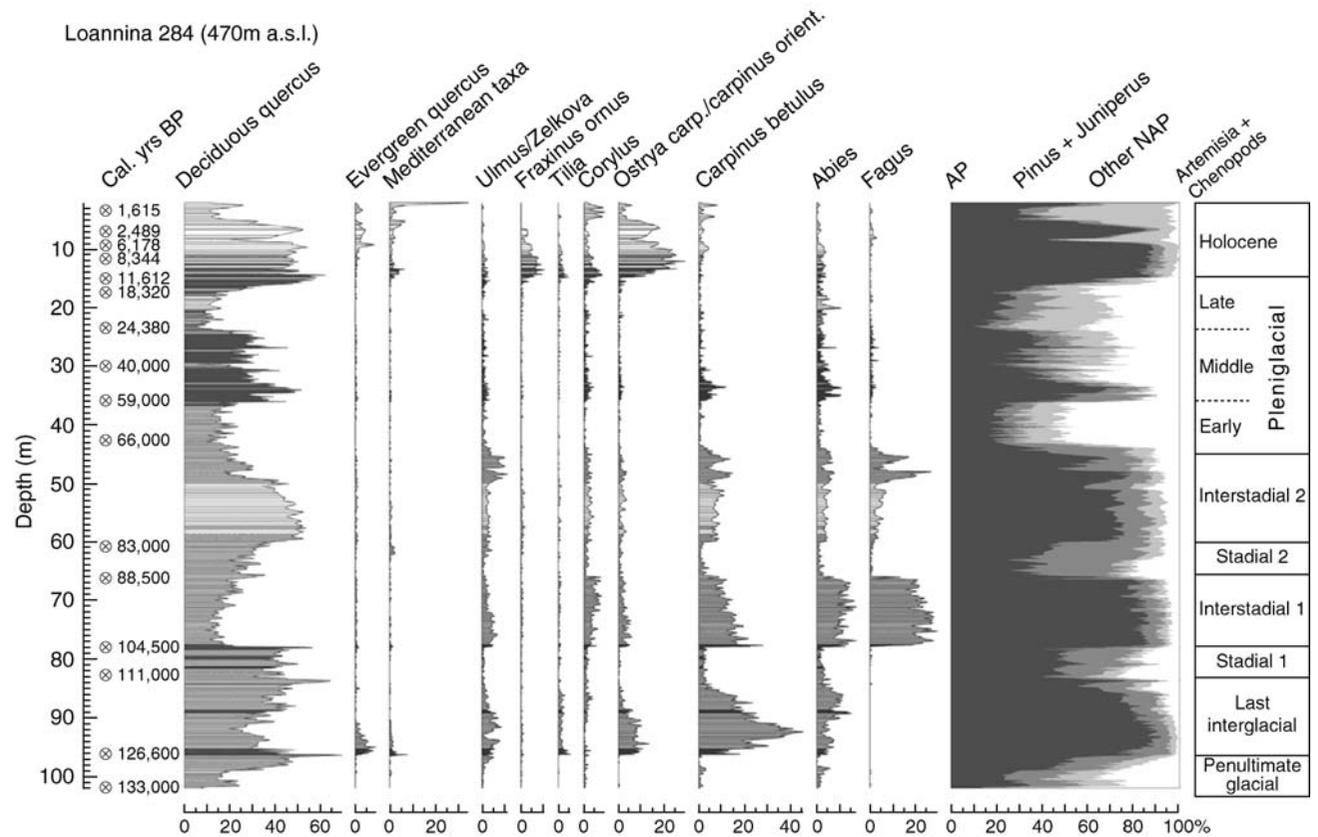

Figure P85 Pollen percentage diagram from borehole loannina 284. The spectra are presented as histograms connected by a sawtooth curve. Depth is on the ordinate axis. Ages are given for specific points: the upper seven ages are calibrated radiocarbon ages, the lower ages are based on astronomical calibration of pollen-vegetation abundance patterns (Tzedakis et al., 2002). often been used as biostratigraphic tools. The correlation of zones amongst sites is a frequent point of discussion and controversy in post-glacial pollen analysis, especially in Western Europe. The recent increased utilization of radiometric dating, most commonly radiocarbon applied to late Quaternary sediments, has somewhat replaced the reliance on zones for site-to-site correlation.

Interpretation

The researcher is striving to interpret pollen assemblages and their changes over time, or from one locale to another, as changes in vegetation. "The vegetation is the central object in pollen-analytic investigations" . . . and yet there is "no one-to-one correlation between the representation of a species in the vegetation cover and in the pollen spectrum (Fægri et al., 1989, p. 129)." Therefore, the soundest interpretations will depend on the researcher's knowledge of all the ecological and geological factors that have affected the final pollen record. The knowledge and skills required making a reasonable interpretation of past vegetation and climate based upon a pollen record will vary as greatly as the vegetation formations and geological regimes encompassed by the pollen record.

Two common methodologies utilized to interpret the pollen assemblages are the "modern analog" and the "indicator species" methods. The modern analog method seeks to elucidate the relationship between the vegetation that covers an area and the *pollen assemblage* found at a point within that area. Much field work has involved the collecting of small surface sediment samples from within different types of vegetation formations: the pollen are separated from the sediment, identified with a microscope, and a spectrum of the identified pollen taxa is produced; the surrounding vegetation is also identified and classified. With sufficient samples, one can at least qualitatively correlate a pollen spectrum with a vegetation formation. Several complications arise: the existing array of pollen surface samples is extensive in some vegetation types and not others, the pollen surface samples are useful only insofar as the vegetation (which produced the pollen) is in a state of equilibrium with the environment (in all aspects), some important geographical regions can yield no information on the modern pollen-vegetation relationships since anthropogenic activity has eliminated all the natural vegetation, and not all pollen assemblages in the geological record have a modern analog. However, in areas with adequate pollen surface samples, quantitative relationships between climate and pollen may be attempted and the specialist literature contains examples of these (for a more detailed introduction see Bradley, 1999).

The indicator species method relies on the ecological or climatological preferences of one (or a few) key taxa. If a taxon's habitat is highly specific, ecologically or climatologically, then the presence of that single taxon may indicate the habitat, even in the past. Alternatively, several taxa might be used to narrow the climatic or ecological range of the spectrum. The indicator species method is valid only if the fossil pollen truly indicates the presence of the plant in the immediate vicinity of the sampled site. Thus, application of this method should also utilize modern pollen distribution studies showing correlations between actual presence of a taxon, and a numerical pollen percentage threshold. The identification of plant macrofossils (seeds, leaves, etc.) can substantiate a specific taxon's presence, which may be doubtful if based on pollen percentages alone.

Conclusions: examples of pollen records

The following examples show pollen analysis applied to late Cenozoic sediments. The pollen taxa identified belong to extant genera (or families) and hence interpretation may be based on modern analogs and indicator species. Chronological resolution varies with the basin cored; chronological control also varies, from volcanic ashes to radiocarbon dates and to correlation with marine records.

The longest continuous terrestrial sediment cores in North America on which pollen analysis have been conducted come from the Great Salt Lake, northern Bonneville Basin region (northwest Utah; Davis and Moutoux, 1998; Davis, 2002). Pollen analysis was conducted from sediment cuttings (which integrate sediment from a range of depths) retrieved during drilling conducted for geophysical exploration. The wells are exceptionally deep, exceeding 3 km. The sampling interval is from 3 to 30 m, and thus chronological resolution ranges from 8 to 23 kyr. The Bridge well (Figure P84) contains the longest accumulation of pollen and sediments. The interpretation of the relationship between vegetation and pollen spectra is based on modern analogs; the fossil pollen samples were compared to 1,367 modern pollen samples from the western United States. The squared chord distance metric statistical method, also called square chord distance, was used to determine the analogy between modern and the fossil pollen samples quantitatively. The environmental development of the Great Basin can be interpreted from these pollen diagrams. Since the pollen spectra were dominated by xerophytic vegetation, *Sarcobatus* and *Ephedra*, from >5 Ma ago to the present, the region's present-day desert vegetation is interpreted to have existed since the late Miocene. In addition, the poor pollen preservation and scarce pollen of wetland plants indicates that lakes and marshes in the Great Salt Lake basin were shallow and intermittent before 2.6 Ma. Between 5 and 0.75 Ma, the *Sarcobatus* and *Ephedra* pollen are replaced by pollen from the wetland plants, "Chenopodiaceae + *Amaranthus*" (these pollen types are indicative of greasewood steppe vegetation), and *Artemisia* (sagebrush), which indicates a regional cooling and increase in moisture. After 0.75 Ma, *Artemisia* and *Pinus* pollen predominate, which is interpreted as downward displacement of vegetation zones by approximately 500 m in elevation, and the replacement of the greasewood steppe by sagebrush steppe in the intermountain basins (Davis, 2002).

The Ioannina basin, Pindus Mountain Range, Greece, contains a 430,000 year record of pollen in which fluctuating percentages can be used to understand the Quaternary climate cycles and the reactions of tree populations (Tzedakis, 1993). It provides a rare combination of stratigraphic continuity, and high sedimentation accumulation rates for the late Quaternary. Several lacustrine cores have been taken from the basin: the increasing detail of the pollen analysis is evident, as the results have been published. The first analysis shows the pollen spectra alternating between forest and open vegetation communities, reflecting the interglacial and glacial climate, respectively. Four cycles are evident, and they are correlated with glacial-interglacial changes registered in other southern European pollen records. However, a unique feature of the Ioannina cores is the continuous presence of *Quercus* and *Abies*, followed by *Pinus*, *Ulmus/Zelkova* and, to a certain extent, *Corylus*: these are temperate trees (Tzedakis, 1993). These temperate tree populations persist even during glacial periods. This record of the continuous presence of temperate tree

pollen is used to support the ecological hypothesis that these mountains provided long-term refugia for the temperate taxa (Tzedakis, 1993).

Increased detail is apparent in the pollen analysis conducted on a borehole called Ioannina 284 (Figure P85) (Tzedakis et al., 2002, 2003). The mean sampling interval has been increased to approximately 225 years. Because of the increased temporal resolution of the record, greater detail within a single glacial or interglacial becomes evident. The onset of the last interglacial has been defined by the authors as occurring when tree pollen consistently rises above 50% frequency, and when tree pollen concentration exceeds 200,000 grains per cm³; the onset of the ensuing colder stadial occurs when tree pollen consistently drops below 50%. Thus, the Last Interglacial is represented in the interval from 96.7 to 83.4 cm depth, or approximately 127.3–111.7 kyr ago (Tzedakis et al., 2003). After the chronology has been determined, the pollen changes in Ioannina 284 are compared with other climatic data from the North Atlantic region. The data indicate that the millennial-scale expansions and contractions of tree populations may be in phase with climate events in the North Atlantic region and Greenland regions. However, sufficient moisture to maintain refugial temperate tree populations is proposed to be linked to the topographic variability of the Pindus Mountains (Tzedakis et al., 2002).

The pollen analyses from these two sites show how both paleoclimatological and paleoecological interpretations may be extracted from the studies. Furthermore, the means of chronological control will vary with the age of the sediments. With basins that encompass the Holocene epoch, laminated sediments may allow high temporal resolution. For older basins (including marine sediments), age may be based on biostratigraphic correlations. Regionally significant climate changes usually cannot be derived from a single pollen record: several fossil pollen records together from a user-defined region are necessary in order to confirm that patterns in pollen spectrum have significance beyond the single site examined.

POTASSIUM-ARGON/ARGON-ARGON DATING

General principles

The K-Ar dating method utilizes the decay of the naturally-occurring radioactive isotope of potassium, ⁴⁰K, into an isotope of the noble gas, argon (i.e., ⁴⁰Ar). ⁴⁰K decays into two different daughter products: the most common path (89.5%) is via beta decay into ⁴⁰Ca; the remainder of the decay paths arrive at ⁴⁰Ar, mostly via electron capture, but also rarely via positive beta (positron emission) decay. The total decay half life for ⁴⁰K is about 1.25 billion years, which means that there is still some of the isotope remaining from the formation of the solar system. Because of the branching decay scheme, the standard radiometric age equation needs to be modified as follows:

$$t = \frac{1}{\lambda} \ln \left(1 + \frac{\lambda}{\lambda_e} \frac{{}^{40}\text{Ar}}{{}^{40}\text{K}} \right) \quad (1)$$

where λ_e is the decay constant leading to ⁴⁰Ar ($0.581 \times 10^{-10} \text{ yr}^{-1}$) and λ is the total decay constant for both branches ($5.543 \times 10^{-10} \text{ yr}^{-1}$).

Much of the natural radioactivity surrounding us is due to ⁴⁰K, but fortunately, it is a quite rare isotope, only accounting for about one atom in 8,570 atoms of potassium. Despite the rarity of ⁴⁰K and the fact that only about one atom in ten decays into ⁴⁰Ar, the K-Ar system is arguably the most versatile of the long-lived decay scheme dating methods. It is nearly an ideal chronometer because K is a major element present in almost all rocks and minerals, but the act of mineral formation is usually exceptionally efficient at excluding atmospheric argon from the mineral's crystal structure. Radiogenic ⁴⁰Ar is well

accommodated in many minerals, which can often quantitatively retain their Ar to temperatures of 300–400 °C or higher. Therefore, K-Ar dating usually has a very clear-cut resetting of the radiometric clock and the clock can faithfully record geological time for durations ranging from thousands to billions of years. Indeed, K-Ar and its cousin Ar-Ar dating have been used successfully to calibrate all of the geomagnetic reversal time scale, much of the history of early humanity, and most of the Phanerozoic timescale, plus ancient samples from Earth, the Moon and Mars.

K-Ar method

In the conventional K-Ar dating method, a part of the sample is analyzed via wet chemistry techniques for K concentration; the remainder of the sample is placed into an ultra-high vacuum system and fused to release all of its trapped gases. The released water vapor is usually trapped in a “cold trap” at dry ice or liquid N₂ temperatures, and the remaining active gases are removed using a “getter” pump, which consists of a highly reactive metal alloy kept at an elevated temperature. The getter removes O₂, N₂, CO₂, CH₄, etc., but leaves the Ar untouched. The remaining “cleaned” Ar sample is usually mixed with a known quantity of the rare argon isotope ³⁸Ar so that the concentration of ⁴⁰Ar can be estimated from the ⁴⁰Ar/³⁸Ar ratio (i.e., isotope dilution). The combined Ar sample is then admitted to a noble gas mass spectrometer. The presence of any atmospheric Ar is corrected by monitoring the ³⁶Ar signal and subtracting an amount 295.5 times larger from the ⁴⁰Ar peak (i.e., the ⁴⁰Ar/³⁶Ar ratio of the atmosphere).

The precision of the K-Ar method is limited by the errors associated with the isotope dilution technique, weighing errors, and the precision of the chemical measurement of K concentration. Typical error estimates are about 1–2% for this method. Accuracy and the reliability of K-Ar ages are further hampered by so-called “nugget effects,” where there may be unusual phases in either the K or Ar sample split. This possibility and the requirement for two separate measurements limit the use of the technique to relatively large and homogeneous samples.

Ar-Ar or the ⁴⁰Ar/³⁹Ar method

In 1966, the team of Merrihue and Turner, working in John Reynold’s laboratory, devised a remarkable enhancement of the K-Ar method that has greatly increased its scope and power (Merrihue and Turner, 1966). In the ⁴⁰Ar/³⁹Ar (or Ar-Ar) dating method, a single split of the sample is sent to a nuclear reactor and irradiated with high-energy neutrons. Some of the most common isotope of potassium, the stable isotope ³⁹K, undergoes a reaction where it briefly absorbs a neutron and expels a proton, thereby transforming into ³⁹Ar. This isotope of argon is radioactive and is not present in the atmosphere in appreciable quantities since it has a half-life of only ca. 270 years. The sample now has both its original radiogenic ⁴⁰Ar and another argon isotope, which can effectively be used as a proxy for potassium. It is possible to measure the ⁴⁰Ar/³⁹Ar ratio, which is proportional to the ⁴⁰Ar/K ratio, which is in turn proportional to the ⁴⁰Ar/³⁹K ratio. The proportionality constant is estimated by analyzing a standard mineral of known K-Ar apparent age during the same neutron irradiation as the sample. The ⁴⁰Ar/³⁹Ar age equation can be written as:

$$t = \frac{1}{\lambda} \ln \left(1 + J \frac{{}^{40}\text{Ar}^*}{{}^{39}\text{Ar}_K} \right) \quad (2)$$

The superscript * denotes radiogenic ⁴⁰Ar. *J* is calculated as:

$$J = \frac{e^{\lambda t_{\text{standard}}} - 1}{({}^{40}\text{Ar}^*/{}^{39}\text{Ar}_K)_{\text{standard}}} \quad (3)$$

The suffix “K” is put on ³⁹Ar to indicate that only the component from potassium is used. There are interfering nuclear reactions, usually from Ca, which produce small amounts of ³⁶Ar and ³⁹Ar, but these can be corrected by calibration analyses of pure Ca salts. Ca also produces significant quantities of the radioactive isotope ³⁷Ar and it is possible to infer the relative concentrations of Ca, Cl, and K by the enhanced abundances of ³⁷Ar, ³⁸Ar, and ³⁹Ar, respectively.

The ⁴⁰Ar/³⁹Ar method eliminates the problem of sample heterogeneity and it has significantly better precision relative to K-Ar dating because all of the measurements are based on isotope ratio measurements, not absolute concentration estimates, and mass spectrometers are much more accurate with the former style of measurement. Age estimates that are precise to within a few tenths of a percent are commonplace, but even more important than laboratory precision are the extra interpretation capabilities of the technique, which lead to more accurate age estimates.

Since age information comes from Ar isotope ratios, it is possible to step-heat a sample in gradually increasing temperature steps and calculate an apparent age for each gas fraction. The sequence of apparent ages is plotted as an “age spectrum,” which can be extremely useful in testing whether or not the sample has remained a closed system during its lifetime. Ideally, the age spectrum will yield a flat sequence of ages or a perfect “plateau age” which can be used with much greater confidence than a comparable single K-Ar age. Alternatively, there are other typical age spectral patterns such as that expected from diffusive loss of Ar or the so-called “saddle shaped” spectrum, which is diagnostic for the presence of excess ⁴⁰Ar. Sometimes it is possible to derive useful age information event from these disturbed age spectra (e.g., Snyder et al., 1996), but at the very least a disturbed age spectrum is a red flag indicating that the data need to be interpreted with care.

⁴⁰Ar/³⁹Ar step-heating also makes it possible to do an isochron style analysis on a single sample, which was impossible with the K-Ar method. Usually in an argon isochron diagram, the ³⁶Ar/⁴⁰Ar ratio is plotted against the ³⁹Ar/⁴⁰Ar ratio, and the intercepts of the fitted line indicate the sample’s initial ³⁶Ar/⁴⁰Ar ratio and apparent age. This kind of analysis is particularly useful for young samples (a few Ma) where the usual assumption of atmospheric composition initial Ar can be rigorously tested.

Finally, the combination of ⁴⁰Ar/³⁹Ar dating with a new generation of low-blank laser fusion systems (York et al., 1981) and high sensitivity mass spectrometers has led to a whole generation of highly automated laboratories capable of routinely analyzing extremely small and extremely young samples. A crucial application has been to revolutionize the dating of volcanic tephra (Lo Bello et al., 1987) by enabling the researcher to date single crystals of volcanic feldspar, thereby eliminating contamination problems, which had long plagued bulk sample analyses. This in turn has allowed for extremely accurate ages for studies ranging from calibrating the geomagnetic reversal timescale to dating early human specimens. For a more complete description of the ⁴⁰Ar/³⁹Ar method, see McDougall and Harrison (1999).

PRECESSION, CLIMATIC

The celestial equator intersects the ecliptic in two points. The vernal equinox is the one at which the Sun in its apparent annual motion crosses from South to North of the equator. The vernal equinox can be used as a reference point to define the celestial longitude locating the Earth along its orbit during the year. The longitude of the perihelion (ϖ) represents the angular position of the perihelion of the orbit from the vernal equinox. This angle gives the position of the Earth on its orbit at the spring equinox. Knowing the longitude of the perihelion, it is possible to determine the Earth-Sun distance at any time in the year. Climatic precession ($e \sin \varpi$) is usually used instead of the longitude of the perihelion. It is the main factor driving the 24 h-mean irradiance.

Astronomers of old civilizations kept records of the direction of the Earth's axis of rotation in the sky. Five thousand years ago, stars circled around α -Draco's in the night sky, while it is now around α Ursa Minor (polaris). Indeed the Earth's axis of rotation does not point towards a fixed direction through time but describes a clockwise circle in space. This happens because the torque of the Moon and the Sun on the Earth's equatorial bulge causes the axis of rotation to wobble (the Earth's equatorial radius is close to 6,375 km while its polar radius is only 6,355 km). This motion of the Earth's axis of rotation, called astronomical precession, is similar to the

precession of a tilted top and it induces the motion of the vernal equinox, with a period of 25,700 years. However, from a paleoclimatic point of view, the situation is not so simple. Indeed, the ecliptic is not fixed in time either, leading to an anticlockwise motion of the perihelion. Consequently the climatic precession, which describes the position of the perihelion with respect to the vernal equinox, varies with a quasi-period of 21,000 years, resulting from the combination of several periods, the most important being around 23,000 and 19,000 years (Berger, 1978; Berger and Loutre, 1991) (Figure P86).

The present-day value of the longitude of the perihelion is $\varpi = 102.04^\circ$, which gives a climatic precession of $e \sin \varpi = 0.01636$. In this situation the Earth is at the closest distance to the Sun in early January (Berger and Loutre, 1994). Therefore the mean solar irradiance received during the southern summer in the Southern Hemisphere is larger than the mean solar irradiance received during the boreal summer in the Northern Hemisphere. Some 11,000 years ago, the Earth was at the closest distance to the Sun around the June solstice. This increased the solar irradiance received during boreal summer and reduced it during Southern Hemisphere summer. The climatic precession therefore plays opposite roles in both hemispheres. Any insolation change in one hemisphere due solely to a variation in climatic precession corresponds to an insolation change of opposite sign and same amplitude in the other hemisphere six months later (Figure P87).

Moreover, the length of the seasons, which vary in time according to Kepler's law, is also strongly dependent on the climatic precession (Berger and Loutre, 1994). Presently the length of the Northern Hemisphere seasons is respectively 92.8 days for spring, 93.6 days for summer, 89.8 days for autumn, and 89 days for winter. In about 4,500 years from now, the Northern Hemisphere spring and winter will have about the same short duration (89.6 days), and summer and fall will also be equally long (93.0 days).

PRE-QUATERNARY MILANKOVITCH CYCLES AND CLIMATE VARIABILITY

Introduction

Cyclic variations in insolation, caused by the precession and obliquity of Earth's spin axis and variations in the eccentricity of Earth's orbit, have been stressed as a driver of Quaternary climate since Hays et al. (1976). The Quaternary, however, comprises only 0.4% of Earth history, and is characterized by unusual "ice house" conditions. In addition, neither the mechanism through which ice house conditions were initiated, nor the mechanism whereby the 100 kyr cycle has come to dominate glacial oscillations are understood (see Muller and MacDonald, 2000). Analysis of pre-Quaternary Milankovitch cycles provides a more synoptic view of the role of astronomically controlled climate change, a context for understanding the present state of the Earth system and anthropogenic modifications, a mechanism for producing high-resolution timescales, and data for calibrating the dynamic evolution of the solar system (see reviews by Berger et al., 1989; Fischer et al., 1991; Schwarzacher, 1993; Weedon, 1993, 2003; Hinnov, 2000, 2005).

Methods

Two fundamentally different, although mutually illuminating, approaches to the analysis of pre-Quaternary Milankovitch cyclicity have been developed. The first, cycle counting, predates acceptance of the Milankovitch theory for Quaternary climate change by nearly a century (e.g., Gilbert, 1895)

(Figure P88). Cycle counting is an inherently typological approach requiring both identification of each sedimentary or proxy cycle and its boundaries within a section and a timescale to determine cycle duration. Bundles of cycles of variable thickness allow recognition of the characteristic Milankovitch cycle hierarchy based on the thickness ratio of short to long cycles, assuming the highest frequency cycles have been correctly identified. A variant of the cycle counting approach is named for Fischer's (1964) analysis of the Triassic asymmetric carbonate Lofer cycles (Figure P89). These so-called Fischer plots are graphs of cumulative departure from average cycle thickness plotted against cycle number, assuming a uniform period for each cycle and modified for assumed constant subsidence during each cycle (see Sadler et al., 1993; Boss and Rasmussen, 1995 for criticism). While the typological cycle counting method allows easy visualization of sedimentological patterns and cycle identification in the field, the numerous ad hoc assumptions that must be made about the variability of the cyclicity makes its practical use treacherous unless there is a known target pattern for correlation, such as an age-appropriate and accurate insolation curve. Additionally, often used as a measure of relative sea-level change, Fischer plots appear to be a poor predictor for Quaternary examples where sea-level change is well understood (e.g., Boss and Rasmussen, 1995).

The second approach, time series analysis, is commonly used in Quaternary analyses and was inspired by the pivotal paper by Hays et al. (1976) that established Milankovitch cyclicity as the "Pacemaker of the Ice Ages," although there were earlier applications. Here, a variable (lithological or climate proxy) is plotted against thickness or time, and Fourier or other quantitative methods are used to determine the frequency properties of the data that can then be compared to a hypothesis of orbital forcing (Figure P90). This method dispenses with the need to identify the cycle type, has the advantage of not requiring variability in the data to be discarded, and thus does not presume the mode of cyclicity (i.e., precession vs. obliquity). The disadvantage is that the variable must have a unimodal relationship to climate or a precise timescale must be available; these become progressively much less common in more ancient deposits. Sequences have typically been analyzed by Fourier methods with the data transformed from the depth or time domain to the frequency domain. The results are usually expressed as a periodogram (a graph of frequency against a measure of the importance of that frequency, such as power). This method, however, presumes little variation in accumulation rate; that is, the frequencies are stationary with respect to the depth scale. This assumption can be considerably relaxed with use of evolutive or depth-frequency analysis. Here, the frequency properties of the section are analyzed by use of a moving window and are plotted with respect to depth (Figure P91). A plethora of techniques is available in which accumulation rate changes can be determined directly from the internal frequency properties of the data.

Timescales

Both cycle counting and time series methods require a timescale to help assess accumulation rates. Accumulation rates are quantified by relying largely on direct dating by annual rhythms (varves) and radiometric methods, indirect dating by correlation to other well established timescales, such as $\delta^{18}O$ curves or magnetic polarity transitions, and tuning to insolation curves based on celestial mechanics. In older stratigraphic

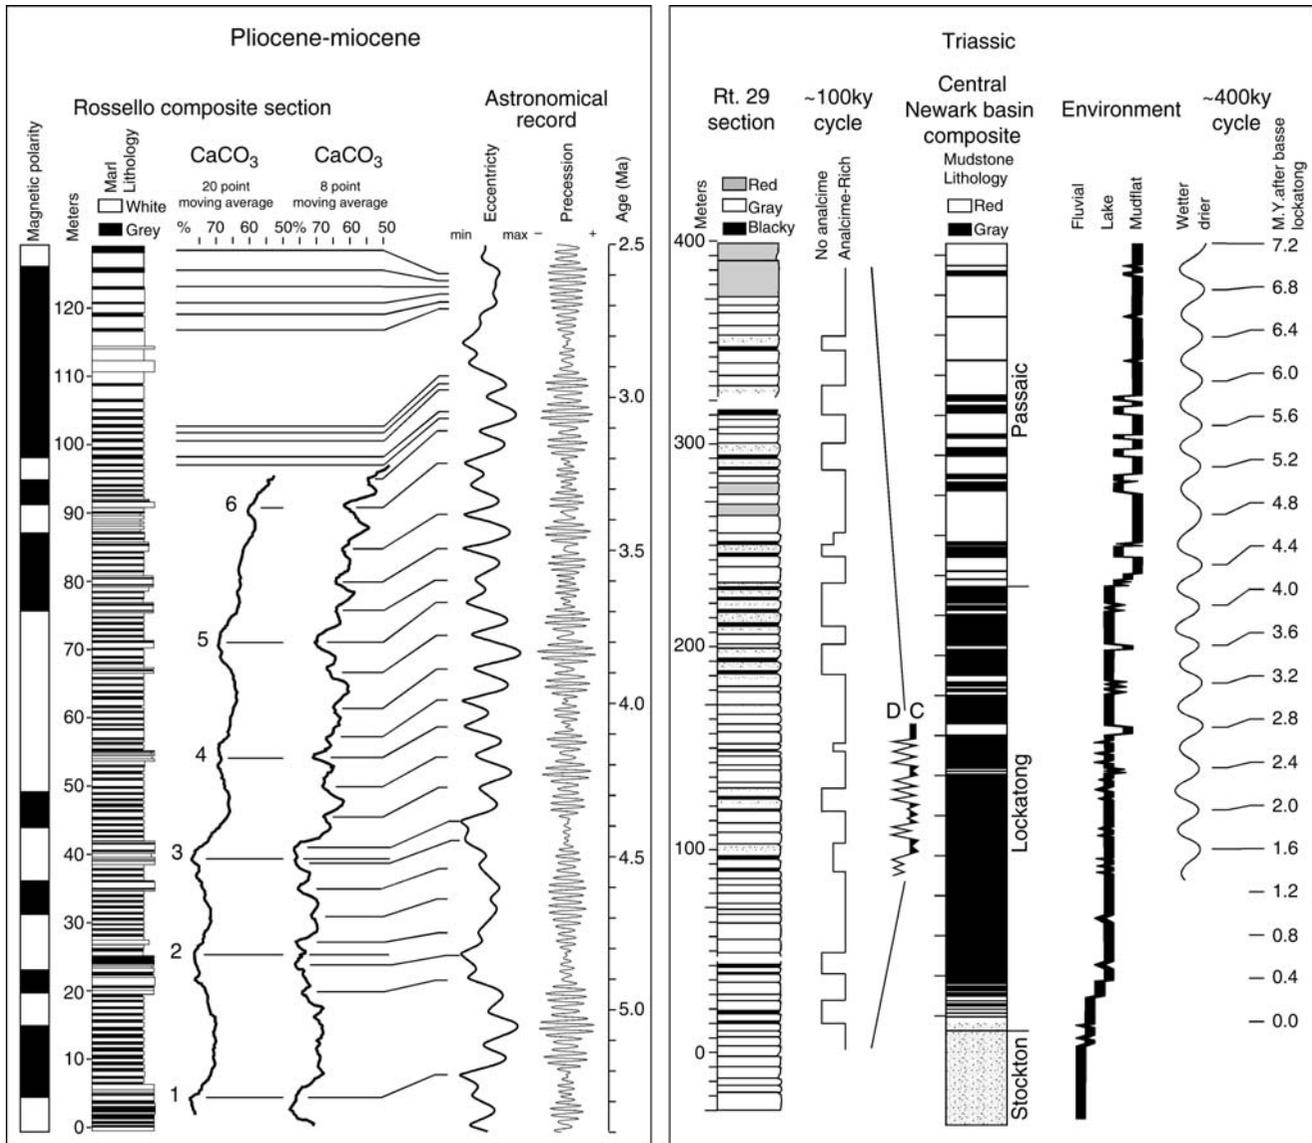

Figure P88 Cycle counting and matching to an astronomical record; *left*: marine Pliocene-Miocene example with astronomical calibration from Sicily modified from Hilgen (1991b); *right*: lacustrine Triassic example, modified from Van Houten (1964) with 400 kyr cycle added.

records, it becomes progressively harder to apply these proxies and dating methods successfully and other, more inferential, methods must be used.

Varves are annual rhythms that can be marine or non-marine and generally consist of couplets or, more rarely, of triplets of heterogeneous laminae (see review by Anderson, 1964; Anderson and Dean, 1988). It is usually assumed that a single couplet or lamina series represents one year, corresponding to summer and winter or wet and dry seasons, although some lacustrine environments could theoretically possess two couplets of laminae series per year, and there can be confusion with tidal banding. Although varve calibration provides direct and very high-resolution records of accumulation rates, varved sequences are rare and when present often constitute only a small part of the sedimentary column.

Radiometric dates provide another direct way to calibrate accumulation rates and a basis for a timescale. To be useful, there must be several dates in a section separated in time sufficiently to exceed error limits, and they must be geologically accurate. Very few sections meet these criteria. It is possible to obtain paleontological or other time-correlative means to tie radiometric dates to sections under analysis. Possible difficulties are exemplified by debates on the Triassic Latemar and the Eocene Green River Formation (Hinnov and Goldhammer, 1991; Brack et al., 1996; Pietras et al., 2003; Machlus et al., 2004, 2008).

As is true for Quaternary records, the relatively well-established marine $\delta^{18}\text{O}$ record provides a powerful tie to published timescales for older Neogene marine sections (e.g., Miller et al., 1987). The temporal accuracy, however, of correlations to the

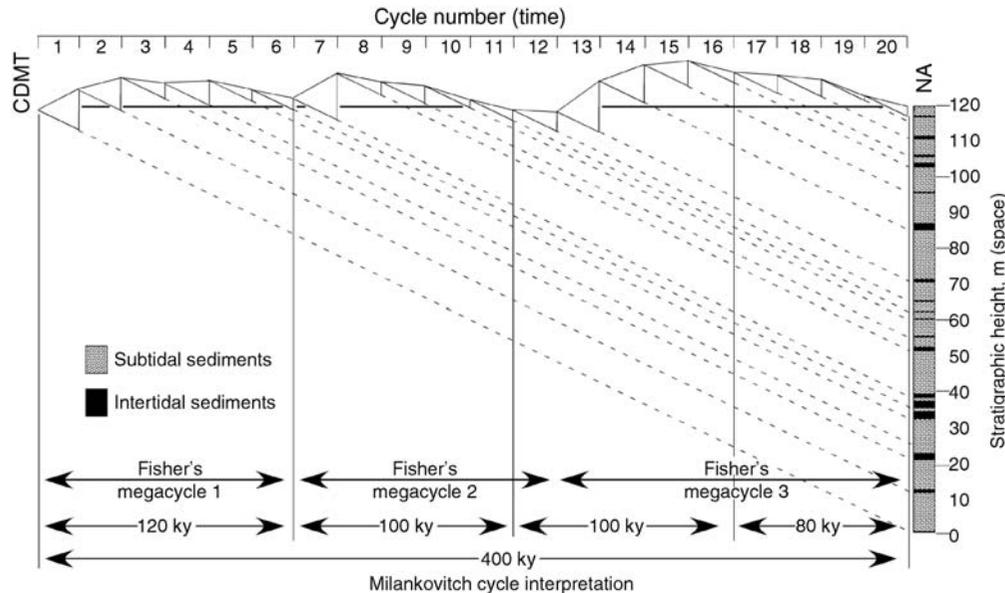

Figure P89 Fischer plot of Fischer's example of Triassic Lofers cycles in marine Triassic carbonates of Austria (modified from Fischer, 1964) with a modern Milankovitch cycle interpretation overlain.

$\delta^{18}\text{O}$ record can be no better than the accuracy of the $\delta^{18}\text{O}$ record itself, which is undergoing significant modifications. Using this technique for accumulation rate calibration, only open marine sections can be meaningfully correlated, and the section being correlated needs sufficient temporal scope to encompass enough of the character of the $\delta^{18}\text{O}$ curve.

Correlation and tuning to insolation curves has been extensively used in strata of Neogene age, but less commonly in the Paleogene (e.g., Hilgen, 1991a,b; Shackleton et al., 2000), and not at all in the Mesozoic and older strata (Figure P88). The production of insolation curves to which ancient proxy curves can be matched is limited by uncertainties in observations, chaotic behavior of the planets, lack of knowledge of the evolution of the Earth-Moon system, and dynamic aspects of mass distribution within the Earth. Insolation curves for the higher frequency climatic precession and obliquity cycles are accurate to 40–50 Ma, and the 405 kyr cycle to 250 Ma. The variations of the 405 kyr cycle beyond 250 Ma are relatively small, and could be used, recognizing the larger uncertainties, back to the age of the Earth (see Laskar, 1990, 1999; Berger et al., 1992; Laskar et al., 1993, 2004; Palike et al., 2004). If the 405 kyr cycle can be identified, it can be used to calibrate average accumulation rate and hence provide a mechanism to establish the period of higher frequency cycles independent of their drift through deep time (e.g., Olsen and Kent, 1999).

For the late Jurassic through Neogene, the well-established marine magnetic anomaly timescale (Cande and Kent, 1995) establishes broad constraints for sections with internal polarity data. Although the average duration of a chron is ~ 0.25 million years (Lowrie and Kent, 2004), correlation to the marine magnetic anomaly timescale is useful only for sections involving millions of years. As there is no marine magnetic anomaly timescale for strata older than late Jurassic, Milankovitch cycles have proved more useful for calibrating the magnetic polarity record than vice versa (e.g., Kent and Olsen, 1999).

One of the most powerful methods of calibrating accumulation rate is via the internal frequency structure of the data series itself, and this takes two basic forms. First, the celestial mechanical theory predicts a very specific relationship between the higher and lower frequencies present in data. The lower frequencies are beat cycles of the higher frequencies within the precession-related bands or the obliquity-related bands. The frequencies of the ~ 100 kyr eccentricity cycles are equal to the differences between the frequencies of the climatic precession cycles because these cycles result from the interaction of the Earth's precession and the gravitational attraction of the planets and the eccentricity cycles result from the gravitational interaction of the very same planets. At present, the main periods that can be recognized in climatic precession are about 19, 23, and 24 kyr. The periods of the linear combinations of differences of the frequencies of these periods are about 93, 125, and 405 kyr (calculated using appropriate precision). This is a mathematical relationship that holds regardless of changes in the value of the precession constant in the deep past (due to the Earth-Moon system evolution or mass distribution within the Earth), or chaotic changes in planetary orbits. The same relationship is maintained for the obliquity-related cycles. However, only the most high-fidelity records (e.g., Triassic Lofertong Formation; Olsen and Kent, 1996; Hinnov, 2005) have this level of detail (Figure P89). The second, more widely used concept is that the ratio of the shorter to the longer periods within the Milankovitch bands, such as precession to eccentricity, changes very slowly through Earth history, presently there is a 1:5:20 ratio of precession (~ 20 kyr) to short (~ 100 kyr) and long (~ 400 kyr) eccentricity cycles. This change is theoretically a steady decrease in the precession period due to tidal friction that should increase the ratio of climatic precession to eccentricity cycles (Figure P92). The same effect is seen in obliquity. The actual change in precession, however, may be more complicated due to other factors, especially the changing dynamic

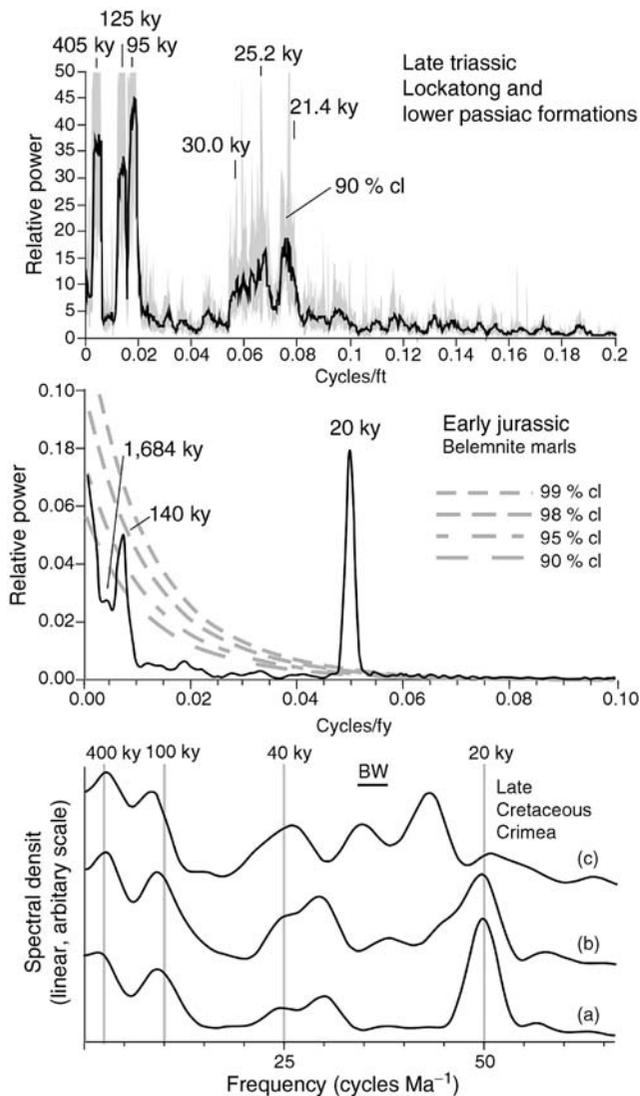

Figure P90 Power spectra of pre-Quaternary paleoclimate proxy time series. *Top*: Thompson multitaper spectral estimate of 3 million year of Triassic lake level data (depth ranks) from New Jersey, USA, modified from Olsen and Kent (1996), shaded area is 90% confidence limits; *middle*: discrete Fourier transform power spectrum of 1.7 million year of wt% CaCO_3 data from the marine Belemnite Marls, England (modified from Weedon et al., 1999); *bottom*: linear Blackman Tukey spectral analysis of grey scale reflectance of a 720 kyr section of Cretaceous marine strata from the Crimea, Ukraine (from Gale et al., 1999).

ellipticity of the Earth caused by movement of continents, mantle, or ice sheets. There should be little measurable change caused by the chaotic diffusion of the planetary orbits for the typically cited 405 kyr and 100 kyr eccentricity periods, and thus the main observable secular change in orbital frequencies should be in precession.

Many authors have used the canonical 1:5:20 ratio of the shorter to longer cycles as strong evidence of the Milankovitch origin of pre-Quaternary cycles, despite uncertainty in the actual ratio, especially in strata hundreds of millions of years old. In the absence of any other time constraints, these ratios may not

be unique (e.g., Latemar controversy, see below). Presuming that the average ratios are broadly consistent with available constraints, and the section covers millions of years, evolutive depth-frequency analysis (as opposed to time-frequency) can reveal shifts in the absolute values of frequencies through a section, while maintaining the ratios of the higher to lower frequencies. Only Milankovitch theory predicts constancy of those frequencies independent of actual accumulation rate. The advantage to this analysis is that the changes in accumulation rate can be derived directly from the spectrogram. At present, only a few sections have been examined this way (e.g., see Olsen and Kent, 1999; Preto et al., 2001; Weedon, 2003).

The interaction of climatic and sedimentological processes should produce a distortion of accumulation rates, resulting in periodograms and time- or depth-frequency spectrograms that are noisy or distorted beyond interpretation. Two techniques, gamma analysis (Kominz and Bond, 1990) and frequency modulation (FM) analysis (Hinnov and Park, 1998) were developed to deal with a situation in which accumulation rate may be a function of Milankovitch cycles themselves. Both involve a version of cycle counting. In gamma analysis, an approximate solution to the relationship between time and facies is found for a succession of sedimentary cycles. Individual facies specific to certain environments are identified within a section and measured in thickness. Assuming that each cycle is of constant duration and each facies is characterized by a specific effective accumulation rate (γ), an approximation of the accumulation rate of each facies can be found by solving a series of simultaneous equations representing the cumulative time of the different facies within each cycle. The fit of these approximations is assessed by an inverse method using the accumulation rates derived from the measured section and Fourier analysis of the resulting time series. If the accumulation rates are identified correctly and the sequence is of Milankovitch origin, the Fourier spectrum should reflect a better fit to the expectations of Milankovitch theory than the original data. Although this method incorrectly assumes a constant duration for the precessional cycles, it might reveal the presence of another cycle to which the section could be tuned, such as the 40 kyr obliquity cycle of relatively constant frequency. This method has been applied to Cambrian marine, and Triassic and Jurassic lacustrine sequences, significantly improving the spectral properties of the data.

FM analysis begins with the identification of the presumed geological expression of precessional (or obliquity) cycles and estimation of the length of each cycle, creating a new time series of depth against cycle thickness. Fourier analysis of this new time series reveals the FM modulating cycles. Since the precession cycle is frequency modulated by the “eccentricity” cycles, FM analysis of a real insolation curve reveals the eccentricity cycles (see Hinnov, 2000). FM analysis of the data curve also has this characteristic shape if it is the result of Milankovitch processes. A tacit assumption of this method is that there is a strong and amplified link between the frequency modulators of accumulation rate and the eccentricity cycles themselves. A major disadvantage to this method is that the higher frequency cycles must be identified, which is nearly impossible in noisy, low amplitude, or clipped records. In addition, the Fourier FM spectral pattern may not be unique to the frequency band characterized by the “usual” Milankovitch frequencies; it may be shared with sub-Milankovitch, yet still quasiperiodic, climatic processes.

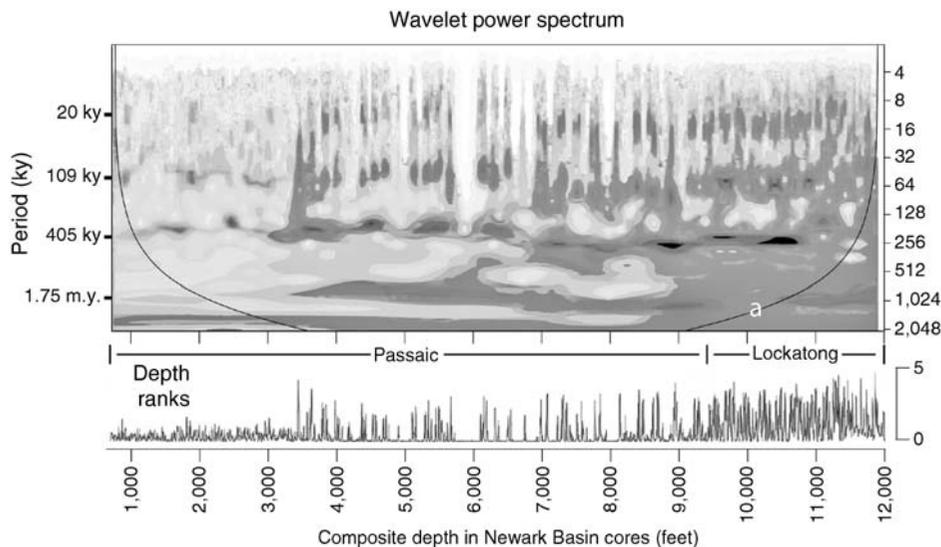

Figure P91 Evolutive spectral analysis of 22 million year of lake level (depth rank) data from the continuously cored Late Triassic age lacustrine Lockatong and Passaic formations of the Newark Rift basin, New Jersey, USA. Above: continuous wavelet transform of lake level data (wavelet provided by C. Torrence and G. Compo; <http://paos.colorado.edu/research/wavelets/run> by M. Machlus); bottom: depth rank data in depth domain (from Olsen and Kent, 1996).

Proxies

Since climate parameters cannot be measured in sedimentary strata, a reasonably direct recorder of a response to climate change, or climate proxy, is necessary. For Quaternary sequences, a vast array of possible climate proxies can be reasonably calibrated because neither the tectonic plate configuration nor species composition has changed much over the last 2 million years. These proxies include $\delta^{18}\text{O}$, a proxy mostly for ice volume (e.g., Hays et al., 1976), eolian dust, a proxy mainly for aridity and wind intensity, and pollen and spores, a reflection of climate-related changes in plant species distributions. Deeper in time these proxies can be affected by diagenesis, lithification, and lack of extant taxa that can be calibrated. Proxies less prone to time-related processes range from sedimentary facies classifications sensitive to water depth (e.g., Olsen, 1986) to geochemical proxies such as $\delta^{13}\text{C}$ of organic matter, carbonate sensitive to climate-related oceanographic processes, and oil-shale yield, related to water depth (e.g., Bradley, 1929).

Examples of pre-Quaternary Milankovitch cycles

Neogene

Largely circum-Mediterranean and deep sea core sections are the basis of a high resolution Miocene to Quaternary Milankovitch-cycle-calibrated timescale (Shackleton et al., 1990; Hilgen, 1991b; Hilgen et al., 1995, 1997). The Mediterranean marine sections exhibit the marl-sapropel cyclicity originally described from Mediterranean cores. The largest-scale bundles of cycles visible are matched to the 400 kyr of a precession-dominated isolation curve, in a portion of the section that is already well dated. Progressively smaller bundles are matched to the insolation curve, followed by precession-related individual marl-sapropel cycles (Figure P88). Older sections are then spliced. The hierarchical nature of both the bundling and the insolation curve limits potential miscorrelations. Radiometric dates have been used to test the timescale. The astronomical calibration is so robust that it has allowed for a recalibration of the ^{40}K decay

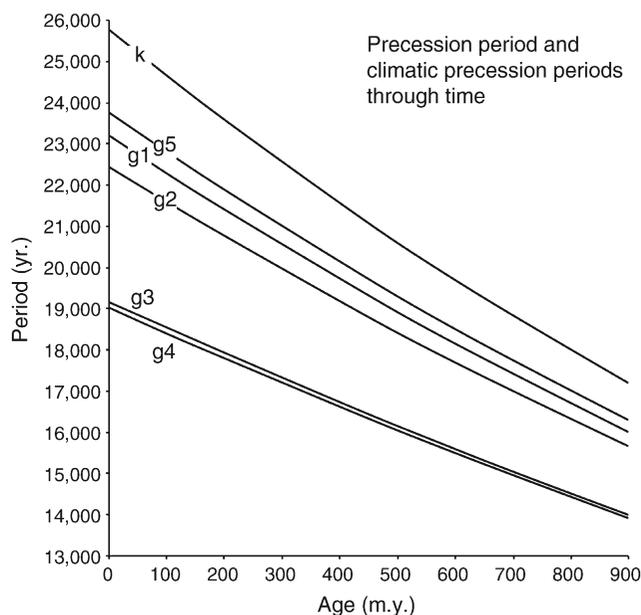

Figure P92 Change in the period of the Earth's axial precession due to tidal friction over the last 900 million years, and the expected changes in climatic precessional cycles. The sum of the frequency of axial precession, k , and the various fundamental frequencies of the planets, g_1 – g_5 (only the most important 5 shown here) is equal to the frequency of climatic precession. For the present day, there is a cluster of 3 periods around 23 kyr and another 2 periods around 19 kyr. Derived from Berger et al. (1992).

constant, itself (Hilgen et al., 1999) now widely adopted. Hilgen's method has also been extended to non-marine strata, particularly in the Miocene (Aziz et al., 2003).

Shackleton et al. (1999, 2000), Palike et al. (2004), and Billups et al. (2004) have used marine cores showing strong

obliquity forcing to produce an astronomical calibration of the Oligocene, Miocene and Neogene. These cores exhibit the usual Milankovitch frequencies and modulation by longer cycles, notably the 1.2 million year cycle of obliquity modulation, and show that the resonance of the orbits of Earth and Mars has not changed state for the last 30 million years.

Paleogene

The description by Bradley (1929) of lacustrine cycles in the Eocene Green River Formation in Colorado and Utah is the classic example of pre-Quaternary Milankovitch cycles. Assuming the relationship between oil shale yield and accumulation rate within each facies to be constant, Bradley used oil shale yield as a proxy for accumulation rate within several sections of a few cycles each. The duration of each cycle was estimated at an average ~21 kyr using the accumulation rates derived from varve calibration. Recently, $^{40}\text{Ar}/^{39}\text{Ar}$ dates from tuffs within the Green River Formation and cycle counting (without quantitative time-series analysis) have been used to argue that the accumulation rate of the strata was too slow for the individual cycles to average 21 kyr (e.g., Pietras et al., 2003; countered by Machlus et al., 2004, 2008).

Cretaceous

One of the first quantitative applications of the astronomical theory of climate change was by Gilbert (1895) who hypothesized that the marine limestone-shale bedding rhythms of the late Cretaceous of Colorado were of precessional origin. Based on extrapolation from admittedly very limited outcrops, he estimated the duration of the late Cretaceous to be between 20 and 40 million year, favoring 20 million year. Current estimates place the duration of that epoch to be ~34 million year. More recent analysis shows that Gilbert's hypothesis is largely correct and that obliquity and eccentricity cycles are also important (Figure P90). There are many other modern treatments of Cretaceous marine cyclicity (see Hinnov, 2005). Herbert and D'Hondt (1990) used the Milankovitch cyclicity of the latest Cretaceous and earliest Cenozoic (Maastrichtian and Danian) cores from the South Atlantic to estimate accumulation rates across the Cretaceous-Tertiary boundary and found an essentially stepwise decrease in accumulation rates consistent with an abrupt boundary event.

Jurassic

Among the first to recognize cyclicity attributable to Milankovitch processes, Schwarzscher (1964) recognized that the Alpine Jurassic carbonate cycles attributed to ~20 kyr precession were bundling into ~100 kyr eccentricity cycles. According to Weedon (2003), the European Tethyan marine sequences are dominated by obliquity-forced cycles in the Hettangian and Sinemurian age parts of the sections, precession in the Pliensbachian (Figure P90), and a mixture of precession and obliquity in the Kimmeridgian (see Hinnov, 2005 for additional references). In eastern North America, Olsen et al. (1996) and Whiteside et al. (2007) described lacustrine cyclicity ascribed to precession and eccentricity forcing, and used it to constrain the duration of the Central Atlantic Magmatic Province (~600 kyr), the most geographically-extensive continental flood basalt province on Earth. Olsen et al. (2002) also used the Milankovitch cyclostratigraphy of the latest Triassic and earliest Jurassic to determine the duration of the Triassic-Jurassic boundary events.

Triassic

Schwarzscher (1948, 1954) and Fischer (1964, 1991) recognized a hierarchy of cycles, termed Lofer cycles, within late Triassic age carbonates of the Italian Alps (Norian-Rhaetian), attributing them to the precession and the ~100 and 405 kyr eccentricity cycles (Figure P89). Van Houten (1964) likewise recognized a hierarchy of lake level cycles within the continental late Triassic Newark Supergroup of the Newark rift basin of New York, New Jersey and Pennsylvania using varve calibration and constraints imposed by the duration of the late Triassic itself (Figure P88). This work has been fully supported by later work (e.g., Figure P90), and led to the Newark Basin Coring Project that continuously cored virtually the entire Newark basin sedimentary record (Figure P93). The lacustrine portion of the core record spans 25 million years (Norian-Hettangian) and is characterized by a continuous Milankovitch pattern of lacustrine cycles revealing the full spectrum of precessional and eccentricity frequencies including the longest frequency cycle with periods of 1.75 and 3.5 million year, corresponding to today's 2.4 and 4.8 million year eccentricity cycles (Figure P91). The difference is attributed to chaotic drift in the fundamental orbital frequencies of Earth and Mars (g_3 and g_4 of Laskar, 1990; Olsen and Kent, 1999). The 405 kyr eccentricity cycle is very clear in this record and provides the basis for an astronomically tuned geomagnetic polarity timescale (Kent and Olsen, 1999, 2000) for the late Triassic that has been recently correlated in detail with Tethyan marine records at the sub-stage level (e.g., Muttoni et al., 2004) (Figure P93).

One of the most contentious debates in pre-Quaternary Milankovitch cyclicity is the Latemar controversy. Middle Triassic age cyclical marine carbonate cycles are well exposed in the northern Italian Alps. Originally, Fischer-plot analysis of this section by Goldhammer et al. (1987) suggested a Milankovitch origin of the cyclicity. Buttressed in their interpretation by Fourier and other numerical analyses, Hinnov and Goldhammer (1991) counted ~600 cycles in ~470 m of section that they attributed to precession cycle forcing of sea level over a period of 12 million year (Hinnov, 2000; Preto et al., 2001). This interpretation is directly challenged by radiometric age data from interbedded and correlative tuffs that imply a duration of 0.5–2 million year for this same interval and by the presence of only two magnetic polarity zones (Brack et al., 1996; Kent et al., 2004). This led to the alternative, perhaps in some ways more interesting, interpretation that what were thought to be precessional cycles are in fact very short, sub-Milankovitch cycles imbedded within much thicker precessional cycles (Kent et al., 2004), highlighting the non-uniqueness of the frequency ratios when order of magnitude differences in the possible timescale are involved.

Paleozoic

There are far fewer convincing examples of Milankovitch cyclicity in Paleozoic records because they tend to be shorter and more poorly temporally constrained (see Hinnov, 2005). Using varves in evaporites, Anderson et al. (1972) calibrated accumulation rates of the Permian Castile Formation of New Mexico and recognized the cycle of climatic precession, sub-Milankovitch cycles that he attributed to sun spot cycles, and other periodicities. Rampino et al. (2000) used evolutive Fourier analysis to determine the duration of Permo-Triassic boundary events.

Carboniferous age, often coal-bearing cycles, termed cyclothem, may have a Milankovitch origin (Fischer, 1986). The Carboniferous was a glacial period and glacio-eustatic

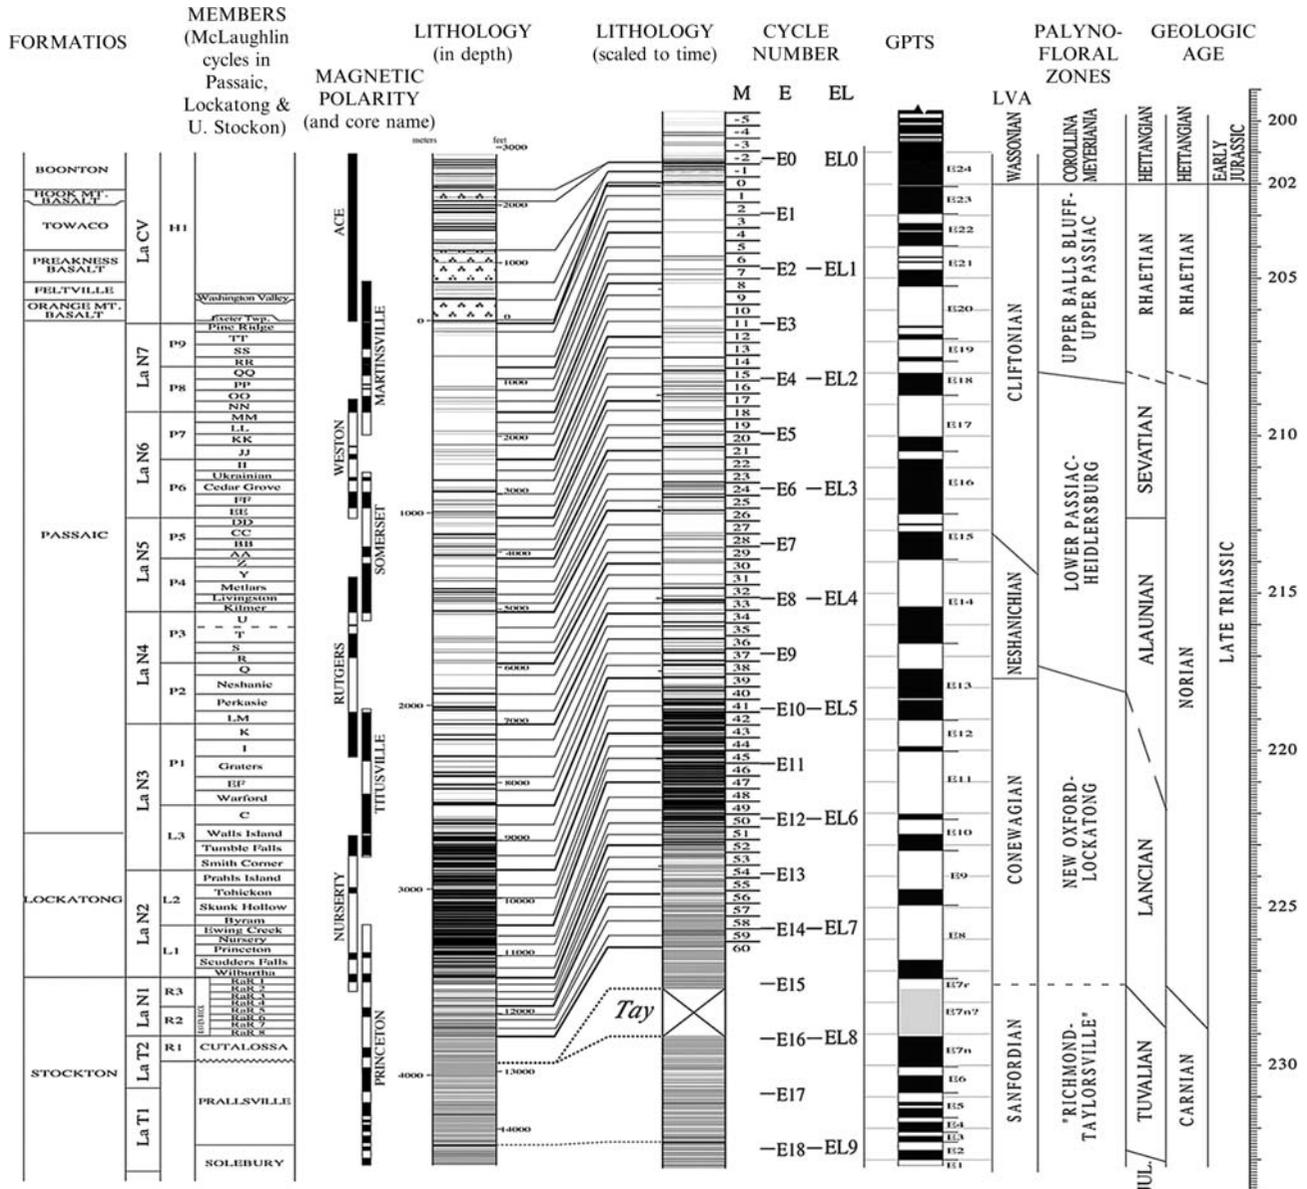

Figure P93 Opposite. Late Triassic and earliest Jurassic astronomically calibrated geomagnetic polarity time scale based on lacustrine strata from the Newark basin and correlation with marine stages and substages (derived from Kent and Olsen, 1999; Olsen and Kent, 1999; Muttoni et al., 2004).

cycles paced in some way by orbital cycles were presumably present. As yet, neither detailed evolutionary techniques nor robust dating techniques have been available to determine the periodicity of these cycles. A similar problem exists for Devonian marine carbonate cycles that have been described in abundance (e.g., Goodwin and Anderson, 1985; Goldhammer et al., 1991; Maynard and Leeder, 1992; Wilkinson et al., 1998; Miller and Eriksson, 1999).

Cyclical lacustrine strata very similar to those present in the Triassic and Jurassic of eastern North America crop out in the Orcadian basin, Scotland (Donovan et al., 1974; Donovan, 1980). Astin (1990) has demonstrated that these strata appear to possess a hierarchy of cycles compatible with a Milankovitch origin.

Older documented Paleozoic examples of Milankovitch cyclicity are much less common, but some convincing examples include the Cambro-Ordovician Aisha-Bibi carbonate seamount (Kazakhstan; Hinnov, 2005) and Cambrian limestones of the Wah Wah range of Utah (Bond et al., 1991). These studies show that the cyclicity is consistent with the estimate of Berger et al. (1989) for the Cambrian precessional frequency.

Precambrian

Precambrian examples of Milankovitch forcing are even less well documented. The best-known example is the 2.2 billion year of cyclicity in the Proterozoic Rocknest Formation of the Wopmay Orogen, N.W.T., Canada (Grotzinger, 1986). The sequence

consists of asymmetrical carbonate cycles analyzed using Fischer plots. Hofmann et al. (2004) used Markov chain analysis and Fischer plots to examine Archean carbonate cyclicity in the Belingwe Greenstone Belt of Zimbabwe. They pointed out a strong correspondence between the bundling of 7–11 short cycles per long cycle and the predicted ratio by Berger et al. (1989) between precession and short eccentricity cycles.

Challenges

Milankovitch cycles result from the combined gravitational effects of the other bodies in the solar system upon the Earth's spin axis and orbit, and similar effects are thought to be present on other planets (e.g., Kieffer and Zent, 1992; Correia and Laskar, 2001). It is not surprising that orbital cycles have affected the climate and the resulting sedimentary record through Earth's history, and thus the discovery of past Milankovitch cyclicity is less interesting for itself than for its possible uses. Four main challenges facing future work on pre-Quaternary Milankovitch cyclicity can be identified: (a) continued documentation of the orbital cyclicity into older strata with sufficient precession to discriminate deviations from the existing simple models of the secular evolution of the Earth's axial and orbital dynamics, (b) analysis of very long records (10s of millions of years) from various parts of Earth's history to calibrate the chaotic drift in the fundamental frequencies of the solar system (e.g., Olsen and Kent, 1999; Palike et al., 2004) with the ultimate goal of producing insolation curves for any arbitrary time in Earth history, (c) using Milankovitch cycles as a tool for high-resolution correlation and the calibration of other processes in truly ancient sequences, and (d) understanding the mechanisms by which insolation changes result in changes in Earth system processes and the resulting geological record.

PROGLACIAL LACUSTRINE SEDIMENTS

Proglacial lacustrine sediments reflect changes in the size of glaciers. Because the size of a glacier depends on its mass balance (e.g., the balance between the amount of solid precipitation and temperature during the ablation season), lacustrine sediments can contribute to our knowledge about climatic change. Proglacial lacustrine sediments will yield information integrating the data on both temperature during the melting season and precipitation during the cold season. In general it is difficult to separate the extent of the contribution of these two factors to changes in mass balance.

Abundant snowfall and/or reduced ablation will yield a positive glacier mass balance; the glacier will respond to these factors by increasing its thickness, surface gradient, flow rate, and surface area (Menzies, 1995). This allows wet-based and polythermal (sub-polar) glaciers to erode the substrate more efficiently, i.e., produce more glacial silt, which will lead to a higher transport of silt in meltwater streams and an increased sedimentation rate in proglacial lakes. There are no streams flowing under cold-based (polar) glaciers, and therefore proglacial lacustrine sediments in these localities do not reflect changes in glacier size but only the fluvial erosion outside of the glaciated area.

Glacial meltwater streams carry the sediment washed out from beneath the glacial. The transport of glacier silt may not be directly related to the temporary glacier size because the streams may also carry sediments that had been previously eroded and trapped beneath the glacier or deposited in front of it. However, variations over periods of centuries are more likely to reflect glacier size. The sediment load can vary considerably and often the color of a glacial meltwater stream is grey or whitish during the melting season.

When glacial meltwater is loaded with sediment, the ratio of the inorganic component of the sediments in a proglacial lake (basically within the silt fraction) increases in comparison to the organic component. The silt content is therefore relatively large during periods with active glaciers; in addition, the rate of deposition of lacustrine sediment is slightly greater than it is during periods of reduced glacier size. Only rarely have annual laminations (varves) been observed in lakes with a high rate of sedimentation (Leonard, 1986).

Even if the influx of glacial silt can vary considerably over time, sediments typically have a relatively homogenous color. Therefore, visual stratigraphic descriptions do not necessarily reveal information about variations in glacier size. Variations in silt

content can be observed as a change in organic content (weight loss at ignition or by using a carbon analyzer). In addition, as silt content affects the penetration of X-ray radiation, even relatively subtle changes in glacial silt content can be detected by X-ray photography. This technique, when applied to thin slabs of sediment, permits the determination of the fine lamination not discernable when only the "weight loss at ignition technique" is applied. The density of an X-ray film will be proportional to the organic/inorganic sediment content. Thus, digitizing the film density will permit a semi-quantitative estimate of sediment influx (Karlen et al., 2002).

Non-glacier processes, such as land slides, avalanches and other rapid slope processes, can also produce high-density stratigraphic units (Rubensdotter, 2002). In non-glacial environments, these units are often distinct and easy to distinguish. The origin of such units can be less obvious in proglacial lacustrine sediments, because of the high inorganic background component and the similarity between units formed due to increased glacial erosion and to rapid slope processes. However, when considered together in combination, the presence of a distinct lower boundary of the unit, as well as a grain size distribution deviating from that of the relatively homogenous deposits of glacial silt facilitates classification. Changes in precipitation and possibly also major changes in vegetation cover can yield a lacustrine sediment signal similar to the one created by a glacial meltwater influx. However, this signal will be markedly weaker.

Information from a proglacial lake is of limited value until a chronology has been established. The most common method is ^{14}C dating of macrofossils or of organic-rich layers (AMS, accelerator mass spectrometry). Additional methods include ^{210}Pb , ^{137}Cs and the recognition of volcanic ashes of known age.

Proglacial sediments yield, in contrast to several other techniques, a continuous record of glacier size variations. These proglacial records can confirm results of studies that yield dates on single events and can also add important details. The sediment record, as well as other records, such as dendrochronology, indicates a frequently fluctuating climate during the Holocene. However, glaciers in many areas, particularly in those areas that are at present marginal, vanished during the early and mid-Holocene, a period well known to have been slightly warmer than the present time.

PROTEROZOIC CLIMATES

The Proterozoic eon is a subdivision of geologic time (Figure P94). It extends from the end of the Archean eon at 2.5 billion years ago (Ga) to the beginning of the Phanerozoic eon/Cambrian period at 542 million years ago (Ma). This long period, encompassing almost half of the Earth's history, has been divided into three parts: the Paleoproterozoic, Mesoproterozoic and Neoproterozoic eras (Figure P94). This brief summary will emphasize some highlights of Proterozoic paleoclimatology.

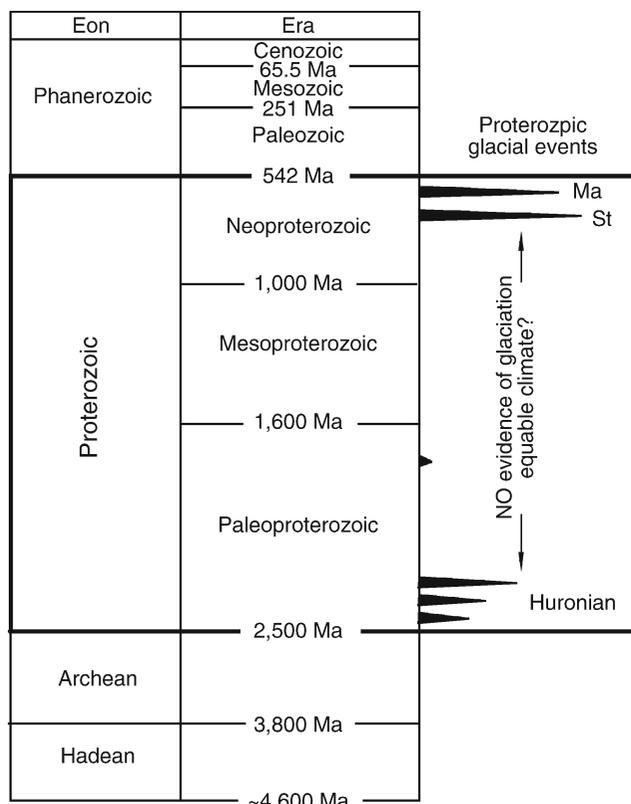

Figure P94 Subdivisions of geologic time to show the occurrence of glaciogenic rocks near the beginning and end of the Proterozoic eon. Three glacial episodes are recorded in the Huronian in North America. *St*, Sturtian; *Ma*, Marinoan. Note there may be more glacial episodes in the Neoproterozoic.

Problems in interpretation of Proterozoic paleoclimates

Interpretation of ancient climatic conditions is based mainly on investigation of sedimentary rocks, but the study of Proterozoic rocks is more difficult than that of younger (Phanerozoic) rocks for several reasons. Fossils of life forms such as land plants and complex animals (metazoans) often play an important role in interpretation of Phanerozoic rocks because many organisms are climatically sensitive, but such fossils are scarce to absent from the Proterozoic record. Some evaporitic minerals, such as sulfate and chloride salts, provide paleoclimatic clues in younger rock sequences but are rare in the Paleoproterozoic. The dearth of evaporitic rocks could be related to a lack of certain solutes (such as sulfate) in ocean waters and/or could be due to the susceptibility of such soluble materials to loss by subsequent dissolution.

One of the great problems in Precambrian paleoclimatology has been the “faint young Sun paradox.” Based on the known life histories of stars, astrophysicists have proposed that the early or “young” Sun must have been considerably less luminous than at present. The figure of ~30% less radiation is commonly used for about 2.5 Ga, the beginning of the Proterozoic. The paradox arises because, with the present atmosphere, it has been calculated that the early Earth's surface should have been entirely frozen but evidence from abundant waterlain Archean sedimentary rocks clearly contradicts this. The solution to the faint young Sun paradox has revolved around the idea that the Earth's atmosphere was different during its early history. Specifically, it has been suggested that liquid water was maintained on the Earth's surface as a result of enhanced atmospheric content of greenhouse gases (carbon dioxide, methane, etc.). If these interpretations are correct, then rocks with a highly “weathered” chemical signature could have been produced under relatively cool conditions (because of the high CO₂ content of the atmosphere, giving rise to extremely acid rains). Likewise, the occurrence of three glacial episodes in Huronian times may be explained by fluctuations in the greenhouse gas content (especially CO₂) of the atmosphere. Descent of the Earth into frigid episodes would have occurred more readily in Paleoproterozoic times because of reduced solar luminosity.

Paleolatitude and paleoclimate

In Phanerozoic (<542 Ma) sedimentary successions (Figure P94), there is some correspondence between ancient latitude (paleolatitude) and climate, as is observed today. Paleomagnetic interpretations are based on the assumption that the magnetic field of the ancient Earth was dipolar and that the orientation of the Earth's magnetic axis was similar to that of its rotational axis. In an attempt to explain the apparent occurrence of Proterozoic glacial deposits in equatorial paleolatitudes, it has been suggested (Williams, 1993) that, prior to the Cambrian, the obliquity of the ecliptic may have exceeded 54°.

Proterozoic glaciations

By far the most striking aspect of Proterozoic paleoclimatology is the evidence of widespread glaciations near the beginning and end of that eon (Young, 2003). The near-absence of such evidence during the long intervening period (spanning about 1.5 Ga) is, however, perhaps even more remarkable. Cold periods in Earth's history, such as that of the Paleoproterozoic, are easily identified from field observations, including the following:

1. Diamicrites are sedimentary rocks that consist of large rock fragments (clasts) “floating” in a finer grained matrix.

Since such sedimentary rocks can form by a variety of sedimentary processes, additional criteria are necessary to confirm their glaciogenic nature, such as the presence of faceted and/or striated clasts, for example.

2. The presence of a scratched or striated substrate, commonly developed beneath a diamictite. Striated “pavements” are a good criterion of glacial activity. They are formed by erosive action of rock fragments carried in glacier ice as it advances over a substrate.
3. Dropstones are isolated rock fragments in laminated or finely bedded sedimentary rocks, generally believed to have been transported by glacial ice that, on reaching a body of water, calved off icebergs that melted, freeing the stones.
4. The occurrence of rhythmic alternations of thin beds and laminae of siltstone and claystone (varves). Such couplets are thought to represent annual accumulations of sediment in proglacial lakes, the coarser layer representing accumulation during the summer months when there was more melt-water available and the finer material being deposited (largely from suspension) during winter.

Paleoproterozoic paleoclimates

The majority of Paleoproterozoic glacial deposits have been documented in North America but similar glaciogenic rocks have also been identified in NW Europe, in South Africa and in Western Australia. The earliest recognized and best known early Proterozoic glaciogenic rocks occur in the Huronian Supergroup, which is a thick succession (up to about 11 km) of mainly sedimentary rocks in Ontario, Canada. Glacial diamictites and associated sedimentary rocks occur at three different levels within the Huronian Supergroup but the thickest and most widespread of these is the Gowganda Formation. This unit is considered to be approximately correlative with similar deposits of similar age (~2.3 Ga) in several places in North America and, less certainly, around the world.

One unusual aspect of the Paleoproterozoic glaciogenic deposits is that they are commonly associated with other sedimentary rocks containing geochemical and other evidence that they were deposited under conditions of relatively intense weathering (Nesbitt and Young, 1982). By calculating a chemical index of alteration (*CIA*), major elements can be used to quantify the degree of chemical weathering to which sedimentary materials have been subjected (Nesbitt et al., 1996). The *CIA* is calculated according to the formula:

$$CIA = (Al_2O_3 / (Al_2O_3 + CaO^* + Na_2O + K_2O)) \times 100 \quad (1)$$

This calculation quantifies the ratio of secondary aluminous clay minerals formed during the weathering process to primary minerals (mainly feldspars). CaO^* means CaO that occurs in silicate minerals, as opposed to that in carbonates and phosphates. The *CIA* formula yields a number that ranges between about 50 (fresh rocks) and 100 (extremely weathered materials). In applying this technique to sedimentary successions, care must be taken to compare values from rocks of similar grain size because clay minerals tend to be smaller than primary minerals such as feldspar and quartz. During natural sorting of weathered materials, the fine grained sediments will tend to have a high proportion of clay minerals, which will yield higher *CIA* values than associated sandy materials. *CIA* values of ancient sedimentary and other materials (e.g., ancient weathering profiles or paleosols) can be modified by metasomatic introduction of elements such as K and Na. Such

alterations can, however, be detected by judicious use of the *CIA* and, in particular by illustrating the data on a triangular plot with Al_2O_3 , $CaO^* + Na_2O$ and K_2O at its apices. For details of this and other aspects of the application of this technique, see Fedo et al. (1995).

Whereas it must be recognized that the *CIA* is not simply controlled by climatic conditions (other factors include tectonism, diagenesis and metasomatic alteration), when judiciously applied, it provides a useful tool for obtaining insight into weathering intensity, which is, in turn, controlled by temperature and rainfall. It can thus provide a powerful proxy for paleoclimate.

In the case of the Paleoproterozoic Huronian Supergroup, *CIA* values from mudstones throughout this thick succession have shown that the three glacial episodes were superimposed on a regime that was characterized by relatively strong weathering (high *CIA* values). This paleoclimatic conundrum – the juxtaposition of deposits formed in a frigid regime with those resembling sediments formed in warm humid regions of the Earth today – may be resolved by invoking differences in atmospheric composition. Various lines of geological evidence from the Huronian Supergroup and similar successions elsewhere also suggest that the early atmosphere was oxygen-deficient before about 2.5 Ga and that during deposition of the Huronian at least some free oxygen accumulated. By about 2.3 Ga, the presence of red beds (clastic sediments that contain red pigmentation, related to the presence of disseminated hematite) suggests that some free oxygen was available in the atmosphere.

The Mesoproterozoic equable interval

Following the glacial episodes of the Huronian and their equivalents elsewhere, the Earth appears to have entered a long period during which equable climates predominated. Stable isotopes of carbon preserved in sedimentary rocks suggest that the oxygen content of the atmosphere may have peaked at about 2.1 Ga and then diminished and remained low until the Neoproterozoic, when the first complex animals made their appearance. This decrease in atmospheric oxygen may have been accompanied by an increase in CO_2 , which, together with strengthening of the Sun's radiative signal, may explain the equable climates that appear to typify this long period of geological history (from about 2.2 Ga to about 750 Ma). However, recently Williams (2005) has described glaciogenic rocks dated at about 1,800 Ma from Western Australia. The widespread development of stromatolitic carbonates and common preservation of red beds have been cited as evidence of warm climatic conditions during the Mesoproterozoic but interpretation of such features is not always certain. Examples of cold water stromatolites have been described from the literature and these organo-sedimentary structures may have proliferated in much more varied environments than at present because of the absence of predatory metazoans. Likewise, red beds are more indicative of the presence of free oxygen in the atmosphere than of ambient temperatures at the time of their formation.

The Neoproterozoic climatic convulsions

Following the enormously long and paleoclimatologically “quiet” period of the Mesoproterozoic, the latter half of the Neoproterozoic (from about 750 Ma to the beginning of the Cambrian period at 542 Ma) was characterized by some of the most extremely cold climatic episodes that the Earth has ever known. These events are inferred from extremely widespread and convincing

evidence (on every continent) of glacial depositional processes. The exact number and extent of glacial episodes remain unresolved but they appear to have ended by the beginning of the Cambrian, which saw a return to relatively warm climatic conditions and a burgeoning in the Earth's population of complex animals (metazoans). Some have suggested that there were two major glacial episodes, known as the Sturtian (~750–720 Ma) and the Marinoan (~620–600 Ma).

When reliable physical criteria for the recognition of ancient glacial deposits were developed, it was realized that Neoproterozoic glaciogenic rocks were extremely widespread. As far back as the 1940s, it was suggested that the Earth may have experienced a glaciation (or glaciations) so severe that its entire surface was frozen (Mawson, 1949). With the development of sedimentological and paleomagnetic techniques, it was also claimed that many of these ancient glaciers had descended to sea level in equatorial latitudes. Although glaciers exist today in low latitude regions (e.g., on Mount Kilimanjaro, which is about 3 degrees south of the equator), they are present only on high mountain tops and melt before they can descend to sea level, because of elevated temperatures. These paleomagnetic findings lent fuel to the concept of a frozen planet.

In recent years another element was added, namely the discovery that there are significant fluctuations in the isotopic ratios of carbon (and oxygen) in carbonate rocks beneath and above many Neoproterozoic glacial successions. The lows and highs in carbon isotopic ratios were interpreted to reflect the near-extirpation and blooms of marine photosynthetic microorganisms, respectively. The photosynthetic metabolic pathways of many marine microorganisms lead to sequestering of the light isotope of carbon (^{12}C), which, in turn, leads to an ocean enriched in the heavier isotope (^{13}C). High $\delta^{13}\text{C}$ values tend to occur during organic blooms. Thus, if seawater and carbonates derived there from exhibit low values of the carbon isotopic ratio ($\delta^{13}\text{C}$), this suggests a dearth of organic activity. Low $\delta^{13}\text{C}$ values were reported from carbonates below and above some glacial deposits and were interpreted to mean the near-extirpation of life during world-encircling glacial episodes (Hoffman et al., 1998). Subsequently it has been shown that many photosynthetic microorganisms survived through the Neoproterozoic glacial episodes and several alternative explanations for the carbon isotopic anomalies have been suggested (e.g., Kennedy et al., 2001). These anomalous geochemical signatures are therefore poorly understood.

The sum of evidence for widespread Neoproterozoic glaciations led to coining of the term, "Snowball Earth Hypothesis" (Kirschvink, 1992; Hoffman et al., 1998). This controversial theory proposed that the Neoproterozoic glaciations were so severe that the entire surface of the planet was frozen. Such global glaciation was explained by a "runaway albedo" effect – when icecaps extend to middle latitudes, it is hypothesized that the amount of solar energy reflected (lost) from the ice is sufficient to promote rapid glacial advance. Escape from such a condition was attributed to gradual build-up of CO_2 in the atmosphere by volcanic activity related to on-going plate tectonics. According to the hypothesis, destruction of the ice cover would be extremely rapid, followed by establishment of very warm conditions and extreme weathering that would flush the oceans with weathering products that gave rise to post-glacial carbonates, the so-called "cap carbonates." This version of the Snowball Earth Hypothesis remains controversial. New evidence for a series of geomagnetic reversals in the cap carbonates suggests that deglaciation was a long process and not a catastrophic event.

Problems with the Snowball Earth Hypothesis

There are many problems associated with the Snowball Earth Hypothesis. A few are discussed briefly below. Many Neoproterozoic glacial successions are very thick (several km). Such abundant glacial sediments are unlikely under the Snowball Earth Hypothesis, for the hydrological cycle would have been essentially cut off. Neoproterozoic glacial deposits that formed at sea level in low latitudes contain evidence of strong seasonality (varved deposits, fossil ice-wedge structures) not seen in tropical regions at present. One possible explanation is that the obliquity of the ecliptic (tilt of the Earth) was much greater (Williams, 1993), leading to low latitude glaciation. It has, however, been suggested by some (e.g., Pais et al., 1999) that the high obliquity hypothesis does not account well for the Neoproterozoic glaciation. Another major problem is that paleontological studies of a number of Neoproterozoic successions appear to show that many life forms survived through the Neoproterozoic glaciations so that the proposed "near-extirpation" of life, proposed as a possible explanation of the C-isotope excursions in associated carbonate rocks, does not seem to have occurred. In any event, the Neoproterozoic was a time when the planet underwent extreme climatic variations. Associated dramatic environmental changes could have been a major factor in promoting evolution of the diverse assemblage of complex life forms that characterizes the remainder of geologic time.

Conclusions

Paleoclimatological studies of the Proterozoic are rendered difficult by the dearth of fossil remains of environmentally-sensitive organisms and the rarity of some rock types (such as coals and evaporites) that facilitate climatological interpretations. Most Proterozoic sedimentary rocks lack evidence of glaciation, suggesting that the typical world temperatures were moderate. Near the beginning and end of the Proterozoic, however, there is abundant evidence of multiple widespread glaciations. Neoproterozoic glaciogenic sediments are the most extensive in the world and provide evidence of tremendous climatic upheaval, but whether the entire surface of the planet was frozen (Snowball Earth Hypothesis) at any one time remains unknown. The dramatic paleoclimatic events at the end of the Proterozoic may have played a significant role in the emergence and proliferation of metazoans at the beginning of the Phanerozoic eon.

Q

QUATERNARY CLIMATE TRANSITIONS AND CYCLES

Introduction

The last few million years have been punctuated by many abrupt climate transitions, many of them occurring on time scales of centuries or even decades. These sudden stepwise climate transitions provide a disturbing scenario in terms of possible human effects on the present climate system through global warming. In order to gain a better understanding of our current climate system, we need to comprehend the causes of past climate transitions and cycles. This paper examines key climate transitions in the Quaternary period identified as: (a) the Intensification of Northern Hemisphere Glaciation (INHG), which heralded the start of the Quaternary period; (b) the intensification of the Walker Circulation; (c) glacial-interglacial cycles; (d) the Mid-Pleistocene Revolution (MPR); (e) Heinrich events and glacial Dansgaard-Oeschger (D-O) cycles; and (f) the last glacial-interglacial transition (LGIT) including the Younger Dryas. For each key climate transition, the current theories of causation are examined in terms of external and/or internal forcing factors.

Modes of climate change

Until a few decades ago, it was generally thought that significant large-scale global and regional climate changes occurred gradually over many centuries or millennia. Hence, the climate shifts were assumed scarcely perceptible during a human lifetime. The tendency of climate to change abruptly throughout the Quaternary period (last 2.5 million years) has been one of the most surprising outcomes of the study of Earth history. Some of these observed regional changes involve a shift in the mean annual temperature of several degrees Celsius within a few decades. These sudden stepwise climate transitions illustrate disturbing scenarios in terms of potential anthropogenic effects on the climate system through greenhouse gas emissions (Maslin, 2004a). Global climate variability in the Quaternary

can be divided into individual transitions; for example, the intensification of glaciation in the Northern Hemisphere is a good example of the global climate system shifting to a new equilibrium. Tied transitions are part of regular or quasi-cyclic climate changes; for example, the waxing and waning of the Ice Ages (or glacial period) which characterize the Quaternary period. Each transition, however, is a response to external and/or internal forcing mechanisms. A good example of an external forcing mechanism is the changing orbital parameters that alter the net radiation budget of the Earth, while an example of an internal forcing mechanism is the carbon dioxide content of the atmosphere, which modulates the greenhouse effect (Maslin, 2004a). We can abstract the way the global climate system responds to an internal or external forcing agent by examining four different scenarios:

1. Linear and synchronous response (Figure Q1a). In this case, the forcing produces a direct response in the climate system with a magnitude that is in proportion to the forcing.
2. Muted or limited response (Figure Q1b). In this case, the forcing may be extremely strong, but the climate system is buffered and therefore has very little response.
3. Delayed or non-linear response (Figure Q1c). In this case, the climate system may have an initial slow response to the forcing. The climate system response may then accelerate in a non-linear way until it overshoots the forcing effect and then drops back in an attempt to reach equilibrium with the forcing.
4. Threshold response (Figure Q1d). In this case, there is initially no or very little response in the climate system to the forcing; however, all the response takes place in a very short period of time in one large step or threshold. In many cases, the response may be much larger than one would expect from the size of the forcing and this can be referred to as a response overshoot.

Although these are purely theoretical models of how the climate system can respond, they are important to keep in mind when trying to understand Quaternary climate transitions. An added complication when assessing the causes of climate transitions is the possibility that climate thresholds contain

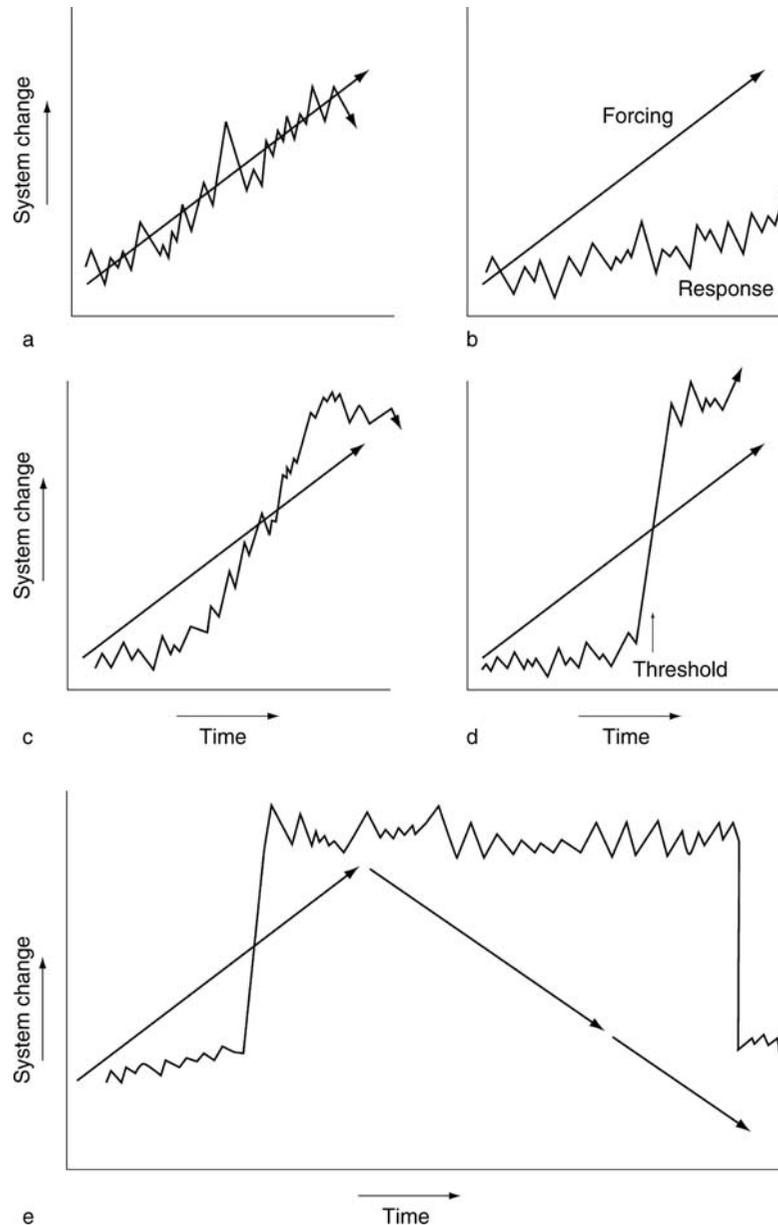

Figure Q1 Schematic diagram of the four alternative responses of the global climate system to internal or external forcing: (a) Linear and synchronous response: forcing produces a direct response with a magnitude that is proportional to the forcing. (b) Muted or limited response: forcing may be extremely strong, but the climate system is in some way buffered and therefore has very little response. (c) Delayed or non-linear response: the climate system may respond slowly to the forcing or is in some way buffered initially, but then responds to the forcing in a non-linear way. (d) Threshold response: very little or no response to the forcing initially, however all the response then takes place in a very short period in one large step or threshold. In many cases, the response may be much larger than expected from the size of the forcing, leading to a response over-shoot. (e) Bifurcation. Similar to the threshold response except that reversing the forcing does not reverse the climate response, see Figure Q2.

bifurcations (Figure Q1e). This means the forcing required to cause a climate transition is different from that needed to reverse it. This bifurcation of the climate system has been inferred from ocean models which mimic the impact of fresh-water (control variable) on deep-water formation in the North Atlantic (climate variable) (e.g., Rahmstorf, 1995). However, a bifurcation relationship could be applied to many forcing mechanisms and the corresponding responses of the global

climate system. For example, Maslin (2004b) applied it to rainfall control on rainforest versus savannah vegetation in the tropics. Figure Q2 demonstrates this bifurcation of the climate system and shows that different relationships exist between climate and forcing mechanism, depending on the direction of the threshold. This is very common in natural systems, for example in cases where inertia or the shift between different states of matter need to be overcome. Figure Q2 shows that

in cases A and B, the system is reversible, but in case C, it is not. Figure Q1e shows how case C would manifest itself if the outcome were plotted on a forcing-response diagram.

In this paper, current theories on major transitions and cycles within the Quaternary period are reviewed, always considering the modes of climate changed discussed above. These include the Intensification of Northern Hemisphere Glaciation (~2.5 Ma), intensification of the Walker Circulation (~1.9 Ma), glacial-interglacial cycles, Mid-Pleistocene Revolution (~1 Ma), quasi-periodic millennial climate cycles and the last glacial-Holocene transition (Figure Q3).

Onset and intensification of Northern Hemisphere glaciation

Heralding the start of the Quaternary period

The earliest recorded onset of significant global glaciation during the last 100 Ma was the widespread continental glaciation of Antarctica at about 34 Ma (e.g., Zachos et al., 2001). Records indicate that ice rafting started in the Arctic as early as 46 Ma (Eldrett et al., 2007) but major glaciation did not occur until 14–6 Ma (Thiede et al., 1998). Marked expansion of continental ice sheets in the Northern Hemisphere was the culmination of a

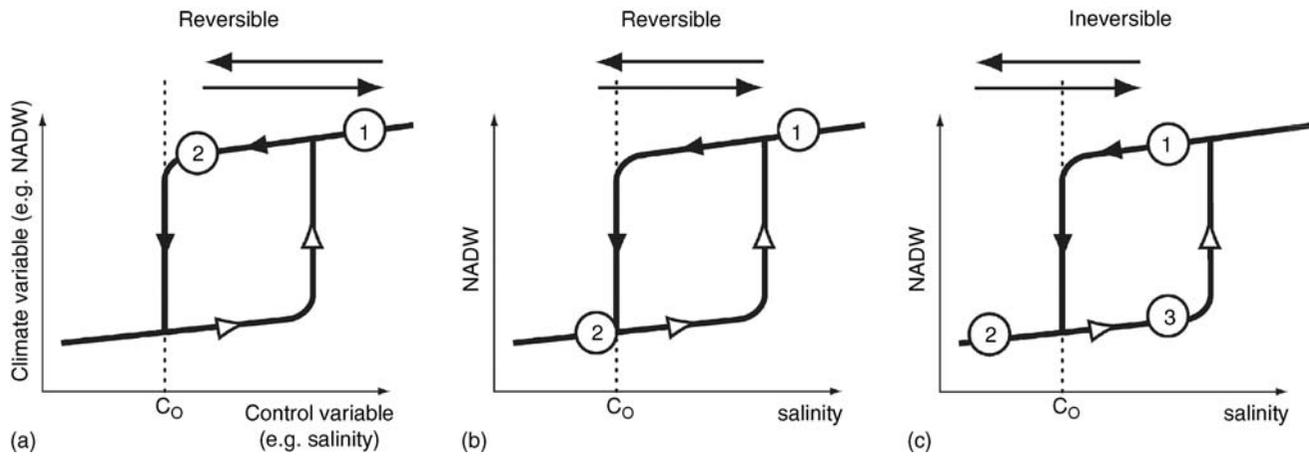

Figure Q2 Bifurcation of the global climate system. For example, the control variable could be North Atlantic salinity and the climate variable could be production of NADW. (a) An insensitive system in which the climate variable does not vary greatly with large changes in the control variable. (b) The control variable drops beneath the critical threshold point C_0 (point 2), causing a major change in the climate variable; however, by returning the control variable to its original state, the system is reversible and the climate variable returns to its original point 1. (c) The control variable drops beneath the critical threshold point C_0 (point 2); however, returning the control variable to its original state does not reverse the change and the climate variable remains at point 3. An additional change to the control variable is required to overcome the bifurcation and return the climate variable back to point 1. If this change cannot occur, then the threshold becomes irreversible. Note that returning the system back to its initial boundary conditions by going beyond point 3 may take the system to a new state of equilibrium that differs from the initial state.

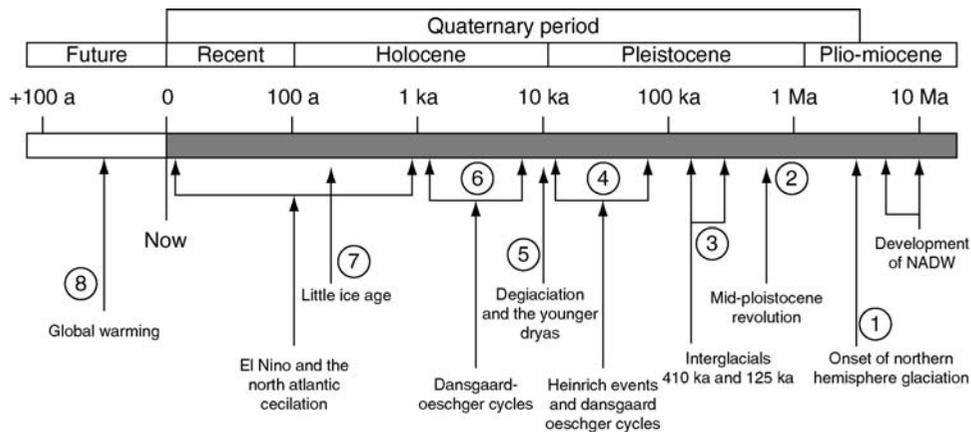

Figure Q3 Schematic diagram (logarithmic timescale) illustrating the most important climate events in the Quaternary period discussed in this entry. (1) Intensification of Northern Hemisphere glaciation (3.2–2.5 Ma), inducing the strong glacial-interglacial cycles characteristic of the Quaternary period. Also in this period is the intensification of the Walker Circulation in the tropics at about 1.9 Ma. (2) Mid-Pleistocene Revolution when the periodicity of glacial-interglacial cycles switched from 41 ka to every 100 ka. (3) Glacial-interglacial cycles (of particular importance are oxygen isotope stages 5 and 11 which may have characteristics similar to the current Holocene interglacial). (4) Heinrich events and Dansgaard-Oeschger cycles. (5) Deglaciation and the Younger Dryas events. (6) Holocene Dansgaard-Oeschger cycles. (7) Little Ice Age, the most recent example of the Holocene D-O cycles. (8) The future and global warming.

longer term, high latitude cooling, which began with the late Miocene glaciation of Greenland and the Arctic and continued through to the major increase in global ice volume around 3.6 Ma (Mudelsee and Raymo, 2005). It has been suggested there were three key steps in this climate transition: (a) Eurasian Arctic, Northeast Asia and North America glaciated at approximately 2.74 Ma, (b) Alaska glaciation occurred at 2.70 Ma, and (c) a significant increase in the glaciation of the North East American continent occurred at 2.54 Ma (Maslin et al., 1998; Kleiven et al., 2002).

Possible causes of the intensification of Northern Hemisphere glaciation

The predominant theories to explain the Intensification of Northern Hemisphere Glaciation (INHG) have focused on major tectonic events and their modification of both atmospheric and ocean circulation (Hay, 1992; Maslin et al., 1998). For example, the uplift and erosion of the Tibetan-Himalayan Plateau, the deepening of the Bering Straits and/or the Greenland-Scotland Ridge, and emergence of the Panama Isthmus have all been suggested.

Ruddiman and Raymo (1988) suggested that the initiation of Northern Hemisphere glaciation was caused by progressive uplift of the Tibetan-Himalayan and Sierran-Coloradan regions. This may have altered the circulation of atmospheric planetary waves such that summer ablation was decreased, allowing snow and ice to build-up in the Northern Hemisphere. However, most of the Himalayan uplift occurred much earlier, between 20 and 17 Ma, and thus is too early to have been the direct cause of the INHG. It was then suggested that uplift caused a massive increase in tectonically-driven chemical weathering in the late Cenozoic. Raymo (1994) argue that carbonation of rainwater removes CO₂ from the atmosphere and forms a weak carbonic acid solution, with dissociated H⁺ ions in the acidified rainwater caused by hydrolysis leading to enhanced chemical weathering of rocks. Only weathering of silicate minerals makes a difference to atmospheric CO₂ levels, as weathering of carbonate rocks by carbonic acid returns CO₂ to the atmosphere. By-products of hydrolysis reactions affecting silicate minerals are bicarbonate (HCO₃⁻) anions and calcium cations. These, when washed into the oceans, are metabolized by marine plankton and are converted to calcium carbonate. The calcite skeletal remains of the marine biota are ultimately deposited as deep-sea sediments and hence lost from the global biogeochemical carbon cycle for the duration of the life cycle of the oceanic crust on which they were deposited. Consequently, atmospheric CO₂ could have been depleted, causing a cooling of the global climate and thus the INHG. This theory, however, suffers from a number of major draw-backs: (a) there is debate whether strontium (Sr) isotope data can be used as evidence of continental weathering, (b) there seems to be no obvious negative feedback mechanism to prevent a complete depletion of the relatively small reservoir of atmospheric CO₂, and (c) there is now evidence that suggest that there was no decrease in atmospheric carbon dioxide during the Miocene.

A second key tectonic control invoked as a trigger for the INHG is the closure of the Pacific-Caribbean gateway. Haug and Tiedemann (1998) suggest it began to emerge at 4.6 Ma and finally closed at 1.8 Ma. The closure of the Panama gateway, however, causes a paradox (Berger and Wefer, 1996) as it would have both helped and hindered the intensification of North Hemisphere glaciation. The reduced inflow of Pacific

surface water to the Caribbean would have increased the salinity of the Caribbean, increasing the salinity of water carried northward by the Gulf Stream and North Atlantic Current, and thus enhancing deepwater formation. Increased deep-water formation could have worked against the initiation of Northern Hemisphere glaciation as it enhances the oceanic heat transport to the high latitudes and would have opposed ice sheet formation (see Figure Q4). This enhanced Gulf Stream would also have pumped more moisture northward, stimulating the formation of ice sheets.

Tectonic forcing alone cannot explain the fast changes of both the intensity of glacial-interglacial cycles and mean global ice volume. It has therefore been suggested that changes in orbital forcing may have been an important mechanism contributing to gradual global cooling and the subsequent rapid intensification of Northern Hemisphere glaciation (Haug and Tiedemann, 1998; Maslin et al., 1998). The observed increase in the amplitude of orbital obliquity cycles from 3.2 Ma onwards may have increased the seasonality of the Northern Hemisphere, thus initiating the long-term global cooling trend (Figure Q4). The subsequent sharp rise in the amplitude of precession and consequently in insolation at 60° N between 2.8 and 2.55 Ma may have forced the rapid glaciation of the Northern Hemisphere. This theory is supported by model simulation of the Northern Hemisphere ice-sheet volume variation (Li et al., 1998; Raymo et al., 2006).

We still do not know what caused the climate transition that induced the Northern Hemisphere to glaciates some two and half million years ago. A plausible theory could be that the Tibetan uplift caused long term cooling during the late Cenozoic. The closure of the Panama Isthmus may then have delayed the Intensification of Northern Hemisphere Glaciation but ultimately provided the moisture which allowed intensive glaciation to develop at warmer high latitude temperatures (Figure Q4). However, Huybers and Molnar (2007) suggest cooling in the Pacific Ocean may also have contributed to the timing of the INHG. The global climate system seems to have reached a threshold at about 3 Ma, when orbital configurations became more influential, leading to building of all the major Northern Hemisphere ice sheets in little over 200 kyr.

Intensification of the Walker circulation

The onset and intensification of Northern Hemisphere glaciation may be seen as a continual cooling of the global climate during the late Cenozoic, which intensified over the last 5 million years. The so-called onset at about 3.2–2.5 Ma may be seen to have occurred as one step in this global transition. Ravelo et al. (2004) have suggested that another step occurred between 2 and 1.5 Ma. They have observed that prior to 1.9 Ma there was no, or very little, East-West sea surface temperature (SST) gradient in the Pacific Ocean. After 1.9 Ma there was a significant East-West Pacific SST gradient which Ravelo et al. (2004) and McClymont and Rosel-Mele (2005) interpret as a switch in the tropics and subtropics to a modern mode of circulation with relatively strong Walker Circulation and cool subtropical temperatures. This major switch at about 1.9 Ma has also been observed in the lake records of East Africa (Trauth et al., 2005; 2007 and Maslin and Christensen, 2007), again indicating a significant shift and intensification in Walker Circulation. If these climate changes are part of the long-term transition to a cooler global climate, then the major step of this intensification of Northern Hemisphere glaciation is the Mid-Pleistocene Revolution, which occurred about 1–0.6 Ma and is discussed in greater detail below.

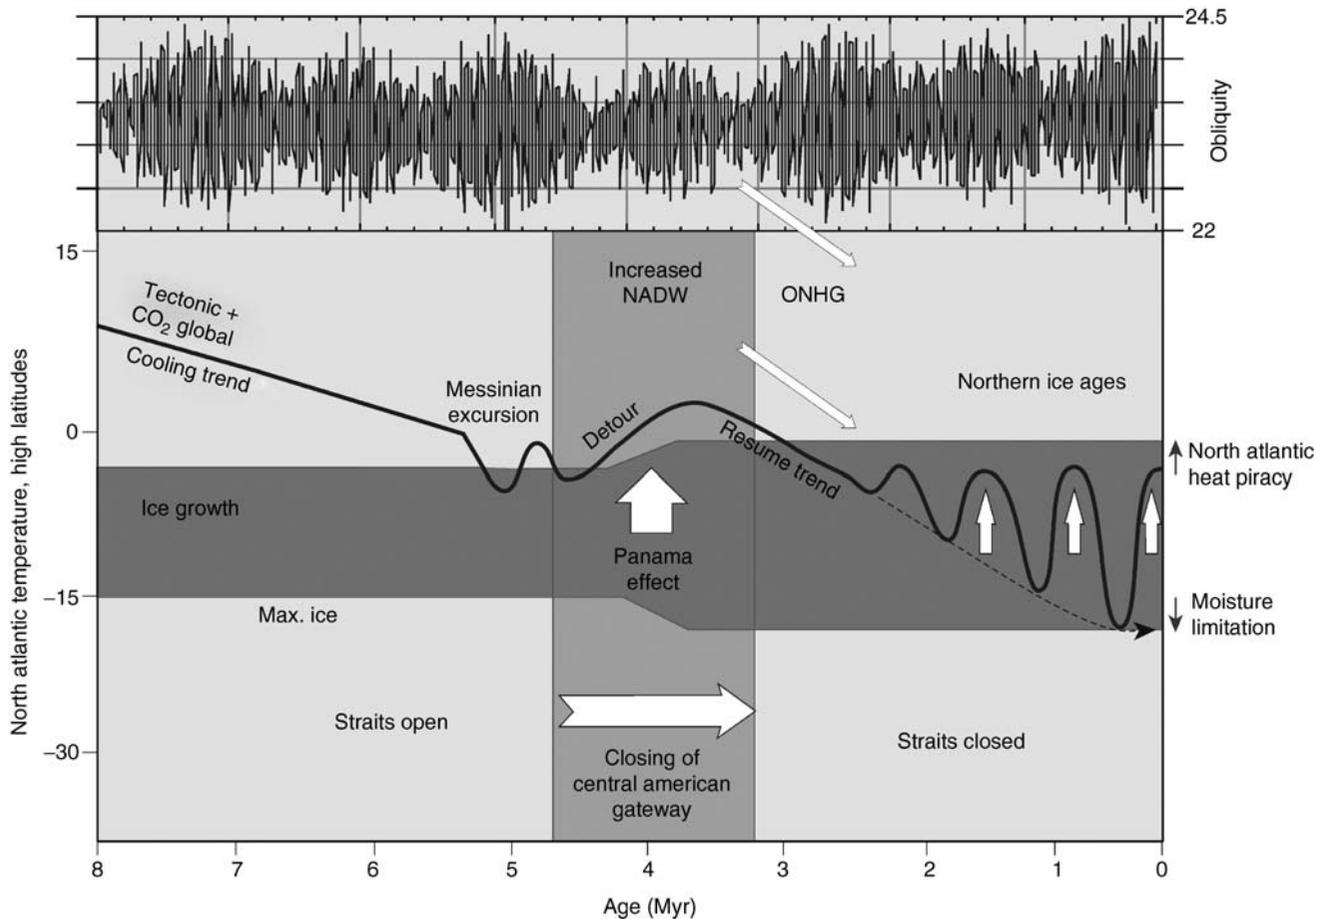

Figure Q4 Summary of the causes of the Intensification of Northern Hemisphere Glaciation (INHG). Note the detour of the cooling trend and the expansion of the temperature range of ice growth caused by the closure of the Central American gateway. Note also the kick in obliquity that occurs between 3.2 and 2.5 Ma and drives the continued cooling of the climate system and the INHG (adapted from Berger and Wefer, 1996).

Glacial-interglacial cycles

Orbital forcing

The most fundamental characteristic of the Quaternary period are the glacial-interglacial cycles. These cycles are believed to be primarily forced by changes in the Earth's orbital parameters. However, these cycles are not caused by Earth's orbital parameters alone, but rather by the Earth's climate system feedback mechanisms, which translate relatively small changes in regional insolation into major climatic variability. An illustration of this is that the insolation received at the critical 65° N was the same level, 18,000, during the Last Glacial Maximum (LGM) and today (Laskar, 1990; Berger and Loutre, 1991). There are three main orbital parameters, eccentricity (96 ka, 125 ka, 413 ka), obliquity or tilt (41 ka), and precession (19 ka, 23 ka) (see individual articles in this volume for greater detail).

Combining the effects of eccentricity, obliquity and precession provides the means of calculating the insolation for any latitude back through time (e.g., Berger and Loutre, 1991). Milankovitch (1949) suggested that summer insolation at 65° N was critical in controlling glacial-interglacial cycles. He argued that if this summer insolation was reduced enough then ice could survive through the summer and thus start to buildup, eventually producing an ice sheet. Orbital forcing does

have a large influence on this summer insolation. The maximum change in solar radiation in the last 600 ka is equivalent to reducing the amount of summer radiation received today at 65° N to that received now at 77° N, over 550 km to the north (Wilson et al., 2000). In simplistic terms, this brings the current glacial limit in mid-Norway down to the latitude of Scotland. These lows in 65° N insolation are caused by eccentricity elongating the summer Earth-Sun distance, obliquity being shallow, and precession placing the summer season at the longest Earth-Sun distance produced by eccentricity. It must also be noted that each of the orbital parameters has a different effect with changing latitude. For example, obliquity has increasing influence the higher the latitude, while precession has its largest influence in the tropics. This is important when investigating different forcing functions (see *Astronomical theory of climate change*).

Feedback mechanisms

Orbital forcing in itself does not cause glacial-interglacial cycles, rather, the climate system must be predisposed to amplify these effects through feedback mechanisms. The insolation changes received by the Northern Hemisphere temperate zone are thought to be critical for driving glacial-interglacial

cycles. This is because the Southern Hemisphere is limited in its response as the expansion of the ice sheets is curtailed by the Southern Ocean around Antarctica. It was initially suggested by Milankovitch (1949) that the critical factor is total summer insolation at about 65° N, as the ice sheets must survive the summer melting. The conventional view of glaciation is that low summer insolation in the temperate North Hemisphere

allowed ice to survive summer and thus start to buildup on the northern continents (Hays et al., 1976). At some point, this expansion allowed the ice sheet to produce its own sustainable environment, primarily by increasing the albedo, and thereby promoting the accumulation of more ice (Figure Q5). The next critical stage occurred when the ice sheets, particularly the Laurentide Ice Sheet on North America, become big enough

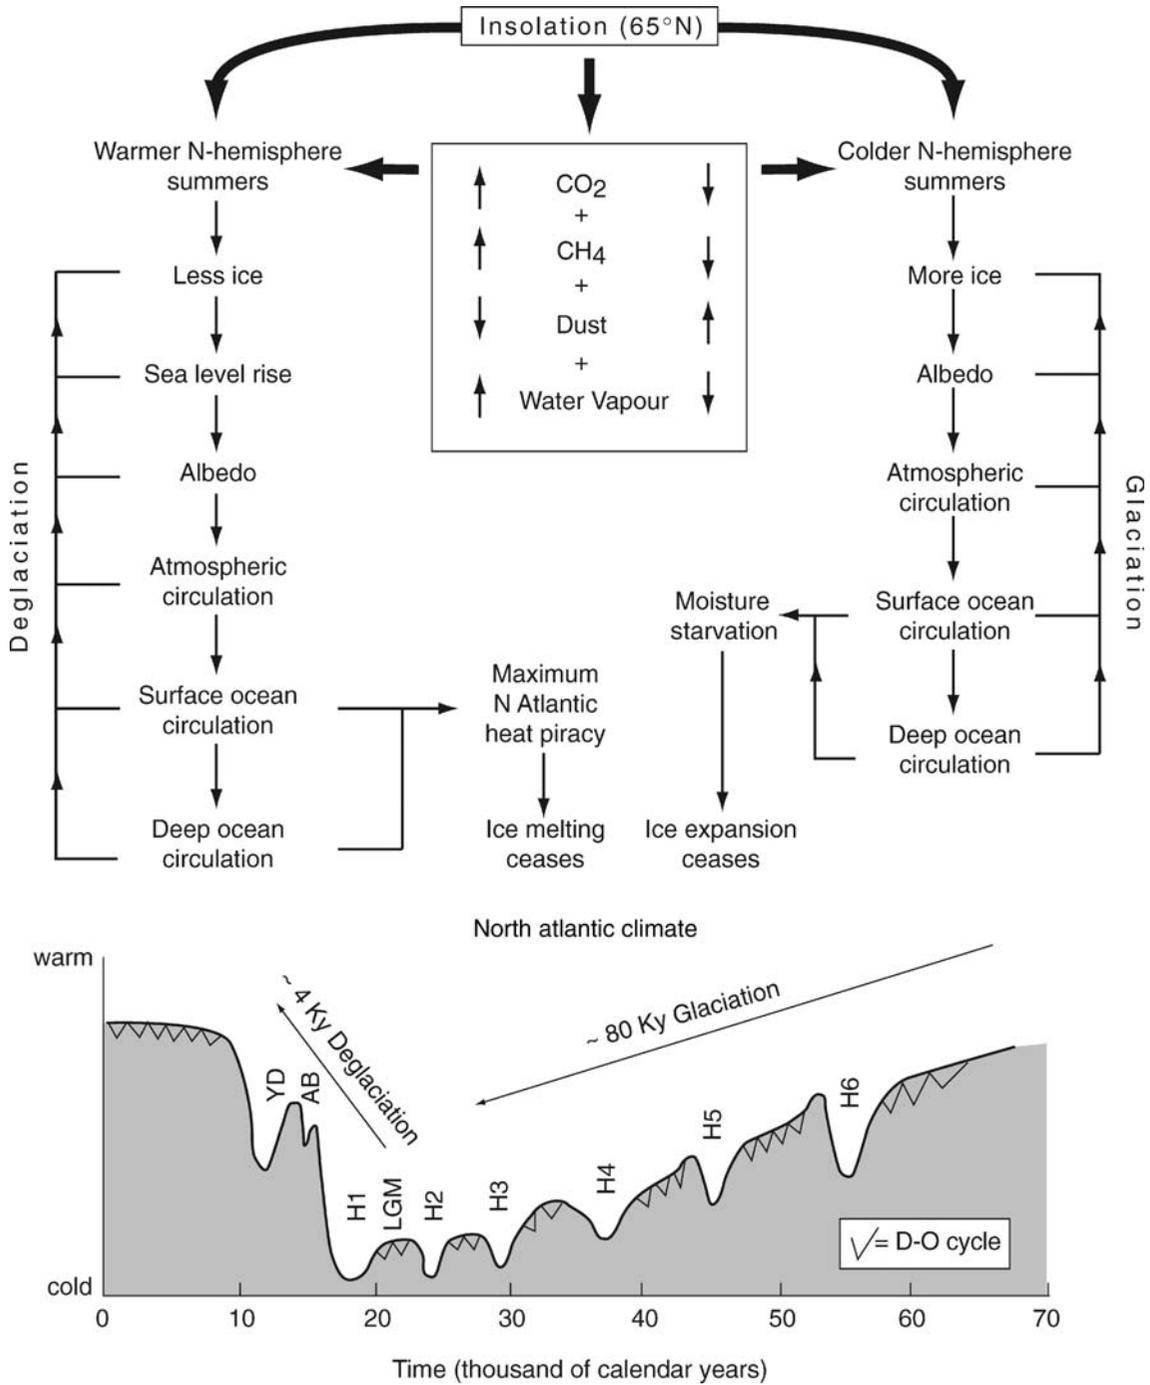

Figure Q5 Summary of the feedback mechanisms forced by insolation at 65° N that drive glaciation and deglaciation. H: Heinrich events, LGM: Last Glacial Maximum, AB: Allerød Bølling Interstadial, YD: Younger Dryas Stadial and D-O: Dansgaard-Oeschger cycles.

to deflect atmospheric planetary waves (Huybers and Tziperman, 2007). This changed the storm path across the North Atlantic Ocean and prevented Gulf Stream penetration as far north as today. This surface ocean change and increased melt-water in the Nordic Seas and Atlantic Ocean ultimately reduced the production of deepwater. This in turn reduced the amount of warm water pulled northwards. All of these led to increased cooling in the Northern Hemisphere and expansion of the ice sheets.

There are other feedback mechanisms that also helped drive the system towards maximum possible glacial conditions (Raymo and Huybers, 2008). These include changes in the carbon cycle that reduced both atmospheric carbon dioxide and methane. Ridgwell et al. (2003) discuss the main controls on the carbon cycle and the possible causes of reduced glacial atmospheric carbon dioxide. They speculate that glacial-interglacial changes in atmospheric carbon dioxide may be primarily driven by changes in oceanography in the Southern Ocean. This could have altered the nutrient supply to the surface waters, and hence surface water productivity. Dust-stimulated increased glacial surface water productivity would have drawn down atmospheric carbon dioxide into the surface water to produce organic matter through photosynthesis. However, the controls on the glacial-interglacial carbon cycle are still very poorly understood. Glacial periods are also by their very nature drier, which reduces atmospheric water vapor. For example, Lea et al. (2000) provide clear evidence that the water vapor production of the equatorial Pacific zone was greatly curtailed during the last five glacial periods. CO₂, CH₄ and water vapor are all crucial greenhouse gases and any reduction in them leads to general global cooling (Figure Q5), which in turn furthers glaciation.

These feedbacks are prevented from becoming a runaway effect by “moisture limitation.” As warm surface water is forced further and further south, the moisture supply that is required to build ice sheets decreases. Moreover, it is very clear that ice sheets are naturally unstable and these feedbacks are constantly altering direction during the whole glacial period, hence it takes 80 ka to achieve the maximum ice extent during the LGM and that period is characterized by rapid oscillations such as Heinrich events and D-O cycles (see below).

The natural instability of ice sheets means that deglaciation is much quicker than glaciation. For example, the last deglaciation or Termination I, endured a maximum of 4 ka including the brief return to glacial conditions called the Younger Dryas period. The increase in summer 65° N insolation (e.g., Imbrie et al., 1993) led to the initial melting of the northern ice sheets. The resultant raised sea level then undercut the ice sheets adjacent to the oceans, which in turn increased sea level. This sea level feedback mechanism was extremely rapid. Once the ice sheets retreated then the other feedback mechanisms discussed for glaciation reversed (see Figure Q5), leading to a massive increase in the greenhouse gases CO₂, CH₄ and water vapor. These feedbacks were prevented from creating a runaway effect by the limit of how much heat the North Atlantic could steal from the South Atlantic to maintain the interglacial deep-water overturning rate.

The latest data concerning the link between orbital forcing and these feedbacks suggests that changes in the carbon cycle lead to changes in global ice volume (Shackleton, 2000; Ridgwell et al., 2003; Ruddiman and Raymo, 2003; Pagani et al., 2005; Raymo and Huybers, 2008). This suggests that orbital forcing has a direct effect on atmospheric carbon dioxide and methane,

which may drive global temperatures, and in turn change global ice volume. Thus, the carbon cycle, instead of being a response to glacial-interglacial cycles, could indeed be one of the key driving forces (see Figure Q5).

The Mid-Pleistocene revolution

Debunking the eccentricity myth?

The Mid-Pleistocene Revolution (MPR) is the term used to denote the marked prolongation and intensification of the global glacial-interglacial climate cycles which occurred between 900 and 650 ka (Berger and Jansen, 1994). Prior to the MPR, since at least the intensification of Northern Hemisphere glaciation (~2.75 Ma), global climate appears to have responded to obliquity variations (Imbrie et al., 1992), i.e., the glacial-interglacial cycles occurred with a frequency of 41 kyr. After about 800 ka, glacial-interglacial cycles became more pronounced and occurred with a frequency of approximately 100 ka. The MPR, therefore, marks a dramatic sharpening of the contrast between warm and cold periods. Mudelsee and Stettger (1997) used advanced methods of time-series analysis to review the deep-sea evidence spanning the MPR and summarized the salient features (Figure Q6). The first transition occurred between 942 and 892 ka when global ice volume significantly increased. However, the 41 ka climate forcing continued. This situation persisted until about 650–725 ka when the climate system entered a bi-modal phase and the strong 100 ka climate cycles began (Mudelsee and Stettger, 1997).

Imbrie et al. (1993) called the MPR the “100 ka problem,” as the eccentricity signal is by far the weakest of the orbital parameters. Hence, it has been assumed that there must have been a change from a linearly to a non-linearly forced climate system (Imbrie et al., 1992, 1993). Many different theories have thus been postulated to produce this critical non-linear transition, including: critical size of the Northern Hemisphere ice sheets, global cooling trend, erosion of regolith beneath the Laurentide Ice Sheet, orbital inclination, Greenland-Scotland submarine ridge and carbon cycle and atmospheric CO₂ (see Maslin and Ridgwell, 2005 for detailed references).

There are a number of problems with associating the 100 ka cycles with eccentricity. The first is that eccentricity has spectral peaks at 95 ka, 125 ka and 400 ka. The spectral analysis of benthic foraminifera oxygen isotopes (SPECMAP) – a proxy for global ice volume – shows a consistent single peak of 100 ka (Maslin and Ridgwell, 2005). However, the lengths of the last 8 glacial-interglacial cycles vary from 87 to 119 ka, averaging about 100 ka. Ridgwell et al. (1999) demonstrated that this strong 100 ka peak could not be produced by eccentricity, but rather by a simple saw-tooth pattern based on a long glaciation period followed by a short deglaciation (Figure Q7). This suggests that the 100 ka cycle seen in the ice volume records is dominated by deglaciations that occur every 100 ka after the MPR, on average. Note that summer insolation at 65° N is also strongly influenced by precession; hence, the saw-toothed pattern of rapid deglaciation occurs every fourth or fifth precessional cycle over the last 600 ka. A similar saw-tooth pattern can be produced from obliquity using every second or third cycle (Ridgwell et al., 1999; Huybers and Wunsch, 2005; Raymo et al., 2006; Raymo and Huybers, 2008), but the spectral analysis does not match the global ice volume signal as well (Ridgwell et al., 1999; Maslin and Ridgwell, 2005). Models have also been used to re-create the 100 ka cycle and the most successful is the LLN 2D model,

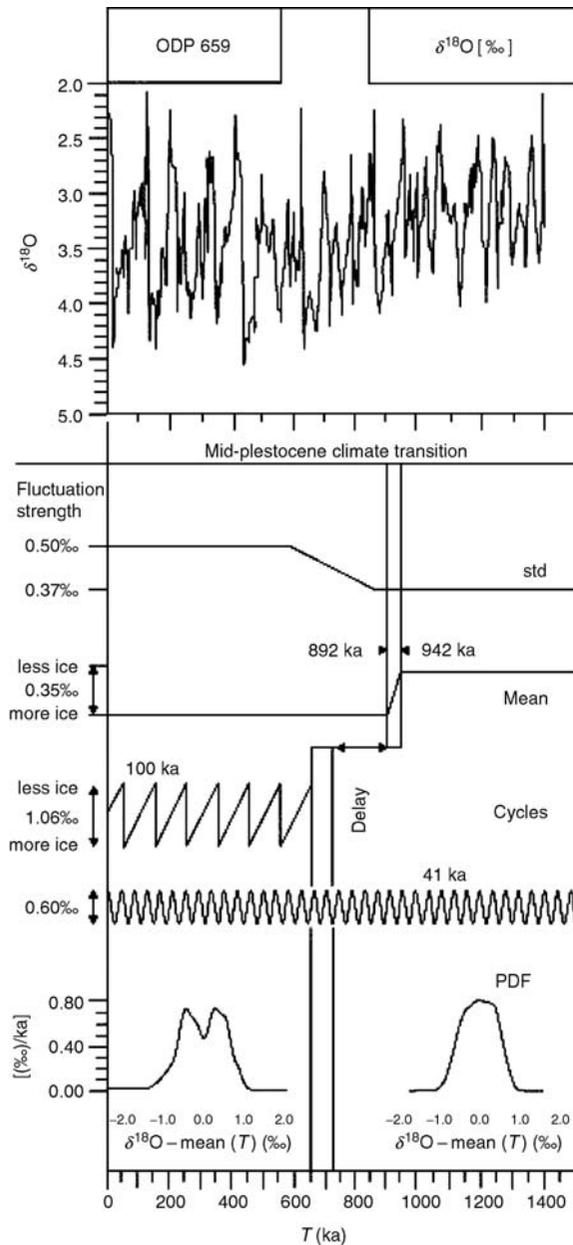

Figure Q6 Detailed breakdown of the Mid-Pleistocene Revolution (after Mudelsee and Statterger, 1997), demonstrating a delay of 200 ka between the significant increase in global ice volume and the start of the 100 ka glacial-interglacial cycles.

which combines orbital forcing with atmospheric carbon dioxide. Hence, the keys to the MPR are precession and atmospheric carbon dioxide. Ridgwell et al (1999) suggested that the episodic occurrence of unusually low maxima in Northern Hemisphere summer insolation is the critical factor controlling subsequent deglaciation. Ruddiman (2003) furthermore suggests that both precession and obliquity affect the concentration of the greenhouse gases carbon dioxide and methane, and this combined influence results in the strong 100 ka cycle. This means that all three orbital periodicities are involved and the

MPR is not a simple non-linear amplification of eccentricity. In effect, this new research from the study of the MPR suggests that it is very hard to get the global climate system out of a glacial or near-glacial condition. Deglaciation can only occur when the climate system has been allowed to reach maximum glaciation by the previous low maxima in Northern Hemisphere summer insolation, for example during the LGM. The following precessionally driven summer maxima pushes the climate system too far and it overshoots the mild glacial (e.g., oxygen isotope stage 3 to 5a) type climate, entering an interglacial period.

The dominance of precession leads to another problem, the assumption of a linear response of the climate system to obliquity prior to MPR (Imbrie et al., 1992), as the insolation records for 2.5–1 Ma for the temperate regions are very similar to the period after 1 Ma, i.e., dominated by precession. Raymo and Nisancioglu (2003) suggest another solution to the obliquity problem: the MPR is a switch from an obliquity-driven latitudinal heat gradient system to a precessional-driven deglacial system. In contrast Raymo et al. (2006) and Raymo and Huybers (2008) suggested that prior to the MPR both the Northern Hemisphere and Antarctic ice sheets are responding to precession; but because they are 180° out of phase the precessional component cancels out leaving a dominant obliquity signal. After the MPR the dominance of the Northern Hemisphere ice sheet is such that Northern Hemisphere precession dominates global climate.

Millennial-climate cycles

Heinrich events

Heinrich events are intense and quasi-periodic ice-rafting pulses that are thought to originate primarily from the Laurentide Ice Sheet (e.g., Ruddiman, 1977; Heinrich, 1988; Bond et al., 1992; Maslin et al., 1995). These events occurred against the general background of unstable glacial climate, and represent the brief expression of the most extreme glacial conditions around the North Atlantic. Heinrich events are evident in the Greenland ice cores as a further 3–6 °C drop in temperature from the already cold glacial climate (Bond et al., 1993; Dansgaard et al., 1993). These events have been found to have a global impact with evidence for coeval climate changes from as far a field as: South America, North Pacific, Santa Barbara Basin, Arabian Sea, China, South China Sea, and Sea of Japan (e.g., reviewed in Maslin et al., 2001). Around the North Atlantic, much colder conditions prevailed in both North America and Europe, while huge armadas of melting icebergs reduced sea surface temperatures in the North Atlantic Ocean by another 1–2 °C and reduced the surface salinity by up to 4‰ (Chapman and Maslin, 1999; Rashid and Boyle, 2007).

Detailed studies of the sequence of events in ocean sediments and ice cores show that Heinrich events occurred on an average of $7,200 \pm 2,400$ calendar years in the time interval between about 70 and 10.5 ka. In between the Heinrich events, much higher frequency, smaller amplitude events occurred about every 1,500 years, which are referred to as Dansgaard-Oeschger events or cycles (Dansgaard et al., 1993; Bond et al., 1997). Heinrich events may in fact be just super Dansgaard-Oeschger events. (see *Dansgaard-Oeschger cycles*; *Heinrich events*).

Dansgaard-Oeschger cycles

Dansgaard-Oeschger (D-O) cycles were first identified in the Greenland ice core records (Dansgaard et al., 1993). A succession

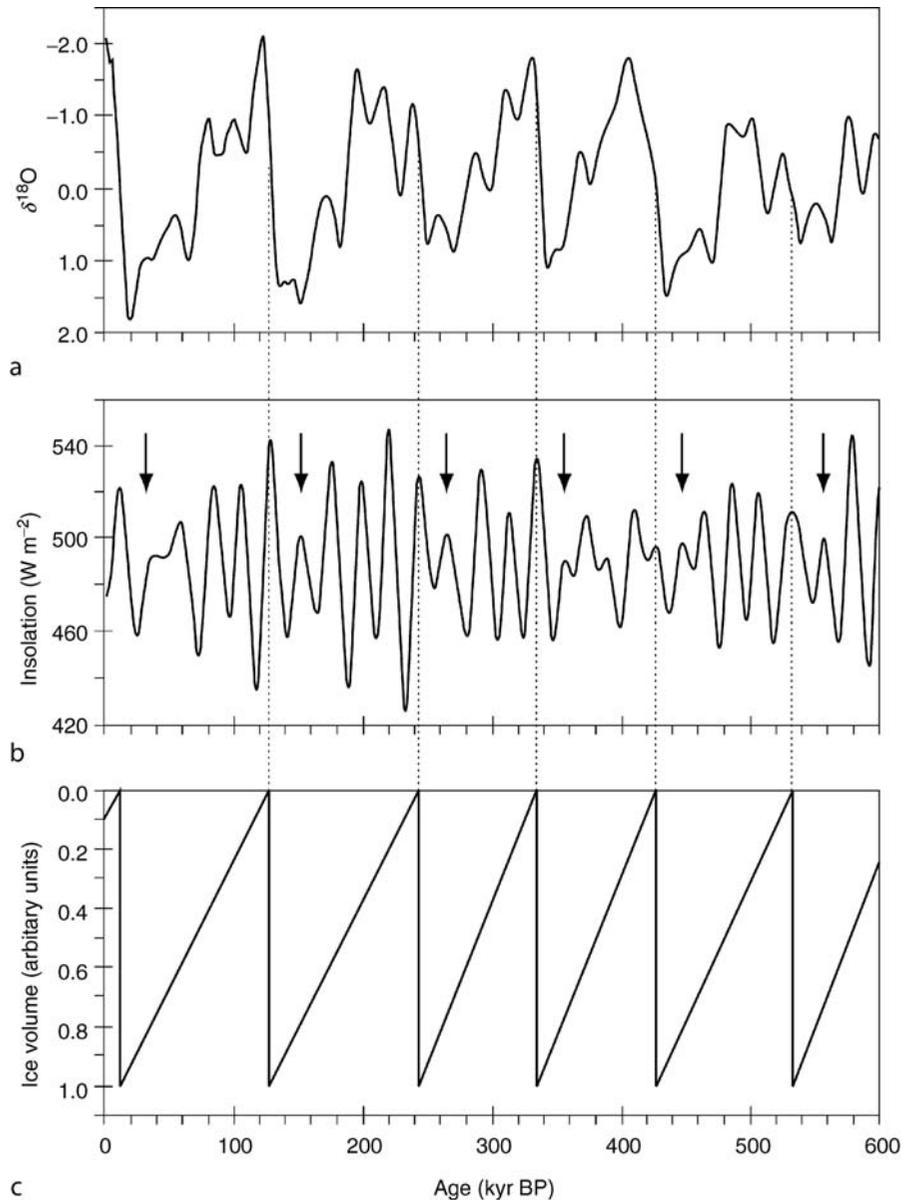

Figure Q7 (a) SPECMAP stacked $\delta^{18}\text{O}$ composite, (b) insolation for June 21 65°N showing the quasi-periodic insolation maxima of unusually low strength (shown by arrows) preceding glacial-interglacial terminations by one precessional cycle in each case and (c) sawtooth artificial ice volume signal.

of short lived “warm” events or Greenland interstadials (GIS) characterize the ice core records of the last glacial episode and are numbered down from the “Bølling” as GIS 1 to GIS 24 at 105 ka. The D-O stadials or cold sections of the D-O cycle have been found in the ice rafting records of the North Atlantic (e.g., Bond and Lotti, 1995). These stadials are characterized by increased meltwater and ice-rafted debris originating from Iceland and East Greenland. These D-O cycles have a frequency of $1,479 \pm 532$ years, and seem to persist into the Holocene interglacial as well as occurring during earlier glacial and interglacial stages (Bond et al., 2001). A precise time-scale for the duration and sequence of these millennial-scale climate events is uncertain, though the events themselves do

not appear to have lasted longer than a few centuries. Furthermore, the transitions marking the beginnings and ends of each Heinrich and D-O event are particularly rapid, probably lasting no more than a few decades, indicating that climate responded in a step-like series of jumps to whatever driving mechanism initiated them.

Possible causes of the Heinrich events and Dansgaard-Oeschger cycles

There are a number of possible causes suggested for these millennial climate cycles, including the theory that they are due to stochastic resonance (Alley et al., 2001). Although none

of these theories is conclusive, the major ones are summarized below.

Internal ice sheet failure

MacAyeal (1993a,b) suggested that the Heinrich event iceberg surges were caused by internal instabilities of the Laurentide Ice Sheet. This ice sheet rested on a bed of soft unconsolidated sediment, which, when it was frozen, did not deform and behaved like concrete, so that it would have been able to support the weight of the growing ice sheet. As the ice sheet expanded, the geothermal heat from within the Earth's crust, together with heat released from friction of ice moving over ice was trapped by the insulating effect of the overlying ice. This "duvet" effect allowed the temperature of the sediment to increase until a critical point when it thawed. When this occurred, the sediment became soft, and thus lubricated the base of the ice sheet, causing a massive outflow of ice through the Hudson Strait into the North Atlantic. This, in turn, led to sudden loss of ice mass, which then reduced the insulating effect and led to re-freezing of the basal ice and sediment bed, at which point the ice reverted to a slower build-up and outward movement. According to MacAyeal (1993a,b), this system of progressive ice build-up, melting and surge, followed by renewed build-up, has an approximate periodicity of 7,000 years, which compares well with the interval between the last six Heinrich events, which is on average $7,200 \pm 2,400$ calendar years. However, different ice sheets may have had different binge-purge times, thus the Fenno-Scandinavian, Greenland and Icelandic Ice Sheets would have surged with different periodicities. An alternative suggestion is that D-O events are caused by the more frequent regular failure of the European and Greenland Ice Sheet, while the larger, more infrequent Heinrich events are caused by collapse of the Laurentide Ice Sheet.

Sea level connection between Heinrich and D-O events

The second theory is that sea level rises induced by the 1,500-year D-O cycles undercuts and thus destabilizes the Laurentide Ice Sheets, triggering a much larger Heinrich event. The periodicities are such that a Heinrich event occurs for every fifth D-O cycle. Support for this theory comes from the detailed analysis of the sources of ice-rafted material in the Heinrich layers. From the detailed breakdown of H1, H2, H4 and H5, it has been shown that European ice-rafted debris was deposited in the North Atlantic up to 1,500 years before the Laurentide material (e.g., Grousset et al., 2000). This theory, however, does not explain what causes the Dansgaard-Oeschger cycles, since they occur with a similar frequency during both glacial and interglacial periods.

Bipolar climate seesaw

Ice core data from Greenland and Antarctica show an out-of-phase relationship in glacial millennial-scale climate cycles for the North and Southern Hemisphere (Blunier et al., 1998), see Figure Q8. It has been suggested that this so-called bipolar climate seesaw can be explained by alternating meltwater events in the North Atlantic and Southern Ocean. Each meltwater event would change the relative amount of deepwater formation in the two hemispheres and the resulting direction of inter-hemispheric "heat piracy" (Figure Q8; Seidov and Maslin, 2001; Seidov et al., 2001; see *Thermohaline circulation*). The

bipolar seesaw model suggested by Maslin et al. (2001) could be self-sustaining with meltwater events in either hemisphere triggering a chain of climate changes that eventually causes a meltwater event in the opposite hemisphere by switching the direction of the hemispheric heat exchange (Figure Q9). The advantage of this theory is that it can explain D-O cycles during both glacial and interglacial periods.

External forcing

Heinrich (1988) originally suggested that ice-rafting events could be forced by harmonics of orbital parameters, as their quasi-cyclicity is on the order of 10 kyr. However, it now seems that the periodicity shortens through a glacial period starting at 13 ka and decreasing to 7 ka. With the discovery that Heinrich events were part of the more frequent D-O cycles and that both hemispheres respond asynchronously, it is unlikely that longer-term orbital forcing (minimum 10 kyr) could be the cause. Hence, until recently it was thought these millennial events were internally and not externally, forced. The latest development in this area is a study showing a significant correlation between drift-ice deposited material in the North Atlantic and the production of both ^{14}C and ^{10}Be in the atmosphere over the last 12,000 years (Bond et al., 2001). Bond et al. suggest that the production of both ^{14}C and ^{10}Be indicates millennial-scale variations in solar output, which may have caused the D-O climate cycles. They further postulate that amplification of relatively weak solar changes was due to the Arctic-Nordic Sea's sensitivity to changes in surface-water salinity. Hence, increased freshening of this region would reduce the North Atlantic Deep Water (NADW) and thus transmit the solar influence globally. However, a number of problems remain with the millennial-scale solar output theory, the most important being how the extremely small solar output variations are translated into regional and global climate changes of over 2°C . The debate about solar forcing on Holocene climate records and its application to glacial periods continues (e.g., Braun et al., 2005; *Holocene climates*).

Last glacial-interglacial transition (LGIT)

The nature of the LGIT

The last glacial-interglacial transition (LGIT, ca. 14–9 ^{14}C kyrBP) was characterized by a series of extremely abrupt climatic changes (e.g., Alley and Clark, 1999; Lowe and Walker, 2000; Stocker, 2003). These abrupt climate shifts are found in earlier glacial terminations and therefore seem to be part of the natural climate variability associated with this type of transition. The two most prominent features are rapid warming at 14.7 k GRIP ice-core years BP (the start of the "Bølling" episode) and the well-known period of severe cooling referred to as the Younger Dryas Stadial, dated to between 12.7 and 11.5 ka BP in GRIP ice-core years. These features are easily recognizable in a wide range of proxy records from sites throughout the Northern Hemisphere (e.g., Alley and Clark, 1999). There is also a growing body of evidence that suggests that parts of the Southern Hemisphere may have experienced a broadly similar sequence of climatic events, including parts of South America and New Zealand.

According to the GRIP and GISP2 ice-core records (e.g., Dansgaard et al., 1993; Alley and Clark, 1999), the sequence of events during the last glacial-interglacial transition were far more abrupt than had been assumed from prior interpretations based on continental and marine stratigraphical records.

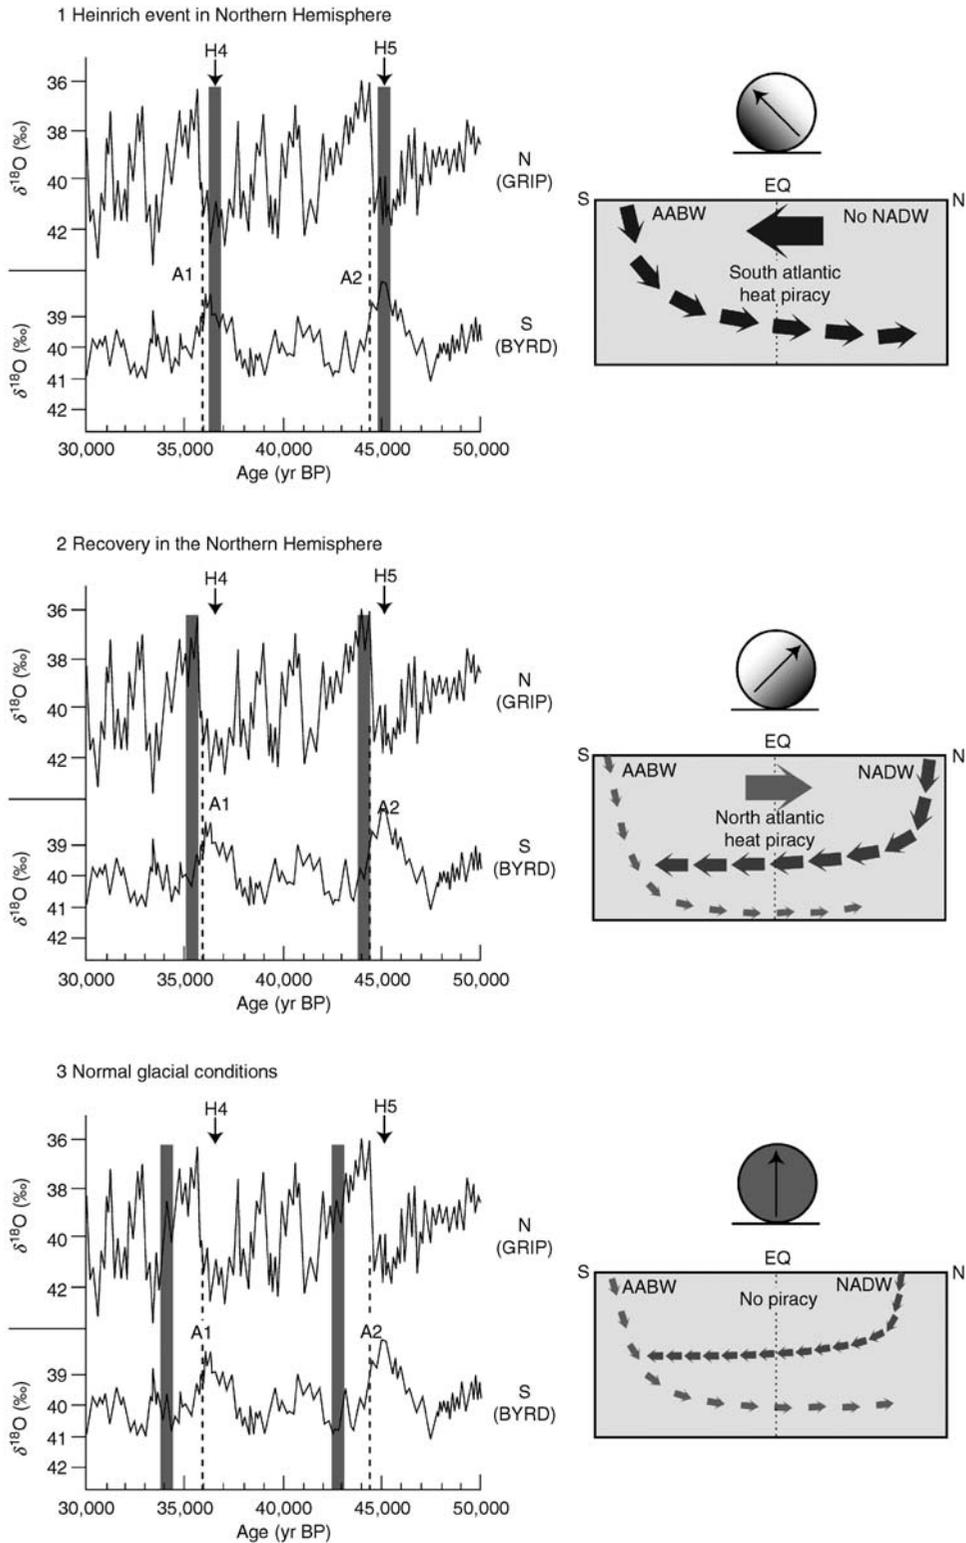

Figure Q8 Left: Greenland (GRIP) and Antarctic (Byrd) ice core $\delta^{18}\text{O}$ temperature proxy records on the age models generated by Blunier et al. (1998). Three time slices are illustrated with *solid bars*; (1) Heinrich event, (2) Northern Hemisphere climate recovery post-Heinrich event, and (3) Normal glacial conditions. Right: Schematic view of oscillating meridional ocean overturning and associated regimes of heat transport in the Atlantic Ocean, showing which hemisphere controls deepwater circulation and thus inter-hemispheric heat transport (adapted from Maslin et al., 2001 and Seidov et al., 2001).

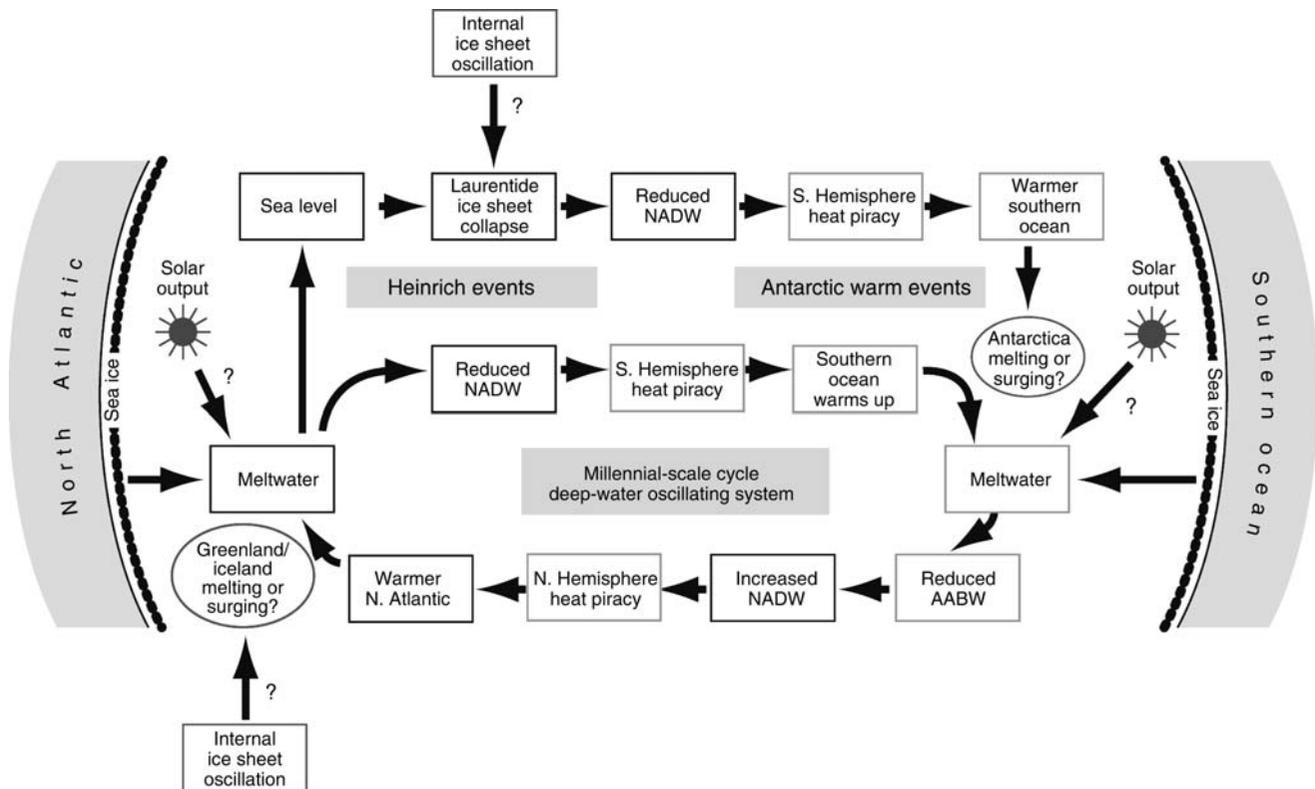

Figure Q9 Possible “deep-water oscillatory system” explaining glacial and interglacial Dansgaard-Oeschger cycles (adapted from Maslin et al., 2001). Meltwater in either the North Atlantic or Southern ocean can start the system. The meltwater caps the sites of deep water formation in that particular hemisphere and reduces the deepwater formation. This increases heat piracy to the other hemisphere, warming that hemisphere, which instigates ice sheet melting after hundreds or thousands of years, thus reversing the whole process. The system is quasi-periodic because of its oscillatory nature. The stochastic element observed in the records (Alley et al., 2001) comes from the different internal dynamics of each ice sheet. The link between the Dansgaard-Oeschger $\sim 1,500$ year cycles and the Heinrich events is through their successive effect on sea level. At a certain point, sea level has risen enough to undercut the Laurentide Ice Sheet and precipitate a full Heinrich event.

For example, a detailed study of the Greenland ice-core records (Taylor et al., 1997) suggests that the transition from the end of the Younger Dryas to the Holocene warm period may have been completed in a series of warming steps lasting no more than a few decades, most probably in less than 50 years (Alley and Clark, 1999). About half of the warming was concentrated into a single short step that lasted no more than 15 years. In contrast to the abrupt warming at the start of the “Bølling,” the cooling from the warm “Bølling” to the Younger Dryas appears to have been a more gradual process, involving a series of steps and minor climatic oscillations extending over a period in excess of 1,500 years.

The extent to which abrupt climate shifts during the LGIT were globally synchronous, or not, is pivotal to our understanding of global climate mechanisms. Detailed comparisons between the Antarctic and Greenland ice cores show that Antarctic climate changes were significantly out of step with those in the North Atlantic (Figure Q10) and provide another example of the bipolar climate seesaw described above. The data suggest that cooling (the Antarctic Cold Reversal) occurred in Antarctica during the period of warming in the North Atlantic region referred to as the “Bølling-Allerød Interstadial.” They also suggest that the severely cold Younger Dryas Stadial was a period of rapid

warming in Antarctica. In addition, Ridgwell et al. (2003) have shown that the majority of the changes in atmospheric carbon dioxide occurred in three major pulses that are synchronous with rapid warming in Antarctica (Figure Q10).

Possible causes of abrupt climate oscillations during the LGIT

It is believed that deglaciations were dominated by orbitally-induced ice sheet and associated climatic changes. The colder episodes, especially the very pronounced Younger Dryas cooling (Dansgaard et al., 1993), are periods imprinted on this trend of warmer interglacial conditions. For example, marine records from all parts of the North Atlantic during the Younger Dryas show significant increases in freshwater and ice-rafted debris input. This has led to the suggestion that the Younger Dryas was caused by a sudden influx of cold fresh meltwater from the North American and European Ice Sheets, which was sufficient to cap deepwater formation in the North Atlantic. Another suggestion is that meltwater diverted through the Gulf of St. Lawrence was enough to stop deepwater formation (Berger and Jansen, 1995; Clark et al., 2001; Carlson et al., 2007; Carlson, 2008). It seems almost axiomatic that the driving

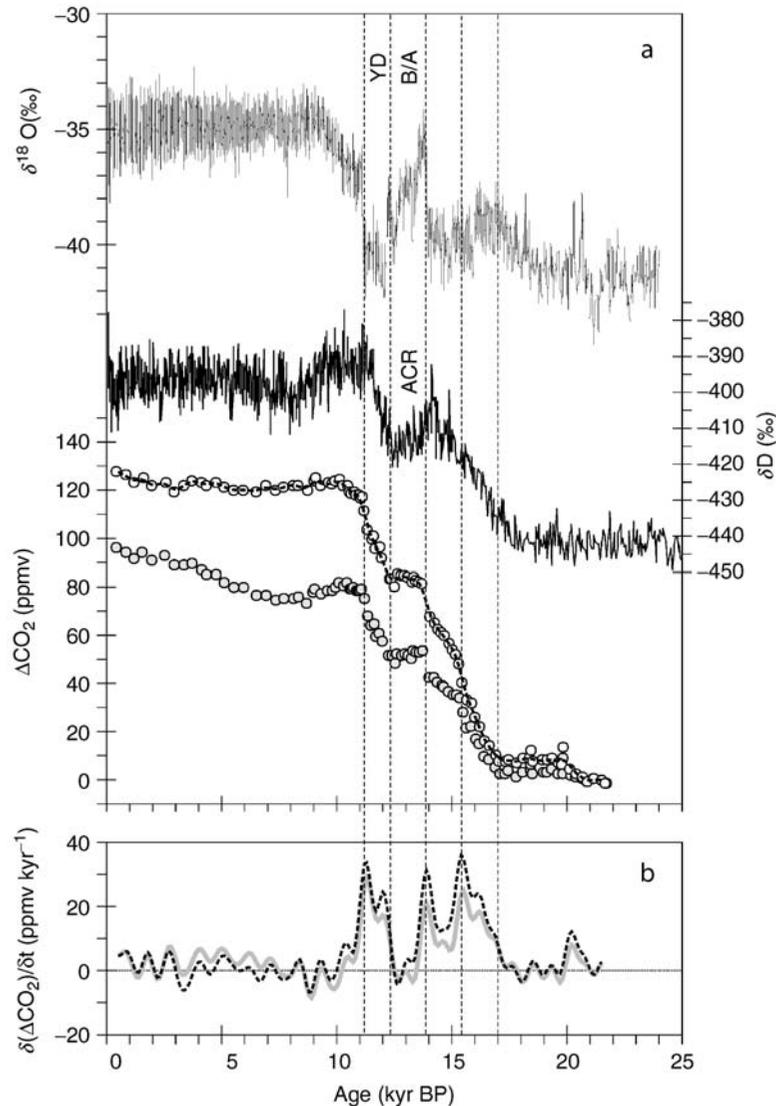

Figure Q10 (a) GRIP $\delta^{18}\text{O}$ “temperature proxy” showing timing of the Bølling/Allerød (B/A), and Younger Dryas (YD) intervals, the Antarctic Dome C δD “temperature proxy” record highlighting the relative timing of the Antarctic Cold Reversal (ACR), and observed atmospheric CO_2 changes as gray-filled circles, and the “residual” CO_2 record as empty circles, formed by subtracting the effects of re-growth of the terrestrial biosphere, sea level and reef buildup (see Ridgwell et al., 2003). Both data sets are now plotted as change relative to LGM values. (b) Rate of change of observed (thick gray line) and “residual” (dashed red line) CO_2 since the LGM. The timing of the sharp spikes corresponds to discernable “jumps” in the observed CO_2 record and correlates with significant warming in Antarctica (adapted from Ridgwell et al., 2003).

mechanism for the Younger Dryas episode, for example, must be some form of internal mechanism, such as oceanic circulation change, since this episode of very pronounced cooling occurred at a time of summer radiation maximum in Milankovitch calculations. There is also a new theory that suggest an asteroid impact may have caused the Younger Dryas event (Firestone et al., 2007) and this may explain why a Younger Dryas event is not seen at other earlier Terminations (Carlson, 2008).

On top of this are climate records of Greenland and Antarctic ice cores showing an anti-phase between the North and Southern Hemispheres through the LGIT. Prominent among the emerging ideas is Broecker’s (1998) suggestion of a “bipolar seesaw behavior in thermohaline circulation” as a mechanism

that explains this anti-phase relationship, as discussed above. Recent modeling work has shown that the anti-phase hemispheric climate during the LGIT can be produced from simple alternation of the deep ocean circulation driven by the Younger Dryas meltwater event in the North Atlantic (Knorr and Lohmann, 2003; Stocker, 2003; Weaver et al., 2003; Carlson, 2008).

Conclusions

Based on our present understanding of Quaternary climate change, large climatic transitions have occurred on the timescale of individual human lifetimes, for example, the end of the Younger Dryas and various D-O cold events. Many other substantial shifts in

climate took at most a few decades or centuries e.g., Heinrich events and events during the LGIT. Despite a huge amount of data, many problems remain in understanding the mechanisms controlling these rapid climate changes. Both external and internal forcing play a part. Of fundamental importance, however, is the discovery of the central role of the deepwater system in controlling past rapid global climatic changes (Stocker, 2003) and this should be of central concern in possible future climate change (Maslin, 2004a).

QUATERNARY VEGETATION DISTRIBUTION

Introduction

All aspects of Quaternary vegetation distributions, from the range and abundance of individual species, to the global position, extent, and composition of biomes, have changed extensively and repeatedly in response to the orbitally-paced oscillations in climate, atmospheric CO₂, and ice extent that are characteristic of the Quaternary. At centennial and longer timescales, the distribution and abundance of plant species closely track shifts in climate, despite the rooted habit of individual plants, via the dispersal of propagules to newly favorable regions, local changes in population abundances, and the dying out of populations in unfavorable locations. Distributions of vegetation formations and biomes emerge from these species-level responses. The history of Quaternary vegetation distributions is thus indirectly a history of global and regional climate change, and paleo-vegetational records are an important source of information about Quaternary environments. As an active component of the Earth system, shifts in the global vegetation affect the biogeochemical and biogeophysical fluxes between the land surface and atmosphere as well as the functioning of the global carbon cycle. Moreover, the present genetic structure and distribution of populations, species, and communities is in part a legacy of late-Quaternary species migrations and colonization history.

Primary sources of information for Quaternary vegetation history are the fossil pollen records collected from lake, wetland, and near-shore marine sediments, supplemented extensively by plant macrofossil, phytolith, and stable carbon isotope records. The present genetic structure of plant populations provides additional information about colonization routes and refugia. Detailed information about Quaternary vegetation distributions is mainly limited to the past 25,000 years, due to the limited length of most terrestrial records and because radiocarbon dating, the primary source of age estimates for late-Quaternary organic sediments, becomes increasingly uncertain after 40,000 years as radioactivity declines to background levels. The accuracy of radiocarbon ages varies over time, due to secular variations in atmospheric radiocarbon concentrations; all radiocarbon ages here have been converted to calendar years unless otherwise indicated. The past 40,000 years include the Last Glacial Maximum, last glacial-interglacial transition, and current interglacial and so may serve as a model for vegetation distributions during previous glacial-interglacial sequences. Individual records can span one million years or more, allowing longer-term reconstructions of vegetation history for certain locales.

Vegetation processes and dynamics

At Quaternary time scales (10²–10⁵ years), vegetation dynamics are mainly forced by climate change, and plant taxa have primarily accommodated late-Quaternary climate change via local changes in abundance and regional to continental shifts in distribution (Huntley and Webb, 1989). These biogeographic shifts can be dramatic: for example, *Picea* (spruce), which today is abundant in boreal and alpine regions, at the Last Glacial Maximum was apparently most abundant in the eastern interior of the USA (Figure Q11), a geographic shift of approximately 2,000 km. The maps of spruce also illustrate

that although migration is an important component of Quaternary vegetation dynamics, within-range changes in abundance are equally significant. The range of spruce (approximated by the 5% pollen contour in Figure Q11) has been relatively stable during the middle to late Holocene, but the area of highest abundance has shifted from western to eastern Canada (Figure Q11). These internal shifts in abundances are the result of changing rates of reproduction, growth, and mortality within and among populations, mediated by climate and disturbance regimes. The changes in extent and abundance differ among plant taxa, and the associations among taxa have changed with time. Species such as *Fagus grandifolia* (American beech) and *Tsuga canadensis* (eastern hemlock) that today are closely associated, had differing late-glacial distributions and migration histories (Figure Q11). Conversely, plant associations existed in the past that no longer exist today (indicated by high dissimilarities in Figure Q11), and may have grown under climatic conditions unlike any found today (Williams et al., 2001). Species movements along altitudinal gradients in response to climate change also display individualistic behavior, rather than wholesale shifts in vegetation zones.

The available evidence indicates that vegetation is in dynamic equilibrium with climate at millennial time scales (Webb, 1986). Climatic reconstructions based on pollen-response surfaces are generally consistent with other climatic proxies and general circulation model simulations and can successfully predict pollen abundances for other plant taxa (Prentice et al., 1991). Multi-proxy sediment records with evidence of abrupt climate change typically show that terrestrial vegetation composition responded to such changes with response times on the order of decades to a century (Tinner and Lotter, 2001). Holocene migration rates based upon pollen data range from 10 to 1,000 m yr⁻¹. However, these migration rates are at the edge of or beyond those predicted by current dispersal theory (Clark et al., 2001), and may be over-estimates in cases where outlier populations invisible to the pollen record are nucleating range expansions. Disturbance agents (fire, flood, windthrow, extreme climate events) contribute to and accelerate vegetation change by increasing plant mortality and opening up gaps for colonization.

At subcontinental to global scales, the individualistic responses of plant taxa to climate change cause the position, extent, and species composition of plant functional types (PFTs) and biomes to change over time. PFTs and biomes are useful units of vegetation at global scales, because they are based upon structural features of the vegetation and so are not constrained by intercontinental differences in evolutionary history and floristic lists (Prentice et al., 2000). Moreover, the number of plant morphological and functional types is limited relative to the number of species, so biomes can persist despite individualistic species behavior.

Vegetation history

Plio-Pleistocene transition to the last glacial maximum (ca. 2.5 million to 21,000 yBP)

The major floristic elements of the Quaternary vegetation were in place by the end of the Tertiary, with few new species or morphological changes apparent in the fossil record. Vegetation distributions during the Plio-Pleistocene transition changed in response to the onset of widespread glaciation in the Northern Hemisphere at ca. 2.45 million yBP, decreased global mean temperatures, and increased climate variability. Vegetation change

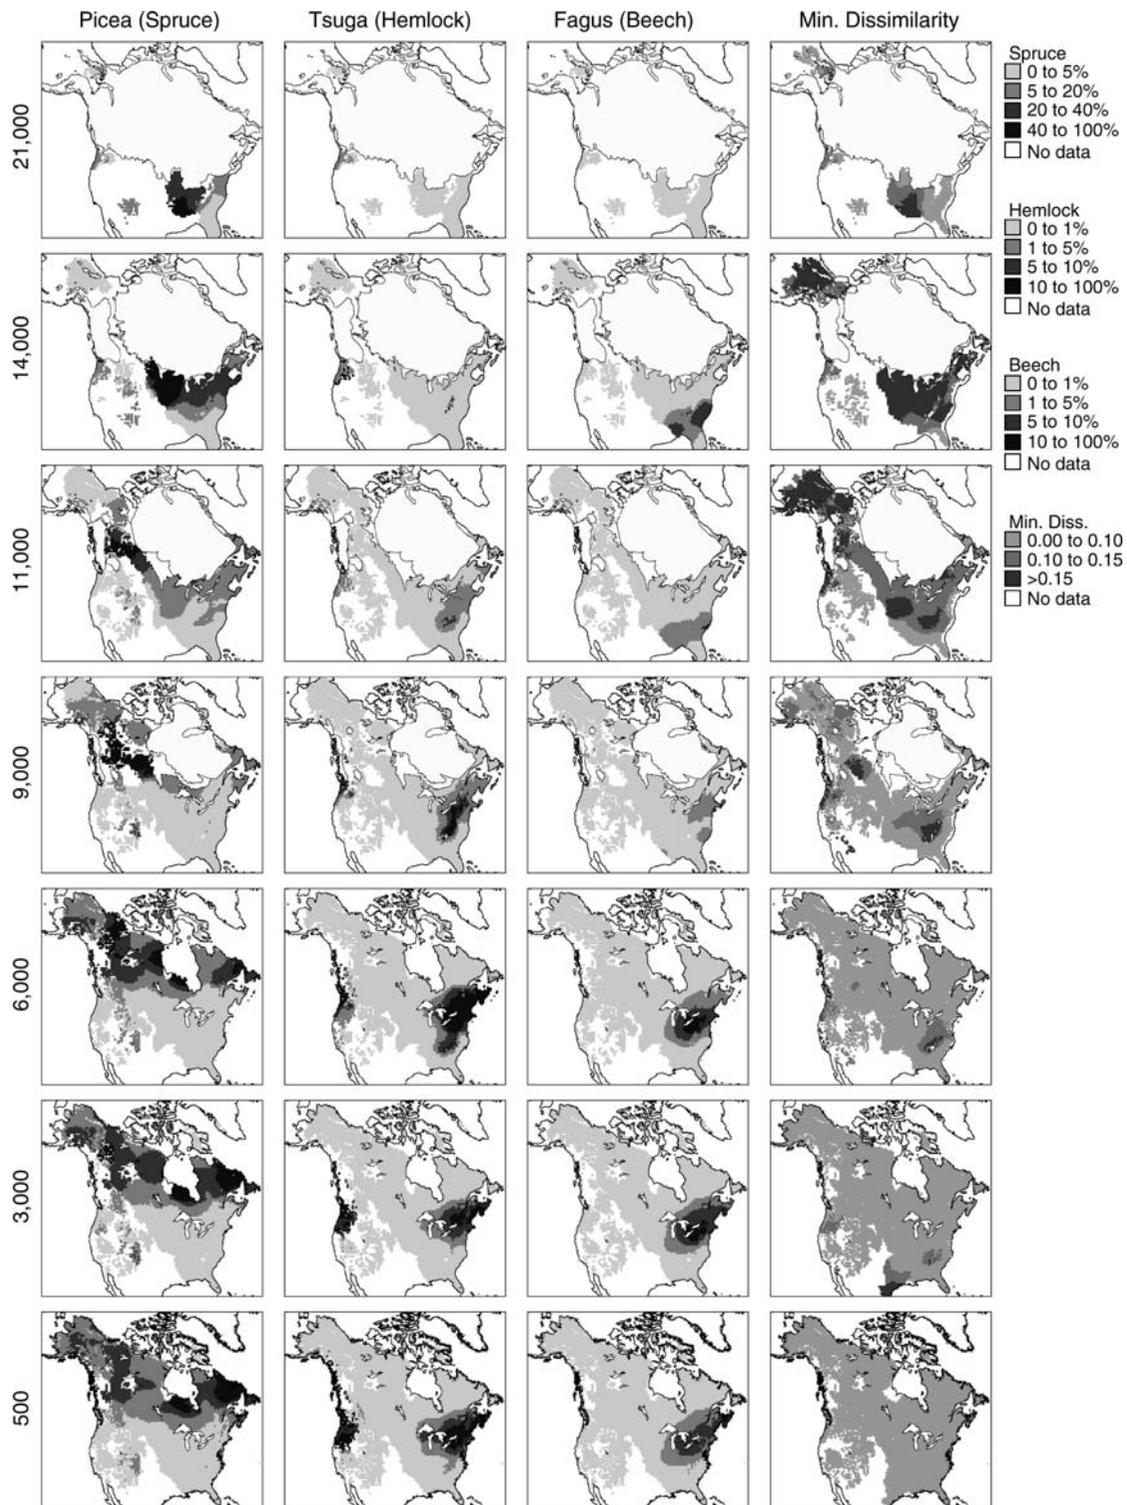

Figure Q11 Rows 1–3: Mapped pollen percentages for spruce (*Picea*), hemlock (*Tsuga*), and beech (*Fagus*) in northern and eastern North America for selected 1,000-year time periods since the Last Glacial Maximum. Each row header indicates the age in yrBP. Maps are based upon fossil pollen records from the North American Pollen Database, and consist of percent pollen abundances calculated relative to a summed pollen count and interpolated to a 50-km grid. Such maps are widely interpreted to represent past shifts of plant distributions, and analyses of modern pollen-vegetation relationships have shown that such maps capture contemporary patterns of plant abundances. Row 4: Mapped dissimilarities between fossil pollen assemblages and a dataset of modern and 500-yrBP pollen samples. High dissimilarities indicate that the fossil pollen assemblage has no close counterpart among modern pollen samples, and is interpreted to indicate plant communities unlike any today.

was most pronounced at high latitudes, where during the relatively warm Middle Pliocene, coniferous forests had grown to the Arctic coast in regions today occupied by tundra; while in the Southern Hemisphere, beech grew in coastal areas of Antarctica (Thompson and Fleming, 1996). Despite the drastic climate changes during the Plio-Pleistocene transition, there is little evidence of significant global plant extinctions, although local extinctions were widespread (Watts, 1988).

For the past 700,000 years, vegetation history has been paced by the pronounced 100,000-year cycle in climate, atmospheric CO₂, and global ice volume. Vegetation distributions at previous interglacials are broadly similar to the current interglacial, with expansions in the abundance and range of thermophilous taxa, but just as climates differed among interglacials, so too did the distribution and composition of the vegetation. The Eemian Interglacial in Europe (130–107 thousand yBP), which is the last interglacial prior to the current one and is particularly well documented, is characterized by high pollen abundances of oak (*Quercus*), hazel (*Corylus*), alder (*Alnus*), beech (*Fagus*), hornbeam (*Carpinus*), and other temperate woody taxa, with differences among sites likely reflecting interregional differences in Eemian climates. After the last interglacial ended, the proportion of treeless vegetation increased, with high pollen abundances of grass (Poaceae), sagebrush (*Artemisia*), chenopods (Chenopodiaceae), pine (*Pinus*), and juniper (*Juniperus*) reported from records spanning the last glacial period (Allen et al., 1999). On both sides of the North Atlantic, the proportion of woody vegetation increased during Heinrich events and interstadials (Grimm et al., 1993). In western North America, high abundances of oak, willow (*Salix*), and alder pollen during interglacials alternated with high abundances of fir (*Abies*), pine, and Taxaceae/Cupressaceae/Taxodiaceae (key taxa include redwood, cedar, and cypress) pollen during glacial periods (Adam, 1988; Heusser, 2000).

Last Glacial Maximum (LGM; 21,000 yBP)

By the last glacial maximum (LGM), enough well-dated paleovegetation records are available to systematically map global vegetation distributions, although tropical regions remain underrepresented. LGM vegetation distributions (Figure Q12a) formed in response to climates that were colder and drier than present. Atmospheric CO₂ concentrations that were 80 ppm lower than pre-industrial levels may have amplified the ecological impact of decreased moisture availability. Treeless conditions predominated in high-latitude regions not buried by ice, with tundra intergrading into steppe in central Asia and China (Figure Q11a) and steppe vegetation in North America along the margin of the Cordilleran and Laurentide Ice Sheets, in southern Europe and Northern Africa, in southern Africa, and in Australasia. Deserts extended to the east coast of China in now-forested regions. In contrast, lake level records from the western interior of North America indicate that full-glacial climates were wetter than present, and conifer woodlands grew widely in areas that today are desert or shrubland-steppe (Thompson and Anderson, 2000). Northern Hemisphere temperate and boreal forests were mainly confined to the southeastern USA, southeastern China, and Japan, and included a large component of cold-tolerant evergreen taxa.

The difference between LGM and modern climate and vegetation in the tropics is less pronounced than in higher latitudes, but neither tropical climates nor vegetation were stable during the late Quaternary (Bush et al., 2001). Tropical lowland

rain forests were somewhat diminished in extent, although the extent of the decrease and degree of fragmentation has been controversial. In Africa, tropical rain forest was partially replaced by tropical seasonal forest, whereas in southern Amazonia and Australasia, grasslands and savanna encroached on areas today occupied by tropical rain forest, subtropical forest, and savanna (Kershaw, 1988; Behling, 2002). The upper treeline was as much as 1,000 m lower than present, as the elevational ranges of upland types moved downslope, and upland evergreen forests were replaced by steppe and sclerophyll shrubland.

Recent explanations for LGM tropical treeline depressions have focused upon the effects of increased aridity and low CO₂ concentrations in addition to lowered temperatures (Jolly and Haxeltine, 1997). Tropical plant communities above treeline are dominated by plants utilizing the C₄ photosynthetic pathway, which enables maintenance of high intracellular CO₂ concentrations despite low ambient CO₂ concentrations. C₃ plants, conversely, are adversely affected by increased photorespiration and decreased water-use efficiency under low ambient CO₂ concentrations and the resulting competitive disadvantage may have depressed tropical treelines. In some areas, however, full-glacial C₃ communities were replaced by C₄ communities during deglaciation, indicating that the physiological effects of varying CO₂ concentrations can be overridden by local climatic controls (Huang et al., 2001). The importance of varying CO₂ concentrations for Quaternary vegetation dynamics remains under debate.

Deglaciation (14,000–8,000 yBP)

Global vegetation distributions were fundamentally transformed during deglaciation as glacial climates warmed to interglacial conditions during a period of higher-than-present seasonal contrasts in insolation. Forest cover increased, thermophilous taxa expanded upslope and northwards, and vegetation formations characteristic of the Holocene (e.g., taiga) emerged from the reshuffling of species distributions. In northwestern Canada and northern Eurasia, the northern treeline reached its northernmost position during the early Holocene, advancing near to the Arctic coastline. It then retreated to its present position by 4,000–3,000 yBP (MacDonald et al., 2000). Montane forest developed in central Africa by 10,000 yBP (Jolly et al., 1997) and podocarp forests in New Zealand by 13,000 yBP (McGlone, 1988). In Europe and eastern North America, thermophilous plant taxa began migrating north between 14,000 and 13,000 yBP. In Africa, C₄ plants diminished in abundance (Street-Perrott et al., 1997).

This period is further marked by abrupt changes in atmospheric and oceanic circulation that were superimposed upon the general transition from glacial to interglacial climates, and vegetation distributions closely tracked these rapid climate events. During the Younger Dryas Chronozone (12,900–11,600 yBP), plant communities adjacent to the North Atlantic reverted to cold-tolerant assemblages, switching to tundra in the European Alps and to alder shrublands in Maritime Canada (Mayle et al., 1993; Ammann et al., 2000). Vegetation changes consistent with a reversion to lower temperatures have been reported in Alaska, the Pacific Northwest, and at individual sites in South America and the Indo-Pacific region (Petee, 1995). In other regions, vegetation shifts coincident with the Younger Dryas suggest variations in moisture balance rather than temperature. In eastern North America, pine rapidly

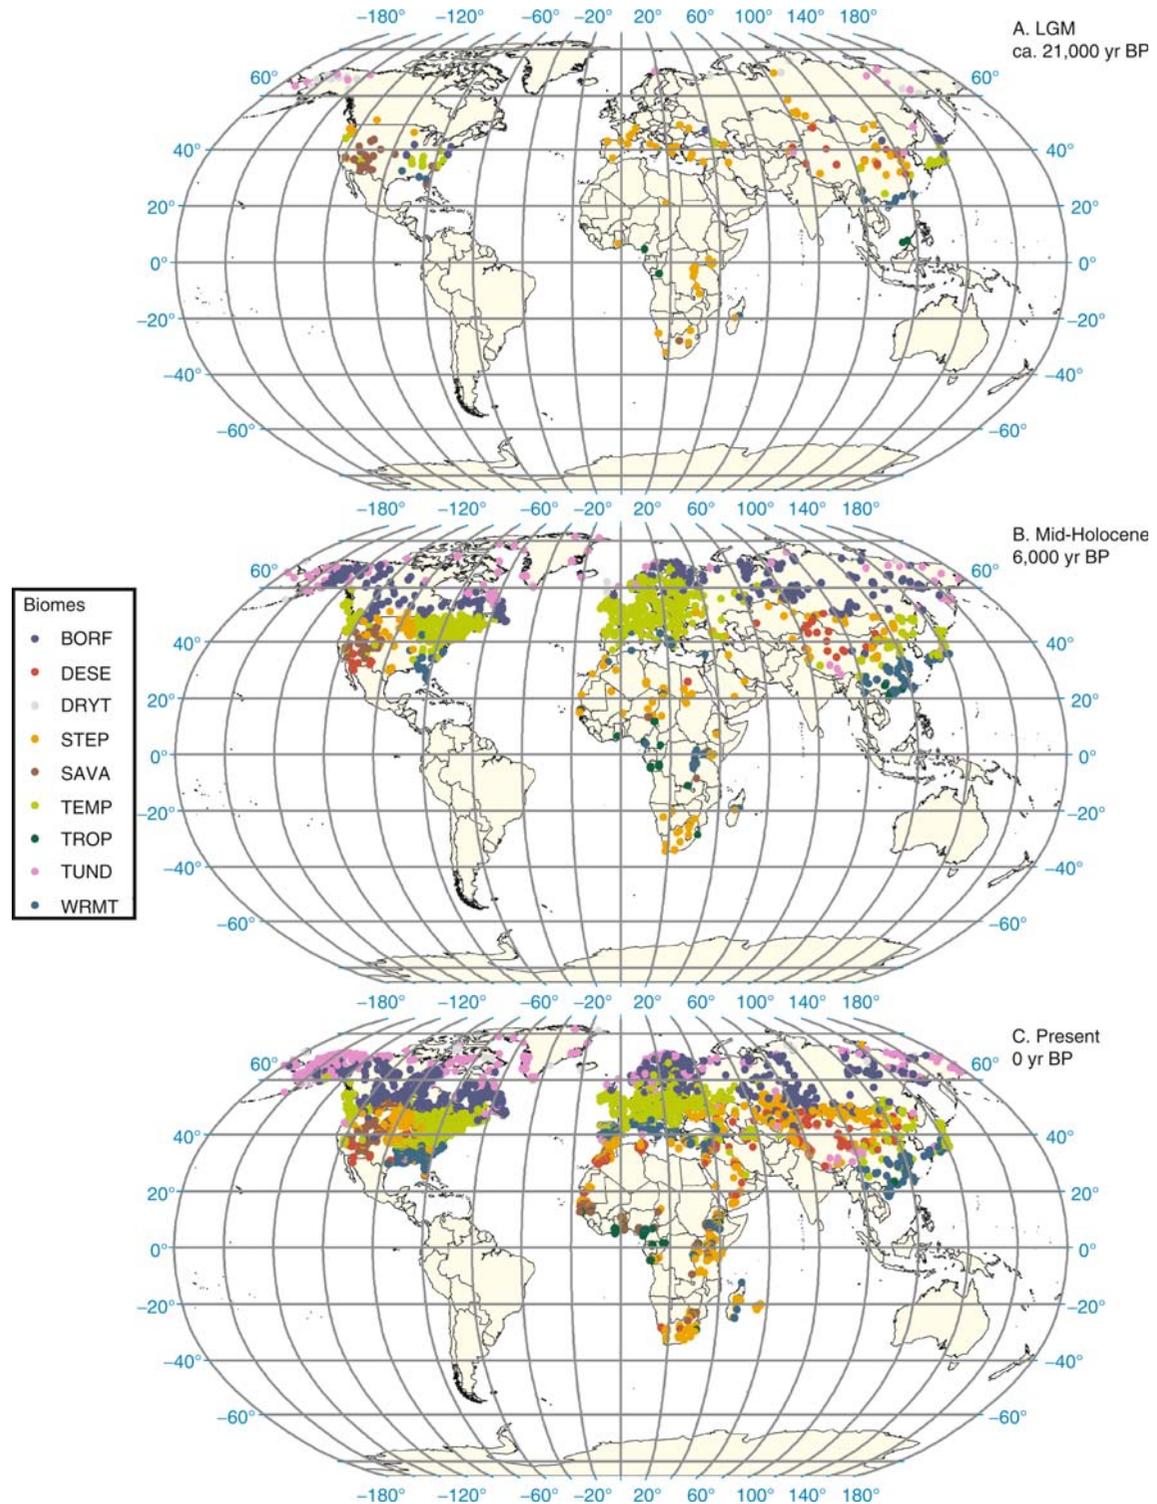

Figure Q12 Global vegetation maps produced by the Biome 6000 working group (Prentice et al., 2000; Bigelow et al., 2003), version 4.1 for the Last Glacial Maximum (18,000 radiocarbon yBP; ca. 21,000 calendar yBP), mid-Holocene (6,000 yBP), and present (0 yBP), based upon systematic application of a standardized classification algorithm to pollen and macrofossil data. The present-day vegetation reconstructions closely agree with independent maps of the vegetation. Ice sheet extent and changes in sea level are not shown. Paleovegetational reconstructions for India, the Indo-Pacific, South America, and Australia will be included in future versions of the Biome 6,000 synthesis. Biome codes: *BORF*, Boreal Forest; *DESE*, Desert; *DRYT*, Dry Tundra; *STEP*, Steppe/Grassland/Dry Shrubland; *SAVA*, Savanna and Open Woodland; *TEMP*, Temperate Forest; *TROP*, Tropical Forest; *TUND*, Tundra; *WRMT*, Warm Temperate Forest.

migrated westwards into the Great Lakes region, and spruce abundances declined (Shuman et al., 2002). Tropical African pollen records indicate that the Younger Dryas coincided with increased aridity. Vegetation distribution shifts during the Younger Dryas thus appear to have varied in direction among regions and continents as changes in climate varied among these regions.

Middle Holocene (7,000–4,000 yBP)

Global vegetation distributions during the mid-Holocene were similar to present, although differences persisted regionally (Figure Q11b). The position of the northern treeline was asymmetric relative to its present position, approximately 25 km north in northwestern Canada, 200–300 km north in central Siberia, and up to 200 km south in eastern Canada (Prentice et al., 2000; Bigelow et al., 2003). Temperate forests in eastern North America, Europe, and China were poleward of their present position, with shifts on the order of 100 km and as much as 800 km in northeastern China. In New Zealand, southern beech (*Nothofagus*) forests expanded (McGlone, 1988). These patterns suggest warmer-than-present temperatures in middle and upper latitudes.

Other distributional differences between the mid-Holocene and present vegetation were likely due to interregional variations in moisture balance. These differences are greatest in northern Africa, where steppe, xerophytic woodlands, and even warm mixed forest grew across a broad area now occupied by Saharan desert (Figure Q12b). Lake level highstands and modeling studies show that the African monsoon was enhanced relative to present (COHMAP Members, 1988). In the Columbian Andes, xeric vegetation types increased in extent during the middle Holocene although vegetation distributions in Chile suggest wetter-than-present conditions (Marchant et al., 2002). Steppe expanded at the expense of forest in the northern Midwest but was reduced in central Asia relative to present.

Consequences of Quaternary vegetation change

Earth system effects and feedbacks

The terrestrial biosphere is an integral component of the Earth system, and changes in vegetation distributions likely affected atmospheric circulation and the functioning of global energy and biogeochemical cycles. At high latitudes, changes in surface albedo associated with shifts in treeline may have amplified the orbitally-induced variations in temperature (Foley et al., 1994). In Northern Africa, the mid-Holocene expansion of steppe at the expense of desert may have enhanced monsoonal strength by increasing rates of evapotranspiration (Kutzbach et al., 1996). At the LGM, decreased vegetation cover in mid- and high-latitudes may have amplified cooling, due to an albedo feedback, whereas decreased evapotranspiration and a weakened hydrological cycle may have enhanced tropical aridity in the tropics (Levis et al., 1999). Furthermore, the LGM decrease in vegetation cover may have increased the source area for dust emissions and increased atmospheric LGM dust loadings (Harrison et al., 2001), thereby indirectly affecting the Earth's radiative budget and increasing rates of nutrient transport. The effects of vegetation change upon glacial-interglacial carbon budgets are large but uncertain, with recent estimates ranging from 500 to 1,100 Pg carbon lost from the terrestrial biosphere at the LGM, compared to present-day stocks of 2,000 Pg C. (Maslin, 2003). Increases in atmospheric methane concentrations from 350 ppbv at the LGM to 700 ppbv at the beginning of the Holocene may be due to expansion in tropical and boreal wetlands, or increased

rates of wetland CH₄ emissions due to increased CO₂ levels (Kaplan, 2002).

Evolutionary and genetic impacts

The close similarities between late Tertiary and Pleistocene faunas and the corresponding lack of widespread extinction and macroevolutionary change during the Quaternary is somewhat surprising given that the signal feature of the Quaternary is its extensive and repeated large climatic fluctuations. Apparently, plant taxa have accommodated Quaternary climate change primarily by ecological rather than evolutionary processes. Bennett (1997) has argued that individualistic species behavior effectively decouples microevolutionary and macroevolutionary processes, as orbitally-paced reorganizations of species associations remove coevolutionary adaptations.

Nevertheless, the repeated range shifts characteristic of the Quaternary are highly likely to have affected species' genetic structure, as individual populations have propagated or gone extinct (Davis and Shaw, 2001). Whether Quaternary vegetation dynamics tended to foster increased or decreased genetic diversity is not yet known. The genetic structure observed in present populations and species is in part a legacy of the biogeographic responses to the last deglaciation. For example, haplotype distributions within European white oaks (*Quercus* spp., subgenus *Lepidobalanus*) and North American whitebark pines have been convincingly related to likely colonization routes and glacial population distributions (Petit et al., 2002; Richardson et al., 2002). Differences in genetic structures among modern populations thus may help refine inferences about vegetation history.

Quaternary environmental variability may have helped shape the modern latitudinal gradient in species richness and other biogeographic patterns of species diversity. Historical explanations for high levels of tropical species diversity include focused upon two contrasting hypotheses: (a) long-term stability of tropical climates encouraging persistence of tropical rainforests and low rates of extinction versus (b) high levels of endemism caused by repeated fragmentation of rainforests during glacial periods (Hooghiemstra and van der Hammen, 1998). The extent of Amazonian rain forest fragmentation remains controversial, but lowland rainforests appear to have persisted as intact, albeit diminished, bodies of vegetation (Colinvaux et al., 2000), weakening the endemism hypotheses.

RADIOCARBON DATING

Radiocarbon (^{14}C) dating, now in its fifth decade of routine use, remains the most widely employed method of inferring chronometric age for organic materials from the late Pleistocene and Holocene. It provides the principal time scale for reconstruction of the history of late Quaternary environments, including the temporal scale for climate proxy records, and documents chronometric relationships for prehistoric human cultures on a world-wide basis.

Radiocarbon dating model

The natural production of ^{14}C is a secondary effect of cosmic-ray interactions with atmospheric gas molecules, with the resultant production of neutrons (Figure R1). Most ^{14}C is formed by the reaction of neutrons with ^{14}N . It is then rapidly oxidized to form $^{14}\text{CO}_2$. In this form, ^{14}C is distributed throughout the Earth's atmosphere by stratospheric winds, becoming generally well-mixed by the time ^{14}C -tagged CO_2 molecules reach the Earth's surface. Most ^{14}C is absorbed in the oceans, while 1–2% becomes part of the terrestrial biosphere, primarily by means of photosynthesis. Plant materials and animals that are, directly or indirectly, dependent on plants, are thus all labeled with ^{14}C .

Metabolic processes in living organisms maintain the ^{14}C content in approximate equilibrium with atmospheric ^{14}C concentrations. While ^{14}C decays in living tissue, it is continually replaced through the biochemical processing of plant or animal tissue. Once metabolic processes cease, as at the death of an animal or plant, the amount of ^{14}C begins to decrease by radioactive decay – in the case of ^{14}C , by beta decay – at a rate measured by the ^{14}C half-life (Taylor, 1987, 1997a).

The radiocarbon age of a sample is based on a measurement of its residual ^{14}C content. For the ^{14}C age of a sample to be equivalent to its true or solar/calendar age at a reasonable level of precision, a set of assumptions needs to be satisfied. These assumptions are that: (a) the $^{14}\text{C}/^{12}\text{C}$ ratio in materials of zero age in each carbon reservoir has remained essentially constant

over the entire ^{14}C time scale, (b) complete and rapid mixing of ^{14}C occurs throughout the various carbon reservoirs on a worldwide basis, (c) carbon isotope ratios (e.g., $^{13}\text{C}/^{12}\text{C}$ as well as $^{14}\text{C}/^{12}\text{C}$) in samples have not been altered except by ^{14}C decay since the death of an organism, (d) the half-life of ^{14}C is accurately known with reasonable precision, and (e) natural levels of ^{14}C can be measured to appropriate levels of accuracy and precision (Taylor, 1996).

A significant portion of contemporary ^{14}C studies involves two major types of efforts. First, there are investigations designed to examine and compensate for the effects of violations of the primary assumptions as applied to specific sample types or portions of the carbon reservoirs. Second, there are efforts to document explicitly the physical association between the organic sample on which a ^{14}C age estimate is obtained and the object, feature, or geological context for which an age determination is desired.

Radiocarbon age estimates are generally expressed in terms of a set of characteristic parameters that define a conventional radiocarbon age. These parameters, introduced in the mid-1970s and explicitly defined by Stuiver and Polach (1977), include (a) the use of 5,568 (± 30) years as the ^{14}C half-life (8,033 year mean life) used to calculate age, although the actual half-life value is probably closer to 5,730 (± 40) years; (b) the use of one of the United States National Institute of Standards and Technology (formerly U.S. National Bureau of Standards, NBS)-distributed oxalic acid preparations – or a secondary standard with a known relationship to the primary standard – as a contemporary or modern reference standard to define a “zero” ^{14}C age; (c) the use of AD 1950 as the zero point from which to measure ^{14}C time; (d) to account for fractionation effects, a normalization of the measured ^{14}C content in all samples to a common $^{13}\text{C}/^{12}\text{C}$ ($\delta^{13}\text{C}$) value of -25‰ (wrt PDB standard); and, finally, (e), an assumption that $^{14}\text{C}/^{12}\text{C}$ ratios in all reservoirs have remained constant over the ^{14}C time scale. In addition, each ^{14}C determination is expected to be accompanied by an expression that provides an accurate estimate of the overall experimental or analytical uncertainty. Since counting statistics associated with the measurement of ^{14}C concentrations in samples are usually the dominant component of the analytical uncertainty, this value is informally referred to as the “statistical error.”

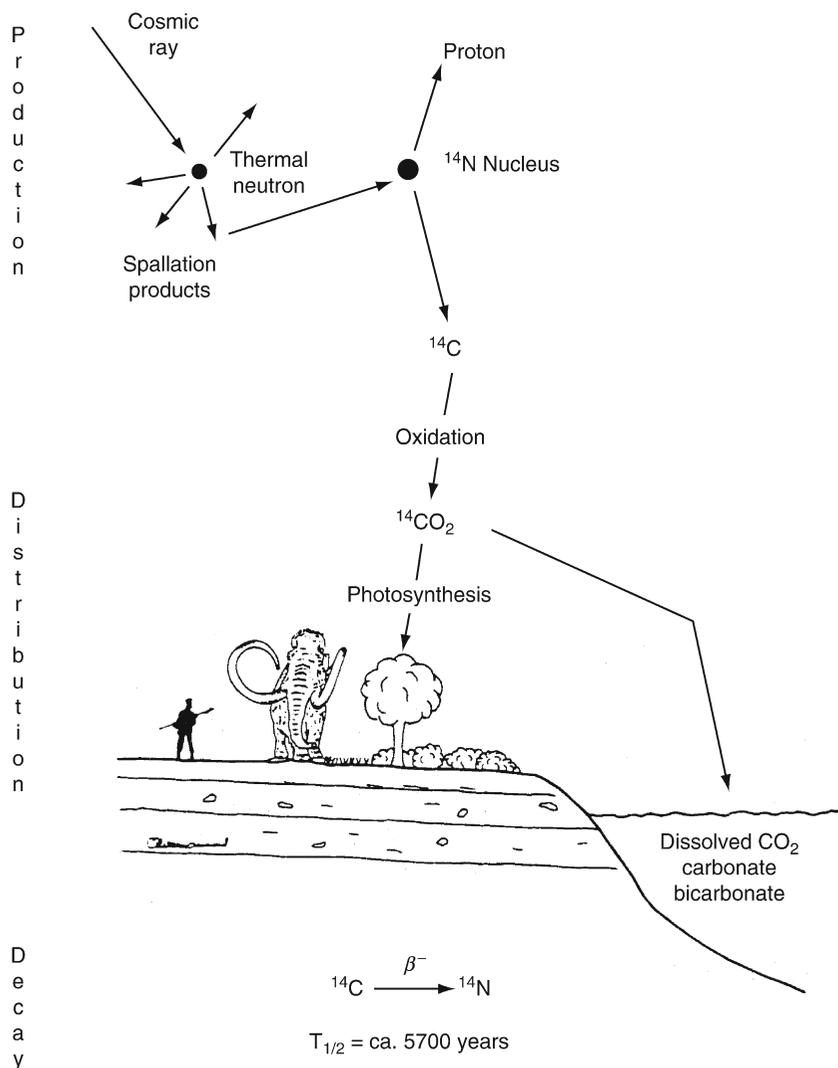

Figure R1 Radiocarbon dating model: production, distribution, and decay of ^{14}C . Figure adapted from Taylor (1997a: Fig. 3.1).

This “ \pm ” term is suffixed to all appropriately documented ^{14}C age estimates and is typically expressed as \pm one standard deviation ($\pm 1 \sigma$).

For samples from some carbon reservoirs, conventional contemporary standards may not define a zero ^{14}C age. A reservoir corrected radiocarbon age can sometimes be calculated by documenting the apparent age exhibited in control samples and correcting for the observed deviation. Reservoir effects are most often observed in samples from fresh water lakes and marine environments. A calibrated radiocarbon age takes into consideration the fact that ^{14}C activity in living organisms, which in most cases directly reflects atmospheric ^{14}C levels, has not remained constant over the ^{14}C time scale because of changes in ^{14}C production rates or reservoir mixing parameters of the carbon cycle. The study of the various factors responsible for the variability in ^{14}C production rates and changes in the world-wide distribution of ^{14}C in various carbon reservoirs over the late Pleistocene and Holocene has occupied the attention of many in the ^{14}C research community for over four

decades (Taylor, 2001). The various issues raised by the nature of the variability over time in the ^{14}C time scale – with the documentation of this variability now extended into the late Pleistocene – will be discussed in greater detail in the next section.

In the current nomenclature of the journal *Radiocarbon* “ ^{14}C years BP” is expressed only as “BP” with the “ ^{14}C years” implied (e.g., $2,510 \pm 50 \text{ BP}$). Calibrated ages, i.e., calendar or solar years, are expressed with only the “cal” (calibrated) designation attached (e.g., cal AD 1520, 3,720 cal BC), with the “years” implied. The journal *American Antiquity* adopted the nomenclature of *Radiocarbon* except for punctuation (B.P. rather than BP). In the early 1970s, the journal *Antiquity* adopted a terminology which distinguished conventional (uncalibrated) and calibrated ^{14}C values whereby “bp” and “ad/bc” are employed to designate conventional ^{14}C values while “BP” and “AD/BC” are used to designate calibrated ^{14}C values.

The ^{14}C time scale now extends from about 300 years to between 40,000 and 60,000 years. The limitations of using

the ^{14}C time scale over the last few hundred years are a consequence of the complex interplay of various recent natural deviations in ^{14}C content (informally referred to variously as “warps” or “wiggles” or more formally as “de Vries effects,” see below) and recent anthropogenic (e.g., “fossil fuel” and “bomb” ^{14}C) effects that have also caused recent deviations in ^{14}C content. The maximum ^{14}C ages that can be inferred using decay counting technology depend on characteristics of different laboratory instrumentation and experimental configurations – e.g., background and sample blank values, counter size, length of counting – and, to some degree, the amount of sample available for analysis. Currently, for laboratories with counters designed to work with older samples, routine upper limits using moderate sample sizes (3–5 grams of carbon) range upward to about 55,000 years. Employing relatively large sample sizes (>15 grams of carbon), a few laboratories have developed the capability to obtain age estimates up to about 70,000 years. With isotopic enrichment – again using relatively large sample amounts – ages up to 75,000 years have been reported on a small number of samples (Grootes et al., 1975; Erlenkeuser, 1979). There are efforts now underway to exploit accelerator mass spectrometry (AMS) technology (see below) to extend the ^{14}C time scale to as much as 70,000–90,000 years using sample weights of less than a gram of carbon.

Development of radiocarbon dating studies

Stages in the history of the development of ^{14}C dating can be distinguished partly by the type of detection technology employed and, partly, on understandings concerning the relationship between radiocarbon and “real” or solar/calendar time. The first generation of ^{14}C studies began with the appearance of the first ^{14}C date list in 1950. In the early 1970s, second generation studies began with the recognition of the existence of systematic temporal offsets in the ^{14}C time scale (Suess, 1970). In the late 1970s, third generation ^{14}C studies were ushered in by a proposal (Muller, 1977) to develop a new approach to ^{14}C measurement by AMS, although routine operation of AMS technology was not achieved until the mid-1980s (Linick et al., 1989).

Several recent technical and methodological advances have provided contexts for a series of significant applications of the ^{14}C method in a number of different disciplines. In addition to the application of AMS technology, these include the extension of the calibrated ^{14}C time scale into the late Pleistocene and a more detailed characterization of Holocene de Vries effects where relatively rapid changes in atmospheric ^{14}C concentrations complicate the inherent precision with which ^{14}C content can be converted into inferred age. The extension of the calibration of the ^{14}C time scale beyond that provided with tree ring data has been accomplished primarily by the use of AMS-based ^{14}C and TIMS (thermal ionization mass spectrometry)-based uranium-thorium (U-series) measurements on marine coral samples.

Extending the calibration of the ^{14}C time scale

Comparisons of ^{14}C with dendrochronological data based on Irish oak and German oak and pine for the earliest portion and Douglas fir, sequoia and bristlecone pine for later periods now document about 12,000 years of solar time (cal BP) (Stuiver et al., 1998a; Reimer et al., 2002). Most of the ^{14}C measurements comprising these data sets are characterized as “high-precision,” referring to carefully measured counting

uncertainties typically at the $\pm 1\sigma$ level of <20 years for the ^{14}C values used to provide the dendrochronologically-based calibration data. The validity of the stated uncertainties has been extensively examined by detailed interlaboratory comparisons among a number of the laboratories producing the calibration data (e.g., Scott et al., 1990). For the period before dendrochronological controls were available, paired uranium/thorium ($^{234}\text{U}/^{230}\text{Th}$) and ^{14}C samples from cores drilled into coral formations (Bard, 1998; Edwards et al., 1993) provide the principal data on which a late Pleistocene ^{14}C calibration curve has been provisionally extended to 24,000 cal BP or, as expressed in ^{14}C time, to 20,300 BP (Bard et al., 1998).

With the extension of the ^{14}C calibration framework using the uranium-series data on corals, it has now become apparent that what was first thought to be a “sine-wave”-like characterization of the Holocene ^{14}C calibration curve was an artifact of the limited time frame documented by the original middle and late Holocene tree-ring/ ^{14}C data set. Figure R2 represents a plot of the off-set between ^{14}C and assumed “true” ages out to about 30,000 years based primarily on the most current combined dendrochronological/ ^{14}C and coral uranium-series/ ^{14}C data, as presented in the INTCAL98 data set (Stuiver et al., 1998b). Based on the expanded calibration data, it now appears that the long-term secular variation ^{14}C anomaly over this period can be characterized as representing a slow-decay function on which has been superimposed middle- and short-term de Vries effects perturbations.

For the period before about 30,000 cal BP, age estimates obtained from ^{14}C and other Quaternary dating methods applied to samples obtained from a variety of contexts are, to varying degrees, inconsistent with regard to indications of the magnitude of the ^{14}C age offsets. For example, comparisons between ^{14}C values (adjusted by 3% to take into consideration the most likely ^{14}C half-life) and thermoluminescence age estimates on materials from hearths at Lake Mungo, Australia suggest deviations in the range of 3,500–5,000 years between 27,000 and 31,000 BP (Bell, 1991). Studies of variations in the intensity of the Earth’s dipole magnetic field – a major cause of the long-term ^{14}C secular variation trend – as well as comparisons of precisely determined ^{14}C and associated $^{40}\text{Ar}/^{39}\text{Ar}$ values from volcanic deposits, suggest somewhat lower age offsets for this period. However, the geomagnetic data suggest an increasing ^{14}C /solar time offset in the range of 1,500–2,700 years between 25,000 and 40,000 years but predict that there will be good agreement between ^{14}C and solar time at about 45,000–50,000 years (Mazaud et al., 1992; Southon et al., 1995). In addition, there also may have been a major “spike” in atmospheric ^{14}C concentrations between 30,000 and 35,000 BP (Voelker et al., 1998: Fig. 6). Further detailed studies will be necessary to clarify the magnitude of the offsets in ^{14}C activity for this period (Geyh and Schlüchter, 1998; Reimer et al., 2002).

Holocene de Vries effects

A fuller rendering of the entire Holocene ^{14}C time scale permits researchers to review more precisely the timing and characteristics of the de Vries effect “wiggles” over the last ten millennia. Figure R3 plots the series of defined Holocene “time warps” reflecting the time ranges of the de Vries effect perturbations in the calibration curve (Taylor et al., 1996: Figs. 3A and 3B). The top panel of Figure R3 represents 0–5,000 BP and the bottom panel the 5,000–10,000 BP period in ^{14}C years.

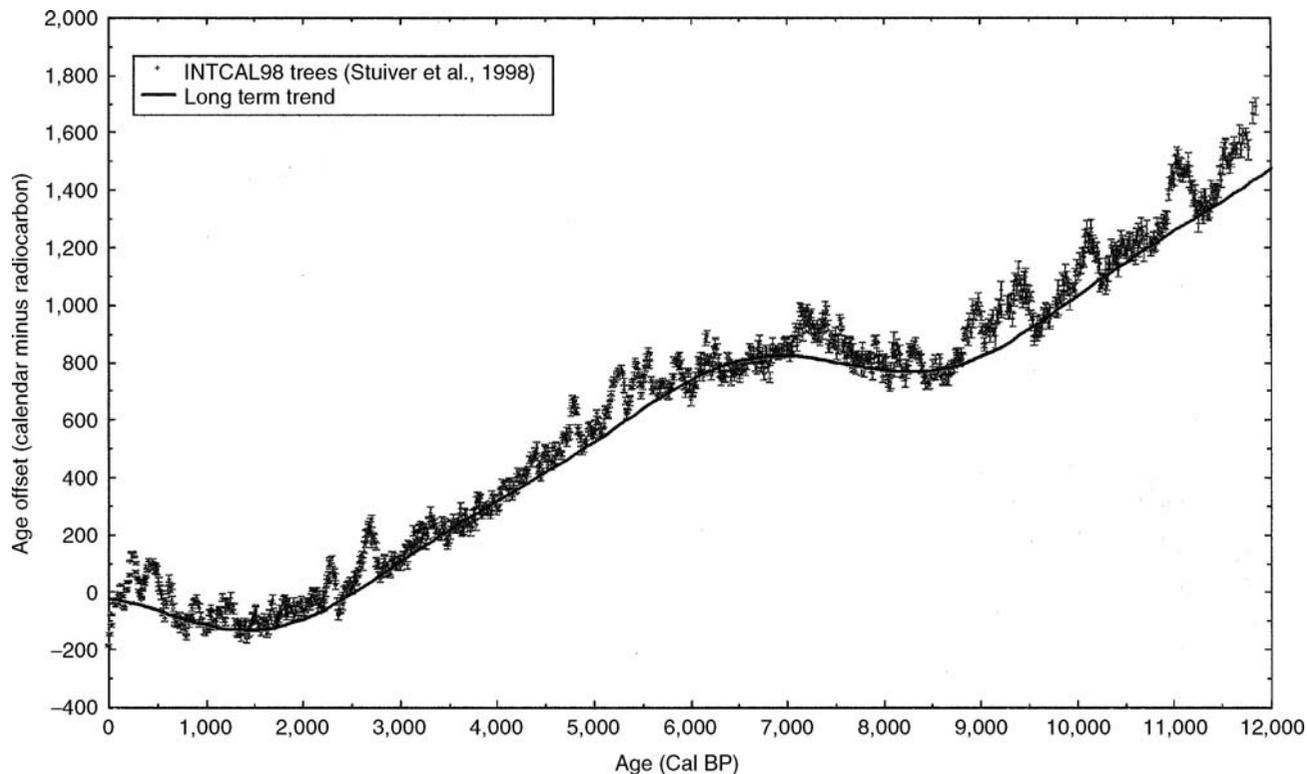

Figure R2 Late Pleistocene and Holocene deviation of ^{14}C from dendrochronological-, uranium-series-, and varve counted marine sediment-based age data (Data from Stuiver et al., 1998a; figure adapted from Taylor 2001: Fig. 2.2).

The inherent uncertainties and fluctuations in the calibration curve cause discrete calibrated ages to broaden into ranges, even when, as in this figure, the ^{14}C ages are plotted with a hypothetical zero variance. Thus, ^{14}C age determinations deriving from time periods with larger calibration range values will be inherently less precise. For example, on average, calibrated age values for 8,000–10,000 BP are inherently much less precise than those in the 0–2500 BP period because of the large ^{14}C de Vries effect “time warps” occurring during in those periods.

In Figure R3, 12 major and 5 intermediate de Vries effect perturbations can be identified. Major de Vries effects have been defined as “time warps” exceeding 250 cal years; intermediate de Vries effects are those that exhibit ranges in excess of 140 cal years, and minor de Vries effects have ranges of less than 140 cal year. The 17 major and intermediate de Vries perturbations have been assigned Roman numeral and letter combinations. Roman numerals identify the ^{14}C millennium, i.e., I = 0–1,000 BP, II = 1,000–2,000 BP, while lower case letters identify the perturbation in chronological order within each ^{14}C millennial period. It should be noted that the INTCAL98 calibration data set shifts the time scale for early Holocene ^{14}C time warps slightly but does not affect their magnitude.

Various strategies to increase the precision of ^{14}C -based age inferences in light of the variable effects of de Vries-type secular variations include the use of Bayesian statistical approaches to calibration procedures (Buck and Christen, 1998) and “wigggle-matching,” in which the known pattern of the de Vries perturbations are matched on an unknown sample of wood

containing a sequence of tree rings by measuring ^{14}C activity in a set of adjacent tree rings in that sample and matching that pattern with the known de Vries pattern. An example of the latter approach includes the determination of a cutting date for a timber from a Japanese tomb to AD 320 with a precision of ± 5 years (Kojo et al., 1994). When precision at the level of $< \pm 30$ years can be statistically justified, concerns about latitude-dependent differences in ^{14}C atmospheric concentrations become relevant. Suggestions of the magnitude of the offset between Northern and Southern Hemispheric samples currently range between 24 ± 3 (Stuiver et al., 1998b) to 40 ± 13 ^{14}C years (Hogg et al., 2002).

Accelerator mass spectrometry

From the initiation of ^{14}C studies until the late 1970s, the basis of inferring ^{14}C concentrations, and thus the ^{14}C age of samples, exclusively employed decay counting technology. In decay counting, isotopic concentrations are measured by counting decay events in an ionization or scintillation detector and comparing the count rate observed in an unknown-age sample to that exhibited by appropriate standards under a common set of experimental conditions. For ^{14}C , this involves counting beta particles, i.e., negatively charged electrons emitted from the ^{14}C nucleus. In decay counting, a relatively small fraction of the ^{14}C atoms present in a carbon sample are actually detected over the course of measurement. While there are approximately 5.9×10^{10} atoms of ^{14}C in 1 gram of modern “pre-bomb” carbon, on average, over a one-minute period, less than 14 of these atoms will decay and be available for

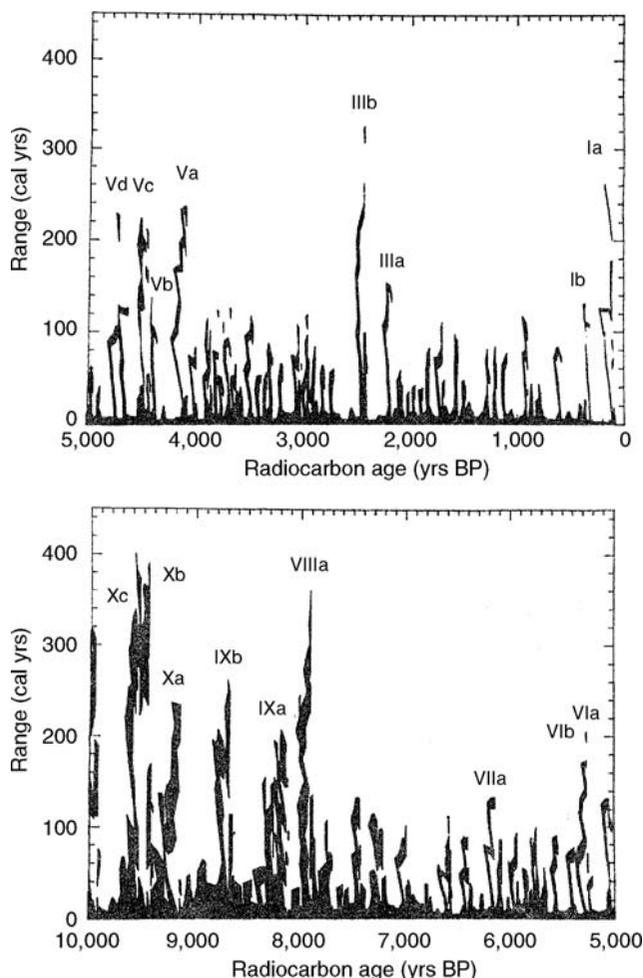

Figure R3 Holocene de Vries effects: Ranges (“time warps”) in calibrated years (cal yr) obtained from the calibration of conventional ^{14}C ages. Figure taken from Taylor et al. (1996) based on data from Stuiver and Reiner (1993: Figs. 3A–3D). Upper panel represents 0–5,000 BP and the lower panel represents 5,000–10,000 BP. Ranges produced for ideal hypothetical samples with zero ^{14}C sample standard deviation that had been formed during a 20-year or shorter interval and with the youngest calibrated age obtained for each ^{14}C age set at zero.

detection. In large part, it was this inherent inefficiency in decay counting that gave impetus to efforts to develop direct or ion counting technology using a form of mass spectrometry.

Within a year of the initial publication of the concept underlying AMS technology, the first published AMS-based ^{14}C determination was obtained using the 88-inch (224-cm) cyclotron at the University of California Lawrence Berkeley Laboratory (Muller, 1977). Because of technical problems with using cyclotron-based AMS systems for natural level measurements, most routine AMS measurements are currently undertaken on another type of particle accelerator, an electrostatic tandem accelerator. Although initially HEMS (high energy mass spectrometry) was used to refer to this technology, typically, TAMS (tandem accelerator mass spectrometry) is now used. “Tandem” here refers to the fact that particle acceleration in

electrostatic systems is accomplished in a two-step “pull-push” process. The TAMS approach proved to be a practical AMS technology for a wide range of rare, cosmogenic isotopes including ^{14}C and, to date, most AMS ^{14}C age determinations have been obtained on a TAMS instrument. By way of a historical footnote, the question of who first conceived the idea that led directly to the development of AMS technology is the subject of continuing discussion (Gove, 1996; 1999; Taylor, 1997b).

Three advantages of AMS technology in the measurement of ^{14}C were anticipated as a result of the greatly enhanced detection efficiency. First, major reductions in sample sizes would be possible – from gram amounts of carbon to milligram amounts and, with additional efforts, to the level of less than 100 micrograms. Second, major reductions in counting times would be possible. Reductions from several days for conventional systems and even weeks and months with micro- and mini-decay counting system could be achieved with several minutes of counting for AMS systems to achieve $\pm 1\%$ counting statistics. Finally, it was anticipated that significant increases in the applicable dating time frame would be possible – from the currently routine 40,000–50,000 years to as many as 100,000 years (Muller, 1977; Gove, 1992).

The first two of the three originally-anticipated benefits of AMS technology – major reductions in sample size and counting times – have been fully realized over the last decade (Taylor et al., 1984; Taylor, 1991; Hedges, 1995). For both sample sizes and counting times, order-of-magnitude reductions have been made possible on a routine basis. However, the projected third advance has not occurred due to the inability, at present, to exclude microcontamination of samples during sample preparation. The source of a significant portion of this contamination results from the current requirement in most laboratories that samples must be converted to graphitic carbon for use in the ion source of an AMS system. Parts per million of modern carbon contamination translates into background levels which generally limit the maximum ages that can be resolved to between 40,000 and 50,000 years. One laboratory has developed a CO_2 gas source but reports similar background values (Bronk and Hedges, 1987). To date, the oldest age reported on a graphitized background blank (Pliocene wood) is 60,500 BP (Kirner et al., 1997).

The development of AMS technology has provided the technical means by which very low organic carbon content sample types, such as organic extracts from bone and ceramics, along with microsample materials such as single seeds and small amounts of hair, can now be routinely dated by ^{14}C . It should be emphasized that AMS-based ^{14}C age determinations are not necessarily more or less accurate or precise than decay counting. Currently, the principal advantage of AMS technology for ^{14}C applications is the ability to obtain meaningful dates with samples containing microgram amounts of carbon (e.g., Kirner et al., 1995).

Applications

Over the last decade, the expanding use of AMS-based ^{14}C analysis has continued to create new and expanded areas of research where ^{14}C data have yielded important new understandings that would not have been possible or practical with decay counting. There have been several issues and topics that have been significantly impacted by the new capability to obtain ^{14}C measurements on milligram amounts of sample.

Hedges (1995) has noted that the advantages of microsample ^{14}C analysis include the ability to increase the reliability of ^{14}C -inferred age estimates as well as the generation of new chronological information. With regard to the former, the capability of remeasuring problematical dating results, the feasibility of undertaking highly selective chemical pretreatment strategies, and the ability to compare different chemical fractions of the same sample and select the most relevant sample material have been made routinely feasible as the result of the development of AMS-based ^{14}C analyses.

Some AMS-based ^{14}C values have been obtained in situations where larger amounts of sample were available. However, those having responsibility for the unique historical object would consent to the removal of only a small portion of the larger sample. Such was the case with the AMS ^{14}C dating of the Shroud of Turin, now perhaps the most widely known sample dated by the ^{14}C dating method. This 4.3 by 1 m rectangular-shaped linen cloth housed in the Cathedral of St. John the Baptist in Turin, Italy has been alleged to have been the burial sheet of Jesus of Nazareth since 1353 when its existence was first documented. The calibrated ^{14}C age of this sample measured by three AMS laboratories indicates that the flax from which the linen was fabricated was most probably growing sometime during the later part of the thirteenth or the fourteenth century AD, exactly the period during which the shroud was first historically documented (Damon et al., 1989). Arguments that ^{14}C activity in portions of the shroud could have been altered by exchange of atmospheric CO_2 with the linen as the result of high temperature effects ("scorching") or other purported chemical reactions have been refuted by experiments specifically designed to test the validity of the hypothetical mechanisms (Jull et al., 1996; Long, 1998).

A good illustration of the effect of being able to target the most relevant sample is illustrated by a study of maize specimens excavated from two rock shelters in the Tehuacan Valley, Mexico. Samples of *Zea mays* from these sites had been regarded as the earliest example of domesticated maize – the most important New World domesticated plant. In the early 1970s, their age had been estimated on the basis of conventional (decay counting) ^{14}C determinations obtained on charcoal assumed to be stratigraphically associated with the maize samples in the Tehuacan Valley sites. In contrast to the 5,350–7,000 BP values on the associated charcoal, the range in ^{14}C values directly obtained on milligram amounts of maize samples using AMS-based ^{14}C analysis was 1,560–4,700 BP for the samples from San Marcos Cave and 450–4,090 BP for the specimens from Coxcatlan Cave (Long et al., 1989). The significantly later occurrence of maize at Tehuacan raised questions concerning assumptions about where the center(s) of maize domestication in the New World may have been and thus the timing of the spread of domestication of this plant in the Western Hemisphere.

Conclusion

The impact of ^{14}C dating on the conduct of research in a number of disciplines has been, in some aspects, clear and explicit and, in others, subtle. In addition to providing a common chronometric time scale for the entire late Quaternary, an important contribution of the ^{14}C method is that the technique provides a means of providing a chronometric time scale using means independent of any assumptions about environmental physical parameters other than radioactive decay, carbon reservoir source, and geochemical conditions.

Radiocarbon data continues to provide the foundation on which most of the most secure chronometric time scales in most areas of the world for the last 40,000–50,000 years are constructed, directly or indirectly, particularly in contexts and areas lacking historical or textual documentation. While currently not often stressed, the influence of ^{14}C data on the pursuit of paleoenvironmental and archaeological studies continues to be profound and pervasive.

RADIOLARIA

Radiolarians are marine protozoa with a geological record ranging from Precambrian to Present. Radiolarians are exclusively marine and are found in all the oceans, in all temperature zones and at all depths. They are also neritic in their distribution, being found in Norwegian fjords, in the plankton (9,000 specimens m^{-3}), more abundantly in the tropics (18,000 specimens m^{-3}), and rarely in the polar oceans. The highest numbers of Radiolaria are found in the upper 50–200 m of the water column. Those radiolarians possessing a skeleton may contribute significantly to the deep sea eupelagic sediments, the so-called radiolarian ooze, which are found deposited in the central parts of the Pacific and Indian Oceans.

Evolution of this group has resulted in a high diversity of both extinct and extant species. Their opal skeleton is characteristic and in many cases is radial, from which the name Radiolaria is derived. Some, however, possess a bilateral skeleton, whilst others have no skeleton at all. The inner part of the protoplasm (endoplasm) houses the nucleus (reproduction), organelles such as mitochondria (respiration) and Golgi bodies (secretion), as well as lipid droplets and vacuoles, all enveloped by an organic central capsule. The outer part of the protoplasm (ectoplasm), the calymma, communicates through openings, or pores, in the central capsular wall (Figure R4). The calymma is a frothy or bubble-like body, which is interpreted as a floating device, besides housing algal symbionts (zooxanthellae), vacuoles, and mitochondria. The outer margin of the protoplasm is characterized by a network of anastomosing

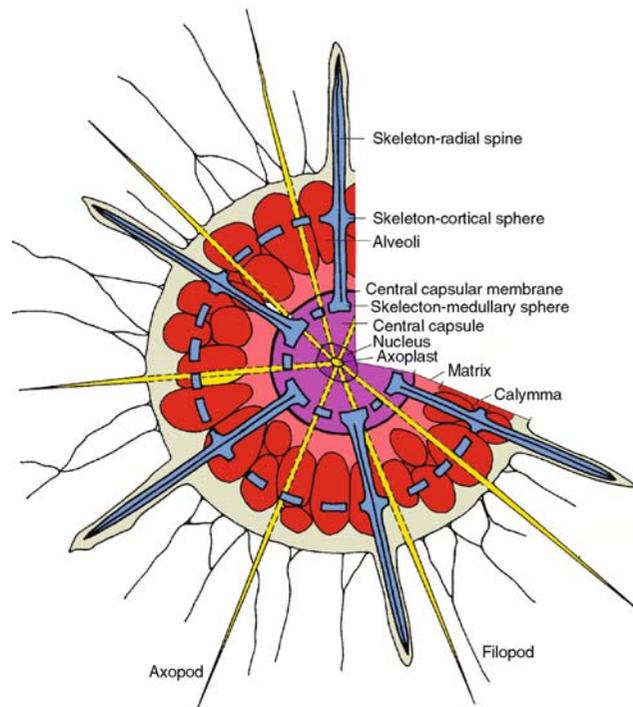

Figure R4 Principal structure of a polycystine radiolarian, showing soft and hard body features (Modified after Kling, 1978).

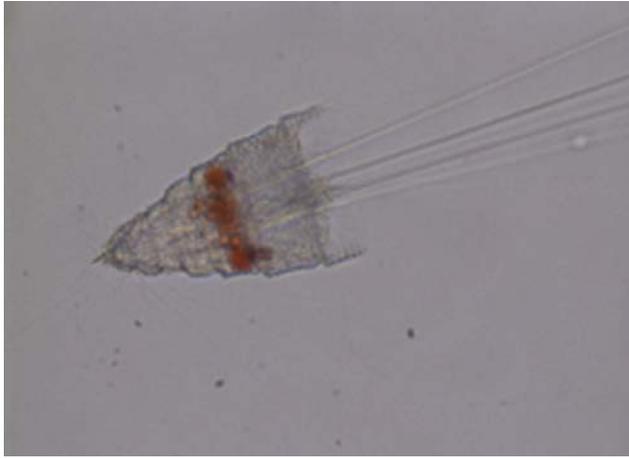

Figure R5 *Spirocyrtis scalaris* Haeckel, a living nassellarian radiolaria taken from the surface water near Okinawa Island, Japan. Photograph provided by Dr. Atsushi Matsuoka.

pseudopodia as well as different irregular rhizopodia, long and stiff radial axopodia (Figure R4), which are clearly seen as a bundle of long, straight spines in the living specimen of *Spirocyrtis scalaris* (Figure R5), and delicate filipodia (Figure R4). The skeletal spines are enveloped by the protoplasm, and therefore protected from being dissolved by seawater. Prey is captured by the pseudopodia and digested in the ectoplasm.

Radiolarian taxonomy was essentially established by Ernst Haeckel when he published an extensive monograph in 1887, based on material collected on the Challenger Expedition (1873–1876) that circumnavigated the world's oceans. This is not a natural taxonomic system, but a useful system to group similar morphotypes. Radiolarian taxonomic studies were initiated in Germany, but subsequent schools developed in France, Russia, and the U.S.A., where taxonomy was based predominantly on intricate skeletal morphologies, as shown in *Callimitra carolotae* (Figure R6), with the exception of the French group who in addition based their taxonomy on microscopic cellular structures. There is no consensus on the higher rank taxonomy within the radiolarians, but the following is often used:

Kingdom PROTISTA Haeckel, 1866
 Phylum SARCODINA Hertwig, 1876
 Class ACTINOPODA Calkins, 1910
 Subclass RADIOLAIRA Müller, 1858
 Superorder PHAEODARIA Haeckel, 1879
 Superorder POLYCYSTINA Ehrenberg, 1838, emend. Riedel, 1967
 Order SPUMELLARIA Ehrenberg, 1875
 Order NASSELLARIA Ehreneberg, 1875

Recent work on radiolarian DNA suggests another relationship of the main Radiolaria groups, in addition to that proposed by Haeckel (1887), above. Yuasa et al. (2003) showed that the Phaeodaria made a separate clade, while the Acantharia, Spumellaria and Nassellaria made another clade. The latter made two subclades where solitary Spumellaria grouped with the Acantharia and the colonial Spumellaria grouped with the

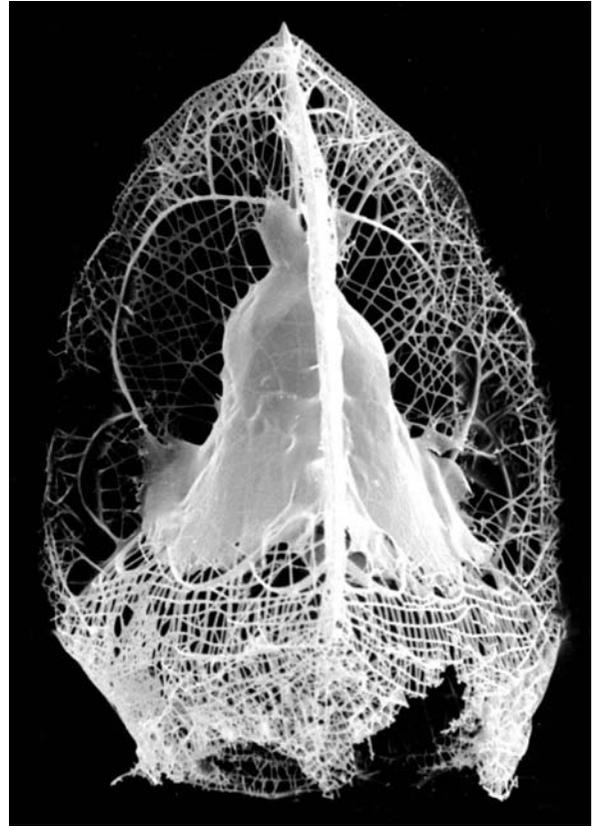

Figure R6 *Callimitra carolotae* Haeckel. Recent, from surface sediments in the Orca Basin, Gulf of Mexico. Photograph by K. R. Bjørklund and R. M. Goll.

Nassellaria. This is supported by other DNA studies (Polet et al., 2004).

The diversity and relatively rapid rate of evolution of Radiolaria through time makes this group very important in Tertiary and Quaternary biostratigraphy, especially in deep-sea sediments where carbonate fossils are dissolved. Levine (1963) calculated the total number of living and fossil radiolarians to be 4,791 and 2,389, respectively. Goll and Merinfeld (1979) concluded that these numbers are inflated by unwarranted taxonomic splitting and suggested numbers that are more conservative: about 200 Acantharia, more than 600 Phaeodarians, and about 1,500 extant and extinct polycystine radiolarians, the latter number is very uncertain.

Polycystine radiolarians are important in deep sea stratigraphy. The Cenozoic is divided into 32 biozones (Recent through Eocene, Paleocene is still unzoned). Radiolarians are also important for paleotemperature proxy data, and estimates for the last ca 13,400 ^{14}C years BP have been successfully applied in the Norwegian Sea (Dolven et al., 2002). Here, the calculations show an average temperature of $12 \pm 1^\circ\text{C}$ during the Holocene (the last 10,000 ^{14}C years). During the Younger Dryas (10,000–11,000 ^{14}C years BP), the temperature decreased to about 7°C in only a few centuries. In the Holocene, the “8,200-year event,” as observed in the GISP2 ice core, is also

observed in the radiolarian paleotemperature estimates, with a temperature drop of ca. 3 °C. The associated radiolarian assemblages changed during this time interval with a relative abundance minimum of the warm water species *Lithomelissa setosa* and *Pseudodictyophimus gracilipes*, while *Stylodictya validispina* displayed an absolute maximum (26%). This evidence proves that radiolarians are a sensitive and powerful paleoclimatic tool.

RED BEDS

Red beds are red-colored clastic sedimentary deposits (Figure R7). The term is widespread in the literature and has been used to describe both marine and non-marine rocks, so it is non-genetic. The presence of oxidized (ferric) iron (usually as fine-grained hematite) disseminated throughout the matrix of the deposits is the unifying feature of red beds. Reddening typically forms as a result of the post-depositional dehydration of oxyhydroxides such as goethite to hematite and indicates +D (positive) Eh conditions. Rocks previously called red beds include paleosols (including laterites), banded iron formations, sandstones, siltstones, conglomerates, and deep sea shales. Marine red beds are rare and form only in areas with little organic matter and slow sedimentation rates that allow all of the organic matter to be broken down prior to burial. Only red bed sequences containing or composed of paleosols or evaporites are useful for paleoclimatic reconstructions.

Paleosols in red bed sequences

Red beds have been interpreted as desert deposits by analogy with modern deserts, which are often red (Walker, 1967), but subsequently it was recognized that the modern red deserts are associated with ancient red beds (e.g., the Simpson Desert of Australia where Folk (1976) showed that the red color of the modern dunes was due to prior laterite formation). More recent work has emphasized a role for strongly seasonal climates (Dubiel and Smoot, 1994), such as monsoons with short wet seasons between long dry seasons during which the soils could dry out substantially, promoting formation of iron oxyhydroxides and a high degree of aeration. However, it should be noted that any well-drained soil has the same aerated conditions, and well-drained soils can form in a variety of climatic settings other than in monsoonal belts (Sheldon, 2005). Diagnostic features of monsoonal settings include concentrically layered carbonate or iron oxide concretions (Retallack, 1991; Table R1), dispersed calcium carbonate throughout the deposits (Retallack, 1991; Table R1), and soil types including Vertisols

Figure R7 Eocene red beds from the Wasatch Formation of Wyoming, US.

Table R1 Some features of red bed sequences useful for paleoenvironmental reconstructions

Feature type	Diagnosis
<i>Soil characteristics:</i>	
1. Gilgai (small-scale anticlinal relief)	1. Pronounced wet-dry seasonality
2. Slickensides, ped morphology, relict bedding	2. Relative weathering intensity
3. Horizon thickness and color	3. Duration of weathering
4. Mottling associated with organic matter (roots)	4. Micro-reducing conditions within the soil
<i>Diagnostic soil types:</i>	
5. Caliche/calcrete soils	5. Sub-humid to arid climatic conditions
6. Duripan/silcrete soils	6. Semi-arid to arid climatic conditions
7. Vertisols	7. Pronounced wet-dry seasonality
8. Laterites	8. Tropical conditions
<i>Soil nodules:</i>	
9. Size	9. Large imply longer formation times
10. Distribution	10. Disbursed implies strong seasonality
11. Concentric growth and alternating carbonate and oxide layers indicate	11. Strong seasonality and/or monsoonal climatic conditions
<i>Evaporites</i>	
12. Gypsum and halite	12. Arid conditions
<i>Eolian deposits</i>	
13. Proportion of silt in thin section point counts conditions	13. Semi-arid to arid climatic
<i>Frost wedges</i>	
14. Clastic dikes	14. Cold (taiga or tundra) climatic conditions
<i>Water table characteristics:</i>	
15. Rooting depth	15. Deeply penetrating implies well-drained
16. Burrowing depth	16. Deeply penetrating implies well-drained
17. Density and tiering of ichnofabrics	17. High density implies low flood frequency
<i>Invertebrate fossils with modern analogs</i>	Depends on the modern analog
<i>Vertebrate fossils with modern analogs</i>	Depends on the modern analog

Information after Birkeland (1999), Dubiel and Smoot (1994), and Retallack (2001).

with their characteristic deep cracking due to seasonal shrinking and swelling of clays, or Mollisols with crumb peds. All of these features are also preserved in paleosols. Model results indicate monsoon-like climatic circulation patterns for the Pangean supercontinent (Kutzbach and Gallimore, 1989), but so far insufficient field work has been performed to confirm monsoonal features in either the sediments or paleosols preserved in the Pangean red bed sequences.

Paleosols are fossil soils, typically buried by subsequent deposition. Many sequences of terrestrial fluvial red beds preserve paleosols that developed on flood deposits, but other preservational settings include sequences of lava flows, and lagoonal, lake, and ocean margins. Each paleosol represents a significant hiatus in deposition ranging in duration from perhaps one hundred years up to millions of years in the case of ultisols, oxisols, and laterites. Because paleosols form in direct contact with the atmosphere, they record both paleoenvironmental and paleoclimatic conditions. Identification of paleosols within a sequence of red beds is made on the basis of a number of morphological features (Table R1). Some of the features of individual paleosols also give information about the depth of the paleo-water table beneath the surface of the paleosol, and by extension, information about how well-drained the paleosol was. In addition to gaining this paleohydrological information about the depositional setting of the red bed sequence, a number of other features of paleosols are quantitatively useful as paleoclimatic indicators. Mean annual precipitation may be estimated from the degree of chemical weathering (Sheldon et al., 2002) or from the depth to a Bk (carbonate-bearing) horizon in a paleosol (Retallack, 1994), and atmospheric pCO₂ can be estimated by measuring the isotopic composition of carbonate nodules (Cerling et al., 1989) or pedogenic goethites (Yapp and Poths, 1992).

Geologic record of red beds

Because the red color in red bed forms is due to oxidized iron, the geologic record of red beds reflects the Precambrian rise of atmospheric oxygen levels. The oldest universally agreed upon red beds are red sandstones, siltstones, and mudstones of South Africa, immediately overlying the so-called Hekpoort Paleosol, which has been dated to about 2.2 Ga before present. Red beds have been common in the geologic record ever since, with their greatest extent in the Phanerozoic, especially during the Paleozoic-Mesozoic transition during which red beds are one of the characteristic depositional facies of the Pangean supercontinent.

ROCHES MOUTONNÉES

Roches moutonnées are classic landforms of glacial erosion (Bennett and Glasser, 1996). They are giant stoss and lee forms carved from bedrock, with smoothly abraded up-ice or stoss faces and roughly quarried/plucked down-ice lee faces. They can occur as isolated forms, can be superimposed on larger asymmetric landforms, or occur as part of erosional landscapes subject to regional scour. Individual forms vary in size from less than 1 m to several hundred meters or even kilometers in diameter (Rastas and Seppälä, 1981). In Sweden, for example, large asymmetric hills (Flyggbergs) exceed 1 kilometer in length; however, most roches moutonnées are much smaller.

Roches moutonnées are the product of both glacial abrasion and glacial quarrying and it is this combination of processes that results in the asymmetric profile. Glacial abrasion occurs on the up-ice or stoss face of the landform, while glacial

quarrying occurs on the lee. Glacial quarrying involves two processes, firstly the exploitation and propagation of rock fractures such as joints and discontinuities, and secondly, the entrainment and removal of bedrock blocks by ice. The characteristics of the rock mass, therefore, are critical to quarrying: the more fractured the rock mass, the more easily it can be plucked by ice. In turn, this means that the morphology of roches moutonnées is closely linked to the depth, orientation and spacing of joints or discontinuities within the rock mass (Gordon, 1981; Rastas and Seppälä, 1981). The exploitation and propagation of joints is assisted by fluctuations in subglacial water pressure (Röthlisberger and Iken, 1981; Iverson, 1991). In addition, the formation of a lee-side cavity between the ice sole and the bed increases the stress gradients imposed on the bedrock hummock by the overriding ice, which again favors fracture propagation. Block entrainment may occur by a variety of processes, not least of which is the regular closure of the lee-cavity, causing the debris within it to be swept clear. Therefore, roches moutonnées are indicative of subglacial conditions in which there is high effective normal pressure on the stoss side of a bedrock bump, but where this pressure is sufficiently low on the down-ice side to allow a cavity to form. Consequently, the up-ice side experiences glacial abrasion, while the down-ice side experiences glacial quarrying. Roches moutonnées tend, therefore, to form in areas of thin, fast-flowing ice and in situations with abundant meltwater. They may also be used as crude indicators of the direction of ice flow.

S

SAPROPELS

The term sapropel is used in a generic sense to describe fine-grained and unconsolidated sediments rich in organic matter that have been deposited under water; in coal petrology, sapropelic coals are those that formed from algal material deposited in aquatic environments. The term sapropel is also often used as a generic term for distinct dark-colored, organic carbon-enriched sediment layers that are found in organic-carbon-poor host sediments. In the Holocene sediment record of several silled basins (e.g., the Baltic Sea, the Black Sea, the Marmara Sea) an organic carbon-enriched sediment layer – often termed sapropel – marks the change in depositional environment and in biological production coincident with the post-glacial transgression.

In a stricter sense, the term stands for a sedimentary feature of the Mediterranean (and Red) Sea with specific connotations regarding the origin: sediment cores and land exposures from the Mediterranean Sea contain rhythmic series of sapropel layers (cm to m thick) sandwiched in carbonate-rich and organic carbon-poor hemipelagic sediments. These sapropels are rich in organic carbon (up to 30% by weight), devoid of benthic organisms and often laminated, and were deposited during periods when the deep waters of the marine basins were anoxic (Comas et al., 1996; Kidd et al., 1978; Emeis et al., 2000). The duration of the numerous anoxic events in the Mediterranean Sea was from a few hundred up to 7,000 years, and the most recent sapropel was deposited between 10,000 and 7,000 years ago. The observed temporal pattern of sapropel deposition is clearly paced by the orbital rhythms of precession, tilt and eccentricity and implies a causal link with orbitally-induced climate change that resulted in changes of the Mediterranean water balance (Cita et al., 1977; Rossignol-Strick, 1983). The link between insolation and sapropel deposition in the eastern Mediterranean Sea is very robust for the last 5.33 million years and the astronomically-tuned stratigraphy established here has set a standard for Pliocene and Quaternary chronostratigraphy world-wide (Hilgen, 1991).

The close link between climate and sapropel formation is firmly established, and a hydrological trigger for sapropel formation is widely agreed. Sapropel periods were preceded by and coincided with changes in surface and deep water circulation that restricted the oxygen supply to the seafloor in the deep basins of the Mediterranean Sea. At present, the deep basins of the Mediterranean Sea are flushed by cold, oxygen-rich waters that are generated during winters in the northern sub-basins – the Gulf of Lyons, the Aegean, and the Adriatic Seas. One prerequisite for anoxic conditions during periods of sapropel formation was a decrease in surface water density (relative to that of deepwater masses) that prevented sinking of oxygenated surface water into the deep basins. Both freshening (indicated by decreasing ratios of stable oxygen isotopes in the tests of planktonic foraminifers and changes in microfossil assemblages) and increasing sea surface temperature (based on evaluation of faunal assemblages and biomarkers) of surface water preceded and accompanied all sapropel events. Because oxygen demand for the mineralization of organic matter that sank from the surface ocean to the deepwater masses continued, the dissolved oxygen in the denser and aging deepwater eventually was depleted. The origin of fresh waters is less clear. The original hypothesis (Olausson, 1961) was that meltwater from the northern catchment (via the Black Sea) prevented deepwater formation. Alternatively, the northern catchment of the eastern Mediterranean Sea may have received increased precipitation during maximum insolation, leading to decreased salinity in the deepwater formation areas of the Mediterranean Sea (Rohling and Gieskes, 1989). However, since approximately 600,000 years ago, sapropels were deposited under fully interglacial, fully glacial, and intermediate climatic conditions.

Because conditions during glacials or cold stadials were as unfavorable for runoff from the northern catchment as for water-column stratification due to warming of the surface layer, sapropel formation even under glacial conditions is a strong argument for a source of freshwater in the monsoon system that influences mainly the southern catchment. According to this hypothesis, sapropel formation would be closely linked to tropical and even Southern Hemisphere climate. A systematic correlation has been observed between the

distribution of sapropels and maxima of the so-called orbital insolation monsoon index (Rossignol-Strick, 1983). Maxima in the monsoon index point to an intensified African summer monsoon, which may have led to enhanced continental humidity in tropical Africa and ultimately enhanced discharge rates of the Nile River. Alternatively, enhanced northward migration of the Intertropical Convergence Zone (the meteorological equator) into Northern Africa has been proposed for sapropel periods; this would have channeled equatorial rainfall into the Mediterranean Sea through what is now the Sahara Desert. A further possible source of freshwater is the Mediterranean Sea itself: virtually all sapropels coincide with significant warming of surface waters at the transition from cold to warm climatic periods. This warming would on the one hand enhance the stratification of water masses and would on the other hand result in increased evaporation and rainfall in the Mediterranean catchment, effectively pooling fresh and warm waters at the sea surface and impeding deepwater formation. It is very likely that all of these sources contributed in succession and in concert to prevent deep convection over several thousands of years.

The immediate reason for the enrichment of organic matter in sapropels is very much open to discussion. Oxygen conditions at the seafloor, biological productivity at the sea surface, and dilution by other sedimentary components are the primary factors controlling concentration and accumulation of organic carbon in marine sediments. Because the rates of sedimentation did not change significantly, the scientific discussion focused on the roles of bottom-water anoxia and biological productivity changes in the formation of organic carbon-rich sediments ("productivity versus preservation"). Much of the data gathered support the hypothesis of anoxic conditions paired with (or possibly accelerated and in part caused by) an increase in biological productivity during sapropel formation. In line with this, many indicators suggest enhanced productivity (assemblages of planktonic and – before and after the sapropel events – benthic foraminifers, the accumulation rates of barium). However, other authors see evidence that the eastern Mediterranean Sea remained nutrient-limited (oligotrophic) and that productivity patterns either shifted to a different type, or were as low as today. A severe obstacle for environmental reconstructions here as elsewhere is diagenesis that erases many indicators after deposition and re-oxygenation of deepwaters.

Detailed investigation of diatom assemblages in one unusually thick sapropel in which biogenic silica was preserved (in the carbonate oozes and in almost all other sapropels, this opal is lost to dissolution) showed that the original sapropel sequence was rich in diatoms that formed a pronounced sequence of laminations, including possible annual bloom layers. The flora consisted of fragile mats of diatoms indicative of stratified, oligotrophic conditions found in association with hydrographic frontal systems. Collecting near the interface between upper and lower water mass in the frontal system, the disintegration of slowly grown mats with large biomass may sporadically have resulted in large flux rates of opal and organic matter to the seafloor (Kemp et al., 1999). Other authors (Sachs and Repeta, 1999) proposed that the productivity level remained similar to the present ultra-oligotrophic nutrient desert during sapropel formation, because cyanobacterial nitrogen fixation then as today apparently was a significant source of the essential plant nutrient nitrate in the water column. In this scenario, anoxia alone was responsible for greatly improved preservation of the sparse rain of organic matter to the seafloor. More recently, the role of phosphate liberated from anoxic sediments as a fuel

for enhanced fixation of atmospheric nitrogen by cyanobacteria has been stressed (Struck et al., 2001; Slomp et al., 2002). In this view, the eastern Mediterranean Sea was fertilized by phosphate diffusing out of suboxic and anoxic sediments. This additional phosphate may have been transported to the surface ocean by ongoing shallow seasonal convection. It may thus have created conditions conducive for massive nitrogen fixation from the atmosphere that added nitrate, and initiated a positive feedback between anoxia at the seafloor and biological productivity in the euphotic zone. The anoxic and fertile sapropel periods ended with the waning of freshwater inputs and warming, and renewed flushing of the deep basins with oxygenated waters. In many cases, the sapropel preceding this flushing was erased by oxygen penetrating into the sediment, burning down the organic matter, and leaving so-called ghost sapropels.

Conclusion

Formation of the Mediterranean sapropels is the result of a combination of factors that include paleoclimate, paleoceanography, and the reactions of marine biogeochemical cycles to changed boundary conditions. Whereas the mechanism of sedimentation and carbon burial can be linked to changes within the depositional environment, these very changes are likely to be forced by processes outside the basin. External forcing is evident from the synchronicity of sapropel deposition in the entire (eastern) Mediterranean. Moreover, the rhythmic recurrence of environmental conditions that produce sapropels on schedules of precessional cycles points to a climatically driven chain of events culminating in sapropel deposition. A tentative chain of events postulates that carbon burial may have been promoted by enhanced rates of marine productivity, fuelled by an as yet contested source of new nutrients, a corresponding increase in oxygen utilization in deep water, and a weakening of deepwater oxygen recharge which all occur at the same time and are driven by the same external motor.

SCANDINAVIAN ICE SHEET

The Scandinavian and adjacent ice sheets

The Scandinavian Ice Sheet is the most commonly used name for an ice sheet that developed over Scandinavia many times during the Quaternary period. It is sometimes called the Fennoscandian Ice Sheet (Fenno = Finland), but as it expanded from the Scandinavian mountains and did not always reach Finland, the Scandinavian Ice Sheet is the most proper name. At its maximum extent, it covered northwestern Europe as far south as the Netherlands (Figure S1). In Eastern Europe it almost reached the Black Sea in southern Ukraine.

During some periods of maximum development, the Scandinavian Ice Sheet coalesced with the Barents-Kara Ice

Sheet, which was centered over the Barents and Kara Seas, and expanded southwards onto Northern Russia and Siberia (Figure S1). At such times, there was a contiguous ice sheet stretching from north of Spitsbergen to the Netherlands and from the Norwegian Sea to the Taimyr Peninsula in Siberia. The Scandinavian Ice Sheet also occasionally met the British Ice Sheet in the North Sea, but these two ice sheets were topographically and dynamically more clearly separated than those discussed above.

The older Scandinavian Ice Sheets

The strong glacial erosion associated with the last ice sheets has removed most of the deposits of the older glacials and interglacials. Glacial erosion also transformed the landscape so that deep U-shaped valleys and fjords now are common, especially in western Norway where vertical erosion of 1,900 m is inferred for part of Sognefjorden (Andersen and Nesje, 1992). The main record of older glaciations is the ice-rafted debris (IRD) found in cores collected from the floor of the deep Norwegian Sea. IRD indicates that the first ice sheets formed in Scandinavia as early as 11 million years ago, whereas the largest ice sheets grew after about 2.7 million years ago (Jansen and Sjøholm, 1991; Mangerud et al., 1996).

It is not known how many times the ice sheet expanded south of Scandinavia. In Germany, there are tills from only three glaciations, the Elsterian, Saalian and Weichselian (Ehlers, 1996). Thus, the classical view is that only at these times did the ice sheet reach this far south. However, Scandinavian erratics found in the Netherlands and glacial deposits in the North Sea indicate that such expansion also happened before the Elsterian (Mangerud et al., 1996).

The last ice age – the Weichselian

The last ice age in Northern Europe is named the Weichselian from the German name of the Vistula River in Poland, where glacial deposits from the Scandinavian Ice Sheet were

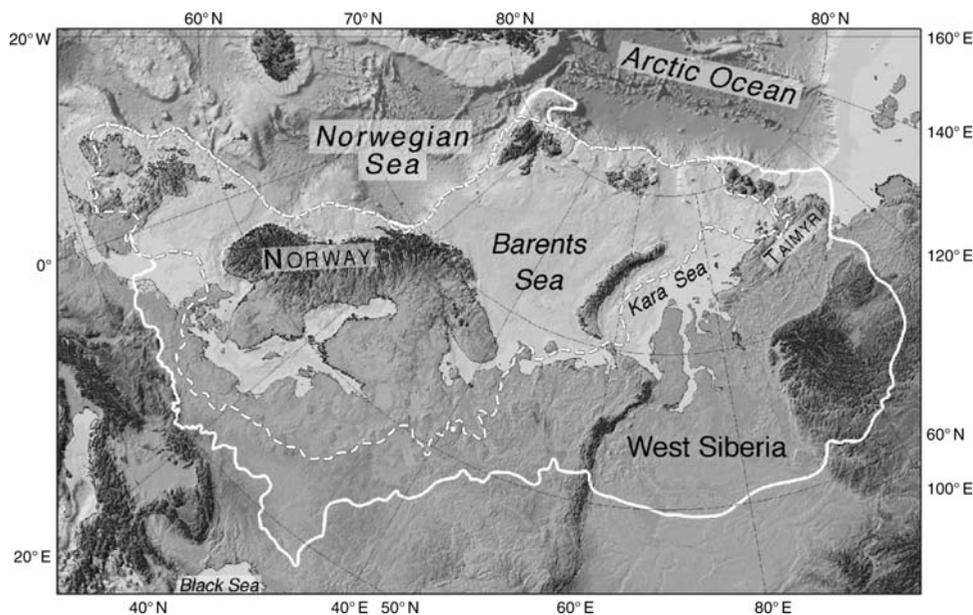

Figure S1 Map showing the extent of the Scandinavian, Barents-Kara and British Ice Sheets during two periods. Full line shows the Saalian glaciation and stippled line the Late Weichselian glaciation. (Modified from Svendsen et al., 2004.)

described by German geologists shortly after 1900 (Ehlers, 1996). We now know that these deposits were formed late during the last ice age, about 20,000 years ago. However, the name Weichselian is accepted for the entire cold period following the last interglacial in Europe, the Eemian. The subdivision and time scale for the Weichselian is shown in Figure S2.

The growth and decay of the Scandinavian and adjacent ice sheets is obviously much better known for the Weichselian than for older glaciations (Ehlers and Gibbard, 2004). However, in most areas, the ice sheets were larger during the Late Weichselian (about 20,000 years ago) than during earlier phases of the Weichselian. Therefore, our knowledge of the first 90,000 years of the Weichselian is limited.

Figure S2 shows a glaciation curve for western Norway for the entire Weichselian (Mangerud, 2004). During the last interglacial, the Eemian, the climate was warmer than at present, and no glacier existed. The first ice advance (Gulstein) almost reached the coast as early as 110,000 years ago.

Subsequently the ice front retreated during the Brørup interstadial when open forests were established over much of Scandinavia (Lundqvist, 1992). As seen from the curve, the ice margin subsequently advanced and retreated several times during the Weichselian. There were probably several more fluctuations than so far identified, although the record of ice rafted detritus in cores from the Norwegian Sea supports the main picture (Figure S2).

It is worth noting that the coast and probably much of the interior of Scandinavia was ice free during and possibly even after the Ålesund interstadial, which ended about 34,000 years ago (Olsen et al., 2002; Mangerud et al., 2003). This means that the ice sheet grew rapidly after this interstadial, until it reached its maximum size about 24,000 years ago.

The extent of the Late Weichselian Ice Sheet is shown in Figure S1. In Denmark, Germany and Poland, the limit of this ice sheet has been known for more than a century (Ehlers, 1996). However, it is still debated whether the British and

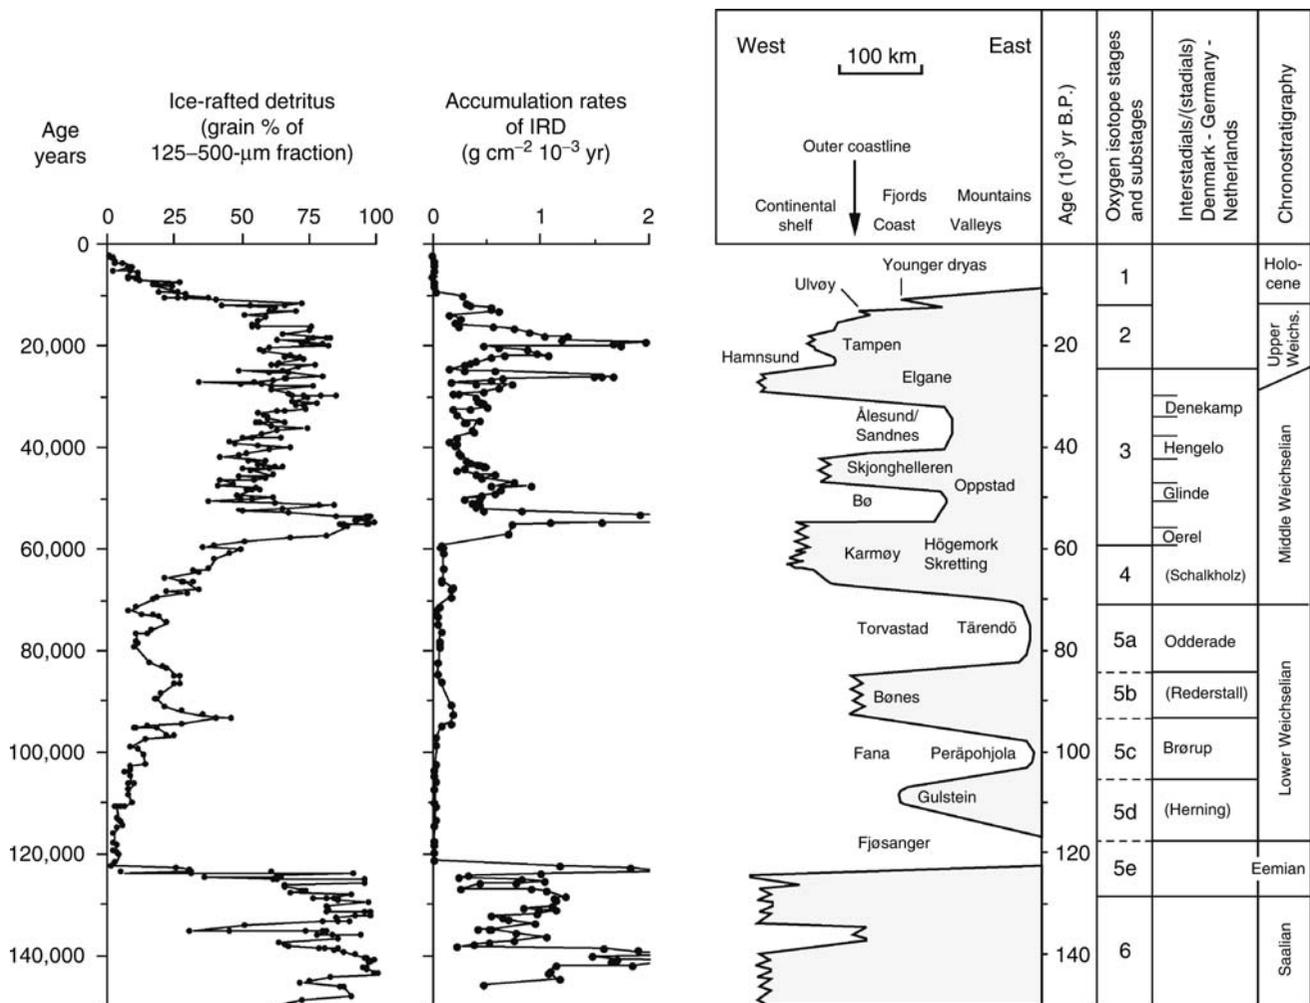

Figure S2 The right hand curve shows fluctuations of the western margin of the Scandinavian Ice Sheet. The lower part of the curve, when the ice front ended at the margin of the continental shelf corresponds with the Saalian ice limit in Figure S1. During the Eemian, the ice sheet disappeared. During the Weichselian, the extent of the ice sheet fluctuated strongly, but about 24,000 years ago it again reached the margin of the continental shelf, as shown in Figure S1. To the left are curves showing the number of ice rafted sand grains and their accumulation rates in cores from the Norwegian Sea (Mangerud, 2004).

Scandinavian Ice Sheets met in the North Sea, although that is assumed on the map. Furthermore, the limit of the ice sheet in Northern Russia has been much debated. A serious problem there is that permafrost with buried glacial ice melted at the end of the Weichselian and created fresh glacial landscapes, even though it had been deglaciated for tens of thousands of years (Svendsen et al., 2004).

The Barents-Kara Ice Sheet

The Barents Sea is located immediately north of Scandinavia, but the Scandinavian and Barents-Kara Ice Sheets did not always react in concert. The Barents-Kara Ice Sheet was much larger during the Early (about 90,000 years ago) and Middle Weichselian (60,000–50,000 years ago) than during the Late Weichselian, in contrast to the Scandinavian and the North American Ice Sheets (Svendsen et al., 2004). During both these periods, the Barents-Kara Ice Sheet moved onto land in Northern Russia, whereas during the Late Weichselian it terminated in the sea (Figure S1). During the Early Weichselian, the northbound rivers in Northern Russia were blocked by the ice sheet and large ice-dammed lakes formed between the ice-sheet and the continental watershed to the south.

SEA LEVEL CHANGE, LAST 250 MILLION YEARS

Introduction

One of the most fundamental geological observations has been that the seas once inundated large areas of the Earth's surface that are now exposed on land. Early observers attributed these marine incursions to one or multiple “Noachian” floods, but empirical science prevailed as uniformitarian concepts were applied to the stratigraphic record. Charles Lyell (1830) recognized that changes in sea level due to volcanic activity were responsible for the submergence and subsequent emergence of the temple at Serapis near Naples, Italy (see discussion by Gould, 1999). Observing cycles of shallow-water sedimentation across Europe, Lyell reasoned that apparent rises in sea level could explain the flooding of the continents (geologists call these “transgressions”) and the subsequent retreat of the seas (called “regressions”). For over a century after Lyell's work, geologists mapped these advances and retreats of the sea, noting that during intervals such as the middle Cretaceous (ca. 80 MyBP), much of the continents were inundated, whereas at other times, such as today, sea level was much lower. Geologists have equated these transgressions and regressions with global sea level (or “eustatic”) changes.

Transgressions and regressions may be related to eustatic sea level changes, but they also are caused by processes of subsidence or uplift, and changes in sediment supply. These processes are revealed by 20th century tide gauge data that indicate a global sea-level rise of $\sim 1.5\text{--}2\text{ mm yr}^{-1}$ (Church et al., 2001), due to the effects of ocean warming and melting of glaciers. However, tide gauge data for the mid-Atlantic United States uniformly show a rise of greater than 3 mm yr^{-1} , in part due to regional subsidence (Psuty and Collins, 1986). Although sea level is rising globally, *relative sea level* (in this region a term encompassing both the effects of subsidence/uplift and eustatic change) is rising much faster. High sediment supply can cause regression even during a relative sea level rise. For example, relative sea level is rising rapidly in the Mississippi Delta region due to the effects of global sea-level rise and rapid regional subsidence. Consequently, this region is generally experiencing a rapid transgression. However, near the mouth of the Mississippi, the high supply of sediments results in regression as the delta builds upward and into the Gulf. These modern examples illustrate the differences between a eustatic rise, a relative rise in sea level, and a marine transgression.

Global sea level has risen and fallen many times in response to growth and decay of the Northern Hemisphere Ice Sheets that have dominated the last 2.5 Myr (“the Ice Ages”). Drilling of submerged reef terrace records off Barbados (Figure S3) and Tahiti provided Rosetta Stone, which showed a 120 m lower sea level than present during the Last Glacial Maximum (Fairbanks, 1989; Bard et al., 1996). Uplifted reef terrace records (corrected for long-term uplift) have extended global sea-level estimates back to 130,000 years ago (Fairbanks and Matthews, 1978; Chappell et al., 1996); however, it has proven difficult to firmly extend reef terrace records further back in time due to dating problems.

Pre-Quaternary sea level change

Oxygen isotope ratios ($\delta^{18}\text{O}$) provide a potential means for reconstructing sea-level change over the past 100 Myr. $\delta^{18}\text{O}$

values reflect the effects of temperature and ice-volume (hence sea level) changes in the shells of single-celled organisms called foraminifera. By calibrating foraminiferal $\delta^{18}\text{O}$ variations to the reef terrace record, geologists can make an estimate of global sea-level changes (Figure S3). However, it is difficult to extend oxygen isotopic sea-level estimates beyond the past million years because the temperature history of the planet prior to this is less well known. In addition, diagenetic alteration potentially overprints Late Cretaceous to early Tertiary $\delta^{18}\text{O}$ values (ca. 100–25 MyBP), whereas records older than 100 Myr are typically altered.

Our primary information on sea-level change prior to the Quaternary (>2 MyBP) is derived from stratigraphic records of continental inundation. Transgressions have flooded the continents on roughly 100-Myr timescales (e.g., Sloss, 1963), reflecting changes in the rates of ocean crust production. Finer-scale cycles (1–10 Myr) have been attributed either to sea-level change (Suess, 1885) or to tectonic controls (Sloss, 1963; Stille, 1924; Grabau, 1936). These cycles are observed in the sediment and rock record with deeper water environments representing transgressions and shallower water environments representing regressions.

Studies at Exxon Production Research Company (EPR) revolutionized our view of the stratigraphic record of sea-level change. Sea level falls and tectonic changes both produce erosion surfaces termed “unconformities”; packages of sediments on continental margins bracketed by unconformities are called “sequences.” Researchers at EPR made a revolutionary breakthrough in using seismic reflection profiles to identify sequences and then using these sequences to estimate the ages and magnitudes of past sea level changes (Figure S4; Haq et al., 1987; Vail et al., 1977). These estimates proved highly controversial, in part because of the proprietary nature of the data used to construct them and in part because of flaws in the method used to estimate the amplitudes of sea-level change. Nevertheless, more than a decade of studies, described below, have been carried out, validating the general number and timing of eustatic events published by EPR – a landmark achievement. However, estimation of eustatic amplitudes remains one of the thorniest problems in geology.

A large mid-Oligocene (ca. 30–32 MyBP) sea level lowering illustrates problems with estimating amplitudes. Vail et al. (1977) initially concluded that this event comprised over

400 m of global sea level lowering, a remarkably large drop. Geophysical studies showed that the methodology employed in these estimates did not properly account for the effects of basin subsidence and water depth and thus grossly overestimated the amplitudes (see summary in Christie-Blick et al., 1990). A further decade of study by EPR scientists provided an estimate of ~160 m of lowering for this mid-Oligocene event (Figure S5), an amplitude that still strained credulity. Stable isotopic studies have long suggested amplitudes closer to 30–60 m for this event (e.g., Miller et al., 1985, 1998). Rigorous studies of borehole transects on the New Jersey margin yield an estimate for this event of 50 m (Kominz and Pekar, 2001) using a method called backstripping (see below for definition), and this estimate is probably correct within ± 10 m. Despite these recent studies, the amplitude of sea-level change remains one of the poorest constrained boundary conditions of the Earth.

Recognizing that it had the unique ability to provide a global dataset, the international Ocean Drilling Program (ODP), operator of the drillship *JOIDES Resolution*, entered into sea-level research in the 1990s. ODP identified four major goals in sea-level research: (a) test the synchrony of sea-level events in widely separated locations; (b) estimate the amplitude of sea-level changes; (c) evaluate various models that seek to explain the stratigraphic response to sea-level oscillations; and (d) determine the mechanisms that control sea level. To accomplish these goals, a strategy of drilling transects of boreholes on passive margins was adopted.

The New Jersey sea level transect

The New Jersey margin was selected by ODP as an ideal location to begin the investigation of the Late Cretaceous to Cenozoic history of sea-level change because of its rapid sedimentation, tectonic stability, good chronostratigraphic control, and abundant seismic well log and borehole data (Miller and Mountain, 1994). To evaluate sequences and sea-level changes, the “New Jersey Sea-Level Transect” was designed as a series of boreholes from the onshore New Jersey Coastal Plain across the continental shelf to the slope and rise (Figure S5). The transect initially focused on the past 34 Myr (Oligocene-Recent; Miller and Mountain, 1996), a time when large ice sheets waxed and waned, potentially changing sea level by up to 100 m. More recent studies

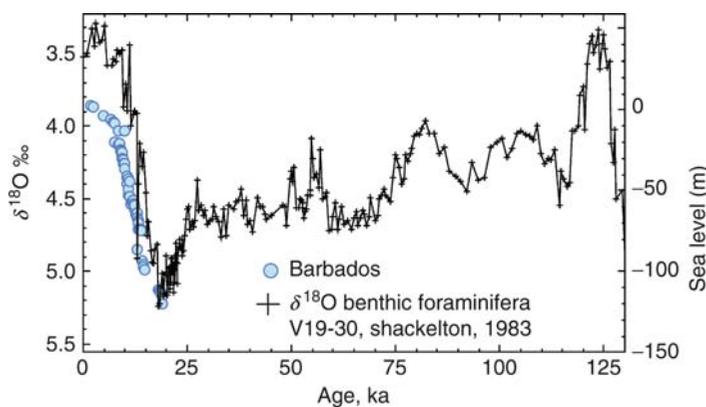

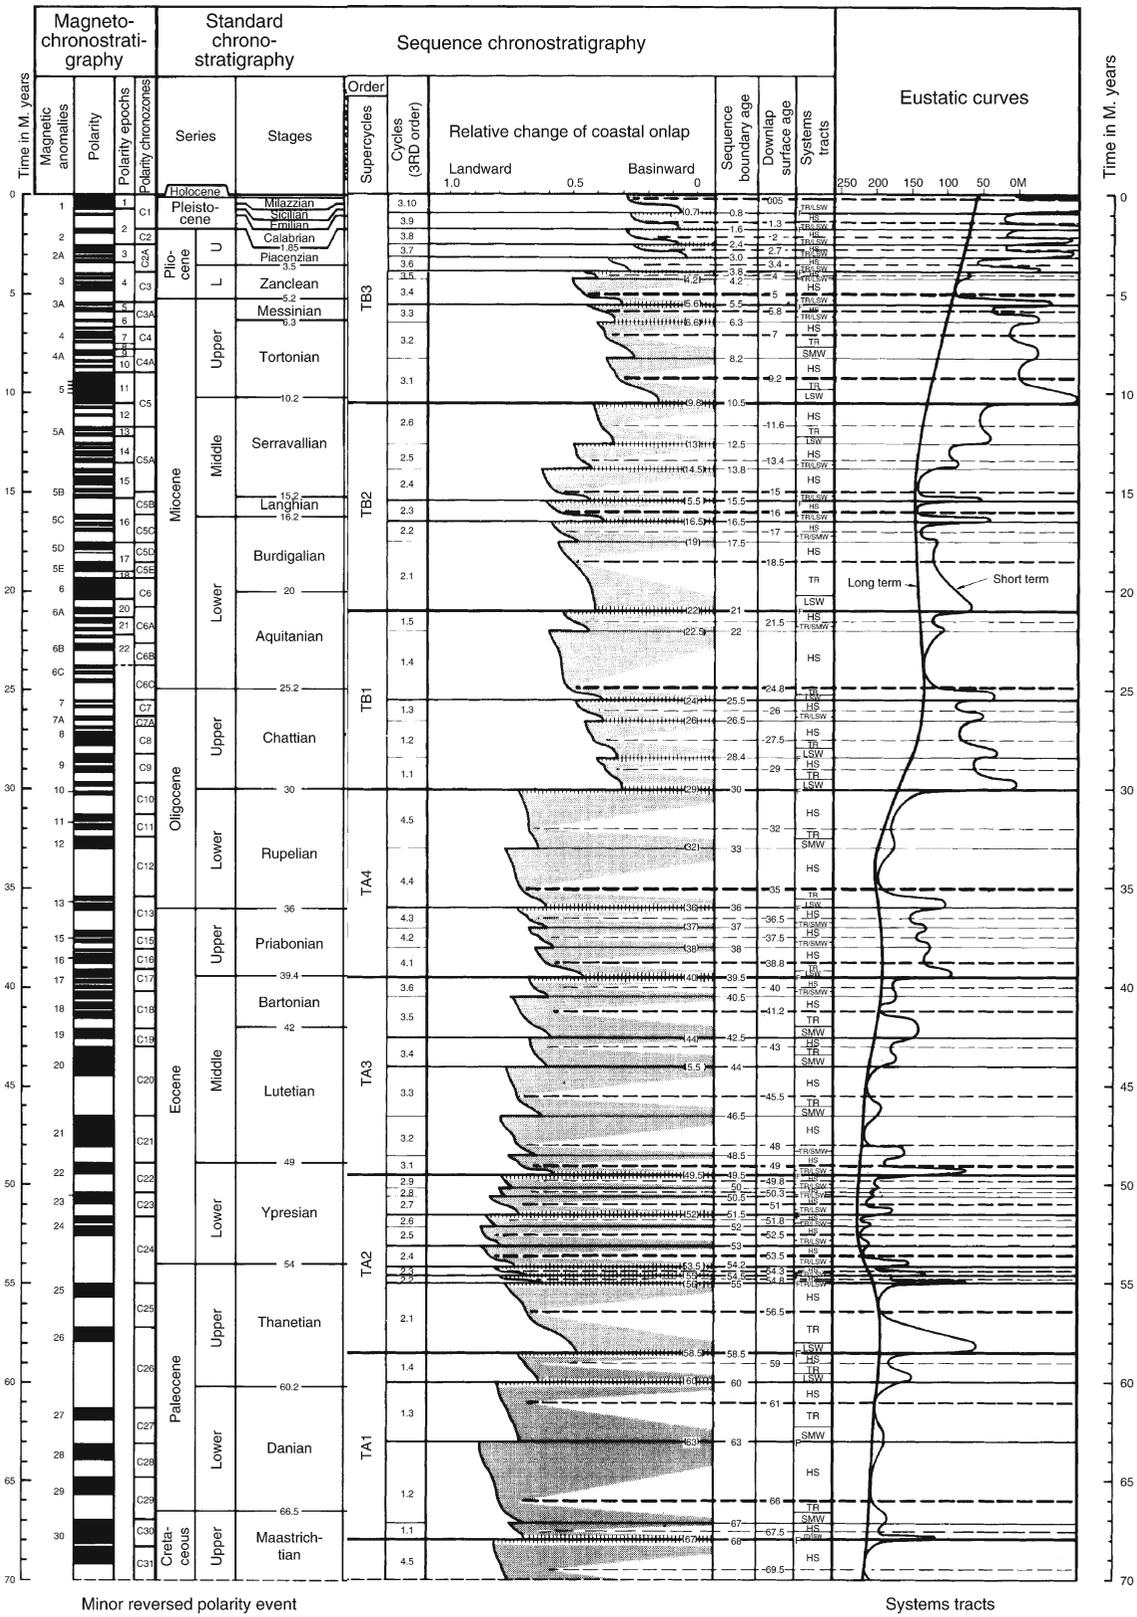

Figure S3 Comparison of the global estimate for sea-level derived from Barbados terraces (Fairbanks, 1989) with deep-sea benthic foraminiferal $\delta^{18}\text{O}$ values from Pacific core V19-30 scaled to sea-level assuming $0.11\text{‰}/10\text{ m}$ of sea-level change (Fairbanks and Matthews, 1978) (Wright, Miller, Sheridan, unpublished).

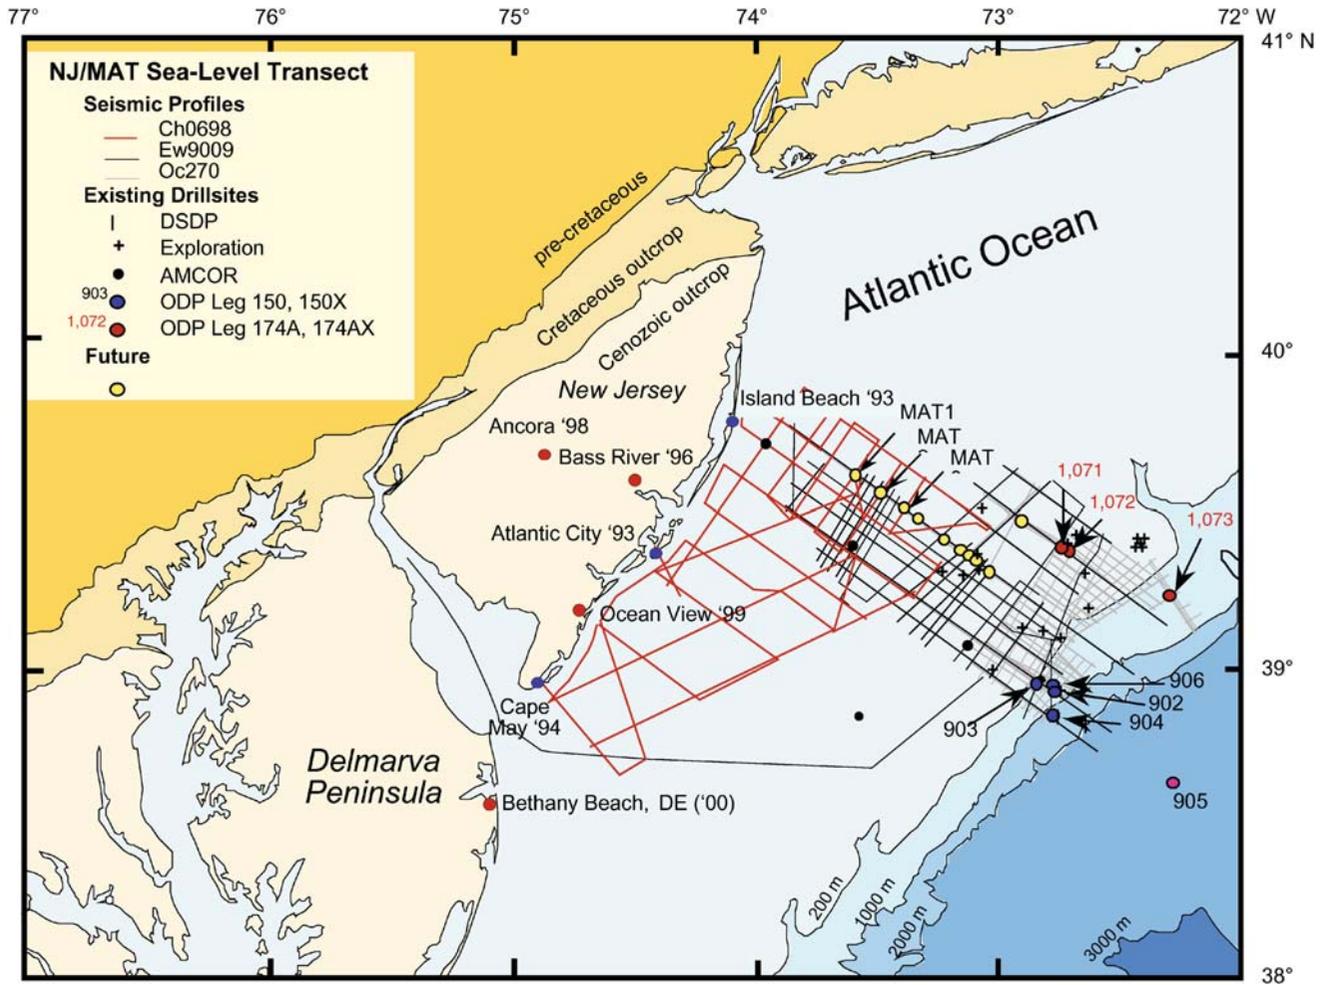

Figure S5 Map showing seismic profiles and boreholes, New Jersey sea-level transect.

have extended back to 100 MyBP (Late Cretaceous; Miller et al., 2003).

Seismic profiles provide a means of imaging strata like a sonogram images structures within the human body. Seismic profiles exhibit stratigraphic geometries resulting from erosion, potentially due to sea-level lowerings ("sequence boundaries"). The seismic surfaces reveal themselves in borehole sediments as erosion surfaces. The New Jersey Transect dated these sequence boundaries by drilling in relatively deep water (400–1,400 m) on the continental slope and rise and using various tools for age control (fossils, magnetostratigraphy, Sr-isotopic stratigraphy). Drilling onshore in New Jersey also dated these sequences in a more proximal nearshore to paleo-shelf setting, where time gaps or hiatuses were longer. Nevertheless, the onshore hiatuses (white gaps between blue boxes; Figure S6) correlate remarkably well with offshore sequence boundaries (m1, m2, etc. on Figure S6). This establishes a regional correlation between these hiatuses and associated sequence boundaries, and a relation to at least regional-scale sea-level lowerings.

Comparison of the New Jersey sequence stratigraphic record with oxygen isotopes provides a link between regional

sea-level lowerings and global changes in ice volume (hence sea level) for the past 34 Ma (Figure S6). Oxygen isotopic ($\delta^{18}\text{O}$) increases in deep-sea Atlantic cores correlate with the sea-level lowerings in New Jersey (Figure S6). This demonstrates that a significant portion of oxygen isotopic changes must be attributed to changes in ice volume. Still, we cannot precisely determine the extent of the role of ice growth versus cooling of bottom waters on any individual $\delta^{18}\text{O}$ increase. For example, a large $\delta^{18}\text{O}$ increase occurred across the Oligocene/Miocene boundary (ca. 23 Ma), correlating with the m6 continental slope and the O6/Kw0 onshore sequence boundaries (Figure S6). If this were attributed entirely to ice volume (presumably from Antarctic ice, because Northern Hemisphere Ice Sheets did not begin to grow until late Miocene to Pliocene), this change would be equivalent to a 90 m eustatic sea level drop. It is likely however, that bottom waters cooled at the same time as the glaciation; during the Quaternary, about two-third of the $\delta^{18}\text{O}$ signal is controlled by ice volume and one-third by temperature (Fairbanks, 1989). Applying this rule of thumb to the older record indicates about 60 m, not 90 m, of eustatic lowering; however, it is still possible that the temperature effects were larger and sea level change would have been correspondingly less.

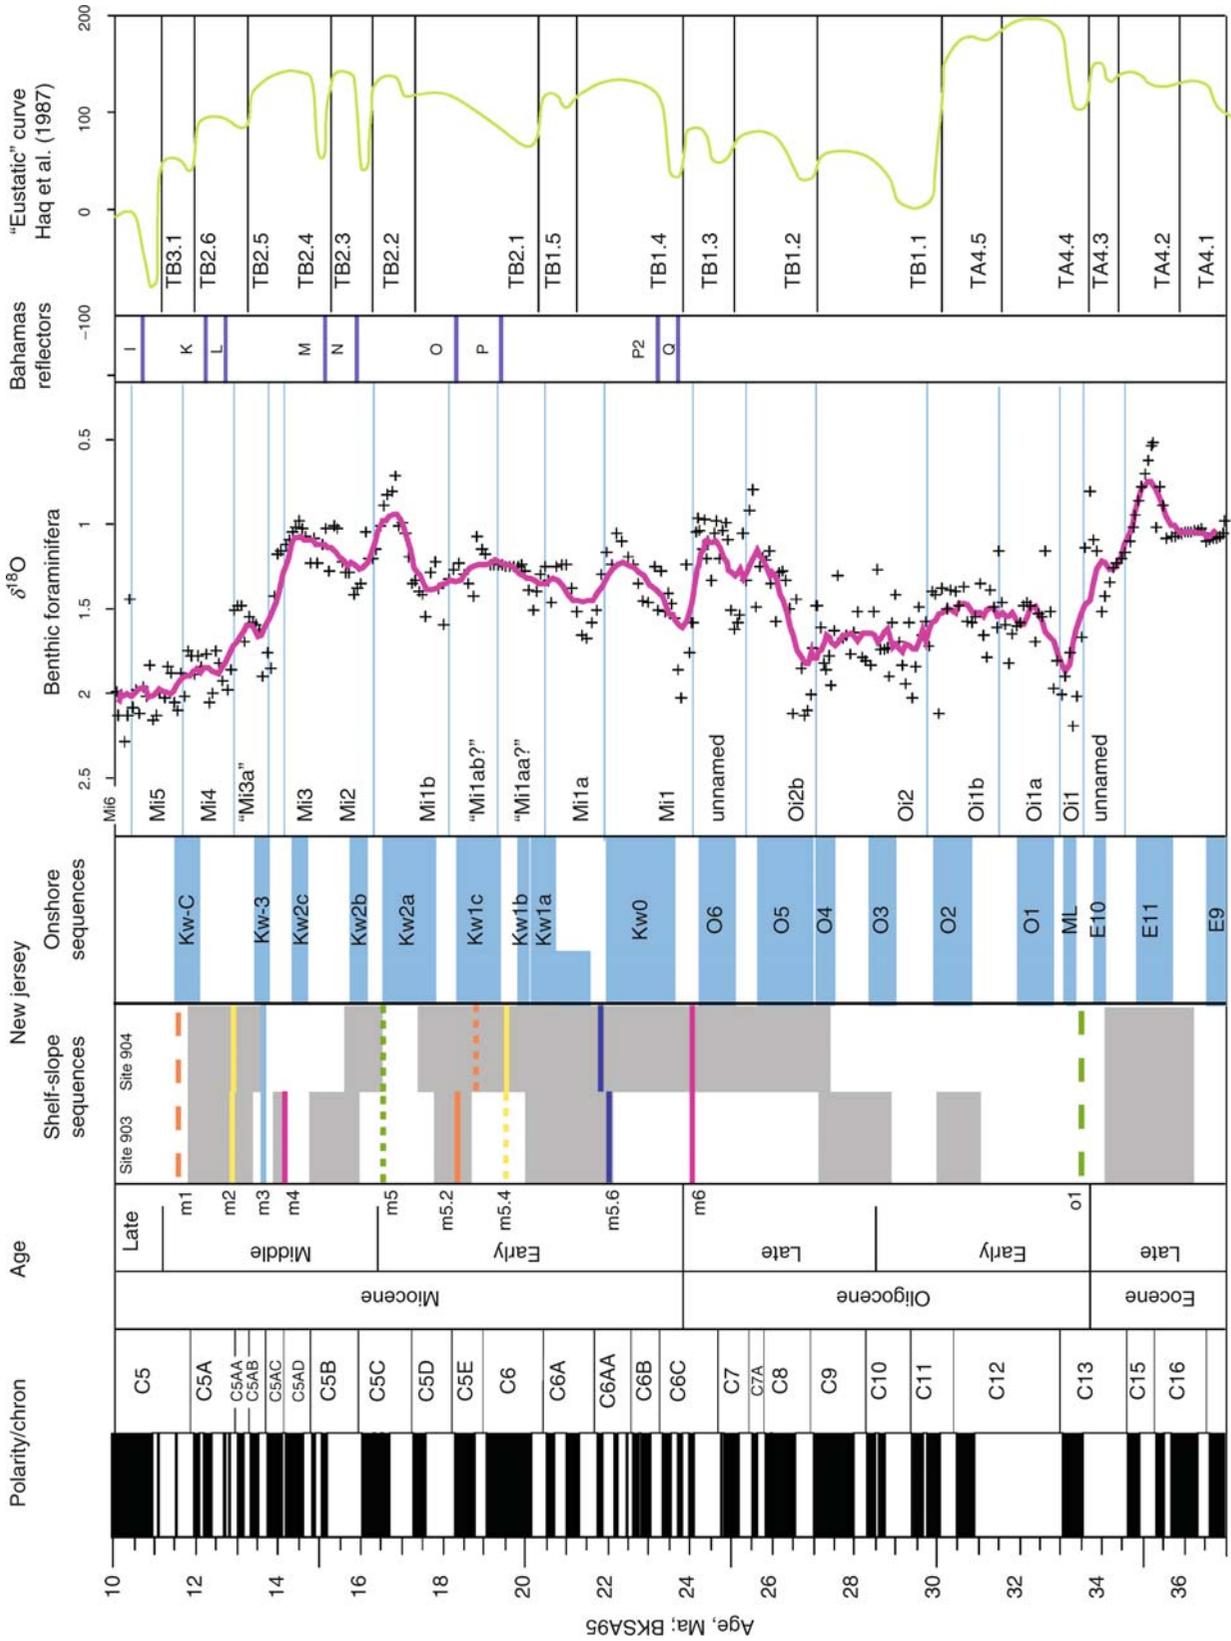

Figure S6 Comparison of offshore New Jersey, onshore New Jersey, global oxygen isotopes, ages of Bahamas reflections, and Haq et al. (1987) sea-level record (Miller et al., 1998). I approximate age error

The above example illustrates the hazards of trying to estimate eustatic amplitudes from oxygen isotopic records. Though continental margin stratigraphic records are complicated by changes in subsidence, it is possible to evaluate subsidence histories using a method called backstripping. This method progressively removes the effects of compaction, sediment loading, and thermal subsidence; the residual provides an estimate of eustatic sea level (e.g., Kominz et al., 1998; Watts and Steckler, 1979). Backstripping requires estimates of age, sediment type (for decompaction), and paleowater depth; the latter is obtained from benthic foraminifera and lithologic data and is the greatest source of uncertainty. Kominz et al. (1998) and Van Sickle et al. (2004) backstripped individual onshore New Jersey boreholes ("1-dimensional" backstripping) and found amplitudes of 20–40 m. Two-dimensional backstripping (backstripping an entire profile using several boreholes) of ten latest Eocene to earliest Miocene sequences provided estimates of ~20–60 m eustatic lowerings (Kominz and Pekar, 2001). Both one and two dimensional backstripping yielded Oligocene-Miocene eustatic estimates that are lower than those published by the EPR group (e.g., Haq et al., 1987) by a factor of two or more (Kominz and Pekar, 2001; Van Sickle et al., 2004).

Studies of sea-level change must be global in scope and ODP has drilled on the Australian margin (Legs 133, 182, and 194) and the Bahamas (Leg 166). Despite the fundamental difference in sedimentation style between carbonate and siliciclastic margins, ODP drilling documented similar-Miocene unconformities in these diverse settings (Figure S6). Drilling in the Bahamas showed that the flanks of a carbonate bank environment develop sequences that are remarkably similar in character to those of siliciclastic margins (Eberli et al., 1997). Though tectonic effects (e.g., rapid subsidence) influence much of the northeast Australian region (Davies et al., 1993), consequences of global sea-level change on the evolution of the Marion Plateau and the Great Barrier Reef were evaluated. Drilling on the Australian margin by Leg 194 (Isern et al., 2002) provided an estimate of a major late middle Miocene eustatic lowering of 33 ± 12 m based on Airy (point) loading to 85 ± 30 assuming rigid crust (flexural loading). These wide ranges again illustrate the difficulty in estimating global sea-level amplitudes.

Causes of sea level change

Drilling on the New Jersey, Bahamas, and Australian margins have firmly demonstrated that ice-volume changes have been one of the primary controls on sea-level change during the Icehouse world of the past 34 Myr. It is not surprising that this is true because ice-volume changes are the only known mechanism for causing the large (>10s m), rapid changes in sea level reported for this time interval. The close correspondence between the oxygen isotopic and continental margin records is testament to this linkage (Figure S6). However, what about the vast amounts of geologic time in which the Earth was presumably ice-free?

Sea level during the Cretaceous (144–65 Ma) was much higher than at present because of long-term changes in sea level. These long-term (10–100 Myr scale) sea-level changes have been largely controlled by tectonics. For example, during the warm interval of the middle Cretaceous (ca. 80–90 Ma), global sea level was between 100 (Miller et al., 2005) and 170 m (Müller et al., 2008) higher than today. However, such high sea levels cannot be explained by a warmer planet and

the absence of ice sheets: even if all of the modern ice sheets were melted (an "ice-free Greenhouse world"), then sea-level would be only 73 m higher than today. Although the Cretaceous oceans were 10–12 °C warmer than today, thermal expansion could only account for another 10–13 m of rise. The generally accepted explanation for the high mid-Cretaceous sea levels is high sea-floor spreading rates; higher rates mean hotter crust, which expands, displacing seawater and causing long-term flooding of the continents (Hays and Pitman, 1973; Kominz, 1984). This pulse of mid-Cretaceous high seafloor spreading has been recently disputed (Rowley, 2002), though various stratigraphic data unequivocally show that relative to the continents, sea level was 100–250 m higher, based on backstripping in the former case (Watts and Steckler, 1979) and continental flooding in the latter (Sahagian et al., 1996). If not caused by high-sea floor spreading rates, the long-term flooding and subsequent retreat of the sea over the past 180 Myr could have been the result of the breakup of the supercontinent Pangea, beginning at 180 Ma, which may have led to overall subsidence of continents relative to the oceans during the Jurassic to mid-Cretaceous.

Even more puzzling than the long-term record is the observation that large (10s to 100 m), rapid (less than 1 Myr) sea-level changes occurred during the Triassic to middle Eocene (ca. 250–50 Ma), a time considered to be an ice-free Greenhouse (Haq et al., 1987; Hallam, 1992). Ice-volume changes (glacioeustasy) are the only known mechanism for producing large, rapid sea-level change (Pitman and Golovchenko, 1983). Although it has been believed in general that there were no significant ice sheets prior to the middle Eocene, Haq et al. (1987) delineated numerous Cretaceous to early Eocene sequence boundaries with associated large (>50 m), rapid (<1 Myr) sea-level lowerings. There are four explanations for this apparent paradox (Browning et al., 1996): (a) the Cretaceous to early Eocene sequences summarized by Haq et al. (1987) were restricted to local basin(s) and do not reflect eustasy (this is unlikely considering that many have been widely recognized; e.g., Aubry, 1985; Mancini and Tew, 1991, 1995; Olsson, 1991); (b) the sequences were controlled by low-amplitude sea-level changes (e.g., 10 m of lowering in 1 Myr can be explained by numerous mechanisms; Donovan and Jones, 1979); (c) mechanisms of sea-level change are not fully understood; and (d) there were ice sheets throughout much of the Cretaceous to early Eocene (e.g., Stoll and Schrag, 1996).

Drilling in New Jersey has recently provided a record of sea-level changes during the warm Late Cretaceous. These studies firmly document that large (>25 m), rapid (<<1 Myr) eustatic variations occurred in the Late Cretaceous, hinting at the presence of ice sheets in this supposedly ice-free Greenhouse world (Figure S7). Continuous coring recovered 11–14 Upper Cretaceous sequences at Bass River and Ancora, New Jersey that were dated by integrating Sr-isotopic and biostratigraphic data (age resolution ± 0.5 Myr) and subsequently backstripped taking into account sediment loading, compaction, paleodepth, and thermo-flexural subsidence, providing a new sea-level estimate. The timing of Late Cretaceous sequence boundaries in New Jersey is similar to sea-level lowerings found by EPR (Haq et al., 1987), NW European sections (Hancock, 1993), and Russian sections (Sahagian et al., 1996), indicating a global cause (Figure S7). However, New Jersey and Russian Platform eustatic estimates are half of the EPR amplitude; the EPR record also differs in shape from the backstripped estimates. The use of the EPR record for the Late

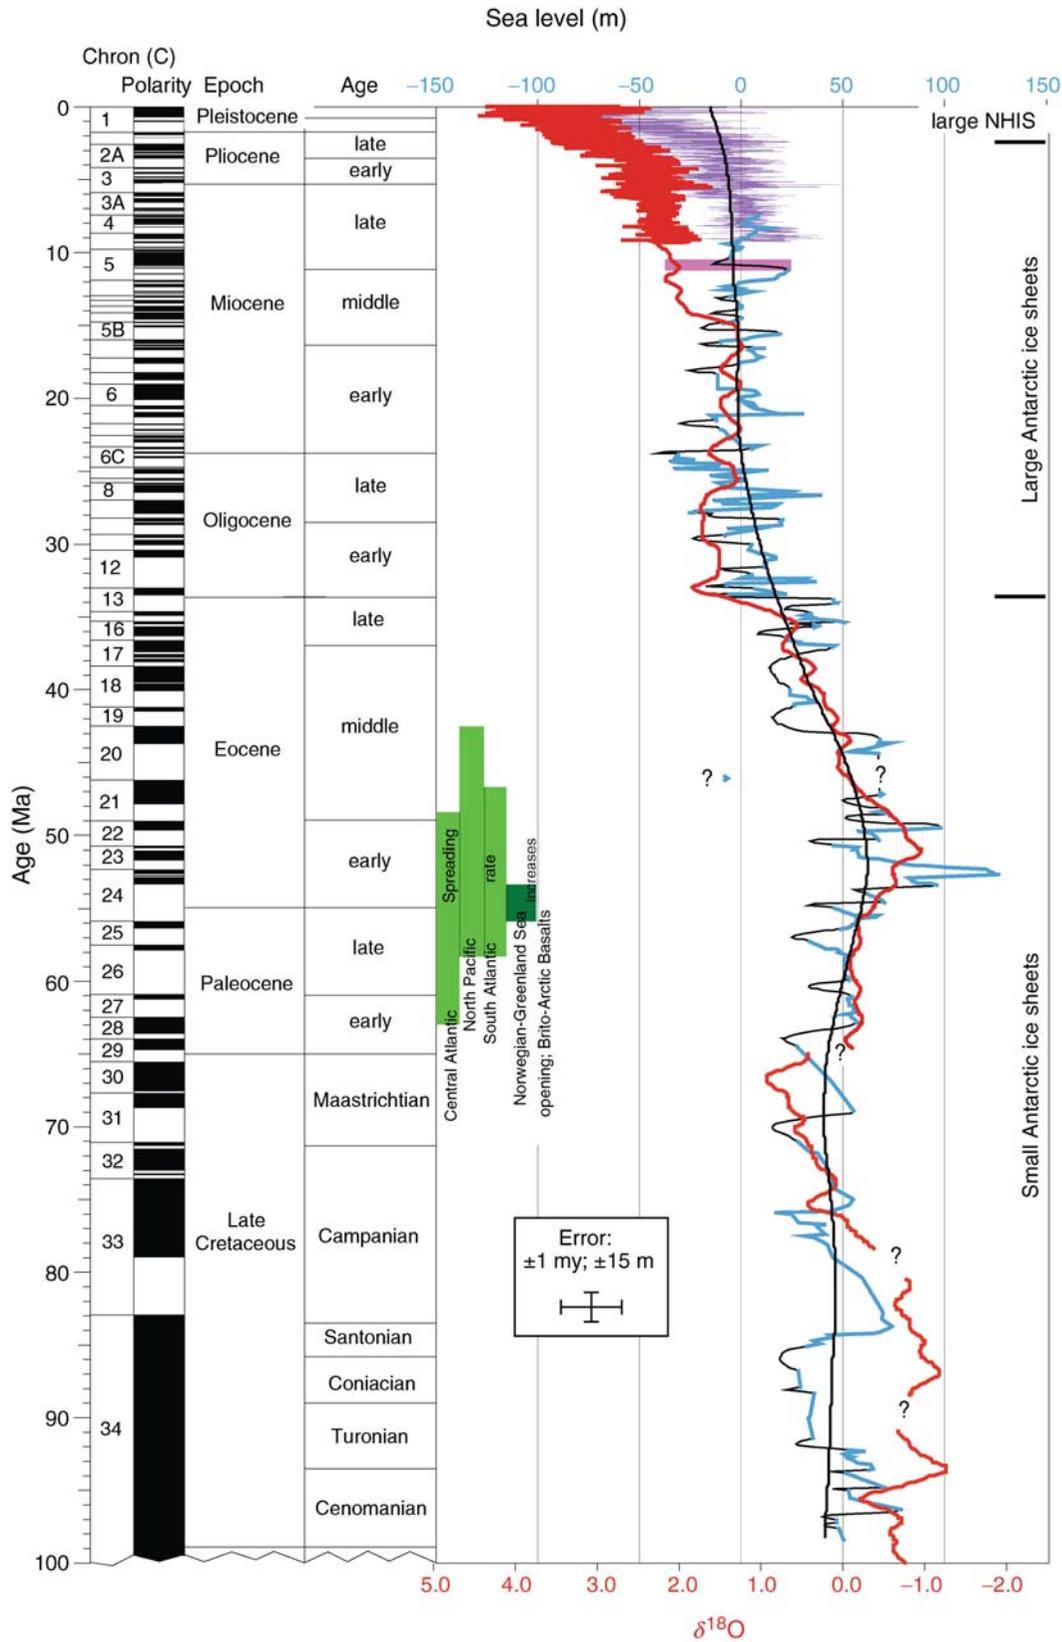

Figure S7 Comparison of Late Cretaceous deep-sea benthic foraminiferal $\delta^{18}\text{O}$ records, New Jersey composite sequences, relative sea level from NW Europe (Hancock, 1993), backstripped Russian platform record (Sahagian et al., 1996), the EPR eustatic estimate for Bass River (Haq et al., 1987), backstripped R2 eustatic estimates for Bass River (black) and Ancora (gray) and our best estimate of eustatic changes (heavy black line constrained by data, dashed inferred). Pink arrows indicate positive $\delta^{18}\text{O}$ inflections (inferred cooling and/or ice volume increases) (after Miller et al., 2004).

Cretaceous should be abandoned; the New Jersey backstripped records provide the best substitute at this time.

The firm documentation of large (>25 m), rapid (<Myr) sea-level changes (Figure S7) indicates some glacioeustatic control during the Late Cretaceous. The apparent inconsistency with evidence for warm high latitudes during the Late Cretaceous can be explained by ephemeral (i.e., lasting $\ll 1$ Myr) ice sheets (presumably in East Antarctica (EAIS)) with volumes approaching one-third to one-half of the modern EAIS (Miller et al., 1999) and intervening warm, ice-free intervals (Miller et al., 2003).

Oxygen isotopic comparisons with Late Cretaceous sequence boundaries have not attained the resolution needed to link the two datasets unequivocally, as has been done for the past 42 Myr (Miller et al., 1998a). Nevertheless, comparisons between Late Cretaceous sequence stratigraphy and $\delta^{18}\text{O}$ records are intriguing (Figure S7), further suggesting small ice sheets in this alleged Greenhouse World: (a) a major mid-Cenomanian sequence boundary (hiatus ca. 96–97 Myr ago) (see also Gale et al., 2002) correlates with a major (>1‰) $\delta^{18}\text{O}$ increase; (b) two minor $\delta^{18}\text{O}$ increases spanning the Cenomanian/Turonian boundary may correlate with sequence boundaries; (c) a mid-Turonian sea-level lowering (91.5–92 Ma) may correlate with a major increase in benthic foraminiferal $\delta^{18}\text{O}$ values ($\sim 1.0\%$), although additional data are needed to determine the precise timing of the increase (Figure S7). Several other Coniacian-Campanian $\delta^{18}\text{O}$ increases (dashed arrows, Figure S7) may be related to sequence boundaries, but the data are too sparse to provide a firm correlation.

The EPR sea-level records (Vail et al., 1977; Haq et al., 1987) are major achievements for the Earth sciences. However, it is not surprising after 15–25 years, that we conclude that these previous sea-level estimates are not entirely correct in their shape and amplitudes. Methods for extracting sea level from stratigraphic data have advanced during this period and the scientific community has begun to document amplitudes of sea-level change with increased precision. Despite their limitations, the EPR curves stand the test of time as an approximate chronology (± 1 Myr) of eustatic lowerings. Studies on the New Jersey and other continental margins have generally confirmed the number and approximate ages of sea-level lowerings of Haq et al. (1987) for the past 100 Myr (Figures S6, S7). In the absence of other datasets for the Triassic-Early Cretaceous, the Haq et al. (1987) record still provides the best estimate for the timing of eustatic lowerings. Although the timing can be estimated, the amplitudes of sea-level change during the Triassic-Early Cretaceous remain poorly constrained and the causal mechanisms for the large, rapid sea-level changes for this interval can only be explained by glacioeustasy. Is our understanding of causal mechanisms for global sea-level change flawed, or is our interpretation of a largely ice-free planet prior to 42 Ma incorrect?

ODP drilling has determined ages of sequence boundaries on continental margins to better than ± 0.5 Myr and provided a chronology of eustatic lowering for the past 42 Myr (Figure S6). ODP has also validated the transect approach of drilling passive continental margins and carbonate platforms (onshore, shelf, slope). Additional integrated geological and geophysical studies of transects of margins are needed to address the history magnitude, and mechanisms of global sea level change over the past 250 Myr.

SEA LEVEL CHANGE, POST-GLACIAL

The late Quaternary glacial period was characterized by massive ice sheets that covered parts of North America, northern Europe, and several other high latitude and high altitude regions. This volume of ice was sufficient to lower global sea level by over 100 m. As the ice sheets began to melt and retreat over 20,000 years ago, sea level rose rapidly. However, the time history and magnitude of sea level rise were widely debated, as data from radiocarbon-dated paleosea level indicators began to accumulate in the 1950s and 1960s. A major point of discussion at that time centered on whether or not the post-glacial marine transgression followed a smooth versus a fluctuating curve that reflected world-wide sea level changes (e.g., Shepard and Suess, 1956; Fairbridge, 1961, 1976). Support for both points of view could be found as recently as 1991 in a compilation of Holocene sea level curves (Pirazzoli, 1991). The acquisition of more accurately dated sea level data and development of a theoretical framework to account for interactions among various geophysical and climatological processes has led to a much clearer understanding of post-glacial sea level rise (SLR) within the last 30 years. The deglaciation was accompanied by a global increase in sea level of ~120 m. Post-glacial sea level did not rise smoothly, but instead jumped in several sharp and rapid spikes, termed “melt-water pulses” (Fairbanks, 1989). However, the exact number, timing, and magnitude of these major pulses, and their relation to paleoclimate events have yet to be resolved. The extent and significance of minor Holocene sea level oscillations also needs further investigation.

Processes affecting sea level

Sea level integrates the effects of diverse geological and climatological phenomena that operate over a wide range of spatial and temporal scales. The dominant processes that have affected post-glacial sea level involve changes in ocean water volume caused by melting of ice sheets (*glacial eustasy*) and changes in ocean basin volume due to re-adjustment of the lithosphere in response to removal of the ice load (*glacial isostasy*) and glacial meltwater loading of ocean basins (*hydro-isostasy*). While of lesser importance during this period, major factors controlling global sea level over geologic timescales (10^7 – 10^8 years) include changes in volume of ocean basins due to variations in rates of seafloor spreading and subsidence of cooler, oceanic crust away from spreading centers (*tectono-eustasy*). Changes in ocean water density, caused by changes in temperature or salinity (*steric changes*) become more significant contributors to sea level on much shorter timescales (10 – 10^3 years). A twentieth century global sea level rise of ~1.7–1.8 mm yr⁻¹ (Church et al., 2004; Holgate and Woodworth, 2004) appears to be related to recent climatic warming, which has been attributed to anthropogenic additions of

greenhouse gases into the atmosphere (e.g., Church et al., 2001, IPCC, 2007). Around 0.4 mm yr^{-1} , or 22–24%, derives from penetration of this atmospheric heat signal into the oceans and the consequent thermal expansion (Antonov et al., 2005); the balance is due to melting of mountain glaciers and ice sheets.

The relative magnitudes of the processes influencing sea level vary from place to place, thus tending to obscure any globally coherent sea level signal. Therefore, the derivation of a eustatic sea level curve requires an ability to decouple the effects of land motions (uplift/subsidence) from processes related to changes in continental ice extent or ocean water volume. Away from convergent plate margins, the main cause of long-wavelength elevation differences during the Holocene is related to changes in ice and water loading. Geophysical models of glacial isostatic adjustment (GIA) account for time-varying gravitational interactions among ice sheets, land, and ocean (Peltier, 2001, 2002, 2004; Lambeck et al., 2002; Mitrovica and Milne, 2002). GIA models calculate the observed sea level change over time at any given location as a function of the volumetric addition of glacial meltwater and contributions from both glacial isostasy and hydro-isostasy. Input parameters include values for maximum ice sheet thickness and extent, a history of ice sheet retreat, and mantle viscosity profiles. The GIA models are “tuned” by fitting the results to radiocarbon-dated sea level records (see *Sea level indicators*) and adjusting the mantle viscosity (Peltier, 2001, 2002, 2004; Lambeck et al., 2002). GIA models predict several zones that display similar sea level patterns (Figures S8–S9). In areas formerly covered by ice that are isostatically rebounding, sea level falls continuously (Figure S8a). Areas marginal to ice sheets that had been upwarped during glaciation (the “peripheral forebulge”) subside following removal of the ice load (Figure S8b). Sea level rises continuously in this zone. Transitional zones between glacial rebound and collapse experience a more complex history of sea level fall followed by a rise (Figure S8c). On mid-ocean islands far removed from former ice sheets (the “far field”), after attaining its maximal height, sea level drops once deglaciation has ceased in the mid-Holocene due to “siphoning” of water toward subsiding forebulges (Figure S9a). Finally, far field continental coastlines show regions of sea-level fall, with rising ocean levels further offshore (due to “continental levering,” see below; Mitrovica and Milne, 2002; Figure S9b). Thus, the observed sea level trend at any given locality depends on the interplay between the effects of glacial eustasy and glacial isostasy. The composite eustatic sea level curve (Figure S10) is based on careful selection of sites where glacial isostatic effects are minimal.

Sea level rise after the last glaciation

A composite curve of post-glacial sea level (Figure S10a) has been derived from radiocarbon- and $^{230}\text{Th}/^{234}\text{U}$ -dated sea level indicators, including corals, plant material, foraminifera, and mollusks from a number of regions with minimal glacial isostatic influence. Figure S10b shows the late Quaternary–Holocene sea level curve calculated from the ICE-5G (VM2) GIA model together with Th-U-dated corals from Barbados (after Peltier and Fairbanks, 2006). Note that the coral data suggest a minimum sea level close to 26,000 years before present, significantly older than the commonly accepted date of ~20,000 BP (Table S1).

The post-glacial eustatic sea level rise, although continuous, was punctuated by several periods of more rapid transgression,

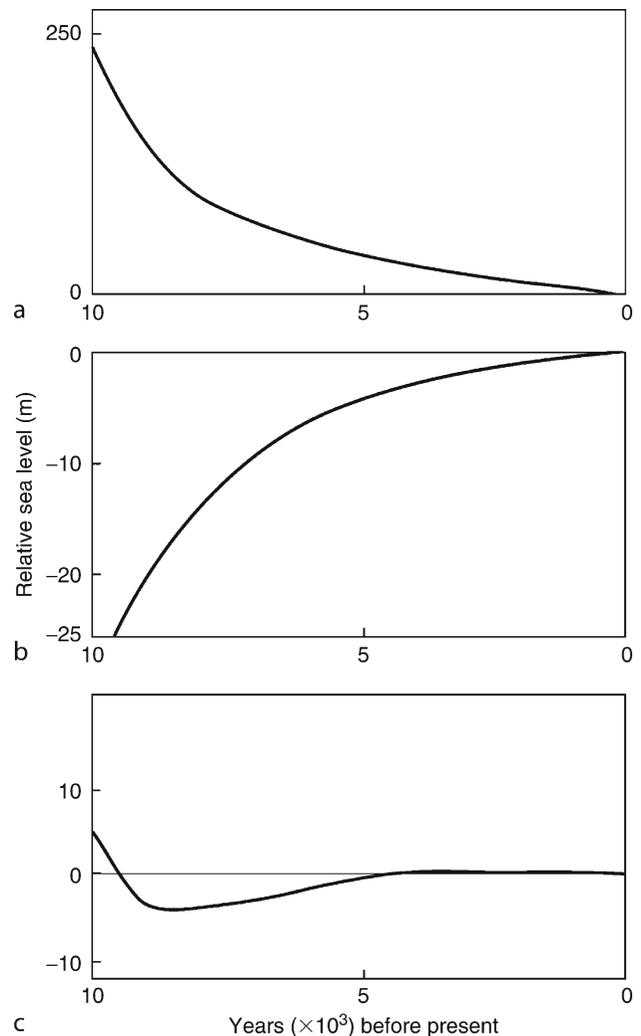

Figure S8 Schematic near field Holocene sea level curves from different zones of glacial isostatic adjustment. The vertical scale represents relative sea level change in meters (negative values are below present sea level, positive values above). These generalized curves do not represent specific localities. (a) Former ice-covered regions—continuous sea level fall (land emergence); e.g., Scandinavia; Canada. (b) Collapsed peripheral bulge—continuous sea level rise (land subsidence); e.g., the Netherlands, Belgium, southern England, East Coast, USA, south of New York. (c) Transitional zone—early Holocene sea level fall followed by sea level rise; e.g., Maine, Canadian Maritimes.

or meltwater pulses. While the exact number and timing of these events has been debated, recent studies support the proposition that rates of sea level rise have varied over this period (see Table S1). Sea level stood close to 120 m below present at the Last Glacial Maximum (LGM) (Table S1). An initial pulse of rapid SLR may have started ~19,000 years ago, at which time ocean levels rose 10–15 m within ≤ 500 year, herein referred to as “meltwater pulse 1A₀” (Yokoyama et al., 2000; Clark et al., 2004). However, this meltwater pulse does not appear in all records (e.g., Hanebuth et al., 2000; Peltier and Fairbanks, 2006), although other paleoclimate proxies suggest a sudden influx of meltwater with accompanying changes in ocean circulation at around this time (Clark et al., 2004). Other

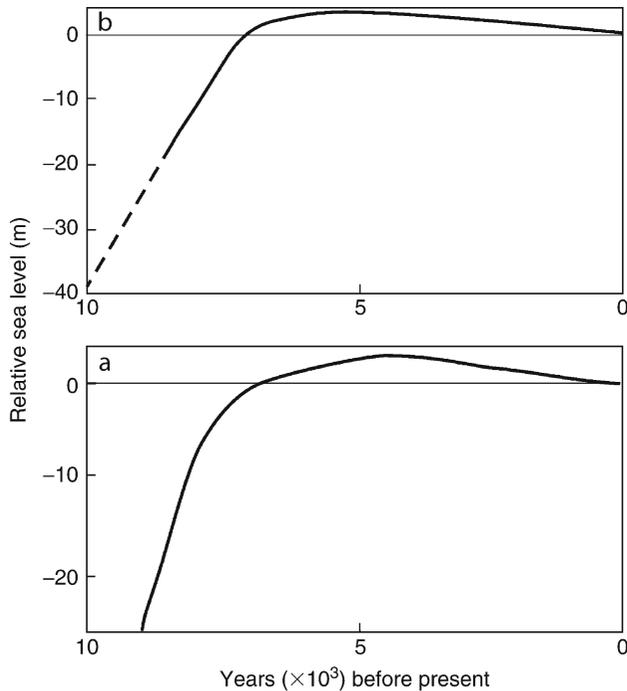

Figure S9 Schematic far field Holocene sea level curves, showing mid-Holocene land emergence. These generalized curves do not represent specific localities. (a) Equatorial ocean islands; e.g., Cocos (Keeling) Islands, Indian Ocean; Fiji Islands, Pacific Ocean. (b) Continental coastlines; e.g., eastern Australia, New Zealand, Brazil, West Africa.

data and theoretical models suggest instead that the post-glacial marine transgression may have begun as early as 26,000 years ago (Figure S10b; Peltier and Fairbanks, 2006).

Another accelerated phase of SLR occurred between 14,600 and 13,500 yBP (meltwater pulse 1A; Table S1), when sea level increased by some 16–24 m (Fairbanks, 1989; Hanebuth, 2000). Depending on its exact timing, this event has been variously associated with the first cold phase during the Bølling-Allerød interstadial or the Older Dryas (Bard et al., 1996), the Bølling warming (Kienast et al., 2003; Peltier, 2005), or the end of the Bølling (Hanebuth et al., 2000; Liu and Milliman, 2004). Kienast et al. (2003), for example, connect a sharp drop in terrigenous organic matter delivered to the South China Sea, a rapid marine incursion, and synchronous rise in ocean temperatures between $\sim 14,600$ and 14,300 yBP with the Bølling warming.

The rate of sea level rise slowed between 14,000 and 12,000 yBP during the Younger Dryas cold period. It was succeeded by a faster phase (meltwater pulse 1B) between 11,500 and 11,000 years ago. Fairbanks (1989) initially estimated that sea level jumped by ~ 28 m during meltwater pulse 1B, but subsequent studies suggest a significantly more modest increase, if at all (Bard et al., 1996; Lambeck et al., 2002).

A fourth surge of rapid sea level rise, herein referred to as “meltwater pulse 1C” has been proposed, but is less firmly established. This meltwater pulse was first identified by a hiatus in coral growth in the Caribbean at $\sim 7,600$ yBP (Blanchon and Shaw, 1995), but neither Bard et al. (1996) nor Lambeck et al. (2002) detected any noticeable increase in sea level at

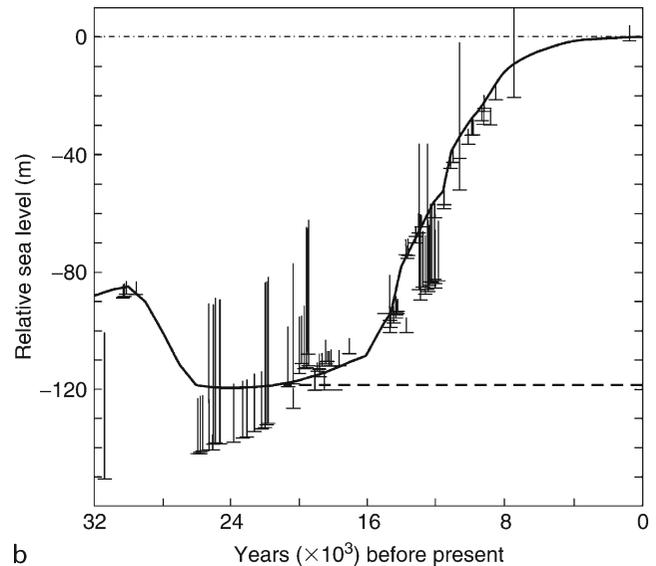

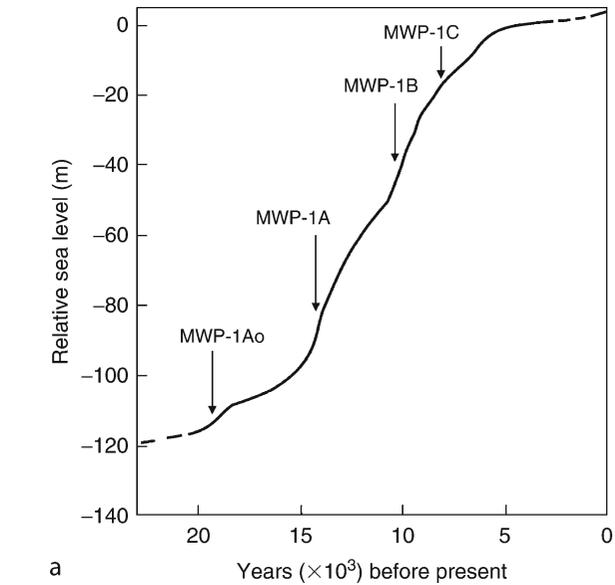

Figure S10 (a) Generalized post-glacial eustatic sea level curve (based on Fairbanks, 1989; Bard et al., 1990, 1996; Hanebuth et al., 2000; Yokoyama et al., 2000). (b) Eustatic sea level curve for the last 32 Kyr corrected for glacial isostatic adjustments using the ICE-5G (VM2) model (smooth curve). Coral data from Barbados are shown by error bars. Horizontal bars indicate depth of coral sample. Vertical bars represent the range with respect to sea level in which the coral species could live. The shortest bars (5 m) correspond to *Acropora palmata*; the intermediate bars (20 m) to *Monasteria annularis*; longer bars to either *Asteroides* or *Diploria* (modified from Peltier and Fairbanks, 2006). The latter species provide only a lower limit of relative sea level.

that time. Nevertheless, findings from diverse locations hint at a possible sudden sea level jump around 8,000 yBP. Data from Chesapeake Bay show a relatively stable period of sea level between 9,200 and 7,900 yBP, followed by a short and rapid spurt of SLR between $\sim 7,900$ and 7,600 yBP (Cronin et al., 2002). Dates on sediment cores from the Mississippi River delta constrain the episode of abrupt SLR to between $\sim 8.5 \pm 0.3$

Table S1 A review of major events associated with post-glacial sea level rise

Sea level at LGM

–121 ± 5 m (Barbados; Fairbanks, 1989)
 –118 m (Barbados; Bard et al., 1990)
 –115 ± 1 m (Sunda Shelf; Hanebuth et al., 2000)
 –125 to –121 m; –135 to –130 m (Bonaparte Gulf, Australia; corrected for glacial isostasy; Yokoyama et al., 2000)
 –123 to –119 m (Barbados; Peltier and Fairbanks, 2006)

Onset of post-glacial sea level rise

18,000 yBP (Barbados; Fairbanks, 1989)
 >19,000–18,000 yBP (Barbados; Bard et al., 1990)
 21,000–19,000 yBP (Sunda Shelf; Hanebuth et al., 2000)
 22,000–19,000 yBP (Bonaparte Gulf; Yokoyama et al., 2000)
 ≥20,000 yBP (Irish Sea; Clark et al., 2004)
 ~26,000 yBP (Barbados; Peltier and Fairbanks, 2006)

Meltwater pulse 1A₀

~19,000 yBP; rate of SLR ~33.3–50 mm yr⁻¹ (Yokoyama et al., 2000)
 19,120 ± 180 yBP; rate of SLR ~20 mm yr⁻¹ (Clark et al., 2004)

Meltwater pulse 1A

~13,000 yBP; rate of SLR, ~39 mm yr⁻¹ (Barbados; Fairbanks, 1989)
 ~13,500 yBP; ~37 mm yr⁻¹ (Barbados; Bard et al., 1990)
 ~14,000 yBP (Tahiti; Bard et al., 1996)
 14,600–14,300 yBP; rate of SLR, 53.3 mm yr⁻¹ (Sunda Shelf; Hanebuth et al., 2000; South China Sea, Kienast et al., 2003)
 14,300–14,000 yBP; rate of SLR, 65 ± 10 mm yr⁻¹ (Liu and Milliman, 2004)

Meltwater pulse 1B

~10,500 yBP; rate of SLR, 26.4 mm yr⁻¹ (Barbados; Fairbanks, 1989)
 11,000 yBP; ~25 mm yr⁻¹ (Barbados; Bard et al., 1990)
 11,300 yBP (Tahiti; Bard et al., 1996)
 11,500–11,200 yBP; rate of SLR ~40 mm yr⁻¹ (Liu and Milliman, 2004)

Meltwater pulse 1C

~7,600 yBP (Caribbean Sea; Blanchon and Shaw, 1995)
 ~8,200 yBP (Mississippi Delta; Törnqvist et al., 2004)
 ~8,000–7,000 yBP (Yellow River Delta, China; their “meltwater pulse 1D,” Liu et al., 2004)
 ~7,900–7,600 yBP; rate of SLR ~40 mm yr⁻¹ (Chesapeake Bay; Cronin et al., 2002)

Other periods of rapid sea level rise

~9,800–9,000 yBP; rate of SLR ~45 mm yr⁻¹ (their “meltwater pulse 1C”; Liu et al., 2004)

and 8.1 ± 0.1 kyBP (Törnqvist et al., 2004). Stratigraphic data from the subaqueous delta of the Yellow River, China (Liu et al., 2004), coastal Lancashire, England and Limfjord, northwestern Denmark (Tooley, 1989) also point to a more rapid marine transgression at around 8,000 yBP. Meltwater pulse 1C has been linked to the 8,200-yBP cold event (Cronin et al., 2002; Törnqvist et al., 2004), which resulted from the catastrophic drainage of proglacial Lakes Agassiz and Ojibway (Barber et al., 1999; Clarke et al., 2004).

Sources of meltwater

Among the proposed episodes of accelerated post-glacial SLR, evidence for meltwater pulse 1A is probably the strongest. This event occurred during a period of maximal ice sheet retreat. Yet, the origin of the meltwater has remained elusive. Meltwater from the breakup of the Laurentide Ice Sheet has generally been assumed to be the main contributor to the rapid SLR, mainly because of its large extent. Geophysical models suggest that sea level changes accompanying rapid melting (or growth) of an ice mass should lead to a spatially non-uniform distribution of sea level change, not only because of ice loading, but also due to gravitational attraction between the ice sheet and ocean water (Clark et al., 2002). As the ice

sheet shrinks, its gravitational attraction on ocean water will diminish and water will flow away from the edge of the ice. Therefore, different sources of meltwater (e.g., the Laurentide, Antarctic, or Barents Sea Ice Sheets) should give rise to different geographic patterns of sea level rise. The closest match between observed sea level records from various parts of the world and model predictions was found when Antarctica made a substantial contribution to meltwater pulse 1A and, in addition, a relatively high value for lower mantle viscosity was assumed (Clark et al., 2002; Bassett et al., 2005). However, from a new reconstruction of ice sheet retreat (Peltier, 2004) based on a glacial systems model that was calibrated by ¹⁴C-dated relative sea level records, geodetic measurements, and geomorphological data, Tarasov and Peltier (2005) determined instead that this meltwater pulse derived largely from North American sources. Furthermore, varved sediments containing diatomaceous ooze from fiords in East Antarctica record the onset of ice sheet recession there at 11,500–10,500 yBP, long after meltwater pulse 1A (Leventer et al., 2006). Thus, Antarctica was not a likely contributor to this meltwater surge. In addition, comparison of relative sea level data from Barbados and the Sunda Shelf, off Indonesia, reveals differences in magnitude of the meltwater pulse 1A at these two far field locations that are much too small to attribute to a specific geographical source (Peltier, 2005).

The signals for meltwater pulse 1B and meltwater pulse 1C are less distinct than that of meltwater pulse 1A. Meltwater from glacial Lake Agassiz has long been thought to have triggered thermohaline circulation changes that led to the Younger Dryas cold period (12,800–11,600 yBP), just prior to meltwater pulse 1B. However, new dates on moraine deposits show that regional deglaciation occurred nearly 1,000 radiocarbon years later than the Younger Dryas (Lowell et al., 2005), and hence Lake Agassiz was not the likely source of meltwater pulse 1B. Instead, glacial models show a period of increased meltwater discharge between 12,900 and 12,800 yBP, originating from outflow into the Arctic Ocean, the Fram Strait, and ultimately the eastern North Atlantic (Tarasov and Peltier, 2005). They suggest that this event may have triggered the Younger Dryas cold reversal, although it has not left a discernable sea level record. On the other hand, the timing of deglaciation in eastern Antarctica roughly coincides with the onset of meltwater pulse 1B (Leventer et al., 2006).

As noted above, meltwater pulse 1C can be identified in a number of widely separated geologic records. This meltwater pulse has been attributed to the catastrophic drainage of proglacial Lakes Agassiz and Ojibway around 8,400 year ago (Barber et al., 1999; Clarke, et al., 2004). The volume released by the sudden outburst flood was ~10⁵ km³ within a few years, or even less. Although this enormous influx of freshwater to the world's oceans probably triggered the 8.2 kyr cold event (see Alley and Ágústsdóttir, 2005; *the 8,200-yBP event*, this volume), the effects on global sea level appear to have been relatively modest. The resulting increase in sea level (assuming an even distribution of this volume over the world's oceans) was only on the order of 1 m or less (Barber et al., 1999; Clarke et al., 2004; Törnqvist et al., 2004). Nevertheless, this minor change in sea level left an imprint in the stratigraphic record.

Middle to late Holocene sea level

By the mid-Holocene, ~6,000–5,000 yBP, glacial melting had essentially ceased. However, glacial isostatic and hydro-isostatic adjustments persisted, although at decreasing amplitudes over

time. Therefore, sea level continued to lower in formerly glaciated regions and rise in areas of the collapsing forebulge. At many equatorial far field ocean island sites, sea level stood several meters higher than present during the mid-Holocene, ~6,000–4,000 yBP, and has been falling slowly ever since (e.g., Dickinson, 2001). This phenomenon has been explained to be a consequence of lithospheric responses due to changes in ice and water loading (Mitrovica and Peltier, 1991; Mitrovica and Milne, 2002). Water is “siphoned” away from the central equatorial ocean basins into nearshore depressions left by the collapse of peripheral forebulges. In addition, the oceanward tilting of far field continental coastlines (“continental levering”) because of hydro-isostasy also leads to migration of ocean water away from central equatorial ocean basins toward the continents (Figure S11). Mid-Holocene sea level high-stands have also been interpreted as eustatic in origin, likely related to minor climate fluctuations. Support for this view comes from well-dated sessile intertidal tubeworms from Western Australia, which show several episodes of higher than present sea level, ranging between 6,000 and 2,000 yBP (Baker et al., 2005). These events are also detected in Antarctic ice cores and several paleosea level proxies elsewhere.

The sea level record of the last 4,000–3,000 years is less-well constrained, in spite of its importance as a baseline for understanding contemporary sea level trends. In part, this arises from a paucity in accurately-dated high resolution sea level proxies, as well as difficulty in extracting a global climatic signal from low-amplitude oscillations. Minor sea level fluctuations of 1–2 m have been reported in a number of records (e.g., Finkl, 1995; Scott et al., 1995a,b; Varekamp and Thomas, 1998). These

probably record local to regional climate-related processes, such as variations in river discharge, storm deposition, or coastal sedimentation, rather than true eustatic changes in sea level.

Recent sea level rise

Twentieth century mean global sea level, determined from tide gauges in coastal harbors, has been increasing by 1.7–1.8 mm yr⁻¹ (Figure S12; Church et al., 2004; Holgate and Woodworth, 2004; Church and White, 2006), apparently related to the recent climatic warming trend (Church et al., 2001, IPCC, 2007). An even higher sea level trend of ~2.8 mm yr⁻¹ has been obtained from the TOPEX/POSEIDON satellite altimeter, since 1993 – a period strongly influenced by major El Niño-Southern Oscillation (ENSO) events, when sea surface temperatures and hence thermal expansion were higher than normal over large portions of the oceans. Nevertheless, analysis of tide-gauge data over a longer period, from 1870 to 2004, shows a twentieth century acceleration in global sea level of 0.013 ± 0.006 mm yr⁻² (Church and White, 2006).

The twentieth century sea level trends are substantially higher than those of the last few thousand years, derived from geological data (Shennan and Woodworth, 1992; Gornitz, 1995; Varekamp and Thomas, 1998; Donnelly et al., 2004). The exact timing for the onset of the current accelerated phase is uncertain because of limited instrumental data prior to the 1850s and lack of high resolution proxy sea level data for the last few thousand years. Although Varekamp and Thomas (1998) claim that the acceleration began at least 200 years ago, other studies point to a mid-late nineteenth century to early twentieth century onset (e.g., Donnelly et al., 2004; Gehrels et al., 2005; Church and White, 2006).

Summary and conclusions

The melting of the ice sheets at the end of the last glaciation, beginning at least 20,000 and possibly as early as 26,000 years ago, produced a rapid rise in sea level of some 120 m, spanning a period of 13,000 years. The post-glacial sea level rise was temporally non-uniform and several periods of more rapid rise may have occurred: ~19,000 yBP (meltwater pulse 1A₀); 14,600–13,500 yBP (meltwater pulse 1A); 11,500–11,000 yBP (meltwater pulse 1B); and 8,200–7,600 yBP (meltwater pulse 1C). However, evidence for some episodes (e.g., meltwater

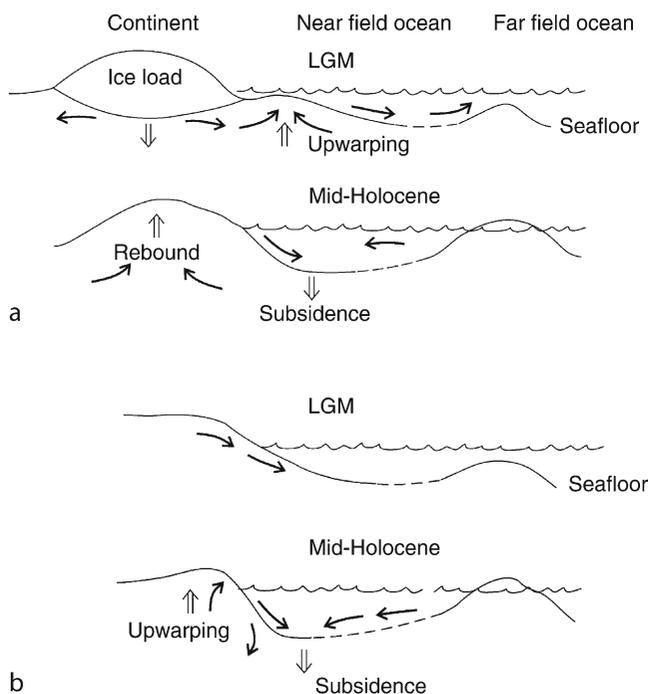

Figure S11 Schematic diagram illustrating processes contributing to mid-Holocene sea level maximum, and subsequent fall, at far field sites (not drawn to scale). (a) Ocean “siphoning” due to flow of water from far field oceans toward collapsed forebulge. (b) “Continental levering” due to ocean loading by meltwater.

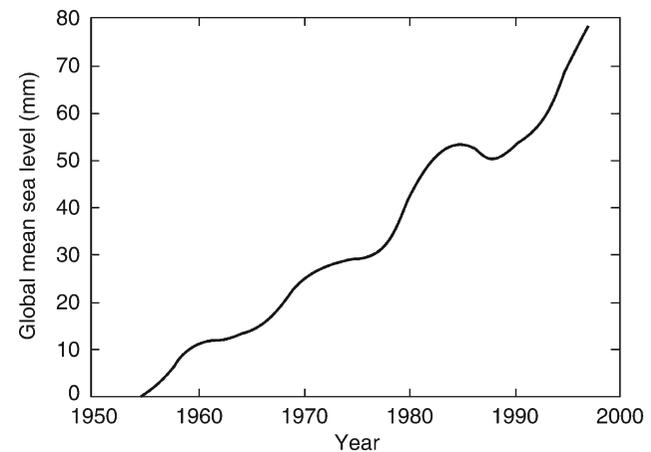

Figure S12 Recent global sea level rise, 1948–2002, from tide gauge data corrected for the effects of glacial isostatic adjustments (after Holgate and Woodworth, 2004).

pulse 1A) is stronger than for others (e.g., meltwater pulses 1A₀, 1C) and further research is needed to confirm dates and magnitudes. During the last 6,000–5,000 years, eustatic sea level changes have been relatively minor after melting of major ice sheets essentially ceased; however, crustal adjustments to glacial and hydro-isostasy have continued, although at diminishing rates, leading to variations in long-term sea level change at different localities. The mid to late Holocene emergence (i.e., apparent sea level fall) of many tropical ocean islands and shorelines has generally been attributed to ocean “siphoning” and continental “levering.” Evidence for low-amplitude Holocene sea level oscillations has been reported from a number of localities, but it remains to be determined whether these represent true eustatic (i.e., global) events or regional to local variability. A recent acceleration in the rate of sea level rise (~1–2 mm yr⁻¹) began within the last 150–100 years and appears to be related to recent global warming (Church et al., 2001, IPCC, 2007).

SEA LEVEL CHANGE, QUATERNARY

Relative to the land-masses, the position of sea level has fluctuated throughout the geologic past, owing to changes in both the quantity of ocean water and the geometry of the ocean basins. The total volume in the hydrosphere (water plus ice) appears to have been constant but the fractions held in land reservoirs – glaciers, lakes, groundwater and, in particular, continental ice sheets – fluctuated significantly. For example, if the present Antarctic Ice Sheet were to melt, sea level would rise by about 55 m; at the height of the last ice age, sea level was about 120–130 m below its present position.

The proportions of land and sea are basically determined by the fact that continents, being composed of rock lighter than oceanic crust, stand about 4.5 km above the ocean floor. However, owing largely to slow variations in the rates of sea floor spreading and plate tectonics, the average depth of the ocean basins has varied throughout geological time and shorelines have periodically advanced and retreated across the continental shelves. [Figure S13](#) illustrates examples of observed sea level change on time scales from about 10⁴ to 10⁸ years. On the

longer timescale, sea level changed globally with amplitudes up to several hundred meters, largely owing to plate-tectonic changes in ocean basin geometry ([Figure S13a](#)). During the Quaternary Era, periodic exchanges of mass between the ice sheets and oceans caused sea level changes of tens to over a hundred meters in amplitude, on time scales of tens to hundreds of thousands of years ([Figure S13b](#)).

Global changes of sea level caused by changes in the volumes of seawater or the ocean basins are referred to as eustatic. Superimposed on these global signals are more regional and local changes, where the relative positions of land and sea are affected by uplift or subsidence of the coastal zone. Observations vary substantially from site to site, even over relatively short distances such as in northwestern Europe, where sea level at Ångerman has fallen nearly 200 m in the past 9,000 years, while at Andøya the level 9,000 years ago was near its present position and in southern England was about 35 m below the present shoreline ([Figure S14](#)).

Several interlinked factors contribute to changes in sea level. When ice sheets melt, the resulting sea level change is spatially variable because the Earth's surface deforms under the changing ice and water load, and the gravitational potential of the Earth-ocean-ice system also changes. The combined deformation-gravitational effects are referred to as glacio-hydro-isostatic contributions to sea level, and it is these effects that cause the spatial variability illustrated in [Figure S14](#). Isostatic warping and subsidence also occur in sedimentary basins, in response to the accumulation of sediments many kilometers deep over millions of years. Furthermore, *tectonic* movements drive mountain uplift, enhancing landscape denudation and leading to rapid accumulation in sedimentary basins; they also contribute to changes of relative sea level through coastal uplift or subsidence.

Knowledge of the complex history of Quaternary changes of sea level is relevant in diverse fields, including the understanding of climate changes, and the determination of deep-earth properties such as the viscosity of the Earth's mantle. Once comprehensive sea level models are developed, it becomes possible to test hypotheses about Quaternary migrations of flora and fauna across shallow seas that are now covered by ocean. Moreover, to understand future sea level rise under atmospheric greenhouse conditions, the background “natural” signal must be known. The success of sea level studies depends very much on the ability to separate the different contributions – eustatic, isostatic and tectonic – in the observational record.

Observational evidence

Direct evidence for Quaternary sea level changes occurs mostly in the form of sediments and biohermal reefs that were formed in coastal and nearshore situations. Upper Quaternary sea level changes are usually pieced together from raised or submerged shoreline features, including shallow-water coral reefs ([Figure S15](#)). Further back in time, relative sea level changes can be deduced from sedimentary basins, in which eustatic variations are registered in cyclic sediments (cyclothem) that show alternating transgressions and regressions of the sea ([Figure S16](#)). Using evidence from seismic, drill-hole and outcrop data, the locus of coastal-zone sedimentation can be traced throughout a given basin sequence, allowing the course of sea level changes relative to the basin to be identified (Hallam, 1992).

A relative sea level curve for a given area can be established from age-height data for a series of ancient shorelines, or other indicator deposits such as shallow marine sediments for which

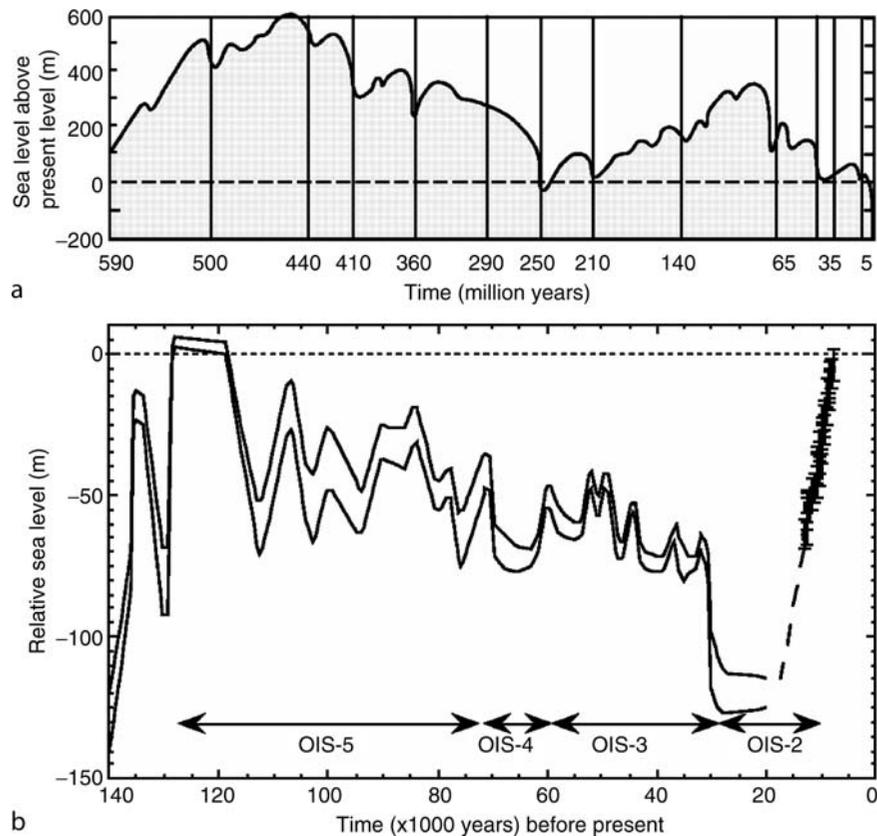

Figure S13 Sea level variation at two time scales. (a) $\sim 10^8$ years, inferred from seismic sequence stratigraphy (Haq et al., 1987; Hallam, 1992). The higher frequency changes reflect both global and local effects; the large, slow changes reflect continental breakup and changes of ocean ridge systems. (b) $\sim 10^5$ years of relative sea level at Huon Peninsula (HP), Papua New Guinea, driven by changes in northern continental ice sheets. Bars show marine oxygen isotope stages (OIS) discussed in text (from Lambeck and Chappell, 2001).

the depth of deposition relative to sea level is determinable. Terrestrial deposits within a sequence, such as peats and floodplain sediments, may usefully indicate levels not reached by the sea. Various methods are used to establish the ages. For deposits less than $\sim 40,000$ years old, radiocarbon dating is used widely, although uranium-series dating is preferable in the case of coral formations and has a time range that extends to ~ 0.5 Myr. Thermoluminescence (TL) and optically-stimulated luminescence (OSL) methods are increasingly used for dating Upper Quaternary shoreline deposits, and amino acid racemization has proven to be useful despite its low precision. Sea level indicator deposits also are correlated to marine oxygen isotope records, described later, that have a chronology based on slow variations in the Earth's orbit, which affect the seasonal receipts of solar radiation and acted as an ice-age pacemaker. Orbital chronology rests on astronomical observations and has been extrapolated several million years into the past. Wherever possible, the dating of older Quaternary and pre-Quaternary deposits is tied to geomagnetic reversal chronology, which in turn is secured by potassium-argon dating methods.

Separation of eustatic, isostatic and tectonic components

Raw separation of uniform uplift or subsidence

A first step towards separation of the tectonic, isostatic and eustatic contributions is subtraction of any obvious vertical

crustal movements from a relative sea level curve. More often than not, this is done by assuming that the sea level for some reference deposit in the record is known and that the rate of uplift (or subsidence) was constant throughout the duration of the record. With these assumptions, the local sea level S represented by a deposit of age t that accumulated at depth d below sea level and now is height H above present sea level, is given by

$$S = H + d - Ut, \text{ with } U = (S_r - H_r + d_r)/t_r \quad (1)$$

where H_r , d_r and t_r are height, depositional depth and age of the reference deposit, and S_r is the sea level at its time of formation. For Upper Quaternary studies, the local height of the Last Interglacial shoreline is widely used to determine uplift rate U , as evidence at tectonically stable sites indicates that the Last Interglacial sea level was 5 ± 2 m above present level, 120,000–127,000 years ago (Chappell et al., 1996). However, for every study, each variable in Equation 1 has an error term arising from dating errors and uncertainties in field relationships. Moreover, in assuming a constant rate of uplift, this approach neglects reversing vertical movements that arise from the global glacio-hydro-isostatic response to advancing and retreating ice sheets. Figure S13b shows the “uplift-free” sea level curve derived by this method from the coral terraces illustrated in Figure S15.

Similar principles are used to derive sea level changes from sedimentary basin sequences, although here the vertical

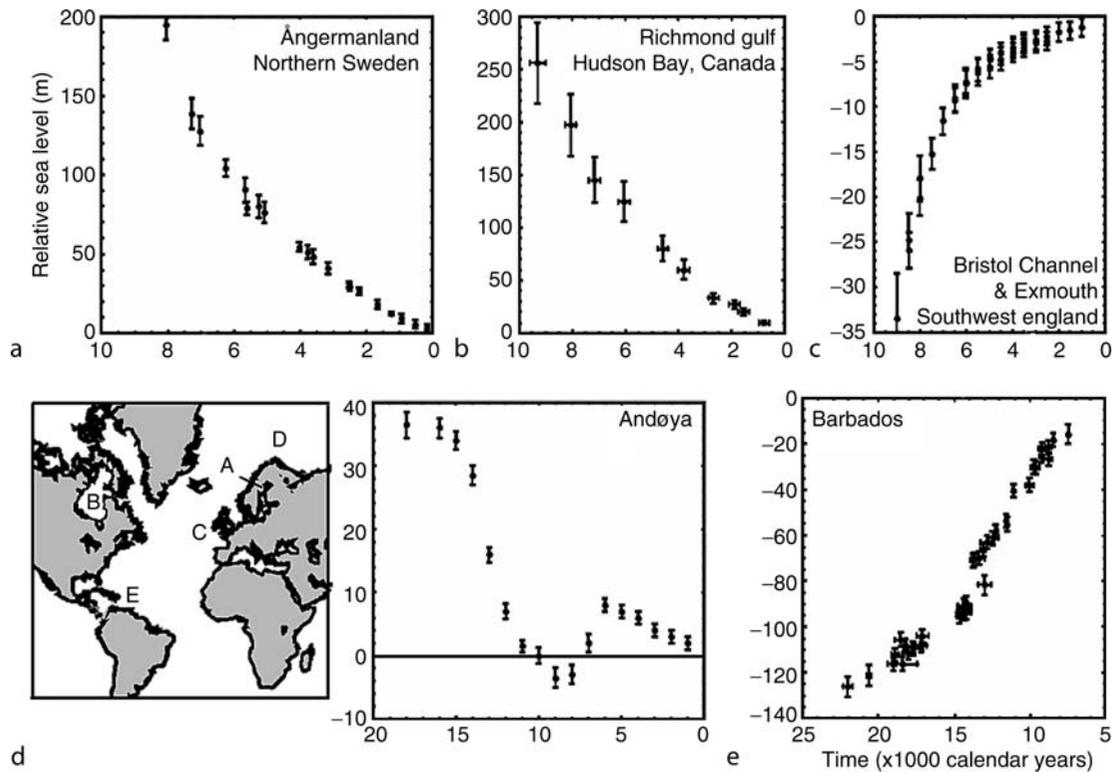

Figure S14 Observed variability of sea level change. Graphs a–c show sea level over the last 10,000 years relative to Ångerman, Gulf of Bothnia, Sweden; Richmond Gulf, Hudson Bay, Canada, and southwest England. Sites A and B were formerly covered by ice sheets and the fall of relative sea level largely reflects isostatic uplift of the land since the ice melted, whereas southwest England lay outside the ice-covered region and rising sea level in this area largely reflects the influx of ice meltwater to the oceans. The counteracting effects of isostatic uplift and ocean increase are reflected in complex sea level changes over the last 20,000 years at Andøya in Norway (d), whereas the ocean increase dominates at sites remote from the former ice sheets, such as Barbados (e) (data sources given in Lambeck and Chappell, 2001).

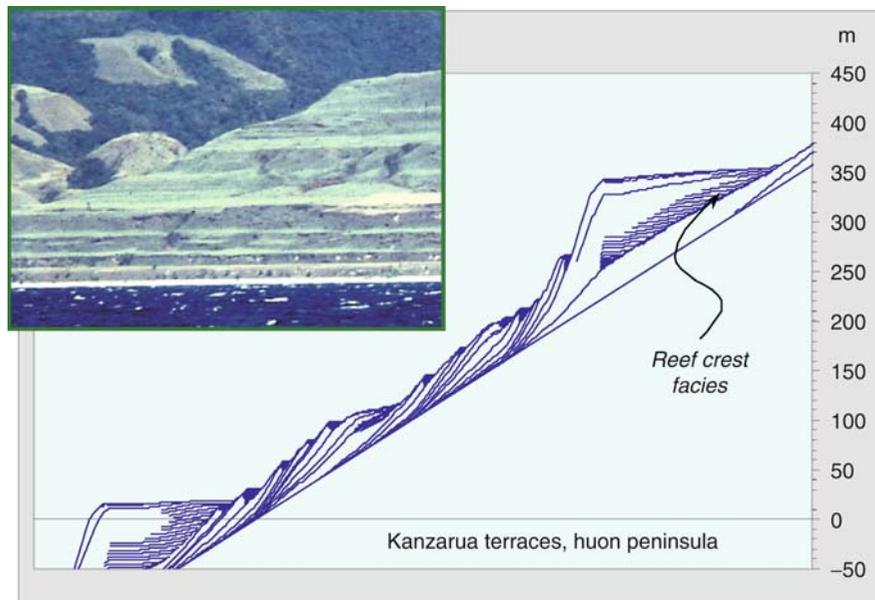

Figure S15 Typical expression of Late Quaternary sea level changes superimposed on tectonically rising terrain: coral terraces Huon Peninsula, Papua New Guinea. The top terrace at right of the inset photo is 350 m a.s.l. and formed at the beginning of the Last Interglacial, ~127,000 years ago. Each of the smaller reef structures within the downstepping stratigraphic sequence was formed during a sea level oscillation within the last glacial cycle. Subtracting the effect of uplift yields the sea level curve shown in Figure S13b.

movement is downwards. In terms of sedimentary facies, individual cyclothem sequences often are very similar from bottom to top of a thick cyclothem sequence (Figure S16), implying fairly uniform subsidence of the basin.

Glacio-hydro-isostasy

When ice sheets melt, to a first approximation the sea level rises by an amount $\Delta\zeta_e(t)$ related to the land-based ice volume V_i (using the notation of K. Lambeck: see Lambeck and Chappell, 2001),

$$\Delta\zeta_e(t) = -(\rho_i/\rho_o) \int (1/A_o(t)dV_i/dt)dt \quad (2)$$

where $A_o(t)$ is the ocean surface area (which changes as sea level rises or falls) and ρ_i , ρ_o are the average densities of ice and ocean water, respectively. $\Delta\zeta_e(t)$ is the ice-volume equivalent sea level change (or equivalent sea level change), which equals eustatic change if no other factors contribute to changes in ocean volume. The relative sea level change $\Delta\zeta_{\text{rsl}}(\varphi, t)$ at position and time t , ignoring tectonic displacements, is

$$\Delta\zeta_{\text{rsl}}(\varphi, t) = \Delta\zeta_e(t) + \Delta\zeta_i(\varphi, t) + \Delta\zeta_w(\varphi, t) \quad (3)$$

where $\Delta\zeta_i$ and $\Delta\zeta_w$ are the glacio- and hydro-isostatic contributions. Both are functions of position and time. The water depth or terrain height, expressed relative to coeval sea level, is

$$h(\varphi, t) = h(\varphi, t_0) - \Delta\zeta_{\text{rsl}}(\varphi, t) \quad (4)$$

where $h(t_0)$ is the present-day (t_0) bathymetry or topography at φ . Both isostatic terms in Equation 3 are functions of Earth rheology as well as of fluctuations in the ice sheets over time.

In formerly glaciated areas, the glacio-isostatic term $\Delta\zeta_i(\varphi, t)$ dominates during and after deglaciation, and leads to uplift at a rate that can exceed the global eustatic rise, so that sea level locally falls (the Ångerman result: Figure S14). Rebound is smaller near the ice margin and although it may dominate initially, the global sea level rise becomes important later. When all melting has ceased, the residual rebound leads to falling local sea level (the Andøya result: Figure S14). During ice sheet growth, mantle material beneath the loaded area is displaced outward and broad bulges develop around the perimeter, which subside when the ice melts, leading to local sea level that slowly rises after melting has ceased. Much further from the ice, the water load becomes the dominant cause of planetary deformation (the hydro-isostatic contribution $\Delta\zeta_w(\varphi, t)$), producing subsidence of the sea floor and adjacent margins. The effect is most pronounced at continental margins far from the ice sheets, such as the Australian coast, and once melting has ceased, sea levels continue to fall at a slow but perceptible rate. The amplitude of this postglacial “highstand” effect can vary by several meters from site to site.

Isostatic corrections and a global eustatic curve can be derived from local sea level curves, using a rheologically appropriate earth model to predict surface deformation in response to changing ice and water loads, with the ocean surface remaining a gravitational equipotential surface at all times. The sea level signal at sites far from the former ice margins approximates the equivalent sea level function to about 10–15% and the isostatic contribution is mainly from water loading, which is insensitive to the details of the ice sheets, provided that the total ice volumes are correct to within about 10–20%. Hence, through an iterative procedure, it becomes possible to estimate

changes in ice volumes V_i from observed sea level changes $\Delta\zeta_{\text{rsl}}(\text{obs})$, using Equations 2 and 5:

$$\Delta\zeta_{\text{rsl}} = \Delta\zeta_{\text{rsl}(\text{obs})} - (\Delta\zeta_i + \Delta\zeta_w) \quad (5)$$

The use of local sea level curves from widely separated places allows earth rheology parameters and models of ice distribution to be evaluated. Recent models include deformation of the basins over time, movement of grounded ice across the shelves, modification of sea level by the time-dependent gravitational attraction between the solid earth, ocean, and ice, and the effect of glacially induced changes in earth rotation on sea level.

Sea level through the Last Glacial Cycle

Sea level data for the last glacial cycle are more plentiful than for earlier periods and at Huon Peninsula, Papua New Guinea provide a near-complete relative sea level curve (Figure S13b), which has been used for reconstructing ice-equivalent sea level for the past 140,000 years (Lambeck and Chappell, 2001). Results indicate that ice melting has varied since the Last Glacial Maximum, with two periods of rapid sea level rise from ~16,000 to 12,500 and from 11,500 to 8,000 years ago, separated by the Younger Dryas cold episode when sea level seems to have risen less rapidly. By 7,000 years ago, the northern ice sheets except for Greenland had gone and ocean volume approached its present level, but Antarctic ice melting may have since contributed a few meters of equivalent sea level.

The Last Interglacial, when sea level was similar to the present, ended about 118,000 years ago with rapidly falling sea level, associated with the growth of northern continental ice. Cyclic sea level changes from 118,000 to ~60,000 years ago reflect the effect of the 20,000-year orbital precession cycle on the ice sheets, although other fluctuations also appear. These occur repeatedly about every 6,000 years from ~60,000 to 30,000 years ago, with amplitudes of 10–15 m, and each rise apparently coincides with a major episode of ice-rafted sediment deposition recorded in the North Atlantic, suggesting that the rise was caused by a large, rapid discharge of continental ice (Chappell, 2002).

Oxygen isotopes and long sea level records

Long, continuous records of oxygen isotopes in calcareous foraminifera preserved in deep-sea sediments have become standard records of Quaternary sea level and temperature changes. The oxygen isotope ratio in foraminifera, conventionally expressed as $\delta^{18}\text{O}$ (the ‰ difference of $^{18}\text{O}/^{16}\text{O}$ in a sample from an international standard), depends on the temperature and isotope ratio of the seawater in which they lived. Furthermore, the seawater isotopic ratio is related to the size of polar ice sheets, because ^{18}O is preferentially removed from atmospheric water vapor as it makes its way poleward, causing the icecaps to be depleted in ^{18}O relative to seawater by ~25–55‰, varying with atmospheric temperature. Thus, foraminiferal isotopes $\Delta\delta^{18}\text{O}_f$ respond to ice volume changes ΔV_i according to

$$\Delta\delta^{18}\text{O}_f \approx \delta^{18}\text{O}_i \Delta V_i / V_w + C_T \Delta T + \varepsilon \quad (6)$$

where ΔV_i is relative to present day V_i , V_w is the present volume of seawater (mean $\delta^{18}\text{O}$ of modern seawater = 0‰_{SMOW}), C_T

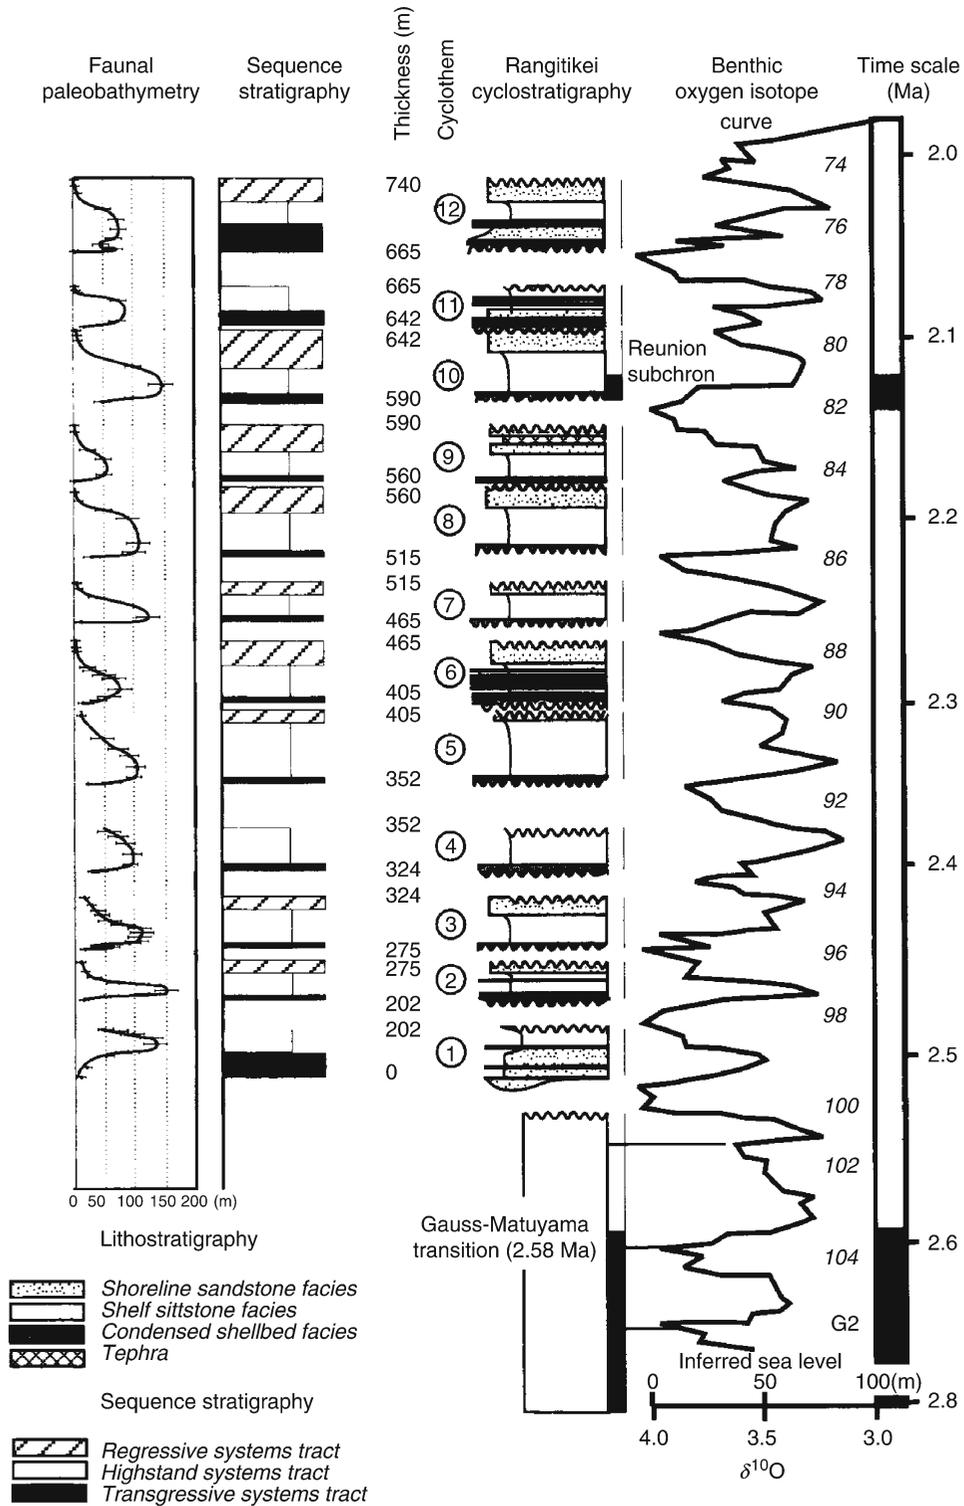

Figure S16 Late Pliocene sea level changes inferred from shallow marine cyclothem in New Zealand. Centre columns show 12 sedimentary cycles; left column shows cyclic variations of water depth at the site of sedimentation, inferred from fossil marine invertebrates. Correlations to global marine oxygen isotope cycles (Shackleton et al., 1995) are shown to the right, tied to magnetic reversal chronology (from Pillans et al., 1998).

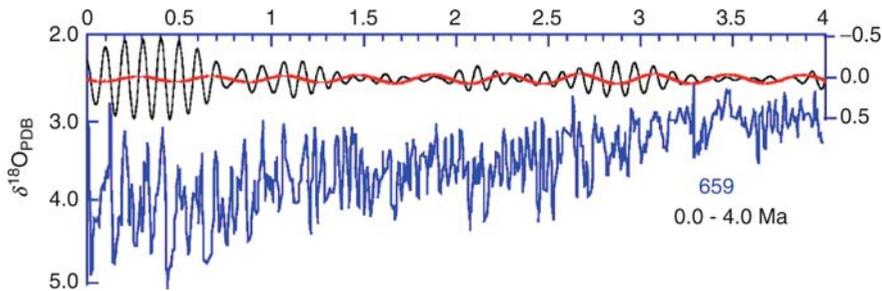

Figure S17 Marine oxygen isotope variations for last 4 Myr indicate sea level changes associated with glacial cycles. The first cycle at the left represents the general curve for the last glacial cycle, shown in detail in Figure S13b. The increase of amplitude in $\delta^{18}\text{O}$ cycles around 2.6 Myr represents the onset of large fluctuations of ice sheets and sea level, which become even more pronounced around 1 Myr, when they adopt a characteristic period of $\sim 100,000$ years. The upper curve shows the changing amplitude of the 100,000 year cycle (after Zachos et al., 2001).

is the coefficient of temperature-dependent isotope fractionation for calcite ($-0.23\text{‰ } ^\circ\text{C}^{-1}$), ΔT is temperature change, and ε represents any local change of seawater $\delta^{18}\text{O}$ not related to ΔV_i . (Equation 6 is approximate because the mean isotopic composition of the ice sheets $\delta^{18}\text{O}_i$ is assumed constant, but the uncertainty here probably is smaller than the effects of ice volume and temperature). Finally, the first term on the right hand side of Equation 6 can be expressed in terms of equivalent sea level $\Delta\zeta_e$: comparison of isotopes and sea levels for the last glacial cycle indicates that $\Delta\delta^{18}\text{O}_w/\Delta\zeta_e \sim -0.009\text{‰ m}^{-1}$.

The numerical value of $\delta^{18}\text{O}_f$ becomes increasingly positive under a fall of both sea level and temperature. Thus, the isotopic affect of temperature and ice-volume changes are additive and the two factors can be decoupled if one or the other is known. After removing the temperature effect, isotopic sea levels for the last glacial cycle derived by Shackleton (1987) compare favorably with Figure S13b. Comparisons further back in time are also encouraging: for example, Figure S14 illustrates typically close correspondence between sea level and isotopic cycles in Late Pliocene times. Thus, oxygen isotopes in continuous deep-sea cores provide proxy records of equivalent sea level (ice volume) changes through and beyond the Quaternary that reveal both progressive global cooling and the onset of ice-driven sea level cycles in the Pliocene (Figure S17). As the history of ocean temperature becomes increasingly well determined, through trace-element analysis of microfossils and other techniques, the sea level contribution in long isotope records is now being isolated (see Zachos et al., 2001).

Shoreline reconstructions and geomorphologic effects

Once a global eustatic curve $\zeta_e(t)$ is established, the course of shoreline changes through time can be predicted. Provided that the present-day shallow water bathymetry is known with high resolution, water depths for any region at any time within the range of the eustatic curve follow from Equation 4, and the paleo-shorelines at time t correspond to the contours $h(\varphi, t) = 0$. Thus, it becomes possible to examine the migrations of shorelines through time for intervals for which sufficient observational data exist to constrain the isostatic variables. Predictions of shorelines since the time of the Last Glacial Maximum have been published for both global and regional reconstructions, which can provide useful insights into the interpretation of prehistoric sites. As Lambeck (1996) has shown, for example, the interpretation of post-Palaeolithic archaeology of the Aegean is intimately linked to reconstructions of shoreline changes, which were a powerful factor in trade and changing human activities in the region.

Rising sea level since the Last Glacial Maximum led to widespread changes in coastal regions. Under the influence of ice-age low sea levels, today's coastal valleys tended to become incised well below present sea level and then became traps for floodplain aggradation when sea level rose, as ice sheets retreated. The alternation of incision and aggradation doubtless was repeated in each glacial cycle throughout the Quaternary, leading to development of broad floodplains on thick sediment valley-fills, which in tectonically stable regions often extend hundreds of kilometers inland. Near-coastal limestone regions under the influence of low sea levels developed vadose karst systems below present sea level, including stream passages and speleothem formations. At coastlines, a range of landforms from drowned valleys through sand-barrier basins to estuarine and deltaic plains were the result of the post-glacial sea level rise, the particular form depending on sediment supply, tidal range and wave energy. In tropical seas, coral reefs were re-established after being reduced by subaerial erosion during glacial-age lowstands.

In tectonically stable terrain, the geomorphic expression of any given Quaternary sea level cycle tends to overprint the record of earlier cycles. In contrast, tectonic uplift results in flights of coastal terraces built at times of high relative sea level (e.g., Figure S15) that often pass inland into flights of river terraces. However, even though a terraced river-valley may grade to present sea level, not all its terraces necessarily relate to sea level highstands. Where continental shelves are broad, a river carrying sufficient fluvial sediment, when sea level was low and the coast far seawards of its present position, may have aggraded to a level higher than the recent floodplain, which thus becomes inset below a Pleistocene lowstand terrace. Given the tendency for all such features to become degraded and overprinted, the geomorphic legacy of past sea levels – while very sharp for recent events – becomes increasingly blurred with time. From this fact springs the irony that, beyond the last glacial cycle, Quaternary sea level changes have become better determined from isotope records in deep sea sediments than from ancient coastal features themselves.

 Sea Level Change, Post-Glacial

SEA LEVEL INDICATORS

Indicators for sea level change encompass direct instrumental evidence of recent changes in sea level at local and global scales to proxy indicators for former sea level variations over the past millennia. The evidence for sea level changes since the late nineteenth century has been mostly derived from tide gauges. However, our knowledge of the sea level record prior to this has been drawn from sources as disparate as former shoreline positions to geochemical and paleoecological data reflecting past changes in local mean tide levels. Considering the variety of indicators, differing widely in timescale, spatial coverage, and accuracy, it is not surprising that they pose considerable problems for the researcher attempting to reconstruct and understand the sea level record.

Instrumental records

Instrumental records for sea level change first appeared in the late seventeenth century in Western Europe. Until the advent of satellites capable of measuring global changes in the ocean surface, instrumental indicators for sea level change – the precision and reliability of the instruments changing with improvements in technology – actually recorded changes in tidal levels over time; variations in mean sea level for an area could be deduced from these data. Because such records are *site-specific*, there has been considerable discussion concerning how such an inherently local nature for sea level change relates to global and even regional sea level trends. In some cases, depending on how the instrument was deployed and monitored, the tidal records derived – and the changes in mean sea level

inferred from them – may have very little to do with the regional sea level history of an area. Historically, many of the instruments for delineating changes in tidal levels were located in ports to aid navigation. Later changes in harbor tidal hydrography from port construction and modification, and even the sinking of docks upon which the instruments were placed into soft, unconsolidated sediments, often introduced considerable errors. Methods (largely statistical) exist for highlighting potential errors in instrument records. These can be augmented by archival evidence for port construction and modification. In particular, comparable instrumental records for sites elsewhere in the region can be very useful in identifying discrepancies. However, such methods may not always be able to pinpoint smaller, but still cumulatively significant, errors due to human activities. Generally, the more recent the instrumental records, the more they are likely to be reliable and free of error – older records should always be approached with caution.

The first instrumental records were derived from a very simple instrument, the tide staff, or graduated staff or rod anchored along a shoreline or dock. Unless monitored throughout the course of the tidal cycle, most early tide staff records were often records of changes in the mean high water mark, the evidence being the highest wetted mark left on the staff. Depending on whether the staff was protected from wave activity, reading the mean high water level accurately as waves rose and fell could be challenging, and making judgment of actual water levels was difficult. Nonetheless, tide staff records comprise the oldest instrumental records of sea level change available; and in the case of the Amsterdam record (Mörner, 1973), extend back to the late seventeenth century, one of the coldest periods of the Little Ice Age.

Since the late nineteenth century, modern tide gauges (mareographs) have provided detailed evidence on tidal variations as indicators of sea level variation. Although problems reflecting such effects as port construction and harbor dredging on tidal hydrography (and the sea level signal) plague many early tide gauge records, modern tide gauges – protected from the “noise” of waves on the tidal signal by stilling wells – yield high precision measurements of daily, monthly and annual tidal variations at a locality. Increasingly automated and capable of downloading tidal data by telemetry, tide gauges are the source for much of what is known about twentieth century sea level rise. They have also revealed considerable information on seasonal (intra-annual), yearly (inter-annual) and longer-term (decadal) fluctuations in regional and global sea level trends (Douglas, 2001). Little progress would have been made in the last two decades toward understanding the linkages between global climatic fluctuations and sea level changes without tide gauge data, though the worldwide rate of sea level rise documented by these records has proved remarkably amenable to interpretation (see Douglas, 1991).

Perhaps the greatest limitations confronting the use of tide gauge records as sea level indicators are the often-short lengths of record available for many areas (especially for developing countries) and the concentration of some of the longest and most continuous archives for the Northern Hemisphere (especially, Northern Europe and Eastern North America). With respect to length of record, 60 years is now recognized as the minimum timescale for which reliable determination of average rates of sea level rise may be made from tide gauge records (Douglas, 2001). The latter problem concerns the lingering effects of glacio-isostasy associated with the Laurentide (North America) and Fenno-Scandinavian (Northern Europe) Ice sheets,

which complicate the delineation of purely eustatic trends in tidal records. Rheological models (e.g., Peltier, 2001) allow for some correction (“detrending”; Douglas, 1991) of northern hemisphere tide gauge records for the phenomena of postglacial rebound and forebulge collapse (for the Atlantic Coast of North America, the hingeline between the two is approximately in the region of the Hudson River estuary). Ultimately, satellite altimetry (e.g., Topex/Poseidon), showing the ocean surface model, should address the spatial limitations of tide gauge data. A recent attempt has been made to reconcile tide gauge data with the ocean surface changes observed from the Topex/Poseidon satellite (Cabanès et al., 2001).

Shoreline features

Ancient shorelines above mean sea level have long been viewed as one of the more persuasive indicators of sea level change. In the last several decades, technological advances like high-resolution seismic stratigraphy (in particular, bottom profilers) have extended the search for evidence of former shorelines to the inner continental shelves of many areas. Nonetheless, though the potential suite of ancient shorelines to be investigated is no longer limited to subaerial features, controversies surrounding whether some fossil shorelines have anything really to do with global sea level trends have not abated. No one argues that former shorelines do not represent a change in mean tide level locally for a sustained period (in some cases, even this argument has been hard to make); rather, the argument centers on whether the change in the elevation of tidal frame was driven by global (i.e., climatic) fluctuations, or was the result of tectonics or possibly even coastal storms. The answer generally lies in the type of feature observed.

Ancient reefs

In the warm tropical waters where ambient temperatures average about 26 °C, coral polyps are able to construct reefs, which over time can build large reef complexes exemplified by the Great Barrier Reef (about 18 million years old). Some of the strongest evidence for global sea level (and climatic with respect to Milankovitch cycles) changes during the Quaternary comes from fossil reefs in Barbados (Mesoletta et al., 1969) and New Guinea (Bloom et al., 1974; Chappell and Shackleton, 1986). The interpretation of fossil reefs as evidence of sea level change must confront the issue of what the relationship of the reef is to modern sea level. For Pleistocene age reefs, the impacts of tectonics are important, as many of the reported reef complexes (e.g., New Guinea) have undergone considerable uplift. Fortunately, in most instances, the rate of long-term uplift appears to have been constant throughout the Quaternary, and adjustment of the elevation of the reef to former sea level (and modern sea level) can be accommodated.

In reefs of late Holocene age (ca. 5,000 BP to present), the species of coral becomes critical to determining the relationship of the reef to former sea level. In areas where the rate of tectonic uplift is very slow, a fossil reef dating from within the last few millennia may be only slightly above present mean sea level. In other instances where tectonism or other crustal movements have been absent, only a few meters may submerge a recent, subfossil reef that is no longer active. Coral species differ significantly in their occurrence with depth of water. Some species (e.g., *Acropora palmata*, or elkhorn coral) grow in very shallow waters, often becoming exposed at low tide. Others, like several brain and head corals (e.g., *Montastrea*),

thrive best in water depths of 5–6 m (Blatt et al., 1972). With the magnitude of sea level changes during the late Holocene amounting to <10 m even along the subsiding US middle Atlantic Coast (Kearney, 2001), the error imparted to a sea level reconstruction by not accounting for the dominant coral species – and relation to former mean sea level – composing a fossil reef could be significant.

“Raised beaches”: berms, strandlines and wave-cut scarps

Apparent beach features occurring above the present limits of the tides (supertidal) have been widely reported as evidence of former sea level high stands. Some of the features undeniably document past sea level highs – whether in response to regional tectonics or possible eustatic events – while others are more ambiguous in the interpretation of their relationship to actual sea level changes.

Along many sandy coasts, like the Florida Panhandle (Stapor, 1973), beach-like features a few meters above present mean sea level have been reported as marking significant transgressive episodes during the late Holocene. These features can be either erosional (scarps) or depositional (berms), but in most cases are relatively small-scale forms (a few meters high at most in height). A common criticism, given their small size, is that these features originated from the penetration of large waves above former tidal limits – perhaps abetted by storm surges – and not from eustatic sea level changes. Certainly, scarps and berms can be observed to have formed after large coastal storms that produced significant storm surges and wave setup. Moreover, some of the most widely cited examples of wave-cut scarps and berms touted as associated with past high stands occur in regions of considerable tropical storm (i.e., hurricane) activity, like the Gulf of Mexico, a coincidence not lost on those who argue that they are largely storm phenomena.

On the other hand, the similar elevation above mean sea level of equivalent-age supertidal scarps and berms over relatively large coastal areas is hard to reconcile with an origin other than a rise in sea level. Wave approach, setup, and similar characteristics from any storm differ across a region, with concomitant changes in the landward penetration of storm waves and the elevation of supertidal forms they create. Assessment, then, of “raised beach” features as sea level indicators is likely to remain contentious.

Wave-cut notches

Wave-cut notches, a phenomenon of rocky cliff coasts, are erosional features produced from abrasion by wave-carried debris at the base of cliffs. Although rock hardness varies, especially comparing relatively soft carbonates to volcanic materials like basalt, wave-produced abrasion is generally a slow process in most rocks. Hence, a significant wave-cut, particularly in hard rocks, indicates a long period of wave impacts against the same spot on the cliff. Most reported wave-cut notches are above present mean sea level, but submerged wave-cut notches marking sea level high stands immediately following deglaciation occur at 60 m depth in areas of Hawaii (cf. Fletcher and Sherman, 1995).

Marine terraces

Marine terraces are former wave-cut platforms that have undergone uplift. Wave-cut platforms typically slope gently seaward,

marking the mean low water level (seaward) and high water level (landward). These features typically characterize rocky cliff coasts. A spectacular flight of marine terraces (>20) fringes parts of San Clemente Island off California. Along the California coast, some of the youngest subaerial terraces date from 100,000 BP, or approximately isotopic Stage 5c. The oldest marine terrace in the Palos Verde Hills of Los Angeles, California rises 394 m above present mean sea level, and is 600,000 years old.

Because they originate as wave-cut platforms, requiring decades or more of corrasion to create, depending on rock hardness, marine terraces clearly represent a considerable period of slow transgression or stable sea level. Thus, if the long-term rate of uplift was known, the original elevation of the terrace – as a proxy for the approximate former sea level position – could be determined. However, coseismic activity is not uniform along long reaches of coast, and deformation of Wisconsinan-age terraces by synclinal and anticlinal folding has been reported for the Santa Barbara area in California (Gurrola and Keller, 1997). Moreover, surface erosion and mass wasting of older Pleistocene terraces can affect their absolute elevation relative to past sea levels, even if corrected for uplift. The determination of sea level position from Pleistocene marine terraces can thus be subject to some error, especially in low terraces of late Sangamonian age (ca. 80–90 ka).

Biological indicators

Biological indicators encompass a great variety of fossil and microfossil animal and plant materials that have been used to reconstruct past sea level changes. Not all are equally useful, and often the accuracy of interpretations of former sea level position derived from many of these indicators is open to question. The keys to using biological indicators are: (a) reliable and precise knowledge of where the organism lives in relation to modern mean sea level, and (b) some certainty that the occurrence of the remains of the organism in the sedimentological record are *in situ*, and have not been subject to post-mortem transport and deposition.

Shells and sponge spicules

Shells of pelecypods, like clams (e.g., *Mercenaria mercenaria*) and oysters (e.g., *Crassostera virginica*), commonly can be found along most coasts. Many of these animals clearly inhabit relatively shallow waters, generally within 5 m or less of mean tide level. Thus, the finding of these shells (if they can be assumed to have buried where the organism lived) can be indicative of relatively shallow water conditions, a particularly useful indicator of former sea level position in long cores of littoral sediments spanning millennia. Nonetheless, because many species of pelecypods can inhabit a range of water depths (e.g., between 3–10 m for *Mytilus edulis*), the usefulness of their shells in littoral sediments of late Holocene age (when the total variation in sea levels was generally <10 m in many areas of the US Atlantic Coast; Kearney, 2001) is substantially limited.

Similar criticisms can be made of employing the occurrence of spicules of shallow water sponges in sediment records as sea level indicators. An additional problem is that these small generally siliceous needles can be widely scattered across the ocean floor after the death of the organism (without breakage and indication of post-mortem transport, necessarily) and, therefore, are often not found *in situ*.

Tree stumps

The finding of rooted fossil tree stumps now submerged in the lower shoreface has been interpreted as marking past sea levels (e.g., Kearney, 1996). However, reconstruction of former sea level position employing submerged tree stumps can be fraught with considerable error, as many riparian or fastland tree species can often occur in strictly upland forests, rendering questionable what the elevation of the tree was to mean tide level at the time of death. Again, this is less of a problem in early Holocene or Pleistocene sea level reconstructions, where the range of total elevational change encompassed in these records is tens of meters. In these instances, they clearly function as dramatic evidence of a substantial change in sea level, despite their limitations in precision.

Intertidal deposits: coastal marshes

The influence of sea level rise on the upward growth (vertical accretion) and overall development of coastal marshes is well-recognized (Stevenson et al., 1986). Theoretically, since the elevation of the marsh surface adjusts to changes in mean tide level, older marsh sediments below the substrate must record similar relationships to ancient tidal levels, and thereby to sea level. Unfortunately, this reasonable assumption was undermined by findings some time ago that older marsh sediments can undergo considerable loss in volume upon burial, initially from dewatering (Kearney and Ward, 1986), and later, by auto-compaction (the collapse of old buried peats under their own weight and that of younger sediments; Kaye and Barghoorn, 1964). These phenomena result in peat sediments sinking below the level at which they were originally deposited in relation to mean tide level, making reliable reconstruction of age-depth relations in long marsh sedimentary records problematic. They also affect the use of geochemical (Varekamp et al., 1992) and faunal indicators of changes in sea level archived in marsh sediments, though these data are typically used for more relative interpretations of the magnitude of past transgressions and regressions. Scott and Medioli (1978) nonetheless have shown that accurate reconstructions of former sea levels are still possible by delineating vertical zonations of marsh foraminifera in marsh cores.

The present use of marsh sediment records as sea level indicators generally is in collection of radiocarbon-dated marsh basal peats. Basal peats are assumed to record the initial conversion of the former upland surfaces to marsh by rising sea (a phenomenon termed marsh lateral accretion). Since the pre-existing surfaces of marshes are typically compacted, dense muds, dates collected from basal peats in contact with these sediments are more likely to be at their original elevation and not to have undergone any auto-compaction. Thus, a more reliable reconstruction of time-depth relationships for sea level change is possible. The only limitation of such indicators is that they are most suited to documenting past rises (transgressions) in sea level, as new marsh covered existing fastlands, and are not suited to documenting significant falls in sea level (regressions), when the marsh may have disappeared with the seaward drop in the elevation of the tides.

Archaeological evidence

Evidence for sea level change drawn from the world archaeological record spans shell middens from Woodland and earlier fishing communities in various sites in North America (see Fairbridge, 1976) to Medieval through Neolithic-age sites

across Mediterranean and Europe (Kearney, 2001). The wealth of archaeological data that has been applied as sea level indicators is so large that it defies easy description. However, archaeological material that is truly useful in sea level reconstruction must fulfill the same criteria as other sea level indicators: (a) the relationship to mean sea level at the time of construction and/or burial can be determined, (b) the material must be *in situ*, and (c) in terms of structures, later modifications of either the structure or the surrounding site must not have changed the initial relationship to mean sea level. The last criterion is especially critical regarding ancient harbor and port facilities that were used for long periods of time. For example, subsequent harbor construction – often many centuries later – to meet demands of increased shipping or better defense, often involved extensive modifications (if not their replacement) of original structures like docks that changed initial relationships to mean sea level in ways that may be not readily discernible. For example, the Port of Alexandria, Egypt, underwent substantial modification over the centuries since Hellenistic times, as waves of conquerors from the Romans to the Mamelukes came and went.

Even when acknowledging the potential problems inherent in the use of archaeological materials, it is not surprising that such evidence is still regarded as highly suspect by many sea level researchers. Nonetheless, the evidence often has the undeniable advantage of being able to be dated to within a decade, even a particular year, especially in the case of Roman (empire) materials. Moreover, in some instances, the relationship to former mean sea level can be deduced with a high degree of precision that similar-age biological materials would never allow.

SEDIMENTARY INDICATORS OF CLIMATE CHANGE

Introduction

Innumerable publications deal with the sedimentary record of past climates (e.g., Nairn, 1961, 1963; Schwarzbach, 1963; Frakes, 1979; Parrish, 1998; and Cecil and Edgar, 2003). Earlier paleoclimatic studies concentrated on identifying paleolatitudes and their shifts in response to plate tectonic movements on timescales of millions of years. Spurred by advances in the understanding of Pleistocene and Holocene climate records, more recent studies have focused on climate changes in response to orbital parameters on the timescale of tens of thousands of years and even shorter time frame variability. The sedimentary indicators of climate change are inextricably linked to biological and chemical criteria, which are typically recorded in sediments. The sedimentary indicators of climate change consist of two broad groupings: (a) sedimentary features that directly relate to climatic parameters such as rainfall or temperature, and (b) successions of sedimentary strata that indirectly reflect relative changes in these parameters. In both cases, the link to climate is the regional distribution and stratigraphic coherency of indicators. Many studies now assume a climate driver for variability unless other mechanisms can be identified.

Sedimentary features directly reflecting climatic conditions

Some sedimentary features reflect conditions of temperature or rainfall, and can be used to reconstruct past climate conditions. However, even the best indicators need to be used in

context of their regional setting and associations. Furthermore, some of the features may be confused with other types of deposits that do not have the same climatic constraints.

Extended periods of cold weather are necessary to produce glaciers and their deposits. Striated boulders and tills are excellent indicators of past glaciers. These, however, may be confused with other boulder deposits such as alluvial fans, talus cones, or debris flows in the geologic record. The mechanical grinding of bedrock to clay-sized sediment (rock flour) by glaciers can be recognized in till deposits and other environments well removed from the glaciers. The re-sedimentation of glacial deposits long after the glaciers have retreated may be misconstrued as evidence of colder conditions. Associated glacial features such as eskers, outwash, and dropstones (Figure S18a) are even less easily distinguished from non-glacial deposits in the rock record. Features formed by ground ice such as solifluction lobes, pingos, and ice wedges are good indicators of cold climates (i.e., Washburn, 1980). Some mineral phases are more stable at low temperatures such as ikaite ($\text{CaCO}_3 \cdot 6\text{H}_2\text{O}$) (Figure S18f), mirabilite ($\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$), natron ($\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$) and hydrohalite ($\text{NaCl} \cdot 2\text{H}_2\text{O}$). Within the proper context, these are strong indicators of cold conditions.

Indications of warm or hot climate are less clear. In marine settings, warm tropical waters favor growth of coral reefs and precipitation of carbonate minerals. The biological component of carbonate buildups in the geological record is less certain, particularly with documented "cool-water" carbonate deposits forming at higher latitudes (see James and Clarke, 1997). There is no clear correlation between accumulations of lacustrine carbonates and temperature.

Continuous growth of vegetation to produce thick accumulations of peat is best developed in rainy climates, as are coal and lignite deposits (Figure S18b). Even in areas of moderate rainfall, well-developed root structures are common in soils. The presence of coal or lignite is not unequivocal evidence of rainy conditions, however, because plants will grow in abundance wherever there is enough water, even in an arid climate. Similarly, perennial rivers, lakes, and swamps may all exist in areas of low rainfall, if the source of water is sufficient. Chemical weathering is best developed in wet, rainy, and warm climates, whereas mechanical weathering is best developed in dry and/or cold climates. The production of high-aluminum or lateritic clays and the removal of labile minerals from sands are good indications of prolonged chemical weathering. Even marine units that are dominated by these sediments may be correlated with rainy paleoclimates if regional and stratigraphic constraints are considered. The absence of these features, however, does not eliminate rainy climates since other factors such as relief, sediment transport, and diagenesis are also important.

Indicators of aridity include saline minerals, eolian sand deposits, ephemeral stream deposits, closed-basin lakes, and dry mudflats. Both marine and non-marine syndepositional saline minerals (Figure S18e) require evaporation to exceed water supply in order to concentrate solutes. The environment of formation, however, may reflect only local dryness or the evaporites may be superimposed on materials originally deposited in a wetter climate. Extensive eolian sand seas (Figure S18c) form where vegetation is sparse in dry climates. Local eolian sand deposits may form in a variety of climatic conditions. River and stream channels may remain completely dry for prolonged periods in areas of low rainfall. Ephemeral streams deposits, however, may be very similar to the deposits of perennial

streams. Dry channels may also reflect local phenomena such as channel switching or small drainage areas. Closed-basin lakes are maintained by evaporation exceeding inflow. The criteria for recognizing closed-basin lakes, which include frequent shifts in depth indicators and accumulation of soluble minerals, are not unique or easily recognized in the rock record. Furthermore, closed-basin lakes may form at a small scale in a range of climates under local conditions. Dry mudflats, which are dominated by desiccation cracks and vesicles, require a depressed groundwater table. The criteria for their recognition are still being developed. The predominance of mechanical weathering in both cold and hot arid settings suggests a mineralogical indication of paleoclimate. The abundance of immature sands such as arkoses or lithic arenites has been used as climate indicators. Red sedimentary deposits, stained by iron oxides, have also been cited as indicators of aridity. The mounting evidence suggests that these are unreliable indicators of paleoclimate. Immature sands appear to reflect relief and rate of transport more than climate, and redbeds are diagenetic overprints that are independent of the depositional climate.

The most promising sedimentary features indicative of climate change are soils (for instance, Retallack, 2001). Modern soils show a strong relationship with both local and regional climate as should their fossil counterparts. Some of the features already mentioned are incorporated into the soil classification, such as aridisol (saline minerals or mudcracks and vesicles), histosol (coal or peat), or gelisol (ground ice features). The climatic divisions, however, can be much finer based upon abundance and depth of mineral horizons (such as carbonate, aluminum, or iron), eluviation features, parting textures (peds), and vegetation overprint. Bauxitic and lateritic soils are good indicators of high rainfall. Vertisols (soils with abundant sticky or swelling clay) and calcisols require at least seasonal desiccation or dryness (Figure S18d). Thick eluviated clay B horizons with abundant roots and no soluble minerals, such as in spodosols (soils with a subsurface horizon containing organic matter, iron, and/or aluminum) or ultisols (soils with a well-developed argillic (clay) horizon and low level of exchangeable base metal cations) (Figure S18b), reflect rainier climates that support vegetation and remove soluble minerals. The drawbacks to using paleosols include the difficulty in recognizing fossil counterparts due to diagenetic changes in color and composition, similar features in different soils, and restriction to subaerial conditions.

Sedimentary features that indirectly reflect climate change

Relative changes in the world climate may be indicated by the changing character of sedimentary environments. Shifts in net precipitation are reflected in certain continental or nearshore settings by relative indicators of wetness or dryness. Relative shifts in temperature are usually more difficult to assess from sedimentary criteria. The problem with indirect climatic indicators is that not all environments react the same way to similar climatic changes and the degree of preservation of these changes is highly variable. In the best cases, relative climatic change is recorded at the millennial or centennial scale of resolution or even finer (for instance Fischer, 1986). More often, the patterns of climate change are coarsely preserved, with numerous gaps or uncertainties. Laminated sediment from lakes or deep marine settings often shows variations in mineralogy, sediment type, or thickness that reflect changes in temperature or precipitation (Figure S19). In some circumstances, these can be documented as annual layers that provide incredible

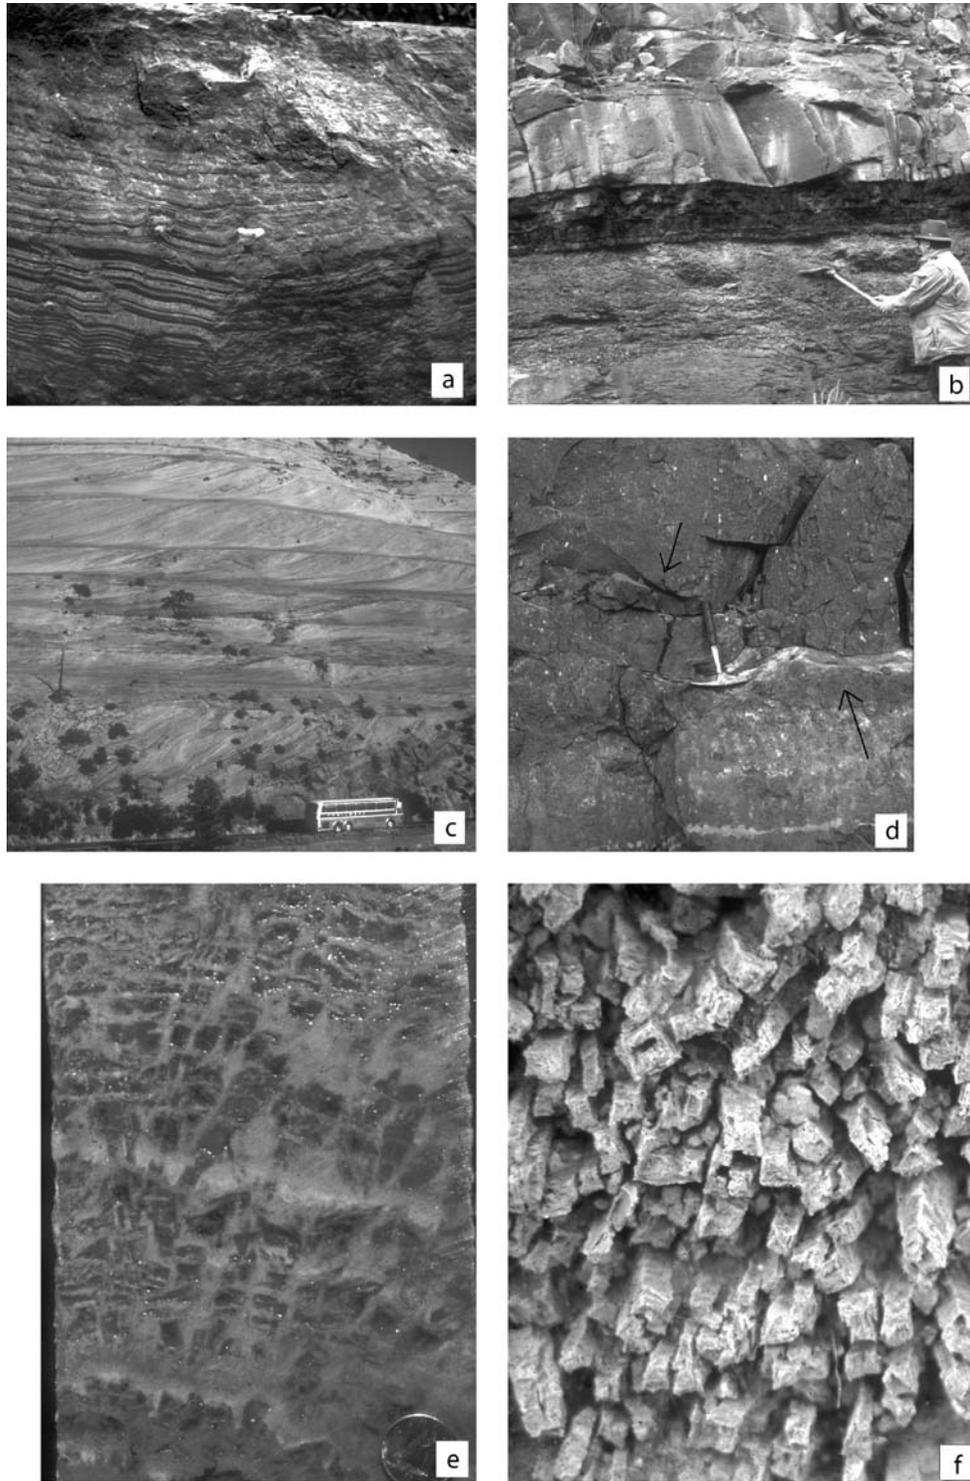

Figure S18 (a) Glacial varves with dropstones, Proterozoic Gowganda Formation near Ontario (thickness shown is about 40 cm). (b) Coal bed (*dark*) in West Virginia overlying an aluminous, blocky, claystone with abundant root casts interpreted as an ultisol. The coal bed is overlain by fluvial sandstone. Pennsylvanian Kanawha Formation, West Virginia. Man is about 1.75 m tall. (c) Eolian cross-bedding formed by migration of large dunes in a sand sea. The Jurassic Navajo Sandstone in Utah. Section shown is about 40 m high. (d) Mudstone with abundant root casts, carbonate nodules (*light blebs*) and curved slickensided planes (*arrows*) interpreted as a vertisol. Silurian Bloomsburg Formation, Pennsylvania. Hammer is about 35 cm long. (e) Gypsum crystals (*dark*) that grew upward from the sediment floor in a standing brine, now replaced by halite (pseudomorphs). Pennsylvanian Paradox Formation, Utah. Section shown is about 14 cm thick. (f) Basal view of pseudomorphs after ikaite ($\text{CaCO}_3 \cdot 6\text{H}_2\text{O}$) now composed of calcite. Pleistocene deposits of Lake Lahontan, Nevada. Section shown is about 30 cm wide.

(d) Outcrop of deepwater marine shale (*dark*) grading upward to shallow-water sandstone with tidal influence (*light*) interpreted as an indication of sea level change. Devonian Mahantango Formation, Pennsylvania. Outcrop is about 18 m high.

Recent sedimentary settings suggests that a climatic effect on sedimentation should be expected. The significance of this sedimentary impact depends upon the depositional setting and the reliability of direct or relative indicators of climate change.

SNOWBALL EARTH HYPOTHESIS

The hypothesis

The snowball Earth hypothesis (SEH) suggests that the Earth experienced surface temperatures so low that virtually its entire surface was covered by glaciers and/or thick sea ice periodically during its early history. Such a condition has been hypothesized for parts of the Neoproterozoic Era from about 750 million years ago (Ma) to about 600 Ma (Figure S21). A similar frozen state has been proposed during the early part of the Paleoproterozoic Era at about 2,300 Ma. There is little evidence of glaciation in the long intervening period but recently Williams (2005) presented evidence for glaciation in the Kimberley region of Western Australia at around 1,800 Ma.

The evidence

Support for this hypothesis comes primarily from field evidence, including the widespread preservation of diamictites, which are conglomerates containing large rock fragments separated by abundant fine grained matrix materials in which they appear to “float.” Included rock fragments commonly have scratched or striated surfaces. Rock fragments with planar surfaces are said to be “faceted.” The presence of many faceted and striated clasts in a diamictite suggests a glacial origin. Another glacial indicator is the preservation of large scale

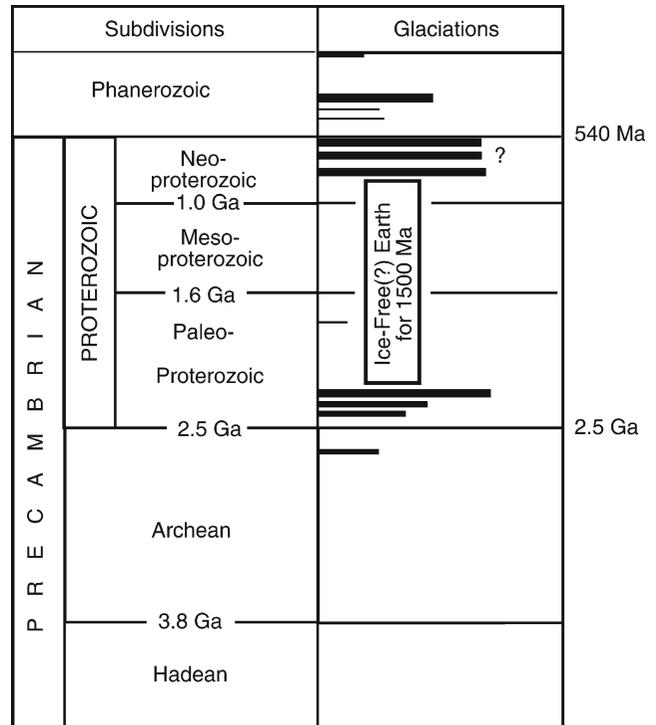

Figure S21 Distribution of glaciations throughout geologic time. Note the large gap between the Paleo- and Neoproterozoic glaciations. Question mark indicates uncertainty concerning the number of Neoproterozoic glacial episodes.

striated or furrowed rock surfaces that are thought to have formed by grinding action as rock-charged glaciers moved over older rocks or penecontemporaneously deposited sediments. Glacial activity is also indicated by the presence of finely bedded (laminated) sedimentary rocks that contain isolated large rock fragments. These fragments commonly show evidence of vertical emplacement in the form of downward penetration of the clast into enclosing sedimentary layers or as “splash up” structures – upfolding of the finely laminated sedimentary rocks on the sides of the fragment. Such rocks are called “dropstones” and are thought to have been released from melting icebergs.

These kinds of evidence have been found in Neoproterozoic rocks on all of Earth’s continents. Rocks with similar glaciogenic characteristics have also been described from older (~2,300 Ma) successions on several continents. The older glacial deposits are best known from North America, where they occur in the Huronian Supergroup on the north shore of Lake Huron in Ontario, Canada. Similar rocks occur in Michigan and bordering states, in SE Wyoming, on the west side of Hudson Bay and in the Chibougamau area of Quebec. Paleoproterozoic glaciogenic rocks also occur in NW Europe, South Africa and Western Australia. Although preserved on four continents, evidence of Paleoproterozoic glaciation is much less widespread than for the younger Neoproterozoic occurrences. It is not known whether this reflects an originally restricted distribution or whether much of the older rock record has been lost as a result of subsequent erosion.

Discovery of the wide distribution of Neoproterozoic glaciogenic rocks led Mawson (1949) and Harland (1964) to suggest

that the surface of the entire planet may have been frozen during parts of the Neoproterozoic. This concept was crystallized in the phrase “snowball Earth” by Kirschvink (1992), who proposed a genetic relationship among Neoproterozoic glaciogenic rocks, banded iron-formations (BIFs), and the snowball Earth state. Banded iron formations are thought to be chemically precipitated sediments that typically consist of finely interbedded (or “banded”) layers of siliceous material (chert and jasper) and iron oxides and other iron-rich minerals. Banded iron formations are common in Late Archean to Palaeoproterozoic successions (2,500 Ma to ~1,800 Ma) but are rare-to-absent from most sedimentary successions deposited in the next billion years. Deposition of the Paleoproterozoic BIF has been attributed to the onset of the oxygenation of Earth’s atmosphere, beginning at about 2,300 Ma. Extensive bodies of younger Fe-rich sedimentary rocks are unlikely because, following oxygenation of the Earth’s atmosphere, large amounts of Fe could not have accumulated in the world’s oceans, since Fe (as Fe^{+3}) is virtually insoluble under oxidizing conditions. Alternatively, the deep oceans were not oxygenated during the period from about 2.3 Ga to 800 Ma but rather were rich in sulfide, which would have reacted with any dissolved iron to precipitate iron sulfides (Anbar and Knoll, 2002). Both scenarios predict a dearth of Fe-oxide-rich chemical sedimentary rocks. The fact that some widespread BIFs, such as those in the Hamersley Basin of Western Australia, appear to pre-date the oxygenation of the atmosphere as indicated by various parameters in the Huronian Supergroup, suggests that deposition of these iron formations was also controlled by other (tectonic?) factors. Kirschvink (1992), however, linked the Neoproterozoic BIFs to the snowball Earth hypothesis. He considered that isolation of the atmosphere (oxygenated) and oceans by ice would have led to the buildup of dissolved Fe in the oceans as the result of on-going hydrothermal activity at subaqueous mid-ocean ridges and other volcanic centers. Once oxygen was re-introduced to the oceans at the termination of the world-encircling glaciation, iron would have precipitated.

Another line of evidence, proposed by Hoffman et al. (1998), involves low $\delta^{13}\text{C}$ values from carbonate rocks both below and above Neoproterozoic glaciogenic diamictites in Namibia. They attributed these unusually low $\delta^{13}\text{C}$ values to the near-cessation of photosynthetic activity in the world oceans, due to the inferred widespread climatic deterioration and development of world-encircling ice sheets and sea ice. Carbonate rocks precipitated from the oceans inherit many of their stable isotopic characteristics from sea water. Many photosynthetic micro-organisms preferentially secrete the lighter isotope of carbon (^{12}C) so that during periods of high biological productivity the oceans are correspondingly enriched in the heavier isotope (^{13}C). Thus, $\delta^{13}\text{C}$ values of carbonates formed in such organic-rich periods would be relatively high, and conversely these values would be low if photosynthetic activity significantly decreased, as might be expected during a global glaciation. Because little evidence exists to support a significant decrease in photosynthetic activity in the Neoproterozoic, Hoffman and Schrag (2002) subsequently suggested that the low $\delta^{13}\text{C}$ values commonly found in post-glacial carbonate rocks (so-called “cap carbonates”) are due to rapid introduction of large amounts of CO_2 to the oceans from the atmosphere, rather than due to a biological catastrophe. The ultimate source of this CO_2 may have been dissociation of oceanic methane hydrate during deglaciation, followed by oxidation to CO_2 (Jiang et al., 2003).

Low latitude glaciation

The angle of inclination of the Earth’s magnetic field to the planet’s surface varies systematically with latitude. The field is steeply inclined in polar regions whereas it is nearly parallel to the Earth’s surface at low latitudes. Thus, if the magnetic field direction is “frozen” into sedimentary rocks at or close to the time of their deposition then the paleolatitude can readily be determined. There are several reports of low (tropical to subtropical) paleolatitudes from both Neoproterozoic and Paleoproterozoic glaciogenic rocks. In some cases, it has been shown that these low latitude glacial deposits were laid down close to sea level. This is very important as some glaciers occur in tropical latitudes (e.g., on Mt. Kilimanjaro) at present but they can exist only above the snowline – at very high altitudes. The widespread nature of low paleolatitude magnetic signals from Neoproterozoic glacial deposits in SE Australia has been demonstrated. This condition was probably long-lived, for it has been shown that it spanned times of magnetic reversals (periods when the Earth’s magnetic field spontaneously reverses direction, so that the north pole becomes the south). Similar low paleolatitudes are also claimed for some Paleoproterozoic glaciogenic rocks in North America and South Africa. These indications of ice at sea level in tropical latitudes have been considered to provide support for the idea of global glaciation – the snowball Earth hypothesis. Even before such paleomagnetic evidence was widely available, Williams (1975) suggested that the unusual rock associations in Neoproterozoic sedimentary successions might be explained as a result of differences in the tilt angle of the Earth’s spin axis. He proposed that there was a significant increase in the obliquity of the Earth’s ecliptic in the Precambrian. He noted that, with a high obliquity (greater than 54°), tropical regions would receive less insolation than polar regions in a given year. If the Earth underwent cooling, the effect would have been greater at low latitudes so that glaciation would have occurred preferentially near the equator. Such a high obliquity would also tend to accentuate seasonal differences throughout the globe and might provide an explanation for evidence of seasonality in some glaciogenic rocks that apparently formed at low latitude (see following section).

Evidence of seasonality at low paleolatitudes

At present, strong seasonality is not observed at low latitudes. In both Pale- and Neoproterozoic glaciogenic successions, however, there is evidence of seasonality in sedimentary rocks that, according to paleomagnetic results, formed in tropical regions. This is manifested by the preservation of laminated sedimentary rocks that closely resemble varves in younger (Pleistocene) glacial sediments formed at high-to-intermediate latitudes. These sediments are organized into couplets, each of which comprises a relatively coarse and fine layer. The fine laminae are thought to represent cold winter conditions when little water or sediment entered the depositional basin and fine material in suspension settled from the water column. The coarse layers formed during summer months when there was abundant sediment-charged meltwater. Many Pleistocene varves contain isolated dropstones. Such clasts are also common in Proterozoic laminated sequences and lend credence to their interpretation as annual deposits formed by significant seasonal temperature changes.

Evidence of strong seasonality in Proterozoic glacial deposits is also provided by large structures that, in plan view, are polygonal and in sectional view take the form of downward-tapering wedges. These structures are typically filled with

sand that exhibits laminations sub-parallel to the edges of the structure. These structures have been described from a number of Neoproterozoic glacial successions, including some that formed at low paleolatitudes. They are interpreted as fossil ice-wedge structures, which are typical of permafrost regions today. They form as a result of thermal contraction and expansion cycles and indicate strong seasonal fluctuations in surface temperature over long periods of time. Although attempts have been made to explain these structures as a result of other phenomena (such as rapid advance-retreat cycles of surging glaciers), the modern and Pleistocene permafrost examples provide the best analog.

Problems with the snowball Earth hypothesis

Lack of precise age control

The ages of Proterozoic glaciations are largely unknown. There is stratigraphic evidence (i.e., one glaciogenic formation occurring on top of another) of several glacial episodes in some areas in both the Paleo- and Neoproterozoic, but the number of glaciations is still under debate. Contemporaneous glaciation of huge areas of the planet is a *sine qua non* for the snowball Earth hypothesis but it has yet to be demonstrated. Part of the problem lies in the fact that most sedimentary rocks (including glaciogenic deposits) cannot be dated using currently available geochronological techniques although some dates are available from contemporaneous volcanic rocks.

Inconsistent geochemical trends

Many diamictite-bearing glaciogenic successions are overlain by carbonate rocks (commonly dolostones). According to Hoffman et al., (1998), the cap carbonates are thought to be the products of extreme alkalization of the oceans brought about by reaction between the abundant CO₂ (that caused destruction of the global ice cover) and fine grained material (rock flour) produced by the grinding of rocks in the glaciers. If this theory is correct then any sediment formed from the residue of the putative extreme alteration should carry chemical evidence of very strong weathering, followed by an upward decrease in weathering intensity as the CO₂ content of the atmosphere diminished. A method of quantifying the degree of weathering of sediments and sedimentary rocks, known as the Chemical Index of Alteration (CIA) was used by Nesbitt and Young, (1982) to study post-glacial sedimentary rocks of the Paleoproterozoic Gowganda Formation in Ontario. This study showed the opposite trend to that predicted by the SEH, i.e., upward-increasing CIA values following the end of glaciation. Similar studies have not been carried out on post-glacial siliciclastic sediments of Neoproterozoic age, but in many cases there could be problems in interpreting such data because of the high proportion of recycled materials (older sedimentary rocks that have been through a previous weathering cycle) and carbonate rocks (which affect the CIA).

Great stratigraphic thicknesses of Proterozoic glaciogenic deposits

Under the snowball Earth hypothesis, it is difficult to envisage accumulation of a thick succession of glaciogenic sedimentary rocks, especially at low latitudes. For glaciation to reach low latitudes, the SEH predicts a totally frozen condition, preceded by rapid onset and followed by abrupt disappearance of glacial ice (Figure S22). On an Earth whose surface was completely frozen, the hydrologic cycle would virtually stop, so that the

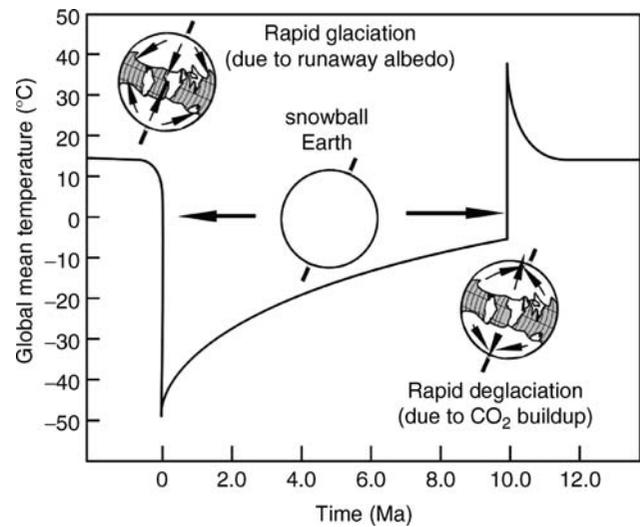

Figure S22 Proposed relationships between geologic time and surface temperature during a snowball Earth period (modified from Hoffman, 2000). Note the rapid growth and destruction of ice sheets.

great ice masses and large-scale ice movements required for production of thick sedimentary successions are unlikely. Many glaciogenic successions, in both the Paleo- and Neoproterozoic, are several km in thickness. It has been suggested by proponents of the SEH that ablation of ice at low paleolatitudes might provide sufficient hydrologic activity but without access to a huge reservoir of water (such as the world oceans). The production of great volumes of glacial sediments remains problematic. It is further hypothesized that much of the continental lithosphere was situated at low paleolatitudes so that in tropical regions, where most ablation would have occurred, there should only have been a thin ice cover and therefore limited ablation (as opposed to having the entire ocean as a moisture source). However, a low paleolatitudinal distribution of continents may not have existed for all snowball Earth glaciations.

Rapid onset and demise of snowball glaciations

Onset of the “snowball Earth” condition has been explained as the result of a “runaway albedo” feedback. If glaciation initiates at the poles and gradually descends to lower latitudes, a threshold occurs beyond which there is rapid lowering of surface temperatures and the entire surface of the planet becomes frozen, due to a positive feedback mechanism. Ice reflects solar energy more efficiently than land or water; therefore, as more of the Earth’s surface becomes ice-covered, it becomes progressively cooler until ice spreads rapidly to cover even low latitude regions of the planet (Hoffman, 2000). Once the entire planetary surface is frozen, the problem becomes one of finding a mechanism to release it from its frozen state. It was proposed (Kirschvink, 1992; Hoffman et al., 1998) that the Earth’s surface was re-warmed through buildup of atmospheric CO₂ from ongoing volcanic eruptions. This would have been accentuated by the absence of normal CO₂ drawdown from rock weathering, which would have ceased during the snowball state because of the widespread ice cover and low temperatures. Thus, the SEH invokes sudden (a few thousand years) onset and demise of glaciations, separated by much longer (several millions of years) glacial periods (Figure S22).

In the Paleoproterozoic Huronian Supergroup, however, there is sedimentological and geochemical evidence that the formations both below and above widespread glaciogenic rocks of the Gowganda Formation testify to a very gradual deterioration of climate before the glaciation and slow amelioration at the end. Likewise, in the Neoproterozoic of the Adelaide geosyncline in South Australia, Sturtian glaciogenic successions are overlain by thick (up to 1 km) accumulations of mudstone with abundant dropstones (Young and Gostin, 1989). Such occurrences testify to a long-lived, gradual amelioration of climate, with abundant floating glacial ice, in contradiction to the rapid amelioration implicit in the SEH. A less-than-catastrophic end to glaciation is also supported by recent evidence for multiple geomagnetic reversals within a cap carbonate, over a span of at least hundreds of thousands of years.

Origin of banded iron-formations associated with Proterozoic glaciogenic deposits

As noted above, the association of banded iron formations (BIFs) with some Neoproterozoic glaciogenic deposits led Kirschvink (1992) and others to propose that there was a genetic link with the snowball Earth condition, with BIFs depositing once deglaciation began. This relationship has also been proposed for the Paleoproterozoic but in the best-known basins, such as the Huronian of Ontario, glaciogenic rocks and Superior-type BIF are separated by about 300 Ma. Likewise, in the Hamersley basin of Western Australia, glacial deposits formed after deposition of major BIF, and not before, as predicted by the SEH. In contrast, there is a much more intimate association between BIF and glacial deposits in the Neoproterozoic. For example, ice-rafted dropstones are present in some laminated iron-formations, clearly attesting to the contemporaneity of glaciation and deposition of iron-formation. This relationship was attributed by some to precipitation of Fe concentrated in the world's oceans as a result of isolation of the atmosphere from the oceans during a snowball Earth period. There are, however, problems with this interpretation. The distribution of Neoproterozoic BIF is much more sporadic than that of the glaciogenic rocks. If deposition of the BIF were the result of global processes in the oceans, they should be much more common. In some cases (e.g., in the Rapitan Group of the northern Cordilleran region of North America), huge deposits of BIF occur below rather than above the glaciogenic diamictites. This is significant because the theory predicts that Fe should be released after the destruction of the oceans' ice cover. Many of the Neoproterozoic BIF occurrences formed in rift basins. This is shown by the presence of strong facies and thickness changes (Yeo, 1981; Young and Gostin, 1989) in the glaciogenic successions and the association, in some basins, with volcanic rocks. Furthermore, the geochemistry of the BIF supports a hydrothermal origin, which is compatible with the glaciated rift hypothesis for their origin (Yeo, 1981). This theory proposes that the iron was produced by hydrothermal circulation of seawater in restricted Red Sea-type rift basins. Iron-charged brines were moved and mixed with "normal" seawater and meltwater as a result of overturn caused by water movements related to release of meltwaters from glaciers that debouched into the basin from surrounding rift shoulders. Experimental studies show that such dilution and oxidation could lead to precipitation of dissolved metals such as Fe. This mechanism provides explanations for the hydrothermal nature of the BIF, their relatively restricted occurrence, fault-related facies and thickness changes and the intimate relationship with glaciogenic deposits.

Conclusions

Glaciogenic rocks are widely preserved in supracrustal successions of early Paleoproterozoic and late Neoproterozoic age and sparse in the long (~1,500 Ma) intervening interval of geologic time. This evidence suggests that the Earth went through significant climatic perturbations near to the beginning and end of the Proterozoic Eon. These perturbations in the Earth's surficial environments may have provided the impetus for significant evolutionary changes in the biosphere, especially near the end of the Proterozoic Eon when the first animals emerged. Whether the Earth's surface achieved a totally frozen condition (the snowball Earth hypothesis) during the great Proterozoic ice ages remains a possibility but currently available evidence is by no means conclusive.

SPECMAP

SPECMAP – major goals and achievements

In the 1980s, the international SPECMAP project (SPECTral MApping Project) was launched with the aim of producing continuous time series of Ice Age climate recorded in deep-sea sediments, and studying their spectral properties. One of SPECMAP's first, and most referenced, achievements was to publish an astronomical time-scale for the upper Pleistocene (last 780 ka) based on an oxygen isotope reference curve constructed from stacking five planktonic foraminifer isotopic records from low- and mid-latitudes (Imbrie et al., 1984). This stacked curve, phase-locked (tuned) to obliquity and precession orbital oscillations, provided a continuous geological time scale for the upper Pleistocene, accurate to within 5 kyr. A few years later, Martinson et al. (1987) developed a 0–300 ka astronomical time scale transferred to a high-resolution oxygen stable isotope reference curve constructed from stacking benthic foraminifer records (Pisias et al., 1984). Four different tuning procedure approaches were followed, each of which was based upon different assumptions concerning the response of the orbital signal recorded in the data. The final chronology has an average error of ± 5 kyr.

The SPECMAP *astronomical time scale* based on stable oxygen reference curves provided a powerful stratigraphic tool to tie deep-sea climatic records within a common temporal framework with the precision needed to analyze the response of the Earth external system to orbital cyclic modulation of solar radiative forcing. For the first time, amplitude and phase of cycles in different climatic proxy records could be compared at different sites with the geographic pattern of insolation changes. This information provided insight into processes responsible for climate change on glacial-interglacial time scales (i.e., Imbrie et al., 1989).

Background: the astronomical theory of Ice Age

About 2.6 million years ago, Earth climate entered the so-called Ice Age, with its large amplitude glacial-interglacial cycles characterized by the quasi-periodical waxing and waning of large continental ice sheets from the Northern Hemisphere. In the beginning of the nineteenth century, the first geological evidence of these major Quaternary glacial episodes came from observations by Louis Agassiz of sediment deposits (moraine) and erosion features attributed to ancient glaciers in the Jura mountains of western Europe. By the middle of the nineteenth century, the French mathematician Joseph Adhémar and the Scottish geologist James Croll had suggested that past climates might have responded to cyclic changes in the orbital parameters of the Earth. In the 1920s and 1930s, the Serbian mathematician Milutin Milankovich produced time-series of the amount of solar energy received by the Earth at different latitudes and different seasons. Based on these data, he proposed an orbital theory of Ice Age in which changes in the intensity of the seasons in the Northern Hemisphere controlled the waxing and waning of northern high latitude ice sheets. In his astronomical theory of climate, the Northern Hemisphere high latitude summer temperatures hold the key to the onset of glaciations.

Within a few decades, however, the astronomical theory of climate was largely disputed, with discussion based on fragmentary geological records supported by incomplete and

frequently incorrect radiometric age data. From the 1960s onwards, access to continuous and longer oceanic records revealed many more than the four glacial periods recognized from the terrestrial record in Europe, providing more support for the astronomical theory of climate. In 1976, Hays and co-authors published a landmark paper in which they convincingly demonstrated that all the orbital frequencies predicted by the astronomical theory of climate could be found through spectral analysis of climate sensitive indicators from deep-sea records (Hays et al., 1976).

The SPECMAP astronomically derived timescale

In order to analyze the geographical propagation and time-dependence (lead/lag) of various climatic responses to seasonal and latitudinal insolation changes, age-models developed from a few, radiometrically-controlled stratigraphic tie-points are not precise enough. With the convincing validation of the astronomical theory of climate by Hays et al. in 1976, Earth sciences were in need of continuous timescales that would allow cross-correlation and aging of deep-sea sedimentary records to be performed with a precision better than a fraction of Earth's orbital periods. To achieve such a precision, various authors suggested that a timescale could be developed from deep-sea sedimentary records by using orbitally-related oscillations of paleoclimatic proxies as internal "pacemakers" (i.e., Morley and Hays, 1981). The so-called astronomical (or orbital) "tuning" approach for developing timescales rests upon the phase-locking of those orbitally-related oscillations in sedimentary records to primary orbital oscillations, namely the climatic precession (with periods of 19–23 kyr) and the obliquity of the Earth's axis (with a main period of 41 kyr).

To get a global, marine stratigraphic framework on which to develop an upper Pleistocene astronomical time scale, Imbrie et al. (1984) selected five planktonic foraminifer oxygen isotopic records from low- and mid-latitudes in which globally persistent isotopic excursions could be graphically correlated. Over the Ice Age glacial-interglacial cycles, global sea water oxygen isotopic excursions recorded in the foraminifer calcite reflect the waxing and waning of continental ice sheets, enriched in the light ^{16}O isotope relative to seawater. The general circulation of the world ocean (the so-called *Great Conveyor Belt* depicted by Broecker in 1987) insures that isotopic changes related to variations in ice-sheet volume are spread globally over the world's ocean water masses within a few hundred years.

An initial, radiometrically-controlled age-model was developed for each of the five isotopic records, using few stratigraphic levels: core tops (with a \sim zero age); two isotopic events in stage 2 with ^{14}C ages of 18 and 21 ka; the 6.0 isotopic state boundary, taken as 127 ka; and the Brunhes-Matuyama magnetic reversal, taken as 730 ka. The astronomical tuning procedure applied by Imbrie et al. (1984) iteratively modified the initial depth-age models to increase the coherency and phase lock between filtered 19–23 kyr $^{-1}$ and 41 kyr $^{-1}$ oscillations of the oxygen isotopic records on the one hand, and the precession and obliquity components of the Earth's orbital variations on the other. Such an orbital tuning approach assumes constant phase lags at the primary Milankovitch frequencies between the marine oxygen isotopic variations and Earth's orbital changes. Those phase lags had been determined in an earlier paper (Imbrie and Imbrie, 1980) by adjusting the parameterization of a nonlinear (exponential) climatic model predicting ice volume variations, so that the model output would match a radiometrically-dated 130 kyr long isotopic record.

The five astronomically-dated isotopic records were finally normalized and stacked, and the resulting curve smoothed with a 9-point Gaussian filter to produce a reference stratigraphic record (Figure S23). The rationale for the stacking approach

is that global isotopic changes related to ice sheet waxing/waning would be enhanced in the resulting composite curve, whereas local or regional isotopic variations would tend to cancel out. Figure S24 shows the comparison of filtered

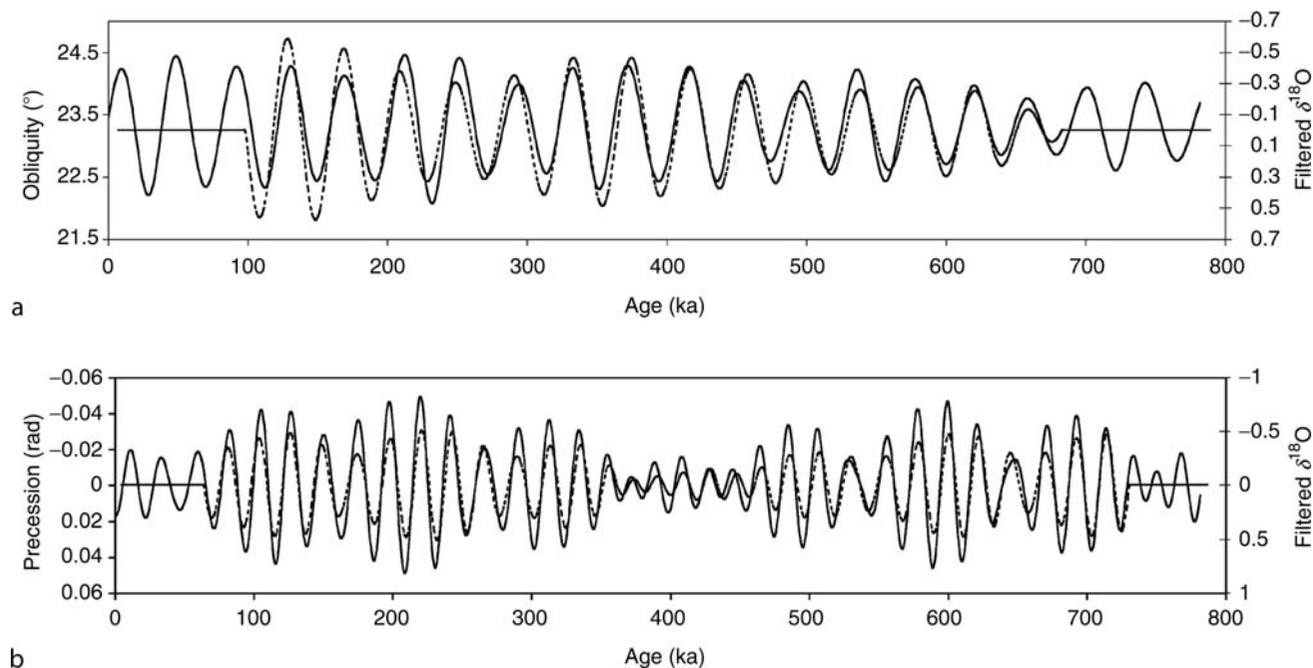

Figure S24 Solid lines show variations in obliquity (a) and precession (b) and the corresponding frequency components extracted by band-filtering the $\delta^{18}\text{O}$ stack record (dashed line) over the past 780 kyr (figure modified from Imbrie et al., 1984).

precession- and obliquity-related oscillations from the stacked isotopic record with obliquity (upper panel) and precession (lower panel) orbital oscillations.

The geological timescale obtained by Imbrie and co-workers for the upper Pleistocene is accurate to within 5 kyr (Imbrie et al., 1984). Since its publication, the orbitally-dated isotopic stacked record has been used in hundreds of paleoceanographic studies as a reference curve for developing age-models and tying marine sedimentary records into a common stratigraphic framework.

Three years after the landmark paper by Imbrie et al. (1984), Martinson et al. (1987) developed an orbital timescale for the last 300 ka that they transferred to the stacked, benthic oxygen-isotope stratigraphy from Pisias et al. (1984; Figure S25). Martinson et al. (1987) followed four different tuning strategies. This made it possible to test the robustness and accuracy of astronomical tuning for developing an upper Pleistocene time scale. The error measured by the standard deviation about the average of their four chronologies has an average magnitude of 2.5 kyr. Transferring the final chronology to the stacked isotopic record of Pisias et al. (1984) leads to additional errors. The final chronology has an average error of ± 5 kyr. Comparison of the younger portion of the chronology of Imbrie et al. and the 300-kyr chronology of Martinson et al. shows that ages of isotopic events agree to within the error bars.

Following the initial SPECMAP effort, astronomical timescales were developed for the Middle and Early Pleistocene periods (Raymo et al., 1989; Ruddiman et al., 1989). It also became increasingly clear that orbital control of climate was not restricted to the Ice Age. This allowed the astronomical tuning approach to be applied to older periods of the Earth history, reaching back to the Neogene (Shackleton et al., 1999).

Limits of the astronomical calibration approach

Orbital tuning provides a global reference standard for dating long, continuous sediment records. However, the approach is not without its problems. Subsequent revisions of the 0–780 ka SPECMAP timescale showed, for instance, that several oscillations predicted by the astronomical theory of climate (in isotopic stages 17 and 18) were apparently missing in the stacked record (Bassilot et al., 1994). Their absence is related

(a) to the incompleteness of some of the isotopic records that reached those stages, and (b) to an erroneous Brunhes-Matuyama (BM) magnetic reversal age assignment in the age-model developed at the first step of the Imbrie et al., 1984 tuning approach. $^{40}\text{Ar}/^{39}\text{Ar}$ radiometric dating of the Brunhes-Matuyama magnetic boundary gives an age of about 780 ka (Baksi et al., 1992), significantly older than the K/Ar age (730 ka) available in the early 1980s, and used by Imbrie et al. (1984) to constrain their initial age-model. Although the time constraint at the B/M boundary was removed midway in the orbital tuning approach of Imbrie et al., it is quite clear that the final age-model suffered from this erroneous tie-point.

Applying astronomical tuning strategies with a higher degree of freedom (i.e., no initial age assignment to the B/M boundary) on carefully selected, high-resolution isotopic records, Shackleton et al. (1990) and Bassilot et al. (1994) obtained astronomical ages for the Brunhes-Matuyama magnetic reversal that are in good agreement with $^{40}\text{Ar}/^{39}\text{Ar}$ radiometric ages. This example illustrates the fact that theoretical precision of astronomical time scales (usually a few thousand years) may actually mask potential, larger uncertainties related to the tuning strategy and/or to incompleteness of paleoclimatic records used to provide the stratigraphic framework on which the astronomical tuning is conducted.

Analyzing the Ice Age record within the framework of the SPECMAP time scale

Using their astronomically dated oxygen isotopic stratigraphy, the SPECMAP group produced a research effort to determine how orbital signals are transferred into climatic responses during the upper Pleistocene part of the Ice Age. The rigorous and robust strategy they developed was based upon partitioning the climatic response at different locations of the world ocean into its frequency components (Imbrie et al., 1989). This strategy allows analysis of three major aspects of the Earth's climatic response to orbital changes in insolation forcing:

1. Examination of climate spectra makes it possible to separate between linear and nonlinear responses to radiative forcing. Many paleoclimatic records indicate that there exist direct, linear responses of Earth's climatic sub-systems to insolation forcing in the precession and obliquity bands (Imbrie

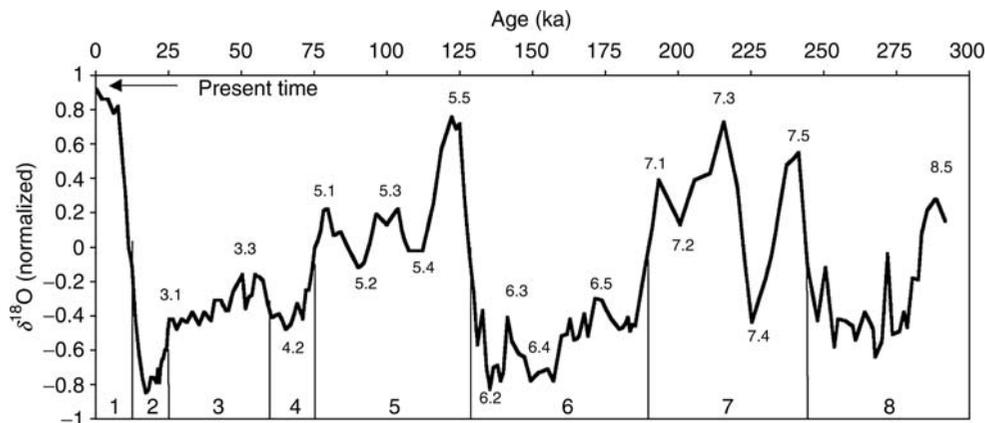

Figure S25 The 0–300 ka time scale developed by Martinson et al. (1987) and transferred to the stacked, benthic oxygen isotopic reference curve of Pisias et al. (1984). Isotopic stages are indicated on the bottom of the figure. Major isotopic events are shown along the isotopic curve, following definition by Pisias et al. (1984) (figure modified from Martinson et al., 1987).

et al., 1992). The dominance of the 100-kyr periodicity in glacial-interglacial oscillations of the last million years, on the other hand, is not easily accounted for by the astronomical theory of climate since eccentricity variations of the Earth's orbit lead to only minor changes in the insolation budget. Non-linear responses to insolation changes have been proposed – amongst several other possible mechanisms – to deal with the puzzling 100-kyr oscillations of the Earth's climate (Imbrie et al., 1993).

2. Analysis of phase relationships provides information about the response time of different oceanic and climate components (i.e., sea surface and deep water hydrology (T, S), surface productivity, wind forcing, etc.) and their causal relationships (e.g., leads/lags indicating which changes might be forcing others).
3. Analysis of geographic distribution of the response provides information about which regions play critical roles in climate changes.

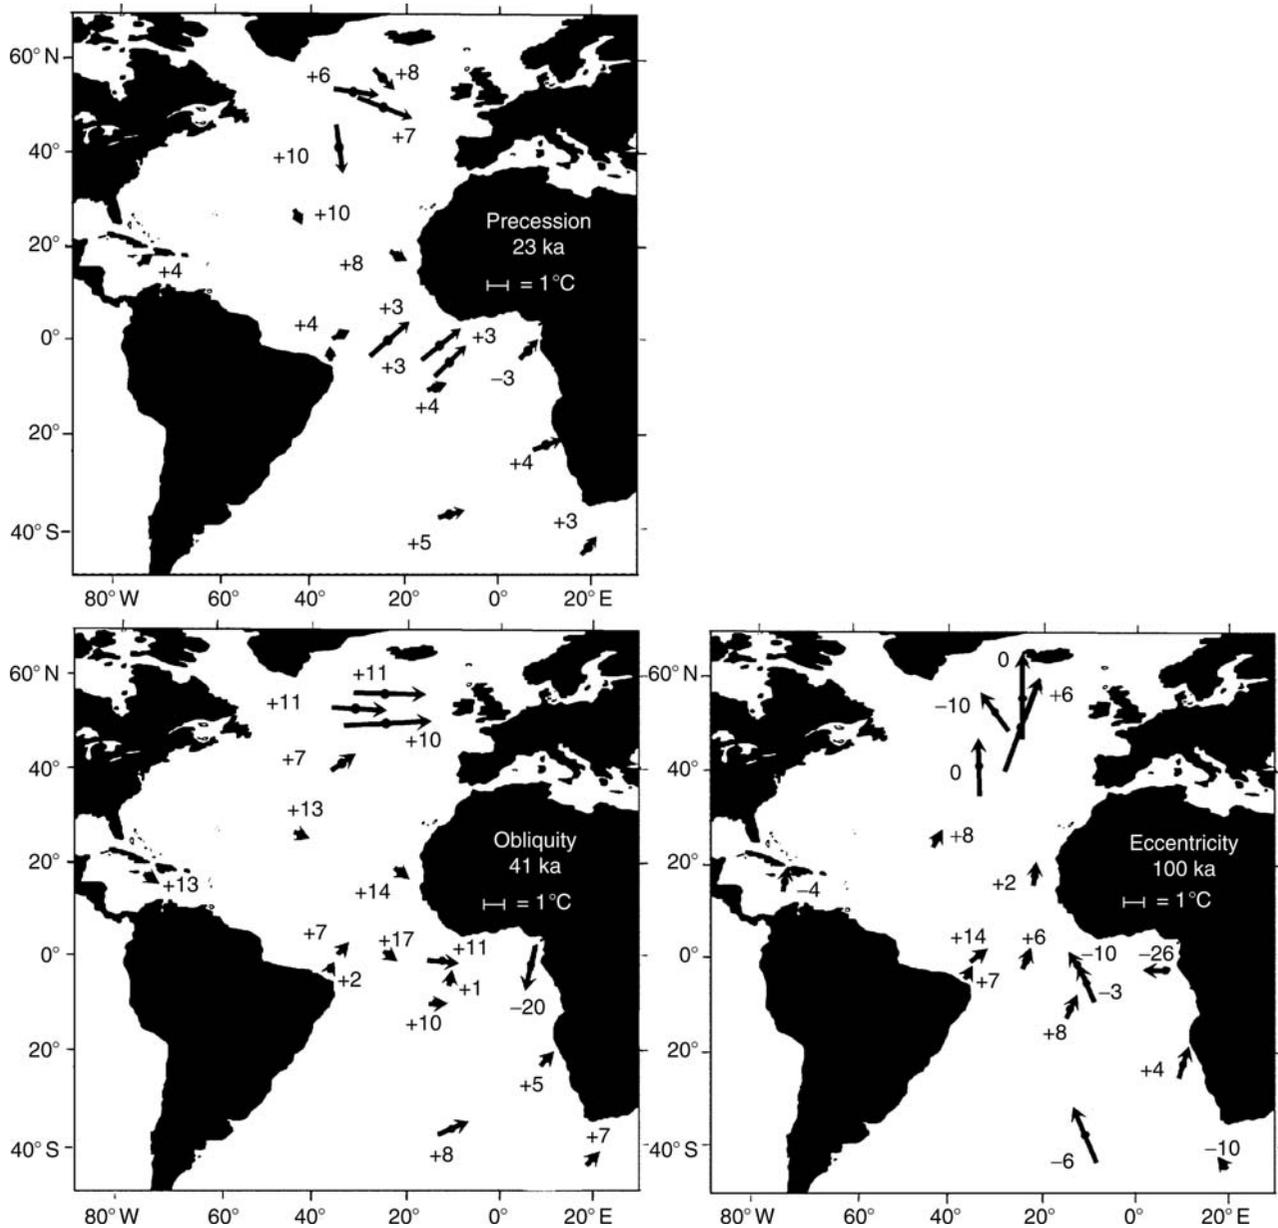

Figure S26 SPECMAP analysis of cold-season SST (Sea Surface Temperature) variations at 17 Atlantic sites in the precession, obliquity and eccentricity frequency bands. Cyclic changes in SST are analyzed relative to $\delta^{18}\text{O}$ oscillations. Phase-relationships between these two signals are displayed as arrows following the so-called “phase wheel” representation, with $\delta^{18}\text{O}$ being set at the “zero phase” (= vertical). The leads/lags (in ka) between $\delta^{18}\text{O}$ and SST are also indicated next to each arrow (a *negative* value indicates that $\delta^{18}\text{O}$ changes *lag* SST changes, whereas a *positive* value indicates that $\delta^{18}\text{O}$ variations *lead* SST changes). The length of each arrow is proportional to the coherent amplitude of the SST cyclic change (see the 1°C reference scale shown in each panel) (figure modified from Imbrie et al., 1989).

Figure S26 shows the amplitude of Atlantic Sea Surface Temperature (SST) oscillations at 17 sites in the precession, obliquity and eccentricity bands, and their phase relationships relative to $\delta^{18}\text{O}$ changes. The largest SST changes (longest arrows) occur generally near 50°N in the North Atlantic and reflect oscillations of the Gulf Stream and North Atlantic polar front in response to changes affecting the nearby continental ice sheets. In this area, SPECMAP results indicate large amplitude SST changes in the obliquity band (Figure S26, lower left panel), a result consistent with the strong influence of Earth's axis tilt oscillations on high-latitude insolation changes. South of about 45°N , the obliquity forcing drops down, as shown by the weak amplitude of SST changes. In contrast, the precession signal keeps its strength closer to the low-latitudes (Figure S26, upper left panel). Major climatic features at low-latitudes – such as monsoons – generally show strong precession variability.

In the eccentricity band, there is a suggestion of a phase shift across the equator: in the South Atlantic, temperature changes generally lead oxygen isotopes, whereas in the North Atlantic the SST changes either are in phase or lag $\delta^{18}\text{O}$ changes (Figure S26, lower right panel). This early response of Southern Hemisphere SST suggests a drawback in Milankovitch's theory of climate changes. Milankovitch proposed that insolation changes in the high-latitudes of the Northern Hemisphere are the key to controlling glacial-interglacial variations. SPECMAP data show that the insolation over the Southern Hemisphere (and inter-hemispheric heat transport) has to be taken into account in scenarios dealing with astronomical control of global Earth's climate.

Conclusion

The SPECMAP project launched in the 1980s radically improved our understanding of how the Ice Age climate responded to changes in latitudinal and seasonal distribution of solar energy controlled by variations in the orbital parameters of the Earth. The development of a high-resolution time frame for the upper Pleistocene made it possible to compare climatic proxy records from sedimentary series at different oceanic sites to the geographic pattern of insolation changes with an unprecedented time precision.

The SPECMAP group also proved to be extremely effective in pointing out some weaknesses of the astronomical theory of climate (i.e., the puzzling 100-kyr cycle that dominates global climate changes over the last million years) and called for more complex mechanisms than those that were originally proposed by pioneers such as Milutin Milankovitch. For instance, the fact that Southern Hemisphere sea surface temperatures seem to lead changes in Northern Hemisphere ice sheets showed the limits of Milankovitch's hypothesis which puts emphasis on insolation changes at about 65°N . Amongst important key players for climate changes that were not taken into account by astronomical theory of climate are greenhouse gases such as CO_2 . Long records of atmospheric composition obtained from bubbles trapped in Antarctica and Greenland ice cores indicate that the $p\text{CO}_2$ of the atmosphere showed large amplitude variations associated with glacial-interglacial global climate oscillations. During the last glacial terminations, the atmospheric $p\text{CO}_2$ rise led the melting of ice sheets by a few thousand years (Broecker and Henderson, 1998). This clearly indicates that atmospheric $p\text{CO}_2$, which is ultimately controlled by changes taking place in the ocean, is an important primary driver of the Earth's climate and that Ice Age

oscillations cannot be fully explained through insolation control on Northern Hemisphere ice sheets.

SPELEOTHEMS

Speleothems, from the Greek *speilaion* (cave) and *thema* (deposit), are chemical deposits formed in caves. Although close to 200 minerals have been identified as secondary minerals in caves, the bulk of formations that occur in caves consist of carbonates. Dripstones, such as stalagmites (Figure S27a) and stalactites (Figure S27b), and flowstones are types of speleothems. Stalactites grow downward from the ceiling, while stalagmites are their counterparts that grow upwards from the floor. Flowstones, as the name implies, form from flowing water. There are numerous varieties of speleothems that form in the cave environment but carbonate dripstones and flowstones are the most common and voluminous.

The chemical evolution that results in the formation of speleothem calcite (CaCO_3) starts by water absorbing carbon dioxide (CO_2), from the overlying soil to form carbonic acid (H_2CO_3) (Reaction 1). CO_2 levels in soil can reach up to two orders of magnitude higher than the atmospheric value of about 370 ppm due to plant respiration and decay of organic matter (Hendy, 1971). As the carbonic acid containing water percolates down, it dissolves calcium carbonate (Reaction 2). Once the carbonate-rich water is exposed to the CO_2 -poor cave

atmosphere, it releases CO_2 , resulting in the precipitation of calcite or aragonite (Reaction 3).

Speleothems are typically made of calcite (CaCO_3), and to a lesser extent of aragonite, another polymorph (same chemical composition but different crystal type) of CaCO_3 . Calcite forms hexagonal crystals, while aragonite forms orthorhombic crystals; which form crystallizes depends on the degree of saturation of the solution. Highly saturated solutions in warm climates tend to crystallize aragonite, this is especially true in caves formed from dolomite [$\text{CaMg}(\text{CO}_3)_2$], because high Mg concentration from the dissolution of dolomite inhibits calcite formation. The occurrence of alternating calcite and aragonite in stalagmites has been interpreted to indicate differences in the severity of aridity in the region where the speleothems are collected (Denniston et al., 2000a; Polyak and Asmerom, 2001).

Growth layering in speleothems

Speleothem growth can vary widely, depending on the cave environment, and in some cases it can preserve annual-scale layering, especially in stalagmites, where growth layering is simple surface addition. Figure S28 shows a photomicrograph of annual growth banding in a stalagmite from a cave close to Carlsbad Caver, New Mexico. Each layer, around 20 microns thick, represents a single year's growth. Annual banding in speleothems was recognized very early (e.g., Broecker et al., 1960), and has been reported from a variety of settings (e.g., Genty and Quinif, 1996; Brook et al., 1999; Polyak and Asmerom, 2001; Hou et al., 2003). Annual banding

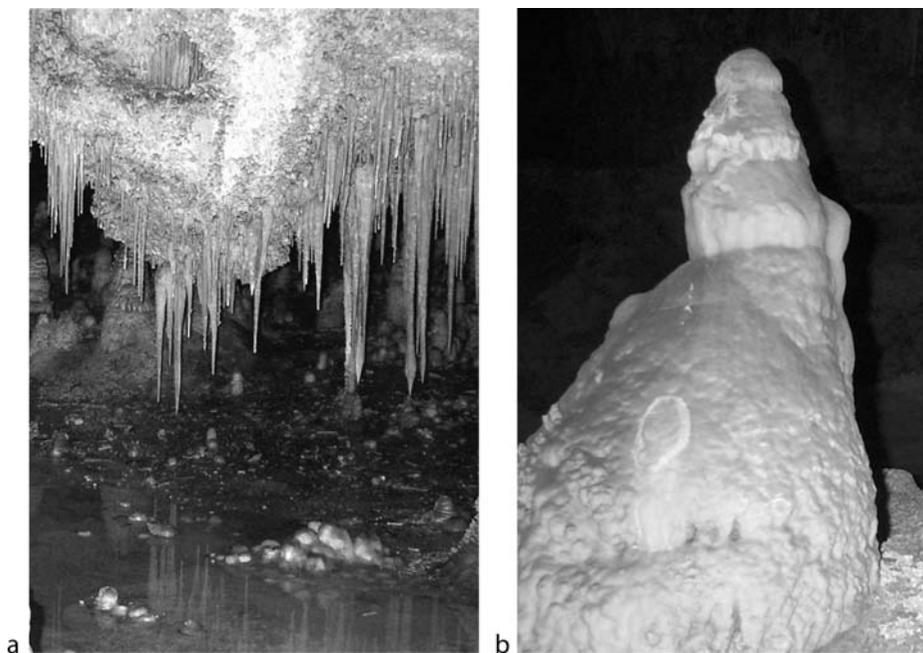

Figure S27 (a) Stalactites hanging from a low ceiling, Slaughter Canyon Cave, Carlsbad Caverns National Park, New Mexico, USA (photo: Yemane Asmerom). (b) Giant Stalagmites, Carlsbad Caverns, Carlsbad Caverns National Park, New Mexico, USA (photo: Yemane Asmerom).

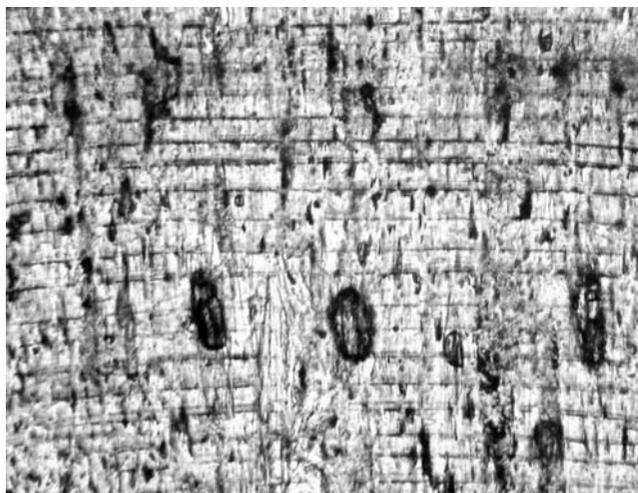

Figure S28 A photomicrograph of annual banding, representing about 17 years of growth in an aragonite stalagmite from Carlsbad Caverns, Carlsbad National Park, New Mexico USA (photo: Victor Polyak and Yemane Asmerom).

can also be expressed in a variety of other ways, including luminescence banding of organic matter (Baker et al., 1993), and in variation of trace elements (e.g., Fairchild et al., 2001; Huang et al., 2001).

Climate and environmental changes from speleothem data

Speleothems contain a wide-range of chemical and physical proxies of past climate in continents that may be resolved at an annual scale, given annual-scale banding and the ability to date them using uranium-series (U-series) isotopic techniques. The method is based on measurement of the decay isotopes of uranium, especially the decay of ^{238}U to ^{234}U , which in turn decays to 230-Thorium. Uranium is soluble in the solution that forms speleothems, while thorium is not. Thus, the amount of ^{230}Th is a measure of the age of the sample and the concentration of ^{238}U and ^{234}U . With the development of modern mass spectrometric techniques for measuring U-series isotopes (Chen et al., 1986; Edwards et al., 1987), it is possible to obtain very precise ages on small amounts, using less than 200 mg of speleothem powder, yielding typical age uncertainties of less than 0.5% ($2-\sigma$) (Dorale et al., 2001).

One of the earliest areas of studies of past climate was looking at the isotopic variations of oxygen (O) and carbon (C) of speleothem calcite. Hendy (1971) outlined the methodology and rationale for the approach. Oxygen has two major (^{16}O , ^{18}O) and one minor (^{17}O) isotopes, while carbon has two stable isotopes, ^{12}C and ^{13}C . The O isotope variations of speleothems reflect processes active in the source and atmosphere meteoric water and the fractionation (one isotope favored another) that occurs when calcite crystallized from drip water. If the O isotope composition of the water is known, either from fluids trapped in the crystal (Matthews et al., 2001) or known independently, and, if the calcite formed in equilibrium with the water, then changes in O isotopes may be related to changes in temperature. In deep enough caves, this generally reflects the mean annual temperature. Variations in O isotopic composition may also indicate changes in the

moisture source of the meteoric water from which the drip water was derived. Such information can give insight into large-scale changes in ocean-atmospheric interactions, such as monsoon intensity (e.g., Wang et al., 2001).

The carbon isotopic composition of speleothems primary reflects: (a) the C isotopic composition of the soil CO_2 , derived from oxidation of local organic matter that dissolves into the drip water; (b) the C isotopic composition of the bedrock, which is constant for a given site; and (c) isotopic fractionation during calcite formation (Hendy, 1971). Carbon isotopes in speleothems have been used to observe the change between plants that utilize the C_3 photosynthetic pathway and plants that use the C_4 pathway. C_4 plants are adapted to an arid, high temperature climate, although it has been suggested that they also evolved to deal with lower atmospheric CO_2 in the Cenozoic (Cerling et al., 1998). C_3 plants have a stronger preference for ^{12}C over ^{13}C , as compared to C_4 plants. Thus, variations in $^{13}\text{C}/^{12}\text{C}$ ratios may indicate variations in C_3 and C_4 plant cover (e.g., Dorale et al., 1998; Denniston et al., 2000b).

A number of other studies have used variations in the growth banding of annually-banded speleothems (Asmerom and Polyak, 2004) as an indicator of changes in precipitation through time. For example, Polyak and Asmerom (2001) reconstructed climate change over the past 4,000 years for the southwestern USA and correlated it with cultural changes over the same time period. Changes in mineralogy of speleothems (aragonite = arid, calcite = wet) have been used to study the relative intensity of the monsoon in Nepal (Denniston et al., 2000a).

The above is a small sampling of the rich-variety of climatic, cultural and environmental studies that are being conducted using speleothem isotopic, chemical and physical data. Above all, speleothems are some of the most beautiful sculptures of nature, worthy of the highest stewardship. A great deal can be learned using speleothems and every effort should be put towards preserving these natural wonders.

STABLE ISOTOPE ANALYSIS

Background

Atoms of an element always have the same number of electrons as protons (atomic number), but may differ in the number of neutrons in the nucleus, producing slight differences in atomic mass. These are referred to as isotopes. Few elements consist of just one isotope; most elements in nature have more than two isotopes. Whereas most of these atoms are naturally stable, some isotopes are naturally unstable (radiogenic), spontaneously releasing energy and transforming into more stable atoms. Stable isotopes with low atomic number – the light stable isotopes – are the major focus of paleoclimate research. These isotopes include those of oxygen (^{18}O , ^{16}O), hydrogen (^1H , $^2\text{H} = \text{D}$), carbon (^{13}C , ^{12}C), nitrogen (^{15}N , ^{14}N), and sulfur (^{32}S , ^{34}S).

Notation

Stable isotopes with lower atomic mass are typically more abundant than their larger counterparts (Table S2), and their

Table S2 Abundance of light stable isotopes

Element	Isotope	Abundance (%)
Hydrogen	^1H	99.985
	$^2\text{H} = \text{D}^*$	0.015
Carbon	^{12}C	98.98
	^{13}C	1.11
Nitrogen	^{14}N	99.63
	^{15}N	0.37
Oxygen	^{16}O	99.959
	^{17}O	0.037
	^{18}O	0.204
Sulfur	^{32}S	95.00
	^{33}S	0.76
	^{34}S	4.22

* ^2H is also called deuterium (D). Although ^{17}O and ^{33}S are stable isotopes, they are not currently used for paleoclimatic studies because reproducible analyses of their abundances in natural materials have only been recently achieved.

abundances in natural materials are reported in relative terms as the ratio of the heavier (rare) and lighter (abundant) isotopes:

$$R = \frac{\text{Abundance of rare isotope}}{\text{Abundance of abundant isotope}} \quad (1)$$

Absolute stable isotope ratios are, however, rarely reported because current analytical instrumentation has a relatively low sensitivity that makes it unsuitable for detecting very small natural variations of stable isotopes. Absolute isotope ratios generally possess poor reproducibility. In paleoclimatic studies, changes in stable isotope ratios are therefore more relevant than the absolute isotope ratios. Thus, it is preferable to use an international reference material with which to compare the samples. This standard can provide information about changes in the ratio of rare and abundant isotopes in the sample relative to the ratio in the standard. Since these variations are less than one and are reported to at least five or six significant figures, the delta (δ) notation is used to represent parts per thousand (per mil) deviation of the isotope ratio of the sample relative to that of the reference material (Equation (2)).

$$\delta_{A/B} = \left(\frac{R_{\text{Sample}}}{R_{\text{Standard}}} - 1 \right) 1,000 \quad (2)$$

where R is the isotope ratio, and the values of δ are given in per mil (‰). Equation (2) indicates that an enrichment of the rare (heavy) isotope in the sample relative to the reference material (standard) produces higher δ values. Positive δ values, then, result when $R_{\text{Sample}} \gg R_{\text{Standard}}$, whereas negative δ values result when $R_{\text{Sample}} < R_{\text{Standard}}$.

Standards

Table S3 lists the internationally accepted reference standards and their absolute isotope ratios. By definition (Equation (2)), the δ value of an absolute standard is 0‰. Since absolute reference materials are currently either exhausted or available in small quantities, laboratories routinely employ internal standards that are calibrated against the absolute standards. These calibrations are needed to convert δ values obtained from internal standards into δ values based on absolute standards (Craig, 1957).

Table S3 Absolute reference material

Standard	Isotope ratio	Abundance
V-SMOW	D/H	1.5575×10^{-4}
V-PDB	$^{12}\text{C}/^{13}\text{C}$	1.1237×10^{-3}
Air	$^{15}\text{N}/^{14}\text{N}$	3.677×10^{-3}
V-SMOW	$^{18}\text{O}/^{16}\text{O}$	2.0052×10^{-3}
V-PDB	$^{18}\text{O}/^{16}\text{O}$	2.0672×10^{-3}
CDT	$^{34}\text{S}/^{32}\text{S}$	4.5005×10^{-2}

Fractionation effects

Despite having the same number of electrons and protons, isotopes of the same element behave differently during chemical and physical processes which results in a dissimilar distribution of isotopes among reactants and products. This partitioning of isotopes is referred to as isotope fractionation. There are fundamentally two phenomena that cause isotope fractionation: lower mobility of heavier isotope molecules and lower binding energies of lighter isotope molecules. The former produces lower diffusion rates relative to those of their lighter counterparts. Lower mobility also produces a reduction in collision frequency with other molecules during chemical reactions, leading to slower rates of chemical reaction for heavier molecules. In addition to higher mobility, faster reaction rates occur with lighter isotope molecules due to their lower binding energies. These two phenomena (i.e., mobility and binding energy) cause, for example, heavier water molecules ($^1\text{H}_2^3\text{O}$ and $^1\text{H}^2\text{H}^1\text{O}$) to evaporate at a slower rate than their lighter counterpart ($^1\text{H}_2^1\text{O}$).

The partitioning of isotopes between substances A and B (either two different chemical compounds or two phases of the same compound) can be represented as:

$$\alpha_{A-B} = \frac{R_A}{R_B} \quad (3)$$

where R is the isotope ratio, and α is referred to as the fractionation factor. The partitioning of isotopes between substances A and B as represented by Equation (3) can be equated to the more familiar equilibrium constant (K) of a reaction by the following equation:

$$\alpha_{A-B} = K^{1/n} \quad (4)$$

where n is the number of atoms exchanged. The magnitude of the fractionation factor depends on temperature, as indicated by the pioneer work of H. Urey (1947). A general expression that relates temperature and α is of the form:

$$\alpha_{A-B} = N e^{M/T} \quad (5)$$

where N and M are temperature-independent coefficients, and T is temperature. Theoretical, semi-empirical, experimental, and observational calculations of the magnitude of α with temperature exist for different chemical reactions, isotope exchange reactions, and phase changes of compounds. These relationships are typically expressed as the power series solution of the natural logarithm of Equation (5):

$$\ln \alpha_{A-B} = C_1 + \frac{C_2}{T} + \frac{C_3}{T^2} \quad (6)$$

where C_1 , C_2 , C_3 are constants, and T is temperature (in Kelvin).

Urey (1947) was the first to predict the paleoclimatic potential of the dependence of the partitioning of isotopes on temperature. His pioneering work focused on thermodynamic equations that describe the partitioning of isotopes between water and calcium carbonate. Based on these equations, Urey argued that the stable-oxygen isotopic composition of carbonate minerals provides information about past temperatures. To assess the temperature-dependent relationship between isotope ratios of calcium carbonate and water, mollusks were grown in water of known isotopic composition at different temperatures (Epstein et al., 1953). The obtained experimental relationship was in close agreement with Urey's theoretical determinations, providing support for the idea that stable-oxygen isotopes can be used for paleoclimatologic research.

Probably the first most significant use of stable isotopes in paleoclimatology was the work of Emiliani (1955). He determined the oxygen-isotopic composition ($\delta^{18}\text{O}$) of foraminiferal shells from cores retrieved around different ocean basins and found numerous fluctuations in ($\delta^{18}\text{O}$) values that he equated with glacial/interglacial cycles. As indicated by Equations (3), (5), and (6), $\delta^{18}\text{O}$ values of foraminifera depend on seawater $\delta^{18}\text{O}$ values and temperature. Paleotemperatures can only be determined when seawater $\delta^{18}\text{O}$ values are known. Emiliani (1955) realized that seawater $\delta^{18}\text{O}$ values have changed through time due to different volumes of continental ice caps. Employing simple assumptions, Emiliani estimated that glacial-related shifts in $\delta^{18}\text{O}$ values of seawater produce less than 20% of the changes observed in foraminifera $\delta^{18}\text{O}$ values, and the remaining effect was due to temperature. However, subsequent work by Shackleton and Opdyke (1973) strongly suggests that changes in $\delta^{18}\text{O}$ values of seawater are the main parameter controlling $\delta^{18}\text{O}$ values of foraminifera.

Although Urey's pioneer work showed that stable isotopes can be used as temperature proxies, the work by Emiliani (1955) and Shackleton and Opdyke (1973) illustrate the most important factors constraining paleoenvironmental interpretations based on stable isotope data. These factors include temperature and the isotopic composition of water.

Stable isotopes in paleothermometry

If the isotopic composition of water is known or is assumed to have remained constant over the time period of interest, past changes in temperature can be estimated from stable isotope data. This approach has primarily been employed on carbonate substrates precipitated in marine settings. For instance, changes in carbonate $\delta^{18}\text{O}$ values of Holocene corals and marine bivalves have been interpreted to indicate changes in seawater temperature, where a decrease in water temperature results in elevated shell $\delta^{18}\text{O}$ values. Corals in particular offer one of the highest resolution (seasonal to century-scale) paleoclimatic archives of the tropics, commonly encompassing the last 400 yr. A strong relationship ($r^2 = 0.92$) has been found between sea-surface temperature and the oxygen isotopic composition of corals (Quinn et al., 1996; Fairbanks et al., 1997). Although the relationship between temperature and the extent of ^{18}O -enrichment in carbonates (Equations (3)–(5)) has been established at equilibrium conditions (e.g., Epstein et al., 1953), $\delta^{18}\text{O}$ values of modern biogenic carbonate in marine settings exhibit a systematic offset from the values expected at equilibrium. For instance, direct measurements of sea-surface

temperature and $\delta^{18}\text{O}$ values of corals indicate a significant (up to 0.5‰) deviation from the value expected at equilibrium; this difference points to a kinetic and/or biological effect during carbonate secretion (“vital effect”). Fortunately, the isotope offset resulting from the biological secretion of carbonate appears to be constant among specimens of the same species, but different among individuals of different taxa. Constant vital isotope effects in corals and bivalves make their $\delta^{18}\text{O}$ values sensitive indicators for paleoclimate because a simple correction factor can be applied to convert biogenic carbonate $\delta^{18}\text{O}$ values into temperature.

Whereas the isotopic composition of seawater can be assumed to remain constant (~ 0 –1‰) in certain locations for at least the late Holocene, the isotopic composition of water on land is extremely variable (from about 0‰ to -35 ‰ for $\delta^{18}\text{O}$). As a result, it is important to distinguish the effect of temperature from changing $\delta^{18}\text{O}$ values of water to make accurate paleoclimatic reconstructions. An extreme situation occurs when the range of variability of water $\delta^{18}\text{O}$ values far exceeds the temperature effect on shell $\delta^{18}\text{O}$ values. Under this scenario, it still might be possible to obtain paleotemperature assessments from changes in shell $\delta^{18}\text{O}$ values as a result of the strong covariance found between surface temperature and the isotopic composition of meteoric water.

Stable isotope ratios in meteoric water

The basis for the use of hydrogen (δD) and oxygen isotopic composition ($\delta^{18}\text{O}$) of meteoric water comes from observations of modern precipitation in mid- and high-latitudes showing a strong ($r^2 = 0.78$) correspondence between temperature and values of δD and $\delta^{18}\text{O}$ of meteoric water. This strong relationship has been found to occur on seasonal, interannual, and multiannual comparisons (Dansgaard, 1964; Rozanski et al., 1992; Fricke and O’Neil, 1999).

The isotopic composition of rainwater chiefly depends on two processes: evaporation and condensation. During evaporation, the lighter isotopes are preferentially incorporated into the gas phase as a result of their higher mobility. Most evaporation in the world occurs at low- and mid-latitudes, and to a lesser

extent from vegetation and lakes. During condensation, the lighter isotopes preferentially remain in the vapor phase due to their higher vapor pressure relative to that of their heavier counterparts. Removal of heavier isotopes during condensation enriches the lighter isotopes in the cloud. Subsequent condensation events produce a further enrichment of lighter isotopes in the cloud, resulting in progressively lower $\delta^{18}\text{O}$ and δD values of rainwater. This progressive depletion of heavier isotopes due to partial rainout is observed when air masses travel landward and poleward. For instance, rainwater at maritime and coastal sites exhibits higher $\delta^{18}\text{O}$ and δD values than rainwater falling in continental interiors (Figure S29). Similarly, rainwater of tropical regions shows higher $\delta^{18}\text{O}$ and δD values in relation to rainwater falling at higher latitudes (Figure S30). Isotope data of meteoric water collected around the world verifies the gradual decrease in $\delta^{18}\text{O}$ and δD values by showing a gradient towards lower $\delta^{18}\text{O}$ and δD values of rainwater with increasing latitude and continentality.

The extent of incorporation of heavier isotopes in condensates (i.e., fractionation between gas and liquid phase) depends on the prevailing temperature at the cloud base (Gat, 1996). This dependence appears to be the source of the strong relationship found between temperature and the isotopic composition of rainwater in mid-latitudes and polar regions (Figure S31).

The dependence of $\delta^{18}\text{O}$ values of meteoric water on temperature has been used in terrestrial records, primarily in ice-core studies, to reconstruct past changes in temperature. In fact, the covariance between temperature and $\delta^{18}\text{O}$ values has independently been confirmed via bore-hole measurements in Central Greenland (Johnsen et al., 1995), validating the accuracy of paleotemperature estimations deduced from isotope data. Using $\delta^{18}\text{O}$ data, Greenland ice records have revealed exceptionally large and abrupt changes in climate during the most recent glacial interval (Dansgaard et al., 1993). These results suggest that climate is highly variable, showing very rapid transitions from “cold” to “warm” modes. In Antarctica, temperature estimates inferred from isotope data reveal a dramatic 10°C temperature variation between glacial and interglacial intervals. Similar to Greenland records, the conversion

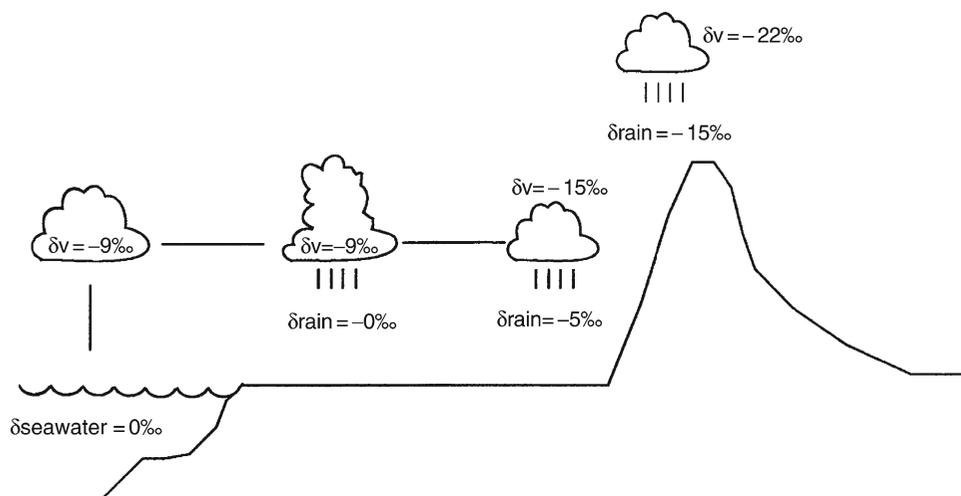

Figure S29 Changes in isotopic composition of air masses as they travel inside continents. Values depicted in the figure correspond to oxygen isotope ratios.

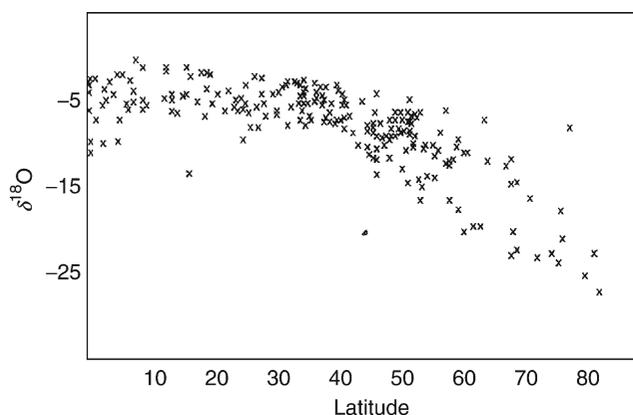

Figure S30 Variation of latitude and the oxygen isotopic composition ($\delta^{18}\text{O}$) of meteoric water. Notice that lower $\delta^{18}\text{O}$ values occur in polar regions.

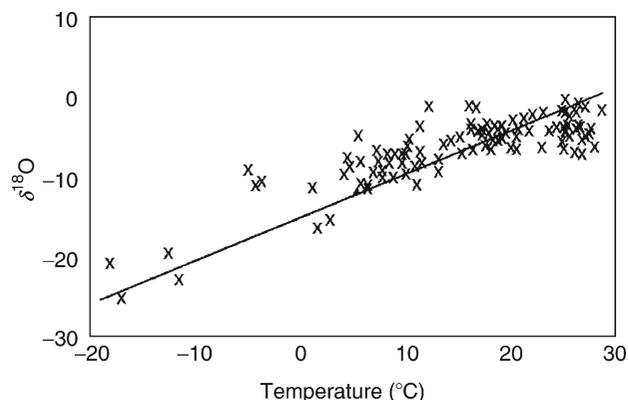

Figure S31 Variation of temperature and the oxygen isotopic composition ($\delta^{18}\text{O}$) of meteoric water.

of temperature from isotope data is based on modern calibration studies of Antarctic snow. It is important to indicate, however, that these modern calibrations might not be directly applicable to snow or ice accumulated during glacial intervals because atmospheric and oceanic processes were different from those operating today. As a result, the isotopic composition of water in clouds, seawater, and rainwater was likely different in glacial times with respect to modern (interglacial) intervals.

Although the strong relationship between surface temperature and $\delta^{18}\text{O}$ values of meteoric water in temperate and polar regions can be used to reconstruct past temperatures, there are a number of confounding factors that also control the isotopic composition of rainwater at a given locality. One of these factors is the so-called “amount effect” (Dansgaard, 1964). Large rain events tend to be associated with an anomalous enrichment of lighter isotopes, leading to lower $\delta^{18}\text{O}$ and δD values of meteoric water. This “amount effect,” characteristic of tropical settings, typically overprints any temperature-dependent isotope fractionation. As a result, tropical regions exhibit a weak relationship between temperature and the isotopic composition of meteoric water.

Another confounding factor is related to the complexity of cloud formation.

Isotopic and thermal equilibrium must exist during condensation in order to use the isotopic composition of meteoric water as a temperature proxy. Non-equilibrium conditions exist in clouds during ice formation or during super saturation events. Moreover, evaporation during travel from the cloud to the ground could result in the removal of lighter isotopes. This evaporation process can also weaken the correlation between temperature and the isotopic composition of meteoric water.

Another potential significant source of error in correlating temperature and the isotopic composition of meteoric water is the mixture of moisture from different sources. For instance, precipitation in North America results from the interplay of air masses coming from the Gulf of Mexico, the Pacific Ocean, and the Arctic region. Because of different evaporation/condensation histories, moisture derived from these masses has distinct isotopic composition. Consequently, the superimposition of moisture from different sources weakens the correlation between temperature and isotope data of meteoric water. This weakening is further enhanced when evapo-transpiration returns significant amounts of moisture to the atmosphere. A typical example of this process includes the Amazon Basin, where about 30% of the precipitation originates from significant evapo-transpiration of rain forests (Gat, 1996). Although the interplay of different air masses and evapo-transpiration affects the relationship between mid-latitude temperature and rainwater $\delta^{18}\text{O}$ values, isotope data from sites where these processes are pronounced can be used to assess the intensity of these processes. In these places, isotope data can consequently be used to assess variations in atmospheric circulation that either shift storm tracks or enhance/suppress evapo-transpiration.

Evaporation/precipitation ratios

The partitioning of stable isotopes that occurs during evaporation has been used as an indicator of the balance of evaporation and precipitation (E/P) in a region. The best systems to assess E/P ratios include relatively closed aquatic systems, where the main source of water is meteoric water. In this setting, the oxygen and hydrogen isotopic composition of the closed aquatic system corresponds to the isotopic composition of meteoric water plus the fractionation effect related to evaporation. One of the substrates employed to reconstruct past E/P ratios include carbonates precipitated in lakes. Since evaporation favors the incorporation of lighter isotopes in the gas phase, carbonates in closed aquatic systems experiencing high evaporation rates (high E/P ratios) exhibit elevated $\delta^{18}\text{O}$ values. The carbonates analyzed for E/P studies primarily come from ostracod shells and lacustrine marls. Isotope analyses on bulk marls in lakes are relatively easy to perform, allowing the possibility of performing high-resolution studies. The disadvantage of lacustrine marl deposits is that bulk carbonates represent a heterogeneous mixture of authigenic, biogenic, and detrital components. Moreover, precipitation of these components could occur under the influence of discrete processes operating at different places, lake depths, and time. In contrast, isotope analyses of biogenic carbonates offer an opportunity to minimize uncertainties related to spatial and temporal heterogeneity.

Whereas lacustrine marls tend to precipitate at steady-state conditions, a number of studies have documented a systematic offset between $\delta^{18}\text{O}$ values of ostracod carbonate relative to expected theoretical calcite $\delta^{18}\text{O}$ values formed at equilibrium (Epstein et al., 1953). This offset (“vital effect”) appears to be constant within a given species, but it is variable among

species, yielding values as low as 0.5‰ to as high as 2‰. Because the offset of ostracod $\delta^{18}\text{O}$ values from those expected at equilibrium is constant, ostracod isotope data have successfully been used to reconstruct past E/P ratios. For example, ostracod isotope data from lakes in the Yucatan Peninsula indicate that the collapse of the Mayan culture coincided with a period of extensive aridity in Meso-America (Hodell et al., 1995).

As indicated before, assessments of E/P ratios from carbonate $\delta^{18}\text{O}$ values can be achieved in closed-basin lakes where rainfall is the main component in the isotopic hydrological balance of lakes. Most lakes, however, are not closed because outlets and groundwater inflow and outflow exist. In these cases, additional information regarding the hydrological isotope balance of the basin is needed to perform accurate interpretations of past changes in E/P ratios from carbonate isotope data. Although groundwater fluxes are difficult to estimate among the different hydrological components, coarse assessments of these fluxes can be achieved from surveys of the isotopic composition of lake-, stream-, and rain-water during the dry and wet seasons. These isotopic data combined with information about rainfall amount, stream flow, and runoff can be used to estimate the influence of groundwater systems into a lake. Although these studies provide only a coarse indication of groundwater fluxes, they are useful to constrain any paleoclimatic interpretation from authigenic and biogenic carbonates in lakes.

A special case is open-basin lakes with short residence times (i.e., low ratios of lake/watershed area) because these lakes tend to exhibit $\delta^{18}\text{O}$ values of lake water close to those of recharging water. Isotopic analyses of lacustrine carbonates formed in these lakes can then provide information about temporal changes in the watershed's hydrology. Although recharge varies from lake to lake, it reflects the balance of precipitation, runoff, evaporation, and groundwater inflow and outflow (Talbot, 1990).

A potential source of uncertainty in assessing P/E ratios is the effect of temperature. Because $\delta^{18}\text{O}$ values of carbonates decrease by about 0.23‰ per + 1 °C, changes in P/E can only be detected in lake carbonates when the effect of evaporation is larger than that of temperature, which is the case for lakes with relatively large surface area and small volume. In contrast, seasonal changes in P/E ratios in large lakes produce a relatively small range of variability in lake water $\delta^{18}\text{O}$ values. This small variability in $\delta^{18}\text{O}$ values can be comparable to the range caused by seasonal changes in temperature, thereby making carbonate $\delta^{18}\text{O}$ values unsuitable for evaluating past P/E ratios unless an independent temperature proxy is utilized.

In addition to lakes, inference of E/P ratios from carbonate isotope data has successfully been employed in corals to assess changes in the balance of evaporation and precipitation in regions where seawater $\delta^{18}\text{O}$ values are sensitive to changes in the balance of precipitation and evaporation. Lindsley et al. (1994), for instance, found decadal changes in $\delta^{18}\text{O}$ values in ~300 year coral record from Gulf Chiriqui, Panama. Because the oxygen isotopic composition of seawater at this site is sensitive to rainfall amount, these changes were interpreted to reflect decadal changes in the strength or position of the Intertropical Convergence Zone.

Carbon isotopes of organic matter

There are two main approaches employed in reconstructing paleoenvironments using stable carbon isotopes. The first approach consists in determining changes in the distribution

of two isotopically distinct groups of vascular plants: C_3 and C_4 . In this approach, increased abundance of C_4 plants reflects increased aridity. The second approach is to infer changes in humidity from the carbon isotopic composition of tree-rings. In this approach, elevated $\delta^{13}\text{C}$ values indicate decreased humidity.

C_3 and C_4 plants possess different photosynthetic mechanisms that produce distinct carbon isotope signatures. The C_4 photosynthetic pathway is an efficient CO_2 concentrating mechanism (Leegood, 1999) that provides C_4 plants with higher water use efficiency. As a result, most C_4 grasses are found today in hot (>22 °C) and relatively dry places (Ehleringer, 1997; Collatz et al., 1998). C_4 plants are common in the monocot families Cyperaceae (sedges) and Poaceae (grasses). Almost 50% of all grasses are C_4 , inhabiting tropical to temperate regions with abundant warm-season precipitation. The C_4 photosynthetic pathway also causes C_4 plants to show $\delta^{13}\text{C}$ values that vary from -9‰ to -16‰. In contrast, C_3 plants exhibit $\delta^{13}\text{C}$ values that range from -21‰ to -30‰. The nonoverlapping $\delta^{13}\text{C}$ values of these two classes of plants produce a distinct isotopic signature that can be identified in past environments, provided that sufficient terrestrial organic matter persists in the geologic record. Changes in the distribution of C_3 and C_4 plant communities have been inferred from stable carbon isotopic composition of soil organic matter, lake deposits, and coastal and marine sediments. In this context, increased abundance of C_4 plants inferred from elevated $\delta^{13}\text{C}$ values has been interpreted to correspond to periods of increased aridity. In addition to widespread aridity, it has been argued that C_4 grasses can out-compete the more abundant C_3 plants under low concentrations of atmospheric carbon dioxide, even under relatively wet conditions. The role of aridity and CO_2 concentrations on expansions of C_4 plants in the geologic record is still unresolved.

Another application of stable carbon isotopes in paleoclimate research consists of inferring changes in relative humidity from changes in the stable carbon isotopic composition of tree-rings. This approach relies on the extent of the biological fractionation effect that occurs during photosynthesis by C_3 trees. The carbon-isotopic composition of a C_3 plant can be expressed by the following equation (Farquhar et al., 1988):

$$\delta^{13}\text{C}_{\text{Plant}} = \delta^{13}\text{C}_{\text{Air}} - a - (b - a)C_i/C_a \quad (7)$$

where a is the fractionation effect of 4.4‰ that occurs during the diffusion of CO_2 through stomata, and b is the biological fractionation effect of 28‰ that results during CO_2 fixation. C_i and C_a represent the concentration of CO_2 inside and outside of the leaf, respectively. $\delta^{13}\text{C}_{\text{Air}}$ is constant for relatively long time-scales because the troposphere is relatively well mixed. Consequently, the only variable actively determining $\delta^{13}\text{C}_{\text{Plant}}$ in Equation (7) is the C_i/C_a ratio. Field observations and laboratory experiments indicate that different plant species could exhibit different C_i/C_a ratios under the same environmental conditions, pointing to a species-specific effect. As indicated before, the natural range of $\delta^{13}\text{C}$ values for C_3 plants is between -21‰ and -30‰, which translates to C_i/C_a ratios of about 0.4–0.8. Elevated $\delta^{13}\text{C}_{\text{Plant}}$ values occur with relatively low C_i/C_a ratios that result when stomata are partially closed. Experimental studies indicate that plants tend to close their stomata under low values of relative humidity in order to suppress water loss associated with transpiration, resulting in elevated $\delta^{13}\text{C}$ values (Farquhar and Richards, 1984). In

addition to humidity, other factors, including light conditions, nutrient levels, and plant maturity, among others, also influence the extent of discrimination against ^{13}C that occurs during photosynthesis in C_3 plants. Despite these complexities, field studies (e.g., Hemming et al., 1998; Edwards et al., 2000) have concluded that a strong correlation exists between relative humidity and $\delta^{13}\text{C}$ values in angiosperm and gymnosperm trees. This covariance is the basis for the use of carbon-stable isotope data in paleoclimate research. The carbon-isotopic composition of tree-rings offer the best substrate for paleoclimate research because a number of confounding factors that affect $\delta^{13}\text{C}$ values in trees are constrained. On the other hand, bulk organic matter appears to be an unreliable substrate because the range of $\delta^{13}\text{C}$ values caused by changes in relative humidity is on the same order of magnitude as that caused by species-specific effects, diagenesis, and admixture of organic matter from different sources.

Summary

Temperature estimations from stable isotope data fall into two categories: (a) those based on fractionation effects related to carbonate formation from water with known or estimated $\delta^{18}\text{O}$ values, and (b) those based on the modern relationship between the isotopic composition of meteoric water and temperature in temperate and polar regions. The isotopic composition of meteoric water in these regions can be assessed from that of a number of substrates including ice, fluid inclusions, groundwater, pedogenic minerals, bones, and organic matter, among others.

Assessments of water balance inferred from stable isotope data can be achieved either through $\delta^{18}\text{O}$ and/or δD at sites sensitive to changes in precipitation and evaporation (such as closed-basin lakes) or via changes in C_3 and C_4 plant communities at sites sensitive to the colonization of these taxa.

STRONTIUM ISOTOPES

Strontium isotope systematics

The element with atomic number 38, strontium, has four isotopes 84, 86, 87 and 88 with approximate proportions of 0.56: 9.87: 7.04: 82.53 (Faure, 1986). Geologically short-lived nuclides (e.g., ^{90}Sr) are not considered in this contribution. The

proportion of ^{87}Sr is somewhat variable because it is a decay product of ^{87}Rb . The decay constant λ for ^{87}Rb is $1.42 \times 10^{-11} \text{ a}^{-1}$, resulting in a half-life T of 48.8 billion years (Ga).

The present-day quantity of isotope 87 ($^{87}\text{Sr}_p$) depends on the initial stock ($^{87}\text{Sr}_0$) and the amount of radiogenic Sr generated by decay of ^{87}Rb over time t

$$^{87}\text{Sr}_p = ^{87}\text{Sr}_0 + ^{87}\text{Rb}(e^{\lambda t} - 1) \quad (1)$$

Because of the design of mass spectrometers, the above quantities are measured as a ratio to the stable isotope ^{86}Sr

$$\left(\frac{^{87}\text{Sr}}{^{86}\text{Sr}}\right)_p = \left(\frac{^{87}\text{Sr}}{^{86}\text{Sr}}\right)_0 + \left(\frac{^{87}\text{Rb}}{^{86}\text{Sr}}\right)(e^{\lambda t} - 1) \quad (2)$$

The young Earth, at the time of its formation ~ 4.55 Ga ago, inherited the $(^{87}\text{Sr}/^{86}\text{Sr})_0$ ratio of 0.699 from its chondritic meteorite building blocks.

From Equation 2, it is evident that the term $(^{87}\text{Sr}/^{86}\text{Sr})_p$ for coeval rocks that originate from the same source and inherit the same $(^{87}\text{Sr}/^{86}\text{Sr})_0$ ratio depends only on their Rb/Sr ratio. The latter is about six times larger for the fractionated rocks that form the continents than for the basalts of the oceanic crust (~ 0.15 vs. 0.027). As a consequence, the average $(^{87}\text{Sr}/^{86}\text{Sr})_p$ for continents is about 0.720 while for the basalts of the oceanic crust it is ~ 0.703 (Figure S32). The temporal evolution of these two geologic entities is the principal control of chemical and isotopic composition of seawater, reflecting the relative inputs from rivers and submarine hydrothermal circulation, respectively.

Strontium isotopic evolution of seawater

The present day $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of seawater is 0.7092 and is uniform worldwide. This is because the average time that an atom of Sr spends in seawater, the so-called residence time, is somewhere between 2 and 5 million years, while the mixing rate of the oceans is only thousands of years. Thus, from the point of view of Sr, the seawater at any given time is well mixed. Even marginal marine basins, such as the almost brackish Hudson Bay of northern Canada, have a Sr isotopic composition identical to that of the open sea. This is because

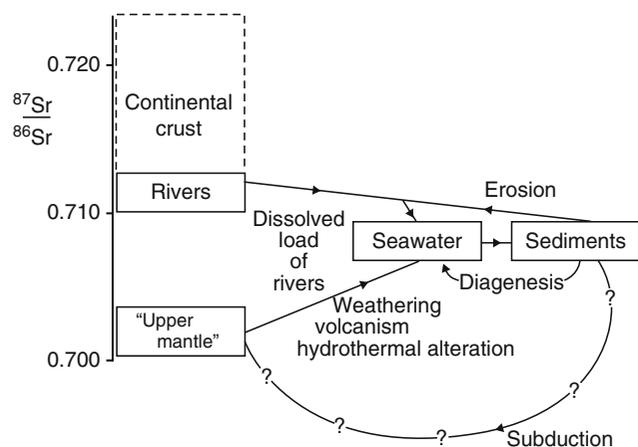

Figure S32 Schematic presentation of Sr isotopic surficial cycle (modified after Wadleigh, 1982).

the Sr concentrations in riverine waters are 2–3 orders of magnitude less than that of seawater, at ~ 8 ppm, and any dilution by river water, while lowering the Sr concentration, will not impact the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio because almost the entire Sr load originates from seawater.

Note that the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of modern seawater is only about 1/3 of the way up the scale between that of oceanic and continental crust (Figure S32), despite the fact that modern river input of Sr is about 6.5 times larger than its hydrothermal flux (2.73 vs. $0.42 \times 10^{12} \text{ g a}^{-1}$), and therefore dominates the oceanic budget. This is because the average $^{87}\text{Sr}/^{86}\text{Sr}$ of river water, at ~ 0.711 , is much less radiogenic than that of the average continental crust. The discrepancy is a reflection of the fact that carbonate rocks almost always account for a substantial proportion of the lithology in the watersheds of major rivers. Carbonate rocks, being marine sediments, inherit the Sr isotopic composition of seawater at the time of their formation. The oceanic, and particularly the continental crust, was less radiogenic in the early history of the Earth (Figure S33) and this was reflected in the contemporaneous seawater and in the sediments that precipitated from it. Subsequently, weathering of ancient marine carbonates, their redeposition in the sea and renewed uplift and erosion resulted in perpetual recycling of this “ancient” Sr, thus “retarding” the $^{87}\text{Sr}/^{86}\text{Sr}$ signal of seawater relative to the development of the continental crust.

Unfortunately, we do not have samples of past seawater that would enable us to measure directly its past chemical and isotopic composition. On the other hand, we do have sediments that precipitated from seawater, either directly (salts, gypsum) or with the help of biological intermediaries that precipitated carbonate (phosphate, siliceous) minerals as shells or crystallites. We can therefore utilize shells for about 540 Ma and carbonate rocks (limestones, dolostones) for almost 4 Ga to decipher the Sr isotopic composition of ancient seawater. The matter is complicated by the fact that many of these shells and rocks were post-depositionally (diagenetically) altered and this often results in alteration of the $^{87}\text{Sr}/^{86}\text{Sr}$ signal. Techniques do exist for at least partial evaluation of the degree of such alteration, but none is foolproof. Usually, the alteration process shifts the $^{87}\text{Sr}/^{86}\text{Sr}$ values upwards and it is common practice to accept the lowest measured value for any suite of samples as the best approximation of the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of the coeval ocean.

In the early stages of isotope geology it was believed that the $^{87}\text{Sr}/^{86}\text{Sr}$ of seawater evolved linearly during geologic history (Wickman, 1948) and it was hoped that such a linear trend could be utilized for dating of (bio)chemical marine sediments. Due to the low sensitivity of early mass spectrometers, this proposition could only be tested some 20 years later, when it was realized that we were dealing with a widely oscillating signal (Peterman et al., 1970). This was subsequently documented by Veizer and Compston (1974, 1976) and Burke et al. (1982). The latest editions of these curves for the entire 4 Ga of Earth history were published by Shields and Veizer (2002) (Figure S33) and for the Phanerozoic by Veizer et al. (1999) (Figure S34).

The most important features of the billion-year trend in $^{87}\text{Sr}/^{86}\text{Sr}$ (Figure S33) are the departure of seawater from mantle values somewhere around the Archean/Proterozoic transition, ~ 2.5 Ga ago; the relatively sharp rise until about 1.8 Ga ago; the flat trend to ~ 900 Ma ago; and another steep rise during the Neoproterozoic, followed by a trough-like structure during the Phanerozoic. The Precambrian portion of the

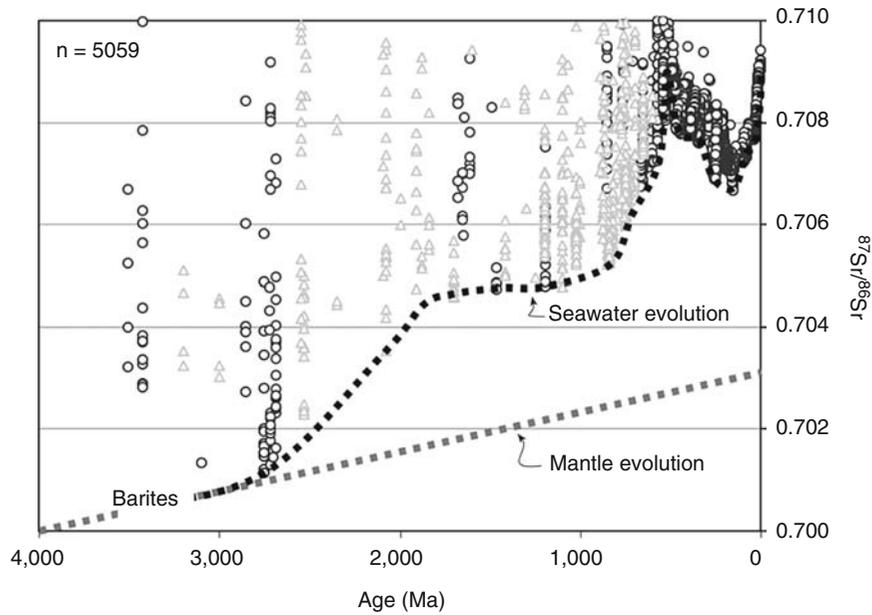

Figure S33 Strontium isotope record of carbonate rocks (seawater) during geologic history. *Full symbols*: chronologically well constrained; *empty symbols*: poorly constrained samples (reproduced from Shields and Veizer, 2002).

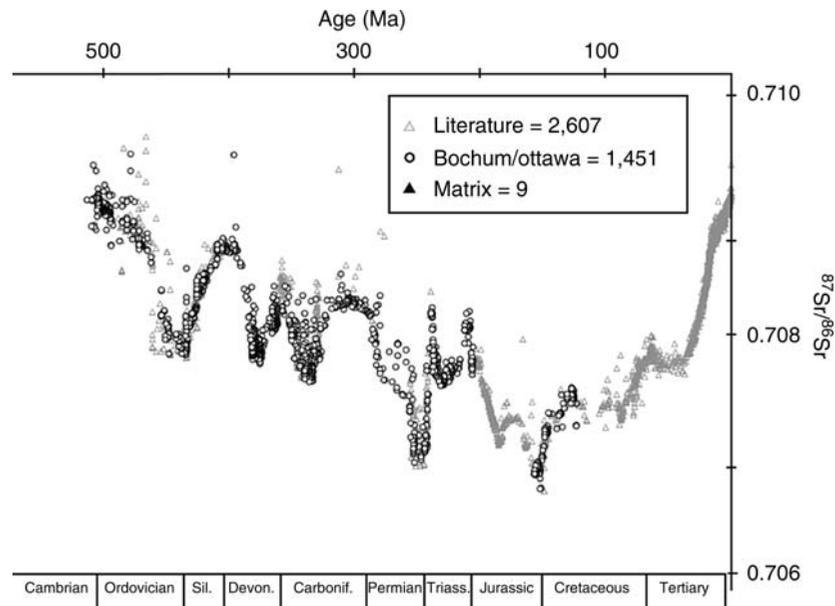

Figure S34 Sr isotope record for Phanerozoic seawater based on 4,055 samples of calcite shells (reproduced from Veizer et al., 1999).

curve is in all likelihood composed of higher order oscillations similar to those of the Phanerozoic, but we do not yet have the geochronological resolution to decipher it. For this reason, we can discuss only the lower bound of the trend. The mantle-like values of seawater during the early Archean indicate that either the river input was negligible, or the hydrothermal flux was much stronger than today, or both. The geological interpretation is that the continents could have been much smaller

and seawater circulation via submarine hydrothermal systems (in order to dissipate heat from the hotter mantle) more vigorous. This was followed by the major interval of generation of continental crust, between ~ 2.7 and 1.8 Ga ago, the cumulative size of continents reached near-modern extent towards the end of this time interval. Simultaneously, the chemical and isotopic composition of the oceans evolved from being “mantle-buffered” to “river-buffered,” and this development

may also have been the cause of other contemporary phenomena, such as the transition from oxygen-poor to oxygen-rich atmospheric composition. The steep rise in $^{87}\text{Sr}/^{86}\text{Sr}$ in the Neoproterozoic may be related to another pronounced phase of continent formation, the Pan African orogeny.

The origin of the trough-like Phanerozoic structure (Figure S34) with its superimposed oscillations is at this stage enigmatic. Attempts to correlate the details of this structure with tectonic development of the Earth have not led to any unequivocal conclusions. A great deal of attention was paid particularly to the steep Tertiary rise of $^{87}\text{Sr}/^{86}\text{Sr}$ values, that was assumed to be a reflection of the collision between India and Asia, with the resulting uplift of the Himalayas. The corollary of such an interpretation was a potential role that this uplift could have played in increased global erosion that, in turn, would have resulted in atmospheric CO_2 drawdown and the overall Tertiary cooling of the globe (Ruddiman, 1997). However, the modeling simulations do not appear to support the validity of such a scenario.

Isotope stratigraphy

Despite the fact that the $^{87}\text{Sr}/^{86}\text{Sr}$ trend for seawater is not linear, the sections of this oscillating trend that show a particularly steep slope can be utilized for dating and correlation of marine (bio)chemical sediments, the approach known as isotope stratigraphy (McArthur, 1994). In particular, the Cenozoic portion of the trend (Figure S34) enabled correlations at levels comparable to biostratigraphic techniques.

SULFUR ISOTOPES

Sulfur isotope systematics

The element sulfur has four stable isotopes ^{32}S , ^{33}S , ^{34}S and ^{36}S with the following natural abundances: 95.02%, 0.75%, 4.21%, and 0.02% (Hoefs, 1997). Most commonly, the two major isotopes (^{32}S , ^{34}S) are being measured and results expressed as $\delta^{34}\text{S}$, defined by the following equation

$$\delta^{34}\text{S}[\text{‰}] = \left(\frac{\left(\frac{^{34}\text{S}}{^{32}\text{S}} \right)_{\text{Sample}}}{\left(\frac{^{34}\text{S}}{^{32}\text{S}} \right)_{\text{Standard}}} - 1 \right) 1,000 \quad (1)$$

and reported as per mil difference with respect to the V-CDT-standard (defining the Zero-Point of the sulfur isotope scale). Due to analytical improvements, the minor sulfur isotopes ^{33}S and ^{36}S can now be measured routinely with their delta values defined analogous to equation 1.

Sulfur is present in the atmosphere, hydrosphere, biosphere and lithosphere (Figure S35). In addition to natural processes, the present day sulfur cycle is strongly affected by anthropogenic sulfur inputs. The transfer of sulfur between the different reservoirs is mediated through abiological and biological processes. Such processes are generally associated with a change in the redox state and an isotopic fractionation of variable magnitude, depending on the mode of isotope exchange (i.e., equilibrium vs. kinetic isotope effect). From the geological perspective, research focuses on sulfate as the most oxidized and sulfide as the most reduced form of sulfur. Respective processes are the precipitation of evaporitic sulfate from seawater and the bacterial cycling of sulfur in sediments.

The pure precipitation of sulfate minerals from evaporating seawater is only associated with a small, almost negligible isotope effect (Claypool et al., 1980). As a consequence, marine evaporites and sulfate incorporated into marine chemical and biological precipitates are regarded as proxy signals for the isotopic composition of seawater sulfate (e.g., Strauss, 1999; Kampschulte and Strauss, 2003).

In contrast, variable but generally substantial isotopic fractionation occurs during bacterial sulfate reduction (e.g., Canfield, 2001). At the expense of sedimentary organic matter, sulfate is reduced to hydrogen sulfide, which subsequently reacts with

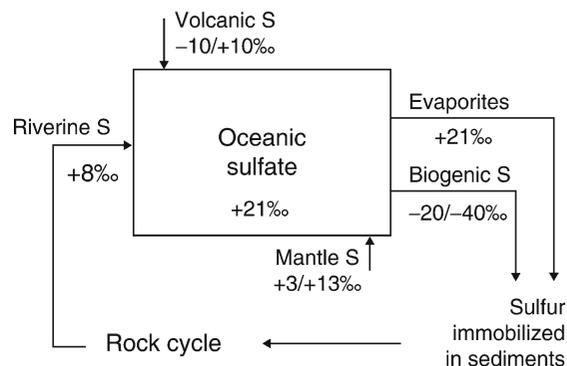

Figure S35 Schematic view of the sulfur cycle showing $\delta^{34}\text{S}$ values for modern reservoirs.

Fe to form sedimentary pyrite (FeS_2). The resulting sulfide is depleted in ^{34}S with respect to ambient sulfate due to the preferential utilization of ^{32}S by sulfate-reducing bacteria. The size of this isotope effect is dependent on the type of organism, the reaction rate, and the availability of sulfate and reactive organic matter (Canfield, 2001). Experimental data from pure cultures indicate an isotopic fractionation of 2–42‰ (e.g., Detmers et al., 2001), whereas natural populations display an isotope effect of 19–43‰ (Habicht and Canfield, 2001). For modern marine sediments, however, the isotope difference between porewater sulfate and sedimentary pyrite amounts to 31–56‰ (Habicht and Canfield, 2001). This additional isotopic fractionation accompanies the disproportionation of partly oxidized intermediate sulfur compounds: elemental sulfur, thiosulfate, and sulfite (e.g., Canfield and Thamdrup, 1994; Habicht et al., 1998). Measurements in recent marine sediments indicate that 41–85% of the apparent isotopic fractionation between seawater sulfate and sedimentary sulfide are the result of bacterial sulfate reduction, with the remaining part being due to disproportionation reactions (Habicht and Canfield, 2001).

Progressive bacterial sulfate reduction under sulfate-limiting conditions (e.g., porewaters in deep sediments) results in a continuous depletion of ^{32}S . As a consequence, the $\delta^{34}\text{S}$ becomes increasingly more positive. This explains part of the sulfur isotope record for reduced sedimentary sulfur.

The oxidative weathering of sulfur-bearing minerals and subsequent riverine delivery as dissolved sulfate from the continents to the ocean is not associated with an isotope effect.

The long-term evolution of the global sulfur cycle can be evaluated via simple isotope mass balance calculations. Considering the two principal output functions as oxidized (sulfate) and reduced (sulfide) sulfur (see Figure S35), this mass balance is defined as:

$$\delta_{\text{Input}} = f_{\text{Sulfide}}\delta_{\text{Sulfide}} - (1 - f_{\text{Sulfide}})\delta_{\text{Sulfate}} \quad (2)$$

with δ_{Input} representing the average isotopic composition of crustal sulfur (assumed constant at +2‰, Holser et al., 1988) and $f_{\text{Sulfide}}\delta_{\text{Sulfide}}$ and $(1 - f_{\text{Sulfide}})\delta_{\text{Sulfate}}$ being the fraction and isotopic composition of sulfide and sulfate sulfur. Fluctuations in the sulfur isotopic composition of seawater sulfate can then

be interpreted as a consequence of temporal variations in the fractional burial of reduced (sulfide) sulfur.

Sulfur isotopic evolution of seawater

The average sulfur isotopic composition of dissolved oceanic sulfate lies at +21‰ (e.g., Rees et al., 1978). Lateral and vertical homogeneity of this value is a consequence of a long residence time for sulfur in the ocean (3 million years) in comparison to the short mixing time for the ocean (1,000 years). Only marginal seas, such as the eastern Mediterranean or the Baltic Sea, represent exceptions. Their isotopic composition is more strongly affected by the riverine input of dissolved sulfate (on average +8 to +10‰). However, part of this input stems from anthropogenic sources (e.g., Grinenko and Krouse, 1992).

Despite its homogeneity at any given point in time (e.g., Nielsen, 1989), empirical data clearly show that the sulfur isotopic composition of seawater sulfate has fluctuated widely throughout four billion years of Earth's history (e.g., Strauss, 2002). However, the existing isotope record is highly variable in its temporal resolution and becomes increasingly fragmentary for the early part of Earth's history (Figure S36).

Early Archean (3.5 billion years ago) barite occurrences from Australia, South Africa and India constrain our knowledge about the sulfur isotopic composition of seawater sulfate from the early part of Earth's history at a value around +4‰ (Strauss, 2002). Sulfate abundance in the global ocean is considered to have been very low (<1 mM, Canfield et al., 2000). This interpretation is supported by a lack of substantial sulfur isotopic fractionation between sulfate and sedimentary sulfide (e.g., Strauss, 2002). Still, contrasting views of an Archean high-sulfate ocean have been proposed (e.g., Ohmoto, 1997).

The sulfur isotopic composition of seawater sulfate increases throughout the Precambrian. Due to the fragmentary record, it is unclear whether this increase is linear or episodic. A significant the sulfur isotopic composition of seawater sulfate is considered to occur between 2.4 and 2.2 billion years ago. It is thought to coincide with a substantial increase in the oxygen abundance in the atmosphere, termed the Great Oxidation Event (Holland, 2002). This would have initiated

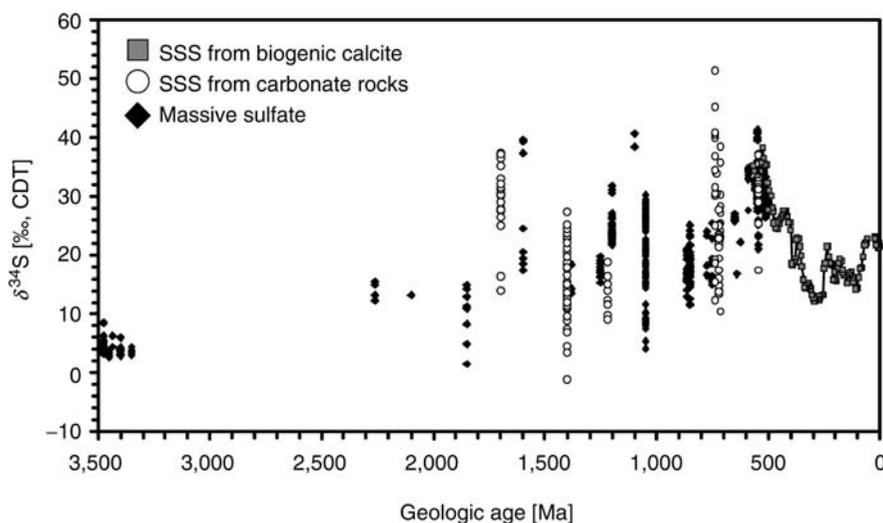

Figure S36 Sulfur isotopic evolution of seawater sulfate.

the oxidative weathering on the continents, delivering dissolved sulfate to the ocean.

The resulting increase in oceanic sulfate abundance would have triggered an increase in sulfur cycling via bacterial sulfate reduction (Canfield and Raiswell, 1999). Supporting evidence stems from the observation that large sulfur isotopic fractionations between sulfate and sedimentary sulfide commence at that time (e.g., Strauss, 2002). These are comparable in size to those recorded from younger times and modern marine sediments.

Towards the end of the Precambrian (600–500 million years ago), the average sulfur isotopic composition of seawater sulfate reaches its all-time maximum at + 35‰. This high $\delta^{34}\text{S}$ value continues into the Phanerozoic.

Substantial fluctuations in the sulfur isotopic composition of seawater sulfate characterize the Phanerozoic (the last 545 million years). The high $\delta^{34}\text{S}$ values at the beginning of this era are followed by a long-term decrease to a minimum value of + 11‰ in the Permian (some 250 million years ago) and a subsequent rise to the present day value. A detailed isotope record with good temporal resolution, based on structurally substituted sulfate (SSS) in biogenic carbonates, reveals additional higher order oscillations (Kampschulte and Strauss, 2003).

Following the simple isotope mass balance (Equation (2)) these temporal variations in $\delta^{34}\text{S}$ of seawater sulfate reflect variations in the fractional burial of reduced sedimentary sulfur. Potential causes for such variations include habitat size (near shore shelf area) and availability of reactive organic matter.

Evolution of biological sulfur cycling

The observation of a large sulfur isotope effect associated with bacterial sulfate reduction has prompted researchers to utilize this as a proxy for biogenicity in their studies of sedimentary pyrite. The resulting sulfur isotope record (Figure S37) reveals a temporal evolution that parallels the evolution of seawater sulfate in many respects.

Early Archean sedimentary pyrite generally displays a very limited variation in $\delta^{34}\text{S}$ near 0‰ and only a small difference to the sulfur isotopic composition of barite sulfur (e.g., Strauss, 2002). Lack of a large isotope effect suggests that bacterial sulfur cycling played only a minor role in sedimentary systems.

Starting in the late Archean/early Proterozoic (about 2.8–2.4 billion years ago) a substantial spread in $\delta^{34}\text{S}$ for sedimentary sulfide indicates sizeable sulfur isotopic fractionations. These are attributed to the activity of sulfate-reducing bacteria. Throughout the Proterozoic (2.5–0.5 billion years ago), the sulfur isotopic composition of sedimentary pyrite remains highly variable. Maximum isotopic fractionation between oceanic sulfate and sedimentary pyrite ranges between 30 and 40‰, reflecting bacterial sulfate reduction. The Neoproterozoic (1,000–545 million years ago) witnesses not only large spreads in $\delta^{34}\text{S}$ but also strongly positive, ^{34}S enriched sulfur isotope values for sedimentary sulfide. Considering minimum $\delta^{34}\text{S}$ values for sedimentary pyrite and $\delta^{34}\text{S}$ values of + 35‰ for Neoproterozoic seawater sulfate results in a maximum isotopic fractionation of 60‰. Such a large apparent isotope fractionation reflects the isotope effect associated with disproportionation reactions in addition to bacterial sulfate reduction.

The Phanerozoic (the last 545 million years) sulfur isotope record for sedimentary sulfur displays comparable large variations in $\delta^{34}\text{S}$ and an apparent isotopic fractionation that reflects sulfate reduction and disproportionation. The sulfur isotope record for reduced sulfur parallels roughly the respective record for seawater sulfate (Figure S36): high $\delta^{34}\text{S}$ values in the early Phanerozoic, followed by a decrease towards the Permian and a subsequent rise during Mesozoic and Cenozoic. The comparable temporal evolution of both sulfur isotope records at least during the last 600 million years suggests that bacterial sulfate reduction and disproportionation of intermediate sulfur compounds have been the key processes in biological sulfur cycling in sedimentary environments.

Multiple sulfur isotopic evidence for an atmospheric impact on the early sulfur cycle

The measurement of multiple sulfur isotopes (^{32}S , ^{33}S , ^{34}S , ^{36}S) reveal that all physical, chemical and biological processes on Earth result in mass-dependent fractionation (MDF) of these isotopes. Hence, mass-dependent relations can be defined as:

$$\delta^{33}\text{S}_{\text{TFL}} = 0.515 \times \delta^{34}\text{S} \quad (3)$$

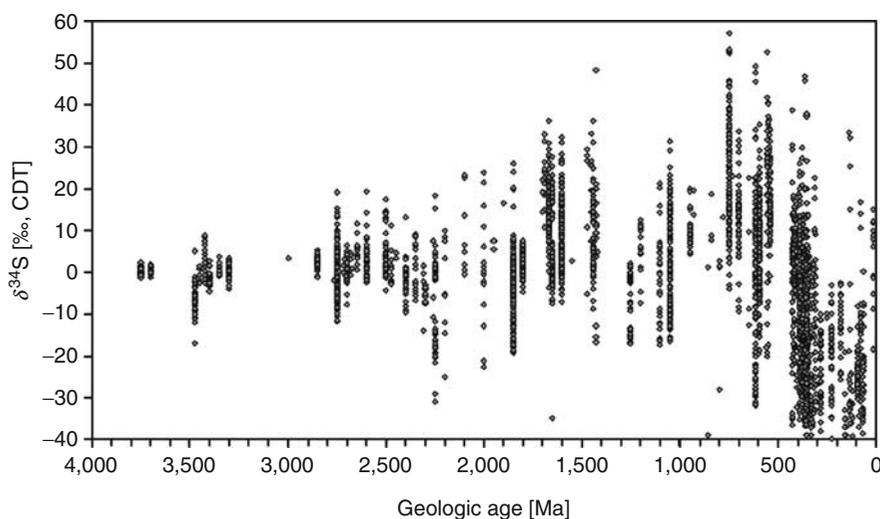

Figure S37 Sulfur isotopic composition of reduced sedimentary sulfur.

$$\delta^{36}\text{S}_{\text{TFL}} = 1.9 \times \delta^{34}\text{S} \quad (4)$$

with data falling on a respective Terrestrial Fractionation Line (TFL) in a three-isotope-plot. Multiple sulfur isotope analyses of sedimentary sulfide and sulfate of Archean and early Paleoproterozoic age (>2350 million years) yielded clear deviations from these mass-dependent relationships (e.g., Farquhar et al., 2000). Such mass-independent fractionation (MIF) in a measured sample can be quantified as:

$$\Delta^{33}\text{S} = \delta^{33}\text{S}_{\text{measured}} - \delta^{33}\text{S}_{\text{TFL}} \quad (5)$$

$$\Delta^{36}\text{S} = \delta^{36}\text{S}_{\text{measured}} - \delta^{36}\text{S}_{\text{TFL}} \quad (6)$$

Based on experimental and modelling data, this mass-independent isotope fractionation is believed to result from photochemical reactions in the atmosphere involving gaseous sulfur species, in particular sulfur dioxide. Furthermore, respective reactions require the absence of an effective UV shield (like ozone). Consequently, the presence of MIF-S has been taken as evidence for the absence of free oxygen in the Archean and early Paleoproterozoic atmosphere (e.g., Farquhar et al., 2000; 2007). Modelling evidence suggests that the maximum concentration of atmospheric oxygen had to be $<10^{-5}$ of the present atmospheric level (PAL) in order to yield MIF-S. Sedimentary sulfur younger than 2350 million years displays only mass-dependent sulfur isotopic fractionation, indicating that the atmospheric oxygen level had increased to $>10^{-2}$ PAL (e.g., Pavlov and Kasting, 2002).

SUN-CLIMATE CONNECTIONS

Introduction

All energy distributed in the climate system originates from the Sun. Earth's surface temperature is maintained by a balance between incoming and outgoing radiation. Irradiance is the most important parameter related to solar variability, as the relationship between irradiance and climate in radiative balance is simple and direct. The Earth currently receives an average of $1,367 \text{ W m}^{-2}$, integrated over all wavelengths. Climate variability directly associated with the radiative imbalance caused by changes in solar radiation is “solar forced.” In contrast, a “solar influenced” or “solar triggered” climate change depends mostly on atmospheric or oceanic feedback mechanisms for the effect.

The Sun also generates strong magnetic fields. Through their interaction with Earth's magnetic field and charged particles such as cosmic rays, magnetic fields are central to both observational and proxy records establishing solar variability. A current challenge in Sun-climate research is the interpretation of long-term proxy records related to the Sun's magnetic activity. It will only be possible to confirm a Sun-climate connection for past climates when the innermost workings of the Sun are understood well enough to quantify the relation between magnetic proxies and irradiance.

On millennial and shorter time scales, there is evidence that small changes in irradiance affect climate. It has proven difficult to identify the physical mechanisms by which small observed and reconstructed irradiance changes (a few tenths of a percent) could produce observed and reconstructed climate changes, up to 2°C within 50 years (Bond et al., 2001). Over

the past ten years, researchers have discovered that the atmosphere and ocean can undergo abrupt re-organizations when perturbed only slightly. This can cause large regional climate change while global average changes are small. Positive feedback systems have been proposed involving the upper and lower atmosphere, oceans, and polar ice. These can amplify the effects of small irradiance changes, and are likely critical for Sun-climate connections unless past solar variability was much larger than present estimates.

Solar variability

Solar cycles and sunspots

Perhaps the best-known indirect index of solar variability is the 11-year sunspot cycle. Over this cycle, the number of dark spots visible on the Sun's surface ranges from 0 to over 200. Sunspots are associated with strong local magnetic activity inhibiting surface convection, leading to cooling and darkening relative to the rest of the visible solar surface. Bright regions called faculae surround sunspots, causing a net increase in total solar irradiance (TSI) of about 0.1% during sunspot peaks relative to sunspot minima. Sunspot numbers from 1610 to present

are shown in [Figure S38](#), with the relationship to TSI measured by satellites since 1978 shown in [Figure S39](#).

Though measured irradiance and sunspot number are highly correlated, direct comparison is only possible for the past three solar cycles. The relation between long-term trends in sunspot numbers ([Figure S38](#)) and irradiance is unclear. Sunspot numbers return nearly to 0 during cycle minima, while during the Maunder Minimum, from 1645–1715, hardly any sunspots were observed in 50 years. If irradiance varied over this period, it must be reconstructed from records of solar activity other than sunspot numbers.

Solar magnetic activity and the geomagnetic field

Solar magnetic activity is evident on Earth due to interaction with the geomagnetic field. The *aa* index ([Figure S40](#)) is a measure of the Earth's magnetic field constructed from surface magnetometers.

A portion of the solar magnetic field is carried through the solar system and beyond by the solar wind. This is the interplanetary magnetic field (IMF), which influences Earth's magnetic field. Increasing IMF strength over the past 100 years

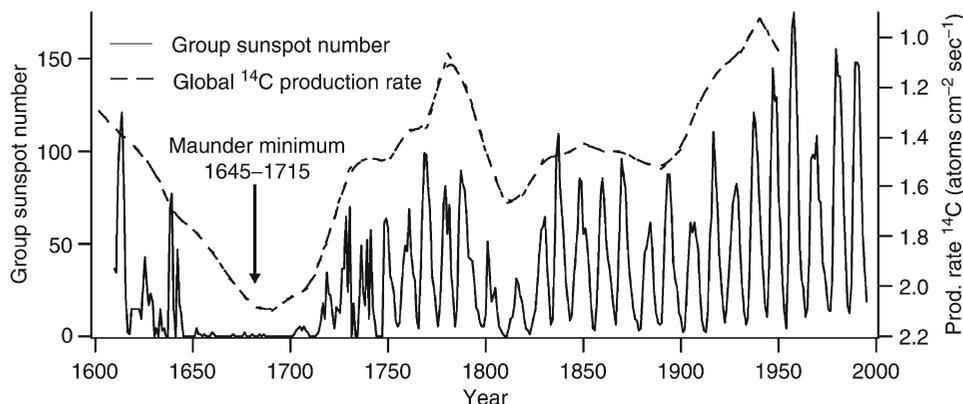

Figure S38 Sunspot numbers and global radiocarbon production rate show coherent variability. Carbon-14 production from nuclear weapons testing limits comparison with sunspots to before 1950. Note the lack of sunspots during the Maunder Minimum, and the increasing amplitudes of the solar cycles (data from National Geophysical Data Center, USA).

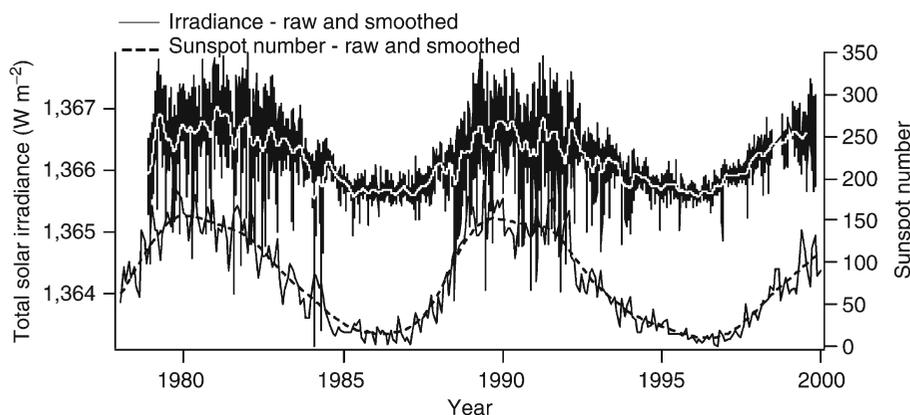

Figure S39 Total solar irradiance and sunspots are closely associated for the past three solar cycles (data from National Geophysical Data Center, USA).

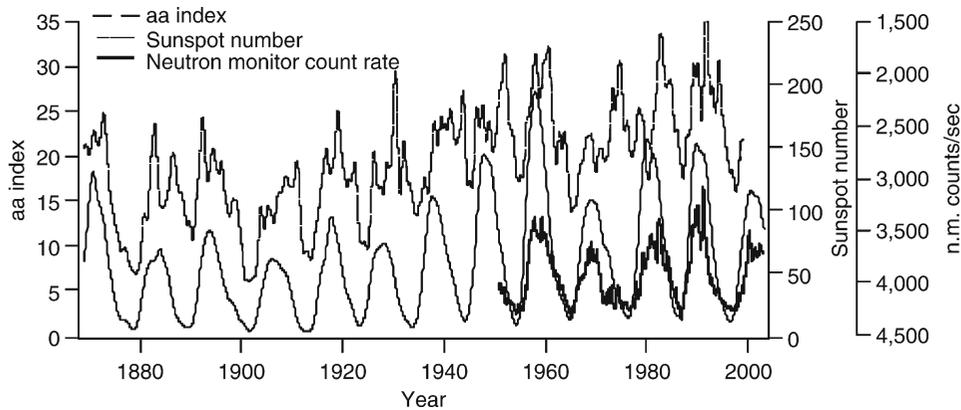

Figure S40 The geomagnetic *aa* index, neutron monitor count rate, and sunspot numbers demonstrate the influence of solar magnetic variability on the geomagnetic field. Cosmic ray flux is lower during solar-geomagnetic maxima (data from National Geophysical Data Center, USA).

is responsible for the long-term upward trend of the *aa* index (Lockwood et al., 1998). Though there is an 11-year cycle in *aa* in addition to the long-term trend, it is not directly convertible to irradiance because the IMF has a different origin from magnetic activity associated with sunspots (Lean et al., 2002).

Solar variability and cosmogenic isotopes

The Earth is continually being bombarded by galactic cosmic radiation (GCR): high-energy charged particles originating mostly from outside the solar system. The charge on cosmic ray particles subjects them to deflection by solar and terrestrial magnetic fields. The partial shielding of Earth by the coupled solar and geomagnetic fields is modulated by variability in those fields. This is clear from cosmic ray neutron monitor measurements taken since the 1950s. Figure S40 shows the neutron monitor counting rate (GCR flux) from Climax, Colorado, USA, which varies inversely with sunspot number.

Cosmic rays interact with Earth materials to produce cosmogenic isotopes, both in the atmosphere and in geologic materials. Two atmospherically produced cosmogenic isotopes, ^{14}C and ^{10}Be , are among the most useful proxy records for solar modulation of cosmic rays. Carbon-14 is produced from cosmic ray neutron reactions with nitrogen. It is rapidly oxidized to $^{14}\text{CO}_2$, and mixed throughout the atmosphere within about one year. Living trees incorporate ^{14}C in their tissues during photosynthesis. Measurements of ^{14}C in German oak tree rings provide a continuous record of atmospheric ^{14}C concentration back to almost 12,000 years. One complication in using atmospheric ^{14}C as a proxy for solar variability is its sensitivity to cycling of carbon in the ocean (Stuiver, 1994). In some ocean basins, surface water is transported to the deep ocean via thermohaline circulation (THC), where it may reside for more than 1,000 years before returning to the surface. Rapid changes in THC can affect atmospheric $^{14}\text{CO}_2$ concentration independently of its production. By increasing THC, more $^{14}\text{CO}_2$ -equilibrated water is sequestered in the ocean, drawing down atmospheric ^{14}C . Atmosphere-ocean carbon cycling effects in tree ring records may be evaluated by comparison with records of other, non-cycling cosmogenic isotopes, such as ^{10}Be .

Beryllium-10 is produced from oxygen and nitrogen in the atmosphere, rapidly sorbed to suspended aerosols, and flushed out in precipitation. The highest quality ^{10}Be records are found in polar ice cores. While ocean circulation changes cannot

directly affect ^{10}Be flux, the ocean can influence polar climate, changing ice-core accumulation rates. Beryllium-10 concentration in the ice is directly convertible to ^{10}Be flux if ice-core accumulation rates are known. Holocene ice-core accumulation rates are believed to have been constant, allowing ^{10}Be variations to reflect changes in production. Figure S41 shows ^{14}C and ^{10}Be production rates for the past 11,000 years.

Ca II emission of sun-like stars

Conversion of the cosmogenic production rates to irradiance remains a major challenge. One approach is to construct an estimate of irradiance for some point in the record, which is then used to scale back from modern irradiance. The most widely cited estimates of irradiance beyond the observed record come from observations of Sun-like stars at wavelengths associated with brightness variations, such as singly ionized calcium (Ca II) (Radick, 2003). Non-cycling stars are observed to be dimmer than those with 8–15 year periods in Ca II emission. Such observations suggest that the Sun was around 0.25% dimmer during the Maunder Minimum, when sunspot cycles ceased (Lean et al., 1995, 1998; Figure S42).

A critical assumption remains unverified, that non-cycling Sun-like stars are in a period of Maunder-type inactivity. None of the non-cycling Sun-like stars observed over the past two decades have resumed cycling. Given this uncertainty, true irradiance change during the Maunder Minimum could be either larger or equal to that during an 11-year cycle.

Correlations between solar variability and climate

In a landmark paper, Eddy (1976) presented evidence suggesting solar influence on climate for periods longer than the 11-year cycle. He noted that the Maunder Minimum corresponded to the coldest years of the Little Ice Age, a period of European history known for its climatic extremes. Eddy described the striking correspondence between minima in sunspot observations and maxima in the tree-ring record of cosmogenic ^{14}C (Figure S38), suggesting that cold years during the Maunder Minimum were linked in some way to reduced solar activity.

In the modern observational record, there have been many attempts to correlate the last three solar cycles with climate-related variables. While some correlations appear convincing, the observational records are typically too short for statistical

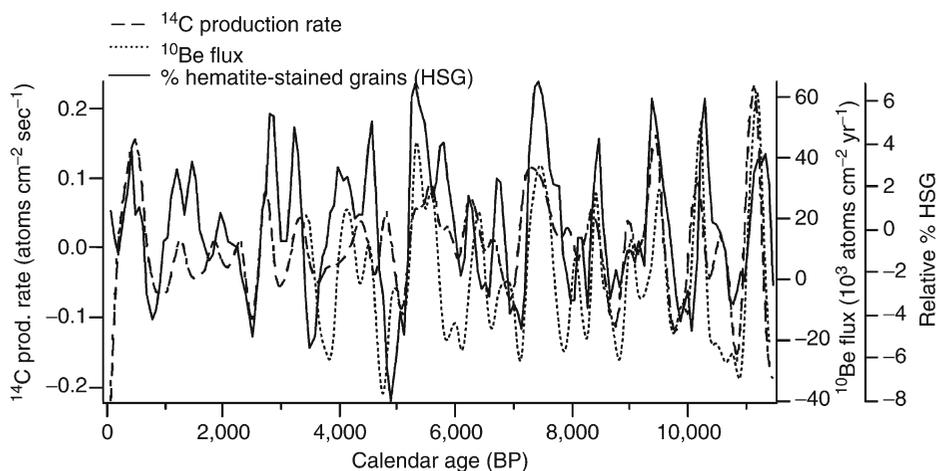

Figure S41 Percentage of hematite-stained quartz grains increases during Holocene cosmogenic isotope maxima, indicating North Atlantic cooling during solar minima. The most recent cold phase corresponds to the Little Ice Age in Europe (data from Bond et al., 2001).

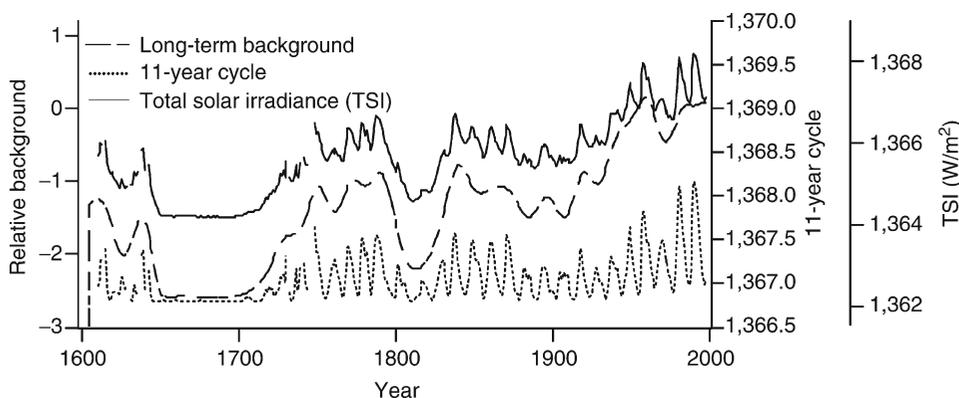

Figure S42 Two components of solar irradiance variability, background and the 11-year cycle, are summed to provide an estimate of total solar irradiance (TSI) since 1610 (data from Lean et al., 1998).

significance (Lean and Rind, 1999). The reviews of Lockwood (2002), Solanki and Fligge (2002), and Haigh (2003) provide excellent summaries of recent Sun-climate correlations using observational records. One example is a study of irradiance correlated with stratospheric temperature by Labitzke and Matthes (2003; Figure S43).

Some correlations imply a physical mechanism other than direct radiative forcing. For example, Marsh and Svensmark (2000) correlated cosmic ray intensity with North Atlantic regional cloud cover. Cloud cover is a potentially powerful climate feedback, critically important in defining climate sensitivity to external forcing in models. The authors suggest a direct link between atmospheric ionization by cosmic rays and cloud nucleation processes. Sun and Bradley (2002) argue that these correlations do not hold using updated data sets. Furthermore, large increases in cosmogenic isotope production such as the Laschamp event around 40 ka appear unassociated with climate. Carlsaw (2002) has reviewed the mechanisms of cloud response to cosmic rays in detail.

Paleoclimate and solar variability

Ocean sediment cores with high accumulation rates ($>20 \text{ cm ka}^{-1}$) can provide paleoclimate records with up to multi-centennial

resolution, currently limited by the accuracy of accelerator mass spectrometer radiocarbon dating. Bond et al. (2001) presented Holocene records of North Atlantic ice rafted detritus (IRD), together with ^{10}Be flux and ^{14}C production rate (Figure S41). IRD consists of mineral grains once frozen in drifting glacier or sea ice. Its occurrence in ocean sediment is evidence of enhanced ice production or survivability, i.e., a cold period. Though climate change could possibly influence ice core ^{10}Be and ocean circulation may influence atmospheric ^{14}C , it is unlikely the agreement between nuclides with different production and transport chemistries could be produced independent of solar variability. The complex patterns of the co-varying IRD and cosmogenic cycles make a strong argument for solar influence on North Atlantic climate.

The Asian monsoon is a climate response to intense summer heating of the Tibetan Plateau, leading to rising of air and low pressure. This low pressure reverses the direction of prevailing winds during summer to bring Indian Ocean moisture onshore. A proxy record for upwelling of deep ocean water from a sediment core off the coast of Oman indicates that during the centennial to millennial coolings in the North Atlantic, winds associated with the summer monsoon were weaker (Gupta et al., 2003; Figure S44).

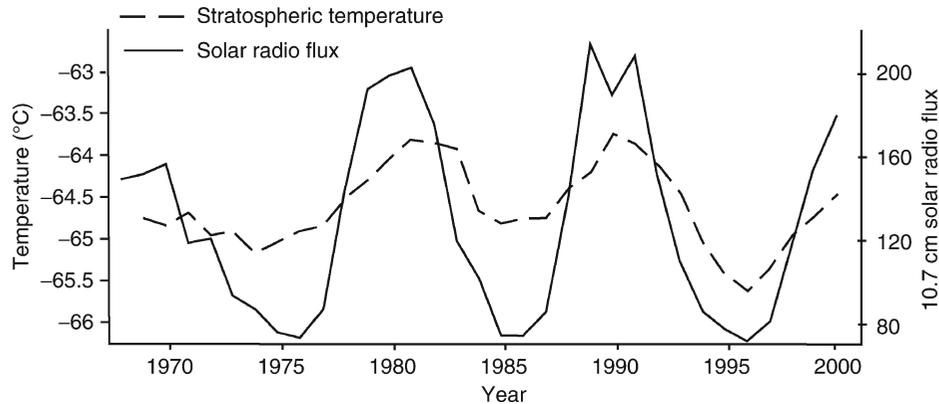

Figure S43 Stratospheric (70 hPa) temperatures at a point 30° N/136° W are correlated with solar radio emission, a proxy for irradiance. The consequences for surface climate depend on uncertain mechanisms of stratosphere-troposphere interaction (adapted from Labitzke and Matthes, 2003).

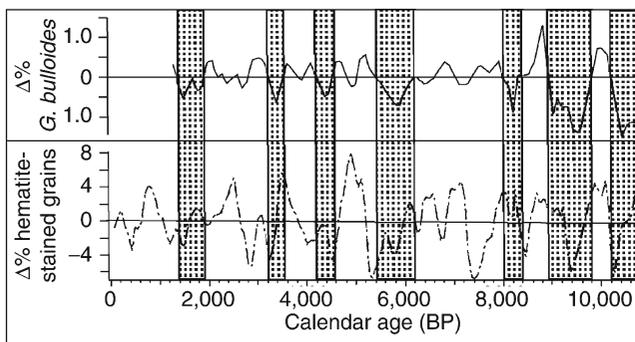

Figure S44 Weak monsoon wind strength results in less nutrient-rich water upwelling off the coast of Oman. This reduces abundance of *G. bullioides*, a hard-shelled plankton whose skeletons may be found in sediment cores. Periods of weak monsoon winds (shaded) correspond to North Atlantic coolings (adapted from Gupta et al., 2003).

Carbon isotope indicators of humidity from lake sediments (Hong et al., 2003) show drier conditions during North Atlantic coolings. Furthermore, Neff et al. (2001) found that rainfall intensity was weaker during solar minima based on a record of oxygen isotopes in Oman cave calcite. These three components of monsoon climate: winds, humidity, and rainfall, all point to a weaker monsoon during periods of reduced solar magnetic activity. Whether it is a direct response, as would be expected only for a large irradiance change, or a response to the solar-influenced climate of the North Atlantic is not yet known.

Amplification of solar influence

The direct radiative temperature response to solar variability is extremely small, around 0.06 °C for a typical solar cycle irradiance change of 0.1%. A measurable climate response therefore requires amplifying mechanisms. One of the simplest amplifiers yet proposed may be the climate system responding with stochastic resonance (Benzi et al., 1982). According to this model, a small signal (solar forcing) by itself would not produce climate change, but once added to a background level of climate system “noise,” the signal crosses a response threshold and is detectable. One candidate for climate noise may be the

El Niño, which has a recurrence interval (2–7 years) well suited to amplifying 11-year solar variability. Modeling has shown that El Niño noise may amplify the solar cycle into decadal variability of climate-related atmospheric anomalies, such as the Pacific North American pattern (Ruzmaikin, 1999).

Another possible amplifier is stratospheric ozone. Irradiance changes in ultraviolet (UV) wavelengths are up to ten times larger over the course of the solar cycle relative to total irradiance change (Lean, 2000). The resulting stratospheric heating due to UV absorption can change ozone concentrations, either amplifying or damping the initial radiative forcing depending on the altitude of ozone change. Aerosols from volcanic eruptions may have affected observational data for the last two solar cycles, so the actual ozone response to the solar cycle is still unclear (Haigh, 2003).

Shindell et al. (2001) simulated climate of the Maunder Minimum assuming a TSI reduction of 0.25%. Ozone concentrations were allowed to vary in response to the larger UV reduction of spectrally resolved irradiance. In the model, the irradiance decrease resulted in Maunder Minimum cooling via two interacting mechanisms. First, stratospheric ozone changed such that the initial negative radiative forcing was amplified. Second, there was a dynamical response resulting in a surface atmospheric pressure pattern resembling the negative phase of the Arctic Oscillation/North Atlantic Oscillation (AO/NAO). The modeled negative AO/NAO was associated with a cooling of nearly 1–2 °C during winter in Northern Europe, consistent with estimates of the coldest Little Ice Age temperatures. Globally, modeled cooling was only around 0.35 °C, emphasizing the role of this amplification mechanism in producing regional climate responses to solar variability.

IRD data of Bond et al. (2001) indicate that for the Little Ice Age, the most recent of the Holocene millennial cycles, the North Atlantic did not cool in the typical dipole pattern of the AO/NAO. Instead, cooling appeared basin-wide. Basin-wide cooling during the Holocene could be achieved via a reduction in thermohaline circulation. Thermohaline circulation transports heat to the North Atlantic region by surface ocean flow from the tropics. It is sensitive to transport of fresher (lighter) water into regions of density-driven convection. If solar influence results in an atmospheric response capable of affecting North Atlantic THC, the regional climate effect could be substantially amplified. A persistent negative phase of the AO/NAO may

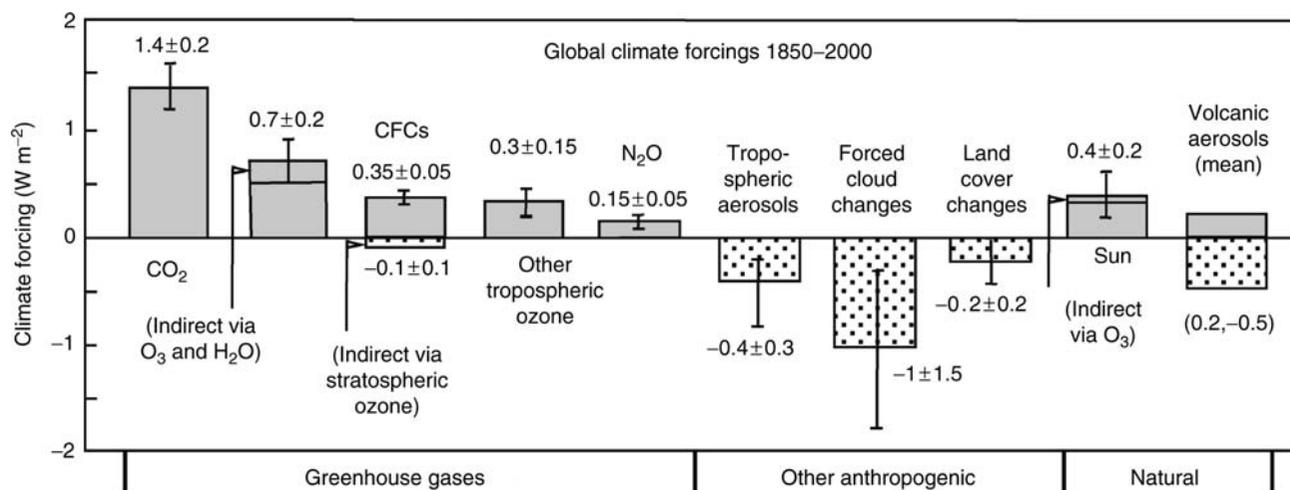

Figure S45 Anthropogenic emissions exert a radiative influence on climate larger than that expected for solar irradiance variability. Solar variability is dominant among natural forcing on decadal and longer time scales (adapted from Hansen, 2000).

be capable of affecting North Atlantic fresh water balance and thus THC. Therefore, the disagreement between the model and paleoclimate data could be a result of differences in the timescale of investigation (i.e., decadal vs. millennial).

Solar forcing and future climate

It has been difficult to confirm solar influence in decadal climate variability, possibly because irradiance records are too short and proxy reconstructions contain much uncertainty. Another reason may be anthropogenic climate forcing obscuring the solar influence. In the future, greenhouse gases (GHG) and tropospheric aerosols such as sulfates and dust could alter Earth's radiative balance with comparable, if not larger magnitudes than solar forcing (Figure S45; Hansen, 2000).

The role of solar forcing therefore depends on future anthropogenic emissions. If efforts to reduce CH₄ and CO₂ emission are implemented, solar forcing may re-emerge as the dominant climate influence on centennial to millennial timescales (Hansen, 2000).

Summary and conclusions

The Sun is a variable star, and from satellite measurements, total solar irradiance varies by 0.1%. Observational records of sunspots, geomagnetic activity, and cosmic ray flux are used as proxies for irradiance variability, though the relationship with irradiance is largely correlational rather than physical. Observations of Sun-like stars, if applicable to our Sun during the Maunder Minimum, suggest an irradiance reduction of around 0.25% relative to today, though key assumptions with this method have not been validated.

Cosmogenic isotopes such as ¹⁰Be and ¹⁴C are among the best records of solar magnetic activity, as they are available for the entire Holocene at high resolution. While the records are subject to complications of accumulation rate variations (ice cores) or changes in deep ocean circulation (atmospheric ¹⁴C), their agreement despite large differences in production and transport chemistry supports their use as proxies for solar variability.

Holocene climate change in the North Atlantic region is influenced by solar variability based on correlations between

cosmogenic isotopes and ice-rafted detritus from sediment cores. The Little Ice Age appears to have been the most recent cold phase of this centennial to millennial cycle. Additionally, several Holocene records of Asian monsoon strength consistently indicate a weaker monsoon during solar minima.

General circulation model simulations suggest a global cooling of around 0.35 °C given an irradiance forcing of 0.25%. North Atlantic paleoclimate records suggest larger regional changes, implying amplification mechanisms such as ozone photochemistry, stochastic resonance, and atmosphere-ocean dynamical responses. Dynamical responses can change climate by affecting the advection of air or water from warmer or colder regions in the absence of large changes in global mean temperature.

Efforts to establish the importance of solar forcing on decadal time scales for recent past climates and the future may be hampered by the growing contribution of anthropogenic forcing. If efforts to curtail emissions are implemented, solar variability may continue to dominate climate change.

T

TEPHROCHRONOLOGY

Introduction

Tephrochronology is a dating method based on the identification, correlation and dating of tephra layers (Thórarinnsson, 1944; Thórarinnsson, 1981). It is important because it can give unusually precise and accurate dating control and may be applied over large areas of both land and sea. As a compound word “tephrochronology” follows the spelling conventions for the use of Greek loanwords in English where the “a” is replaced by an “o.”

Tephra

Tephra is a “catch-all” term to describe essentially unconsolidated pyroclastic material produced by a volcanic eruption. The term tephra is derived from the Greek word τέφρα, and was introduced as a modern scientific term by Sigurdur Thórarinnsson in his 1944 doctoral thesis. Thórarinnsson wanted a general term for pyroclastic ejecta, a definition that could not be satisfied by existing terms such as “volcanic ash”, “lapilli” and “bombs” which described very specific types of volcanic products. He proposed using tephra, noting how it complemented the use of other Greek loanwords “magma” and “lava” already in use in geology. There has been debate as to what is, or is not, strictly defined as tephra. Its scope may be clarified by considering what it is not: tephra does not include volcanic gases (yet tephra can be an aerosol); it is not a consolidated rock (yet tephra can become one); it is not a liquid (although tephra is formed from molten rock). Tephra is often composed of glass particles formed by the rapid chilling of droplets of magma. These grains may be vesicular or composed of solid fragments or plate-like bubble walls. Tephra can also include varying proportions of crystal and mineral components derived from either magma or the walls of the vent. Violent eruptions may result in the incorporation of significant fractions of lithic fragments either from the vent or, in the case of large-scale eruptions, the edifice of the volcano. As the density of these different fractions varies, their relative abundance will vary with distance from source, due to gravitational sorting. Originally, an “airborne” qualification

was considered in the definition of tephra, but in practice, this condition has been dropped so that the term may be robustly applied to essentially all unconsolidated deposits. This applies whether or not they have ever been truly airborne (as in a volcanic plume), or transported at the ground surface in a flow (as in co-ignimbrite ashes, pyroclastic flows or surges), or generated and transported in water (as in the products of sub-marine, sub-glacial or other sub-aqueous volcanic eruptions). This wide-ranging, inclusive definition of tephra is important when it comes to the use of tephrochronology because it removes any need to consider the exact mode of formation and, the wider the definition of tephra, the wider the applications of tephrochronology.

Characterization

The fundamental properties of tephra that underpin tephrochronology are its potentially rapid and widespread dispersal and distinctive physical and chemical characteristics. Atmospheric dispersal in a volcanic plume may be considered effectively instantaneous. As a result, tephra deposits may be used to define “isochrons”, or horizons of the same age, which are most precisely defined by the basal surface of the tephra deposit. This horizon may be used to define an area of environment at a “moment” in time. The destruction of the Roman cities of Pompeii and Herculaneum by tephra from the AD 79 eruption of Vesuvius defines an isochron and has been used to study cityscapes frozen at one point in time. Likewise tephra horizons may be used to study the characteristics and spatial patterns of other past environments, be they peat bogs, glacier forelands or ocean floors. They can be employed for precise correlation of contemporaneous records from radically different environments.

Significant temporal patterns caused by changing winds can occur within the horizon defined by a single tephra unit. For example, an early stage of an eruption may produce different types of tephra than a later stage, and may inject material into different levels of the atmosphere, where it will be affected by different types of wind. The result can be different dispersal patterns for contrasting stages during the formation of tephra. In this case, one should recognize that somewhat different tephra deposits could record a single event and that associated

deposits could be contemporaneous. Characterization of tephra deposits is best achieved by combining a variety of data and utilizing physical characteristics of the layers as a whole, such as: layer thickness; particle size ranges and particle shapes; composition in terms of glass shard, crystal mineral or lithic content; layer color (although this may be significantly affected by the nature of the enclosing strata); stratigraphic location and stratigraphic relationships. Bulk chemistry has been used to characterize tephra layers, but this has been superseded by discrete grain analyses, generally undertaken by electron probe microanalysis and capable of accurately determining major (and minor) element abundances. Where tephra layers are invisible to the naked eye ("micro" or crypto tephra), the approach has to be modified and generally focuses on the physical and chemical properties of separate grains and stratigraphic data. Collectively, these data may be used to determine characteristics best conceived as "signatures" rather than "fingerprints"; while chemical compositions may be distinctive, they are too frequently similar to be described as a "fingerprint." Examples of this similarity may be found for a wide range of tephra compositions from different eruptions, both silicic and basic (Larsen et al., 1999, 2001). One unambiguously unique characteristic is age. This in combination with the consequential differences, such as dispersal pattern and stratigraphic location, can be used to achieve unambiguous identifications and so correlate widely separated deposits of the same tephra.

Tephra dispersal may follow a series of different environmental pathways leading to distinctively time-transgressive characteristics for the deposit as a whole. For example, fallout from the volcanic plumes of Late Glacial eruptions in Iceland has produced extensive isochronous deposits, but tephra fallout also occurred on sea ice that, through time, has transported the tephra to new locations where the ice melted, releasing the tephra to fall to the seabed. Other more lengthy dispersal routes have resulted from tephra fall onto glaciers, incorporation into glacier ice, transport within the glacier system and later deposition at the ice margin. As another twist, ice calving can result in deposition from melting icebergs long after the formation of the tephra and far from the source volcano. In this case, tephra can form horizons within strata that were not necessarily produced at the same time as the volcanic eruption. This is not, however, a problem, as tephrochronology can be used to determine the time taken for movement through these contrasting environmental pathways, and so it can be used to constrain assessments of environmental process. This may be considered to be "tracer" tephrochronology.

An important aspect of the application of tephrochronology is the use of multiple tephra horizons to constrain periods of time. This may be crucial for the effective integration of some types of environmental data. For example, sediment accumulation rates are best compared over clearly defined time periods rather than in reference to a single moment or "spot" date. If tephrochronology (based on the same tephra layers) is used, then the intervals of time considered at different sites will be precisely comparable.

Chronology

Tephrochronology is indivisible from volcanic history but forms a subset of it, inasmuch as some key aspects of volcanic history (such as lava production) may not be associated with tephra production. Dating tephra layers can harness the full range of chronological methods available to earth science. The age of tephra may be determined either directly or indirectly: direct dating of tephra may come from historical records

or dating the tephra itself. Depending on age and composition, these direct dating methods may include K/Ar, Ar/Ar, fission track, U-series or luminescence dating.

Frequently, tephra are dated by the analysis of related material in which the tephra is found. In this case, depending on the age and location, these indirect dating methods may include ice core, varve, radiocarbon dating and dendrochronology. Crucially, the extensive dispersal of tephra layers means that dating may be optimized by finding the best place within the overall distribution to apply any particular dating method. This has the added benefit that dating specific to one environment (such as ocean core isotope stages) may be applied in another (the distribution of the Toba tephra across India).

Tephrochronologies

Parts of the world where tephrochronologies have been successfully developed and are now an integral part of paleoenvironmental research include the British Isles (Dugmore et al., 1995); Iceland (Thórarinnsson, 1981); Japan (Machida, 1999); New Zealand (Shane, 2000); Mexico (Newton and Metcalfe, 1999); and Alaska (Carson et al., 2002).

THE 8,200-YEAR BP EVENT

Overview

The 8,200 year event, alternatively called the 8.2 kyr event or more simply the 8k event, refers to the last major abrupt climate change, a Northern Hemisphere cooling event that occurred approximately 8,200 years before the present (BP). The 8.2 kyr event is the largest anomaly in the Greenland ice

cores during the Holocene (see *Holocene climates*), a period otherwise marked by a relatively stable climate. Paleoclimate records from Europe, North America, South America, and Africa indicate an abrupt cooling event in the Northern Hemisphere. Separate geologic evidence documents the collapse of the remnants of the Hudson Bay ice dome dam and subsequent catastrophic final drainage of glacial Lakes Agassiz and Ojibway into the Hudson Bay, at approximately the same time. These lakes once occupied northern portions of the Canadian provinces of Manitoba and Ontario, respectively.

A potential atmospheric link between the disappearance of the glacial lakes and the far-field climate events was pointed out first by Hillaire-Marcel and de Vernal (1995). Further evidence for cooling and speculation on the connection to drainage of the glacial lakes was presented by de Vernal et al. (1997) and von Grafenstein et al. (1998). Barber et al. (1999) provided stronger evidence for the connection between the cooling event in Greenland and the disappearance of glacial Lakes Agassiz and Ojibway through improved interpretation of dates derived from the geologic evidence. Dating suggests the disappearance of the glacial lakes and drainage occurred at ~ 7.6 ^{14}C BP, while the anomaly in Greenland ice cores, dated using layer counts, occurred about 8,200 calendar years ago. Reasons for the difference between the calendar date and the ^{14}C date include changes in the production of ^{14}C through time as well as “reservoir age” corrections (see *Radiocarbon dating*).

The pattern of cooling around the North Atlantic basin and related changes in precipitation patterns from paleoclimate studies of the 8.2 kyr event is consistent with a decrease in Atlantic thermohaline circulation (THC, see *Thermohaline circulation*). This outpouring of glacial freshwater in a meltwater pulse (MWP) has been widely hypothesized as a mechanism for abrupt climate change (Broecker et al., 1985). Additional freshwater input into the North Atlantic decreases the density of surface waters and thus the formation of North Atlantic Deep Water (NADW, see *North Atlantic Deepwater and climate change*); this decreased THC reduces the amount of heat transported by the Atlantic Ocean and causes widespread cooling. However, the 8.2 kyr event is thus far the only well-established example of coincident cause and effect.

The well-quantified cause and climate changes of the 8.2 kyr event provide an opportunity to evaluate the effectiveness of global climate models. The ability of climate models to simulate this past abrupt climate change improves confidence in simulating future climates (Schmidt and LeGrande, 2005). In particular, modelers need to be able to evaluate their models’ ocean responses to climate change. The spread in model projections for the North Atlantic THC as a function of increasing greenhouse gases is extremely large, ranging from an almost 50% decrease to a small increase by 2,100. In part, this uncertainty stems from tuning the models for the existence of a stable North Atlantic circulation, but not being able to tune for its sensitivity because of the lack of appropriate data. The 8.2 kyr event thus provides an excellent opportunity to test the ability of the models (“model skill”) to simulate the oceans’ response to freshwater forcing (Schmidt and LeGrande, 2005). A successful model simulation of this last major abrupt climate change will improve confidence in the model’s accuracy, including its ability to simulate future climate changes.

Long term changes versus the abrupt 8.2 kyr event

Naming the “8.2 kyr event” for its occurrence in time lends itself to confusion – an anomaly that occurred around 8.2 kyr

ago need not be an expression of the “8.2 kyr event.” Orbital, orographic, and potentially solar-forced climate changes during the early to mid Holocene may be distinct from the 8.2 kyr event that was likely caused by the final drainage of glacial Lakes Agassiz and Ojibway.

The 8.2 kyr event appears to overlay a strong quasi-millennial-scale oscillation that is potentially linked to small changes in solar forcing (see *Sun-climate connections*; Bond et al., 2001). The production of cosmogenic isotopes (^{10}Be and ^{36}Cl from ice cores and ^{14}C from tree-ring records) is related to solar activity. An increase in Greenland ^{10}Be flux in the GRIP ice core around 8.2 kyr could be interpreted as a decrease in solar activity (Yiou et al., 1997). However, this increased flux is not unique – several such events occur throughout the Holocene, suggesting that solar activity changes are not responsible for the 8.2 kyr event (Muscheler et al., 2004; Field et al., 2006), though they might be responsible for century to millennial scale oscillations during the Holocene.

Another potential confusion results from orographic changes, or changes that occurred as a result of the retreat of the Laurentide Ice Sheet. In North America at roughly $\sim 8,000$ yBP, the shift in atmospheric circulation towards more westerly flow became more pronounced (e.g., Dean et al., 2002) – in archeological records, the subsequent mid-Holocene period is referred to as the “Altitheimal,” or “Hypsithermal” period (see *Hypsithermal*). Ancillary to the orographic changes could be long term shifts in meltwater and precipitation run-off from the Laurentian Ice Sheet. Although these climate shifts are also related to the collapse of the Hudson Bay ice dome dam, they are more generally related to the retreat of the Laurentide ice sheet and thus may be distinct from the abrupt 8.2 kyr event.

Orbital forcing of the Northern Hemisphere was stronger during the early Holocene, and many records document a “Holocene Thermal Optimum” in the early to mid-Holocene (see *Hypsithermal*) that is distinct from the 8.2 kyr event. The timing of the retreat of the ice sheet is tied to these long term changes, but the 8.2 kyr event is ostensibly linked to the climate changes that resulted from the outburst flooding.

The 8.2 kyr event thus refers to Greenland ice core and other records that document an abrupt (less than a few centuries) Northern Hemisphere cooling event that likely resulted from the collapse of the Hudson Bay ice dome dam and subsequent drainage of the glacial freshwater lakes and perturbation of THC in the North Atlantic. Simple “anomaly hunting” for events around 8,200 years ago is insufficient. Since the 8.2 kyr event is extremely abrupt, only high resolution records with excellent chronologies can be confidently correlated with the ice core event – extreme caution should be applied before linking any single anomaly in a record to the 8.2 kyr event (Morrill and Jacobsen, 2005).

Geology of the flood

During the final stage of Lake Agassiz, it was combined on its eastern edge with Lake Ojibway (thus called the “Ojibway Phase”), and the total surface area of these lakes is estimated at 841,000 km², corresponding to a volume of 163,000 km³ (Leverington et al., 2002). Subglacial outflow (run-off beneath the ice sheet), similar to modern Icelandic jökulhlaups, likely initiated the collapse of the ice sheet dam and allowed rapid drainage of these combined lakes into the proto-Hudson Bay (called the Tyrrell Sea) down to the Kinojévis level (also referred to as the Ponton Level for Lake Agassiz) (Teller et al., 2002; Clarke et al., 2004). Complicating this simple drainage

scenario is the Fidler beach level (Klassen, 1983) which lies below the Kinojévis level, possibly suggesting a two-stage drainage of the glacial lakes – first Lake Ojibway and some of Lake Agassiz, followed shortly by the remnants of Lake Agassiz (Teller et al., 2002). Either way, this final drainage of the two lakes exceeded any previous drainage of Lake Agassiz by an order of magnitude (Dyke, 2004).

Scours along the Hudson Bay sea floor, as well as other geomorphic evidence of the quick movement of icebergs, point to a rapid, large flood event along the western edge of the Hudson Bay (Josenhans and Zevenhuizen, 1990). Kerwin (1996) identified a red, hematite-rich, clay layer through the Hudson Strait, deposited at approximately 8,000 ^{14}C yBP that was likely deposited as material fell out of the Agassiz-Ojibway MWP. From the Hudson Strait, the waters traveled through the Labrador Sea and into the North Atlantic Ocean.

Paleo-hydraulic modeling studies (Clarke et al., 2004), or studies that take into account the geometry of the lake basins as well as the estimated volumes and rates of discharge, have constrained the magnitude and length of the event to approximately 5 Sv (1 Sv = 10^6 m s^{-1}) for 0.5–1 year; this is equivalent to $0.79 \times 10^{14} \text{ m}^3$ – $1.58 \times 10^{14} \text{ m}^3$ or 22–44 cm of sea level given the current surface area of the ocean. Alternatively, the best guess for the volumes and rates of a two-phase event are an initial drainage of about 3.6 Sv for 1 year, followed shortly (decades) by 1.6 Sv for 1 year (Teller et al., 2002). The volumes in these estimates are smaller than the upper boundary of 1.2 m of sea level rise indicated by Mississippi delta sediments (Törnqvist et al., 2004).

The link between the geologic evidence of a drainage event and paleoclimate records of an abrupt climate change was initially stymied because the initial dating of the geologic evidence indicated that the large MWP that followed the drainage of the glacial lakes pre-dated the ice core and other paleoclimate records by several centuries. Barber et al. (1999) determined that an additional marine reservoir age correction (see Radiocarbon dating) to the ^{14}C dates was required, and they established that the two events were close enough in time – both around $8,400 \pm 100$ yBP – for the MWP to be the catalyst that caused the abrupt climate cooling events in the paleoclimate records.

Ice cores and important records of the 8.2 kyr event

The largest Holocene abrupt climate change in the GISP2, GRIP, and NGRIP Greenland ice core records occurs from 8,200 until 8,000 years ago (Dansgaard, 1987; Alley et al., 1997). An approximate negative 2‰ excursion in the oxygen isotopic composition of Greenland ice cores indicates that temperatures may have been as much as 6 °C cooler for approximately 200 years at about 8.2 kyr (Cuffey et al., 1995; Alley et al., 1997); although some estimates for the cooling suggest cooling of up to 11 °C (Leuenberger et al., 1999). Paired with this abrupt cooling is decreased snow accumulation (Alley et al., 1993; Spinelli, 1996) and increased deposition of aerosols – e.g., salt, dust, sulfates (and associated cosmogenic isotope ^{10}Be) – characteristic of a cooler, drier regional climate (O'Brien et al., 1995; Muscheler et al., 2004). The approximate 75 ppbv abrupt decrease in methane concentration in bubbles in the Greenland ice cores at 8.2 kyr (Chappellaz et al., 1993; Brook et al., 2000) indicates a hemisphere-wide cooling and drying, since this concentration change would most likely have resulted from decreased wetland methane emissions that were the dominant pre-Industrial source for methane emissions (Houweling et al., 1999). Many records corroborate this indication of cooling and drying in both boreal (Northern

Hemisphere) as well as tropical regions, and an extensive review is available in Alley and Ágústsdóttir (2005). Here, the focus is on records with high resolution and a clear 8.2 kyr event or on records that directly correlate to records with high resolution and a clear 8.2 kyr event.

Glaciers in Scandinavia advanced and quickly retreated roughly synchronously with the 8.2 kyr event; this advance in southern Norway is called the “Finse Event” (Dahl and Nesje, 1994). Tree-ring thickness changes and alterations in the oxygen isotopic composition of a lake from Germany reflect a cooling of 1–2 °C (Klitgaard-Kristensen et al., 1998; von Grafenstein et al., 1998).

Ocean sediment core records off the south-western coast of Norway document an increase in abundance of the cold water planktonic foraminifera species, *Neogloboquadrina pachyderma* (left) (Klitgaard-Kristensen et al., 1998), but no change in its oxygen isotopic composition of planktonic foraminifera (Klitgaard-Kristensen et al., 2001). However, further north in the East Norwegian Sea, the oxygen isotopic composition of *N. pachyderma* (left) does become enriched by 0.7‰, indicating a cooling of 3–4 °C (Risebrobakken et al., 2003).

Interestingly, many Labrador Sea sediment core records do not show a significant change in the oxygen isotopic composition of foraminifera at this time (Hillaire-Marcel et al., 1994). Keigwin et al. (2005) suggest that the MWP may have traveled southward along the coast of North America as a boundary current, thus preventing a significant oxygen isotope signal within the Labrador Sea.

Deep Lake, Minnesota (USA) records a spike in varve thickness, interpreted as an increase in aeolian deposition, at around 8.2 kyr (Hu et al., 1999). A spike in montane conifers in Virginia indicates a short-lived cooling period approximately synchronous with the 8.2 kyr event (Kneller and Peteet, 1999).

Model studies consistently indicate that when the Northern Hemisphere cools, the inter-tropical convergence zone (ITCZ) shifts south (Stouffer et al., in press). The ITCZ is essentially a tropical rain “belt” that generally occurs along the zone of highest sea surface temperature. Hughen et al. (1996) and Haug et al. (2001) used a gray-scale record from an ocean sediment core in the Cariaco Basin, off the Venezuelan coast to infer a southward shift of the Atlantic ITCZ roughly synchronous with the 8.2 kyr event. Brazilian speleothems (stalagmites) suggest a southward shift in the ITCZ as well (Wang et al., 2005). Tropical ice cores from Kilimanjaro, Africa show a dramatic increase in dust deposition, suggesting a drop in African lake levels (Thompson et al., 2002) that could be associated with this southward migration of the ITCZ. Lake records from Africa indicate a dry spell around the same time (e.g., Gasse and Van Campo, 1994), but they lack the resolution to be definitively tied to the 8.2 kyr event.

At about the same time, the ice core record of δD in Vostok, Antarctica shows a negative 22‰ excursion, indicating a warming of approximately 2.5 °C (Petit et al., 1999); however, the dating of the ice core is sufficiently uncertain (± 500 years) to question the link with the 8.2 kyr event of the Northern Hemisphere. Furthermore, not all Antarctic ice cores indicate such an oscillation (Masson et al., 2000). This implied warming Southern Hemisphere coupled with the colder Northern Hemisphere might be an expression of the bi-polar seesaw (Broecker, 1998).

The evidence outlined thus far makes a clear case for cooling in the Northern Hemisphere at around 8.2 kyr ago, but it does not indicate the cause of the abrupt cooling. McManus

et al. (2004) use $^{230}\text{Pa}/^{231}\text{Th}$ (protactinium-thorium) in an ocean sediment core from the Bermuda rise as an indicator of changes in NADW; higher resolution examination of this same record indicates a decades to century long slow-down of Atlantic THC at around 8.2 kyr. The dissolution of aragonite index in an ocean sediment core off the north-eastern coast of Brazil also implies a reduction of the NADW at approximately 8.2 kyr (Arz et al., 2001).

Modeling of the 8.2 kyr event

The 8.2 kyr event particularly lends itself to paleoclimate model simulation for proxy data comparisons (Schmidt and LeGrande, 2005). The outburst flood from the drainage of Lakes Agassiz and Ojibway into the Hudson Bay provides a plausible and interesting hypothesis for the forcing. Geologic evidence paired with modeling efforts has provided specific constraints for the volume and duration of the event (Clarke et al., 2004). Abundant, widespread, and clear proxy data of the climate response provides multiple opportunities for comparing model results to the paleoclimate record (Alley and Ágústsdóttir, 2005). The magnitude of the climate response implies an intermediate THC response (e.g., not “on” or “off,” rather “in between”). It has several more features that make it an especially desirable event to model using fully coupled (atmosphere-ocean-sea ice) general circulation models (GCMs) – the boundary conditions for the 8.2 kyr event are relatively similar to today, and its length is relatively short, an important characteristic since coupled GCMs can take many months to simulate 1,000 years of climate (Schmidt and LeGrande, 2005).

LeGrande et al. (2006) simulated the 8.2 kyr event using the Goddard Institute of Space Studies ModelE-R by adding freshwater to the Hudson Bay at the rate and duration suggested by Clarke et al. (2004). This coupled GCM also tracks water isotopes throughout the hydrologic cycle, and the atmosphere component tracks changes in wetland methane emissions and aerosol deposition. Temperatures over much of the North Atlantic cooled by up to 2°C, while Europe, Asia, and parts of North America cooled by 0.5–1°C. Temperatures in the South Atlantic and Southern Ocean warmed by ~ 0.5°C, which is an expression of the bi-polar seesaw (Broecker, 1998). Storm tracks in the Atlantic became more zonal, and the ITCZ shifted southward. This pattern of climate change is typical for GCM experiments of reduced THC in the North Atlantic, though the magnitude of the climate change is smaller than “hosing” experiments that apply a larger volume of freshwater over a longer period of time and shut down NADW (e.g., Stouffer et al., 2006).

LeGrande et al. (2006) directly compared model tracers to the paleoclimate proxy record and found that the freshwater forcing is a viable cause for the climate anomalies recorded in the Greenland ice cores and elsewhere. Generally, water isotopes in precipitation became more depleted with colder or wetter conditions. Their simulations showed that the water isotopes in precipitation over much of the North Atlantic, Greenland, and Europe became depleted. In addition, bands of enriched and depleted water isotopes in precipitation occurred north and south of the equator, reflecting the southward migration of the ITCZ.

The drier atmosphere over Greenland caused an increase in dust and ^{10}Be deposition (LeGrande et al., 2006). Both wet and dry ^{10}Be deposition over Summit, Greenland increased, implying that ^{10}Be flux (important for inferring changes in solar

activity) cannot be estimated using the ^{10}Be concentration and snow accumulation alone (Field et al., 2006). The cooling and drying of boreal (Northern Hemisphere) areas caused a decrease in wetland methane emissions that resulted in an approximate 60 ppbv shift in atmospheric methane concentration.

The LeGrande et al. (2006) results indicate that the lack of evidence for the 8.2 kyr event in the oxygen isotopic composition of foraminifera from many ocean sediment core records may be due to “canceling” effects in the proxy record – in this case, depleted seawater oxygen isotopes and colder ocean temperatures.

Two Earth system intermediate complexity models (EMICs) have studied the 8.2 kyr event by applying freshwater forcing to “8k appropriate” simulations that include orbital and greenhouse gas forcing. Renssen et al. (2001, 2002) simulated the addition of $4.67 \times 10^{14} \text{ m}^3$ of freshwater to the Labrador Sea at a range of rates (1.5 Sv for 10 years, 0.75 Sv for 20 years, and 0.3 Sv for 50 years) using the ECBilt-CLIO model. They found that the model THC response varied greatly and that the length of the simulated climate event ranged from a few hundred to a few thousand years, suggesting that the climate response to freshwater forcing is strongly dependent on non-linear dynamics within the climate system. Using another EMIC model (CLIMBER-2), Bauer et al. (2004) simulated the addition of 2.6 Sv freshwater for 2 years ($1.6 \times 10^{14} \text{ m}^3$) to a band of the Atlantic Ocean between 50 and 70° N, and also introduced “white noise” to the climate system in the form of small (0.01–0.1 Sv), random inputs of freshwater in this same band. They also found a large range of model responses to the same freshwater forcing, and suggested that “chance” played a role in the temporal evolution of the 8.2 kyr event.

Ágústsdóttir (1998) simulated the 8.2 kyr event using the GENESIS climate model. This model is an atmosphere GCM coupled to a slab (e.g., 50 m thick) ocean; thus, the event was simulated through (a) specifying 8k appropriate greenhouse gas, orbital, and ice sheet forcing; and (b) changing the heat convergence in the Norwegian Sea, where the convection associated with THC occurs, not through freshwater forcing. They found the “typical” pattern of THC perturbation: cooling over the North Atlantic, zonal shift in precipitation bands, and southward migration of the ITCZ.

Summary

Around 8,200 years before the present, Greenland ice core records document the last major, abrupt climate change. Multiple paleoclimate records elsewhere in the Northern Hemisphere provide other evidence for a short-lived (about 200 year) cooling event (Alley and Ágústsdóttir, 2005). Geologic evidence indicates the final drainage of glacial Lakes Agassiz and Ojibway into the Hudson Bay occurred at about the same time (Teller et al., 2002). The coincidence of these two effects suggests that the additional freshwater from the drainage of these lakes may have been the catalyst for this abrupt climate change (Barber et al., 1999).

The theory for the cause of the abrupt climate change is that the drainage of the glacial lakes caused changes in thermohaline circulation, also called meridional overturning circulation (e.g., Broecker et al., 1985). The drainage of the glacial lakes decreased the surface density of the North Atlantic Ocean, causing a decrease in the formation of North Atlantic Deep Water. This “slowdown” of the so-called global conveyor belt caused cooling of around 1–2°C around the North Atlantic

Ocean and surrounding land masses, and perhaps up to 6 °C of cooling in Greenland.

The 8.2 kyr event is well documented in the paleoclimate record, and it has an interesting viable cause, or trigger, for the abrupt cooling. These two properties in addition to its short length make it an excellent candidate for simulation using GCMs (Schmidt and LeGrande, 2005). Modeling studies of the 8.2 kyr event support this theory of abrupt climate change (LeGrande et al., 2006). Conversely, the match between model simulations and paleoclimate record provides a means to evaluate the skill of climate models.

THERMOHALINE CIRCULATION

Definition

Formally defining thermohaline circulation is difficult and numerous definitions exist within the literature. Historically, thermohaline circulation has been defined as the component of oceanic circulation driven by fluxes of heat and freshwater (sometimes combined into a buoyancy flux) through the ocean's surface. This particular definition of thermohaline circulation is prevalent among ocean modelers, wherein ocean models driven exclusively by boundary conditions on heat and freshwater, with wind forcing set to zero, lead to a global-scale meridional overturning.

However, in many cases, anomalies of the surface buoyancy flux, and particularly its thermal component, strongly depend on the thermohaline circulation itself. For example, an intensified meridional overturning cell would lead to stronger poleward heat transport in the ocean. At steady state, this heat transport anomaly must be balanced by more heat loss to the atmosphere over the regions towards which the heat is being transported, and by more heat gain by the ocean over regions from which the heat is being transported (Figure T1).

A further problem with the above definition arises when one tries to separate the thermohaline ocean circulation from the wind-driven circulation. For example, turbulent fluxes (latent and sensible heat fluxes) represent a sizable part of the net heat flux and are highly dependent on the near surface wind speed. Furthermore, evaporation, which represents a negative part of the total freshwater flux into the ocean is essentially given by the latent heat loss, and hence is also proportional to the strength of surface winds. In addition, ocean models and the ocean component of coupled models typically specify a fixed value of diapycnal mixing (mixing of heat and

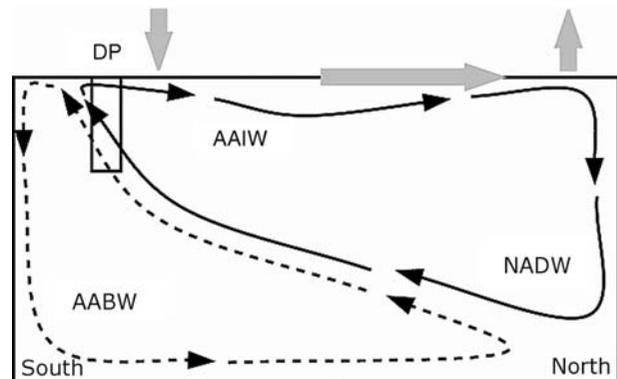

Figure T1 A sketch of the two main cells of the meridional overturning circulation (MOC). One cell is associated with the formation of the North Atlantic Deep Water (NADW) in the North Atlantic, its upwelling in the Southern Ocean, around Drake Passage (DP) and its return flow as a lighter Antarctic Intermediate Water (AAIW); this cell essentially represents the Atlantic Meridional Overturning (AMO). The second cell is associated with the formation of Antarctic Bottom Water (AABW) in high southern latitudes, its spread northward, mixing with NADW, and its return to the Southern Ocean. Arrows illustrate the notion that an intensified (weakened) AMO cell would lead to a stronger (weaker) northward oceanic heat transport in the Atlantic. This would have to be balanced by stronger (weaker) heat loss in the north and by stronger (weaker) heat gain in the south.

salt across surfaces of constant density in the ocean). This representation of diapycnal mixing is a parametrization of internal wave breaking which in turn originates from wind (and tidal) forcing.

Thermohaline circulation is also defined as the density-driven global-scale oceanic circulation. This too has serious shortcomings, as density gradients in the ocean are largely set up by the winds. In particular, the density structure in subtropical and subpolar gyres is determined by Ekman dynamics. The wind stress anomalies themselves are functions of sea surface temperature. Finally, in the ocean, which is typically in geostrophic balance over the spatial and temporal scales of interest to climate and paleoclimate researchers (100s of km and years, respectively) one cannot separate the existence of the density gradients from the existence of the currents.

Wunsch (2002) defined the thermohaline circulation as the circulation of temperature and salt. This definition, however, is not one that is readily accessible to paleoclimatologists. A more practical approach is to move away from the use of the term thermohaline circulation and to focus on the three dimensional (3D) global overturning circulation (GOC). For many paleoclimatological applications, a sufficient representation of the GOC is in terms of the meridional overturning circulation (MOC) and its manifestation in the Atlantic as the Atlantic meridional overturning (AMO), which represent mass transport in the 2D meridional/vertical plane (Figure T1). Inherent in this approach is the acknowledgement that wind and buoyancy forcing are inseparable, and that wind and tidal forcing play a fundamental role in diapycnal mixing within the ocean.

Here, we focus our discussion on the MOC as a fundamental diagnostic in understanding the role of the ocean in past, present and future climate change. Furthermore, sudden changes in the strength of the MOC, and in particular the AMO, are associated with the abrupt climate change prevalent in high resolution proxy records over the last glacial cycle. The importance of the AMO to climate lies in its association with much of the total oceanic poleward heat transport in the present-day Atlantic, peaking at about 1.2 ± 0.3 PW (1 PW equals 10^{15} Watts) at 24° N. Since the MOC represents the ocean circulation in the meridional-vertical plane, its existence and structure is fundamentally connected with the locations of deep water formation in the ocean.

Locations of deep water formation

Two distinct forms of deep water formation occur: near-continent and open ocean. The former involves one of two simple processes: evaporation, or more typically brine rejection, above a continental shelf produces dense heavy water which sinks down and along the slope under the combined forces of gravity, friction and the Coriolis force (Killworth, 1983); alternatively supercooled water may be formed at the base of a thick ice shelf during freezing or melting and this dense water may in turn flow down-slope. By contrast, open ocean convection is observed in areas remote from land and is characterized by a large-scale cyclonic mean circulation which causes a doming of the isopycnals and weakens the static stability over an area tens of kilometers wide. The convection itself is short-lived, is restricted to a narrow circumference and is typically driven through intense surface cooling. These narrow convective chimneys are almost purely vertical and usually do not entrain large volumes of surrounding water as in near-continent convection.

The two main constituent water masses of the deep North Atlantic Ocean – North Atlantic Deep Water at the bottom and Labrador Sea Water at an intermediate level – are currently formed in the Greenland-Iceland-Norwegian Seas and the Labrador Sea, respectively. Deep convection also occurs at a number of locations around Antarctica (Adéle Coast, Amery Ice Shelf, Ross Sea, and Weddell Sea), but the dense bottom water is susceptible to being trapped by topographic sills (as in the Bransfield Strait), or by local circulation patterns (not excluding the Antarctic Circumpolar Current – ACC). In the Southern Ocean, around the southern tip of South America, an enhanced formation of low salinity Antarctic Intermediate Water (AAIW) also occurs.

In today's climate, there are no sources of deep water in the North Pacific Ocean, although North Pacific Intermediate Water (NPIW), characterized by a salinity minimum in the subtropical gyre at depths of 300–800 m within a narrow density range, is locally produced. This water mass is mainly constrained to the subtropical gyre, unlike the Labrador Sea intermediate water mass which is largely confined to the subpolar gyre of the North Atlantic. The original source water for NPIW is thought to be sinking in the Sea of Okhotsk.

Deep convection also occurs in the Mediterranean Sea, but the dense salty outflow that exits into the Atlantic gains buoyancy by mixing with lighter environmental water and spreads out at mid-depth rather than sinking to the bottom. Similar, but weaker, saline outflows have been detected issuing at mid-depth from the Red Sea and Persian Gulf.

In summary, two main bottom water masses exist whose trajectories can be traced by their temperature and salinity characteristics throughout the rest of the world ocean. These are (see Figure T1): (a) the component of Antarctic Bottom Water (AABW) which is largely produced in the Weddell Sea before mixing with Circumpolar Deep Water in the ACC and then flowing into the major ocean basins; (b) North Atlantic Deep Water (NADW), which lies above the AABW at all latitudes except north of 40° N in the North Atlantic. The North Pacific Ocean, although a source of North Pacific Intermediate Water is not a source of bottom water.

In addition, as discussed below, AAIW plays a critical role in linking the Pacific and Atlantic Oceans and in particular on the stability of the AMO. In the present climate, about 13 Sv ($1\text{ Sv} = 10^6 \text{ m}^3 \text{ s}^{-1}$) of cold, fresh Antarctic Intermediate Water (AAIW) flows into the South Atlantic, about 8 Sv of which is converted into thermocline water through mixing by 32° S (Rintoul, 1991). Further mixing converts the remaining 5 Sv of AAIW into thermocline water as it approaches the equator (Schmitz and McCartney, 1993; Table T1). At 24° N there is about 13 Sv of thermocline water which flows northward into the high northern North Atlantic where it is converted into NADW. AABW flows into the South and North Atlantic where it is modified into and exported as NADW into the Southern Ocean.

Table T1 Transport (in Sv) summary from Schmitz and McCartney (1993)

Water type	32° S	24° N
Thermocline water	8	13
Intermediate water (AAIW)	5	–
Deep water (NADW)	–17	–18
Bottom water (AABW)	4	5

Hysteresis behavior of the MOC

Sea water density is a function of not only temperature, but also salinity. Furthermore, at low temperatures, such as those that exist in the deep water formation regions, the density of sea water is more sensitive to changes in salinity than to changes in temperature. In addition, throughout the Quaternary, large quantities of freshwater have been periodically stored on land at middle to high latitudes in the form of continental ice sheets. During the growth or melt of these continental ice sheets, tens of meters of sea level equivalent freshwater have been taken from or released back to the ocean. As a consequence, numerous studies have been conducted in an attempt to understand the role of freshwater perturbations on the stability of the MOC.

The dependence of sea water density on salinity is a key player in what is now known as a hysteresis behavior of the AMO. Recently it has been discovered that the AMO behaves like a “see-saw,” with relatively warm surface conditions in the North Atlantic and relatively cool surface conditions in the South Atlantic occurring when NADW formation is active, and conversely, with relatively cool surface conditions in the North Atlantic and relatively warm surface conditions in the South Atlantic occurring when NADW formation is inactive (Figure T2). Such a finding is supported by both modeling studies, proxy records, and from combined model/proxy record studies. More recently still, it has been realized that the “see-saw” nature of the AMO is fundamentally linked to a coupling between the strength of AAIW formation and the strength of NADW formation (Figure T3).

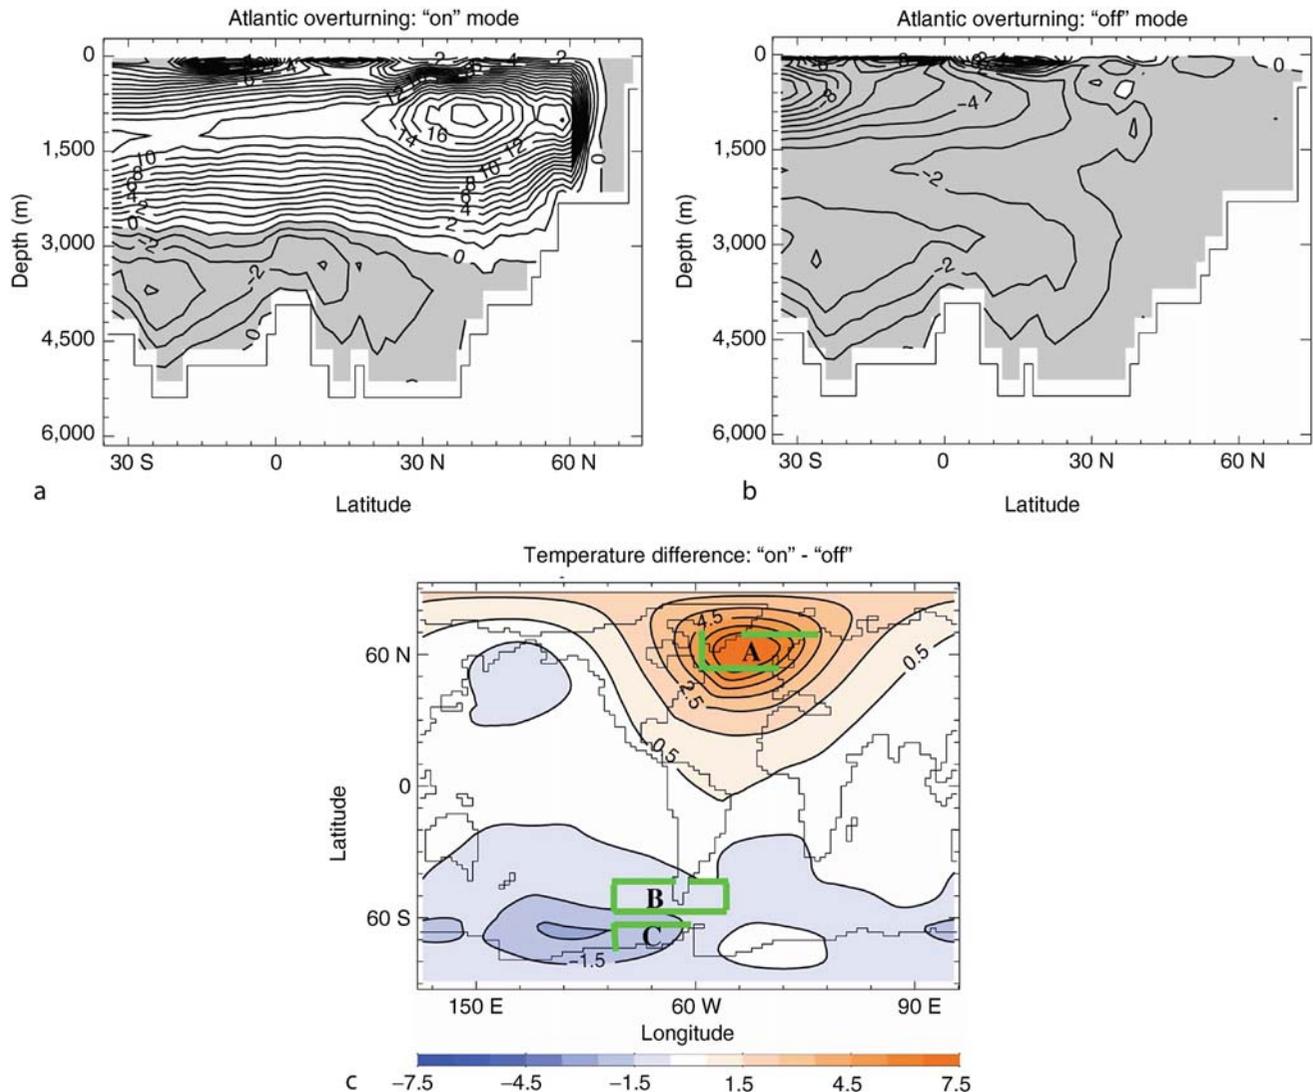

Figure T2 Atlantic meridional overturning circulation (Sv) for: (a) the stable active mode of NADW formation; (b) the stable inactive mode of NADW formation. The inactive mode (b) was obtained by adding freshwater (100 Sv years) to region A. Notice the enhanced intrusion of AAIW and the absence of NADW in (b). (c) Surface air temperature (°C) difference between the climatic states represented by (a) and (b). Region B in (c) is where freshwater is added to get the hysteresis of Figure T3, although similar results are found when freshwater is added to region C. Taken from Weaver et al. (2003).

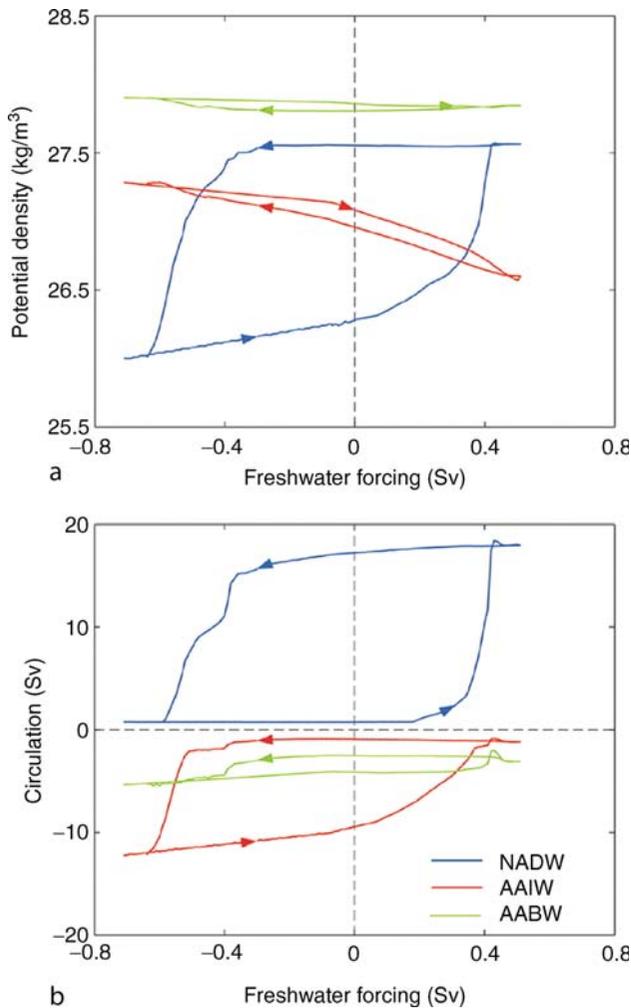

Figure T3 The UVic Earth System Climate Model (Weaver et al., 2001) hysteresis of NADW (blue), AAIW (red), and AABW (green), showing: (a) surface densities in the source regions of these water masses; (b) maximum (or minimum) MOC cells associated with these water masses. The model was started from a mode with no NADW formation with zero externally imposed freshwater flux. A freshwater perturbation was then applied to the AAIW formation region with a linearly-increasing rate of 0.2 Sv/1,000 years. This rate was small enough to ensure a nearly steady-state system, except for abrupt transitional events. Upon transition to a mode with active NADW formation, the freshwater perturbation was reduced at the same rate back to zero, and then to negative values, in order to trigger a transition from the active to the inactive mode of NADW formation. To complete the whole hysteresis loop, the model was integrated for more than 11,000 years. Transitions between the active and inactive modes of NADW formation occur when the surface densities at the site of AAIW and NADW formation cross. Taken from Saenko et al. (2003).

The meridional overturning circulation and Quaternary climate change

Early ice core records for the last glaciation have revealed large amplitude variability on the millennial timescale characterized by abrupt warming events (interstadials) lasting from several hundred to several thousand years. These oscillations (Figure T4 and T5), known as Dansgaard-Oeschger (D-O) oscillations, also appear in North Atlantic sediment records suggesting a

role or response of the ocean. Evidence from the Santa Barbara basin and the Northeast Pacific suggests that a signature of these D-O oscillations is also present in the Pacific Ocean, while further recent sediment analyses suggest they may be an inherent part of late and early Pleistocene climate.

In an attempt to provide a mechanism for the observed D-O variability, it was initially proposed that a stable AMO was not possible during glacial times, when the northern end of the Atlantic Ocean was surrounded by ice sheets. Furthermore, when the AMO was weakened or shut down and ice sheets were growing, there was little oceanic salt export from the Atlantic to the other ocean basins. Assuming a net evaporation over the North Atlantic, its salinity continued to increase as moisture was deposited on land as snow, thereby expanding the ice sheets. Upon reaching a critical salinity, deep convection, and subsequently the AMO, turned on, transporting and releasing heat to the North Atlantic and thereby melting back the ice sheets. The fresh water flux into the North Atlantic from the melting ice sheets (or enhanced iceberg calving) eventually reduced or shut off the AMO, causing the process to begin anew. This hypothesis fundamentally assumed that most of the evaporation from the Atlantic basin was balanced by a net freshwater transport into the Atlantic associated with an active AMO. While this in itself has not yet been established, it could be true for a climate with an active AMO. However, it is clear that the weakening of the AMO would trigger a reorganization of the circulation in the South Atlantic, but it is not clear whether this reorganized circulation would be able to balance the required Atlantic evaporation.

Recent models, including an interactive continental ice sheet, showed that the earlier mechanism for D-O oscillations was in fact opposite to what actually occurred within the coupled system. During the cold, glacial climate, when the AMO was *still* active, the mass balance over continental ice sheets was positive. That is, rather than melting the ice sheets when the AMO was active, they grew, since the warmer atmosphere allowed greater precipitation (in the form of snow). The models also found a mechanism for D-O oscillations that involved an interaction between the AMO and the adjacent continental ice sheets, by assuming that the rate of iceberg calving into the North Atlantic was not constant in time, which is consistent with observations of ice-rafted debris. It was shown that after a delay of several hundred years following a major surging event and a reduction of the iceberg calving rate, the AMO intensified and the North Atlantic experienced an abrupt shift to a much warmer climate. This mechanism appears to be more intuitively appealing than a competing hypothesis involving stochastic resonance of the AMO, which relies upon the existence of an unknown 1,500 year external periodic forcing.

Heinrich (1988), in analyzing marine sediments in three cores from the North Atlantic, noted the presence of six anomalous concentrations of lithic fragments over the last glaciation. Since the source for these fragments was the land (and in particular Canada), he argued that this provided evidence for six anomalous surges of icebergs into the North Atlantic (Figure T5). The so-called Heinrich events (H) were even more striking when expressed in terms of the ratio of lithic fragments to the sum of lithic fragments and foraminiferal shells, due to the low foraminiferal counts in the Heinrich sediment layers. A simple model illustrates the mechanism for Laurentide Ice Sheet instability, which ultimately gives rise to an ice-sheet surge and a Heinrich event. It has been argued that the Heinrich

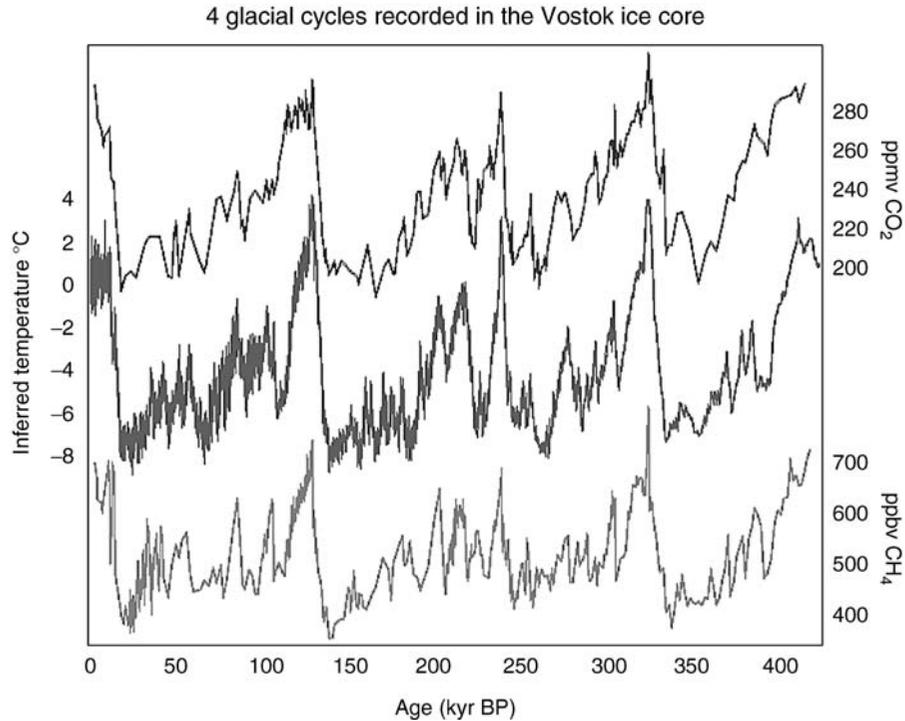

Figure T4 Variations in local Antarctic atmospheric temperature, as derived from oxygen isotope data, as well as concentrations of atmospheric CO_2 and CH_4 from Vostok, Antarctica ice core records over the last four glacial cycles. The rapid oscillations represent Dansgaard-Oeschger cycles. Figure redrawn from Petit et al. (1999).

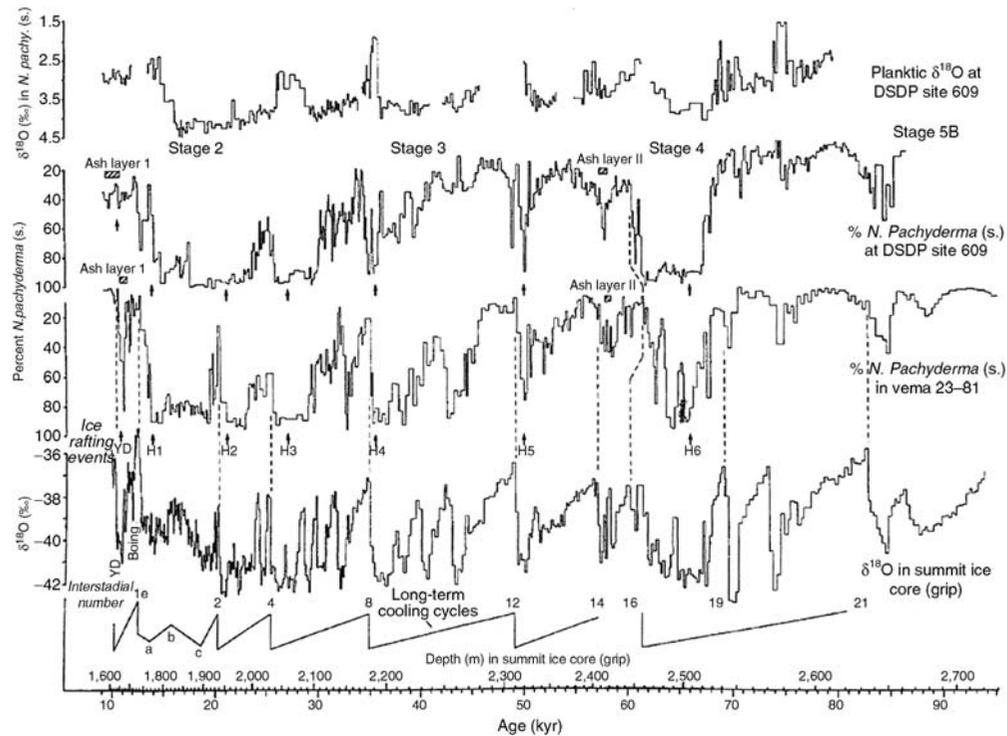

Figure T5 Sediment foraminiferal records from Bond et al. (1993) and ice core oxygen isotope records from Dansgaard et al. (1993) and GRIP (1993) as correlated by Bond et al. (1993). The Younger Dryas (YD) and six Heinrich events (H1–H6) are indicated. Also shown at the bottom is the saw tooth Bond Cycle pattern of successively weaker interstadials associated with a sequence of D-O oscillations following a Heinrich event (from Bond et al., 1993).

cycle consists of two phases. In the growth phase, the Laurentide Ice Sheet grew through snow accumulation while remaining attached to the bedrock. In the purge phase, the high pressures caused by the deep ice sheet caused thawing near the base of the ice sheet thereby allowing the ice sheet to surge seaward over a lubricated base through Hudson Strait. The resulting freshwater discharge into the North Atlantic would be of the order of 0.1–0.2 Sv over a period as short as 250–500 years.

Heinrich events, appearing about every 10,000 years, occur at the end of a sequence of D-O cycles during a prolonged cold period. Bond et al. (1993) noted that the sequences of D-O oscillations tend to follow a saw-tooth cycle (now termed a Bond Cycle) with successive D-O oscillations involving progressively cooler interstadials (Figure T5). They argued that this Bond Cycle was terminated by a Heinrich event, after which a rapid warming occurred and the process began anew.

The last cold event, known as the Younger Dryas (YD) (also known as Heinrich event zero, H0) took place between 12,700 and 11,650 years BP and terminated abruptly within a few decades. Proxy data suggest that during the YD, even the AMO was weakened. Further analysis of the proxy record indicates that the YD was preceded by a warm period in the North Atlantic climate, known as the Bølling-Allerød (B-A) warm interval (Figure T5). The B-A interval was accompanied by a strong global sea-level rise, apparently due to the melting of continental ice sheets. Until recently, it was not clear how to reconcile the warm North Atlantic climate during the B-A with melting of adjacent ice sheets. The latter would have caused a reduction of AMO, leading to a cooling, rather than warming of the North Atlantic. A possible explanation lies in the hypothesis that a significant portion of the observed rapid sea level rise during the B-A could have originated from the melting of Antarctic ice sheets, rather than solely from melting of the ice sheets surrounding the North Atlantic. A meltwater pulse into the Southern Ocean, originating from the partial collapse of an Antarctic ice sheet, could trigger an enhanced formation of NADW and an onset of warming in the North Atlantic (Weaver et al., 2003).

Despite these fundamental advances over the last few years, many challenges remain. In particular, a complete explanation including the essential role of the MOC, for the existence of millennial timescale (D-O) variability and its packaging into Bond Cycles in cold climates, its association with Heinrich events, and its dependence on the mean climatic state remains elusive to the paleoclimate community. Another major climate mystery is the cause of atmospheric CO₂ and CH₄ changes during the glacial cycles (Figure T4) and their possible connection to long-term changes of structure and strength of the GOC.

Andrew J. Weaver and Oleg A. Saenko

TILLS AND TILLITES

Tills, and their lithified equivalents, tillites, are sediments deposited by glacier ice. In the past, this definition has been employed in a very broad sense, to include unsorted sediments deposited in subglacial, supraglacial, ice-marginal, and subaqueous environments. Such a broad definition is difficult to apply in practice, because it may hard to differentiate sediments deposited directly from ice and those later reworked by non-glacial processes. Many researchers now prefer to restrict the term *till* to sediments deposited directly by grounded glacier ice, in subglacial and supraglacial environments, and which have not undergone significant reworking by fluvial, gravitational, or other processes (Dreimanis, 1989; Benn and Evans, 1998). The non-genetic terms *diamict* and *diamictite* have now generally replaced the older, broad usage of till and tillite. The correct identification of tills and tillites is important, because they provide direct evidence for the former distribution of glaciers, and hence have wide-reaching paleoclimatic implications.

The main processes of formation of tills are: lodgement, deformation, melt-out, and sublimation. Lodgement refers to frictional retardation of clasts or slabs of debris below sliding

ice, and deformation is the re-molding of pre-existing sediments or debris in a subglacial deforming layer (Boulton, 1982). Melt-out and sublimation remove interstitial ice from englacial debris (Paul and Eyles, 1990). Tills rarely form by a single process (Hicock, 1990). Many tills exhibit evidence of subglacial deformation, indicating shear of unlithified sediments below glaciers and ice sheets although this is contested by some researchers. Unmodified melt-out tills are rare, because high pore-water pressures during de-icing encourage re-molding by gravitational processes. Sublimation tills are restricted to arid polar environments, where temperatures never exceed 0 °C and melting does not occur.

The identification of tills and tillites should be based on multiple criteria, including: (a) faceted and striated clasts, with stoss-lee forms; (b) far-traveled, erratic clasts; (c) moderate to strong a-axis fabrics, which show regional consistency; (d) evidence of shear (e.g., low-angle faults, attenuated stringers, and overfolds) at macro- and micro-scales; (e) tabular geometry; (f) massive, matrix-supported character; (g) multi-modal grain-size distributions, often with a significant silt fraction ('rock flour'); and (h) association with folded and thrust sediments (glacitectorites). Not all tills will exhibit all of these characteristics, and some non-glacial sediments may exhibit some of them. Tills form a very variable group of sediments, and their recognition requires careful study.

TIME-SERIES ANALYSIS OF PALEOCLIMATE DATA

Introduction

This article is a brief synopsis of time-series analysis methods that have proven to be useful in the analysis of paleoclimate data. Space limitations precludes all but the briefest outline of the actual mathematics involved, but references are provided. The following sections define some basic functions such as spectrum and autocorrelations, outline the basic multitaper methods that are recommended to estimate them, describe

periodic components and Cramér–Rao bounds for frequency estimation, and coherence estimates. Other sections below discuss jackknife confidence limits for spectra and similar functions, spectrogram methods useful with nonstationary processes, discusses wavelets, Lomb–Scargle and Blackman–Tukey estimates which should be avoided for these applications. Finally, the last section summarizes the points made.

One should not expect the analysis of paleoclimate data to be easy. If one considers the effort that has been made over the last three or four decades in making general circulation models reproduce even fairly gross features of the climate system, one should not expect that the analysis of data produced by the real, and obviously far more complicated, climate system can be done simply. Added to this intrinsic difficulty, paleoclimate data is usually a proxy, the geographic distribution of samples is far from ideal, and from a data analysis viewpoint, the fact that the timescale is uncertain can be a major problem. Worse than these, however, is the problem that the climate system is nonstationary. *Stationarity* in this context implies that the *statistics* of the process do not depend on time.

Theoretical quantities

In this section we define some functions of a time series. Here we assume that the process $x(t)$ is stationary, that is its statistical properties do not vary with time; that the expected value of $x(t)$ is zero, denoted $\mathbf{E}\{x(t)\} = 0$; and that $x(t)$ has a Gaussian distribution. The samples are assumed to be equally spaced in time at a unit sampling rate. Thus the Nyquist frequency, $\frac{1}{2\Delta t}$ (where Δt is the time between samples) is $\frac{1}{2}$. Generally, the single most useful description of a time series is its power spectrum, also known as the power spectral density, or plain spectrum. The spectrum is a decomposition of the variance of the process as a function of frequency, and functionals of the spectrum give most of the interesting descriptive statistics of a time series. Thus, if we denote the spectrum at frequency f by $S(f)$, with $-\frac{1}{2} \leq f < \frac{1}{2}$, one has the process variance

$$\sigma^2 = \int_{-\frac{1}{2}}^{\frac{1}{2}} S(f) df \quad (1)$$

The units of the spectrum are $(data - units)^2$ per $(cycle/time-unit)$. As an example, if one has $\delta^{18}\text{O}$ data with samples measured at a rate of one per thousand years, the frequency range will be from $-\frac{1}{2 \times 1000}$ to $\frac{1}{2 \times 1000}$ and the spectrum will be in units of $(\delta^{18}\text{O})^2$ per $(cycle/1000\text{years})$. Most of the series encountered in paleoclimatology are real-valued so the spectrum is symmetric, that is the power at $-f$ is the same as the power at $+f$, so it is sufficient to plot the spectrum for positive frequencies only. However, if one has a series of directional data, say the north-south and east-west components of a magnetic field or flow, it makes sense to treat them as a complex-valued time-series, and in this case, the spectrum $S(-f)$ is different from $S(f)$.

Possibly as important as the variance, the one-step ahead prediction variance is given by:

$$\sigma_p^2 = \exp \left[\int_{-\frac{1}{2}}^{\frac{1}{2}} \ln S(f) df \right] \quad (2)$$

Climate studies are often associated with prediction and this formula shows that the overall shape of the spectrum on a logarithmic power scale is the critical parameter, not just the largest peak.

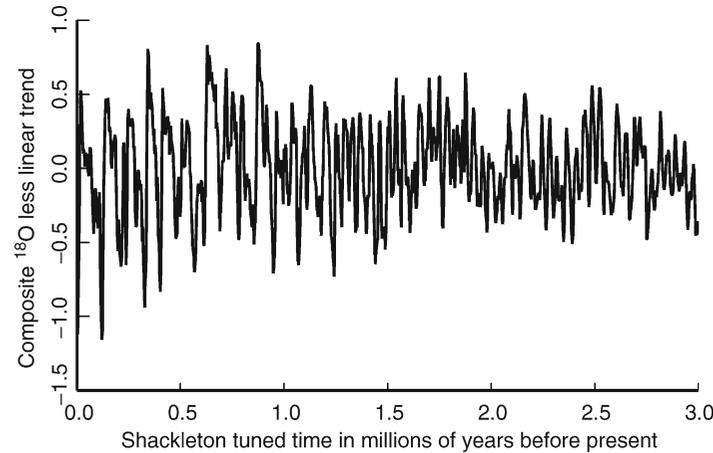

Figure T6 Shackleton's composite benthic $\delta^{18}\text{O}$ record, minus a linear trend, for the past 3 Myr.

Similarly, the single-sample interpolation variance given by

$$\sigma_I^2 = \frac{1}{\int_{-\frac{1}{2}}^{\frac{1}{2}} \frac{1}{S(f)} df} \quad (3)$$

shows that a missing sample may be interpolated with an accuracy approaching that of the measurement error. Together, equations (1), (2), and (3) are the arithmetic, geometric, and harmonic means of the spectrum, respectively.

The autocovariance function,

$$R(\tau) = E\{x(t)x(t+\tau)\} \quad (4)$$

is the Fourier transform of the spectrum

$$R(\tau) = \int_{-\frac{1}{2}}^{\frac{1}{2}} e^{i2\pi f\tau} S(f) df \quad (5)$$

so, comparing (1) and (5), $R(0) = \sigma^2$. The *autocorrelations*, $\rho(\tau)$ are just the autocovariances normalized by the variance $\rho(\tau) = R(\tau)/\sigma^2$ and are, as the name implies, the correlation of the process with delayed versions of itself. The Fourier transform of the autocovariance is the spectrum. Experience shows that the autocovariance is useful for prediction and interpolation. Even though the autocovariance and spectrum carry equivalent information, plots of the autocorrelation are usually remarkably uninformative. (John Tukey remarked that "I only knew one man who could look at an autocorrelation function and make sense of it, and he's dead.") One useful formula is that for the zero-crossing rate, the expected number of zeroes per sample (Kedem, 1994),

$$E\{R_z\} = \frac{1}{\pi} \arccos(\rho(1)) \quad (6)$$

As an example, the Lag-1 correlation of the data shown in Figure T6 is 0.978 with (6) evaluating to 0.0668, so one expects the curve to cross its average about every 15 samples or so.

Since the true spectrum is not known, the best estimate possible of a spectrum must be made. In estimating a spectrum, there are several competing criteria to optimize: bias, frequency resolution, variance, efficiency, ability to distinguish periodic from non-periodic components, minimum assumptions, and

robustness. The spectrum is, of course, not the only useful function and one should always plot the raw data and ancillary functions such as histograms, plots of $x(t)$ vs $x(t-1)$, Q-Q plots, as well as basic data checks such as histograms of bit and digit frequencies. Also, if the data is nonstationary (as much climate data is) one plots a *spectrogram*, see below, basically a sequence of spectrum estimates, usually computed on overlapping time segments and displayed as a function of both time and frequency.

Estimating the spectrum

As a data example, one can use the first 3 Myr of Shackleton's composite benthic $\delta^{18}\text{O}$ data from V19-30, ODP 677, and ODP 846 (see Shackleton et al., 1990, 1995a,b)¹. The time step was scaled by a factor of the ratio 41090.0/41234.9 to bring the strong obliquity line frequency into exact agreement with Laskar (1990). For the 3 Myr period being studied, this may be the most accurate orbital frequency available, see Laskar (1999). Assuming that a timescale has been established (see Pälike and Shackleton, 2000), and N data samples, $x(t)$, are available at a time-spacing of Δt years, the preferred method of estimating the power spectrum is the *multitaper* method. While the details of this method has been described in a series of papers (Thomson, 1982, 1990a,b, 2001; Thomson et al., 2007), and several books (Percival and Walden, 1993; Rao et al., 2003; Weedon, 2003), the basic idea is simple and consists of the following steps:

1. Choose the time-bandwidth product controlling frequency resolution and bias,

$$c_o = NW = BT = B \times N\Delta t \quad (7)$$

so, at unit sampling rate the bandwidth, W , is $W = c_o/N$ or, in physical units one has $B = c_o/T$ where T is the total duration of the data sample, $T = N\Delta t$. Usually one should choose $2 \leq c_o \leq 10$ and, for most paleoclimate data sets, a choice of 4 or 5 is a reasonable starting point. In this example $c_o = 5$ was used.

¹The data was obtained from [//delphi.esc.cam.ac.uk/coredata/v677846.html](http://delphi.esc.cam.ac.uk/coredata/v677846.html) and the few gaps interpolated; see Appendix A of Thomson et al. (2001).

The time–bandwidth product, c_o , is the dimension of the space of duration T and bandwidth T and to represent the information in such a space one needs c_o bases functions. It is convenient to work with real-valued bases functions, with the result that the true bandwidth spans the range from $-B$ to $+B$ and consequently one has a space of dimension $2BT$. Thus one has a set of $K \sim 2BT$ bases sequences that, in spectrum estimation problems, have historically been known as *data windows* or *data tapers*. A typical choice is $K = 2c_o - 2$, or $2NW - 2$ so if, takes $c_o = 5$ as we do here, one would use $K = 8$ windows.

The choice of c_o is fairly critical: if c_o is too small the estimate will have a high variance and relatively poor bias protection, but if c_o is too large, one will have poor frequency resolution. In this example values of the spectrum go from a minimum of ≈ 15 to a maximum of $\approx 4.7 \times 10^4$, a range of $\sim 3,000$, so extreme bias protection is not required.

2. Compute the first K lowest order *discrete prolate spheroidal sequences* or *Slepian sequences*, $v_t^{(k)}(N, W)$ where $0 \leq t \leq N - 1$. These sequences (Slepian, 1978), have the greatest possible energy concentration within the frequency band $(-W, W)$ of any time-limited sequence and, in sampled data, define the time–frequency uncertainty principle. They are defined by the algebraic eigenvalue equation

$$\lambda_k(N, W)v_t^{(k)}(N, W) = \sum_{m=0}^{N-1} \frac{\sin 2\pi W(t-m)}{\pi(t-m)} v_m^{(k)}(N, W) \quad (8)$$

The eigenvalues, $\lambda_k(N, W)$, define the energy concentration in $(-W, W)$. The first $K \approx \lfloor 2NW \rfloor$ are close to one and are the ones used in spectrum estimation. Although the Slepian sequences are defined by (8), this is emphatically *not* the way to compute them; see Appendix B of Thomson (1990a). For the rest of this article, the explicit dependence on N and W in the sequences and eigenvalues is dropped and λ_k and $v^{(k)}$ are used.

3. Subtract the mean, and possibly trend, from the data denoted $x(t)$.
4. For $k = 0, 1, \dots, K - 1$ compute the *eigencoefficients*

$$x_k(f) = \sum_{n=0}^{N-1} x(n)v_n^{(k)} e^{-i2\pi nf} \quad (9)$$

Normally the eigencoefficients are computed using a zero-padded fast Fourier transform (FFT). The procedure is:

- (a) Choose the number of transform points $M \geq N$ and usually $M \gg N$. The proper choice depends on how good the signal-to-noise ratio of your data is, with better data requiring larger M . It is generally unwise to choose $M < 2N$. For paleoclimate data, the choice $M = N$ is almost always a poor one as it implies circular correlations. (This means that the sample autocovariances obtained by taking the Fourier transform of the spectrum estimate, the sample equivalent of (5), would include both “legitimate” terms such as $x(n)x(n + \tau)$ and “illegitimate” ones such as $x(n)x(n + \tau - N)$ where the end of the sample wraps around and is correlated with the start.) The efficiency of the FFT algorithm depends on M being factorable into small primes, so choosing M as a product of 2’s, 3’s, 5’s, and other small primes up to 19 is necessary. Also note that, if one has a few hundred data points and the estimated spectrum differs noticeably between the choice of $M = 4000 = 2^5 \times 5^3$ and $M = 4096 = 2^{12}$, you are likely doing something wrong.

- (b) Multiply the data by the k^{th} taper. If one is using a standard (Singleton, 1969) FFT, say $\text{FFT}(M, X, Y)$ where X and Y are arrays of length M , X being the real part and Y the imaginary, one sets

$$X(n) = \begin{cases} x(n)v_n^{(k)} & 0 \leq n \leq N - 1, \\ 0 & N \leq n \leq M - 1 \end{cases} \quad (10)$$

$$Y(n) = 0 \quad 0 \leq n \leq M - 1 \quad (11)$$

The FFT computes

$$X_{out}(j) + iY_{out}(j) = \sum_{n=0}^{M-1} [X_{in}(n) + iY_{in}(n)] e^{-i2\pi \frac{nj}{M}} \quad (12)$$

for $j = 0, \dots, M - 1$. Because the data encountered in paleoclimate work is usually real-valued, it is only necessary to keep the outputs for positive frequencies, that is for $j = 0, 1, \dots, M/2$. Taking the time at the n^{th} sample to be $t_n = n\Delta t$ and the frequency at the j^{th} FFT bin as $f_j = j\delta f$ and comparing exponents it is evident that

$$\delta f = \frac{1}{M\Delta t} \quad (13)$$

so the effect of zero padding is simply to compute the frequencies on a finer grid. Note that one occasionally sees statements to the effect that “a FFT was not used and the Fourier transform was computed exactly.” This is a fallacy: not only is the FFT far quicker than naive evaluation of the formula, but it also computes exactly what it claims to compute and, because it uses far fewer operations to do it, suffers less from roundoff error than direct evaluation of the formula.

5. In practice one estimates the spectrum by solving (17) below, but to understand the properties of a multitaper estimate, it is easier to use the approximation

$$\bar{S}(f) = \frac{1}{K} \sum_{k=0}^{K-1} |x_k(f)|^2 \quad (14)$$

on the grid of frequencies $f_j = j\delta f$, $j = 0, 1, \dots, M/2$. This estimate has the following properties:

- (a) The bandwidth is

$$B = \pm \frac{c_o}{T} = \pm \frac{c_o}{N\Delta t} \quad (15)$$

Specifically, given a pure sinusoid at frequency f_o , one-half of the energy in the sinusoid would be distributed across the band $(f_o - W, f_o + W)$, and the other half of the energy across the symmetric band $(-f_o - W, -f_o + W)$. As will be described in the next section, when sinusoids are *known* to be present, one can estimate their frequencies much more accurately than B .

- (b) Under reasonable conditions the estimate (14) will have a chi-squared distribution with $2K$ degrees-of-freedom, written χ_{2K}^2 . At frequencies where there is a periodic, or other narrow-band component, the distribution will be a non-central chi-square, while at frequencies between such components *i.e.*, at frequencies where the signal is noise-like, the distribution is central chi-square. It is safer to

estimate the variance by using a jackknife than by relying on classical distribution theory. See below for details. As standard practice, both the classical and jackknife estimates are computed and compared.

- (c) The bias of the estimate, the energy leaking into the band $(f - W, f + W)$ through the sidelobes of the windows, can be bounded by

$$B(f) < \frac{1}{K} (1 - \lambda_{K-1}) \sigma^2 \tag{16}$$

where λ_k is the eigenvalue of the k^{th} Slepian sequence defined in (8), and σ^2 the process variance.

Finally, while (14) is easy to describe, in practice one uses an adaptively weighted estimate. Details are given in Thomson (1982) or on p 546 of Thomson (1990a), but the critical step is to solve

$$\sum_{k=0}^{K-1} \frac{\lambda_k (\hat{S}(f) - |x_k(f)|^2)}{[\lambda_k \hat{S}(f) + (1 - \lambda_k) \sigma^2]^2} = 0 \tag{17}$$

for $\hat{S}(f)$. It can be shown that this solution is between $\min_k \{|x_k(f)|^2\}$ and $\max_k \{|x_k(f)|^2\}$ and, in practice, an iterative solution starting at $\hat{S}(f) = (|x_0(f)|^2 + |x_1(f)|^2)/2$ usually converges in 2 or 3 iterations. The properties are very similar to those listed above except that, with (17), the effective degrees-of-freedom will be frequency dependent and usually lower near the minimum of the spectrum. This loss of degrees-of-freedom can be reduced by prewhitening.

Lines and Cramér–Rao bounds

A source of confusion in the analysis of paleoclimate data (and elsewhere) is the distinction between the continuous and line components of the spectrum. The lines are isolated periodic components such as those occurring in the familiar, e.g., Berger (1977, 1978), trigonometric expansions of eccentricity, obliquity, and precession, that is, sinusoids at discrete frequencies. The continuous part of the spectrum is basically everything else: measurement errors and related problems such as bioturbation, and non-deterministic parts of the climate process with a short prediction horizon.

The basic multitaper estimate for periodic components can be understood by considering the effects of a single sinusoid in noise. Define

$$y(t) = x(t) + A \cos(2\pi f_0 t + \phi) \tag{18}$$

which can be written

$$y(t) = x(t) + \frac{A}{2} e^{i\phi} e^{i2\pi f_0 t} + \frac{A}{2} e^{-i\phi} e^{-i2\pi f_0 t}, \tag{19}$$

where $A2e^{i\phi} = \mu$ is the complex amplitude and $x(t)$ is assumed to be non-periodic. The eigencoefficients of $y(t)$ are

$$y_k(f) = x_k(f) + \mu V_k(f - f_0) + \mu^* V_k(f + f_0) \tag{20}$$

where $V_k(f)$ is the Slepian function

$$V_k(f) = \sum_{n=0}^{N-1} v_n^{(k)} e^{-i2\pi f n} \tag{21}$$

Because of the energy concentration properties of the Slepian sequences, the term $\mu^* V_k(f + f_0)$ can usually be ignored if

$f_0 > W$. Because it is assumed that $x(t)$ is a zero-mean process, the expected value

$$E\{y_k(f)\} = \mu V_k(f - f_0) \tag{22}$$

One does a formal hypothesis test for the presence of a periodic component. The null hypothesis, \mathbf{H}_0 , is that the frequency band $(f - W, f + W)$ has an approximately flat (called “locally white”) spectrum of unknown power. The alternative hypothesis, \mathbf{H}_1 , is that in addition to the locally white noise, there is a sinusoid at frequency f . Estimate its amplitude μ by least-squares, that is minimize the error at frequency f between the data, the $y_k(f)$ ’s, and the model, (22). For an assumed complex amplitude $\hat{\mu}(f)$, the error is

$$E^2(f, \hat{\mu}(f)) = \sum_{k=0}^{K-1} |y_k(f) - \hat{\mu}(f) V_k(0)|^2, \tag{23}$$

where the assumption that the line frequency $f_0 = f$ results in the zero argument of the Slepian function. Taking the partial derivative of E with respect to $\hat{\mu}(f)^*$, one obtains

$$\hat{\mu}(f) = \frac{\sum_{k=0}^{K-1} y_k(f) V_k(0)}{\sum_{k=0}^{K-1} |V_k(0)|^2}, \tag{24}$$

the regression of the eigencoefficients on their expected values. One tests this regression in the usual way by using an F -test. This is the ratio of the energy explained by the assumed periodic component at frequency f to that remaining in the residuals,

$$F(f) = \frac{\frac{1}{2} |\hat{\mu}(f)|^2 \sum_{k=0}^{K-1} |V_k(0)|^2}{\frac{1}{2K-2} E^2(f, \hat{\mu}(f))}. \tag{25}$$

To understand this equation, recall that an F -statistic is defined as $(\chi_p^2/p)/(\chi_q^2/q)$ where χ_p^2 and χ_q^2 are independent chi-squared variables of p and q degrees-of-freedom, respectively. If there is no periodic component present, just “noise”, then, because $\hat{\mu}(f)$ is complex, $|\hat{\mu}(f)|^2$ is chi-squared with two degrees-of-freedom. The residual, E^2 , has $2K - 2$ degrees-of-freedom and is independent of the estimated mean, so $F(f)$ has a central F -distribution under \mathbf{H}_0 .

It can be shown by some tedious algebra that if one uses the frequency where $F(f)$ is maximized as an estimate of f_0 , it is usually within a few percent² of the Cramér–Rao bound on the achievable accuracy of a frequency estimate.

Notes on the harmonic F -test

When interpreting F -tests for lines, some precautions should be observed.

1. Because the F -test is computed as a function of frequency, there are approximately N independent tests in the frequency domain. Thus one should expect some false detections. For example, if one adopts a conventional 95% level, one should expect about $0.05N$ “detections” in cases when there are no lines present.
2. When there are strong lines present, the single-line F -test given above will suppress false detections within $\pm W$ of these lines.

²The actual factor is the estimate efficiency Ξ defined in Thomson (1982) §VII.

3. The test is sensitive to departures in assumptions. For example, an amplitude or phase modulated sinusoid will usually be rejected if the amplitude varies by a factor of two over the sample interval, or if the frequency, $\frac{1}{2\pi} \frac{d}{dt} \phi$, varies by about one-third of a Rayleigh resolution, that is, $1/(3T)$.
4. The test usually rejects multiple lines within the band.
5. When one observes a roughly rectangular peak of total width $\geq 2W$ in the spectrum without a peak in the F -test at the center frequency of the peak, one should test for multiple lines or for a modulated periodic component. (The lower precession band in Figure T8 is typical; this band, 42–45 c/Myr, contains four strong lines of which two are detected.) Tests are described in Thomson (1990a) and Johnson et al. (1996).
6. A peak in the F -test corresponding to a local minimum in the spectrum is usually a false detect. The line marked “20,850” in Figure T8 is almost certainly in this category. Similarly, the lines marked “13,397,” and “12,540” may be false detections, but could be a nonlinear interaction between obliquity and precession. Similarly, maxima in F on the sides of peaks, or on very steep slopes, are often false detections. The line marked “37,430” in Figure T8 is on the shoulder of the obliquity band. The reason for these false detections is that the “locally white” condition is violated, causing the y_k 's to be correlated.

7. When a sharp peak in the F -test occurs near the center of a roughly rectangular peak of total width $\approx 2W$, it is usually reliable. The 41,090-year obliquity line and 18,957-year precession line are prime examples, but again, the upper precession band contains lines at several closely-spaced periods.

The Cramér–Rao bound

The Cramér–Rao bound is a fundamental statistical inequality that gives lower limits on the accuracy with which various quantities can be estimated; here the frequency. For a single, isolated line, *i.e.*, one that is isolated from other lines by at least $\max(2, c_0)/T$, the bound is approximately

$$SD\{\hat{f}\} \geq \frac{1}{2\pi T} \sqrt{\frac{6}{\rho}} \tag{26}$$

where ρ is the effective signal-to-noise power ratio,

$$\rho = \frac{\frac{A^2}{4} T}{S_c(f)} \tag{27}$$

where $S_c(f)$ is the noise spectrum. This is the spectrum *without* the periodic components; in Figure T7 the noise spectrum near the 41,000 year obliquity line is about 500. Combining (26) and (27) it can be seen that, other things being equal, the variance of a frequency estimate decreases as T^{-3} . Thus, when a choice can be made, effort should be made obtaining longer series, not in making more precise measurements in a shorter series. As an example, if one wanted to double the accuracy of a frequency estimate one could consider either making more precise measurements or increasing the length of the series. The first choice, implies that σ^2 must be reduced by a factor of four, usually corresponding to a four-fold increase in measurement effort. The second requires increasing T by $\sqrt[3]{2}$, or

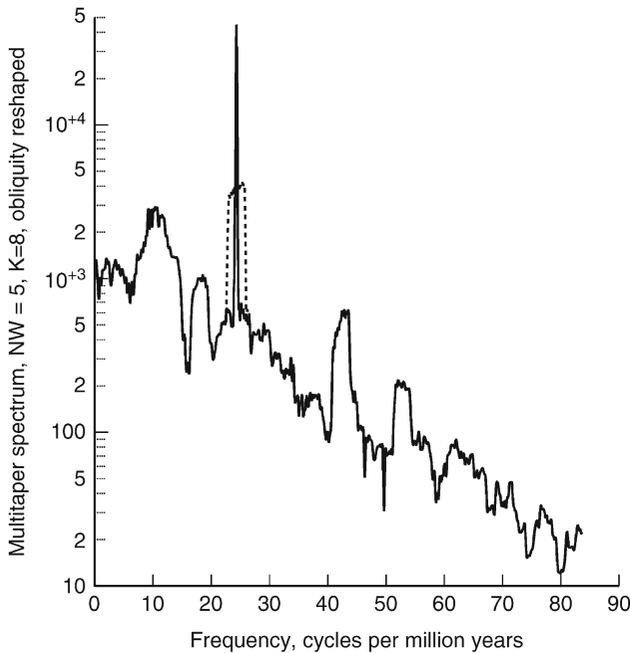

Figure T7 A multitaper estimate of the spectrum of the 3 Myr record shown in Figure T6. In making this estimate, $c_0 = NW = 5.0$ with $K = 8$ windows were used with adaptive weighting, (17). The dashed curve near 25 c/Myr (the 41090-year obliquity line) is the “raw” spectrum estimate, while the sharp black curve is the “reshaped” estimate. Because the significance level of the F -test exceeded the 99.999% level, the raw estimate was replaced with a peak at the estimated frequency. The width of the peak is given by the estimated frequency uncertainty, and the height is scaled to preserve power. The precession peaks (near 43 and 52 c/Myr) were not reshaped because they both consist of multiple lines and the eccentricity lines (7.8 – 10.5 c/Myr) are not resolved.

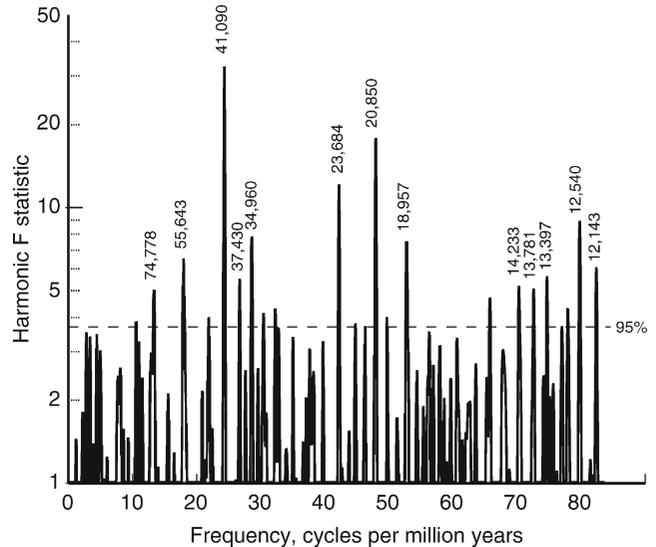

Figure T8 The single-line F -test for periodic components, (25). The data is the 3 Myr record shown in Figure T6, with parameters are as in Figure T7, so the test has 2 and 14 degrees-of-freedom. The low-frequency part is shown in Figure T10 and the horizontal dashed line shows the theoretical 95% level of the $F_{2,14}$ distribution.

about 26% more samples. Note that this calculation ignores the tuning problem.

If one is interested in estimating the *period* of a component, as is common in paleoclimate data, a Taylor's series argument shows that (26) becomes

$$SD\{\hat{P}\} \geq \frac{P^2}{2\pi T} \sqrt{\frac{6}{\rho}} \quad (28)$$

The F -test on the 41,000 year obliquity line was ~ 30 , and can be used as an estimate of ρ . Thus, if one oversimplifies things to ignore fine structure, possible frequency-modulation from changes in the earth's moments of inertia (see §11 of Thomson (1990a) and Figure T14 of Laskar et al., 1993) the accuracy of any estimate of the period from the 3 Myr record is bounded by

$$SD\{\hat{P}\} \approx \frac{41000^2}{2\pi \cdot 3 \times 10^6} \sqrt{\frac{6}{30}} \approx 38 \text{ years} \quad (29)$$

Because the period estimated from the original time scale was 41,234.9 years, 3.8 standard deviations from the nominal period of 41,090 years, the time was scaled by a factor of 41090.0/41234.9 to bring the two into agreement.

Equation (28) has further implications for data analysis. Because the Cramér–Rao bound is a fundamental statistical inequality, it does not apply to one particular estimation method or another, it simply says that one cannot estimate parameters with arbitrary accuracy. Arguments based on wavelet analysis of paleoclimate data claim that the precession line is frequency modulated. The usual trigonometric expansions used in celestial mechanics are, in fact, the Bessel function expansions of a frequency-modulated sinusoid. Since wavelets sequentially use data blocks half the length of the preceding one, the effective T in (28) at a given stage is much less than the length of the series. Thus (28) implies that the standard deviation will be proportionally larger, negating the argument.

Equation (26) also determines the amount of zero-padding necessary. A minimum requirement is that the frequency mesh, (13), should be less than about one-half the standard deviation implying

$$M \geq 4\pi \sqrt{\frac{\rho}{6}} N \quad (30)$$

For the 3 Myr series this implies that the 1,000 samples should be zero-padded to $2M \geq 28,000$ points and, in fact, these examples were zero-padded to $2M = 2^{17} = 131,072$.

When lines are *not* isolated and, in particular, when they are separated by less than twice the Rayleigh resolution, computing the bounds is more difficult. The bounds depend on the amplitudes and phases of the lines in addition to the frequency separation. Looking at the eccentricity expansions, there are four major lines with periods near 100,000 years. They are, explicitly, 94,782, 98,715, 123,818, and 130,615 years. Note that these come in two pairs; the frequency difference between the two frequencies in the first pair and those in the second both correspond to a period of 2.4 Myr. This means that estimating these frequencies with less than 4.8 Myr of data will be difficult even in utopian circumstances. Figure T9 shows the bounds for the four-line case computed using the frequencies, phases, and amplitudes from Berger (1977) as a function of the observation span. Note that, when the data span is less than 800,000 years, the *bound* on the standard deviation is 100,000 years, about the same as the period. Note also

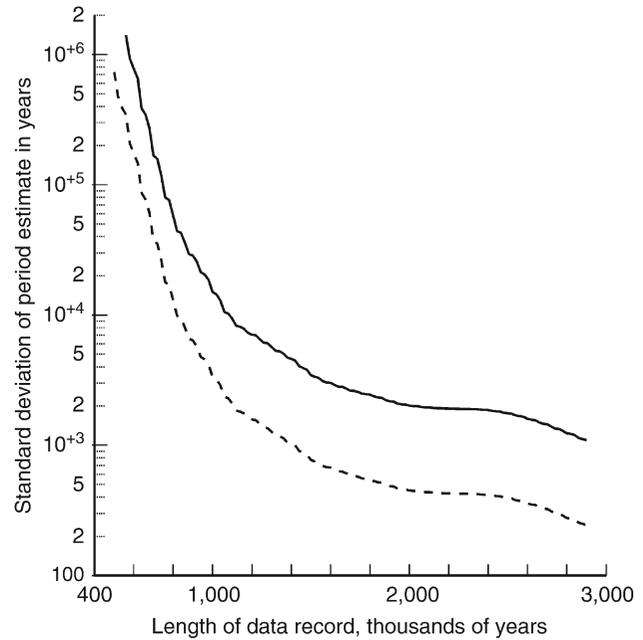

Figure T9 The Cramér–Rao *lower* bound for the standard deviation of the 123,000-year eccentricity line as a function of sample duration. A uniform sampling rate of $\Delta t = 1,000$ years is assumed. The upper curve corresponds to a signal-to-noise ratio $\rho = 5$, the lower to an unrealistically high value of 100. For a perfectly-tuned 800 Kyr record the standard deviation of the best period estimate is about the same as the period.

that these bounds are for Gaussian noise with a *known* timescale; when the timescale is estimated the bounds will be worse. Moreover, four pure sinusoids are assumed, whereas the eccentricity expansion includes dozens of lines in this band so, again, the bounds will be even worse than shown here. Thus, for example, attempts to discriminate between frequencies of 77,000 years and 95,000 lines with less than a few million years of data are futile. (It may be futile even with a few million years of data because 4.8 Myr is long enough for continental drift to significantly change climate dynamics.)

The multitaper setup for multiple lines is discussed in Thomson (1990a), and an example using the above data is shown here in Figure T10. The two-line test used here assumed a *known* frequency offset between the two lines, $1/2.2379 \times 10^6$ cycle/year, but even with this assumption, the test is only significant at about the 97% level.

Coherence

Many analysis problems in paleoclimate data involve studying several different series. The simplest case is the bivariate one, that is where one has two time series, $x(t)$ and $y(t)$. These are assumed to be on the same timescale, are sampled at the same time-step, and have the same number of samples³. Keeping the

³If the time-steps and number of samples are different one can still do the analysis as long as the total time span is the same and, obviously, one can always truncate a longer series. The frequencies used must be the same, so it may be necessary to use a “slow” Fourier transform (see e.g., Gentleman, 1969).

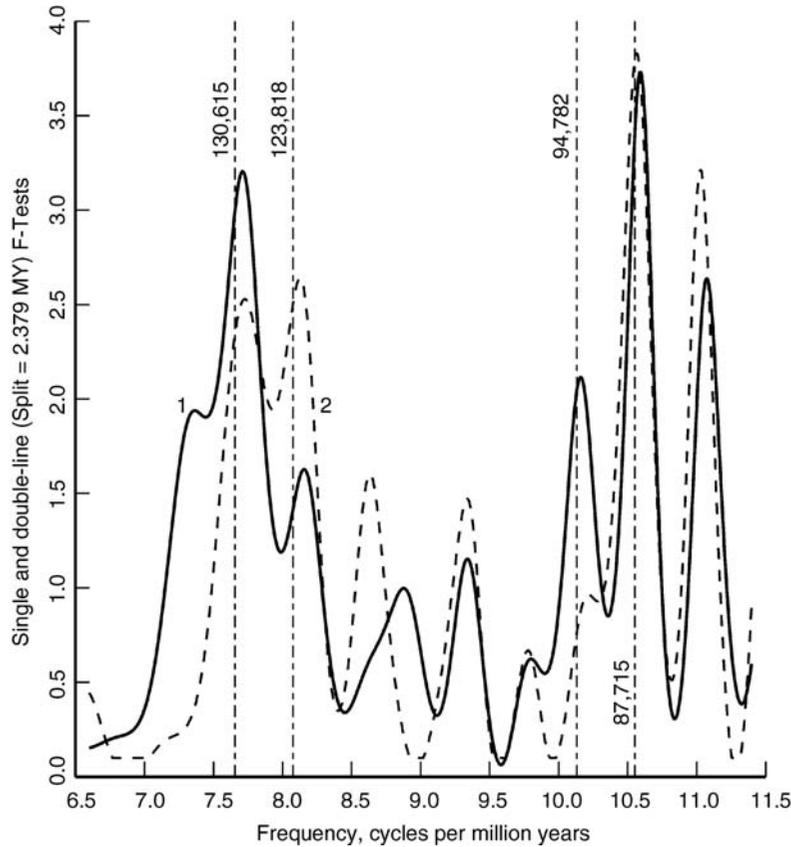

Figure T10 One (black) and two (dashed) line F-tests for periodic components in the eccentricity band. The two-line test assumed a frequency separation corresponding to a period of 2.379 Myr (this is the separation between each of the two pairs of lines).

definition of the eigencoefficients of $x(t)$ from (9), define those of $y(t)$ identically

$$y_k(f) = \sum_{n=0}^{N-1} y(n)v_n^{(k)} e^{-i2\pi n f} \quad (31)$$

and compute the *cross-spectrum*, $S_{xy}(f)$

$$S_{xy}(f) = \frac{1}{K} \sum_{k=0}^{K-1} x_k(f)y_k^*(f) \quad (32)$$

where, as before, the superscript “*” implies complex conjugate. It is usually more convenient to work with the complex quantity, *coherency*,

$$\gamma(f) = \frac{S_{xy}(f)}{[S_{xx}(f)S_{yy}(f)]^{1/2}} \quad (33)$$

where $S_{yy}(f)$ is the spectrum of $y(t)$. The absolute value $|\gamma(f)|$ is known as *coherence*; however, because usage in the literature has not been consistent, it is safer to use redundancy and refer to $\gamma(f)$ as “complex coherency.” In practice, use of *magnitude-squared coherence*, or MSC, defined as $|\gamma(f)|^2$ is preferable.

In common with correlation coefficients, one has $|\gamma(f)| \leq 1$ with $|\gamma(f)| = 1$ implying perfect correlation at frequency f , and $|\gamma(f)| \approx 0$ implying that the series are not related at that

frequency. One can, and often does, encounter both conditions in the same data, but usually, something in between occurs.

In data analysis one does not have the true coherence, but an estimate. The formal distribution of coherence estimates is complicated, but to answer the often-asked question “are these two series coherent, or can they be treated as independent?,” one can use a special case.

If the series are *independent* the probability distribution of an estimate of MSC, say \hat{C} , is

$$P\{\hat{C} < u\} = 1 - (1 - u)^{K-1} \quad (34)$$

so, if one has $K = 8$ windows, the probability that an estimate of coherence *at a given frequency* will be less than, say, 0.4 is $1 - (0.6)^7 = 0.972$. As with most frequency-domain statistics, the problem is that there are as many independent frequency estimates as there are data points with the result that, if one has 1,000 data samples, the odds are good that, at some frequency, an estimate will exceed the 99.9% significance level. This is where scientific judgement comes in; if such an event occurs at, for example, a period of 41,000 years in two long, well-dated ocean cores, one would be remiss in saying there is no evidence for coherence. If, however, it occurred at some “random” and otherwise unknown frequency, the most likely explanation is that it is a sampling fluctuation, not a new discovery. Here, looking at the two power spectra, $S_{xx}(f)$ and $S_{yy}(f)$ and the jackknife confidence intervals of these and coherence can help. If there are

pronounced peaks in both spectra, and the confidence intervals are tight, the peak is much more likely to be real than it is if the confidence bounds are wide and, particularly, if either or both of the spectra have local minima at f .

It is also useful to count the number of frequencies where the sample coherence is above the 10, 50, 80, and 90% significance levels. If one finds, for example, that the fraction of estimates above the nominal 90% level is 11% the series are probably independent. If, in contrast, 30% of the coherence estimates are above the nominal 90% point, one should assume that the series are related.

Coherency is a complex quantity, but thus far, we have only discussed its magnitude. Its phase is also important, primarily because it shows the delay characteristics between the series. One of the fundamental properties of the Fourier transform (see *e.g.*, Papoulis, 1962), is that a time-shifted function has the Fourier transform

$$\begin{aligned} F\{x(t - t_o); t \rightarrow f\} &= e^{-i2\pi f t_o} F\{x(t); t \rightarrow f\} \\ &= e^{-i2\pi f t_o} X(f) \end{aligned} \quad (35)$$

so that the phase $\theta(f) = 2\pi f t_o + \text{phase}\{X(f)\}$ has a linear frequency trend. In a coherence estimate between $x(t)$ and $x(t - t_o)$, the conjugate on $y_k(f)$ in (32) cancels the *phase* $\{X(f)\}$ term leaving $2\pi f t_o$. Thus, if $x(t)$ and $y(t)$ only differ in relative amplitude and a time delay, the phase of the coherency will be a linear slope in frequency. There are two things to remember about doing this in practice: first, a phase *estimate* is ambiguous to multiples of 2π radians or 360° , and these phase ambiguities need to be resolved. One way is to take at the difference between phases at adjacent frequencies and when the magnitude of the difference exceeds 180° , add or subtract 360° with the sign chosen to minimize the difference. Second, paleo-data is *not* noise-free, so that phase estimates are likely to be unreliable unless the coherence is high. One strategy for revealing phase trends is to pick frequencies where: (a) the MSC has a local maxima, and (b) is significant above, say, the 90% significance level. Then, at these frequencies, plot the uncorrected phase θ plus $\theta - 360^\circ$ and $\theta + 360^\circ$, and inspect.

Jackknife

The statistical *jackknife* was invented by Quenouille and named by Tukey after the boy scout's general purpose tool. It is a useful and reliable method to estimate variances of complicated statistics. The jackknife and the newer, and computationally more difficult, bootstrap are covered in several recent texts (see *e.g.*, Efron and Tibshirani, 1998; Davison and Hinkley, 1999). Lahiri (2003) describes resampling methods for dependent data, but the reliability of these for paleoclimate data has yet to be determined. Generally speaking, resampling schemes are intended for independent, identically-distributed data, and so cannot be applied naively to time series data. The eigencoeficients, $\{y_k(f)\}$ can be jackknifed (Thomson and Chave, 1991; Thomson 2007), and this has been a reliable method of assessing confidence limits on the various quantities. The basic rule is to delete each eigencoeficient in turn, then compute the mean and variance of the K "delete-one" estimates. To give a specific example, if one uses the frequency where the F -test is maximized as an estimate of location, one can write the sequence of operations (24) to (25) as

$$\hat{f}_{all} = \text{argmax}_f \{F(f) | x_0(f), x_1(f), \dots, x_{K-1}(f)\} \quad (36)$$

Now repeat these calculations for $0 \leq j \leq K - 1$ withholding the j^{th} eigencoeficient on each calculation

$$\begin{aligned} \hat{f}_{\setminus j} &= \text{argmax}_f \{F(f) | x_0, x_1, \dots, x_{j-1}, x_{j+1}(f), \\ &\quad \dots, x_{K-1}(f)\} \end{aligned} \quad (37)$$

where the subscript $\setminus j$ means that the j^{th} eigencoeficient has been omitted. One now computes the average,

$$\bar{f} = \frac{1}{K} \sum_{j=0}^{K-1} \hat{f}_{\setminus j} \quad (38)$$

and the variance,

$$\text{Var}\{\bar{f}\} = \frac{K-1}{K} \sum_{j=0}^{K-1} [\hat{f}_{\setminus j} - \bar{f}]^2 \quad (39)$$

where the extra factor of $K - 1$ in the variance formula occurs because the different delete-one estimates contain dependent data.

Nonstationarity and Holocene data

A major source of controversy in climate data is that the data is nonstationary, while the majority of papers appear to implicitly assume stationarity, at least when judged by the way they are analyzed. Such a dichotomy is almost guaranteed to cause problems on all timescales, but the higher time resolution of much Holocene data requires that the way the data is analyzed take nonstationarity into account.

In specific, lunar and solar influences on climate appear to be nonstationary. With the moon, the coupling is presumably tidal modulation of storm tracks while several mechanisms have been suggested for solar coupling. As specific examples, attempts to detect the 18.61 year period of the lunar node, the ordinary 11 year sunspot cycle, or the 22 year solar magnetic cycle in instrumental climate data usually either fail or else yield contradictory results. Both, however, appear to modulate the statistics of the climate system and are easily detectable in the central England temperature series as nonstationary features. Another family of periods that commonly occurs in climate data is the 104-year "Suess" cycle and harmonically related frequencies. While data from ocean and lake cores rarely have fine enough sampling to resolve these frequencies, the way they enter into instrumental data carries an important lesson for the analysis of paleo data. To put this idea into more definite form consider two oversimplified examples:

$$y_+(t) = x(t) + a \cos 2\pi f_o t, \quad (40)$$

and

$$y_{ns}(t) = (\alpha + \beta \cos 2\pi f_o t) y_{ns}(t-1) + x(t) \quad (41)$$

where $x(t)$ is an ordinary stationary process and a , α , and β constants. In the first example, $y_+(t)$, the sinusoid is easily detectable if a is sufficiently large and a long enough sample of the process is observed. This is what is usually assumed. Over a few years, the annual temperature cycle is of approximately this form. However, over longer time spans, the more complicated form of the annual cycle described in Thomson (1995) must be considered. In the second example, $y_{ns}(t)$ the periodic component only enters because it modulates the structure of the process. Thus, even though $y_{ns}(t)$ varies periodically,

it is not an additive periodicity and something more complicated than a simple spectrum is necessary to detect it.

As an example, Figures T11 and T12 show dynamic spectra and F -tests for the benthic $\delta^{13}\text{C}$ record from Core V19-30 (Shackleton and Pisias, 1985). The data was gap-filled and interpolated to be equally-spaced in time, then prewhitened using an AR-1 prediction error filter

$$y(t) = x(t) - \alpha x(t-1), \quad t = 1, \dots, N-1 \quad (42)$$

with $\alpha \approx 0.99878$, the one-step autocorrelation. Next, adaptively weighted multitaper spectra (17) and F -tests were computed on 399 overlapping 8,000 year blocks each offset

by 800 years. Because the prewhitening reduces the range of the spectrum, extreme bias protection was not as essential, so a time-bandwidth product of $c_o = 2.7$ and $K = 4$ tapers were used on each block. However, even with prewhitening, one notes that the range of the spectrogram, Figure T11, is $> 10^{10}$.

The corresponding F -test (Figure T12) shows a band of reasonably consistent maxima around 400 c/Myr ($\sim 2,500$ years) and another near the Bond period (Bond et al., 2001) of $\sim 1,500$ years, or 666 c/Myr. Because short windows were used in this example to highlight nonstationary aspects of the data, the fact that these are observed at all is rather surprising.

Turning again to the spectrogram (Figure T11), one of the more prominent features is the series of vertical “stripes” where

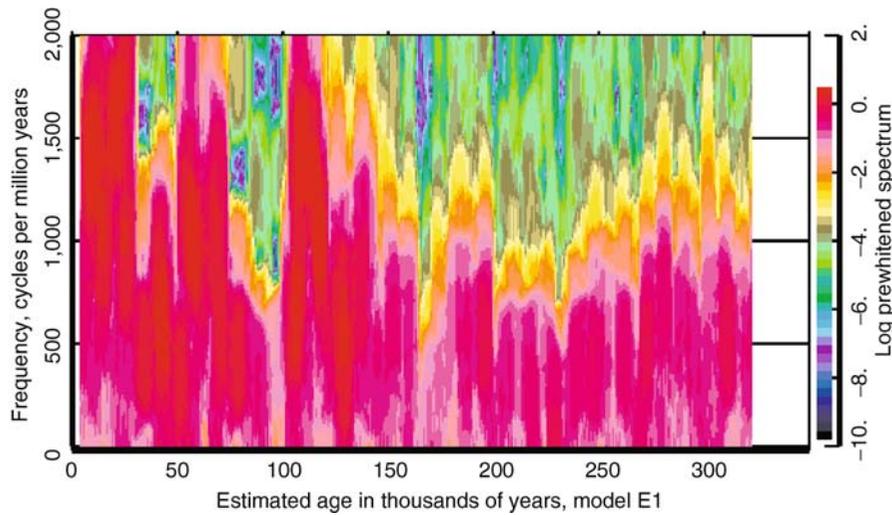

Figure T11 Log_{10} of a multitaper spectrogram for $\delta^{13}\text{C}$ in marine core V19-30. 8,000-year blocks, offset by 800-years were used with $c_o = WT = 2.7$ and $K = 4$ tapers on each block. The data was prewhitened using an autoregressive filter of order 1 (also known as a prediction error filter) and, even so, the range of the spectrum exceeds ten orders of magnitude. Much of the apparent structure appears to be systematic.

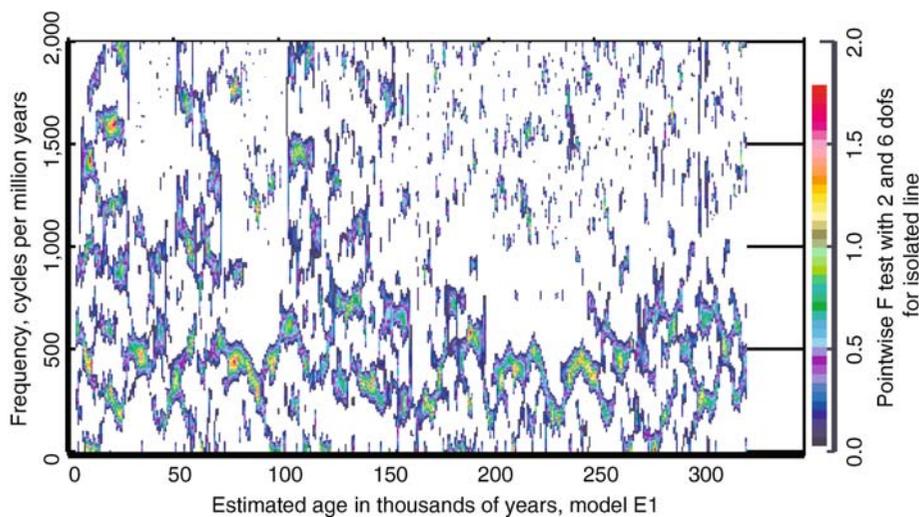

Figure T12 The single-line F -test, (25), for $\delta^{13}\text{C}$ in Core V19-30 with parameters as in Figure T11. The most unusual feature of this plot is the band of reasonably significant peaks visible near 440 c/Myr, corresponding to an average period of about 2,300 years.

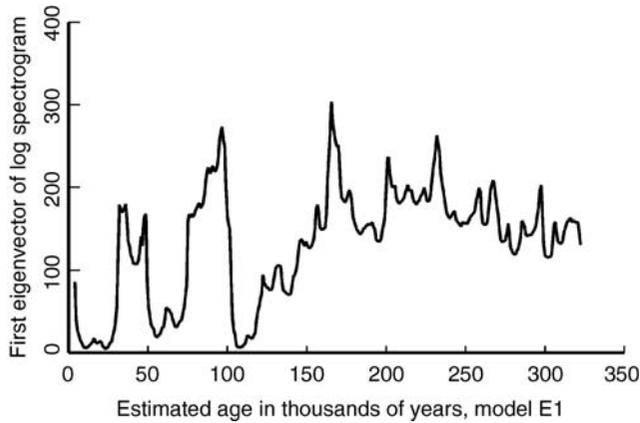

Figure 13 The first eigenvector in the time dimension of the SVD of $\ln S(t, f)$ of the core V19-30 $\delta^{13}\text{C}$ data shown in Figure T11. This is the eigenvector corresponding to the largest singular value.

one can count ~ 13 during the first 150,000 years. This corresponds to an approximate period of $\approx 11,500$ years, about one-half the 23,000 year precession cycle. More formally, on taking the singular value decomposition (SVD) of the log-spectrogram as described in Thomson (1990b), one finds that the *first* eigenvector accounts for more than 95 % of the variation on the log scale. This eigenvector is shown in Figure T13 where the most alarming features are the abrupt transitions.

Wavelets, Lomb–Scargle, Blackman–Tukey

There are several estimates that should be avoided when analyzing paleoclimate data. Some, including the periodogram and Blackman–Tukey estimates, are simply obsolete. It has been recognized for over a century (Rayleigh, 1903), that the periodogram is unreliable. Thomson (1977) has shown examples where the periodogram was in error by over a factor of 10^{12} over most of the frequency range. Examples where it is off by a factor of 10^3 and more, are common in geophysical problems.

The Blackman–Tukey estimate is a smoothed periodogram and inherits its bias problems, a fact that was recognized by Tukey himself. In Tukey (1967), John was recommending “direct” spectrum estimates with data tapering, basically the $k = 0$ term in (14).

Lomb–Scargle estimates (Lomb, 1976; Scargle, 1981) are simply least-squares fits to the data with a single sinusoid at a time, and reduce to the ordinary periodogram when the data is equally-spaced. They have their place, but are even more dangerous than the ordinary periodogram. For most of the problems considered here, it is safer to interpolate the data to an equally-spaced grid, then proceed as above. This is certainly the case if only a few samples are missing.

Wavelets, again, are dangerous for unskilled users. More than one example exists where a wavelet analysis was used to “prove” that precession was frequency modulated. The problem lies in (26); that is, when one makes the effective window length T shorter, as one does in a wavelet analysis, the variance of a frequency or period estimate increases as T^{-3} . Thus, if one uses a short window, line frequencies appear to be variable. This said, if wavelets are appropriate, read Daubechies (1992), Mallat (2001), and Percival and Walden (2000).

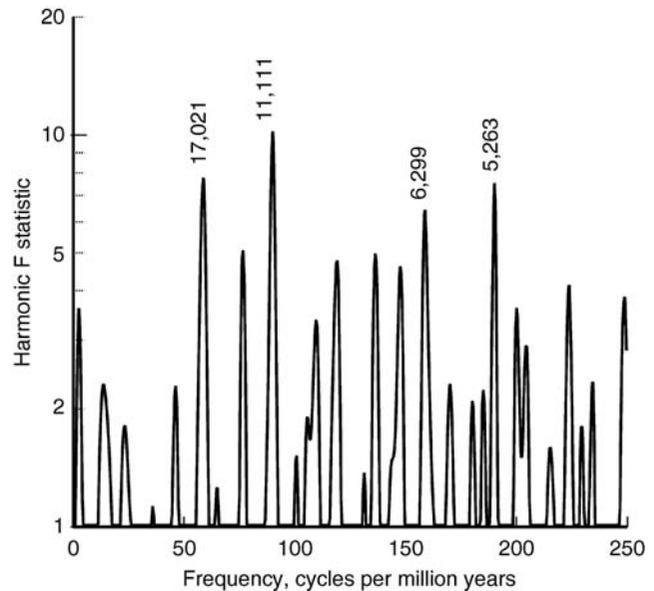

Figure T14 The F -test for periodic components from a multitaper of the eigenvector shown in Figure T13 using $c_0 = 4$ and $K = 5$. Periods of components with individual significance levels above the 97 % level are shown.

Summary and Recommendations

The major facts to remember in the analysis of paleoclimate data are as follows:

Analysis of paleoclimate data is difficult. Noting the efforts that have gone into getting general circulation models to reproduce even fairly gross features of the climate system, one should not expect that the analysis of data produced by the real (and obviously far more complicated) climate system to be simple.

The complexity of the data is not helped by the timing being uncertain. However, a carefully tuned series is preferable to an untuned one. While there is still some debate about whether the tuning process is a form of circular argument, my opinion is that the major remaining uncertainty is the change in precession and obliquity from glacial loading, and the earth’s response to this loading.

The power spectrum is almost always more informative than the autocovariance.

The best way to estimate a power spectrum from data is by multitaper methods.

Blackman–Tukey estimates are obsolete and should not be used. Parametric methods (ones based on autoregressive, moving average, and related models) rarely work well enough to bother computing them. Similarly, the periodogram should *never* be used as a spectrum estimate.

Paleoclimate data is almost certainly nonstationary, but much of the nonstationarity appears to be systematic. One should attempt to identify it.

As always, try several different methods to analyze data. It is recommended to choose the method that gives a good description of the observations with the simplest assumptions.

TRANSFER FUNCTIONS

Introduction

Paleoecologists use a number of different methods to reconstruct past changes in the Earth's climate and environment. One of the most useful is the analysis of the remains of microscopic plants and animals preserved in ocean, lake, and mire sediments. Interpretation of these biostratigraphic records is usually based on the principle of uniformitarianism: that is, knowledge of an organism's present-day ecology and climate preferences can be used to make inferences about past conditions. Transfer functions are mathematical response functions that allow paleoecologists to formalize this procedure by defining a series of equations that relate a set of biological species data to climate or other environmental parameters.

The transfer function methodology has developed rapidly since the early 1970s following the pioneering work of Imbrie and Kipp (1971) on sea surface temperature reconstruction from fossil foraminifera. Since then the approach has become one of the main tools for studying environmental change on a range of timescales, and has been used to derive quantitative paleoclimate and other environmental estimates from various

Table T2 The main biological proxies used in transfer functions and applications

Biological proxy	Archive	Application	Examples
Foraminifera, diatoms, coccoliths, dinoflagellates	Marine sediments	Sea surface temperature	Kucera et al. (2005); Andersen et al. (2004); Peyron and De Vernal (2001)
Terrestrial pollen	Marine, lake and mire sediments	Temperature, precipitation, growing degree days	Davis et al. (2003)
Coleoptera	Lake and mire sediments	Temperature	Coope (2002)
Diatoms, chironomids, Cladocera	Lake sediments	Temperature, salinity, pH, nutrients	Mackay et al. (2003); Larocque and Hall (2003)

biological proxies preserved in different sedimentary archives (Table T2).

Methods

The basic idea behind the transfer function approach to environmental reconstruction is that we can model a set of biological responses (Y) as a function of one or more environmental parameters (X) (Birks, 1995):

$$Y = f(x) + \text{error}$$

If we understood and could quantify the various physical, chemical and biological processes that determine the distribution and abundance of the taxa in question, we could derive the response functions $f(x)$ directly. Such detailed autoecological information is usually lacking, so instead we adopt an empirical approach and relate the modern distribution and abundance of taxa to contemporary environmental measurements. This usually involves a modern “training” or “calibration” dataset consisting of biological census counts extracted from surface sediments together with environmental measurements from the same sites. The relationship between the modern biological and environmental datasets is then used to solve $f(x)$ and the resulting transfer functions are applied to fossil assemblages in order to derive estimates of the environmental variable for times in the past (Figure T15).

The resulting accuracy and applicability of the transfer function depends in part on the size and quality of the training set from which it is derived. The training set is usually derived from the same type of sedimentary environment as the fossil material to minimize the influence of taphonomic effects. More important is that the training set includes the range of taxa present in the fossil assemblages and that it spans the range of environments likely to have occurred in the past. This requirement cannot always be met using small regional training sets so paleoecologists are increasingly collaborating to merge regional datasets into large continental or global training sets for some organisms (e.g., pollen: Davis et al., 2003; foraminifera: Kucera et al., 2005).

Modern training sets usually contain many taxa (20–300), have abundances expressed as percentages or proportions (i.e., have a constant-sum constraint), and individual taxa often exhibit a non-linear relationship with the environmental variable of interest. Such properties make the derivation of $f(x)$ a difficult statistical problem of multivariate calibration. Not surprisingly, a number of different numerical methods have been proposed, and some have a stronger ecological or statistical basis than others (see Birks, 1995; ter Braak, 1995).

Most methods can be classified into one of two groups. The first seeks to fit a single model to the training set data, providing a generalized description of the relationship between

taxa and environment. Examples of this approach are the principal component regression method of Imbrie and Kipp (1971), neural networks (Malmgren et al., 2001) used in paleoceanography, and the weighted averaging method and its extension – weighted averaging partial least squares – used in paleolimnology (e.g., Birks, 2003). The second group of methods includes the so-called modern analog technique (MAT) and its variants, known in the statistical literature as k -nearest neighbors. This is perhaps the most simple and intuitive method of calibration: rather than fitting a single model to the entire training set, MAT derives what is essentially a local model by searching the modern data for samples that most closely resemble the fossil assemblage. The dissimilarity between the modern and fossil assemblages is calculated by a numerical distance measure (e.g., squared chord distance), and a reconstruction is derived by averaging the environmental value of a small number (usually 10) of the closest analogs.

Differences in the properties of proxies in terms of training set size, taxonomic diversity, and complexity of the species-environment relationship make some numerical techniques more useful than others for particular biological groups. However, it is clear that there is no single mathematical technique that can be recommended as optimal, on either theoretical or empirical grounds. Because of this, many paleoecologists have moved away from the search for a single “best” method and recommend comparing results from several different techniques and combining them to derive a consensus reconstruction (e.g., Birks, 2003; Kucera et al., 2005).

How accurate are the reconstructions?

Given a modern training set and a series of fossil assemblages, all transfer function methods will produce some result. It is therefore important to evaluate the accuracy and reliability of the reconstructions. Direct comparison of the reconstructions with historical monitoring records provides perhaps the most powerful way of validating records for the recent past (e.g., Malmgren et al., 2001; Larocque and Hall, 2003). Over longer periods, independent environmental measurements are usually not available and some form of internal validation based on an analysis of the training set must be used. In this case, the prediction error of the transfer function is typically estimated by comparing the measured environmental variable with the predicted value across the training set samples. Since the same data is being used to both generate and test the model, some form of data splitting or computer-intensive resampling scheme is employed to better simulate the likely errors when the transfer function is applied to new data outside the training set (Birks, 1995).

One of the main assumptions of the transfer function approach is that the modern training set encompasses the range

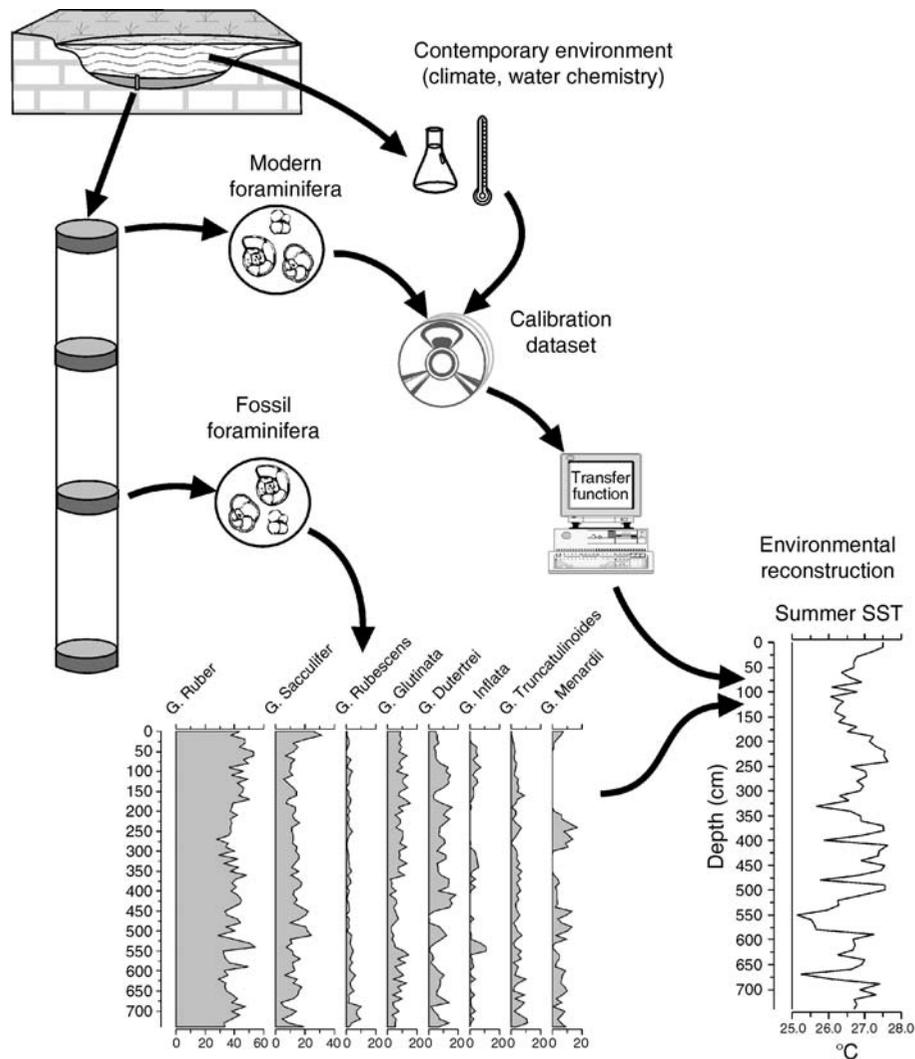

Figure T15 A schematic illustrating the transfer function approach to deriving a quantitative reconstruction of past sea-surface temperature from foraminifer biostratigraphic data using a modern training or calibration dataset.

of biological and environmental variability expressed by the fossil assemblages. This can be partially tested by calculating an analog measure between individual fossil samples and the training set: reconstructions for samples that lack good modern analogs are likely to be less reliable and should be treated with caution. Comparison of reconstructions obtained from the same fossil assemblages using different numerical procedures can highlight technique-specific bias, and together with analog measures, can be used to give a reliability rating to each reconstructed value (Kucera et al., 2005). In some cases, paleoecologists are able to compare reconstructions derived from independent biological or geochemical proxies measured on the same, or closely related, sedimentary sequences (e.g., Birks et al., 2000; Bard, 2001; Larocque and Bigler, 2004). Such comparisons are beginning to focus attention on the potential biases of individual proxies and on the need to understand the processes controlling organism distribution in the training set better.

An important corollary of the above assumption is that not only should the relationship between biota and the environmental variable of interest be invariant through time, but also that the joint distribution of other environmental factors controlling species distribution should have been the same in the past as it is today. This assumption is probably violated in many cases. Where the environmental variable is a strong determinant of species distribution and biological changes are large (e.g., in studies of recent lake acidification or eutrophication), such biases are likely to be small. Over longer timescales where the current training set does not encompass the past range of environmental conditions, or where the environmental variable being reconstructed is not a major determinant of species distribution, biases may be significant and are a focus of current research (e.g., Watkins and Mix, 1998; Anderson 2000).

TRIASSIC-JURASSIC CLIMATES

Ever since the late nineteenth century discovery of fossil conifers, ferns and cycadlike plants in Spitzbergen and Greenland, the Triassic and Jurassic periods of geological time (250–144 Ma) have been regarded as times of unusual global warmth. The twentieth century discovery of continental drift and plate tectonics did not explain paleoclimatic anomalies of forests at high latitudes, and even higher paleolatitude fossil forests were found in Antarctica. These observations, coupled with a likely role for carbon dioxide in global warming comparable with panes of a greenhouse, which was first suggested by nineteenth century physicists John Tyndall and Svanté Arrhenius, have led to the concept that “greenhouse paleoclimates” (as in Triassic and Jurassic) alternated with “icehouse paleoclimates” (such as Permian and modern) over the course of Earth history. In the current atmosphere of early twenty-first century global warming, the details and causes of such warm periods of the geological past remain of great interest.

Rock and fossil record

Especially obvious as evidence of greenhouse global warmth in the past are permineralized tree stumps and logs at high latitudes, well south or north of the modern treeline. Early Triassic fossil logs from Antarctica (Figure T16), for example, grew at paleomagnetically estimated paleolatitudes of 69–73°S, not very different from present paleolatitudes (76°S); however, at present there is a landscape of bare rock and ice with nothing larger than endolithic lichens growing. The fossil logs are up to 19 m long, and judging from their diameters compared with those of living pines, would have been trees 50 m high (Retallack, 1997a). Although these fossil logs are within ancient stream deposits and have been transported, they are associated with permineralized chunks of peaty soils that have not traveled far. Furthermore, untransported ancient soils containing large tree roots are found within the same sedimentary sequence (Figure T17).

The marked tree rings of Antarctic permineralized logs indicate strong climatic seasonality (Del Fueyo et al., 1995), presumably due to an annual snowy season. Fossil leaves of many high paleolatitude floras, such as the *Dicroidium* flora of Antarctica (Figure T18), show evidence of deciduous leaf shedding found in seasonally snowy climates today. The petioles of the fossil leaves have basal smooth callus tissue indicating that they were deliberately shed, rather than torn from their branches. Other fossils from the *Dicroidium* flora, presumably torn off during storms, show clustering of leaves in bundles (Anderson and Anderson, 1985), similar to short shoots and buds of cool temperate plants, such as oaks and pines.

Living relatives of high latitude fossil plants were the greatest surprise to pioneering paleobotanists. Jurassic floras of Greenland are dominated by leaves like those of living cycads and marattiaceous, matoniaceous, dipteridaceous and gleicheniaceous ferns, which are plants now found in warm temperate and tropical climates. Subsequently it was shown that the ferns belong to extinct species, and only a few of the cycadlike leaves were closely allied to modern cycads. Many of the cycadlike leaves belong to an extinct cycadlike group, the cycadeoids, with very different reproductive structures. Nevertheless, many of the fern and cycadlike leaves were large, too

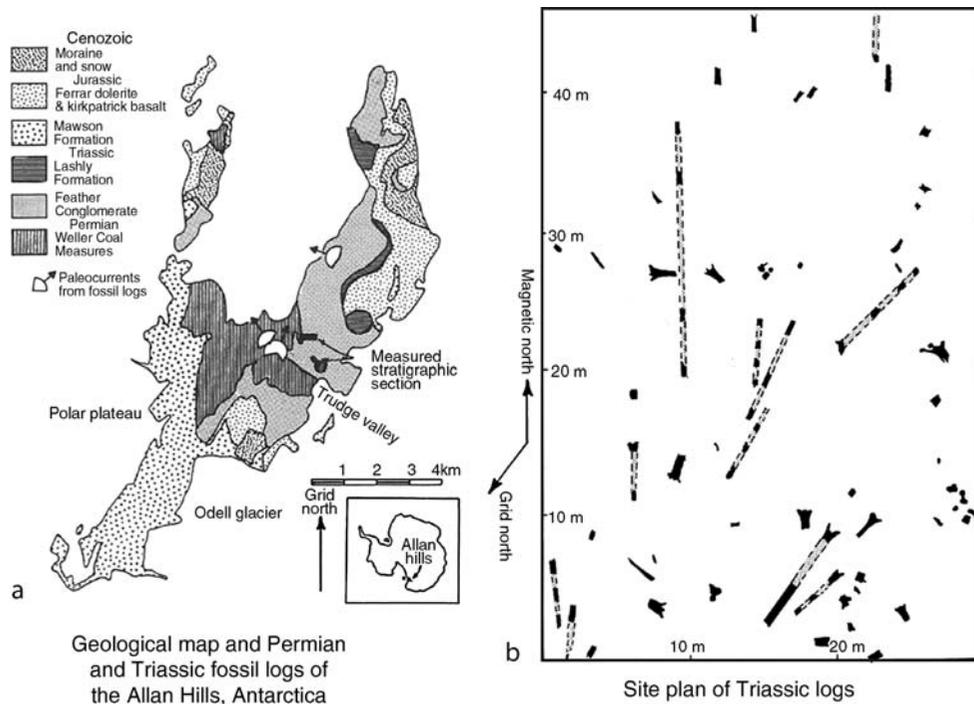

Figure T16 Geological map, paleocurrents (a) and site plan of fossil stumps and logs in Early Triassic sandstones (b) of the Feather Conglomerate in the Allan Hills, Victoria Land, Antarctica, currently at 76°S , and with estimated paleolatitude of $69\text{--}73^{\circ}\text{S}$ (after Retallack, 1997a).

large for polar tundra or taiga vegetation. Furthermore, some of the fossils had a palmlike growth form, with a large terminal meristem and a single parasol-like canopy of large spreading leaves. Frost sensitivity of such large terminal meristems is the main reason why palms, cycads and tree ferns fail to grow much further north or south of 30° latitude, unless in a greenhouse. This argument does not apply to fossil gleicheniaceae ferns, which today are mainly scrambling vines, or to all fossil cycadeoids and cycads, some of which differ from modern cycads in having slender and copiously branching twigs (Willis and McElwain, 2002). Nevertheless, the overall appearance of some high latitude Jurassic floras is more like a Malaysian jungle than taiga or tundra vegetation.

Fossil animals and their traces can also be evidence of global warmth. Large labyrinthodont amphibians from the early Triassic of Antarctica, for example, were probably “cold blooded” (ectothermic poikilotherms) like modern alligators of frost-free climates (Retallack and Krull, 1999). The paleoclimatic significance of dinosaurs is less clear, because their physiology (perhaps inertial or endothermic homeotherms) does not have modern analogues. Ground-dwelling termites are restricted to tropical and subtropical regions (Retallack, 2001a), and could be exploited as paleoclimatic indicators now that their distinctive nests have been recognized in paleosols (Hasiotis and Dubiel, 1995). Coral reefs spread to higher latitudes during global warming (Kiesling et al., 1999). However, some times of restricted reef distribution during the early (Pliensbachian) and middle Jurassic (Bajocian) and earliest Cretaceous (Berriasian), as well as prolonged disappearance of reefs during the earliest Triassic (Griesbachian), appear to have been due to mass extinctions, rather than paleoclimatic cooling (Hallam and Wignall, 1997).

Figure T17 An ancient soil of early Triassic age from the Feather Conglomerate in the Allan Hills, Antarctica. The clayey profile with large root traces and cracks was buried by a cross-bedded sandstone of an ancient river. Chemical analysis of this paleosol show that it was deeply weathered and depleted in common plant nutrients (Ca, Mg, K, Na), like modern Ultisols found no further south than 48° latitude (Retallack and Krull, 1999).

Fossil soils (paleosols) also present striking paleoclimatic anomalies indicative of unusually warm polar paleoclimates. Paleosols associated with early Triassic fossil logs in Antarctica (Figure T17) not only confirm that trees grew nearby, but show a degree of chemical leaching of common plant nutrients (Ca, Mg, K, Na) comparable to that found no further south than 48° latitude. These paleosols are enriched in clay and chemically weathered to the same extent as modern Ultisols, which

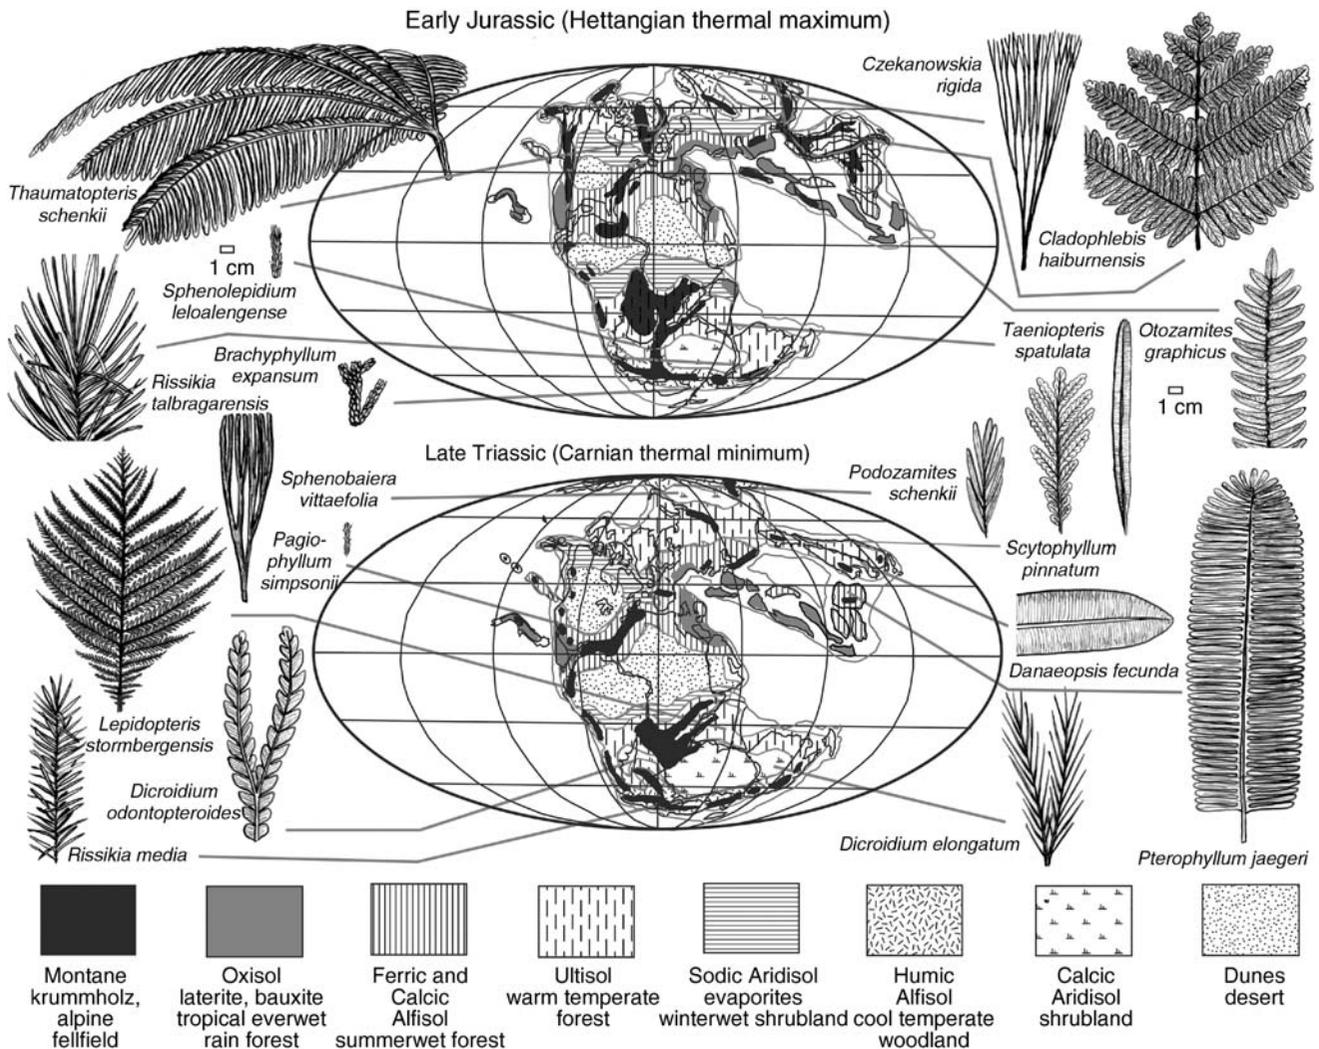

Figure T18 Late Triassic (Carnian) and early Jurassic (Hettangian) paleobiogeographic maps and world vegetation inferred from fossil soils and plants (after Retallack, 1997b, 2002; Willis and McElwain, 2002). Base maps © C. Scotese.

are a soil order found no further south than Tasmania and the North Island of New Zealand and no further north than the Chehalis lowlands of Washington State, USA (Retallack and Krull, 1999). These non-calcareous Antarctic paleosols are evidence of warm, as well as humid, paleoclimates.

Paleosols are especially useful paleoclimatic indicators because they are found in many places where fossil plants are not, as well as where conditions were suitably swampy, frequently flooded, or covered by volcanics, leading to fossil plant preservation (Retallack, 2001a). Paleosols thus provide a more comprehensive view of Triassic and Jurassic global paleoclimate and ecosystems than fossil plants. Fossil rain forest plants are not common, but rain forest paleosols (Oxisols) and their characteristic horizons (bauxites and laterites) can be locally common. Semiarid to subhumid shrubland and wooded shrubland, which can be inferred from fossil therapsids and dinosaurs, also have a very limited paleobotanical record, but can be inferred from sodic Aridisols and evaporites of winterwet subtropical regions and calcic Aridisols and calcretes of summer-wet tropical to temperate regions (Retallack, 1997b).

Fossil plants of summer-wet subtropical forests (such as the late Triassic flora of the Chinle Formation of Arizona) are associated with ferric and calcic Alfisol paleosols. Fossil plants of temperate broadleaf forests (such as the early Triassic flora of the Newport Formation of Australia) are associated with Ultisol paleosols. Fossil plants of cool temperate deciduous woodlands (such as the late Triassic flora of the Falla Formation of Antarctica) are associated with humic Alfisols. Provisional soil-vegetation maps of the late Triassic and early Jurassic (Figure T18) are in substantial agreement with such maps constructed from paleobotanical data alone, or from computer modeling of potential vegetation (Beerling and Woodward, 2001). Interpreted Triassic and Jurassic plant biomes reveal no indication of tundra or taiga, and temperate forests extend within both the Arctic and Antarctic Circles.

Paleosols are evidence not only of regional variation in climate and vegetation, but also of paleoclimatic changes through time. The Karoo Basin of South Africa, for example, had sodic-calcic paleosols (Aridisols) of desertic paleoclimates during the early Triassic (Scythian Katberg Formation), but by late

Triassic (Carnian Molteno Formation), the paleoclimate was humid with formation of non-calcareous red paleosols (Alfisol) and swamp paleosols (Histosols). By early Jurassic (Hettangian-Toarcian Elliot and Clarens Formation), paleosols were again calcareous and nodular, like dry climate soils (Aridisols).

Other indications of Triassic and Jurassic paleoclimates come from sedimentary indicators such as coals, evaporites, laterites, and bauxites (Parrish, 1998). These indicators of wet, dry and tropical climates, respectively, confirm paleoclimatic restorations based on plants and soils. Such linkage is not surprising considering that most coals form in Histosol soils, many evaporites in salid Aridisols, and many bauxites in Oxisols (Retallack, 2001a). One exception to the use of coal as a paleoclimatic indicator is a lack of coal anywhere in the world during the entire duration of the early Triassic. This multimillion-year coal gap may be due to extinction of coal-forming plants during the Permian-Triassic life crisis (Retallack, 1996), or to some continuing hazard such as methane degassing, which would have reduced oxygenation of already near-stagnant wetlands (Sheldon and Retallack, 2002).

Quantitative paleoclimatic proxies

Among a variety of proxies for the ups and downs of greenhouse paleoclimate, the best known is the oxygen isotopic composition of fossil seashells. This approach was first applied to the study of glacial versus interglacial benthic foraminifera by Cesare Emiliani, who found low isotopic values ($\delta^{18}\text{O}$) at times of warm oceans and high isotopic values at times of cold oceans. Such isotopic measurements have been extended to a variety of tropical fossil seashells ranging back in age by 550 million years (Veizer et al., 2000). The variation in isotopic value reflects increased temperature-dependent evaporation of the light isotope of oxygen (^{16}O) from the ocean relative to the heavier common isotope (^{18}O), and its sequestration in snow and ice of polar ice caps. There is also a salinity effect, because there is more evaporation of the light isotope than the heavy one from fresh waters. The net effect is that when the oxygen isotopic value ($\delta^{18}\text{O}$ in ‰ of standard notation) goes down, the ocean is warm, less saline and with small ice caps. Salinity and ice cap effects are generally disregarded in using a transfer function for the relationship between temperature and isotopic composition of modern foraminifera to estimate paleotemperatures of the past (Parrish, 1998). During the Triassic and Jurassic, however, there was a long-term increase in isotopic values, which is probably due to greater facility of the light isotope to emerge at the surface after subduction and crustal recycling in sedimentary pore water (Veizer et al., 2000). Nevertheless, the oxygen isotopic record is valuable because it is known in considerable detail, and because it indicates paleoclimatic volatility (Figure T19). This record suggests that tropical marine temperatures have varied considerably, perhaps by as much as 6 °C, between relatively cool periods that were nevertheless warmer than at present, and peaks of warmth during the earliest Triassic (Griesbachian), early-middle Triassic (Spathian), early Late Triassic (Carnian), earliest Jurassic (Hettangian), early-middle Jurassic (Toarcian), middle Jurassic (Bathonian-Callovian), and earliest Cretaceous (Berriasian).

These various peaks of warmth indicated by oxygen isotopic composition of tropical sea shells are also times of peak atmospheric carbon dioxide revealed by studies of the stomatal index of *Lepidopteris* and *Ginkgo* leaves (Figure T19), thus

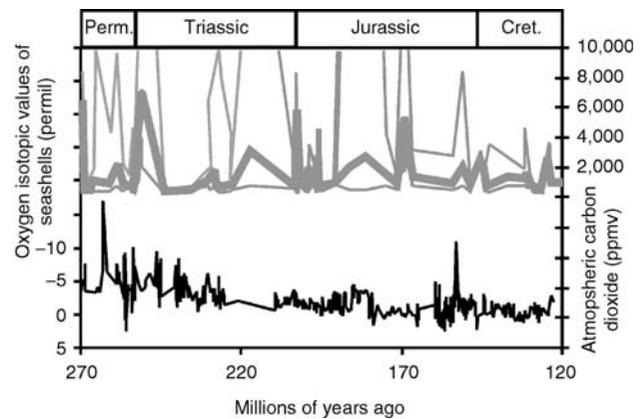

Figure T19 Ups and downs of the early Mesozoic greenhouse revealed by biogenic carbonate oxygen isotopic composition as a proxy for paleotemperature, and by stomatal index of fossil plants as a proxy for atmospheric carbon dioxide concentration (data from Veizer et al., 2000; Retallack, 2002). The oxygen isotopic data is plotted in reverse order so that peaks are warm and valleys are cold, and its long-term trend is in part an artefact of crustal recycling.

supporting a greenhouse mechanism for paleoclimatic change in the past. The stomatal index is a measure of the number of plant gas-intake pores (stomates) normalized to the total number of epidermal cells in well-preserved fossil leaves from which cuticles can be prepared and examined under the microscope. Plant leaves have fewer stomates when atmospheric carbon dioxide is high in order to conserve water transpired through the same stomatal pores. Quantification of this well-known plant response to rising atmospheric carbon dioxide has come from greenhouse studies of living *Ginkgo* plants, as well as of *Ginkgo* leaves conserved in herbaria during the past century of industrially generated increase in atmospheric carbon dioxide (Retallack, 2002). The amounts of atmospheric carbon dioxide revealed by this method are close to modern levels (280 ppmV) for Permian time, when glacial ice caps were as extensive as they are today. This result indicates that this quantification does not show long-term drift, as is apparent from the oxygen isotopic record (Figure T19). Earliest Triassic (Griesbachian), earliest (Hettangian) and middle Jurassic (Bathonian), and earliest Cretaceous (Berriasian) peaks of carbon dioxide abundance are startlingly high (>2,000 ppmV), and coincide with mass extinctions of life on land and in the ocean. There are other peaks of lesser magnitude, and intervening times of atmospheric carbon dioxide about twice modern levels (ca. 500 ppmV).

Paleosols also can provide proxies for paleoclimatic mean annual precipitation and mean annual temperature. Mean annual precipitation, for example, can be inferred from the relationship observed in modern calcareous soils of increased depth to the horizon of carbonate nodules in increasingly humid climates. For paleosols, compaction correction needs to be made to the depth of the calcic horizon in a paleosol in order to restore it to the original thickness before burial by overlying sediments (Retallack, 2001a). Mean annual precipitation and temperature also can be approximated by the degree to which non-calcareous, clayey, subsurface horizons of paleosols have been leached of alkaline earth (Ca, Mg) and alkali elements (K, Na). Both methods have been used to estimate paleoclimatic parameters of paleosols (Sheldon et al., 2002), but not

widely applied to Triassic and Jurassic paleosols. The Triassic and Jurassic paleosol record of the Colorado Plateau looks especially promising in this regard (Retallack, 1997b), because early middle Triassic paleosols (Anisian, Moenkopi Formation) are weakly calcareous, as are early late Triassic paleosols (Carnian Chinle Formation), but later Triassic paleosols (Carnian-Norian Chinle Formation) become increasingly calcareous with shallow calcic horizons. Earliest Jurassic paleosols (Hettangian Kayenta Formation) are weakly calcareous, but those few paleosols known from the early-middle Jurassic (Pliensbachian-Bajocian Navajo Sandstone – a desert dune sequence) are dolomitic and shallowly calcareous. Weakly calcareous paleosols are again found in the later middle Jurassic (Bathonian-Callovian Curtis and Summerville Formations), but calcareous paleosols are abundant in the late Jurassic (Tithonian-Kimmeridgian Morrison Formation). These observations suggest that global warm spikes were also wet spikes in the paleosol record. Warm-wet paleoclimatic spikes alternating with cold-dry paleoclimates can also be inferred from vegetation modeling (Beerling and Woodward, 2001) and biome reconstruction (Figure T18). Global thermal maxima of the Triassic and Jurassic were times when cool temperate vegetation retreated to higher latitudes and altitudes, temperate and tropical shrublands covered smaller areas, and summerwet subtropical and rain forests covered larger areas, compared with global thermal minima.

Yet another quantitative approach has been computer modeling of paleoclimate using modern general circulation models adjusted for ancient paleotopography, and for estimates of soil and vegetation albedo and other ecosystem properties. These models have predicted extreme seasonal paleoclimates for the continental interiors and megamonsoons for peritropical margins of the northern supercontinent Laurussia and the southern supercontinent Gondwana. Such paleoclimatic extremes are not compatible with the fossil plants, animals, and soils found there (Retallack, 1997b; Retallack and Krull, 1999). Some, but not all, of these problems are mitigated by running the computer models with elevated atmospheric carbon dioxide (Wilson et al., 1994), thus giving theoretical confirmation of the observed link between paleotemperature and greenhouse gases.

Causes of Triassic and Jurassic global paleoclimatic variation

Triassic and Jurassic records are effective tests for theories of global climatic variation because they allow exploration of greater paleoclimatic extremes than found during the Cenozoic, yet with animals and plants of more familiar kinds than found in the Paleozoic and Precambrian. The distinctive paleogeographic arrangement of a meridional supercontinent of Pangea, barely including the poles (Figure T18), is a striking difference from the scattered continents today, with one polar and several northern peripolar continents.

The supercontinent Pangea has been blamed for climatic cooling by virtue of its large size and drawdown of atmospheric carbon dioxide by soil formation and weathering, which proceeds by consumption of carbonic acid. In contrast, greenhouse pulses have been related to times of active sea floor spreading when mid-ocean ridges were high and displaced ocean water to form epicontinental seas. This idea was first advanced to explain long-term paleoclimatic change. The Permian icehouse

was caused by assembly of Pangea and the Mesozoic greenhouse by Pangean breakup and dispersal, followed by a Cenozoic ice-house initiated by Northern Hemisphere aggregation of Asia and North America (Fischer, 1984). Detailed paleoclimatic records now available (Figure T19) show paleoclimatic volatility on shorter timescales than continental drift, so this mechanism is not the whole answer.

Transient greenhouse warming has also been linked to volcanic activity, especially to continental flood basalts which coincide with observed warm spikes (Figure T19): earliest Triassic (Griesbachian Siberian Traps), earliest Jurassic (Hettangian Newark and Brito-Arctic volcanics), early-middle Jurassic (Toarcian Ferrar-Karoo basalts) and middle Jurassic (Bathonian Antarctic basalts), and earliest Cretaceous (Berriasian Parana-Etendeka traps). Global cooling, or “volcanic winter,” can be produced by eruptions of ashy particles and sulfate aerosols into the atmosphere, as first observed by Benjamin Franklin during Europe’s “year without a summer,” 1783, following the eruption of the Icelandic volcano Laki. Large flood basalts were not explosive eruptions like those of Laki, Pinatubo and Mt. Helens. Instead, flood basalts were low-viscosity lavas, which flowed without large explosions over large areas. Both kinds of eruptions also release enormous amounts of carbon dioxide and water vapor, which are potent greenhouse gases, their effects are felt after particles and aerosols are scrubbed from the atmosphere by rain. Unfortunately, the currently estimated gas release from even these enormous eruptions is too spread out in time and too small (Wignall, 2001) to have created the likely variation in atmospheric carbon dioxide (Figure T19).

Impact of large asteroids and comets also create global paleoclimatic havoc (Rampino, 2002), including short-term impact-winter from dust and aerosols cast aloft by crater excavation. This dust is more strongly acidic than for volcanic eruptions as it includes sulfur oxide gases that are rained out as sulfuric acid. Sulfuric acid may be very abundant if asteroids or comets vaporize gypsum or other sulfur-bearing rocks within the impact crater, as at the Chicxulub crater, Yucatan, Mexico. Another strong acid formed during impact is nitric acid, generated by impact shocking, and oxidation and hydration of atmospheric nitrogen. Both sulfuric and nitric acids are suspected to have created strongly leached boundary beds, and to have extinguished many shelled marine organisms at the Cretaceous-Tertiary boundary. These days to years of strong acid rain were followed by several tens of thousands of years of paleoclimatic warming, due to elevated greenhouse gases including water vapor and carbon dioxide. This carbon dioxide could have come from multiple sources including the death and decay of many kinds of organisms from the trauma of impact and impact winter, and the burning of forests browned by acid rain. Although scenarios for impact perturbation of life and paleoclimate have been most thoroughly explored for the Cretaceous-Tertiary boundary, large impacts coincide with other mass extinctions and global warm spikes during the Triassic and Jurassic (Rampino, 2002), including the early-late Triassic (Spathian) Araingahua Crater (40 km), the late Triassic (Norian) Manicougan (100 km) and Rochechouart (23 km) Craters, the middle Jurassic (Bajocian) Puchezh-Katunki Crater (80 km), and the earliest Cretaceous (Berriasian) Morokweng Crater (>70 km). Like flood basalts, however, the magnitude of the perturbations does not currently correlate closely with impact magnitude, as judged from crater size, or other evidence of impact (Rampino, 2002).

Another important cause of global paleoclimatic perturbation is methane hydrate destabilization, which could exacerbate impact and volcanic warming to truly catastrophic proportions. Methane created by microbial decay of organic matter deep within sediments and permafrost accumulates within subsurface heat traps maintained by geothermal gradients beneath cold oceans and permafrost. The methane is hydrated within ice crystals and is physically stable, but can be released by volcanic eruption, meteorite impact, submarine landslides, or general warming of overlying sediments or ice. This form of methane has a very distinctive isotopic composition, which has been used as a tracer for massive releases of methane, now well documented for the earliest Eocene (Ypresian), early Cretaceous (Aptian), early-middle Jurassic (Pliensbachian) and earliest Triassic (Griesbachian). The global warming and unusual abundance of ^{12}C at these times is attributed to thousands of gigatons of methane released to the atmosphere, where the isotopically light methane was oxidized to isotopically light carbon dioxide within 7–24 years, and this in turn fixed within isotopically light organic carbon and carbonate. Methane itself is a powerful greenhouse gas, 50 times more effective than carbon dioxide. Atmospheric pollution by methanogenic hydrocarbons has had catastrophic effects in the past, because some documented releases were also times of mass extinction (Hesselbo et al., 2000; Krull and Retallack, 2000).

If volcanoes, impacts, and methane release are the principal agents of global warming, the principal agent of global cooling is life itself, particularly its photosynthetic ability to reduce carbon within the bodies of organisms and to bury much carbon within sediments. Root respiration and soil animals also promote consumption of atmospheric carbon dioxide, as carbonic acid, the principal agent of silicate weathering that releases alkali (Na, K) and alkaline earth (Ca, Mg) elements, which fuel plant growth (Berner and Kothavala, 2001). Mountain uplift has also been proposed to cool the planet by means of silicate weathering (Raymo and Ruddiman, 1992). The mountains themselves do not promote cooling because silicate weathering is reduced under alpine meadows and ice fields compared with lowland forests and grasslands. Nevertheless, glacial loess from montane glaciers and desert dust from montane rain shadows are important sources of nutrients for soil formation and silicate weathering, which could have climatic ramifications. Changing ocean currents and thermohaline circulation also have been thought to have a cooling effect (Broecker, 1997), but these are also mechanisms for increasing biological productivity of surface waters and creating organic matter, which then sinks and is buried in oceanic sediments. Most marine productivity and carbon sequestration is nearshore and fueled by leakage of nutrients from soils and ecosystems on land. Transient global warming events caused by geological catastrophes were probably curtailed largely by biotic recovery and carbon sequestration in soils, lakes and nearshore marine environments.

Carbon sequestration by Triassic and Jurassic terrestrial ecosystems was probably different from that in both modern and Permian ecosystems for purely evolutionary reasons. Unlike modern ecosystems, there were no grasses or grasslands during the Triassic and Jurassic (Retallack, 2001b). Dry continental interiors supported dry shrublands of small-leaved cycadeoids, conifers and seed ferns in soils lacking the fine cracking and carbon-rich surface horizons of grassland soils. An array of rain forest, summerwet tropical forest, winterwet subtropical to

temperate woodland, warm temperate forest, and cool temperate woodlands formed similar soils to these plant formations today (Figure T18). No tundra and taiga vegetation was known in polar regions, but the montane equivalents alpine fellfield and krummholz were probably present, because there is evidence from fossil soils that plants had evolved into tundra and taiga vegetation as old as Carboniferous and Permian, respectively (Retallack, 2001a). Triassic and Jurassic ecosystems, unlike Permian ecosystems, had enormous herbivores and hordes of social insects. Early to middle Triassic therapsids were as large as rhinos, and late Triassic and Jurassic dinosaurs exceeded the bulk of large elephants. Ants and termites are known as body fossils only as old as Cretaceous, but fossil nests suggest comparable insects as old as Triassic (Hasiotis and Dubiel, 1995). Dinosaurs and social insects would have consumed large amounts of vegetation, and could have contributed to general global warmth during the colder and drier phases of early Mesozoic climatic oscillations (Retallack, 1997b). Climate and life on Earth have long been intimately interrelated because of their complimentary dependence on greenhouse gases.

U

URANIUM-SERIES DATING

The discovery of natural radioactivity at the beginning of the twentieth century fundamentally changed our understanding of the physical and biological history of the Earth. Before then, the antiquity of the Earth was a very debatable issue and thus any process that required a long time, such as Darwin's theory of evolution, was very much in doubt. A number of clever approaches, based on estimates of time required for certain physical processes, were used to constrain the age of the Earth, such as Lord Kelvin's estimates based on the assumption of a molten Earth cooling to its present state. All of these estimates greatly underestimated the age of the Earth. The discovery of natural radioactivity (Becquerel, 1896) and the fact that the rate at which a particular radioactive nuclide decays is constant opened the way to obtaining absolute dates.

Many light elements, such as carbon and potassium have isotopes that decay in a single step to a stable isotope of another element. For example, ^{14}C decays to ^{14}N and ^{40}K decays to ^{40}Ar . All isotopes of elements heavier than bismuth are radioactive and have decay schemes that involve multiple stages of decay to intermediate isotopes. One of these elements, uranium, has two primary isotopes, ^{238}U and ^{235}U ; ^{234}U , is an intermediate daughter of ^{238}U . The decay of ^{238}U to ^{207}Pb involves 18 intermediate nuclides, while the decay of ^{235}U to ^{207}Pb involves 14 intermediate nuclides. U decay-series nuclides that are currently utilized for dating and their respective half-lives are shown in Figure U1.

Principle of radiometric dating

For a simple decay scheme, such as ^{87}Rb decaying to ^{87}Sr , where the radioactive isotope decays to a stable isotope, the amount of daughter isotopes, D , that is present after a time, t , has elapsed is related to the amount of parent isotope, P , at present as follows:

$$D = D_0 + P(e^{\lambda t} - 1) \quad (1)$$

where D is the total number of atoms of the daughter isotope at present, D_0 is the number of daughter isotopes present at

the beginning (since t time has passed, for example the age of a rock if one is dating a rock), P is the number of atoms of the parent isotope at present, λ is the decay constant and t is the age. As stated previously, the decay constant for a given radioactive isotope is constant and is related to the half-life (the amount of time required for a given number of atoms of a given radioactive isotope to be reduced by half due to decay) according to:

$$t_{1/2} = \frac{\ln 2}{\lambda} = \frac{0.693}{\lambda} \quad (2)$$

where $t_{1/2}$ is the half-life and λ is the decay constant for a particular radioactive isotope.

The range of events that are datable using a given parent-daughter isotope system depends on the half-life of the parent isotope. Typically, we cannot date events that are older than about seven half-lives of a given system. Conversely, to date young events we need to utilize isotope pairs with a short half-life parent. A number of the U-series nuclides have short half-lives that are useful to date recent events of human interest, such as past climate and environmental change and also, archeological and volcanic processes.

For radioactive isotopes that decay to another radioactive isotope, such as U-series nuclides, the number of an immediate daughter isotope that remains after time t is related to the number of atoms of the immediate parent:

$$D = \frac{\lambda_P}{\lambda_D - \lambda_P} P_0 (e^{-\lambda_P t} - e^{-\lambda_D t}) + D_0 e^{-\lambda_D t} \quad (3)$$

where D is the number of atoms of daughter isotope at present, D_0 is the number of atoms of the daughter isotope present initially, P_0 is the number of atoms of the parent isotope present initially and λ_P and λ_D are the decay constants of the parent isotope and the daughter isotope, respectively. The last term accounts for the decay of the daughter nuclide since time t . Expressions can be written describing the relationship between one nuclide and another nuclide at any stage in a given decay scheme.

After about seven half-lives of the shorter-lived nuclide of any two nuclides in a given series, the two nuclides reach

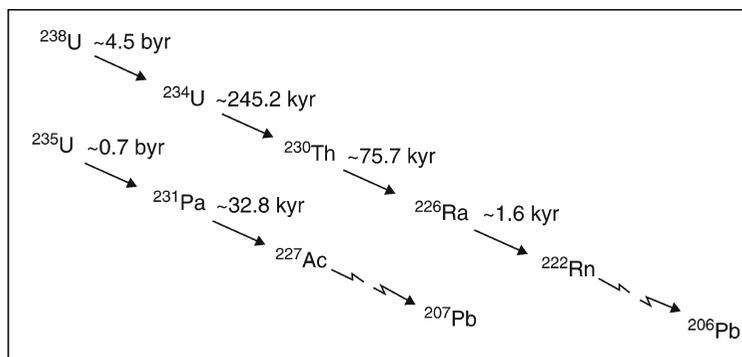

Figure U1 Schematic diagram of the U-series decay chain, showing some of the nuclides utilized in chronology and their approximate half lives. *byr*, Billions of years; *kyr*, thousands of years.

a state called “*secular equilibrium*.” When secular equilibrium is reached, the activity (the number of atoms of a nuclide multiplied by its decay constant) of both nuclides is equal, i.e.,

$$\frac{\lambda_1 N_1}{\lambda_2 N_2} = 1$$

In other words, their atomic ratio is constant from then on, equal to λ_1/λ_2 , and the age can no longer be determined.

Methods of U-series isotope analysis

The utility of U decay series isotopes for dating was recognized very early (Bateman, 1910) but the application was limited by technical difficulties related to separation chemistry and measurements of very small amounts of daughter nuclides. For example, in most rocks the abundance of ^{230}Th , the daughter of ^{238}U through ^{234}U (see Figure U1), is about one atom for every million atoms of uranium. Moreover, the ionization efficiency of Th in thermal ionization mass spectrometers (TIMS), the mass spectrometers used until recently for such measurements, is typically about 2×10^{-4} . In other words, about two ions (only ions are detected by TIMS) are produced for every 10,000 atoms loaded into the mass spectrometer.

The theoretical limit to precision of data (the counting statistics) is related to the number of ions detected as follows:

$$\text{Uncertainty } (1\sigma) = \frac{1}{\sqrt{N}}$$

where N is the number of atoms detected. Thus, the combined low abundance and low ion yield for many of the nuclides of interest made the application very difficult.

Early measurements, requiring large samples (thus low temporal resolution) were performed by alpha or gamma counting (e.g., Cherdynstev, 1956; Broecker, 1963; Ku, 1965). Advances in separation chemistry and mass spectrometry using TIMS (e.g., Chen et al., 1986; Edwards et al., 1987 for measurements of uranium and thorium isotopes, respectively; and Pickett et al., 1994 for measurement of protactinium by mass spectrometry) have made it possible to obtain high-precision U-series data for dating and isotope tracer application.

Application of U-series dating

A requirement for the application of U-series nuclides for tracer and dating purposes is that the process of interest has to fractionate one nuclide from another partially or completely.

The most widely used application of U-series dating has been for dating corals (Edwards et al., 1987) and speleothems (e.g., Polyak and Asmerom, 2001) for studying the timing of past climate change. These materials are ideal for dating because uranium under oxidizing conditions, which is the case in surface oceans and caves, is preferentially dissolved in water, while thorium is not soluble. Carbonate, calcite (CaCO_3) in speleothems and aragonite in corals (also CaCO_3 , but different crystal form), can contain up to 4 parts per million (ppm) U and negligible amounts of the daughter ^{230}Th nuclide, making them readily and precisely datable using the ^{238}U – ^{234}U – ^{230}Th series (Edwards et al., 1987). Assuming the sample did not contain ^{230}Th initially:

$$\left(\frac{^{230}\text{Th}}{^{238}\text{U}}\right) = (1 - e^{-\lambda_{230}t}) + \left(\frac{\lambda_{230}}{\lambda_{230} - \lambda_{234}}\right) \left(\frac{\delta^{234}\text{U}_m}{1,000}\right) (1 - e^{-(\lambda_{234} - \lambda_{230})t})$$

where

$$\left(\frac{^{230}\text{Th}}{^{238}\text{U}}\right)$$

is the activity ratio, t , is the age of the sample and $\delta^{234}\text{U}$ is equal to:

$$\left[\frac{^{234}\text{U}}{^{238}\text{U}} - 1\right] 1,000$$

$^{234}\text{U}/^{238}\text{U}$ is the atomic ratio. Uranium and thorium are chemically separated from carbonates and the ^{238}U , ^{234}U , and ^{230}Th are measured in a mass spectrometer. The age, t , is calculated iteratively. Any event or process that is associated with the formation of carbonate can be dated using this method.

Similar equations are written for dating volcanic rocks (Allègre, 1968), except that in the case of volcanic rocks, one cannot assume zero initial ^{230}Th . For volcanic rocks, the most versatile application of U-series nuclides has been in tracing sources of magma, constraining the time-scale of magma formation and evolution and providing relative timing of these events.

One of the novel applications for chronology using U-series nuclides has been combining ^{238}U – ^{234}U – ^{230}Th and ^{235}U – ^{231}Pa chronology on the same sample. If the ages are concordant (i.e., the two systems give the same age) it gives added validity

to the age (e.g., Edwards et al., 1997). In another approach, the presence of an excess or deficiency in daughter activity, i.e., daughter/parent ratio $\neq 1$, puts a maximum limit on the age of the material. For example, the presence of excess ^{210}Pb , which has a half-life of 22.3 years, indicates that an object is no older than around 150 years. ^{210}Pb is widely used for dating recent sediments in environmental research.

The utility of U-series isotopes for chronology and tracer work has been recognized for a long time, beginning after the discovery of radioactivity. However, implementation of the system was hindered by technical difficulties. Recent advances in mass spectrometry enable realization of the full potential of the system. One of the most exciting areas of application of this method that benefits from these technical gains is the study of past climate change, in particular dating annually banded speleothems (Asmerom and Polyak, 2004). These specimens often contain a variety of proxies of past climate change, including isotopic, chemical and physical proxies.

Recent advances in mass spectrometry, whereby a plasma source is combined with a magnetic analyzer and multiple detectors that consist of either a combination of Faraday cups and multiple electron multipliers, or Faraday cups and multiple channeltrons, stand to revolutionize the field. These high-resolution multi-collector inductively-coupled plasma mass spectrometers (MC-ICPMS) are capable of greater ion yields, up to an order of magnitude and greater, as compared with TIMS (Robinson et al., 2002), allowing for high spatial and temporal resolution.

V

VARVED SEDIMENTS

Introduction

Varved sediments are sequences of sedimentary laminations deposited within a single year. A varve (Swedish: varv, layer) is a pair or set of laminae formed during different seasons within a year (varves – seasonal rhythmites – annually laminated sediments). Varves have been described in glacial, lacustrine and marine environments. Clastic varves in glacial lacustrine environments, i.e., glacial varves, are classic examples of varved sediments, but seasonal, rhythmic changes in biogenic production (e.g., diatoms) or water chemistry (e.g., carbonate content) also give rise to varve formation. In addition, annual layers in ice cores are varves, and chemical varves may be formed in precipitates and evaporates, such as stalagmites and gypsum beds.

Glacial varves

Varved clays are commonly found in Quaternary deposits in glaciated areas, but they have also been identified in deposits of older glaciations, such as the Carboniferous, Ordovician, and the late and early Proterozoic.

Glacial varves reflect the seasonal fluctuation of glacial meltwater flow from continental ice sheets or smaller glaciers (Figure V1). During the intensive melting period in spring and summer, coarse grained silt and sand is transported and deposited at the bottom of a water body, whereas finer particles settle out slowly, the finest clay particles only doing so during the next winter when the water bodies are frozen. The bedding in the coarse summer part of a varve is graded and the boundary between the fine winter layer and the next summer layer is sharp. Varves of this type are diatactic. They are formed in fresh water, whereas symmictic glacial varves that are formed in salt or brackish water are more complicated to identify because fine suspended particles group together into larger grains and settle rapidly with coarser grains. The varves that are formed close to a melting glacier may be up to several

tens of centimeters thick, whereas varves deposited distally may be less than a millimeter thick. Varve thickness also varies from year to year due to variations in climatic and local factors, e.g., the intensity of melting, the material supply and the velocity of meltwater flow. Variations in the thickness of varves within a sequence form a basis for correlating sequences, in addition to their color, grain size and chemical composition.

Nonglacial varves

A single annual unit – a varve – is composed of two or more layers (laminae) that can be distinguished on the basis of their thickness, composition and texture. In most cases, these individual layers are identified as representing certain seasons or even short-term events within seasons, e.g., spring flood allochthonous discharge or vernal precipitation of calcite crystals (Figure V2). The annual structure of the sediment is only preserved if there are no post-depositional disturbances of the sediment surface, such as bioturbation or water turbulence in the sediment-water interface.

In different lake environments worldwide, various characteristic limnological and hydrological processes govern the composition and structure of varves and the laminae they contain. They usually appear as calcareous (Brunskill, 1969), ferrogenic (Anthony, 1977; Renberg, 1981), biogenic (Saarnisto et al., 1977), clastic (Sturm, 1979) or clastic-organic (Renberg and Segerström, 1981; Ojala et al., 2000) (Figure V3) laminae couplets. The majority of identified varved lake records are located either in North America (Anderson et al., 1985; Lamoureux et al., 2001) or in Europe, particularly in the Alpine areas, in Fennoscandia, and in number of maar lakes (Pettersson, 1996; Zolitschka, 1998; Brauer et al., 2000; Ojala et al., 2000). However, they are also found in many other localities, such as Japan (Fukusawa, 1999) and Africa (Johnson et al., 2001).

Varved-clay chronology

Varved-clay chronology is based upon correlations between short varve series (50–200 years, but rarely as much as 1,000 years) from site to site in the general direction of ice-margin

Figure V1 Varved glacial clays in Tampere, southern Finland, which were deposited in the early Holocene Baltic basin. (Photo by J. J. Sederholm, 1907.)

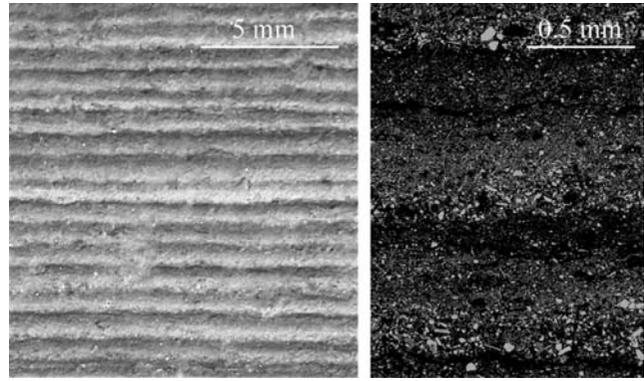

Figure V3 Images of Lake Nautajärvi (central Finland) clastic-organic nonglacial varves at ca. AD 200 taken from the fresh sediment surface (left) and thin-section using a back scattered mode of surface scanning electron microscope (right).

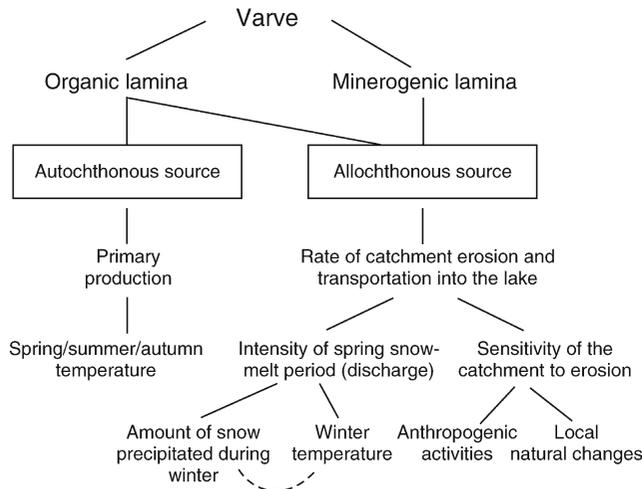

Figure V2 A simplified sketch of the formation of clastic-organic varves in temperate areas.

retreat. The original principle of De Geer (1884, 1940) was adopted in Finland by Sauramo (1918). The Swedish glacial varve chronology has been connected to the present-day through studies on postglacial and recent, varved deltaic sediments in

the Ångermanälven river in northern Sweden (Cato, 1998). The Swedish chronology covers 13,300 years, including the deglaciation from Scania to the Ångermanälven river area. The Swedish varve chronology has been constantly revised since De Geer's original work, and its correlation with the Greenland ice core records suggests that nearly 900 (875) varves have not been recognized in the Holocene part of the Swedish varve chronology (Andrén et al., 1999). The Finnish varve chronology covers nearly 2,800 years (Sauramo, 1929), 13,000–10,200 year, when the ice margin retreated from the Gulf of Finland to the Gulf of Bothnia. It is a floating chronology that has been connected to the calendar year time scale by reference to characteristic varves formed in connection with the drainage of the Baltic Ice Lake and the dating of this event (e.g., Strömberg, 1990).

Attempts to construct a regional deglaciation chronology using varved sediments outside Sweden and Finland have been rare. In North America, Antevs (1928) worked out a varve chronology based on 4,000 varves in Connecticut Valley, which was later extended by ca. 1,000 glacial varves by Ridge and Toll (1999). Glacial varves have also been investigated in a number of localities in Patagonia and other parts of northern Europe (Estonia, NW Russia).

Varved sediment sequences have been widely applied to reconstruct a continuous timescale of the sediment (varve chronology) and to determine the rates of annual accumulation of sediments and of any particular substance or organism in the sedimentary basin, as expressed in spatial and temporal units (influx). The longest known varved lake sediment sequence, Lago Grande di Monticchio (southern Italy) (Brauer et al., 2000), extends back to more than 100 ka interrupted by several tephra layers, but continuous records typically cover ca. 10,000 years or less. Among the most studied records in Europe are those from Lake Holzmaar (western Germany) covering 14,000 years (Zolitschka, 1998), Lake Gościąg (central Poland) covering 13,000 years (Goslar, 1998) and Lake Kassjön (northern Sweden) covering 6,500 years (Renberg and Segerström, 1981). However, some of these chronological sequences are floating in time (i.e., not fixed to the present day deposits). Moreover, even the best quality varves cannot provide a completely accurate chronology as they have been accumulated in a naturally variable environment. In most cases, and in the long-term, an acceptable margin

of varve counting error can be expected to be around $\pm 2\%$, and at best it yields an accuracy of $\pm 1\%$, as in Lakes Kassjön and Nautajärvi (central Finland) (Ojala and Saarinen, 2002). Corresponding chronological accuracy has been postulated for the Holocene part of Greenland ice core records (Alley, 2000).

Nonglacial Holocene varves have also been applied in assigning ages in relative sediment dating methods, such as paleomagnetic reference curves and widely distributed tephra layers. In Fennoscandia, Ojala and Saarinen (2002) and Snowball and Sandgren (2002) dated the features of paleomagnetic secular variation curves using the varve chronology of nearly 10,000-year-long sections of clastic-organic varves, whereas Zillén et al. (2002) assigned varve ages to several tephra layers deposited in southern Sweden in the Mid-Holocene.

Recently, the application of varve records has transformed from providing stratigraphical and chronological tools to being high-resolution indicators of the paleoenvironment, and in particular, they are being used as a tool to study the effects of climate forcing during the Holocene. Advancements in sediment sampling (e.g., epoxy-embedding, thin sectioning) combined with digital image analysis have provided an effective means to record and study the physical properties of varves with a high temporal resolution. Proglacial lakes in the Canadian Arctic are perhaps the most carefully studied environments (Hardy et al., 1996; Hughen et al., 2000; Lamoureux et al., 2001). Physical varve data (varve thickness, laminae thickness) have been shown to be strongly correlated with summer temperatures through their effects on the intensity of snowmelt runoff and the discharge of suspended sediment. In Fennoscandia, fluctuations of clastic-organic varves have been correlated with winter climate components, namely temperature and the amount of precipitated snow in the catchment. Based on such connections, it is possible to reconstruct past climatic conditions, thereby providing important knowledge about the global climate system in order to better predict the future.

VOLCANIC ERUPTIONS AND CLIMATE CHANGE

Introduction

Volcanoes erupt fragmented mantle material into the upper atmosphere. Only the lightest particles remain suspended, however. These tiny supplements to the ordinary air, water vapor, and dust can strongly affect the chemical, radiative, and dynamical properties of the atmosphere. Critical to assessing the magnitude of these effects is knowledge of the sizes and chemical compositions of the volcanic particles, the total mass of particles injected, the vertical distribution of the injected particles, the geographical location of the volcano, and the prior state of the atmosphere. Detailed chronologies of modern volcanic eruptions and of their spreading particulate clouds (called “dust veils” or “dry fogs”) have been constructed in order to associate known volcanic eruptions with changes of long-term weather (“climate”). The volcano-climate connection can be studied either empirically, by using actual climate observations, or theoretically, by computing a general circulation model (GCM) of the atmosphere. Interest focuses on how global and regional climates respond to volcanic forcing on various timescales. Such an understanding of the consequences of historical eruptions can help to illuminate both the past and the future of the atmosphere of our planet, especially under different assumptions made about the frequency of large volcanic eruptions, the amount of solar variability, and the inputs of other natural and anthropogenic sources of atmospheric pollution.

History

On the day after the great eruption of Mount Vesuvius in the year 79, Pliny the Younger noted that the Sun appeared “lurid as if in eclipse,” but this atmospheric effect was probably only local. More widespread hazes after other eruptions during antiquity (e.g., Etna in 44 BC), although noted, were never associated with volcanoes by anybody at the time. Benjamin Franklin is the first person known to have inferred a relationship between the regional state of the atmosphere (North Atlantic dry haze in 1783 and a cold winter in 1784) and a large volcanic eruption (Laki, Iceland, 1783). Chemists at the time identified the dry tropospheric haze as being primarily what we would today call sulfuric acid (H_2SO_4). The ancient manifestations of it could now also be provisionally interpreted. However, it was the eruption of the Indonesian volcano Krakatau 100 years later that brought a volcano’s worldwide atmospheric effects to public attention: a fading and unusual coloration of the Sun, Moon, and stars, and an enhancement of the red twilight sky glow. A peculiar reddish ring seen around the Sun was named after its discoverer, Sereno Bishop, and the darkness of a total eclipse of the Moon in this period was traced to volcanic particles in the Earth’s upper atmosphere by Camille Flammarion. The particles were thought to be silicic ash and possibly sulfurous gases. The zonal circulation of the upper atmosphere (named the “stratosphere” by Teisserenc de Bort in 1900) was mapped by visually following the westward drift of the volcanic cloud. Only in hindsight were the unusual optical aftereffects of the even greater eruption of Tambora, Indonesia, in 1815 now associated with that event.

After a series of three large Caribbean eruptions in 1902 and Alaska’s Katmai (Novarupta) eruption in 1912, C. G. Abbot and W. J. Humphreys independently concluded that volcanic

eruptions produce temporary climate cooling, at least hemispherically. Many studies since 1913, with much impetus coming from Harry Wexler and H. H. Lamb, have confirmed this fundamental result. In 1961, C. E. Junge and his coworkers discovered an apparently permanent layer of sulfate particles in the lower stratosphere, which, in 1973, A. W. Castleman, Jr., and his coworkers conclusively demonstrated were volcanic in origin. Fresh stratospheric particles collected in situ by S. C. Mossop after the Agung, Indonesia eruption of 1963 had already shown most to be sulfuric acid aerosols. Numerous studies from the ground, air, and space were pursued after the eruptions of Mt. St. Helens, United States (1980); El Chichón, Mexico (1982); and Pinatubo, Philippines (1991). These results have enormously increased our detailed knowledge of volcanic aerosol clouds and their effects on climate.

Aerosol chemistry and physics

Although some small silicic ash particles remain suspended in the stratosphere for several weeks after a powerful volcanic eruption, the major constituents injected are gaseous: primarily CO_2 , H_2O , N_2 , SO_2 , and H_2S , and some HCl and HF. With both pre-existing and volcanically injected H_2O , the sulfur gases undergo a complicated series of heterogeneous chemical reactions in the presence of sunlight to form sulfuric acid aerosols (75% H_2SO_4 and 25% H_2O). These tiny droplets then grow by coagulation and mutual collisions over a period of weeks. Typically, their final mass density is 1.65 g cm^{-3} and their complex index of refraction in the visible is $m = 1.43 - 0i$, indicative of negligible light absorption at short wavelengths. Their shape appears roughly spherical and their size distribution can be described as approximately lognormal with an effective (area-weighted) radius of $r_{\text{eff}} = 0.3 \text{ }\mu\text{m}$, increasing with time to $0.5 \text{ }\mu\text{m}$, but this description is very crude and may be inaccurate for some eruptions and for some layers of the stratosphere. After the initial formation period, the size distribution continues to evolve owing to horizontal dispersion of the particles and to gravitational and convective sedimentation of the larger particles. The role of sulfate aerosols in destroying ozone (O_3) involves heterogeneous chemical reactions with primarily anthropogenic chlorine, and so would have been unimportant before the late twentieth century. Volcanic halogens are mostly scrubbed out of the eruption column before reaching the stratosphere.

Scattering of radiation by the aerosols leads to an attenuation of the incoming solar beam, whose incident intensity is I_0 . The optical depth of the light-scattering medium, defined as $\tau = -\ln(I/I_0)$, can be calculated by multiplying the cross-sectional scattering coefficient by the particle number density and integrating the product over the path length of the direct solar beam. Since τ is wavelength-dependent, a standard reference wavelength is taken to be $\lambda = 0.55 \text{ }\mu\text{m}$, which lies in the visible. Essentially, only the two quantities r_{eff} and τ_{vis} are needed, in practice, to compute the amount of radiative forcing by an aerosol cloud. Reflection of some incoming solar radiation back into space by the stratospheric aerosols reduces the total insolation in the troposphere, which in turn lowers the global-average surface air temperature. Absorption of long-wave radiation from the ground, troposphere, and Sun by the aerosols partially counters this effect, and manages to warm the stratosphere. However, the net result of the competition between the aerosols’ albedo and the greenhouse effect for the troposphere is always a cooling.

The total mass of the stratospheric aerosol veil, M_D , can be computed from the global-average stratospheric optical depth τ_D . It is given by $M_D = 150\tau_D$ megatons (Tg).

Records of volcanic eruptions

Catalogs of known volcanic eruptions during the Holocene epoch (the past 10,000 years) have been published by the Smithsonian Institution, making use of either eyewitness reports or geological studies of pyroclastic deposits around the volcano. Even earlier eruptions are known in a few cases from conspicuous eruptive deposits. These can be dated radiometrically or stratigraphically. They include the huge continental and oceanic flood basalt eruptions of the past 300 Myr, of which about a dozen have been recognized. The flood basalts were primarily effusive in style and sulfur-rich (like Hawaii's Kilauea), whereas most known volcanic eruptions have been of explosive type and silica-rich (like Indonesia's Krakatau).

All other methods of detecting volcanic eruptions are indirect. One method uses sulfate acidity and tephra fragments deposited from the stratosphere onto polar ice fields and incorporated in the annual layers of polar ice. Tephra found in sea, lake, and bog sediment cores (usually sited not far from the erupting volcano) can also be used. Documentary records of unusual atmospheric optical effects and even of abnormal regional cooling have proven especially valuable, because historically derived dates going back to 300 BC are typically accurate as to year and month. Ice-core dates are available for eruptions as far back as 100,000 years ago, but they begin to degrade in accuracy before AD 1000.

Quasi-periodicities in global volcanism occur on various timescales. A weak annual cycle exists, perhaps coupled to the hydrological cycle. Two other periods, 11 year and 80 year, are probably solar in origin, through the influence of solar variability on the atmosphere. Slower cycles of 10^4 – 10^5 year may be due to the influence of climate change on volcanism, arising from Milankovitch periodicities in the Earth's orbit that affect the amount of insolation and hence glaciation and sea level. Tectonic plate movements may also produce spurts of volcanism, at intervals of a few Myr. Flood basalt eruptions apparently follow a roughly 30-Myr cycle of uncertain origin. Even slower cycles may exist, e.g., a 300-Myr cycle of tectonism and associated volcanism.

Explosive strengths of volcanic eruptions have been estimated from such observable quantities as volume of pyroclastic ejecta and height of the eruption column. An example is the Volcanic Explosivity Index (*VEI*) of Newhall and Self (1982). The older Dust Veil Index (*DVI*) of Lamb (1970) includes solar-beam transmission data and surface air temperature decreases in addition to the near-source tephra volume. Robock and Free's (1995) newer Ice-core Volcanic Index (*IVI*) utilizes solely sulfate acidity in polar ice cores. The *VEI* of course does not take into account the variable sulfur content of volcanic tephra, while the *DVI* is an uneven and mixed indicator, and the *IVI* suffers from the special restrictions of the ice-core method, including the highly uncertain rates of aerosol deposition and the necessary corrections for non-stratospheric transport of aerosols and for the volcano's latitude (often unknown). Statistically, however, all indices are found to be correlated with τ_D whenever τ_D is available, and therefore they can be used to estimate τ_D when this is otherwise unknown.

Table V1 contains the stratospheric aerosol masses estimated for Pinatubo-class and larger volcanic eruptions of the past 75,000 years. The peak visual optical depth over Europe is also listed. The table is incomplete before 1883 and becomes more so the farther back in time one goes, especially for the Southern Hemisphere. Flood basalt eruptions, which are not listed, probably produced 10^4 Tg of aerosols; typical examples are the Columbia River Basalts (16 Myr ago) and the Deccan Traps (65 Myr ago). The cumulative effect of smaller, but more frequent, eruptions could have perturbed the Earth's radiative balance during some periods.

Movements of volcanic aerosol veils

Volcanoes are not distributed uniformly, or even randomly, over the globe. They are found in regions of exceptional geologic activity, e.g., along the "ring of fire" around the Pacific Ocean and along the Atlantic Mid-Ocean Ridge. Flood basalt eruptions occur over mantle plumes and hotspots. For purposes of climate studies, however, all volcanoes can be divided simply into extratropical (latitudes above 30°) volcanoes and tropical (or equatorial) volcanoes.

Stratospheric aerosol veils from tropical volcanoes are distributed by zonal winds very quickly so that they cover all longitudes in only 2–3 weeks. Their meridional dispersion is

Table V1 Major aerosol-producing volcanic eruptions of the past 75,000 years

Volcano	Latitude	Year	<i>DVI</i> / E_{\max}	<i>VEI</i>	<i>IVI</i>	European τ_{vis}	Aerosol M_D (Tg)
Pinatubo, Philippines	15° N	1991	1,000	6		0.2	30
Agung, Indonesia	8° S	1963	800	4	0.06	0.03	20
Santa Maria, Guatemala	15° N	1902	600	6	0.05	0.2	30
Krakatau, Indonesia	6° S	1883	1,000	6	0.12	0.2	44
Tambora, Indonesia	8° S	1815	3,000	7	0.50	1.3	200
Laki, Iceland	64° N	1783	2,300	4	0.19	~2	200
Huaynaputina, Peru	17° S	1600	>1,000	5			100
Unknown	Tropical	1258					400
Eldgjá, Iceland	64° N	934		4			130
Unknown	Northern?	797				~1	40?
Unknown		626					100?
Unknown		536				~2.5	300?
Etna, Italy	38° N	44 BC		3+			200
Unknown		145 BC					80?
Thera, Greece	36° N	1640? BC		6			200
Toba, Indonesia	3° N	74000? BC					3,000?

much slower (usually taking a few months), depending on the season of the year, the phase of the quasi-biennial oscillation (QBO) of the tropical stratospheric winds, and probably other factors. For unknown reasons, cross-equatorial spreading is occasionally inhibited, sometimes remarkably so (e.g., after El Chichón and especially after Agung). Almost complete halts of the poleward flow regularly occur at the Hadley cell circulation barrier (near 30°) in the summer and at the polar vortex edge (near 70°) in the winter. In this cyclical, seasonally dependent way, the equatorial reservoir of aerosols (discovered after the Agung eruption) replenishes the higher latitudes during the course of the year. Simultaneously, aerosols are constantly falling out of the stratosphere, the average time for depletion of the dust veil by a factor of e being 1 year. Once through the tropopause, aerosols are swept to the ground in a few days by either wet or dry deposition. In the wintertime polar vortex, too, they descend quickly in spite of a lower tropopause near the poles.

High-latitude volcanoes generate stratospheric aerosol veils that spread equatorward only as far as about 30°. Thus, they do not produce full hemispheric coverage (this was first realized after Laki and confirmed after Katmai). Using both Arctic and Antarctic ice cores, an unidentified volcano that erupted somewhere on the globe can usually be characterized at least as being tropical or extratropical, with always the possibility of error in an Agung-type situation.

Climatic effects (general)

Underneath the ash cloud in the volcano's vicinity, the surface air temperature initially rises but then falls precipitously as sunlight is blocked off. Such an extreme cooling happened noticeably after Laki, Tambora, and Krakatau. If the ash cloud either is very thin or resides at a high altitude, as was the case after Mt. St. Helens in 1980, the initial warming caused by the blanketing effect does not occur.

Feedback from the stratospheric aerosol veil on the global atmosphere is fairly complex. The simplest element in the feedback is a global-average cooling – as theoretically expected and observationally confirmed. Finer observational analysis, based mostly on compositing the effects of several modern eruptions, reveals more structural detail, both temporal and spatial. A prompt cooling (at least in the hemisphere of origin) lags the eruption by about 1 month and lasts 3–6 months. A rapid recovery is then followed by a prolonged cooling for 1–5 years, beginning with a comparable temperature drop in the year of the first post-eruption winter (but sometimes later). This first winter can be very cold for extratropical eruptions, but for tropical ones there occurs a slight winter warming over Northern Hemisphere continents at middle and high latitudes. This is caused by a faster zonal advection of warm (and wet) marine air that is associated with a strengthening of the stratospheric meridional temperature gradient and stratospheric polar vortex. The more rapid response of the land than the sea to radiative forcing is another factor that can explain the smaller winter warming in the land-starved Southern Hemisphere.

If the surface air temperature is arbitrarily assumed to have some power-law dependence on the transmitted intensity of the solar beam, say $T \propto F$, then $\Delta T \propto \tau$ for $\tau \ll 1$. In practice, the drop in hemispheric-average temperature amounts very roughly to $\Delta T (^{\circ}\text{C}) = 1.5 \tau_{\text{D}}$ for eruptions up to Pinatubo-class. However, average temperature is given by $\Delta T \propto \tau_{\text{D}}^{1/2}$ for significantly larger eruptions. The cooling is usually accompanied by increased cloudiness and precipitation.

Complications confuse this tidy picture, especially for very small eruptions whose climatic effects are easily masked. The El Niño-Southern Oscillation (ENSO) phenomenon, a quasi-cyclical warming of equatorial Pacific waters every 3–7 years, induces teleconnection effects elsewhere, notably an atmospheric warming over North America. Although its cause is uncertain, it is very doubtful that a sudden volcanic cooling is able to trigger an El Niño warming event. Outbreaks of cold polar air into mid-latitudes, on the other hand, certainly follow an eruption. The Icelandic pressure low and the northern jet stream move southward, for example; thus, the North Atlantic Oscillation (NAO), which is part of the overall Arctic Oscillation (AO), shows a disturbance of its normal modal pattern. The patterns of the NAO and SO consist of a cyclical shift in relative sea-level pressure (and other meteorological variables) between Iceland and the Azores (NAO) and between the Indian Ocean and the South Pacific Ocean (SO). Other climate forcing factors, however, can disturb these patterns. Natural variability of the climate system, characterized by chaotic, unpredictable behavior, also plays a role.

Climatic effects (specific eruptions)

Depending on the most characteristic method of dating or measuring the aerosol veil, six different periods in Earth history can be identified: geochemical, before 50,000 BC; ice-core, 50,000–300 BC; historical, 300 BC–AD 1880; pyrheliometric, 1881–1960; stellar-extinction, 1961–1978; and satellite, 1979–present. The pre-instrumental years (before 1881) have been divided into a prehistoric part (before 300 BC), for which indirect geological approaches are used, and a historical part, employing visual observations that can be calibrated by using modern techniques. If the total mass of sulfuric acid aerosols has been estimated by using either polar ice-core sulfate acidities or geochemical analyses of the sulfur content of local volcanic deposits, then the stratospheric turbidity can be computed from $\tau_{\text{D}} = M_{\text{D}}/150$. During the historical period, visual observations of solar dimming, of red twilight glows (dust-veil reflections), of Bishop's ring (aerosol diffraction pattern around the Sun), and of lunar-eclipse darkening (an inhibited refraction of sunlight into the shadow cone) can be used to obtain τ_{D} directly. The optical methods and the ice-core method in the historical period are about equally sensitive; the threshold aerosol mass for detecting a tropical eruption is a Pinatubo-class cloud of 30 Tg.

The largest known aerosol veils during the historical period occurred in 44 BC and AD 536, 626, 934, 1258, 1783, and 1815 (see Table VI), although the nature of the 536 veil is still controversial. Eruptions producing these veils are known to have been of explosive type in two cases (Etna and Tambora), and probably also in the 1258 case, but of effusive type in at least two other cases (Eldgjá and Laki). The crude climatic data available for these seven eruptions strongly indicate that their meteorological consequences followed the patterns for modern eruptions. However, these older eruptions were large enough to have had more severe impacts, including greater cold and raininess, extensive crop damage, famine, and serious disease outbreaks, as documented in written sources from the Mediterranean and Middle East. For still larger eruptions, the stratospheric residence time of climatically significant aerosols may be prolonged to 6 years or more. If so, tropospheric cooling could be augmented by positive feedbacks such as a larger planetary albedo arising from increased cloud, snow, and ice cover. It is not known, however, whether such large eruptions,

or even a long series of smaller eruptions, could cause an abrupt climate change that lasts for decades or longer, although this is thought to be theoretically possible in a metastable state of the climate system. Possibly, the long cold period known as the Little Ice Age (AD 1400–1900) was volcanically forced, at least in part, although a protracted solar minimum at this time is a more likely cause.

Less is known about prehistoric eruptions. The protohistorical eruption of Thera (Santorini), Greece, in the seventeenth (possibly sixteenth) century BC may have been of Tambora class. Toba, Indonesia, erupted about 74,000 years ago in a far greater paroxysm – a supereruption that exacerbated an existing climatic downturn and probably caused extensive loss of life, perhaps related to the human evolutionary “bottleneck” around this time. Pleistocene glacial fluctuations have also been attributed to volcanism.

At the top of the ladder are the flood basalt eruptions. These outflows must have led to massive pollution of air, land, and water, as well as to local darkness in the atmosphere for months at a time, regional wildfires, and global cooling for many years. Laki might represent a recent small-scale analogy. Flood basalt eruptions appear to have coincided with mass biotic extinctions, especially marine mass extinctions. Their release of heat-trapping CO₂ would have been sufficient to counteract, in part, the cooling brought on by the efficiently back-scattering sulfate aerosols. Very early in Earth’s history, and during periods of rapid ocean-floor subduction and accretion, when volcanism was more active, outgassing of CO₂ may even have been the predominant factor. Probably, outgassing supplied the atmosphere and oceans with their main constituents after the end of the massive early bombardment of Earth by comets and asteroids (3.9 Gyr ago).

Cultural impacts of the greatest volcanic eruptions should also be mentioned. Poetry has immortalized the atmospheric aftereffects of Thera, Etna, Laki, Tambora, and Krakatau in the Bible’s *Exodus*, Virgil’s *Georgics*, Cowper’s *Task*, Byron’s *Darkness*, and Tennyson’s *St. Telemachus*. A few memorable expressions have endured, such as “the year without a summer” in 1816. “Tambora skies” and “Krakatau sunsets” are possibly depicted in some paintings contemporary with those eruptions. However, the major cultural impacts were probably negative, reflecting the famines, epidemics, and social disorders that grew with the climate deterioration.

WEATHERING AND CLIMATE

Weathering is an important biogeochemical process that is both influenced by and influences climate over the course of Earth history. Weathering processes control the flux of solutes and many nutrients to the oceans and the marine and terrestrial biospheres, and the transfer of carbon from the ocean-atmosphere system to sedimentary rocks. Weathering rates are dependent on climate, among several factors, and vary widely across the Earth's surface. In turn, weathering processes can alter the atmospheric concentrations of the important greenhouse gas, carbon dioxide. Weathering processes thus have the potential to act as a climate feedback, an idea that has been important in our understanding of the long-term evolution and stabilization of the Earth's climate for over 150 years.

"Weathering" refers to the chemical alteration of rock and sedimentary deposits under sub-aerial conditions at the Earth's surface. While some analogous processes occur in the oceanic crust during low temperature alteration by seawater, or during higher temperature hydrothermal alteration of the continental or oceanic crust, they fall outside the traditional definition of weathering. The kinds of geological materials that undergo weathering may be conveniently classified into silicates, carbonates, and organic matter. The types of weathering reactions, their products, and their dependence on and implications for climate differ between the three.

Weathering of both silicate and carbonate minerals can be described as an acid-base reaction, in which naturally occurring acids generated by volcanic gas emissions, weathering of sulfide minerals, dissolution of CO₂ in water, or decomposition of soil organic matter react with minerals phases to consume acidity and generate dissolved cations and, in most cases, alkalinity. One important difference between silicate mineral weathering and carbonate mineral weathering is that with silicates, an additional product of the weathering reaction is often a secondary alteration mineral ("clay"), whereas carbonate minerals generally dissolve completely. In both cases, weathering acts as a buffer to acidification, but the strength of the buffer depends on the mineral phase(s) involved.

Of the natural acids, carbonic acid (a "weak" acid, implying incomplete dissociation of the proton donor) and sulfuric acid are the most important. Sulfuric acid can be generated by the oxidation of sulfide minerals, volcanic gases (which commonly contain sulfur dioxide), or biogenic volatile compounds like carbonyl sulfide and dimethyl sulfide. These last reactions are important for atmospheric aerosol formation but are not significant sources of weathering acidity. Carbonic acid is generated by the dissolution of CO₂ in water:

Carbonic acid produced by the hydration of CO₂ (Reaction (1)) will partially dissociate to produce acidity and bicarbonate ion (Reaction (2)). At present atmospheric levels (PAL) for CO₂ (360 ppmv), the pH of water in equilibrium with the atmosphere is ca. 5.6. *p*CO₂ in soils can be much higher due to the decomposition of soil organic matter, and the pH of soil waters consequently lower. At *p*CO₂ = 10 PAL, pH = 5.1; at 100 PAL, pH = 4.6

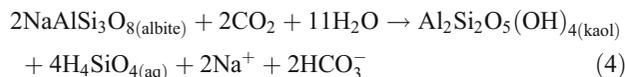

Carbonate rocks (primarily limestones and dolomites) play an important role in weathering fluxes at the Earth's surface because they are relatively soluble under typical conditions and act as a strong buffer to either natural or anthropogenic acidity. Natural acids react quickly with carbonate minerals, neutralizing the acidity and generating alkalinity in the form of bicarbonate and carbonate ions. An important reaction is:

in which CO₂ (from the atmospheric or from the decomposition of organic matter) reacts with calcite and water to produce dissolved calcium and bicarbonate ions. Under open system conditions and under present-day *p*CO₂, the pH at equilibrium with this reaction is near 8.6. Thus the hydrogen ion activity of the water-carbon dioxide system, with an ideal pH of ca. 5.6, is reduced by three orders of magnitude, illustrating the strong buffering effect that carbonate dissolution has on aqueous solutions. Bicarbonate ion is the dominant form of

dissolved inorganic carbon (DIC) at pHs between 5.7 and 10.2, which covers the range of most natural waters. Carbonate minerals are widely distributed, and most rivers have pHs that reflect their influence. The strong buffering effect ensures that waters in systems containing carbonate will generally be at neutral to slightly alkaline pH, which has important effects on the rates of other reactions involving aluminosilicate minerals and the solubility of many metals.

The weathering of aluminosilicate minerals is generally a more complicated process than for carbonates. Many reactions can be written depending on the phases involved. One important example is:

which illustrates a weathering reaction involving primary albite (Na-feldspar) and carbonic acid that yields a hydrated secondary clay mineral (kaolinite) which is depleted in cations and silica relative to the primary mineral. The other products are dissolved silicic acid, sodium ions, and bicarbonate. This type of weathering reaction, in which a new secondary phase is formed, is termed “incongruent” weathering, and is of fundamental importance for soil formation. Aluminosilicate mineral weathering rates depend strongly on pH, temperature, and reactive surface area, and are generally at a minimum at neutral pH. Thus, the presence of carbonate minerals in a soil may greatly reduce the rate of silicate mineral dissolution by buffering the pH to a range in which dissolution rates are slowest. Laboratory studies have documented that, under ideal conditions, reaction rates for aluminosilicate minerals increase by roughly a factor of three for each 10 °C temperature increase (Lasaga et al., 1994). Field studies have produced much more ambiguous results, probably in large part because of the difficulty in defining the effective surface area and also because of the inhibiting effects of ion sorption on some reactions (Drever and Clow, 1995).

Old organic carbon, stored in sedimentary rocks as “kerogen” also undergoes oxidative weathering reactions. These reactions are less well understood than those for mineral weathering, as they often involved the production of oxidized functional groups that may later serve as sites for bacterial attack. A schematic reaction may be written:

Reaction (5) illustrates that the weathering of organic matter consumes oxygen and produces carbon dioxide, although as written it provides little insight into the actual reaction pathways. Unlike carbonate and silicate weathering, organic carbon weathering is oxidative rather than fundamentally an acid-base reaction, although the production of organic acids ($\text{R-COOH} \rightarrow \text{R-COO}^- + \text{H}^+$) by partial oxidation may accompany kerogen degradation (Petch et al., 2000). Organic rich sediments such as shales and coals often contain pyrite, and the accompanying oxidation of FeS_2 results in the formation of sulfuric acid, which can lead to very low pHs. Sulfuric acid is a far stronger acid than carbonic acid, and may account for a significant fraction of the natural acidity even when pyrite is a minor component of the weathered rock.

In a classic work, Jenny (1941) laid out “state factors” that affect soil formation, and these generally apply to weathering

in natural systems. They include time, climate, topography and vegetation. Since most weathering reactions are strongly rate-limited, weathering can be slow even on a geologic time scale. Deeply weathered landscapes often have been stable for long times (10^6 – 10^8 years). Second, both temperature and rainfall are strong controls on natural weathering rates. Aluminosilicate reaction rates generally follow the Arrhenius relationship and can be strongly temperature dependent. Reaction rates can also depend on the degree of undersaturation of the solution in contact with the mineral and thus increased rainfall and more rapid flushing can enhance reaction rates and weathering reaction progress. “Wet” systems may leach out the available carbonate, removing the principal buffer, allowing pH to decrease and silicate weathering reaction rates to increase (Chadwick and Chorover, 2001). The decomposition of soil organic matter and production of organic and carbonic acids also depend positively on both temperature and (to the limit of saturation) moisture. Thus weathering rates can be expected to depend significantly on climate, and the global distribution of highly weathered soils supports this hypothesis. The removal of soil and regolith by erosion can expose fresh bedrock and enhance the overall weathering flux, although rapid removal will prevent weathering reactions from going toward completion. Two end member cases can be defined: “transport” limited systems, in which erosion removes regolith before it has a chance to undergo much chemical attack, and “weathering” limited systems, in which the development of a thick mantle of weathering products inhibits the introduction of water and acids to fresh mineral surface, thus slowing the overall weathering rate (Stallard and Edmond, 1983). A currently important area of study is the relationship between physical erosion, climate and weathering fluxes in difference environments, as it has been difficult to unambiguously point to a simple set of weathering rate controls across a variety of environments and spatial scales.

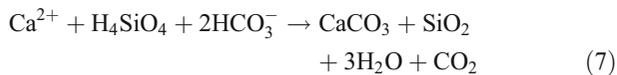

Interpretation of paleoclimate from paleoweathering studies

Paleosols are preserved weathering profiles found throughout most of the geological record. Their interpretation is complicated by a number of factors, including the state of preservation and the relationship of the regolith to the bedrock. For example, many soils have a significant (and in some cases like loessic soils, dominant) component of allochthonous transported material in them, transported by wind or other agents. Calculating the chemical weathering depletion of a soil by comparing its bulk chemistry to that of the underlying bedrock may not be meaningful in such cases, unless considerable care is taken to account for atmospheric deposition fluxes. Furthermore, it is often impossible to constrain the time scale of paleosol formation. However, some useful inferences can be drawn about paleoclimate from paleosol studies. These include qualitative data on precipitation and paleovegetation from isotopic studies of paleosol carbonates (Quade et al., 1989), and constraints on the composition of the atmosphere from models that use the differences in diffusivity of $^{13}\text{CO}_2$ and $^{12}\text{CO}_2$ to calculate $p\text{CO}_2$ in the overlying atmosphere (Cerling, 1992). The “paleosol $p\text{CO}_2$ barometer” has been widely applied to Phanerozoic sites, and gives a picture of the history of $p\text{CO}_2$ that is in broad agreement with modeling studies (Mora et al., 1996).

Influence of weathering processes on atmospheric $p\text{CO}_2$

The three basic weathering processes described above all involve CO_2 as a product or reactant. Recognition of the role of weathering process in controlling CO_2 , the role of climate in controlling weathering rates, and the role of CO_2 as a greenhouse gas led to the qualitative notion that a negative feedback existed in the geologic carbon cycle as early as the mid-nineteenth century (Ebelmen, 1845; Arrhenius, 1896; Chamberlin, 1899). The basic hypothesis is that increasing $p\text{CO}_2$, whether from volcanic emissions or some other source, would cause a warming of climate. The warm climate would enhance weathering reactions by a direct temperature effect, by increasing precipitation on land, or by increasing the activity of plants that would enhance weathering rates through increased soil $p\text{CO}_2$. The faster weathering reactions would result in enhanced consumption of CO_2 , eventually reducing the greenhouse effect and causing climate to cool. Conversely, an "externally" forced fall in $p\text{CO}_2$ would result in cooling and reduced weathering, gradually allowing natural sources of CO_2 to build up in the atmosphere and increase greenhouse warming. Beginning in the 1980s, these concepts were quantified with computer models, and the possibility of a viable climate stabilization with weathering-greenhouse feedback was demonstrated (Walker et al., 1981; Berner et al., 1983).

The three kinds of weathering processes have different impacts on the long-term carbon cycle. Carbonate weathering has no long-term effect – in the oceans, Reaction (1) is exactly reversible, and the formation of carbonate (biogenic or abiogenic) sediments in the ocean consumes the Ca^{2+} ion and the bicarbonate and returns the CO_2 to the ocean atmosphere system. In contrast, aluminosilicate weathering can be a net sink for CO_2 where Ca and/or Mg silicates are involved. A simple schematic pair of reactions illustrates the point:

Here a calcium (or equivalently magnesium) silicate undergoes attack by CO_2 and water to form Ca^{2+} ion, bicarbonate and silicic acid, consuming two moles of CO_2 per mole of mineral dissolved. In the ocean, the bicarbonate and calcium can precipitate to form sedimentary carbonate, releasing one mole of CO_2 back to the ocean-atmosphere system but with a net removal of one mole of CO_2 as carbonate. The net reaction is:

Because weathering of silicates is dependent on climate (temperature and rainfall), the weathering of Ca-Mg silicates can act as a feedback mechanism to stabilize atmospheric $p\text{CO}_2$ and thus climate. The weathering of K- and Na-silicates does not interact with the carbon cycle so simply, as K and Na do not form significant carbonate deposits. A fraction of K^+ and Na^+ released by mineral weathering undergoes ion exchange with Ca^{2+} , and thus can contribute to CO_2 consumption via this pathway, but the fraction is uncertain and probably not large, so weathering of alkali silicate minerals is an inefficient sink for CO_2 (France-Lanord and Derry, 1997). The direct role of Ca-Mg (alkaline earth) silicates in the carbon cycle and their generally faster weathering rates than K and Na

silicates indicate that weathering of mafic-intermediate rocks is the critical process by which silicate weathering can act as a climate feedback (Dessert et al., 2003).

Geochemical models that seek to investigate the global inter-dependence of climate and weathering have been used to estimate past atmospheric $p\text{CO}_2$, climate and weathering fluxes. Critical to these models is the formulation of the temperature dependence of weathering rate, typically according to the Arrhenius relationship:

$$k = A \exp(E_a/RT) \quad (9)$$

where k is the weathering reaction rate, A is a reaction-specific constant, R is the Universal Gas Constant, T is temperature (Kelvins), and E_a is the activation energy. This latter term determines the overall temperature sensitivity of the reaction. Two difficulties are immediately apparent with this approach. First, the Arrhenius "law" is most properly applied to a specific elementary reaction, but in practice the modeled reactions are composed of several (even many) elementary reactions, and it is not certain that the Arrhenius relationship holds under these circumstances, for which it was not originally determined. Second, determining an average temperature sensitivity (E_a) for silicate weathering reactions at a large scale is difficult. Most experimental data point toward values of E_a near 60 kJ per mole for the relevant silicate weathering reactions, which would imply about a factor of 5–6 increase in reaction rate between a cool climate (mean annual temperature 5 °C) and a warm climate (25 °C). Potentially more important than temperature changes are changes in precipitation that would result from global climate change. The primary driver for a weathering feedback to climate change may well be via global precipitation (White and Blum, 1995). Under warmer conditions, more water vapor should cycle through the atmosphere, resulting in greater rainfall and runoff. Complicating these relatively simple physico-chemical factors are the composition of exposed rock types, and the location of land masses in different climatic zones (Bluth and Kump, 1994). To illustrate the potential effects of these two factors, consider a paleogeography in which highly weatherable mafic-intermediate volcanic rocks were confined to high, cold and dry latitudes. The combination of low temperatures and low runoff should produce relatively low rates of CO_2 consumption. Alternatively, if these lithologies were primarily exposed in the warm and wet tropics, Ca-Mg silicate weathering should be enhanced, and CO_2 consumption maximized.

The weathering of organic matter has the opposite effect on the atmospheric CO_2 budget. Oxidation of kerogen releases CO_2 . This effect is, in the long term, nearly balanced by the burial of new organic matter in sediments, but sedimentary budget and carbon isotope studies indicate that there have been periods when the oxidation of old sedimentary carbon and burial of newly reduced carbon are not in balance. For example, changes in the net storage of organic carbon in sediments appear to have played a role in creating cool conditions in the Carboniferous (Canfield and Berner, 1989), but the impact of climate variability in creating suitable conditions for large burial fluxes of carbon as coal poses the problem of which came first. Glacially forced eustatic sea level variations appear to have been important in burying large quantities of terrestrial plant material in marginal swamps, while increasing this burial rate had the effect of further decreasing the quantity of carbon in the ocean-atmosphere system, which may have led to further

cooling. As in other intervals of Earth history, the feedback nature of the carbon-climate system can make it difficult to determine ultimate cause-effect relationships.

Mountain building episodes and weathering

The original quantitative models linking weathering, CO₂ and climate were essentially driven by the degassing fluxes from the Earth's interior, generally scaled to estimates of mid-ocean ridge crustal production rates. They did not take into account changes in "weatherability" of the mean continental surface, either by changes in the average composition of exposed rock types or by the enhancing effects of uplift and erosion on chemical weathering rates. The extent to which uplift affects regional or global scale weathering rates has been the focus of considerable debate in the geological literature in recent years (Raymo and Ruddiman, 1992). Fluxes of sediment are much higher from orogenic areas, particularly those located in wet climates (Milliman and Syvitski, 1992). Chemical weathering fluxes also are higher in streams that drain uplifted regions. Much of this enhanced flux is apparently due to carbonate dissolution, but silicate weathering fluxes have also been shown to be higher in regions of high relief (Sarin et al., 1989; Jacobson and Blum, 2003). More difficult is the question of how CO₂ consumption by weathering depends on uplift history, as both rock type and climate appear to play important roles as well. For example, the modern Himalaya do not appear to be a site of strongly enhanced CO₂ consumption by weathering, in part because rapid erosion limits the extent of completion of chemical alteration reactions, and in part because the alkali silicates common there are not efficient sinks for CO₂ (Galy and France-Lanord, 1999). The creation of large-scale topographic features may alter climate locally or regionally in ways that impact weathering. Perturbation of atmospheric circulation patterns by mountain uplift can create regional climates that are quite different from what would be expected in the absence of high topography. The current impact of the Tibetan plateau on monsoon circulation is the outstanding modern example (Prell et al., 1992). Many mountain ranges across the world strongly focus and intensify precipitation locally by orographic effects even if they are too small to drive major circulation patterns like the Indian monsoon. Increased precipitation is often associated with more rapid and/or complete weathering, but, conversely, rain shadow effects can result in significant areas of aridity and low weathering rates. The combination of regional circulation patterns, rain shadows, and low ocean surface temperatures results in low precipitation on the high Andean plateaus and on the west flank of the Andes, and very low weathering fluxes to the Pacific Ocean. On the east side of the Andes, high rainfall produces rapid erosion, and most of the solute fluxes in the large Amazon and Orinoco rivers are generated there (Stallard and Edmond, 1983). Thus, the effects of Andean uplift on weathering rates are highly asymmetric.

Mountain building can impact the organic part of the carbon cycle as well, through enhanced erosion and oxidation of old sedimentary kerogen, or through enhanced burial of "new" organic matter. Organic carbon sequestration rates are highest in areas of high sedimentation rates, and a large fraction of organic carbon burial takes place along continental shelves where productivity is high and sedimentation rates fast enough to ensure rapid burial and isolation. Currently, high sedimentation rates and a supply of refractory terrestrial organic matter make the Bengal Fan, the major sedimentary repository of the Himalaya, the largest site of organic carbon burial globally.

Because carbon-poor rocks are being eroded from the Himalayas, while carbon-rich sediments are deposited in the huge submarine fans, Himalayan erosion is a net sink for the organic carbon sub-cycle (France-Lanord and Derry, 1997).

The impact of the Himalayan (or any other) carbon sink on climate during the last 20 million years is not clear, as available paleoproxy data do not indicate any large shift in atmospheric *p*CO₂ since the early Miocene, a period during which large scale global cooling is well documented (Pagani and Freeman, 1999; Pearson and Palmer, 2000). The overall relationship between the carbon cycle and climate is not yet well understood, although there are a number of indications that the carbon cycle does play an important role in long-term climate change. The impact of weathering processes on the long-term carbon cycle, and the potential feedbacks involved remain one of the more interesting and complex features of the Earth system. The weathering-climate feedback is an attractive hypothesis for the stabilization of the Earth's climate over very long time scales (10⁸–10⁹ years). Changing solar output over those time scales could have forced drastic climatic changes in the absence of a stabilizing feedback, but for all but a few brief episodes of Earth history, surface temperatures appear to have been in the range of stability of liquid water. Gradually increasing solar luminosity may have been balanced by decreasing *p*CO₂, as weathering reactions gradually increased the storage of carbon in sediments at the expense of the ocean-atmosphere system. Such a transfer would be important from an atmospheric point of view, but quite small in terms of the sedimentary rock reservoir (a relative change on the order of 10⁻⁴).

Long term changes in global weathering rates: Sr isotope evidence

Available data from various sources, including paleo-sea level reconstructions, paleobotany, and oxygen isotopes in marine fossils, indicate that the Earth's climate has been considerably warmer at times in the geologic past. These "greenhouse" intervals, such as the Eocene warm period, or the mid-Cretaceous, should be associated with higher rates of weathering if the hypothesis of a long-term feedback between climate and weathering is valid. Conversely, "icehouse" intervals, with overall cool climates (such as the Pleistocene), should have lower globally averaged weathering rates. Model studies that incorporate a climate-weathering feedback do support this relationship, but that is clearly in part a function of the construction of the model around such a relationship (Berner, 1991). A reasonable question is whether there is good independent evidence of changes in global weathering rates that are correlated with climate on these long time scales. While paleosols do preserve information on weathering intensity from a particular location, they cannot be used to reconstruct global weathering rates reliably. Changes in ocean chemistry should result from long-term changes in weathering fluxes. Because the major element chemistry of seawater is, at best, imperfectly preserved in old sediments, attention has been given to isotopic tracers such as ⁸⁷Sr/⁸⁶Sr. Because strontium is a fairly abundant constituent of seawater and has a long residence time, it has a uniform isotopic composition in the world oceans at any one time. In a closed system (such as a given mineral phase), the ⁸⁷Sr/⁸⁶Sr ratio will increase over geologic time because of the decay of ⁸⁷Rb to ⁸⁷Sr, with a half life of 42 Ga. Minerals with a high parent-daughter ratio (high Rb/Sr) will evolve more rapidly than those with low Rb/Sr.

Analysis of many well-preserved marine carbonate samples has demonstrated that the ⁸⁷Sr/⁸⁶Sr ratio of seawater has varied

significantly over time (Burke et al., 1982; Veizer et al., 1999). Marine carbonates have very low levels of ^{87}Rb , and so should not evolve significant ^{87}Sr after their formation in the marine environment. The main causes of variation in the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of seawater (as recorded in marine carbonate sediments of various ages) must be changes in the fluxes of Sr to the oceans from sources with different characteristic $^{87}\text{Sr}/^{86}\text{Sr}$ ratios. The prime candidates are: (a) changes in the isotopic composition of Sr in the global river flux, and (b) changes in the relative contribution of Sr from submarine hydrothermal alteration and the river flux. The current value of $^{87}\text{Sr}/^{86}\text{Sr}$ in the oceans is 0.70917, while the global average river value is near 0.712. Mid-ocean ridge hydrothermal vents are near 0.7034, a value similar to the upper oceanic crust that they sample. In the simplest case, these input values imply that rivers supply two-third of the total Sr flux to the oceans, while hydrothermal systems supply the other third (Palmer and Edmond, 1992). Lower $^{87}\text{Sr}/^{86}\text{Sr}$ values of the oceans in the past would imply an increased hydrothermal flux, a reduced river (weathering) flux, or some combination. However, there are a number of important caveats to this simple approach. First, the estimate of the hydrothermal contribution to ocean chemistry based on Sr isotopes is higher than independent estimates from other chemical or isotopic tracers, and suggests that there are significant sources of non-radiogenic Sr to the oceans from crustal alteration of the oceanic crust at low temperature, away from ridge axes (Elderfield and Schultz, 1996). Second, the oceans are not now at steady state with respect to their Sr budget, and this disequilibrium results in an over-estimate of the hydrothermal contribution (Galy et al., 1999). Third, changes in the isotopic composition of the river flux with time can be large enough to confound attempts to extract the balance between hydrothermal and weathering fluxes through time. For example, Himalayan rivers have unusually high Sr concentrations as well as very high $^{87}\text{Sr}/^{86}\text{Sr}$, and the Neogene development of the Himalaya is at least in part responsible for the high average value of the global river flux to the present oceans (Edmond, 1992; Krishnaswami et al., 1992; Richter et al., 1992). Further, the $^{87}\text{Sr}/^{86}\text{Sr}$ of Himalayan rivers has changed significantly during the last 10 Ma (Derry and France-Lanord, 1996; Quade et al., 1997). The impact of Himalayan tectonic processes on the $^{87}\text{Sr}/^{86}\text{Sr}$ of the global river flux illustrates how changes in the types of rocks weathered at the Earth's surface can change the isotopic composition of one of the major contributors to the ocean Sr budget, and over time change the $^{87}\text{Sr}/^{86}\text{Sr}$ of the oceans, without necessarily implying large changes in globally averaged weathering rates or CO_2 consumption.

Finally, the fundamental interest in strontium isotope ratios as a measure of weathering fluxes is that strontium is chemically similar to calcium. Ideally, changes in the Sr mass balance of the oceans could be used to estimate changes in the global weathering calcium flux to the oceans. Carbonate sediments (limestones and dolomites) should record the $^{87}\text{Sr}/^{86}\text{Sr}$ of the ocean at the time they were deposited. Conversely, some silicate rocks, particularly those with granitic bulk compositions, can have high Rb/Sr ratios, and over time generate high $^{87}\text{Sr}/^{86}\text{Sr}$ ratios. The weathering of continental rocks should therefore yield high Sr isotope ratios in river waters, and the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of seawater should reflect increases in the weathering flux from old continental material on a million year time scale. Upon further consideration, an interesting conundrum appears. Granitic silicates have high Rb/Sr ratios and thus evolve to high $^{87}\text{Sr}/^{86}\text{Sr}$ values, but they also have relatively low Ca and Mg abundances.

Thus, their potential to act as weathering sinks for CO_2 via reactions like Reaction (8) is modest. Mafic silicates, including basalts and intermediate compositions generally have low Rb/Sr and low $^{87}\text{Sr}/^{86}\text{Sr}$ ratios, yet these compositions have abundant Ca and Mg, and can act as strong sinks for CO_2 (Dessert et al., 2003). The widely held view that increasing $^{87}\text{Sr}/^{86}\text{Sr}$ in the oceans should correlate with increased CO_2 consumption via silicate weathering is unlikely to be generally applicable (Raymo and Ruddiman, 1992).

A comparison of the available data on paleoclimate reconstructions with the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of past oceans suggests that at least some warm "greenhouse" periods of Earth history are associated with low $^{87}\text{Sr}/^{86}\text{Sr}$. This could reflect increased hydrothermal fluxes, but recent independent work strongly suggests that ocean crustal production rates have varied little since the Jurassic (Rowley, 2002). Instead, low $^{87}\text{Sr}/^{86}\text{Sr}$ during much of the Cretaceous and Paleogene may in part reflect enhanced alteration of mafic and intermediate silicate rocks, and thus relatively high rates of CO_2 consumption. The increase in marine $^{87}\text{Sr}/^{86}\text{Sr}$ since the Eocene is almost certainly in part due to changes in the types of rocks undergoing weathering, and may not reflect increased CO_2 consumption rates. It may reflect increased weathering rates of granitic materials, but as noted above, the associated CO_2 consumption can be modest.

Unfortunately, the question posed at the beginning of this section cannot be easily answered at present. While model results predict enhanced global weathering rates under warm "greenhouse" climates, there is no well-understood and fully independent data set that verifies this hypothesis. An increasingly well-documented set of laboratory and field experiments does support the general outlines of the hypothesis first posed by Ebelmen over 150 years ago, but we remain far from a complete understanding of weathering-climate relationships over geologic time.

WISCONSINAN (WEICHSELIAN, WÜRM) GLACIATION

Introduction

The term “Wisconsinan Glaciation” refers to the last major glacial episode that affected North America, more properly referred to as the Wisconsinan Stage (Black et al., 1973; Fulton, 1989; Clark and Lea, 1992) (Figure W1). The term should be restricted to the deposits and events of the Laurentide Ice Sheet (LIS; see *Laurentide Ice Sheet*), which extended from the Canadian Arctic coast to the northern states in the USA, and across the Dakotas eastward to New England (Figure W2). In this sense, the term is not properly used to describe events of the Cordilleran Ice Sheet (see *Cordilleran Ice Sheet*), which extended from the Alberta foothills to the coast of British Columbia. Weichselian and Würm glaciations refer to the last glacial period in Fennoscandia and the Alps, respectively, although these terms, in addition to the “Wisconsinan,” are frequently applied to regions well-removed from the type areas.

The problem in nomenclature stems from efforts to integrate the mapping of glacial and other sediments associated with climatic variations into the standard American and International Stratigraphic Code (Hedberg, 1976). Terms such as Wisconsinan Glaciation or Sangamon Interglaciation are “Geologic-climate units” whereas Wisconsinan Stage is a time-stratigraphic unit that requires, by definition, upper and lower isochronous boundaries throughout the geographic area to which it is applied (Flint, 1971). By contrast, geologic-climate units are not constrained to be synchronous, which in reality agrees with the efforts to date the maximum limit of the LIS during its last major glacial advance (Dyke and Prest, 1987; Dyke et al., 2002). Such efforts indicate that the Last Glacial Maximum (LGM; Figure W1) is a global concept and the timing of the maximum of the late Wisconsinan Glaciation varies around its margins from around 22 to possibly as young as 13 cal ka BP (BP = Before Present with “present” equal to AD 1950). Frequently used terms such as the “late Wisconsin” generally refer to Marine Isotope Stage (MIS) 2 (Figure W1), but the definitions of middle and early Wisconsin are more varied in their usage and definitions (Fulton, 1989). The discussion gets convoluted in terms of definitions and semantics, leading to a lack of simplicity and uniformity in usage. For example, as a time-stratigraphic term, the Wisconsinan Stage ends at the Pleistocene/Holocene boundary, which

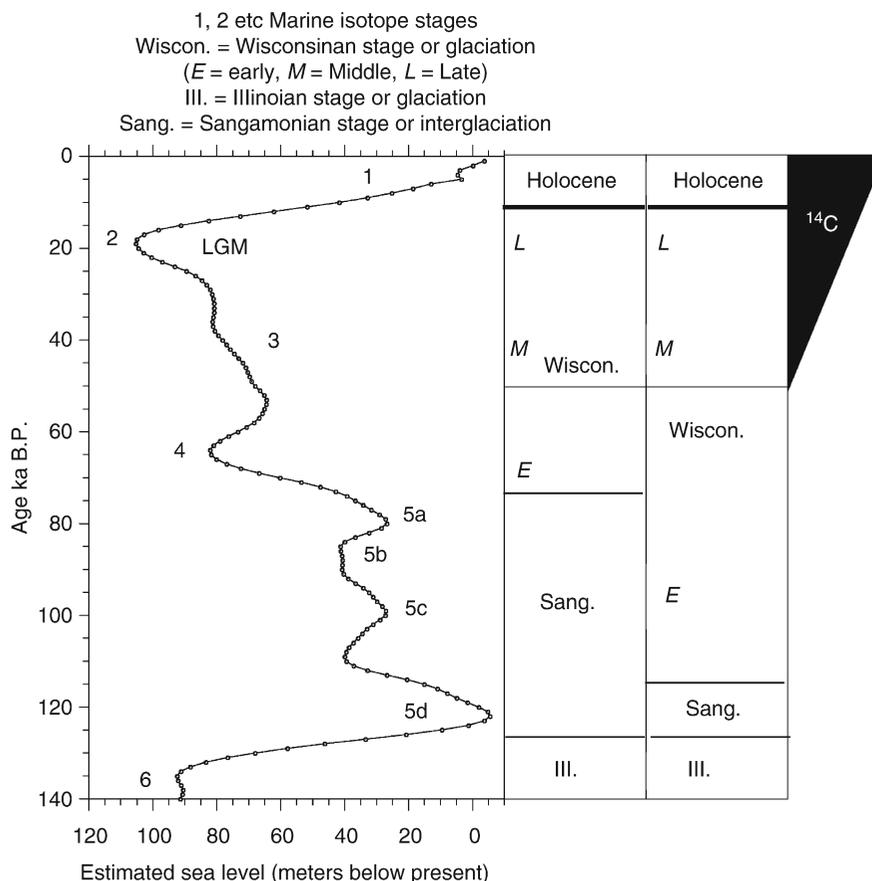

Figure W1 Estimated global changes in sea level over the last 140,000 years associated with the growth and retreat of the integrated global ice volume. The two columns to the right of the figure show alternative scenarios for Wisconsinan Glaciation and the boundary between the Pleistocene and Holocene. *E*, *M*, and *L* standard for early, middle and late Wisconsinan. *Sang.* is the Sangamonian Stage (Interglaciation), and *Ill.* is the penultimate Illinoian Stage (Glaciation). *LGM* is the late glacial (global) maximum. The final column shows the interval over which radiocarbon dating can be employed.

by international accord is 10,000 radiocarbon yBP or about 11,600 calendar yBP. However, the Wisconsinan Glaciation in the form of the LIS still covered vast areas of northern North America at this boundary time, and in fact, glacier ice associated with the geologic-climate unit still exists in the form of the Barnes Ice Cap on central Baffin Island, Nunuvit, Canada. The boundary for the transition between the last interglacial stage and the Wisconsinan Stage (Figure W1) can either be set to include the need for ice growth during MIS 5d and 5b, or the sustained interval of global ice expansion during MIS 4.

The Wisconsinan Glaciation is, however, of global importance because the LIS at its maximum at around 22,000 cal yBP (the Last Glacial Maximum or LGM, Figures W1 and W2) (see *Last Glacial Maximum*) was similar to the present Antarctic Ice Sheet in terms of area and volume. Hence, of the approximate 120 m of equivalent fall in global sea level (Figure W1), some ~70 m is attributed to the LIS (Denton and Hughes, 1981; Lambeck and Chappell, 2001). Actually, the terms Wisconsinan Glaciation or Weichselian Glaciation (NW Europe) are frequently used as general terms for the last glacial cycle *sensu lato*. However, this statement begs the question of when did the “Wisconsinan” Glaciation of North America really commence? The term “Wisconsinan” above is in quotations because

stratigraphic practice in North America variously defines the “Wisconsinan” Glaciation as beginning about 100 cal ka year ago or at the MIS 5/4 boundary ca. 75 cal ka (Figure W1). These temporal boundaries are not numerically dated but inferred from the stable oxygen isotope records preserved in deep sea sediments.

The Wisconsinan Glaciation and the marine isotope and sea level records

The overall structure of the last glaciation at a global scale is most frequently determined from a combination of studies of deep sea benthic foraminifera $\delta^{18}\text{O}$ variations (Shackleton, 1987), and evidence for past sea levels on tectonically active coastlines (Chappell et al., 1996). The chronology of these events is based on a combination of radiocarbon and U-series dating (see *Radiocarbon dating*), and fitting (tuning) the data to variations in orbital insolation (see *Astronomical theory of climate change*). Both methods explicitly track the global hydrological balance and seek to determine the volume (global) of ice located on land areas. Figure W1 illustrates the history of global ice sheet growth and melt from marine isotope stage (MIS) 5 to 1 (~130–10 cal ka).

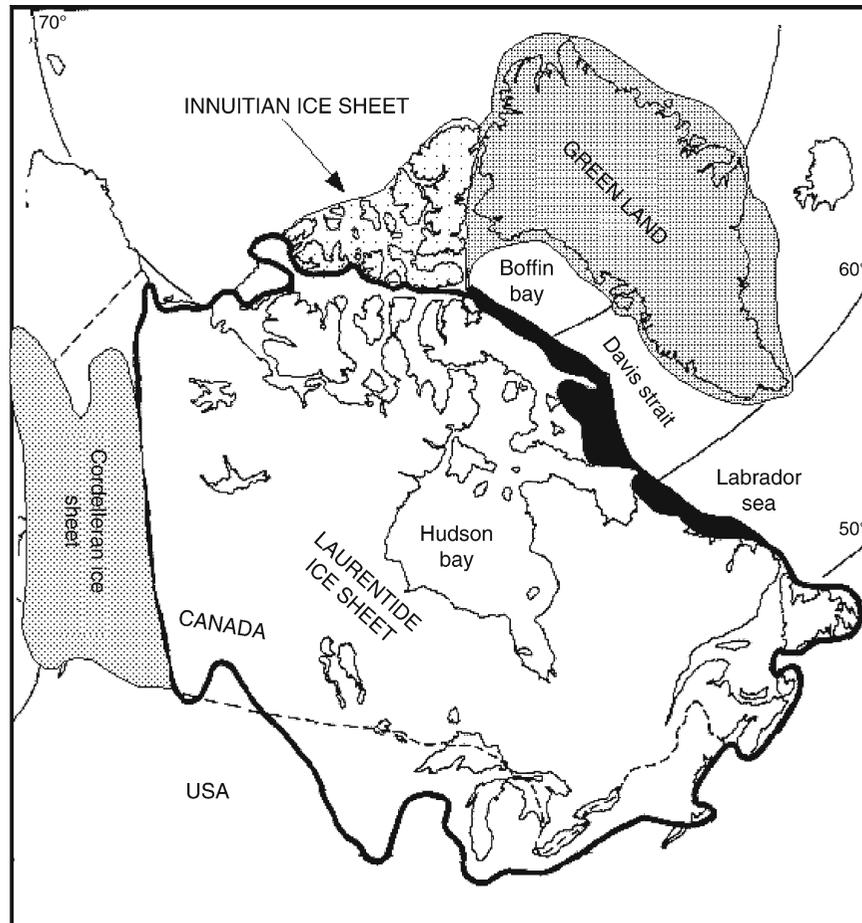

Figure W2 Extent of the ice sheets over North America and Greenland around 18,000 years ago. The regional glacial maxima vary around the ice sheet (see text). The *solid black area* represents the mapped extension of the Laurentide Ice Sheet during the late Wisconsinan Glaciation along the eastern margin of the ice sheet based on the 1987 compilations of Dyke and Prest (see Dyke et al., 2002).

Both approaches indicate that sea level was ~ 5 m above present during the last interglacial around 125 cal ka (MIS 5e) but then fell dramatically by 115 cal ka (MIS 5d), indicating that significant ice growth occurred somewhere on the planet. In terms of volume, this increase in glacier ice amounted to the equivalent of several present-day Greenland Ice Sheets. A Greenland Ice Sheet Unit (GISU) amounts to ~ 5 m of global sea level and the change in MIS 5d is in the range 4–10 GISU. Global sea level rose and hence ice sheets melted during MIS 5c and 5a, with an interval of growth during MIS 5b. It thus appears certain that significant ice sheets were present on the Earth's surface during MIS 5, but the exact location and individual sizes of these ice masses is uncertain at best and basically unknown.

Onset of glaciation in North America

The question of when the glaciation began is, at present, very difficult to answer because deposits associated with the early Wisconsinan Glaciation lie beyond the limits of radiocarbon dating, i.e., >45 ka BP (Figure W1). As noted above, a common approach is to examine the history of changes in global sea level since the last interglacial, the Sangamonian Interglaciation in North America. Because the LIS was the dominant factor in

changes of sea level on glacial timescales, the history of global sea level must therefore represent significant aspects of the volume history of the ice sheet, but it is probably not a 1:1 correspondence. It is possible that different sectors of this vast ice sheet experienced different chronologies because of the enormous range of glacial-climatic conditions that must have prevailed over such a massive ice sheet.

At present, the presumed centers of ice sheet growth and dispersal of the LIS are located in the vast uplands of the Eastern Canadian Arctic and Keewatin (Williams, 1979), which today have mean annual temperatures of between -13 and -5°C , with winter snowfalls ranging between 20 and 50 cm water equivalent. On Baffin Island, large areas of lichen/vegetation-free surfaces, caused by snow-kill, suggest that permanent snow/ice covered a large fraction on the region even as recently as the Little Ice Age, approximately 300–400 year ago. Significantly, the marine isotope data (Figure W1) indicate a very rapid increase in ice volume from MIS 5e to 5d. Such a rapid growth of ice sheets is incompatible with the slow growth associated with decreased temperatures (which would also decrease the precipitation) and therefore several authors have linked the onset of LIS glaciation with increased winter snowfall (Johnson and Andrews, 1979). These models

call for increased cyclonic activity in Baffin Bay, probably as the result of increased advection of warm modified Atlantic Water via the West Greenland Current. According to such a scenario, the development of ice over the islands and channels of the High Canadian Arctic would cut off the outflow of cold, “fresh” Polar Waters into Baffin Bay, resulting in a reduction in the extent and severity of sea-ice, in turn leading to increased fall precipitation over the uplands of Baffin Island and Labrador-Newfoundland. Such a paleoceanographic/climatic scenario is supported by the stratigraphy and molluscan faunas for glacial events along the eastern seaboard of Baffin Island that now lie beyond the limits of glaciation. Based on amino acid racemization constraints, these events are probably >75 cal ka and might be correlated with intervals of ice growth in MIS 5b and 5d (Figure W1).

However, even with such a “snowfall” model, Andrews and Mahaffy (1976) had great difficulty in driving a 3-D glaciological model to accommodate around 20 m of global sea level lowering in the 10,000 year required by the oxygen isotope data. However, this and later models all show the nucleation of ice sheets over the Canadian Arctic eastern uplands and growth across Hudson Strait. This must have resulted in the ponding of a large lake within Hudson Bay and the possibility of large outburst floods or subglacial release of water resulting from such a configuration.

The center of the Wisconsinan Ice Sheet – the record from Hudson Bay

The geographic center of the LIS during the Wisconsinan Stage was the area of Hudson Bay (Figure W2). Hence, the LIS is a marine-based ice sheet, defined as an ice sheet with a substantial fraction of its area located below sea level, with a major drainage directed through Hudson Strait into the Labrador Sea. Because of the density difference between ice (ca 900 kg m^{-3}) versus marine water (ca $1,028 \text{ kg m}^{-3}$), ice margins ending in the sea, or a lake, have the potential to “lift off,” resulting in a rapid increase in ice flow and the collapse of ice centers. The LIS thus had the potential to experience extensive deglaciation due to massive calving and collapse – this certainly occurred at the end of the glaciation some 8–9 cal ka but did it occur earlier in the last glacial cycle?

The late Quaternary stratigraphy of the Hudson Bay Lowlands (SW area of Hudson Bay) is beautifully preserved along hundreds of km of river section (Andrews et al., 1983; Thorleifson et al., 1992) (Figure W3). Although well preserved, the glaciological interpretation of the sequence is complicated by: (a) problems of assigning ages to materials at or beyond the limits of radiocarbon dating, and (b) differing interpretations of the genesis of rippled sands and laminated silts. Amino acid racemization data on marine mollusks, which are a product of both time and temperature, show that the presumed last interglacial marine sediments of the Bell Sea have ratios of around 0.24 compared with ratios of ~ 0.03 for the early Holocene Tyrrell Sea. Intermediate ratios of 0.12–0.14 were obtained from shells in sediments associated with the Prest Sea. Radiocarbon dates on the Prest Sea shells give finite dates between 35 and 40 ka BP and an age of ca. 40 cal ka is compatible with a reasonable thermal history for the site. It is possible that partial deglaciation occurred after Heinrich event 4 at around 38 cal ka (see below).

The glacial chronology of the Hudson Bay Lowlands is a critical but disputed element in our knowledge of the dynamics of the LIS.

Wisconsinan Ice Sheet instability – Heinrich events

Our understanding of ice sheet behavior during the Wisconsinan Glaciation has undergone substantial changes over the last few decades. In the 1970s and 1980s the focus was on the relationships between ice sheet mass balance, climate, and the Milankovitch orbital variations as the “pace maker” of the ice ages (Hays et al., 1976). Thus, thinking was restricted to cycles of ice sheet growth and retraction at 20, 40, or 100 ka insolation cycles. However, parallel with this paradigm was the realization (largely from theory) that marine-based ice sheets should be, or might be, unstable. This thinking was largely directed to the present and future history of the West Antarctic Ice Sheet. However, Heinrich (1988) presented a coherent argument for significant, but short-lived, ice-rafted detritus (IRD) events in the North Atlantic. This initial paper was followed by a deluge of studies that documented and tried to explain what are now universally referred to as Heinrich or H-events (Broecker et al., 1992; Andrews, 1998) (see *Heinrich events*).

Heinrich events represent 500–1,000-year intervals when the normal influx of IRD (see ice-rafted debris) into the North Atlantic was dramatically elevated. A key component of the Heinrich events is detrital carbonate. Using this as a tracer, plus studies of the isotopic composition and ages of the non-carbonate fraction, indicates that the primary source of the IRD in Heinrich-sediments is from Hudson Strait, demonstrating the inherent instability of marine-based ice sheets.

The elusive Middle Wisconsinan

The Middle Wisconsinan generally encompasses MIS3 or between 55 and 25 cal ka. Global sea level was higher than during the main global glacial intervals of MIS4 and 2, but still well below the interglacial levels of MIS5e and 1 (Figure W1). Ice sheet instability characterized some of this time (see above). A major problem is that these ages lie beyond 5 and 9 half-lives of the most-commonly used dating method, ^{14}C dating of wood, peats, mollusks, foraminifera, etc. (Figure W1). Contamination can frequently result in finite dates on material that show infinite ages, and temporal correlations are often unreliable as the stratigraphy of terrestrial deposits is difficult to trace unambiguously from outcrop to outcrop, often compounded by the absence of marker beds (such as tephra beds) around the margins of the LIS.

A survey of the glacial and non-glacial stratigraphy for northern North America (Andrews, 1987) indicated that middle Wisconsinan Glaciation (\sim MIS3) is absent from the mountains of Alberta and British Columbia (there appears to have been no middle Wisconsinan Cordilleran Ice Sheet), and moreover there is no evidence that the Prairie provinces were covered by an ice sheet (Figure W3). Similarly, in the Yukon Territory and the mountains of Alaska, the Boutellier non-glacial interval represents a long, middle Wisconsinan interval with reduced glacial cover when compared with the expansion of glaciers and ice sheets during MIS2. However, in the area of the Great Lakes, glacial and interstadial deposits exist, dated from >45 to ca. 25 cal ka. The Plum Point interstadial was followed by the LGM.

During MIS3, the LIS was restricted to the hard bed (glaciologically speaking) of the Canadian Shield, with limited advances and retreats along the southern margin (Figure W3). The location of the ice margin around two third of its perimeter during MIS3 is difficult to define at present. Cosmogenic dating and deep-sea sediment records suggest a series of rapid

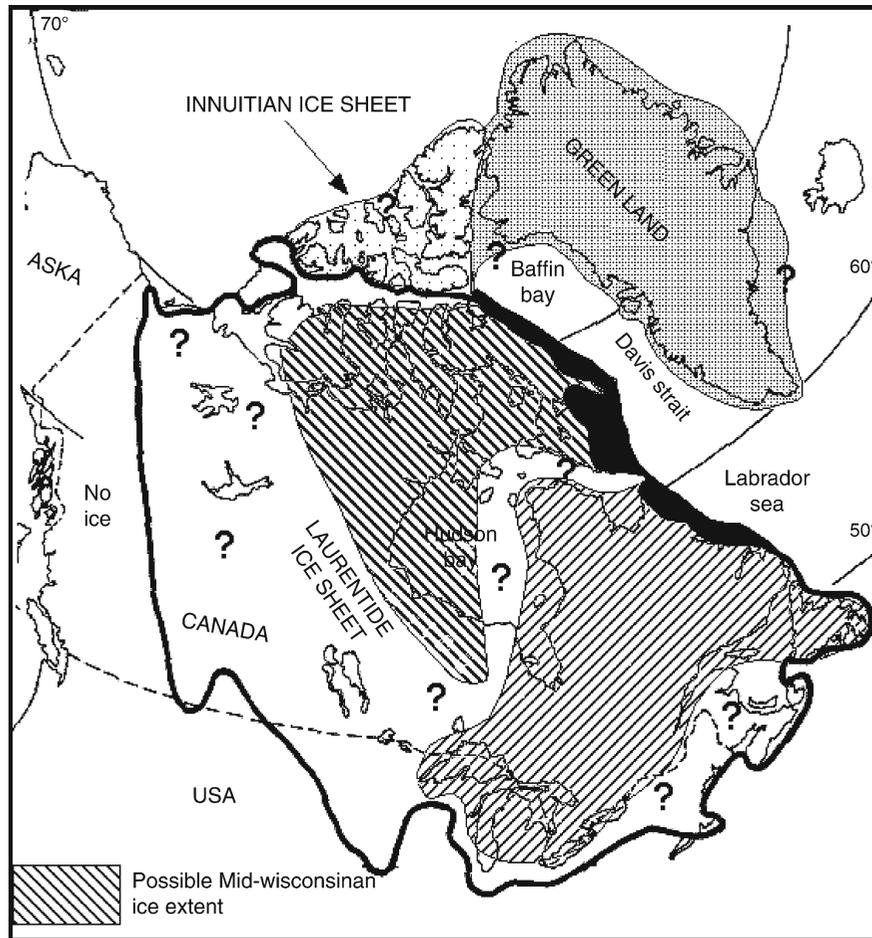

Figure W3 Extent of ice over northern North America and Greenland during the mid-Wisconsinan (Marine Isotope Stage 3) interval. Note the absence of ice over the Cordilleran region and over the western sector of the Laurentide Ice Sheet. The numerous question marks (?) indicate the major uncertainties in terms of timing and ice extent.

expansions and contractions especially as seen in Heinrich events 4 and 3, which occur within MIS3. In Baffin Bay, equivalent but possibly lagging IRD-rich units also are found, suggesting that the northern channels and ice streams in the Canadian Arctic Archipelago displayed a glaciological behavior similar to that of the Hudson Strait ice stream.

Big ice versus small ice at the LGM

There is a long-running dispute over the area and volume of the ice sheets during the LGM phase of the Wisconsin Glaciation. This was detailed in a global analysis by Denton and Hughes (1981), who highlighted the difference between a “big” ice sheet model, which placed large ice sheets and connecting ice shelves over vast areas of the Arctic and the Northern hemisphere, and a “small” ice world, where ice shelves were restricted and continental margins frequently terminated on land. In the last two decades, new tools, new insights into ice sheet behavior and basal conditions, and the exploration of new areas, have delineated ice margins that show a mosaic of “big ice” in some areas, whereas “small ice” appears necessary in other areas. Few papers deal with evidence for massive ice shelves across

the Arctic Ocean and marginal seas, and the implications for deep-water iceberg scouring at some sites is frequently ambiguous because of the inability to date the iceberg plough marks.

The ice sheet margin at the LGM has been extended seaward along the Labrador and Baffin Island coastline, largely on the basis of marine studies and cosmogenic dating (Steig et al., 1998). The consensus now maintains that an ice sheet extended across and drained through the Canadian High Arctic Channels and was contiguous with both the Greenland Ice Sheet along its eastern margin and the LIS along its southern limit (Dyke et al., 2002). A large ice sheet occupied the Barents Sea but the extent of LGM ice sheets further east along the arctic Eurasian margin is now restricted, and there is no evidence for such an ice sheet on the east Siberian shelf (Svendsen et al., 1999).

The concept of the Late Glacial Maximum (LGM) – is it useful?

The literature is now replete with the term “Late Glacial Maximum” or LGM (Figure W1). In a global sense, the term applies to the interval within MIS2 when ice volumes reached

a maximum and local sea levels at sites far removed from the ice sheet were at their lowest. However, the term should not be taken to imply that all ice sheets and glaciers experienced a synchronous interval of maximum extent around 22 cal ka. It is well known that various margins of the North American ice sheets reached their late glacial maxima at different times. As an example, the Puget Lobe of the Cordilleran Ice Sheet advanced south into the Puget Lowland at around 16 cal ka, which is also the date of the main advance across Des Moines, Iowa (Denton and Hughes, 1981). Hence the term “LGM” should not be used indiscriminantly and it should be made clear whether the term is being used in the global, integrated ice volume concept (Figure W1), or whether it is being used to refer to a regional glacial maximum limit that took place at a specific time within MIS2.

Pattern of deglaciation

The advent of radiocarbon dating in the late 1950s and 1960s rapidly led to the acquisition of data on the retreat of the Wisconsin Ice Sheet across the northern USA states and most of Canada (see *Laurentide Ice Sheet*). The first maps to show deglaciation isochrones were similar (Bryson et al., 1969). Subsequent maps show changes in important details, but not in the overall pattern and timing of retreat (Dyke and Prest, 1987). The isochrones are in 1,000s of radiocarbon years and hence underestimate the true ages by a few hundred to 1,000–2,000 years. Several authors used the maps to determine changes in area, and to derive estimates of volume changes over time.

The main pattern of retreat for the LIS can be summarized as follows:

1. Rapid deglaciation of the SW and W margins of the ice sheet. These margins lay on soft, deformable sediments.
2. During the time of rapid retreat of the SW and W margins, there was little change in the eastern margin facing Labrador and Baffin Bay.
3. Starting ca. 14 cal ka, the retreating S, SW, W, and NW margins frequently were adjacent to massive proglacial lakes which drained via several complex routes into the Gulf of Mexico, the shelf off the Hudson River, the St. Lawrence River, Hudson Strait, or the Mckenzie River in Arctic Canada (Dyke and Prest, 1987; Clark et al., 2001).
4. By 12 cal ka, the ice sheet had retreated across the St Lawrence Estuary and lay along the north shore of the Great Lakes.
5. Around 8–8.5 cal ka, a massive outburst flood linked the proglacial lakes in southern Hudson Bay and northern Quebec/Ontario with the encroaching sea in Hudson Strait. Earlier outburst floods had been directed via the other routes noted above.
6. By 7.5 cal ka, the last remnants of the LIS and the Wisconsin Glaciation were restricted to Baffin Island and other sites in eastern and northern Canada where modeling implied that the ice sheet had started its growth.
7. Technically speaking, the geologic-climate event of the Wisconsin Glaciation still persists in terms of deposits and climatic inferences that pertain to the Barnes Ice Cap, Nunavit, Canada, hence the obvious time-transgressive nature of this stratigraphic concept versus the chronostratigraphy embedded in the Wisconsin Stage and the Holocene.

The terms Wisconsin, Weichselian, and Würm glaciations

The application of the stratigraphic code (Hedberg, 1976) to issues of describing, naming, and correlating units within the Quaternary Era was a matter of considerable concern to terrestrial glacial stratigraphers from NW Europe, the northern USA, and Canadian researchers in the 1970s and early 1980s. However, the 1990s have seen the focus shift to the glacial impact on marine records, and the climatic significance and regional and global importance of abrupt climate “events,” such as the sequence of Heinrich IRD-rich sediment layers, the Younger Dryas cold event, and the impact of large freshwater outbursts on the regional to hemispheric climate. As a result, little attention has been paid to formal definitions and these terms are being largely used in an *ad hoc* manner.

Summary

The Wisconsin Stage and the Wisconsin Glaciation represent two different stratigraphic codes, although for many the differences are unclear. Radiocarbon dating of terrestrial and marine materials serves to define events and effect correlations over the last 30–40 ka (Figure W1), but correlations and events beyond the Middle Wisconsinian lie beyond the limits of radiocarbon dating and “dating” is frequently based on correlations to the marine isotope record (Figure W1) or relies on a range of new dating methods, including cosmogenic exposure ages, various luminescence methods, and amino acid racemization. Consequently, as yet there is little absolute knowledge about the timing of the onset of the last glaciation on North America or its history of expansion and retraction during MIS5, 4 and early stage 3 (Figure W1). However, it is known that the LIS suffered major catastrophic loss of mass during Heinrich events 4 through 1 (ca. 38 cal ka to 16 cal ka) as massive iceberg armadas carried sediments with provenance tracers indicative of sources in Hudson Strait and Hudson Bay into the North Atlantic to sites just west of Portugal and Ireland. How these events were manifest around the other sectors of the ice sheet is unclear, especially given the evidence for relative little ice in the Canadian Prairie provinces and even over the Cordilleran mountains during mid-Wisconsinian time (Figure W3).

Y

YOUNGER DRYAS

Introduction

Abrupt climate changes are events that have affected the Earth many times; it is not only possible but also likely that these will affect us in the future (Alley et al., 2002). While gradual climate changes allow time for those affected to adjust, rapid events often cause greater impact simply because of their rapidity. While we do not yet understand past rapid climate events enough to predict them, we can examine past data and use models to test our ideas about why they occur. One of the most useful ways to approach the data is to examine the occurrence, magnitude, timing, and distribution of these events, fitting together the pieces of a global puzzle.

Younger Dryas – prime example of abrupt climate change

The Younger Dryas (YD) is known as the best example of an abrupt climatic event recorded on land, in the oceans, and in ice cores (Alley et al., 2002, 2003). It was a cold event that occurred between 11,000 and 10,000 ¹⁴C years ago, (approximately 12,800 and 11,600 calendar years ago), and it lasted about 1,200 years. About 15,000 years ago, as Northern Europe ice sheets were retreating and trees were beginning to move northward replacing tundra, several brief returns to cold conditions suddenly took place. The most pronounced of these reversals, which could be correlated from place to place in Europe, was called the Younger Dryas. The name “Younger” was used because it was the last of these rapid cold events, while earlier events were called the Oldest Dryas and the Older Dryas (Jansen, 1938). The name *Dryas* was used because the layer contained fossil leaves and fruits of the *Dryas octopetala* plant, a member of the rose family (Rosaceae) that colonizes arctic-alpine regions. The layer just below the Younger Dryas that contained tree fossils was named Allerød for the Scandinavian locale.

After this striking reversal in macrofossils was noted by paleoecologists in Northern Europe in the late nineteenth and early part of the twentieth century, it was correlated from place to place using

palynology, the study of pollen and spores. Hundreds of pollen diagrams throughout Europe now show the effect that this event had on ecosystems and landscapes, causing the demise of forests and the increase of erosion and expansion of tundra (Watts, 1980) during this cold interval. Radiocarbon dating beginning in the 1950s secured the correlation of the reversal in Europe. However, more recent comparison of calendar ages to the radiocarbon scale indicates that plateaus exist in the radiocarbon scale, complicating the correlations somewhat.

Over the last twenty years, many scientists have studied the Younger Dryas in order to better understand rapid climatic events. The geographic range (Figure Y1), timing, and magnitude of this event are crucial to understanding its origin.

Europe

While the timing of the event in Europe was synchronous from place to place, each locale varied in the specific vegetational changes that took place. For example, while tundra herbs indicative of open, disturbed landscapes such as *Artemisia* (wormwood) and *Chenopodiaceae* replaced birch trees and conifers in the British Isles (Walker, 1994), in Scandinavia the change was more subtle, with colder tundra herbs replacing some that inhabited warmer environments. Some of the strongest effects of the Younger Dryas are noted in southern Europe, where summer temperatures may have been 8 °C lower than today. In Norway, Birks and Ammann (2000) estimated mean July temperature to be about 7–9 °C lower than today, and about 2–4 °C lower than the preceding Allerød warm interval. Substantial changes in vegetation characterized both coastal and inland areas all the way from northern Norway to the Mediterranean (Walker, 1994).

North America

While originally the Younger Dryas was thought to be solely a European phenomenon, the advent of accelerator mass spectrometry resulted in improved radiocarbon dating and the identification of plant macrofossils permitting identification of plants to the species level. Along with palynology, these vegetational changes resulted in proof of cooling that was correlative with the European YD. These results demonstrated the presence of a Younger Dryas event in the maritime provinces of Canada

Figure Y1 Global map of distribution of palynological evidence for the Younger Dryas cooling 11–10 ^{14}C kyBP (12,800–11,600 calendar years). Cooling is strongest in regions surrounding the N. Atlantic, including Greenland, Europe, and eastern North America. Cooling has also been identified in many places far from the N. Atlantic, such as N. Pacific Canada and Alaska, and East Asia. Tropical cooling has also been noted. Many sites are still controversial, where some evidence points to cooling and other evidence does not show the oscillation (i.e., New Zealand, Chile; after Peteet, 1995; Peteet et al., 1993).

(Mayle et al., 1993) and the northeastern coast of the United States (Peteet et al., 1993). Estimates of the cooling range from 3–4 °C in southern New England to 6–7 °C in eastern Canada. In the Maritime Provinces of Canada, shrub tundra was replaced by herb tundra in some places, while in others shrub tundra replaced spruce forest. In the mid Atlantic and southern New England regions, a mixed boreal and deciduous forest was replaced by boreal forest (spruce, fir, larch, alder, paper birch). Further investigations continue to document the YD event in the mid-Appalachian region, Midwestern USA, coastal British Columbia and Alaska, and Arctic Alaska. Documentation of the YD event in terrestrial locations as far west as Alaska revealed that the geographic extent of this cooling was not limited to the North Atlantic region, and that the forcing was possibly not limited to the North Atlantic Ocean (Figure Y1).

South America

Evidence for the YD event in South America is mixed. Evidence is most convincing in Colombia, where many sites show a late-glacial palynological oscillation but precise dating is lacking. In southern South America, while some data shows a prolonged YD which begins earlier than the North American event, some data suggests a correlation and some does not. In Peru, glacial advances do indicate a YD age advance.

Asia

North Pacific investigations now show that the YD was expressed in the Japan Sea as well as off coastal California (Behl and Kennett, 1996). While a cold interval on land in Japan has been linked to the YD, with indications of colder temperatures and declines in moisture, recent evidence from other annually laminated lakes suggests that the cooling event of about 3 °C lagged the European event by a few centuries (Nakagawa et al., 2003). The high-resolution speleothem monsoon record from coastal mid-latitude Hula Cave, China, also clearly shows a YD event (Wang et al., 2001), as do loess records in the region.

Marine evidence

In the 1980s, North Atlantic faunal changes concurrent with the terrestrial European signals led ocean paleoecologists to the conclusion that the North Atlantic polar front re-advanced to its glacial position at that time (Ruddiman and McIntyre, 1981). Subsequent geochemical analyses indicate that the production of North Atlantic Deep Water (NADW), which today is responsible for bringing heat to Europe, was greatly reduced at this time, as it was during the ice age (Broecker et al., 1985). The cause for the presence of this deep-water reduction is still in dispute, but it has been linked to diversions of Laurentide meltwater to specific locations in the North Atlantic. Convincing

marine evidence from the Atlantic for the YD shift comes from the Cariaco Basin, where sediment color and other data is interpreted as an increase in wind-induced upwelling off coastal Venezuela (Hughen et al., 1996) or decreased riverine runoff from adjacent countries.

North Pacific evidence for a YD event comes from the Santa Barbara Basin (Kennett and Ingram, 1995), the Gulf of California, the northwestern North Pacific, and even the eastern equatorial Pacific. An arid interval is correlated with the YD in the tropical Atlantic (Maslin and Burns, 2000) and off Africa.

Ice cores

The advent of ice core research was very important in demonstrating the importance of the Younger Dryas in the history of climate change. Camp Century, Dye 3, and Renland first illustrated this change, which was then confirmed in the GRIP and GISP-2 deep cores (Dansgaard et al., 1993). The signal is observed as a several per-mil shift in oxygen isotope ratios, corresponding to about 15 °C colder than today (Cuffey et al., 1995). What is unusual about the ice core shift as compared to pollen records is that the magnitude of the shift in the ice cores is almost equal to that of full-glacial conditions, while in pollen records throughout Europe, this shift is probably at most equal to half the shift in temperature represented by full-glacial conditions. Thus, the isotopes are complicated to interpret, either suggesting locally colder conditions than on continents adjacent to the North Atlantic, or a transport or source problem. In the ice cores, the YD is also marked by much higher dust levels and chemical concentrations than the previous Allerød or the subsequent Holocene. While the onset of the YD in the ice cores is gradual, the termination is very abrupt, occurring in as little as 1–3 years in some indicators. Snow accumulation rates during the YD were about half that of the Preboreal, and about one third of modern rates. The changes at the end of the YD were completed in three 5-yr steps spread over about 40 years (Taylor et al., 1993), and snow accumulation changed by about 90% in one year (Alley et al., 1993). The discovery of a YD methane signal in Antarctic ice was the first indication that this event made a global imprint. However, more recent ice core evidence for the YD event correlative with the European and Greenland ice cores is conflicting, suggesting that in some locations a YD is correlative but in others it precedes the northern hemisphere change. Ice cores from more temperate locations in Peru and Bolivia also show evidence of a late-glacial reversal, which probably is the YD but age control is problematic.

Mechanisms

The decreased NADW production during the YD is the chief hypothesis among those proposed as the reason for the cooling throughout the Northern Hemisphere (Broecker et al., 1985). Cold meltwater from the late-glacial release of Lake Agassiz to the North Atlantic would have been located in such a position that it could have slowed down the thermohaline circulation (THC). The 1,500-yr oscillations in marine, terrestrial and ice cores throughout the Holocene suggests that YD-type signals may be a complex recurring climate oscillation that was magnified during the YD by meltwater from receding ice sheets (Bond and Lotti, 1995). One potential problem with the THC hypothesis for YD and other similar events is that most atmospheric models show a restricted circum-North Atlantic response to the YD when a shutdown is forced (Rind et al., 1986; Renssen, 1997), although others show a muted cooling in the North Pacific (Mikolajewicz et al., 1997). Understanding how this mechanism could cause a

significant YD signal around the globe is a major challenge to modelers. Some recent research has focused on the tropics as a possible amplifier of abrupt climate change caused by shifts in the intertropical convergence zone (ITCZ) (Clement et al., 2001).

The impacts of the YD on human populations was probably extreme, and may have contributed to the beginnings of agriculture around the fertile crescent (Moore and Hillman, 1992). On the North Slope, Alaska, changes in human migration (Kunz and Reanier, 1996) during the YD are linked to a shift to major changes in moisture (Mann et al., 2002). Added to the human factor in North American mammal extinctions, it is possible that the YD pushed populations over the brink (Petee et al., 1990). Abrupt climate changes of lower magnitude than the YD occurred throughout the Holocene; these have been linked to reduced solar radiance (Bond et al., 2001). Much is still to be learned regarding the Younger Dryas event.

EARTH HISTORY TABLE

Table 1 Major Events in Earth's Climate History

PHANEROZOIC EON

Cenozoic Era

Quaternary Period (1.8 my–present)

Holocene (Recent) Epoch (12 ky–present) Maunder Minimum (~1645–1715 AD). Little Ice Age (~1400–1850 AD). Medieval Warm Period (~900–1200 AD). Rise of cities and irrigation (~5 ky). Hypsithermal (~9–5 ky). The 8,200-year cold event. Sea level meltwater pulse 1B (11,500–11,000 ky). Megafaunal extinctions.

Pleistocene Epoch (1.8 my–12 ky)

Younger Dryas cold spell (12.8–11.6 ky). Antarctic Cold Reversal (14.5–13.0 ky). Bølling-Allerød interstadial (14.5–12.7 ky). Sea level meltwater pulse 1A (~14.6–14.3 ky). Onset of post-glacial sea level rise (22–20 ky). Last Glacial Termination (20–14.7 ky). Last Glacial Maximum (23–19 ky). Last (Eemian) interglacial (126 ky, equivalent to base marine isotope stage 5e). Earliest *Homo sapiens* (<200 ky). Brunhes-Matuyama magnetic reversal (781 ky). Mid-Pleistocene Revolution: transition from 41 to 100 ky ice age cycles (1–0.8 my).

Neogene Period (1.8–23.0 my)

Pliocene Epoch (5.3–1.8 my)

Earliest *Homo* (~1.9–1.8 my). Intensification of the Walker circulation (~1.9 my). Onset of Northern Hemisphere glaciation (~2.5 my). Intensification of Asian monsoon (2.6 my). Oldest stone tools (2.6–2.5 my). Closure of Isthmus of Panama (4.25–3.4 my). Mid-Pliocene warm period (3.15–2.85 my). Earliest australopithecines (4 my). Progressive narrowing of Indonesian gateway and drying of East Africa (5–2 my).

Miocene Epoch (23.0–5.3 my)

Messinian salinity crisis (5.33–5.96my). Earliest hominins (7–6 my). Development of Indian and east Asian monsoon (9–8 my; possibly at 22 my). Accelerated phase of eastern Himalayan uplift (13–9 my). East African rifting (12–1.5 my). Deep-water cooling and east Antarctic ice sheet expansion (15 my).

Paleogene Period

Oligocene Epoch (33.9–23.0 my)

Initiation of Antarctic Circumpolar Current (~25–23 my). Initiation of North Atlantic Deep Water current. Opening of Tasmanian Passage (~33.5 my). Onset of ice build-up, Antarctica (34 my).

Eocene Epoch (55.8–33.9 my)

Opening of Drake Passage (~44–22 my). Onset of Himalayan uplift (~40 my). Gradual cooling trend (49–37 my). Early Eocene climatic optimum (55–50 my). Paleocene–Eocene Thermal maximum (55.5 my) – warm episode, large negative $\delta^{13}\text{C}$ anomaly.

Paleocene Epoch (65.5–55.8 my)

Late Paleocene – India collides with Asia.

Mesozoic Era

Cretaceous Period (145.5–65.5 my)

Cretaceous–Tertiary impact. Major mass extinction. Last dinosaurs, ammonites, and others. Massive eruption of Deccan Traps (~65 my). Some short-lived cold episodes. Ocean anoxic events. Starting ~125 mya, generally warm. Elevated sea level. Massive flood basalts – southwest Pacific Ocean. Increased CO₂ outgassing.

Jurassic Period (199.6–145.5 my)

Break-up of Gondwanaland; separation of India, Australia, Antarctica, Early Cretaceous. Temperate climate.

Triassic Period (251.0–199.6 my)

Rifting – eastern North America. Sea floor spreading and sea level rise. Generally warm. Ocean anoxic event. Mass extinction – end Triassic. Onset of Pangean break-up, Late Triassic. Generally warm. Monsoonal climate. Extensive evaporites – hot and dry – interior Pangea.

Paleozoic Era

Permian Period (299.0–251.0 my)

End-Permian mass extinction. Onset of warm climate. Ocean anoxic event. Massive eruption of Siberian Traps (flood basalts) (249.4 my). Glaciation persists to Middle–Late Permian. Final assembly of Pangea. First mammals.

Carboniferous Period (345–299.0 my)

“The Coal Age”.

Pennsylvanian (318.1–299.0 my)

Onset of Southern Hemisphere glaciation (320 my). Extensive paleoequatorial coal deposition. Cyclothem.

Mississippian (359.2–318.1 my)

Warming trend. First land vertebrates.

Devonian Period (416.0–359.2 my)

Mass extinction. Late Devonian to early Carboniferous glaciation (~374.5 my). Early-mid Devonian, warm, and dry.

Silurian Period (443.7–416.0 my)

Moderate climate, high sea levels, shallow continental seas.

Ordovician Period (488–443.7 my)

Mass extinction – end Ordovician. Late Ordovician to early Silurian high latitude, Southern Hemisphere glaciation. First land plants. Early Ordovician – warm, arid climate.

Cambrian Period (542.0–488.3 my)

Generally warm and arid. First exoskeletal invertebrates. “Cambrian explosion.” Ocean anoxia at Precambrian–Cambrian boundary.

PROTEROZOIC EON (2,500–542 my)

Neoproterozoic Era (1,000–542 my)

First preserved macroscopic soft-bodied fossils (Ediacaran fauna ~600 my). Neoproterozoic glaciations (~725–635 my).

Mesoproterozoic Era (1,600–1,000 my)

Paleoproterozoic Era (2,500–1,600 my)

Huronian glaciation (2400–2200 my). Early increase in O₂; massive banded iron and manganese formations during the Huronian.

ARCHAEAN EON (~4,000–2,500 my)

Earliest fossil evidence for life, Apex Chert Australia (~3.5 by). Oldest water-deposited rocks, Isua Supracrustal sequence, Greenland (3.7–3.8 by). “Late heavy bombardment” by meteorites (~3.9 by), by analogy to the Moon.

HADEAN EON (~4,650–4,000 my)

Oldest minerals/rocks: zircon crystals, Narryer Gneiss Complex, Western Australia (4.4–4.0 by); Acasta Gneiss, Great Slave Lake, NW Canada (4.03 by). Low surface temperature (4.4–4.0 by), based on oxygen isotope ratios in zircon.

Age of Earth (4.54 by)

Age of Solar System (4.57 by)

Dates for geologic periods are taken from *International Commission on Stratigraphy* (2004) Overview of Global Boundary Stratotype Sections and Points (GSSP's) (<http://www.stratigraphy.org/gssp.htm>). Major events listed in the table are described in the individual articles in this volume unless otherwise indicated.
